(Received February 11, 1985; accepted April 23, 1985)

Abstract—The cocoa pod borer, *Conopomorpha cramerella* (Snellen) (Lepidoptera: Gracillariidae), is the most serious pest of cocoa in Southeast Asia. Analyses of ovipositor washings and entrained volatiles from virgin female moths by gas chromatography (GC) linked to electroantennography (EAG), and comparison of EAG responses from the male moth to synthetic compounds indicated the presence of the *E,Z,Z* and *E,E,Z* isomers of 4,6,10-hexadecatrienyl acetate and the corresponding alcohols, and of hexadecyl alcohol. Amounts of pheromone produced were less than 0.1 ng/female, and no peaks for the unsaturated components were observed on GC analysis. Extensive field testing of synthetic mixtures in Sabah, East Malaysia, showed that traps baited with a polyethylene vial impregnated with 1.2 mg of a mixture of the above five components in 40:60:4:6:10 ratio caught more male *C. cramerella* moths than traps baited with a virgin female moth.

Key Words—Cocoa pod borer; *Conopomorpha cramerella*; *Acrocercops cramerella*; Lepidoptera; Gracillariidae; sex pheromone; sex attractant; 4,6,10-hexadecatrienyl acetate; 4,6,10-hexadecatrien-1-ol.

INTRODUCTION

The cocoa pod borer, *Conopomorpha cramerella* (Snellen) [previously *Acrocercops cramerella* (Snellen); (Bradley, 1985)] (Lepidoptera: Gracillariidae), is the most serious pest of cocoa in Southeast Asia (Mumford, 1984). The larvae bore into immature cocoa pods and disrupt the development of the beans. This may cause production of smaller beans, difficulties in extraction of beans from

0098-0331/86/0100-0001$05.00/0

the pods and yellowing of immature pods leading to premature harvesting. Losses can be in excess of 50% of the crop. The biology and life cycle of this pest have been summarized by Wessel (1983) and Lim et al. (1982), and control has been attempted by cultural and chemical means as described by Mumford (1984).

In 1981, Day showed that caged virgin female *C. cramerella* moths attracted male moths to sticky traps hung in cocoa trees in Sabah, East Malaysia (Mumford, 1984). Since control methods currently available for this pest are not always effective and are labor intensive, the possibility of control using a synthetic pheromone was attractive. Furthermore, the pest–crop system appeared to be suitable for control methods based on pheromones since it is a relatively low density pest with limited dispersal ability in a stable environment. Beevor et al. (1984) have reported preliminary studies to determine the best design, position, and color of pheromone traps for *C. cramerella*. This paper describes the identification and synthesis of components of the female sex pheromone and trials to determine the most attractive blends of these components in a field trapping system.

METHODS AND MATERIALS

Insect Material. Pupae were collected in Sabah, East Malaysia, and sent by air to London, still in their membranous cocoons attached to cocoa leaves. They were maintained in individual containers in an environmental cabinet on a reversed 12-hr–12-hr light–dark cycle with temperature alternating between 27°C and 22°C and relative humidity 90%. Adult moths were sexed on emergence and maintained under the same conditions.

Pheromone Collection. Ovipositor washings in carbon disulfide, dichloromethane, or heptane were prepared from virgin female moths, usually 8–9 hr into the first dark period after emergence. Female moths had been observed to be most attractive to male moths at this time in the field (R.K. Day and J.D. Mumford, unpublished observations). In attempts to improve pheromone yields, numerous variations of this procedure were tried. Thus, ovipositor washings were made from older female moths, after shorter or longer periods into the scotophase, and under natural conditions of lighting, humidity and temperature in Sabah. Whole body washes of female moths were made, as were solvent extracts of excised pheromone glands.

Volatiles were collected from individual virgin female moths on filters containing 5 mg of activated charcoal (Grob and Zurcher, 1976; Nesbitt et al., 1979; Tumlinson et al., 1982). Females were typically entrained for 10 hr into the dark period. In further attempts to improve yields of pheromone, the female moths were entrained in the presence of cocoa leaves, or placed on cocoa leaves prior to making ovipositor washings.

Electroantennography (EAG). Male *C. cramerella* moths were immobilized in an atmosphere of carbon dioxide, mounted on a plasticine block, and held in position with a strip of expanded polystyrene. The antennae were secured along the surface of the plasticine with small wire staples. The tip of one antenna was removed with a razor blade and the cut end inserted into the end of a glass microelectrode from which the tip had been broken. The other antenna was reduced to 4–5 proximal segments and inserted into a similar glass microelectrode as reference. The microelectrodes contained saline solution (Roelofs and Comeau, 1971), with 0.2% agar added to reduce leakage of saline, and were connected by means of chloridized silver wires to a Grass P16 microelectrode DC preamplifier linked to a Tetronix 5110 oscilloscope and Siemens Minograf 34T recorder.

Gas chromatographic analyses with simultaneous recording of EAG responses to the column effluent (GC-EAG) were carried out essentially as described by Moorhouse et al. (1969). The antennae were maintained under a constant stream of humidified air (400 ml/min), and the column effluent collected in the reservoir was blown over the recording antenna with nitrogen (400 ml/min) for 3 sec at 17-sec intervals.

To record EAG response profiles to synthetic hexadecenyl acetate isomers, a solution of the test compound in heptane was syringed onto the inner walls of a disposable Pasteur pipet and the solvent removed with a stream of nitrogen (500 ml/min for 10 sec). The pipet was positioned with its tip 0.5 cm above the center of the recording antenna and a 3-sec pulse of nitrogen (500 ml/min) blown through the pipet. An interval of 3 min under a constant flow of humidified air (2.5 liters/min) was allowed between successive stimuli.

Gas Chromatography (GC). Analyses by GC, with and without simultaneous recording of EAG responses to the column effluent, were carried out with the following columns and conditions: glass columns (1.8 m × 2 mm ID) with nitrogen carrier gas at 25 ml/min, packed with: (A) 5% SE30 and 0.5% Carbowax 20 M on Chromosorb W HP, temperature programmed from 100°C to 220°C at 4°C/min; and (B) 1.5% Carbowax 20 M on 100–120 mesh Chromosorb G AW DMCS, temperature programmed from 100°C to 210°C at 4°C/min; fused silica capillary columns (25 m × 0.32 mm ID, Chrompack) with Grob splitless injection and helium carrier gas at 0.4 kg/cm^2, coated with: (C) CP Sil 5CB (chemically bonded methyl silicone), oven temperature held at 70°C for 2 min, then programmed to 150°C at 34°C/min and at 0.4°C/min to 165°C; and (D) CP Wax 57CB (chemically bonded, cross-linked polyethylene glycol), oven temperature held at 70°C for 2 min, then programmed to 150°C at 31°C/min and at 1°C/min to 185°C.

Flame ionization detectors were used throughout, and in linked GC-EAG analyses the column effluent was split 1 : 1 to the GC detector and the EAG preparation by means of a glass-lined T piece (SGE). With capillary columns, carrier gas makeup (5 ml/min) was introduced just before the T piece.

Synthetic Chemicals. The monounsaturated 16-carbon acetates were prepared by standard acetylenic or Wittig routes and were purified by liquid chromatography on silica gel impregnated with 20% silver nitrate to give products containing less than 0.1% of the opposite geometrical isomer.

The (*Z*)-10 isomers of 4,6,10-hexadecatrienyl acetate and alcohol were prepared as outlined in Figures 1–5, using the appropriate sequences of acetylenic and Wittig reactions. The corresponding (*E*)-10 isomers were obtained from (*E*)-4-decen-1-ol which was derived from intermediate (IV) in Figure 1 by reduction with sodium in liquid ammonia and diethyl ether followed by deprotection, in 96% yield.

The route described for the *E,Z,Z* isomer is preparatively useful, and the yields quoted are for reactions giving 5 g of final product. Isomerization of the conjugated double bonds was easily effected by brief exposure to sunlight of a 0.1 M solution in hexane containing a catalytic amount of iodine (Klug et al., 1982). The isolated double bond was unaffected by this treatment, and the product contained the *E,E,Z*, *Z,E,Z*, *E,Z,Z* and *Z,Z,Z* isomers in 67 : 15 : 15 : 3 ratio. The pure *E,E,Z* isomer could be isolated by liquid chromatography on silica gel impregnated with 20% silver nitrate. In separate experiments, this was shown to provide good separation of the (*Z*)-10 and (*E*)-10 isomers, but separation of the isomers differing only in geometry of the conjugated double bonds was poor and only about 10% of the available *E,E,Z* isomer could be isolated pure from the isomerized mixture.

Treatment of the isomerized mixture with liquid sulfur dioxide for 5 days gave a good yield (approximately 70% of theoretical) of the cyclic sulfone (XIII in Figure 3) derived from the *E,E,Z* isomer, which could be isolated by flash

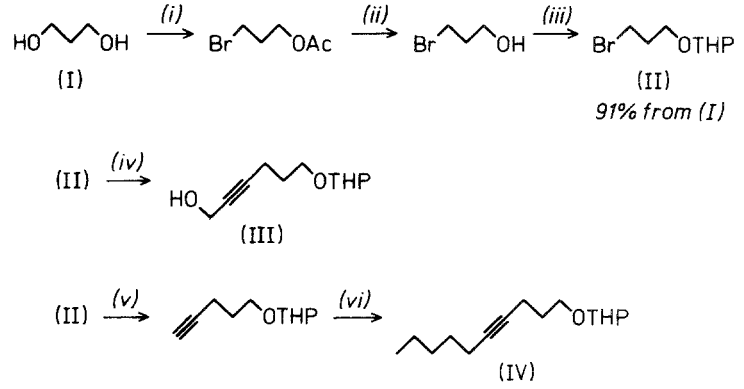

FIG. 1. Preparation of precursors II, III, and IV. (THP = 2-tetrahydropyranyl). Reagents: (i) HBr in acetic acid; (ii) K_2CO_3/MeOH; (iii) dihydropyran/ether/0°C; (iv) propargyl alcohol/$LiNH_2$/liq. NH_3/THF; (v) acetylene/$LiNH_2$/liq. NH_3/THF; (vi) $LiNH_2$/liq. NH_3/THF/$C_5H_{11}Br$.

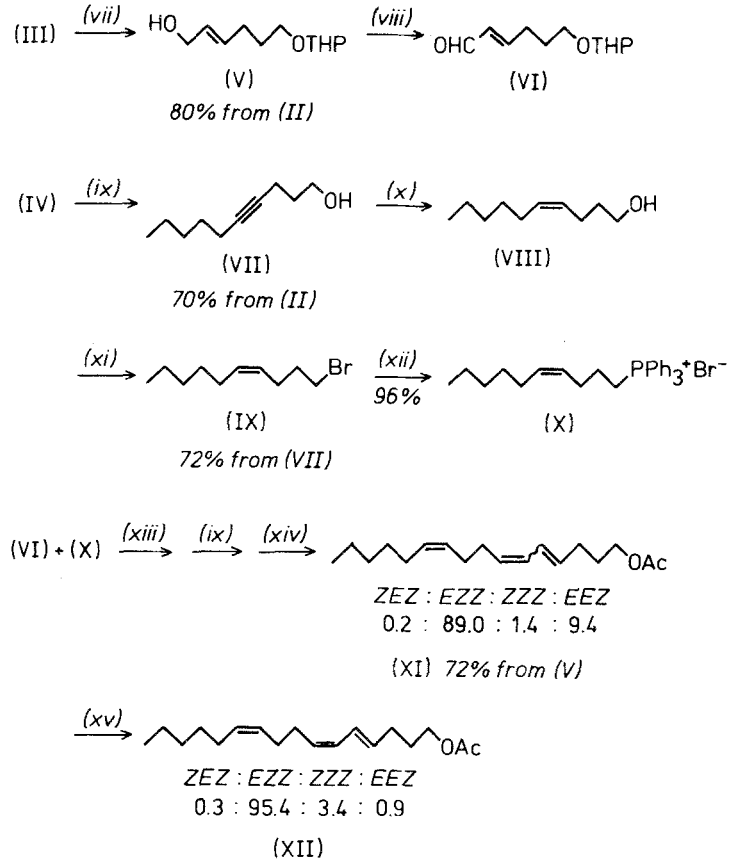

FIG. 2. Synthesis of (*E*, *Z*, *Z*)-4, 6, 10-hexadecatrienyl acetate (XII). Reagents: (vii) $LiAlH_4$/THF; (viii) pyridinium chlorochromate/sodium acetate/ CH_2Cl_2; (ix) *p*-toluenesulfonic acid/MeOH; (x) H_2/Lindlar catalyst/quinoline/EtOH; (xi) $CBr_4/Ph_3P/CH_2Cl_2$; (xii) Ph_3P/CH_3CN/reflux 18 hr; (xiii) $KOBu^t$/THF/−30°C; (xiv) Ac_2O/pyridine; (xv) tetracyanoethylene/THF.

chromatography on silica gel with 25% ethyl acetate in petroleum spirit. Injection of the sulfone onto a GC column with the injector at 200°C gave quantitatively a single peak corresponding to the *E*,*E*,*Z* isomer, but this conversion could not be carried out on a preparatively useful scale. Heating the sulfone in solvent or short-path distillation under reduced pressure gave black tars.

The products were analyzed by GC using the fused silica capillary columns described above or a column coated with OV-275 (Chrompack; 25 m × 0.22 mm ID; oven temperature held at 70°C for 2 min, then programmed at 20°C/min to 160°C; helium carrier gas at 0.8 kg/cm^2) which provided excellent sep-

arations of the isomeric acetates but which could not be used for analysis of the alcohols.

The products were characterized by the reasonably unambiguous methods of preparation used, by their GC retention characteristics, by the relative proportions observed in equilibrium mixtures of isomers, and by spectroscopic methods.

The mass spectra of all the acetate isomers were essentially identical and showed a diagnostic base peak at *m/e* 107. This presumably corresponds to the fragment $(-CH_2-CH=CH-CH=CH-CH_2-CH=CH_2)^+$ formed from the molecular ion by loss of acetic acid and cleavage to give the allylic ion stabilized by the 4,6-conjugated diene system. In the [^{1}H]NMR spectra at 270 MHz, signals due to the olefinic protons could be assigned unambiguously on a first-order basis. The [^{13}C]NMR spectra of the acetates all showed the expected 18 signals with six in the olefinic region, but these could not be assigned unambiguously.

Field Tests. Field testing was carried out in cocoa plantations in Sabah, East Malaysia, during 1983–1984. During initial studies, Beevor et al. (1984)

showed that many of the commonly used trap designs, e.g., sticky delta, water and funnel traps, are unsuitable for *C. cramerella*. It was also found that trap positioning was important and that traps just above the cocoa canopy caught most moths.

The most effective trap design used in this work consisted of two horizontal sheets of plastic Correx (30 × 30 cm; Corruplast Plc, Gloucester, England) held 5 cm apart by wire spacers, with another Correx sheet coated with polybutene sticker clipped to the upper surface of the lower sheet. Traps were suspended on strings from the branches of *Gliricidia* shade trees and were adjusted to a height approximately 1 m above the top of the cocoa canopy, approximately 8 m above ground level.

Pheromone dispensers were closed polyethylene vials (35 × 8 × 1.5 mm thick) impregnated with the synthetic compounds and an equal weight of 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant. The dispensers were mounted at the center of the trap through a hole in the upper sheet. In virgin female-baited traps, a single virgin female moth was housed in a small plastic mesh container in place of the pheromone dispenser. Female moths were used on the second night after emergence and were renewed each night.

Typically 10–12 replicates of each experiment were carried out simultaneously over 4–5 days depending upon whether 4–5 treatments were being compared. Traps were positioned approximately 50 m apart in a circular arrangement within a replicate, and replicates were at least 100 m apart. Moth catches were recorded each day when traps were moved on one position within a replicate.

The data were analyzed using a Generalized Linear Interactive Modeling (GLIM) statistical package (Baker and Nelder, 1978). This allows one to fit a series of models, as in a stepwise regression, so that the statistical significance of treatment effects may be measured while controlling for differences in overall trap catch from night to night or plot to plot. The models used had a Poisson distribution and a "log link" (Baker and Nelder, 1978), so that the ratios between trap catches were measured, and these ratios were tested for differences between treatments significant at the 5% level by the *t* test.

RESULTS

Yields of pheromone from virgin female *C. cramerella* were very low, less than 0.1 ng/female, and these could not be improved by varying conditions for solvent extraction or entrainment of volatiles, as described above. No consistent GC peaks corresponding to the unsaturated pheromone components were ever observed, and the identification of these was carried out on the basis of GC retention data derived from linked GC-EAG analyses, EAG responses to synthetic compounds, and extensive testing of synthetic compounds as attractants in the field.

[a] Equivalent chain lengths relative to the retention times of *n*-alkyl acetates.
[b] Major response.

Analyses of ovipositor washings and entrained female volatiles by GC-EAG using packed GC columns gave up to three responses (Table 1). The responses were broader than expected, suggesting that they were due to more than one compound. The first response on both the nonpolar (A) and polar (B) column occurred at the retention time of 1-hexadecanol (16:OH), and a small GC peak was observed. Subsequent analyses on fused silica capillary GC columns (C and D) also showed a small peak cochromatographing with 16:OH.

The retention times for the other responses were similar to those for 16-carbon acetates with two conjugated double bonds, and the corresponding alcohols. Retention data for the isomers of 9,11-hexadecadienyl acetate (9,11-16:Ac) and the corresponding alcohols (9,11-16:OH) is given in Table 1.

The EAG responses to a range of saturated, straight-chain acetates, alcohols, and aldehydes were recorded, and the most significant responses were elicited by hexadecyl acetate (16:Ac) and 16:OH (Table 2).

[a] Using linked GC-EAG as delivery system with 30 ng injected, 15 ng to the antenna.

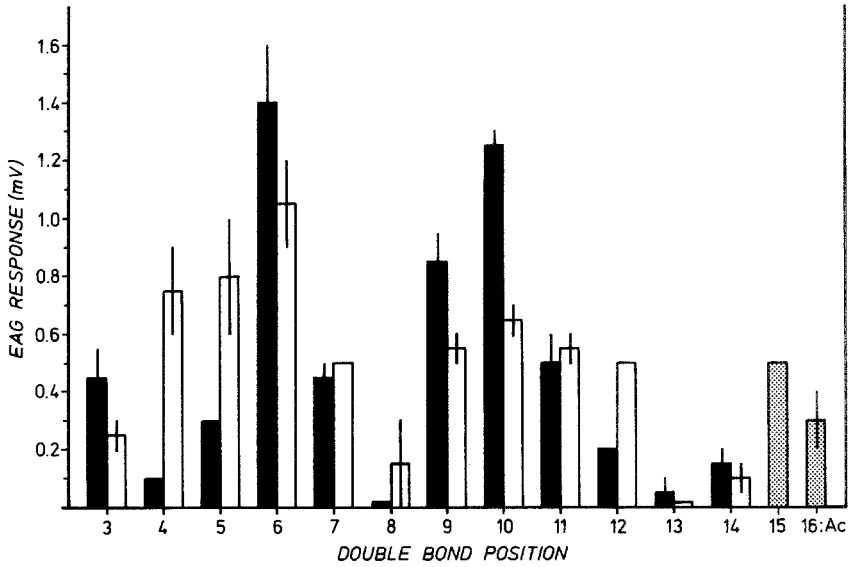

FIG. 6. EAG responses of male *C. cramerella* moth to monounsaturated 16-carbon acetates and hexadecyl acetate (16:Ac); ■ *Z* isomers; □ *E* isomers. Results are the means of duplicate recordings from the same moth to 4 ng at source, and the bars indicate the spread of the results.

The EAG responses to a range of monounsaturated, 16-carbon acetates were then recorded, and the largest responses were caused by the (*E*)-4, (*E*)-5, (*Z*)-6, (*E*)-6, (*Z*)-9, and (*Z*)-10 isomers (Figure 6). These results suggested that the pheromone might include at least one triunsaturated, 16-carbon acetate, possibly the (*E*,*Z*,*Z*)-4,6,10 and/or (*E*,*E*,*Z*)-4,6,10 isomer. The high EAG responses to the monounsaturated compounds with the double bonds between the two double bonds of a conjugated diene pheromone component—here the (*E*)-5 isomer in particular—have been observed with other insects having conjugated dienes as pheromone components (Hall et al., 1980, and references therein).

The isomers of 4,6,10-hexadecatrienyl acetate (4,6,10–16:Ac) and alcohol (4,6,10–16:OH) were synthesized, and several of these, particularly the *E*,*Z*,*Z* isomer, were found to be extremely potent olfactory stimulants for the male *C. cramerella* moth (Table 3).

Analyses of the natural pheromone by GC-EAG using fused silica capillary columns provided further evidence that the pheromone consisted of isomers of 4,6,10–16:Ac and 4,6,10–16:OH, although the results were less clear-cut than they would have been if GC peaks had been recorded. Up to five different responses were recorded during analyses of both ovipositor washings and female volatiles on the nonpolar (C) and polar (D) columns (Figure 7), and these

TABLE 3. EAG RESPONSES[a] OF MALE *C. cramerella* MOTH TO ISOMERS OF 4,6,10-HEXADECATRIENYL ACETATE

Configuration of 4,6 bonds	EAG response (mV), configuration of 10 bond	
	Z	*E*
Z,E	0.50	0.32
E,Z	1.01	0.57
Z,E	0.19	0.0
E,E	0.44	0.0

[a] Using linked GC-EAG as delivery system with 1.0 ng injected, 0.5 ng to the antenna.

were designated I–V on the basis of their order of elution from the polar column (D). Response I was only recorded in a few samples. It was not resolved from response II on the nonpolar column (C), but the retention time on the polar column (D) fitted with that of *E,Z,E*4,6,10–16:Ac. Response II was consistently the largest in all the samples analyzed, and the retention times fitted only those of *E,Z,Z*4,6,10–16:Ac on both columns. Response III occurred at retention times which matched those of *E,E,Z*4,6,10–16:Ac unambiguously on both columns. Responses IV and V occurred at the retention times of isomers of 4,6,10–16:OH. The retention times of response IV matched only those of *E,Z,Z*4,6,10–16:OH on both columns, and those of response V fitted those of *E,E,Z*4,6,10–16:OH unambiguously on both columns.

The above analytical results indicated that the pheromone of *C. cramerella* consisted of at least four components, and the available evidence suggested that these were *E,Z,Z*4,6,10–16:Ac, *E,E,Z*4,6,10–16:Ac, *E,Z,Z*4,6,10–16:OH and *E,E,Z*4,6,10–16:OH. Other possible components were 16:OH and *E,Z,E*4,6,10–16:Ac, but the results provided little information on the relative proportions of any of these components.

Field tests. In initial field tests, it was assumed that the major component of the pheromone was *E,Z,Z*4,6,10–16:Ac which was responsible for the most significant EAG response in linked GC-EAG analyses. It was also assumed that the isomeric ratio of the alcohol components was the same as that of the acetates. During 1982–1983, polyethylene vials impregnated with 1 mg *E,Z,Z*4,6,10–16:Ac + 0.1 mg *E,E,Z*4,6,10–16:Ac + 0.1 mg *E,Z,Z*4,6,10–16:OH + 0.01 mg *E,E,Z*4,6,10–16:OH + 0.1 mg 16:OH were shown to attract male *C. cramerella* moths to traps at least as effectively as virgin female moths, although catches were uniformly low.

In 1984, experiments were carried out to optimize the proportions of the above five components and to test the effect of adding *E,Z,E*4,6,10–16:Ac.

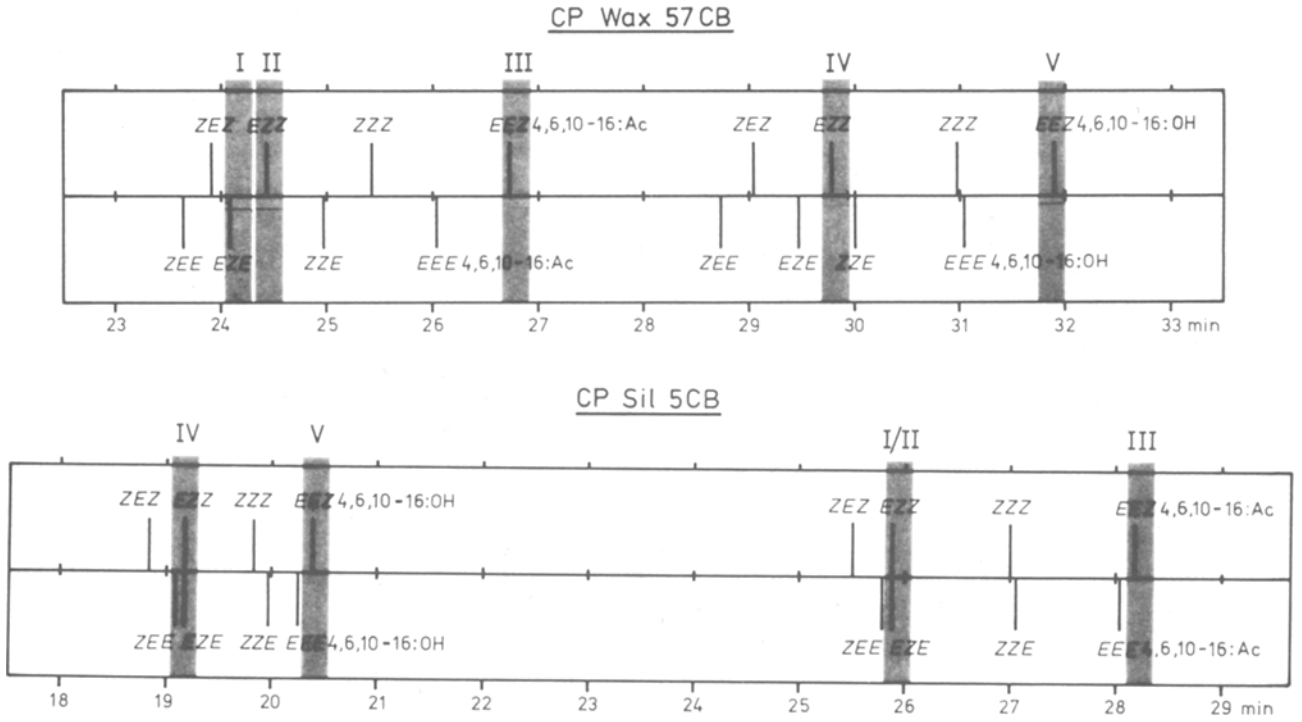

FIG. 7. GC retention data for synthetic isomers of 4, 6, 10–16:Ac and 4, 6, 10–16:OH and for EAG responses recorded during GC-EAG analyses of the natural pheromone on fused silica capillary columns. ■ Band width covered by observed maximum EAG responses numbered according to their order of elution from the polar column, as in the text. Columns coated with CP Wax 57CB (column D: 16:Ac at 16.78 min. 18:Ac at 24.52 min, 20:Ac at 34.78 min) and CP Sil 5CB (column C: 14:Ac at 15.98 min, 16:Ac at 26.39 min, 18:Ac at 40.03 min).

The most important finding was that the attractiveness of the five-component mixture tested in 1982–1983 was greatly increased by using approximately equal amounts of the *E,Z,Z* and *E,E,Z* isomers of the acetate and alcohol. A series of experiments showed that the optimum ratio fell within the range 50:50 to 30:70 *E,Z,Z–E,E,Z*, and the results of two typical experiments are shown in Tables 4 and 5. In subsequent experiments, a 40:60 ratio of *E,Z,Z* and *E,E,Z* isomers was used.

Omitting the unsaturated alcohol components markedly reduced attractiveness (Table 5), and, keeping the isomeric ratio of the alcohols the same as that of the acetates, 10% of the alcohol components relative to the acetates was found to be the optimum proportion (Table 6). Varying the proportion of each alcohol component independently showed that 10% of each, relative to the corresponding acetate, was indeed the optimum proportion (Tables 7 and 8).

Addition of *E,Z,E*4,6,10–16:Ac and *E,Z,E*4,6,10–16:OH, also in 10:1 ratio, to the five-component blend caused a progressive decrease in attractiveness with increasing amounts (Table 9).

In all the above tests, the mixtures contained 10% 16:OH relative to the total amount of *E,Z,Z*4,6,10–16:Ac and *E,E,Z*4,6,10–16:Ac. Varying the amount of 16:OH had little effect on catches except at very high levels when catches were reduced (Table 10).

From the above results, the most attractive mixture was deduced to be a 40:60:4:6:10 mixture of *E,Z,Z*4,6,10–16:Ac, *E,E,Z*4,6,10–16:Ac, *E,Z,Z*4,6,10–16:OH, *E,E,Z*4,6,10–16:OH, and 16:OH. With the polyethylene vial dispensers, those impregnated with this mixture containing 1 mg of the two acetates were shown to be more attractive than those impregnated with lesser amounts (Table 11), and very significantly more attractive than a virgin female moth (Table 12).

DISCUSSION

A synthetic mixture has been defined which catches more male *C. cramerella* moths than a virgin female moth when used to bait traps in the field. This consists of a 40:60 mixture of *E,Z,Z*4,6,10–16:Ac and *E,E,Z*4,6,10–16:Ac with 10% of the corresponding alcohols in the same proportions, dispensed from a polyethylene vial. In the experiments reported, 10% of 16:OH was also added to this mixture, but this is probably not necessary. It is not possible to say that this mixture is identical with that produced by a virgin female moth because only extremely small amounts of the natural pheromone were available for analysis, but the laboratory and field results taken together indicate that the structural assignments and general proportions are correct. However, there may be other components not identified. In particular, the EAG response recorded in some samples and attributed to *E,Z,E* 4,6,10–16:Ac may

be due to some other compound which is an essential component of the pheromone.

This is the first recorded identification of a female sex pheromone in the family Gracillariidae, although attractants for several species in this family have been found by random screening (Roelofs et al., 1977; Ando et al. 1977, 1981; Voerman and Herrebout, 1978; Booij and Voerman, 1984). These attractants include a range of unsaturated acetates, alcohols, and aldehydes, but there is a noticeable predeliction for compounds with the double bond at the 10-position.

Only one other triunsaturated acetate or alcohol has been identified as a pheromone component of a lepidopterous species: (*E,Z,Z*)-4,7,10-tridecatrienyl acetate is one of the components of the pheromone of the potato tuberworm moth, *Phthorimaea operculella* (Lepidoptera: Gelechiidae) (Persoons et al., 1976; Yamaoka et al., 1976).

Use of pheromone-baited traps for control of *C. cramerella* by mass trapping is under investigation in a 200-hectare trial in Sabah.

Acknowledgments—We wish to thank the East Malaysia Planters' Association and the Malaysian Cocoa Growers' Council for funding the field trials carried out in Sabah. We are indebted to Mr. Ho Shui Hing and to Mr. S. Shah and his staff for assistance in these trials. Thanks are also due to Miss Jane Mullings (TDRI) for skilled technical assistance in the laboratory work, to Mrs. Janet Robinson (TDRI) for carrying out the mass spectral analyses, to Mr. R. Dybowski (Laboratory of the Government Chemist, London) for recording the NMR spectra and to Dr. A.R. Ludlow (Imperial College) for advice on statistical analyses.

SENSORY AND BEHAVIORAL EFFECTS OF GOSSYPLURE ALCOHOL ON SEX PHEROMONE RESPONSE OF MALE PINK BOLLWORM MOTHS, *Pectinophora gossypiella*

W. LI,[1] K.F. HAYNES, and T.C. BAKER

(Received March 22, 1985; accepted May 20, 1985)

Abstract—(*Z,Z*)- and (*Z,E*)-7,11-hexadecadienol, reported to be pheromone precursors, interfere with the normal sequence of behavioral response of male *Pectinophora gossypiella* to sex pheromone. The magnitude of the interference can be diminished with higher release rates of the sex pheromone. (*Z,Z*)-7,11-Hexadecadienol is more effective than its *Z,E* isomer in eliciting the reduction in the behavioral response. Electroantennographic evidence suggests that each alcohol may be interfering more with receptor sites for the conformationally similar pheromone acetate than with receptor sites for the other pheromone isomer. Defining behavioral and physiological effects of pheromone analogs such as the alcohols of gossyplure may help to determine their potential for behavioral manipulations.

Key Words—Lepidoptera, Gelechiidae, *Pectinophora gossypiella*, pink bollworm, (*Z,Z*)-7,11-hexadecadienyl acetate, (*Z,E*)-7,11-hexadecadienyl acetate, (*Z,Z*)-7,11-hexadecadienol, (*Z,E*)-7,11-hexadecadienol, pheromone analog, behavior, electroantennogram.

INTRODUCTION

The pheromonally mediated behavioral responses of many species of moths have been found to be adversely affected by compounds that are related in structure to the pheromone components (Beevor and Campion, 1979; Cardé, 1976;

[1] Visiting Scientist from Shanghai Institute of Entomology, Academia Sinica, Chungkin Road (S) 225, Shanghai, P.R.C.

0098-0331/86/0100-0025$05.00/0

Roelofs and Cardé, 1977). Some of these compounds have been synthesized and tested in part because of their structural similarity to the naturally occurring sex pheromone (e.g., Beevor and Campion, 1979). Other chemicals have been identified from extracts of sex pheromone glands and subsequently were found to interfere with the normal sequence of male responses to sex pheromone (e.g., Cardé et al., 1973). These latter compounds may not be emitted by the female and often are likely candidates to be pheromone precursors.

The sex pheromone of the pink bollworm, *Pectinophora gossypiella* (Saunders), has been identified as a 1:1 blend of (*Z*,*Z*)-7,11-hexadecadienyl acetate [(*Z*,*Z*)-7,11-16:Ac] and (*Z*,*E*)-7,11-hexadecadienyl acetate, [(*Z*,*E*)-7,11-16:Ac] (Hummel et al., 1973; this blend was called gossyplure). When Bierl et al. (1974) confirmed the identity of this sex pheromone, they also determined that (*Z*,*Z*)-7,11-hexadecadienol [(*Z*,*Z*)-7,11-16:OH] and (*Z*,*E*)-7,11-hexadecadienol [(*Z*,*E*)-7,11-16:OH] were present in gland extracts of female moths and they assumed that these alcohols were precursors of the sex pheromone. Zhu et al. (1983) detected the same two alcohols only in mated female *P. gossypiella*. In addition they determined that ca. a 1:1 blend of these alcohols (gossyplure OH) reduced captures of male *P. gossypiella* in traps in the field. We felt that it was important to gain a better understanding of the mode of action of this communicative interference at the sensory and behavioral levels in order to determine the potential for mating disruption using these compounds.

METHODS AND MATERIALS

Insects. P. gossypiella larvae were reared in half-gallon cartons containing shredded wheat-germ diet modified from the diet described by Adkisson et al. (1960). Pupae were segregated by sex, and male moths were aged daily and held in 25 × 25 × 30-cm screen cages. Larvae and adults were maintained at ca. 28°C on a 14:10 light–dark cycle (lights on at noon). Adult males had access to an 8% sucrose solution. Individual 2- to 4-day-old male moths were transferred to cylindrical screen cages (3.5 × 3.3 cm diam) during the photophase and were tested during the seventh through ninth hour of the next scotophase.

Chemicals. (*Z*,*Z*)-7,11-16:Ac and (*Z*,*E*)-7,11-16:Ac were purchased from Pest-Select (Buckeye, Arizona), and we determined that they were greater than 93% free of other sex pheromone-like volatiles by a GC analysis using a 3-m column packed with 4.2 g of 10% Silar 10C (N_2 flow rate 30 ml/min; temperature 180°C; OD 4 mm). (*Z*,*Z*)-7,11-16:Ac contained as much as 4% (*Z*,*E*)-7,11-16:Ac and no detectable (*Z*,*Z*)- or (*Z*,*E*)-7,11-16:OH. (*Z*,*E*)-7,11-16:Ac contained as much as 3% (*Z*,*Z*)-7,11-16:Ac and no detectable (*Z*,*Z*)- or (*Z*,*E*)-7,11-16:OH. (*Z*)-7-16:Ac was obtained from Farchan (Wil-

loughby, Ohio), and was greater than 96% free of other sex pheromone-like volatiles. (*Z,Z*)-7,11-16:OH, (*Z,E*)-7,11-16:OH, and (*Z*)-7-16:OH were derived from the acetates by base hydrolysis (as in Bjostad et al., 1984). (*Z,E*)-7,11-16:OH contained as much as 3% (*Z,Z*)-7,11-16:OH and no detectable 7,11-16:Ac. (*Z,Z*)-7,11-16:OH used in behavioral tests contained as much as 4% (*Z,E*)-7,11-16:OH and 5% (*Z,Z*)-7,11-16:Ac. The presence of up to 5% (*Z,Z*)-7,11-16:Ac in the solution of (*Z,Z*)-7,11-16:OH did not pose a problem for behavioral tests since this alcohol was always incorporated into a blend of (*Z,Z*)-7,11-16:Ac and (*Z,E*)-7,11-16:Ac. The blend ratio of the pheromone would only be shifted by at most 1.2%. However, in the electroantennogram (EAG) study, it was important that the alcohols contained no acetates. The alcohols were rederived from the acetates, and this time we could detect no evidence of acetate contaminants in our alcohol solutions. Solutions of the compounds to be used in behavioral and EAG tests were made in hexane.

Behavioral Tests. Male *P. gossypiella* in individual screen cages were transferred to the room housing the flight tunnel at least 0.5 hr prior to the beginning of observations, in order to acclimate the moths to wind-tunnel conditions (0.3 lux from incandescent white lights; supplemental incandescent red lighting; temperature ca. 26°C; wind speed 0.5 m/sec). The wind tunnel was similar to that described by Miller and Roelofs (1978). Cotton dental rolls (1 × 1 cm diam) were loaded with 10-μl hexane solutions containing the indicated amount of compounds about 10 min before the start of a test. Treatments within an experimental series were drawn in random order for each day's test. At the beginning of a trial, a cotton wick treated with the test compounds was placed at the center of a piece of sheet metal (15 × 15 cm) situated 15 cm above the tunnel floor on a sheet-metal platform that was 50 cm from the upwind end of the tunnel and equidistant from the walls of the tunnel. Each male was released 1.4 m directly downwind of the source by placing a cage, open end up, on a metal platform. Cages and platforms were washed with acetone daily after use. The behavioral responses of males were noted in the following categories: wing fanning in the release cage (WF); taking flight (F); upwind flight in the pheromone plume (UFW); making contact with the source (SC); and the time from introduction of the moth into the flight tunnel to initiation of flight. Ryan's (1960) multiple-comparison test for proportions was used to evaluate differences between probabilities of displaying a behavior, and Duncan's multiple-range test following an analysis of variance was used to separate mean latencies.

Electroantennogram. Aspects of our EAG studies followed procedures previously described by Baker and Roelofs (1976), Payne and Dickens (1976) and Roelofs (1977). A 2- to 4-day-old male was captured and its head was removed. The base of the head was placed into saline solution (9.0 g/liter NaCl, 0.2 g/liter KCl, 1.0 g/liter BES (buffer), 4.0 g/liter sucrose, 0.2 g/liter $CaCl_2$) on a wedge of clay that was partially submerged. One antenna was teased up and the terminal two or three segments were removed. A capillary input elec-

trode (containing saline solution and silver chloride-coated silver wire) was moved into position so that it contacted the cut end of the antenna. A chloridized silver wire submerged in the saline solution served as the ground electrode. The EAG response was preamplified with a gain of 100 and frequency range of DC 5 kHz. The signal was displayed on a Tektronic 5113 storage oscilloscope with 1 vertical division equal to 1 mV and 1 horizontal division equal to 1 sec. The EAG responses were recorded to the nearest 0.1 mV.

The first electroantennogram study involved exposing the antenna of a male *P. gossypiella* to one of three adapting stimuli: (1) solvent blank (10 μl of hexane); (2) 10 μg of (*Z*,*Z*)-7,11-16:Ac in 10 μl hexane; and (3) 10 μg (*Z*,*E*)-7,11-16:Ac in 10 μl hexane. Adapting stimuli were loaded onto a 1 × 2-cm piece of fluted filter paper (Z-fold) and, following solvent evaporation, were placed into the proximal end of elbow-shaped glass cartridges (each arm of an elbow was 4 cm long and 1 cm ID). Each cartridge was connected to a laboratory airstream flowing at 2 liters/min after passing through an activated charcoal filter. Test stimuli were the following: (1) solvent blank (10 μl of hexane); (2) 10 μg of (*Z*,*Z*)-7,11-16:Ac in 10 μl of hexane; and (3) 10μg (*Z*,*E*)-7,11-16:Ac in 10 μl of hexane, each on a 1 × 2-cm fluted filter paper. The filter paper was inserted following solvent evaporation into the lumen of a disposable Pasteur-type glass pipet (14.5 cm long). During the first 3 min of exposure to each adapting stimulus, a test stimulus was puffed into the airstream using 2 ml of air forced from a 10-ml glass syringe connected by a rubber septum to the test cartridge. Adapting stimuli and test stimuli were presented in random order within each block of treatments. Each antenna was exposed to one adapting stimulus, and all of the test stimuli. In order to examine antennal recovery following removal of adapting stimuli, test stimuli were again puffed onto the antennae after 2 min in clean air.

The second EAG experiment was designed to examine the effect of the alcohols of gossyplure on the response to (*Z*,*Z*)-7,11-16:Ac and (*Z*,*E*)-7,11-16:Ac. In this experiment the adapting stimuli were 30 μg of the alcohols loaded in 30 μl hexane onto separate pieces of fluted filter paper. The solvent blank adapting stimulus was 30 μl of hexane. Test stimuli were the same as in the previous experiment and were puffed the same way into the adapting airstream as above.

RESULTS

Effects of Gossyplure Alcohol on Behavioral Responses to Gossyplure. As the total quantity of a 1:1 blend of (*Z*,*Z*)-7,11-16:OH and (*Z*,*E*)-7,11-16:OH (this blend will henceforth be referred to as gossyplure OH) was increased, there were several effects on the behavioral responses of males to 1000 ng of gossyplure (Table 1). The addition of 100 ng of gossyplure OH resulted in a sig-

[a] Proportions in the same column are significantly different if they do not share a letter in common ($P < 0.05$; Ryan's multiple-comparison test for proportions. S = stationary; WF = wing fanning; F = flight; UWF = upwind flight in pheromone plume; SC = source contact.

[b] Time from introduction of the moth into the wind tunnel to initiation of flight. Mean latencies in the same column are significantly different if they do not share a letter in common ($P < 0.05$; analysis of variance followed by Duncan's multiple-range test).

[c] Probability of completing the entire behavioral sequence from stationary to contacting the source of pheromone.

nificant decrease in the probability that males would initiate wing fanning (S to WF) and flight (S to F). In addition, this quantity of gossyplure OH resulted in a significant decrease in the conditional probabilities of the transition from flight to upwind flight (F to UWF) and upwind flight to source contact (UWF to SC). A significant decrease in the overall behavioral sequence was noted even when only 10 ng of the alcohols were added to 1000 ng of gossyplure. When equal amounts of gossyplure and gossyplure OH were present on the cotton wick, no males completed the sequence of behaviors involved in location of a pheromone source. In addition to these effects on the behavioral transitions of mate location, the gossyplure OH affected the mean latency of taking flight; a significant increase in the latency was found at the 100-ng dose.

A constant amount of gossyplure OH (100 ng) added to wicks loaded with various quantities of gossyplure (1, 10, and 100 μg) resulted in a significant reduction in males landing at the source (SC) only at the lowest ratio of gossyplure to gossyplure OH (10:1) (Table 2). When the ratio was 100:1, the percentage of males contacting the pheromone source was reduced slightly, but not significantly.

Effect of (Z,Z)- *and* (Z,E)-*7,11-16:OH on Behavioral Responses to Gossyplure.* Gossyplure OH (100 ng) and one of its component isomers, (*Z,Z*)-7,11-16:OH (100 ng), were similarly effective in reducing the percentage of landing at the pheromone source in the wind tunnel. In contrast, (*Z*)-7-16:OH and (*Z,E*)-7,11-16:OH had no effect on this response at the same amount (Table 3). However, in another experiment, increasing the amount of (*Z,E*)-7,11-16:OH to 1000 ng resulted in a significant decrease in the percentage of males reaching the source (reduced from 46.7% to 13.3%; $N = 30$; $P < 0.05$). No males contacted the source when 1000 ng of (Z,Z)-7,11-16:OH was present (0%, not significantly different from 13.3%).

TABLE 2. EFFECT OF 100 ng OF GOSSYPLURE OH ON PERCENTAGE OF MALE *Pectinophora gossypiella* CONTACTING PHEROMONE SOURCE[a]

1000	(Z,Z)-7,11-16:OH (100 ng)	21.2b	50.0
1000	Gossyplure OH (100 ng)	22.4b	47.2

[a] 85 males/treatment. Percentages in the same column are significantly different if they do not share a letter in common [$P < 0.05$; Ryan's (1960) multiple-comparison test].
[b] Percentage of males that completed the entire behavioral sequence from stationary to contacting the source of pheromone.

Effect of (Z,Z)-*7,11-16:OH and* (Z,E)-*7,11-16:OH on Behavioral Response to Blend Ratios of Pheromone.* The addition of 10 ng of (Z,E)-7,11-16:OH to a 30:70 blend of (Z,Z)-7,11-16:Ac and (Z,E)-7,11-16:Ac (1000 ng) resulted in a significant increase in the number of males contacting the pheromone source (Figure 1). The same quantity of (Z,E)-7,11-16:OH resulted in a significant decrease in the response to an 80:20 blend of (Z,Z)-7,11-16:Ac and (Z,E)-7,11-16:Ac and had no effect on the response to a 60:40 blend ratio. (Z,Z)-7,11-16:OH (at a 10-ng dose) did not significantly affect the response to any of the blend ratios of (Z,Z)-7,11-16:Ac and (Z,E)-7,11-16:Ac. The percentage of males contacting the pheromone source was significantly attenuated by 100 ng of (Z,Z)-7,11-16:OH at the 60:40 and 80:20 blend ratios of pheromone (Figure 1).

Electroantennogram. The adapting stimuli (Z,Z)-7,11-16:Ac or (Z,E)-7,11-16:Ac reduced the EAG amplitudes to puffs of either of these same isomers (Figure 2A). However, (Z,Z)-7,11-16:Ac diminished response to (Z,Z)-7,11-16:Ac more than it diminished the response to (Z,E)-7,11-16:Ac, as illustrated by the significant differences in the ratio of antennal response (Z,Z:Z,E). Similarly, the (Z,E)-7,11-16:Ac adapting stimulus diminished EAG responses to superimposed puffs of (Z,E)-7,11-16:Ac more than it reduced responses to puffs of (Z,Z)-7,11-16:Ac. This bias in the ratio of response was still significant 2 min after the adapting stimulus was turned off (Figure 2A).

When (Z,Z)-7,11-16:OH or (Z,E)-7,11-16:OH were used as adapting stimuli, the response to the acetate isomers was significantly diminished (Figure 2B). Again there seemed to be some specificity to this adaptation as evidenced by significant differences between the ratio of response to the acetates during

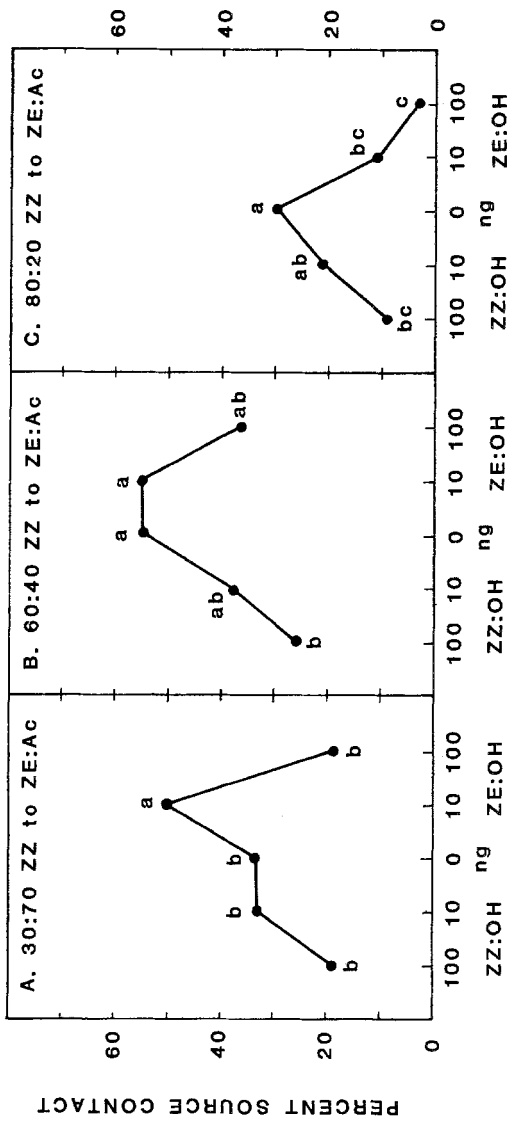

FIG. 1. Percentages of male *Pectinophora gossypiella* contacting a source (cotton dental wick) of three different blends of (*Z*,*Z*)-7,11–16:Ac (*Z*,*Z*:Ac) and (*Z*,*E*)-7,11–16:Ac (*Z*,*E*:Ac) (total 1 μg) when either (*Z*,*Z*)-7,11–16:OH (*Z*,*Z*:OH) or (*Z*,*E*)-7,11–16:OH (*Z*,*E*:OH) is added to the source. Percentages are significantly different if they do not share a letter in common [Ryan's (1960) multiple-comparison test].

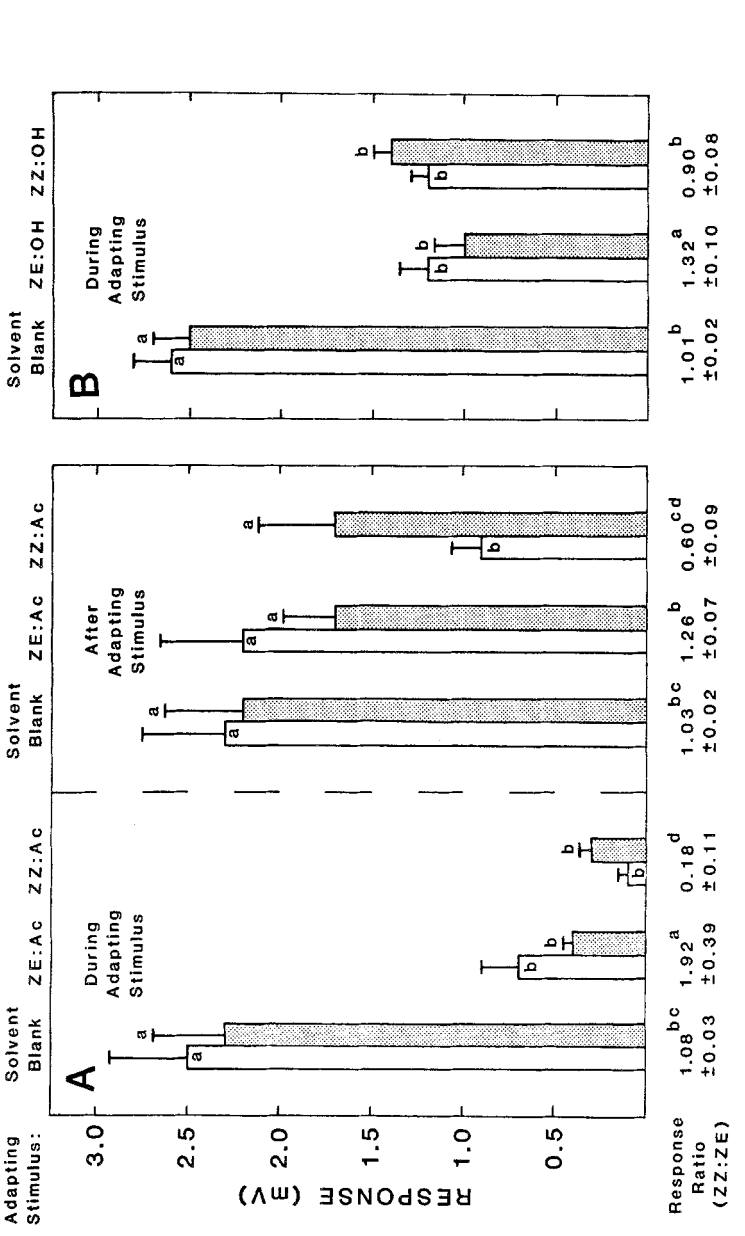

FIG. 2 (A) The electroantennogram responses of male *Pectinophora gossypiella* to (*Z*,*Z*)-7,11–16:Ac (*Z*,*Z*:Ac), and (*Z*,*E*)-7,11–16:Ac (*Z*,*E*:Ac) puffed concurrently (left) or after (right) a continuous adapting airstream containing either solvent blank, *Z*,*E*:Ac, or *Z*,*Z*:Ac. (B) Electroantennogram responses to *Z*,*Z*:Ac, and *Z*,*E*:Ac puffed concurrently with a continuous adapting airstream containing either solvent blank, (*Z*,*E*)-7,11–16:OH (*Z*,*E*:OH) or (*Z*,*Z*)-7,11–16:OH (*Z*,*Z*:OH). Vertical lines above bars indicate standard errors. Mean response ratios are shown ±SE. Mean EAG responses to the same puffed stimulus and mean response ratios within an experiment are significantly different if they do not share a letter in common ($P \leq 0.05$; Duncan's new multiple range test following ANOVA).

the (*Z*,*Z*)-7,11-16:OH adapting stimulus versus the (*Z*,*E*)-7,11-16:OH adapting stimulus.

DISCUSSION

Gossyplure OH effectively interferes with the normal sequence of behavioral responses observed when male *P. gossypiella* are stimulated by sex pheromone (Table 1). The negative effects are significant at each step in the sequence including the transition of upwind flight to source contact. This contrasts with reduced responses to off-ratios of the two acetate isomers, which most severely diminish the transition from flight to upwind flight without reducing the probability of the upwind flight to source contact transition (Linn and Roelofs, unpublished data). The cumulative effects of gossyplure OH on the behavioral responses at all stages account for the observations of Zhu et al (1983), who found that this alcohol blend interferes with the effectiveness of pheromone-baited traps. They observed that 2.5 μg of these alcohols in 30 μg of gossyplure resulted in a 97.6% reduction in trap catch of male *P. gossypiella* (0.5 μg of gossyplure OH reduced trap catch by 81.0%).

In other insects, "inhibitors" have been documented to have effects at specific stages in the behavioral sequence. For instance, (*Z*)-7-dodecenol, which decreases trap catch dramatically, does not eliminate upwind flight to pheromone in *Trichoplusia ni* (McLaughlin et al., 1974). In the gypsy moth, *Lymantria dispar*, the putative pheromone precursor found in the pheromone glands (2-methyl-*cis*-7-octadecene) actually stimulates "searching" behavior by males when it is dispersed in the environment, but reduces pheromone trap catch when volatilizing from a point source releasing disparlure (Cardé et al., 1973, 1975). Clearly the type of behavioral effect elicited by so-called inhibitors varies from species to species and from one compound to another.

The absolute amount of gossyplure OH is not as critical as its amount relative to gossyplure in determining the potential for behavioral interference. A large amount of gossyplure can overcome the negative effect of gossyplure OH. In addition, (*Z*,*Z*)-7,11-16:OH (*Z*,*Z*:OH) was more effective than (*Z*,*E*)-7,11-16:OH (*Z*,*Z*:OH) in interfering with the ability of male moths to locate a pheromone source in the wind tunnel, suggesting that the antagonistic effect of gossyplure OH may be largely due to *Z*,*Z*:OH. To explain these two findings, we propose that there are independent receptors for the two pheromone isomers, (*Z*,*Z*)-7,11-16:Ac (*Z*,*Z*:Ac) and (*Z*,*E*)-7,11-16:Ac (*Z*,*E*:Ac). Second, we suggest that *Z*,*Z*:OH and *Z*,*E*:OH interact more with receptor sites for their corresponding acetate isomers than with sites for the "opposite" isomers. Third, the interaction of alcohol molecules with acetate receptor sites interferes with the ability of those sites to produce optimal responses in the presence of the acetate isomers.

Our data provide much support for these hypotheses. If they are correct, then there should be a suboptimal blend of acetate isomers that is actually *improved* by the addition of a low dose of one of the alcohol isomers, because it interferes with the activity of the corresponding acetate. This increased response to an off-ratio should be eliminated at higher doses of that alcohol isomer. We observed precisely this pattern in response to a 30:70 blend of Z,Z and Z,E:Ac. The addition of 10 ng of Z,E:OH improved the overall response to this blend, and the improvement was eliminated at a higher dose of the alcohol. [The natural blend of Z,Z:Z,E:Ac is 61:39 according to Haynes et al. (1984), and Linn and Roelofs (unpublished data) have found the peak response of males is centered about a 60:40 and 65:35 blend ratio of Z,Z to Z,E:Ac.] Furthermore, as we expected, the addition of 10 ng of Z,E:OH to an 80:20 blend of Z,Z and Z,E:Ac resulted in a significant reduction in the response. However, we did not find a dose of Z,Z:OH that improved the response to 80:20 blend, so our hypotheses were only partially supported by the behavioral data.

The EAG results were consistent with the existence of functionally different receptor sites for each acetate isomer. In our experiments, during adaptation, the EAG response was greater in response to a puff of the acetate isomer that was not used as the adapting stimulus. Tang et al. (1980) have also postulated the presence of independent receptor sites based on an EAG study. Since both alcohols have a detrimental effect on the EAG response to both acetates, it is possible that their observed negative effect on behavior is a general, not a specific one. However, behavioral results (Figure 1) indicate that there is some independent activity of the two alcohol isomers. This independence is also seen at the receptor site level in the small but significant differences in the ratio of acetate response amplitude during adaptation with alcohols. Thus it appears plausible that the negative behavioral effects of the gossyplure alcohols are caused by an interaction of the alcohols with the acetate receptor sites, thereby reducing optimal binding with the acetates.

There are many reports of pheromone-related compounds that can interfere with the behavioral responses of male moths to sex pheromone (see references in Beevor and Campion, 1979; Cardé, 1976; Roelofs and Cardé, 1977). Unfortunately, most of the time we must infer the types of behavioral effects that these pheromone analogs elicit, since usually their effectiveness has been documented only by measuring a reduction in the number of males caught in traps. Compounds that reduce attraction are often closely related in structure to a pheromone component, suggesting that they may be interacting (suboptimally) with the same receptor sites as the pheromone component (Arn et al., 1974; Cardé et al., 1973; Roelofs and Comeau, 1971). In contrast, some evidence suggests there may be independent receptor sites for some pheromone components and "inhibitors" (McLaughlin et al., 1974; Miller et al. 1977; O'Connell et al., 1983; Schneider et al., 1974, 1977). The putative presence of independent receptors for the pheromone and "inhibitors" suggests a functional rationale for

the behavioral inhibition, such as detection of pheromone components of other species (and thus reproductive isolation could be ensured, as suggested by Roelofs and Cardé, 1977) or elimination of behavioral responses to mated females. The latter hypothesis was tested and was not supported by Cardé et al. (1973) for disparlure's olefin precursor which interrupts the response of male gypsy moths to pheromone traps.

Our behavioral and EAG studies suggest that gossyplure OH has some potential as a behavioral disruptant, but this potential is limited relative to the synthetic pheromone. Bartell (1982) suggested several mechanisms which could explain communication disruption using synthetic pheromone, including: (1) adaptation or habituation; (2) "false trail following;" (3) inability of insects to distinguish pheromone plumes from an odor background; and (4) an "imbalance in the pattern of sensory input." Bartell (1982) included an additional category which broadly covered communication disruption with nonpheromone compounds. Clearly this latter category includes compounds that could operate through one or more of the four mechanisms mentioned above. In *P. gossypiella*, gossyplure OH reduces both activation and long-range orientation to sources of pheromone, and thus may have an advantage over some "inhibitors" of other species that only affect close-range orientation [e.g., (*Z*)-7-dodecenol for *T. ni*]. However, communication disruption with gossyplure OH may be limited because sensory adaptation to *Z,Z* or *Z,E*:OH was not as severe as adaptation to *Z,Z* or *Z,E*:Ac, suggesting that one of the mechanisms hypothesized to work in mating disruption (Bartell, 1982) may not be as effective with the alcohols as with the acetates. In addition, gossyplure OH could not serve as a "false trail," and thus another hypothetical mode of action of communication disruption would be limited.

Presumably, one could use just *Z,Z*:OH and stimulate an "imbalance in the pattern of sensory input" when male *P. gossypiella* perceived the pheromone blend released by a female and this alcohol simultaneously. However, because of the greater impact of the acetates on the EAG response, it would seem that using a single acetate to disrupt mating would be more effective in this respect if one's objective is this sensory imbalance. Flint and Merkle (1983, 1984) have already documented the potential for this "sensory imbalance" using just *Z,Z*:Ac to disrupt mating. In addition to the aforementioned limitation, gossyplure OH could not be used in "attracticide" or "bioirritant" approaches, since the "attracticide" formulation relies on responders contacting the odor source (which includes insecticide), and the "bioirritant" approach relies on increased movements of the target insect in fields sprayed with the volatile chemical and an insecticide, thus presumably increasing the probability that a male will pick up a lethal dose.

We are left with two major questions that can only be addressed through field tests: (1) Does the effectiveness of gossyplure OH in interfering with ori-

entation to a point source extend to the very different situation of mating disruption? (2) How effective is mating disruption with gossyplure OH (or only a single alcohol isomer) relative to mating disruption with gossyplure (or a single acetate isomer)? The practicality and biological potential for mating disruption with gossyplure OH rests on economic considerations and the answers to these questions.

Acknowledgments—We are grateful to R.S. Vetter for drawing the figures and rearing the insects. We thank Dr. P.L. Phelan for help with deriving the alcohols from the acetates.

BEHAVIORAL RESPONSES OF MALE AND FEMALE MEXICAN FRUIT FLIES, *Anastrepha ludens*, TO MALE-PRODUCED CHEMICALS IN LABORATORY EXPERIMENTS

D.C. ROBACKER and W.G. HART

Subtropical Crop Insects Research,
USDA-ARS,
Weslaco, Texas 78596

(Received March 12, 1985; accepted May 21, 1985)

Abstract—The behavioral responses of male and female Mexican fruit flies elicited by male abdominal extracts were measured in laboratory cages where pheromone was applied to the undersides of some leaves on a treated tree but to none of the leaves on a control tree. After arrival to the treated tree, females came directly to pheromone sources. Females on the treated tree visited leaves and fought other females at higher rates than on the control tree. Females stayed on treated leaves and trees longer than on control leaves and trees. In separate experiments, the number of males on pheromone-treated trees and leaves was higher than on controls, but other behavior was unchanged. The results indicate that the pheromone stimulates a complex of behavior involved in the mating ecology of the species.

Key Words—Sex pheromones, Mexican fruit flies, Diptera, Tephritidae, *Anastrepha ludens*.

INTRODUCTION

Male-produced sex pheromones are known in several species of tephritid fruit flies including *Ceratitis capitata* (Ohinata et al., 1977), *Dacus tryoni* (Fletcher, 1968), *D. dorsalis* and *D. cucurbitae* (Ohinata et al., 1982), *D. oleae* (De Marzo et al., 1978), *Rhagoletis pomonella* (Prokopy, 1975), *R. cerasi* (Katsoyannos, 1982), *Anastrepha suspensa* (Nation, 1972) and *A. ludens* (Esponda-Gaxiola, 1977). Most studies have focused on attraction of sexually active females to a pheromone source. A few studies have also demonstrated that male-produced chemicals attract conspecific males in the field (Fletcher, 1968; Per-

domo et al., 1976; Ohinata et al., 1977). Other than attraction, little has been published on the behavior of either males or females elicited by the pheromones of their species. The purpose of this paper is to investigate behavior of both male and female Mexican fruit flies (*Anastrepha ludens* Loew) elicited by the male-produced pheromone in laboratory bioassays.

METHODS AND MATERIALS

General. All flies were from a laboratory culture maintained for ca. 60 generations with no wild fly introductions. The original stock came from mango (*Mangifera indica* L.) fruit collected near Mexico City, Mexico.

All experiments were conducted in the laboratory. Temperature varied between 20 and 30°C and relative humidity between 50 and 70%. Photoperiod was shifted so that lights came on at 0230 hr and went off at 1630 hr CST or CDT depending on the time of year.

Pheromone extract was prepared by grinding abdomens of sexually mature, virgin males in hexane and allowing them to soak overnight. The extract was filtered through glass wool and concentrated to one male equivalent (ME) per 5 μl of solvent under a stream of nitrogen. Extracts were stored at 0°C.

Experiments. The experiments were intended to investigate the following aspects of behavior: attraction to the vicinity of the pheromone, leaf visitation rate in the vicinity of pheromone, searching strategy near pheromone sources, attraction directly to pheromone point sources, searching strategy after arrival to point sources, and agonistic behavior and sexual displays by males near and at pheromone sources. Attraction to the vicinity of the pheromone was measured by the number of arrivals to the trees. Leaf visitation rate in the vicinity of pheromone was investigated by analysis of the number of flights (walking from leaf to leaf was negligible) originating and ending within the trees, per female on the trees. The number of females was estimated from the number observed during counts. The null hypothesis was that the number of leaves visited per female on each tree should be the same if the pheromone did not stimulate leaf visitation. Searching strategy near pheromone sources was evaluated by analysis of the time spent by individual females on the treated (T) and control (C) trees. Attraction directly to pheromone point sources was determined from the number of arrivals to T and C leaves on the T tree. Searching strategy after arrival to point sources was investigated by analysis of the time spent by females on T and C leaves. Tendencies for agonistic behavior and male displays (calling) were determined from the number of fights and calling displays, respectively, which occurred in various locations, per fly present.

Bioassays were conducted in wood-framed cages (0.7 × 1.6 × 1.0 m) with aluminum screening and a Plexiglas door (0.7 × 0.9 m) with two round service openings (15 cm diam). The cages contained a 2-cm layer of sand and

2 potted sour orange (*Citrus aurantium* L.) host trees, ca. 1 m tall. Filter paper squares (1.5 × 1.5 cm) were attached to the undersides of 20 leaves of each tree with double stick cellophane tape. Pheromone extract was applied to 10 T papers on the T tree (T = pheromone treated). The other papers on both the T and C trees were treated with hexane only and served as controls (C). Undersides of leaves were chosen as treatment sites since male sexual displays (calling) and mating frequently occurs there in *A. ludens* (Robacker and Hart 1985).

For each replication, 50 sexually mature, virgin females (experiment 1) or males (experiment 2) were released into a cage containing water but not food between 0900 and 1100 hr on the test day. *A. ludens* is not sexually active at this time (Robacker and Hart 1985). Flies were between the ages of 7 and 20 days posteclosion. Tests began at 1400 hr when *A. ludens* is sexually active. At the beginning of each test, the 10 T leaves were treated with 1.0 ME of abdominal extract in 5 μl of hexane and the 30 C leaves with 5 μl of hexane. One observer then recorded the number of flies to arrive on the T tree during a 2-min period, followed by 2-min observations of arrivals to the C tree, the T tree again, and the C tree again. The number of arrivals on T and C leaves was also recorded at this time. Next, the number of flights originating and ending in each tree was recorded for 2 min per tree. At this point, the numbers of flies on the T and C leaves and on the T and C trees were counted. Finally, arrivals to trees and leaves were monitored for another 2 min. per tree.

Agonistic interactions (physical fighting only) were recorded whenever observed throughout the experiment. During experiment 2, the number of sexually displaying (abdomen puffing, rectal pouch eversion, rapid wing vibration; Robacker and Hart, 1985) males was also recorded during the fly-location counts. In both experiments, a second observer recorded the amount of time individual flies spent on various locations during the experiment. For this purpose, a fly was considered to be on a tree until it flew away from the tree and landed somewhere else. A fly was considered to be on a leaf until it arrived at another location. Thus, flights which ended where they began were not departures from the original location.

As part of the same replication, the positions of the two trees were switched and the papers on the leaves were treated again with 1.0 ME of abdominal extract or hexane. The same series of observations was recorded again. After each test the trees were cleaned with soap and water. The two trees alternated as T and C trees and the positions of the T and C leaves were rerandomized for each replication. Twenty replications of experiment 1 and 30 of experiment 2 were conducted. Each replication took about 1 hr to conduct.

Statistical Analyses. Responses of flies on T vs. C trees were compared using paired t tests. Responses on T leaves, C leaves on T trees, and C leaves on C trees were compared with t tests using the error mean square obtained from a randomized complete block analysis of variance. Tendencies for certain

behaviors to vary either with the number of flies present at various locations or with other behaviors was measured by regression.

RESULTS AND DISCUSSION

Experiment 1. Responses of Females. The average number of arrivals to T trees was not significantly greater ($P = 0.14$) than to C trees (Table 1). Therefore, no conclusions concerning attraction to the vicinity of the pheromone source from distances of at least 0.3 m, the distance from the cage walls to the T tree canopy, can be inferred from the experiment. The variable attraction response may have been due to lack of consistent air currents in the cage which could have enabled orientation to the T tree.

The total number of within-tree flights on the T tree was significantly greater ($P < 0.01$) than on the C tree (Table 1). The number of within-tree flights per female on the T trees was also significantly greater ($P < 0.01$) than the corresponding values for C trees. Regressions of the number of within-tree flights per female on the number of females on trees were not significant (C tree: $b = 0.035$, $P = 0.5$; T tree: $b = 0.24$, $P = 0.21$), thus discounting the possibility that within-tree activity per female was related to the number of females. Regression of within-tree flights on the number of agonistic interactions was also not significant for the C trees ($b = 1.9$, $P = 0.5$), but was significant for the T tree ($b = 2.3$, $P = 0.05$). These results demonstrate that females visited leaves (made "within-tree" flights) at higher rates in the vicinity of the pheromone, but they do not show whether the increase in activity was caused directly by pheromone or indirectly through agonistic encounters with other females on the T trees.

Another question investigated was whether females modified their searching strategy so as to remain for longer periods near the pheromone source. The amount of time spent searching (flying, walking, and sitting) T trees was significantly greater ($P = 0.01$) than C trees (Table 1). Combining this result with the effects on leaf visitation rate, we conclude that females not only searched more leaves per unit time but also spent more time searching on the T trees. These pheromone-induced modifications in searching should cause higher encounter rates with males.

The number of arrivals to T leaves was significantly greater ($P = 0.001$) than to C leaves (Table 1), demonstrating that females are probably attracted directly onto male territories after arrival to the vicinity (<0.3 m) of the pheromone source. This confirms and expands the finding of Esponda-Gaxiola (1977), who showed that male abdominal extract acts as an attractant to sexually active females.

Females spent significantly greater ($P = 0.001$) amounts of time on T than on C leaves of the T trees (Table 1). Thus, searching strategy after arrival to

[f] Number of agonistic interactions, per tree or leaf.

pheromone point sources was also modified relative to strategy on untreated leaves. It was not possible to determine from our data whether locomotor arrest or a modified searching strategy in which females engaged in short, round-trip flights was responsible for the increase in time spent on T leaves since both behaviors were regarded as time spent on the leaf. However, the conclusion that females modified their searching strategy so as to remain near the pheromone point source is justified. This translates into a tendency for females to remain on male territories if pheromone is released by the male.

At this point it is appropriate to return to the subject of leaf-visitation rates. The number of arrivals to C leaves was almost identical on the T and C trees, per female on each tree (Table 1). This result suggests similar searching rates on the two trees, thus contradicting the previous conclusion that the pheromone stimulated activity on the T tree. However, the number of females actually available to respond to C leaves on the T tree was probably less than the number observed on the tree since females spent so much time on or near T leaves as a result of modified searching strategy. If the number of females available to respond to C leaves could be determined, the number of arrivals to C leaves on the T tree per available female would probably be greater than the arrival rate to leaves on the C tree.

Much more agonistic behavior occurred on T vs. C trees and T vs. C leaves of the T tree both before and after the appropriate conversions to the number of agonistic interactions per female present on the trees or leaves ($P < 0.01$). Regression of the number of agonistic interactions per female on either the number of females present on trees (C tree: $b = 0.04$, $P = 0.07$; T tree: $b = 0.08$, $P = 0.05$) or the number of females on leaves of the T trees (C leaves: $b = 0.05$, $P = 0.10$; T leaves: $b = 0.16$, $P = 0.08$) showed that, with more replications, significant positive relationships may exist. However, in each case, the regression coefficient is too small to account for the dramatic differences in the number of agonistic interactions on T vs. C treatments. This discounts the possibility that the greater number of females on T trees and leaves was primarily responsible for the increase in agonistic behavior. Rather, the increase in agonistic behavior was probably caused by the presence of pheromone which altered the tendency of individual females to fight.

Experiment 2. Responses of Males. Behavior at pheromone-treated vs. untreated trees and leaves was not quantitatively different, with a few exceptions. The numbers of males on the T trees during counts was significantly higher ($P < 0.05$) than on the C trees (Table 2). Also, the number of males on T leaves was significantly greater ($P = 0.01$) than on C leaves of the C tree. These results suggest that pheromone either attracted or arrested flight behavior of males. However, there were no significant differences in arrivals to T vs. C trees and leaves or in the time spent at T vs. C trees and leaves. The contradictory nature of these results compels us to accept the null hypothesis that male distribution was not affected by pheromone.

[g] Number of agonistic interactions, per tree or leaf.

More sexual displays and agonistic interactions were also observed on T leaves (T tree) than on C leaves of the C tree ($P = 0.05$) (Table 2). Dividing by the number of males on T and C leaves showed that these results reflect the greater number of males on T leaves rather than any stimulatory effect of the pheromone on sexual displays or agonistic behavior.

Compared to female responses in Table 1, male responses to pheromone treatments were weak or absent for most behaviors examined. To date, no published reports have demonstrated that tephritid males respond in laboratory bioassays specifically to pheromone from conspecific males, even though conspecific females do respond in laboratory bioassays (Nation, 1977). Males of at least three species apparently are attracted to male-produced pheromones in field assays (Fletcher, 1968; Perdomo et al., 1976; Ohinata et al., 1977). Also, the lek system used by most tropical Tephritidae requires that males have an aggregating mechanism, and possible roles of pheromones have been proposed (Perdomo et al., 1976; Prokopy, 1980; Burk and Calkins, 1983). It seems likely that experimental designs are at fault for the lack of success at proving responses of males to pheromone in the lab. One possible problem is that males themselves act as treatments wherever they produce pheromone in the bioassay chamber. These unwanted pheromone sources may then compete with the experimental treatments and also convert controls to treatments. Field tests avoid this problem since males are less likely to produce pheromones at sites where control traps are installed. Better designed laboratory and field experiments are needed to elucidate the roles of male-produced pheromones in the mating ecology of both male and female tephritid fruit flies.

FLAVONOID PIGMENTS AND WING COLOR IN *Melanargia galathea*

ANGELA WILSON

Department of Zoology,
University of Oxford
South Parks Road, Oxford, U.K.

(Received April 2, 1985; accepted May 23, 1985)

Abstract—*Melanargia galathea* L. from four different populations were classified into three categories, white, cream, and yellow, according to the background color of their wings. The flavonoid content of the wing and body tissues of butterflies in each of these categories was spectrophotometrically determined. A direct relationship was found between the wing background color and the flavonoid content of the wings; the greater the flavonoid content, the yellower the wings. Butterflies from the yellow category contained an average of 19.6 μg flavone/mg wing tissue; those from the cream, an average of 14.1 μg/mg tissue; and those from the white an average of 8.3 μg/mg wing tissue. Flavonoids represent on average about 1.9% by weight of the yellow wings; 1.4% of the cream wings; and about 0.8% by weight of the white wings. The most frequently encountered wing background color in each of the populations examined was cream; far fewer individuals had white or yellow wings. Flavonoids were not evenly distributed in the wings of *M. galathea*; greater quantities occur on the underside of the hindwings and front margins of the forewings, while the ocelli centers of the underside of the hindwings, and the inner margins on the upperside of the hindwings lack flavonoids. Furthermore, flavonoids were found in the white scales of *M. galathea* but not in the black. The flavonoid content of the body of *M. galathea* was found to be much lower than that of the wings. When expressed as a percentage of that in the wings, the flavonoid content of the body of both sexes was relatively constant; however, the flavonoid content of the female body represents on average about 59% of that in the wings, compared to about 20% in the male. Both the gross flavonoid content and the flavone concentration per milligram of tissue were found to be greater in female than male butterflies. Since the concentration of flavone per cm^2 of wing tissue was the same in both sexes, the greater flavonoid content of female than male *M. galathea* has been attributed to the deposition of relatively large quantities in the reproductive tissues of the female. The possible role(s) of flavonoid pigments in wing coloration, in protecting vulnerable tissues from damaging ultraviolet radiation, in mate selection and/or sex recognition, in insect de-

0098-0331/86/0100-0049$05.00/0

fense against vertebrate predators, and as antimicrobial agents in *M. galathea* has been discussed.

Key Words—*Melanargia galathea*, Lepidoptera, Satyridae, marbled white butterfly, flavonoids, wing pigmentation, flavonoid localization, scales, reproductive tissues, sex differences, ultraviolet radiation protection, Oudeman's phenomenon, sex recognition/mate selection, chemical defense, insect-plant interactions.

INTRODUCTION

Flavonoid pigments are known to contribute to flower color in most angiosperms. The yellow flavonols quercetagetin, gossypetin (Figure 1), and their derivatives, for instance, are responsible for providing color in the primrose, cotton flowers, and in various composites, while derivatives of the flavones luteolin and apigenin are common pigments of white, ivory, or cream flowers (Scott-Moncrieff, 1936; Harborne, 1967, 1977).

Ford (1941) suggested that flavonoids perform a similar role in butterflies, providing wing pigmentation. Although not common, flavonoids are widespread within the lepidoptera, occurring in 36 of 327 butterfly genera, 11.5%, (six of 11 families) examined, and in 10 of 192 moth genera, 5% (four of 13 families) examined (Ford, 1941; 1944). The contribution made by flavonoids to butterfly coloration is particularly noticeable in the forms of *Eurytides lysithous* Hbn. (syn: *Graphium lysithous* Hbn.), *Eurytides ariarathes* Esp. (syn: *Graphium ariarthes* Esp.), and *Atrophaneura* (syn: *Polydorus*) species, with yellow or cream markings, but they are absent from the forms with white markings (Ford, 1941).

In the marbled white butterfly (*Melanargia galathea* L.), the white coloring is structural; however, the background color of the wings is not a pure white, and varies from a creamy white to a distinct yellow. It has been shown that qualitative differences in the flavonoids sequestered by *Melanargia* from its larval food plants are not responsible for this color variation; all the individuals examined from six *Melanargia* species have the same flavonoid pattern

luteolin, R=OH

FIG. 1. Some flavonoid pigments of yellow and white flowers.

(Wilson, 1985a). However, it is possible that quantitative differences in their flavonoid contents are responsible.

In this paper the concentrations of flavonoids in the wings of individual *M. galathea* butterflies have been measured and the relationship between flavonoid content and wing color determined. The distribution of flavonoids within the wing and body tissues has also been examined, and the possible role(s) of flavonoid pigments in *M. galathea* is discussed.

METHODS AND MATERIALS

M. galathea was collected by the author from sites at North Moreton and Aston Tirrold, in Oxfordshire; Wayland Smithy, in Berkshire; and Barbury Castle, in Wiltshire, during July and August 1982. Only small numbers of female butterflies were collected from each site to minimize damage to population numbers in subsequent years. Butterflies were killed in the field using ethyl acetate vapor.

M. galathea Color Classification. Four of the author's collegues (two males and two females) independently classified male *M. galathea* collected from each population into three categories, white, cream, and yellow, according to the wing background color. Female *M. galathea* were not color classified; instead the flavonoid contents of their wing and body tissues were measured to determine if the quantities present were similar to those in the males.

Determination of Flavonoid Content. Flavones, which represent the class of flavonoid present in *M. galathea* exhibit two major absorption peaks in the region 200–400 nm, referred to as bands I and II. Band II of the flavones characteristically occurs between 240 and 280 nm, and band I between 304 and 350 nm.

Flavonoid extracts of *M. galathea* exhibit peaks at 272 nm and 347 nm. Because the absorbance of flavonoids in band I is less affected by impurities, the absorbance of extracts at 347 nm was selected as a measure of the flavonoid content; the higher the absorbance, the greater the concentration of flavonoids.

Ten male *M. galathea* were randomly selected from each of the white, cream, and yellow color categories of all four populations. The wings and body of each butterfly were separated, weighed, and then ground up using a pestle and mortar in a small volume (1–2 ml) of 70% ethanol. Each extract was then filtered into a 50-ml round-bottomed flask using Whatman No. 1 filter paper, concentrated to dryness in vacuo on a rotary evaporator, and the absorbance at 347 nm in 10 ml of 100% methanol determined on a Perkin-Elmer 551S spectrophotometer.

Ultraviolet Absorbance of M. galathea Wings. The presence of flavonoids in *M. galathea* causes the wings to exhibit absorption properties very similar to those of pure flavonoids. In long-wave ultraviolet light, the areas of wing which

are white in visible light appear as dark absorbing regions; the black areas of wing, though, remain black. The intensity of the absorbance in ultraviolet light is proportional to the concentration of UV-absorbing flavonoid in the butterflies' wings; the greater the absorbance, the higher the concentration.

In long-wave ultraviolet light, the appearance of the wings of two yellow category males, one white male, and one uncategorized female, from the North Moreton population, was examined. Flavonoids were removed from wings on the right-hand side of one of the yellow category males by first dipping them into 95% ethanol to "wet" them, and then immersing and gently agitating the wings in 70% ethanol at room temperature for 5 min. The immersion process was repeated several times using fresh 70% ethanol, and the wings were then dried using a hair-dryer. Unfortunately, handling this butterfly to remove flavonoids from the right-hand side damaged some of the scales on the left hand side. Ultraviolet photography, using a UV filter (wavelengths 320–366 nm) was used to record differences in the UV absorbance of these butterflies.

Determination of Distribution of Flavonoids in Wings. Ten male and ten female *M. galathea* were randomly selected from the butterflies collected. The wings of each butterfly were removed and their areas measured. Each wing was ground up using a pestle and mortar in a small volume of 70% ethanol, the extract filtered into a 50-ml round-bottomed flask using Whatman No. 1 filter paper, and concentrated to dryness in vacuo on a rotary evaporator.

To the residues of the wing extracts of male and female *M. galathea*, 2 ml and 2.5 ml, respectively of 100% methanol were added, and the absorbance at 347 nm determined.

Determination of Flavonoid Content of Black and White Scales. Areas of wing composed predominantly of black or white scales were cut from the wings of a number of butterflies. Obtaining samples of black or white scales free from contamination by each other was virtually impossible due to the nature of the black and white patterning; areas of black scales on one surface of the wings often coincide with white on the other.

Derived from predominantly black or white areas of wing, 1.8 mg of each of the black and white scales, respectively, were ground up using a pestle and mortar in a small volume of 70% ethanol, the extracts filtered using Whatman No. 1 filter paper, concentrated to dryness in vacuo on a rotary evaporator, and their absorbance at 347 nm in 2 ml of 100% methanol determined.

RESULTS

M. galathea males from all four populations were readily classified into the three color categories, white, cream, and yellow, by all four colleagues. The numbers of butterflies placed in each category are given in Table 1. More male butterflies from each population were placed in the cream category than

TABLE 1. NUMBERS OF MALE *M. Galathea* FROM FOUR POPULATIONS WITH WHITE, CREAM, AND YELLOW WING BACKGROUND COLORS

Population	No. of males in color category[a]			Total No. of males
	White	Cream	Yellow	
North Moreton	24 (24)	52 (53)	22 (23)	98
Wayland Smithy	22 (28)	41 (52)	16 (20)	79
Barbury Castle	15 (28)	27 (51)	11 (21)	53
Aston Tirrold Downs	12 (21)	30 (54)	14 (25)	56

[a] Percentages of butterflies from the four populations in each color category are given in parentheses.

in either the white or yellow. Cream therefore appears to be the most common wing background color in the wild.

In Table 2 the absorbance at 347 nm of extracts of the body and wings of male *M. galathea* in the three color categories from all four populations are given. From these data it can be seen that the wing absorbance value is directly related to the wing background color; the yellower the wings the higher the absorbance. Despite variation in the flavonoid contents of butterflies, the range of variation within each population is similar. The absorbance values range from 0.23 to 0.99 for white category wings; from 1.03 to 1.47 for cream wings; and from 1.49 to 1.94 for yellow category wings.

The mean absorbance and mean weight of the wing and body tissues of male butterflies in each color category from all four populations has been used to calculate the mean flavone concentrations (μg flavone/mg tissue) (Table 3). Flavone concentrations have been calculated on the basis that a solution of tricin containing 30 μg/ml methanol has an absorbance of 1.45 at 347 nm. Butterflies from the yellow category contain an average of 19.6 μg flavone/mg of wing tissue; those from the cream, an average of 14.1 μg/mg; and those from the white an average of 8.3 μg flavone/mg wing tissue. Flavonoids represent approximately 1.9% by weight of the yellow wings, 1.4% of the cream wings, and 0.8% by weight of the white wings.

The flavonoid content of the body of male *M. galathea* is much lower than that of the wings. From the absorbance values which are directly related to the concentration of flavone present, it can be seen that there is approximately five times as much flavone in the wings than body of *M. galathea*. In addition, when the body absorbance values are expressed as a percentage of the wing absorbance values, it appears that the flavonoid content of the body represents a relatively constant proportion, on average 20%, of that in the wings (Table 3). The wing and body absorbance values have been used to calculate the values above because, although calculations based on the absorbance of the tricin stan-

[a] Flavone concentrations have been calculated on the basis that a solution of tricin containing 30 μg/ml methanol has an absorbance of 1.45 at 347 nm.

dard provide a fair estimation of the quantities of flavone present, tricin is only one of 18 flavonoids previously identified in *M. galathea* (Wilson, 1985a). Further calculations based on these figures would therefore increase the likelihood of error.

The flavonoid content of the wings of the female *M. galathea* examined lies within the same range as those of the males (Table 4) and, as in the males, the flavonoid content of the body is lower than that of the wings. However, when the body absorbance value is expressed as a percentage of the wing absorbance value, it can be seen that the proportion of flavonoids in the female body is greater than that in the males; on average the flavonoid content of the female body represents about 59% of that in the wings, compared to about 20% in the male.

Differences in the flavonoid concentrations of male *M. galathea* with white, cream, and yellow wing background colors revealed by spectrophotometric examination are supported by their appearance in long-wave ultraviolet light. The ultraviolet absorbance of both the upper and undersides of the wings of males in the yellow category is greater than that of males in the white category (Figures 2 and 3). Since the intensity of UV absorbance is related to the quantity of flavonoid present, the greater absorbance of the yellow than white category males indicates that the wings of the former contain more flavonoids.

Washing the wings on the right-hand side of the yellow category males with 70% ethanol to remove flavonoids altered their behavior in long-wave ultraviolet light; wings previously ultraviolet absorbing become ultraviolet reflecting, whereas the unwashed left-hand side wings remained UV absorbing (Figures 2 and 3). Unfortunately, holding the yellow category male by the left-hand side wings during the washing procedure damaged some of the scales on this side. As a result, the wings on the left-hand side appear to be absorbing less than those of the unwashed yellow category male whose scales are intact. Prior to washing the wing, absorbance of both males was the same.

Judging from the appearance of the female butterfly in Figures 2 and 3, it is likely that had this butterfly been color classified it would have been placed in the white category since its absorbance in long-wave ultraviolet light is nearer to that of the white than to that of the yellow category male.

Similar concentrations of flavone per cm^2 of wing tissue were found in the forewings of each male and female butterfly, and, despite variation in the flavonoid contents of individual butterflies, the mean flavone concentration in the forewings of both sexes was approximately the same (Tables 5 and 6). Mean flavone concentrations of 26.65 and 25.89, and 26.63 and 25.62 $\mu g/cm^2$ wing tissue were found in the forewings of male and female butterflies, respectively. The hindwings of each butterfly also contain similar flavone concentrations, and again, the mean flavone concentration in the hindwings of both male and female butterflies was approximately the same. Mean flavone concentrations of 35.6 and 35.43, and 35.70 and 37.57 $\mu g/cm^2$ wing tissue were found in the hind-

TABLE 7. ABSORBANCE VALUES (AT 347 nm) AND FLAVONE CONCENTRATIONS IN BLACK AND WHITE SCALES OF *M. galathea*

Scale color	Absorbance/1.8 mg tissue	Flavonoid conc. (μg flavone/mg tissue)
Black	0.04	0.92
White	1.75	40.23

ures 2 and 3). In view of the limited distribution of this intense UV absorption, it appears that the greater hind- than forewing flavonoid content is due to a higher concentration of flavonoids in the scales on the underside but not on the upperside of the hindwings.

Besides the areas of wing which contain relatively large quantities of flavonoids there are areas of wing which reflect UV light and therefore lack flavonoids. These occur at the inner margins of the hindwings on the upperside, and at the ocelli centers on the underside of the hindwings (Figures 2 and 3). When viewed in UV light, the absence of flavonoids from the ocelli centers produces a series of white or light reflecting spots along the outer margin of the hindwings, particularly noticeable due to the deposition of relatively large quantities of flavonoids elsewhere on the underside of the hindwings.

The flavone content of the white scales of *M. galathea* (40.23 μg flavone/mg tissue) is almost 44 times greater than that of the black (0.92 μg flavone/mg tissue) (Table 7). Although a small amount of flavone was found in the black scales, this is probably due to contamination of the extract by white scales. The black scales of *M. galathea* therefore lack flavonoids.

DISCUSSION

The results of this investigation have shown that there is a direct relationship between the flavonoid content of *M. galathea* and the wing background color; the greater the flavonoid content, the yellower the wings. Even in those butterflies with the palest wing background color, flavonoids represent on average about 0.83% by weight of the wing materials and therefore contribute "body" as well as some color to the wings. In flowers, it is usually the presence of specific flavonoids that are responsible for color differences; this is in contrast to the situation in *M. galathea* where it is different concentrations of the same combination of flavonoids that are responsible for color variation.

At first glance, the greater number of butterflies in the cream than in either the white or yellow categories of each population, and their ratios to one another (1:2:1), suggests a fairly simple Mendelian inheritance, i.e., the white and yellow winged individuals are homozygous recessive (ff) or homozygous dom-

inant (FF), respectively, for the flavone alleles, while the cream individuals are heterozygous (Ff). This, however, is not the case as the wings were only divided into three color categories for convenience; in fact, a gradation exists between them and the wings could have been divided into many more color classes, for example, very white, white, cream-white, cream, cream-yellow, yellow, very yellow. Thus, it is unlikely that a simple Mendelian inheritance is involved, and rather that wing color in *M. galathea* is polygenic and susceptible to environmental modification.

Expressing the flavonoid content of the butterfly body as a percentage of that in the wings has revealed that the proportion of flavonoids in the female body is greater than that in the male, and therefore that a sex difference exists in the distribution of flavonoids. Wilson (1985a) has shown that the eggshell, first instar pharate larvae, and first instar larvae of *M. galathea* before feeding on the larval food plants, contain flavonoids which could only have been derived from the reproductive tissues of the female. The higher concentration of flavonoids in the female than male body is therefore probably due to the localization of flavonoids in both the scales and reproductive tissues of the former. Since the flavonoids in *M. galathea* are of a dietary origin, obtained by the larval feeding habits (Wilson, 1985b), a decrease in the flavonoid content of the female is likely throughout the season concomitant with the deposition of flavonoids in the eggs.

The sequestration of flavonoids by *M. galathea* has a number of features in common with the sequestration of other secondary plant substances, particularly the cardenolides, by insects. In an earlier report (Wilson, 1985b), it has been shown that distinct and constant flavonoid patterns are produced in *M. galathea* reared on different species of grasses, defined as the *Pestuca rubra* L. flavonoid fingerprint profile, the *Lolium perenne* L. fingerprint profile, and so on. A similar phenomenon occurs when the monarch butterfly *Danaus plexippus* L. is reared on *Asclepias eriocarpa* Benth, *A. speciosa* Torr., and *A. californica* Greene; relatively constant patterns of 16–20, 20, and 18 distinct cardenolides appear in the insect, defined as the *A. eriocarpa*, *A. speciosa*, and *A. californica* cardenolide fingerprint profiles respectively (Brower et al., 1982, 1984a, b).

The flavonoid content of female *M. galathea*, which is the larger sex, when expressed as either the mean concentration per milligram of tissue, or as the total concentration per butterfly, is greater than that of the males; the mean flavone concentration per cm^2 of wing tissue is approximately the same in both sexes. In *D. plexippus* the mean cardenolide content (μg/mg tissue) of the females is also greater than that of the males; however, the males of this species are heavier than the females so that the total cardenolide content of the two sexes is approximately the same (Brower et al., 1982). More flavonoids and cardenolides, respectively, are present in the wings than body of both *M. galathea* and *D. plexippus*; approximately twice as much cardenolide occurs in the

wings than body (thorax and abdomen) of *D. plexippus* (Brower and Glazier, 1975) compared to about five times as much flavone in the wings than body of *M. galathea*. In *D. plexippus* it appears that it is not only the quantity of cardenolides in the respective tissues that differs but also their emetic potency (Brower and Glazier, 1975). While the concentration of cardenolides is greatest in the wings, intermediate in the abdomen, and lowest in the thorax, the most emetic cardenolides are found in the abdomen, followed by the wings and then the thorax, in both sexes. As yet it remains to be determined whether the different concentrations of flavonoids in the various tissues of *M. galathea* confer different properties to them.

On average flavonoids represent between 0.2 and 0.56% of the dry weight of *M. galathea*. These values are very close to those reported for *D. plexippus* in which cardenolides on average represent between 0.14 and 0.61% of the dry weight (Brower et al., 1982). The similarity in these figures suggests that both cardenolides and flavonoids are sequestered to the same extent by *D. plexippus* and *M. galathea*, respectively.

The deposition of flavonoids in relatively large quantities on the underside of the hindwings and front margins of the forewings, but their absence from the ocelli centers on the underside of the hindwings and the inner margins of the hindwings on the upperside, suggests that the distribution of these pigments within the wings is under very fine control and that they have a specific role in *M. galathea*. As the insect visual system possesses both UV and visible light receptors, it is likely that both areas of wing can be detected by *M. galathea*. Hence, it is possible that these UV reflecting areas of wing may be used by *M. galathea* in mate selection and/or sex recognition, particularly if used in conjunction with wing movements. Further support for the participation of flavonoids in a role involving the insect's visual system is provided by Ford's (1941) observation that flavonoids are only found in day-flying forms of lepidoptera.

Compared to the rest of the wings, the areas of relatively high flavonoid concentrations, namely the underside of the hindwings and front margins of the forewings, are a much darker yellow color. This may be seen in connection with Oudeman's phenomenon in which the areas of wing on display when a butterfly is in its resting position are adjusted to the color of its environment. When *M. galathea* is resting, it is the dark yellow areas of wing that are displayed; the butterfly's color therefore resembles that of the dry grasses typically found in its habitat during July and August, thus concealing it from potential predators.

The deposition of flavonoids in the reproductive tissues of *M. galathea*, particularly those of the female, mirrors the deposition of carotenoids in the reproductive organs of animals (Goodwin, 1950), and suggests their well-marked physiological function. Flavonoid pigments in *M. galathea* may function by protecting vulnerable tissues from damaging ultraviolet radiation; such a role has been suggested for flavonoids in plants (Harborne et al., 1975). Be-

sides protecting the gametes, the localization of flavonoids in the reproductive tissues will permit their transfer to the developmental materials, and so protect the developing pharate larva after leaving the insect's body.

Variation in the cardenolide content of butterflies in *D. plexippus* populations produces the well-documented palatability spectrum (Brower et al., 1969, Brower and Moffitt, 1974); variation in the flavonoid content of *M. galathea* produces a wing background color spectrum. Although flavonoids are not normally noted for their toxicity to birds and mammals, it is possible that they may be responsible for the unpalatability of *M. galathea*. Pocock (1911) reported that *M. galathea* was distinctly unpalatable although eaten by a number of birds, while Lane (1957) found that a male Shama (*Kittacincla malabarica* Gm.) would not eat *M. galathea*. Hence, the wing background color spectrum observed in *M. galathea* may be the result of a palatability spectrum involving the flavonoids. Unfortunately, at this stage, *M. galathea*'s unpalatability cannot be attributed any more to the presence of flavonoids in the insect than to any of the other substances present. However, it does seem that the striking black and white coloration of this butterfly is aposematic.

In view of the meager immunological system of insects, and the considerable bacteriocidal and antimycetic activities of flavonoids (Havsteen, 1983), it is possible that if flavonoids are involved in a protective role, their prime targets are alien microbes and invertebrate parasites rather than vertebrate predators, thus performing a role similar to that suggested for aristolochic acids in *Battus archidamas* Bsdv. (Urzúa et al., 1983) and cardenolides in *Danaus chrysippus* L. (Smith, 1978).

Despite the lack of information concerning the role of flavonoids in insects, there are a number of similarities between the roles suggested for them in this paper and those suggested in the literature for other secondary plant substances in insects. Both carotenoids (Kayser, 1982) and flavonoids appear to be involved in insect pigmentation; while both pyrrolizidine alkaloids (Edgar et al., 1974; Edgar and Culvenor, 1974) and flavonoids may be used in courtship displays. Common to the aristolochic acids (Urzúa et al., 1983), cardenolides (Smith, 1978), and flavonoids are antibiotic properties. Finally, it is possible that the cardenolides (Brower and Brower, 1964; Brower et al., 1982; Roeske et al., 1976), pyrrolizidine alkaloids (Rothschild and Aplin, 1971), aristolochic acids (Urzúa et al., 1983; Rothschild et al., 1972), mustard oils (Aplin et al., 1975), and flavonoids are involved in insect defense against vertebrate predators. Unfortunately, these roles must remain as mere speculation until further investigations elucidate the precise role(s) of flavonoid pigments in *M. galathea* and other insects.

Acknowledgments—The investigation reported in this paper was performed as part of a PhD study at Reading University. I should like to thank the University of Reading for financial support, Mike Amphlett for preparing the figures, Howard Jones for photography, Martin Dandridge, Mrs.

K. Wilson and Messrs. D. and S. Wilson for assistance collecting *M. galathea*, and finally my supervisor Professor J. B. Harborne for introducing me to the flavonoids.

2,6-DICHLOROPHENOL IN THE TICK *Rhipicephalus appendiculatus* NEUMANN
A Reappraisal

P.G. McDOWELL AND S.M. WALADDE

International Centre of Insect Physiology and Ecology
P.O. Box 30772
Nairobi, Kenya

(Received March 11, 1985; accepted May 28, 1985)

Abstract—Certain olfactory cells of male *Rhipicephalus appendiculatus* Neumann are known to be stimulated by 2,6-dichlorophenol. *R. appendiculatus* has been reexamined for the presence of 2,6-dichlorophenol, and it has been detected in both male and female adults. Unfed females contain 12 ng/tick, declining to 2 ng/tick after six days of feeding, while unfed males contain 2 ng/tick, falling to 0 after feeding. Larval tick extracts which are also known to stimulate 2,6-dichlorophenol-sensitive cells were examined and found to contain this phenol, whereas *R. appendiculatus* eggs did not contain this compound.

Key Words—*Rhipicephalus appendiculatus*, Acari, Ixodidae, Tick, 2,6-dichlorophenol, female, larvae, eggs.

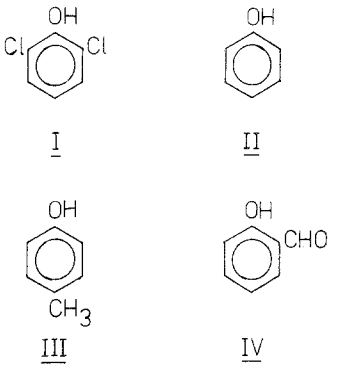
INTRODUCTION

According to Berger (1983), the presence of 2,6-dichlorophenol (2,6-DCP) (I) has been reported in nine tick species since its first discovery in the lone star tick *Amblyomma americanum* (L.) (Berger et al., 1971; Berger, 1972), where the principal role assigned to it was that of a sex pheromone. A report by Silverstein et al., (1983) on additional species containing this compound brings the number to 12.

Other phenols such as phenol (II) itself, *p*-cresol (III), and salicylaldehyde (IV) have also been proposed as sex pheromones in ticks (Wood et al., 1975) (Scheme 1).

Rhipicephalus appendiculatus Neumann, the vector of East Coast fever (ECF) was reported by Wood et al. (1975) to contain phenol (II), *p*-cresol (III),

0098-0331/86/0100-0069$05.00/0



SCHEME 1

and salicylaldehyde (IV). These investigators did not find evidence of 2,6-DCP, but did, however, report that authentic 2,6-DCP attracted male *R. appendiculatus* in their T-tube bioassay. Waladde (1982) reported electrophysiological studies on *R. appendiculatus* and *Amblyomma variegatum* (Fabricius). Certain cells of particular olfactory sensillae were found to respond to low doses of 2,6-DCP (ca. 0.04 ng), while other compounds (such as II–IV) required much larger amounts. Responses of the same sensillae to tick odors and hexane washings were similar to those of 2,6-DCP. This led us to reassess *R. appendiculatus* for the presence of 2,6-DCP through analysis with capillary gas chromatography with electron capture detection (ECD), gas chromatography–mass spectrometry, and UV spectroscopy.

METHODS AND MATERIALS

Rhipicephalus appendiculatus in various stages of development were obtained from the colony maintained at the Kenya Veterinary Research Organisation, Muguga, Kenya, and maintained and fed on rabbits as described by Bailey (1960).

Extracts of male and female ticks were made by using sufficient redistilled hexane to cover the ticks and extracting for 24–48 hr at 4°C, before removing the material which was then reextracted with a minimum of hexane. The combined washings were dried briefly over sodium sulfate, then reduced in volume under a stream of nitrogen to a convenient volume depending on the original number of ticks extracted (in the range 100 μl to 2 ml). Both unfed and fed male and female ticks were extracted. Fed ticks were extracted after six days of feeding.

Each extract of adult ticks was separated by extraction with 1 N NaOH into a neutrals and bases fraction (NB) and, after acidification and reextraction of the aqueous extract with hexane, an acids and phenols fraction (AP). The acids and phenols fraction was further separated by extraction with 5% aqueous

sodium bicarbonate into a phenols fraction (P) and, after acidification and reextraction, an acids fraction (A).

An extract of 44.46 g *R. appendiculatus* larvae was obtained using hexane for 24 hr at 4°C, then removing the ticks and evaporating the solvent to a volume of 2 ml. A portion of this was further concentrated by a factor of ca. 4 for analysis.

An extract of *R. appendiculatus* eggs was obtained by thorough extraction of 10 g of eggs (produced by 75 females) with hexane at 4°C. Following removal of the eggs, the extract was briefly dried over sodium sulfate and reduced in volume to 200 μl for analysis.

The electrophysiological tests were carried out as described previously by Waladde (1982). Briefly, adult male ticks were immobilized on their ventral surface and one of the forelegs oriented to expose the desired sensillum (md 3) and the pedal nerve severed to eliminate motor activity. The tip of the sensillum was removed using metal knives on micromanipulators. Glass microelectrodes filled with tick saline and mounted on Ag–AgCl wires were used. The indifferent electrode was inserted into the tick body, while the tip of the recording electrode was brought into contact with the distal open end of the sensillum. The electrodes were connected to a Grass PI 6 preamplifier. Signals were displayed on a Tektronix oscilloscope and stored on magnetic tape using a stereo tape recorder (Recal 4DS). Olfactory stimuli were presented in an air stream of 100 ml/min passed through a glass cartridge containing a filter paper impregnated with the test sample, for a period of 1.3 sec. Clean air was passed over the preparation at all other times through a similar cartridge. Both cartridges were positioned with the outlet at 45 mm from the preparation. The air stream was switched between cartridges using an electrically operated two-way valve.

Capillary column gas chromatography (CGC) was performed on a Packard model 438 chromatograph (Packard-Becker B.V., 2624 AV Delft, The Netherlands) equipped with a Packard model 902 electron capture detector (ECD) employing a 10 mCi ^{63}Ni foil as the beta source. Capillary columns employed were either 50-m × 0.22-mm ID fused silica CP Sil 5 (OV-101 type) WCOT column operated at 170 or 180°C isothermally, or 50-mm × 0.22-mm ID fused silica CP Wax 51 (Carbowax 20 M type) WCOT column operated at 220°C isothermally (Chrompack, P.O. Box 3, 4330 AA Middleburg, The Netherlands). Injections were performed in the split mode with a split ratio of 10:1 or by splitless injection. Nitrogen, the carrier and scavenge gas for the detector, was passed through an indicating oxygen trap (Chrompack) as well as through molecular sieve water traps.

Packed column gas chromatography (GC) was performed on a Packard model 428 chromatograph (Packard-Becker B.V.) equipped with a Packard model 902 electron capture detector (ECD) employing a 10 mCi ^{63}Ni foil as the beta source. An all-glass column (3-m; 2-mm ID, 6-mm OD) packed with 5% OV-17 coated on Chromosorb W-HP, 80–100 mesh (Johns-Manville). The

column was operated at 150°C isothermally with the injector at 210°C and the detector at 300°C.

Preparative gas chromatography was carried out using an all-glass splitter as described by Baker et al. (1976), modified in shape to fit the Packard model 428 configuration. Preparative separation of *R. appendiculatus* female extract was performed on the 5% OV-17 column adapted to fit the preparative splitter device. Preparative GC was performed on the phenols fraction (P) from an extract of 2880 unfed female ticks. Three preparative fractions were obtained: PF1, PF2, and PF3.

GC peak area integration was achieved by the use of a Packard model 603 computing integrater.

Identification of 2,6-DCP from adult females ticks was confirmed by gas chromatography–mass spectrometry (GC-MS) on a Finnigan 1015D GC-MS, fitted with a Teclab I microcomputer (Tecmar Inc., Cleveland, Ohio) acting as a data system. The ion source was operated at 70 eV energy, with mass scanning in the range m/z 160–170. Identification of 2,6-DCP in larval tick extract was performed by GC-MS on a VG 12-250 quadrupole instrument at VG Analytical, Manchester, U.K. Ultraviolet spectra were recorded on a Perkin-Elmer model 402 UV-Visible spectrophotometer.

RESULTS

Acid–base extraction of male and female *R. appendiculatus* extracts indicated that electrophysiological responses were produced primarily by components in the phenol-containing fraction (P). Figure 1 shows single-cell responses to the acids and phenols fraction (AP) and neutrals and bases fraction (NB) from both fed and unfed female extracts, while Figure 2 indicates the responses from the separated phenols fraction (P) and acids fraction (A) from unfed female extracts. The response to 2,6-DCP is shown in each case for comparison. GC analysis of the extracts revealed the presence of a component with the retention time 2,6-DCP in females, fed and unfed, and in unfed males. None was detected in the fed males. Figures 3A and 3B show typical chromatograms of the phenols fraction (P) from (A) unfed females and (B) unfed males. Coinjection studies by GC with authentic 2,6-DCP showed that component 1 (Figure 3) was 2,6-DCP [coincidence occurred on all columns: OV-17 (packed column), and CP Sil 5 and CP Wax 51 capillary columns]. The largest amounts appeared in unfed females, while fed females and unfed males contained similar amounts as shown in Table 1.

Preparative gas chromatography on a 5% OV-17 packed column was used to isolate components 1 and 3 (Figure 3A) from the phenols fraction (P) of an extract of 2880 unfed adult females. Three fractions were obtained; PF1 con-

Table 1. Estimated Quantities[a] of 2,6-DCP per Tick in *Rhipicephalus appendiculatus*

	Determination (ng/tick ± SD)				
	1	2	3	4	Mean
Unfed female	11.3 ± 1.6 $N = 9$	12.5 ± 2.2 $N = 9$	12.2 ± 1.8 $N = 9$	11.8 ± 1.5 $N = 9$	11.9
6-day fed female	2.1 ± 0.4 $N = 9$	1.9 ± 0.4 $N = 9$	2.1 ± 0.3 $N = 9$	2.3 ± 0.3 $N = 9$	2.1
Unfed male	2.2 ± 0.3 $N = 5$	1.9 ± 0.3 $N = 5$	1.8 ± 0.5 $N = 5$		2.0

[a] Quantities estimated by peak area comparisons with 2,6-DCP solutions of known concentration. The means of four separate determinations are given (three for unfed male).

tained component 1, PF2 contained component 3, while PF3 contained all other components. Components 1 and 3 were in high purity as estimated by reanalysis.

Ultraviolet spectra were recorded for fractions PF1 and PF2. PF1 displayed a spectrum similar to that of an authentic sample of 2,6-DCP with maxima occurring at λ_{max} 268, 276, and 284 nm. The relative intensities of the peaks were slightly different from those of the standard. This was shown to be due to a contribution in the UV spectrum from GC column bleed during preparative fractionation (OV-17 is a 50% phenyl silicone). Figure 4 shows the UV spectrum of component 1 and the effect of column bleed.

To confirm the identity of component 1, a mass spectrum was obtained. The spectrum was acquired only in the region of the molecular ion cluster *m/z* 160–170 in order to provide greater sensitivity. The isotope ions at *m/z* 162, 164, and 166 were found in the ratio of ca. 8.9:6.6:1.0, which approximates to the theoretical value for a compound containing two chlorine atoms (9:6:1).

The structure of component 3 (Figure 3A) remains unknown. The UV spectrum revealed little of its nature.

Fractions PF1, PF2, and PF3 were assayed electrophysiologically by the tip recording technique described by Waladde (1982). Both fractions PF1 and PF2 produced strong responses similar to those produced by 2,6-DCP, while fraction PF3 produced little stimulation.

From these data, we concluded that 2,6-dichlorophenol is indeed present in *R. appendiculatus* males and females, but predominantly in unfed females.

Waladde (1982) also reported that hexane extracts from larvae of *R. appendiculatus* stimulated the same 2,6-DCP-sensitive cells in the male, whereas extracts from eggs did not produce stimulation. A larval extract was examined by GC and GC-MS for the presence of this compound. Fig. 5 shows a GC (EC detection) of whole larval extract. The chromatogram showed a peak with the

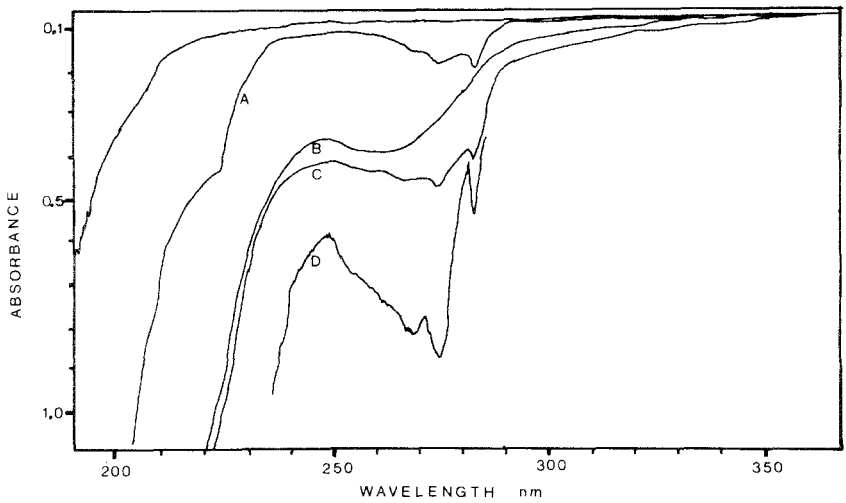

FIG. 4. Ultraviolet spectra of 2,6-dichlorophenol (authentic and isolated) in hexane solution from 190 nm to 360 nm. (A) Authentic 2,6-dichlorophenol; λ_{max}: 268, 276, and 284 nm. (B) Background spectrum due to OV-17 preparative GC column bleed. (C) 2,6-Dichlorophenol isolated from extracts of unfed female *R. appendiculatus*, λ_{max}: 268, 276, and 284 nm. (D) Trace C with magnification factor of five.

correct retention time for 2,6-DCP. GC-MS analysis of this extract showed that this component had a mass spectrum (Figure 6) matching that of authentic 2,6-DCP. Extracts of eggs were also examined by GC and 2,6-DCP was not detected. We therefore concluded that larval ticks also possess the compound.

DISCUSSION

The ubiquitous 2,6-dichlorophenol has been found in *R. appendiculatus*, contrary to the original report on this species (Wood et al., 1975). Both adult males and females contain the compound, with largest amounts occurring in unfed females adults. The levels of 12 ng/unfed females are comparable to quantities found in other species.

The onset of feeding in the ticks appears to stimulate the release of 2,6-DCP into the environment as evidenced by the reduced amounts found in fed ticks. This is in keeping with observations made by Waladde (1982) that, while tick washes from unfed and partially fed females were equally stimulatory, vapors emanating from live unfed females were not as stimulating as those from live partially fed virgin females.

Other investigators have noted variations in 2,6-DCP content with feeding. For example, in *Dermacentor variablis* (Say), feeding appears to cause release

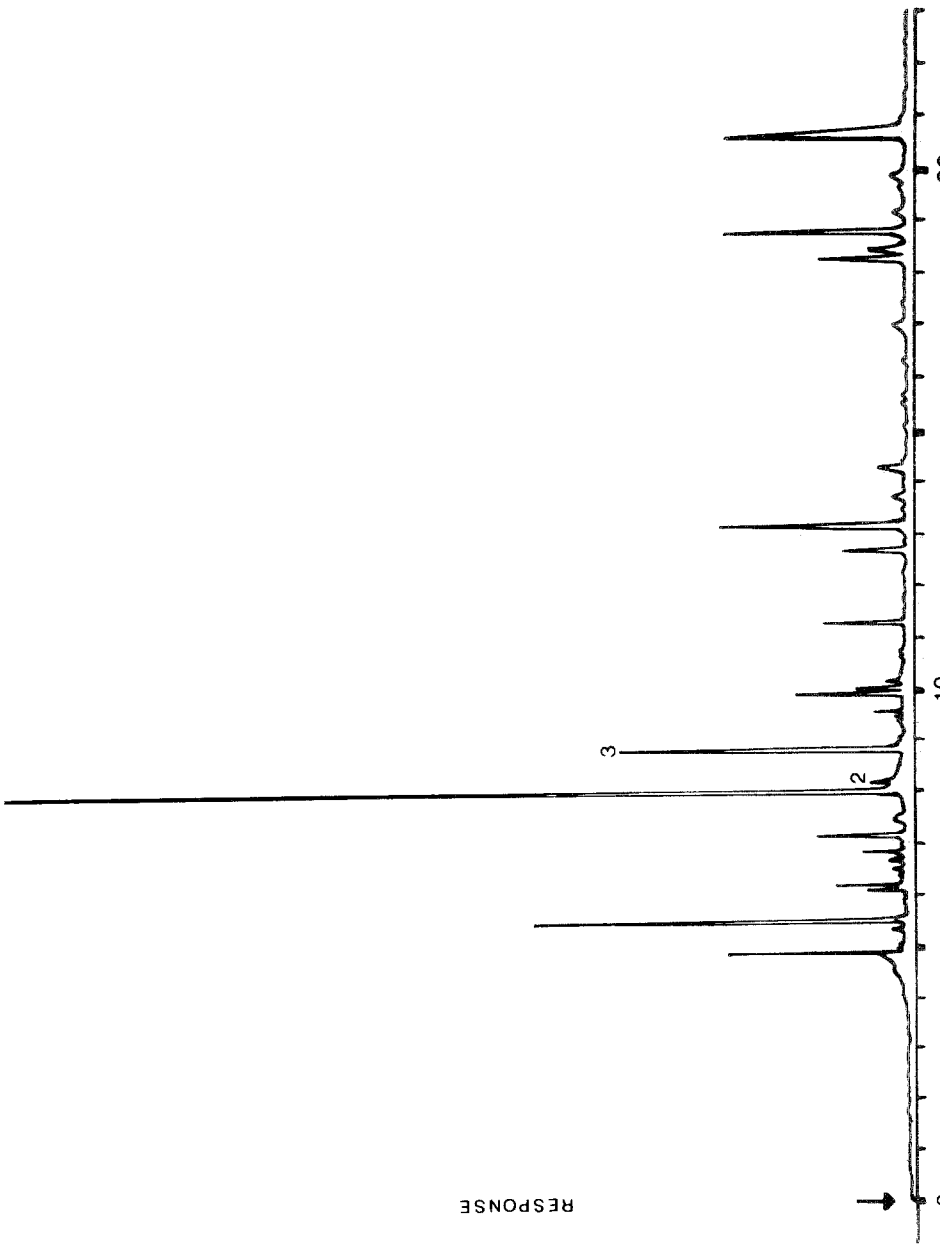

FIG. 5. Gas chromatogram of extract of *R. appendiculatus* larvae. Capillary GC on 50-m CP Sil 5 fused silica column, 0.22 mm ID, splitless injection at 30°C (injector 200°C) with isothermal analysis at 180°C.

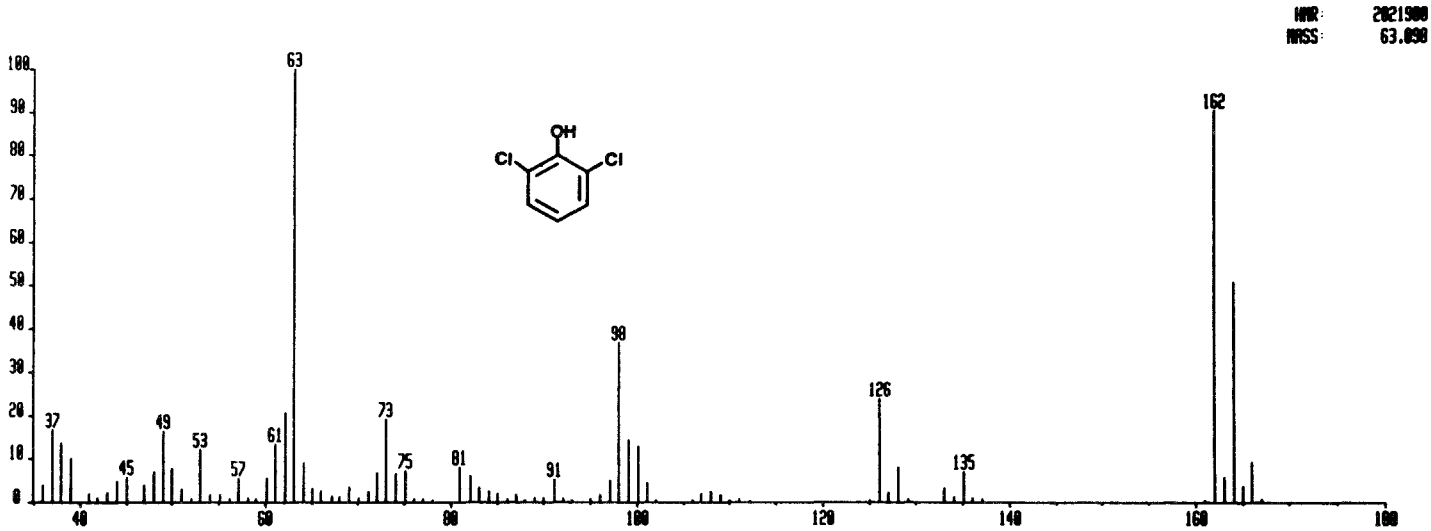

FIG. 6. Mass spectrum of 2,6-dichlorophenol from larval tick extract.

of the compound (Sonenshine et al., 1982). In other cases, feeding does not appear to cause a decrease in 2,6-DCP content. In *Amblyomma americanum* and *A. maculatum* (Koch) females, 2,6-DCP content increases from almost nothing in newly emerged adults to a maximum after 16 days. Subsequent feeding does not significantly increase or decrease the 2,6-DCP content (Kellum and Berger, 1977). These investigators suggested that it would be dangerous to assume that whole-body analysis gives a true indication of the dynamic production of 2,6-DCP. It is rather a measure of the ability of the animal to synthesize and store the compound. In the case of *R. appendiculatus*, it seems that the newly emerged adults already have a significant reserve of the compound. While feeding stimulates the release of 2,6-DCP in the adult, it is not known if further synthesis takes place, as suggested by the general production and storage scheme proposed by Sonenshine et al. (1979).

Waladde (1982) clearly showed that larval washes of *R. appendiculatus* contained a compound or compounds that stimulated 2,6-DCP-sensitive cells in the male, whereas vapors from egg washes did not stimulate these cells. Our analyses of egg and larval extracts have shown that eggs do not contain 2,6-DCP, whereas larvae do contain the compound. We therefore presume that larvae are capable of producing the compound, although we have not yet estimated the quantities they contain. Analyses are currently being performed to quantitate 2,6-DCP in larvae and to detect and quantitate 2,6-DCP in nymphae (preliminary evidence suggests that it is present in nymphae).

The precise role of 2,6-DCP in *R. appendiculatus* is unclear, but it may well act as a sex pheromone, as in other species. Females attach and feed at one site until they are fully engorged, but males achieve sexual maturity after feeding for a few days and later detach to seek receptive females. This male activity coincides with the copious release of 2,6-DCP by the females. It is possible that copulatory behavior is evoked when a male encounters a female emitting a high concentration of 2,6-DCP. Wood et al. (1975) clearly demonstrated that 2,6-DCP attracts male ticks in a T-tube bioassay, although they did not detect it in *R. appendiculatus* females. Waladde's results (1982) suggested that the cells of sexually immature males were more responsive to 2,6-DCP than those of sexually mature males, the opposite of the situation for *R. americanum* as reported by Haggart and Davis (1981).

A multicomponent system seems a likely possiblity here in that phenol and *p*-cresol, which increases with feeding in *R. appendiculatus*, also attracted males in a T-tube bioassay (Wood et al., 1975). The sensitivity of the tick olfactory cells to phenols is evidently variable. In the case of the latter two phenols the cells highly responsive to 2, 6-DCP in males require much higher doses of phenol and *p*-cresol to give responses (Waladde, 1982). It is clear that the role of phenolic compounds in *R. appendiculatus* is poorly understood and behavioral studies are planned to define the role played by 2,6-DCP and other phenols

in this species. Further chemical studies are ongoing to structurally elucidate other compounds which stimulate *R. appendiculatus* olfactory cells, and confirm the presence and quantitate 2,6-DCP in larvae and nymphs.

Acknowledgments—The authors would like to thank V.G. Masslab, Altrincham, Cheshire, U.K., for spectra of components of *R. appendiculatus* larvae extracts, and Dr. W. Voigt of the International Laboratory for Research on Animal Diseases (ILRAD), Nairobi, for supplying some of the ticks used in this work.

(Received March 28, 1985; accepted May 28, 1985)

Abstract—By adding the effects of a series of the stereoisomers to the pheromonal activity of serricornin, (4*S*,6*S*,7*S*)-7-hydroxy-4,6-dimethyl-3-nonanone, the sex pheromone of the cigarette beetle *Lasioderma serricorne* (F.) was investigated. The experiments using synthetic enantiomeric mixtures and optically active stereoisomers showed that the (4*S*,6*S*,7*R*)-isomer inhibited significantly the pheromonal activity of serricornin.

Key Words—Sex pheromone, cigarette beetle, *Lasioderma serricorne* (F.), *Coleoptera*, *Anobiidae*, serricornin, 7-hydroxy-4,6-dimethyl-3-nonanone, inhibitory action of diastereoisomer.

INTRODUCTION

Serricornin, (4*S*,6*S*,7*S*)-7-hydroxy-4,6-dimethyl-3-nonanone, is the sex pheromone of the cigarette beetle *Lasioderma serricorne* (F.), which is a worldwide pest for cured tobacco leaves and various dried foodstuffs (Coffelt and Burkholder, 1972). As the serricornin molecule has three chiral centers at C-4, C-6, and C-7, there are eight possible stereoisomers shown in Figure 1, in which the isomers in the upper row, such as (4*S*,6*S*,7*S*), and the corresponding ones in the lower row, such as (4*R*,6*R*,7*R*), are enantiomerically paired, respectively.

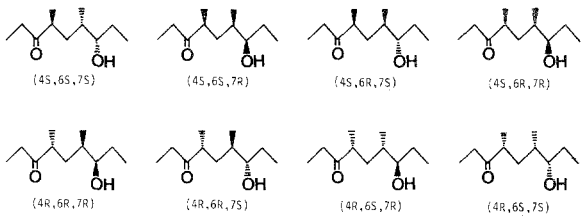

FIG. 1. Eight possible structures of serricornin and diastereoisomers in acyclic forms.

Up to now six of them have been synthesized as such or as the O-acetyl derivatives (Chuman et al., 1981; Mori et al., 1982a,b; Mori and Watanabe, 1985).

Our serial studies on the relationship between the stereochemistry of the serricornin molecule and biological activity revealed that the (4*S*,6*S*,7*S*)-stereoisomer, which is the natural form of the sex pheromone (Mori et al., 1982a,b), is at least 10^3 times more active than any of the other diastereoisomers (Chuman et al., 1982a,b; Mochizuki et al., 1984). In this paper we report the additive effect of these stereoisomers in enantiomeric mixtures and of the optically active stereoisomers on the pheromonal activity of serricornin.

The enantiomeric mixtures used are designated herein as SSS, SSR, SRS, and SRR which mean mixtures of (4*S*,6*S*,7*S*) and (4*R*,6*R*,7*R*) isomers, (4*S*,6*S*,7*R*) and (4*R*,6*R*,7*S*) isomers, (4*S*,6*R*,7*S*) and (4*R*,6*S*,7*R*) isomers, and (4*S*,6*R*,7*R*) and (4*R*,6*S*,7*S*) isomers, respectively.

METHODS AND MATERIALS

Rearing the Insects. The beetles were reared on corn flour supplemented with 8% dried brewer's yeast (EBIOS®, Asahi Breweries Ltd., Tokyo) at 28°C and 60% relative humidity. For the following pheromonal bioassay, virgin males were sexed during the pupal stage by their external characteristics and reared separatedly from the atmosphere of female adults under the same condition.

Pheromonal Bioassay. The method of pheromonal bioassay is essentially the same as described previously by Chuman et al. (1982a) and Mochizuki et al. (1984). At 9–10 AM of the day for bioassay, ten healthy virgin males 7–10 days after adult emergence were put on an arena of filter paper tightly fitted on the floor of a Petri dish (60-mm ID, 15-mm height). Meanwhile almost all of these insects came to rest on the arena. At 2–3 PM of the same day, the cover was opened and a small screen made of rectangular filter paper (5-mm height, 25-mm length, folded in W-letter shape), which was previously impregnated with the test substance, was put on the center of the arena, the dish was covered again immediately (Figure 2). Impregnation of the test substance on the screen was performed just before the bioassay by adding 2 μl of *n*-hexane solution, pipetted from an appropriately diluted solution prepared from stock solution (5

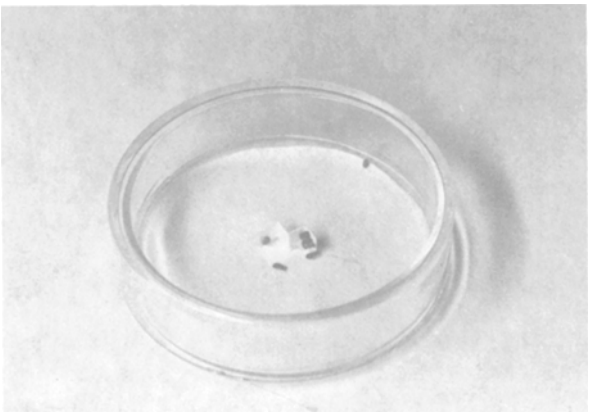

FIG. 2. Pheromonal bioassay using a Petri dish. Many virgin males are crowding on the folded paper screen (center), which has been previously impregnated with a pheromonally active substance. Some of them are attempting to mate with each other. See Methods and Materials for the preparation.

mg/ml), and evaporating the solvent by allowing the preparation to stand for ca. 10 sec.

If the test substance was active as the sex pheromone, the males became alert, raised their antennae, and quickly walked in a zig-zag fashion on the arena seeking the pheromone source. Then they climbed and dropped from the screen and, after a while, attempted to mate with each other. Observation was maintained for 10 min after setting the screen on the arena. Evaluation of the pheromonal activity of each test substance was performed with respect to the following three parameters: (1) attractiveness (accumulated number of times that males climbed the screen), (2) sex stimulation (accumulated number of attempted matings), and (3) maximum aggregation number (maximum number of males staying simultaneously on the screen). Each male was used only once during bioassays.

Enantiomeric Mixtures. Four enantiomeric mixtures SSS, SSR, SRS, and SRR were obtained with purities of more than 99.6% by chromatographic separation of the conventionally synthesized serricornin, a mixture of diastereomers (Ono et al., 1980) with or without C-4 epimerization (Mori et al., 1984a).

(4S,6S,7S)-7-Hydroxy-4,6-dimethyl-3-nonanone (Serricornin). Optically active serricornin was synthesized by the method of Mori and Watanabe (1985). This compound exists as a mixture of the cyclic hemiacetal and acyclic forms (Mori et al., 1984b) in a molar ratio of 2.5 : 1 in benzene solution.

(4S,6S,7R) Isomer. The (4*S*,6*S*,7*R*) isomer was prepared according to the synthetic method for serricornin (Mori and Watanabe, 1985) by the coupling of

diethyl ketone with (2*R*,3*R*)-3-*t*-butyldimethylsilyloxy-2-methylpentyl iodide instead of its (2*R*,3*S*) isomer, followed by silica gel column separation. GLC analysis (cross-linked methyl silicone, fused silica capillary column, 50 m) of the corresponding acetate, $[\alpha]_D^{23}$ + 21.38° (c = 0.32, *n*-hexane), showed the optical purity to be more than 98%. The 500-MHz PMR spectrum of the underivatized sample in deuterobenzene also showed the absence of any of the other diastereoisomers.

RESULTS AND DISCUSSION

Biological Assays Using Enantiomeric Mixtures. As SSS has been proven to have an efficient activity as the sex pheromone substance to male cigarette beetles (Chuman et al., 1979), the effect of the addition of other enantiomeric mixtures, namely SSR, SRS, and SRR, was examined individually. In these systems, the level of SSS was fixed as 1×10^{-1} μg and that of added agents was varied as 0.1×10^{-1}, 0.5×10^{-1}, and 1×10^{-1} μg, respectively. The results are summarized in Figure 3, in which the activity is expressed in relative values. The absolute values for SSS itself (1×10^{-1} μg) were 70.7 (±SD 25.6, $N = 5$), 8.5 (3.9), and 7.9 (1.6) for attractiveness, sex stimulation, and responding ratio, respectively.

These data indicate that the activity of SSS is remarkably decreased in all three parameters by adding SSR even in the ratio of 1:0.1 ($t = 3.51$; $P < 0.01$, $t = 2.48$; $P < 0.05$, and $t = 3.19$; $P < 0.01$ for attractiveness, sex stimulation, and maximum aggregation, respectively). The addition of SRS or SRR caused neither inhibitory nor synergistic effect on the activity of SSS up to the ratio of 1:1. (The differences between controls and $0.1–1.0 \times 10^{-1}$ μg additions were not significant at $P > 0.10$ in all cases.) From this observation, the enantiomeric mixture SSR was considered to play an inhibitory role against the natural stereoisomer of serricornin.

Inhibition by (4S,6S,7R) Isomer. To confirm the above results and to determine the exact inhibitory component, the same bioassay was carried out by using optically active serricornin and the (4*S*,6*S*,7*R*) isomer. Here also the level of serricornin was fixed as 1×10^{-1} μg and that of the adding agent (4*S*,6*S*,7*R*) isomer was varied as 0.1×10^{-1}, 0.5×10^{-1}, and 1×10^{-1} μg. As seen in Figure 4, the result obtained in this experiment seemed to be almost identical to that obtained for SSR against SSS (Figure 3). Both parameters, attractiveness and sex stimulation, for serricornin are decreased to 20–30% of the originals by adding the same amount of (4*S*,6*S*,7*R*) isomer ($t = 7.91$; $P < 0.001$ and $t = 8.93$; $P < 0.001$, respectively, Figure 4). This result indicates that the inhibitory component against the pheromonal activity of serricornin is its (4*S*,6*S*,7*R*) isomer.

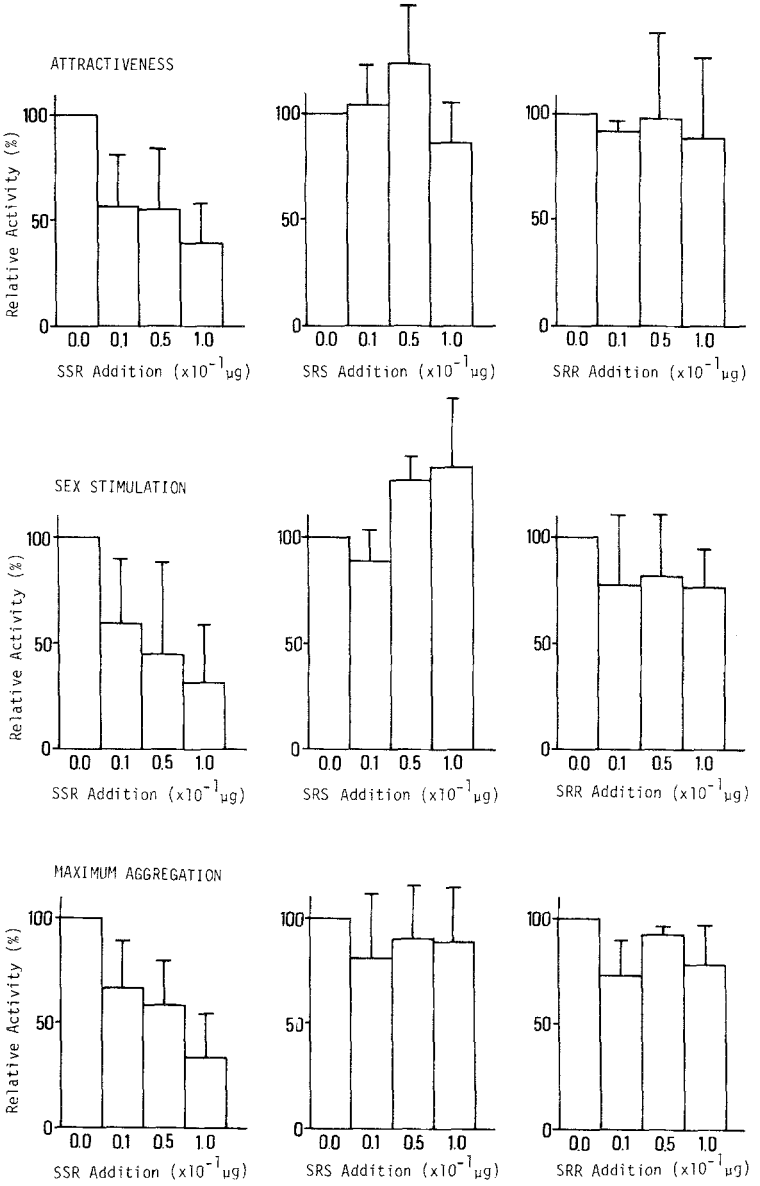

FIG. 3. The effect of enantiomeric mixture addition on the pheromonal activity of SSS. Each test was replicated five times and the standard deviations are shown by T bars.

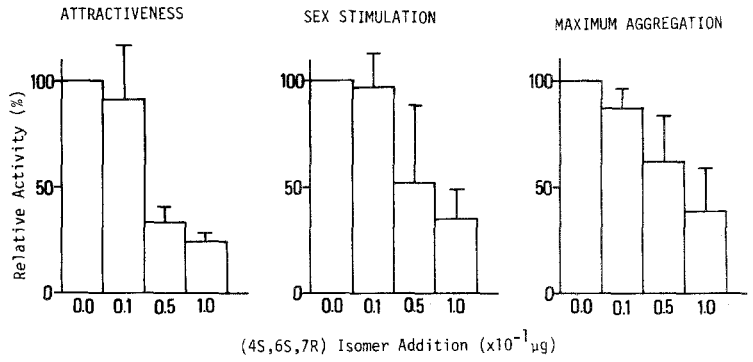

FIG. 4. The effect of (4*S*,6*S*,7*R*) isomer addition on the pheromonal activity of serricornin. See the caption of Figure 3.

These findings suggest that (4*S*,6*S*,7*R*) isomer competitively participates in the receptor for serricornin on the antennae of male cigarette beetles. In fact, recent results of EAG (electroantennography) experiments for all four enantiomeric mixtures indicated higher responses of SSS and SSR than those of SRS and SRR (Mochizuki et al., 1984).

One possibility, that the (4*R*,6*R*,7*S*) isomer, which is the enantiomer of (4*S*,6*S*,7*R*) isomer, also inhibits the pheromonal action of serricornin still remains. But this possibility is precluded because the profiles and the magnitudes of the inhibitory actions of SSR against SSS (Figure 3) and of (4*S*,6*S*,7*R*) isomer against serricornin (Figure 4) were coincident with each other.

Serricornin thus is an example of those pheromones in which a nonnatural, synthetic diastereoisomer inhibits the pheromonally active stereoisomer; similar inhibition by the enantiomers of certain sex pheromones has already been reported for gypsy moth *Porthetria dispar* (Yamada et al., 1976; Klimetzek et al., 1976), Japanese beetle *Popillia japonica* (Tumlinson et al., 1977), and southern pine engraver *Ips calligraphus* (Vité et al., 1976).

ORIENTATION OF BOLL WEEVIL, *Anthonomus grandis* BOH. (COLEOPTERA: CURCULIONIDAE), TO PHEROMONE AND VOLATILE HOST COMPOUND IN THE LABORATORY[1]

JOSEPH C. DICKENS

USDA-ARS
Boll Weevil Research Laboratory
Mississippi State, Mississippi 39762-5367

(Received February 25, 1985; accepted May 30, 1985)

Abstract—Behavioral responses of male and female boll weevils to the aggregation pheromone, grandlure, and the major volatile of cotton, β-bisabolol, were investigated using a new dual-choice olfactometer. Dosage-response experiments revealed both males and females to be attracted by the aggregation pheromone at the 1.0 μg dosage. However, only males were attracted to β-bisabolol (1.0 μg). Both sexes were repelled by the highest dosage of β-bisabolol tested (10 μg). In preference experiment, males chose grandlure over β-bisabolol, while both sexes chose the combination of grandlure + β-bisabolol over β-bisabolol alone. There was some evidence for synergism between pheromone and plant odor for the females. The results correlate well with previous electrophysiological and behavioral experiments.

Key Words—Boll weevil, pheromone, host odor, olfactometer, preference, *Anthonomus grandis*, Coleoptera, Curculionidae, cotton, behavior, bioassay, orientation.

INTRODUCTION

The orientation of insects to their host plants and mates has been the subject of numerous investigations (see Bell and Cardé, 1984). In certain coleopterous insects this relationship is complex since the sex reponsible for host selection

[1] Mention of a trademark, proprietary product, or vendor does not constitute a guarantee or warranty of the product by the U.S. Department of Agriculture and does not imply its approval to the exclusion of other products or vendors that may also be suitable.

often releases in its frass an aggregation pheromone which attracts members of both sexes for both feeding and mating purposes (Birch, 1984; Dickens, 1984). Thus at any one time in the field, insects must choose between suitable host plants and those that have already been colonized or fed upon by pheromone-producing conspecifics. The relationship of the boll weevil, *Anthonomus grandis* Boh. (Coleoptera: Curculionidae), to its host plant, *Gossypium hirsutum* L. (Malvales: Malvaceae), is particularly interesting since this species is narrowly oligaphagous and must find a suitable host for production of its pheromone and subsequent mating and egg deposition (Cross, 1983).

Overwintered males consistently compose 60–65% of boll weevil populations emerging in the spring, and there is some evidence that the first few weevils to emerge are males (Cross, 1983). These males may be responsible for locating a suitable host. Upon locating a suitable host, the male begins to feed and release an aggregation pheromone which attracts both sexes for feeding and mating (Tumilinson et al., 1969; Hardee et al., 1969, 1972).

Two theories have been proposed for host location by adult weevils. One theory asserts that boll weevils locate potential hosts by random flights and are not attracted to the cotton plant from distances over a few centimeters (Hunter and Pierce, 1912; Hardee et al., 1969; Cross, 1973, 1983). Another theory maintains that volatiles emanating from the cotton plant attract boll weevils from some distance (Parencia et al., 1964; Smith et al., 1965; Mistric and Mitchell, 1966; Mitchell and Taft, 1966). Both of these theories have their adherents. Those who adhere to the random flight theory cite the experiments of Hardee et al. (1969) which showed that response of overwintered and migrating boll weevils to males and plants + males greatly exceeded response to fruiting cotton plants which was similar to control (empty) traps. However, cotton plant volatiles have been shown to be attractive in laboratory bioassays (Hardee et al., 1966; Minyard et al., 1969; Thompson et al., 1970) and field tests (Keller et al., 1965; McKibben et al., 1977).

Recent electrophysiological investigations revealed male boll weevils to be as sensitive to certain plant odors, e.g., β-bisabolol (the major volatile of cotton, Thompson et al., 1971), as to components of their aggregation pheromone (Dickens, 1984). Furthermore, threshold and saturation levels determined for various odorants by these investigations also indicated the presence of at least two olfactory receptor populations: one primarily responsive to pheromone components and related compounds; the other primarily responsive to plant odors, e.g., β-bisabolol.

The purpose of this study was to investigate the behavioral effects of activating pheromone and plant odor receptor populations. The experiments were also intended to elucidate enigmatic field and laboratory data on response of the boll weevil to insect and host-plant volatiles. To accomplish these objectives, a new dual-choice olfactometer for the boll weevil was designed.

METHODS AND MATERIALS

Insects. Newly emerged *A. grandis* adults were obtained from a small laboratory colony annually infused with feral insects. Insects collected in the morning (ca. 0800 hr) were sexed and held in Petri dishes (1.0 × 10 cm; 5 insects/dish) on moist filter paper at 26°C without feeding until testing that afternoon (ca. 1400–1700 hr).

Chemical Stimuli. Odorous stimuli used in this study are listed in Table 1. The aggregation pheromone of the boll weevil was a 3:4:3 mixture of compounds I:II:III + IV. The plant attractant chosen, β-bisabolol, was previously shown to be attractive in laboratory bioassays (Minyard et al., 1969). Both the aggregation pheromone and plant attractant were diluted in nanograde pentane. Stimulus dilutions were delivered as 10-μl aliquots placed on filter paper discs (2.15 cm diameter) inserted diagonally into the test vials (Figure 1).

Bioassay Device. A dual-choice behavioral bioassay was devised for use in these experiments (Figure 1). Five insects were released from a 1 dram screw-cap vial through a hole (1 cm diameter) located 1 cm from the center of the bottom of an 8.0 × 4.0 cm crystallizing dish (lower chamber). The lower chamber was covered by Plexiglas into which two holes (1.5 cm diameter) were cut 0.5 cm from the sidewall of the lower chamber. Test vials (4 dram shell vials; 7.0 × 2.1 cm) containing odorous stimuli were positioned over the two holes leading to the lower chamber. In order that volatiles emanating from the test vials did not accumulate in the lower chamber, and to facilitate gradation of olfactory stimuli, air was continuously exhausted from the device at a rate of 1.8 liters/min from a hole (1.0 cm diameter) in the center of the lower chamber.

TABLE 1. SOURCE AND PURITY OF ODOROUS STIMULI USED IN BEHAVIORAL EXPERIMENTS

Function	Compound	Chemical purity (%)	Source of supply[a]
Aggregation pheromone	I [(±)-*cis*-2-isopropenyl-1-methylcyclobutaneethanol]	85–90	A
	II (*cis*-3,3-dimethyl-$\Delta^{1,\beta}$-cyclohexane ethanol)	85–90	A
	III + IV (50:50 mixture of *cis*- and *trans*-3,3-dimethyl-$\Delta^{1,\alpha}$-cyclohexane-acetaldehyde)	85–90	A
Plant attractant	β-Bisabolol	83	B

Experimental Protocol. Just prior to beginning an experiment, insects were taken from Petri dishes and placed in groups of five in screw-cap vials. Odorous compounds were then applied to filter paper discs within test vials which were subsequently put in place on the bioassay device. Positions of test stimuli were alternated for each replicate. The screw-cap vial from which the insects were to be released was then screwed to the bottom of the lower chamber. The insects were allowed to orient for 20 min in the dark. At the end of the orientation period, lights were switched on and the number of insects in each test vial was counted and recorded. For each experiment 20 replicates were performed for both males and females. A paired *t* test was used to evaluate differences between various treatments (Ostle, 1969).

RESULTS AND DISCUSSION

Response to Serial Dilutions. Responses of both male and female *A. grandis* to serial dilutions of grandlure were significantly different from reponses to the pentane control only for the 1.0 μg dosage ($P < 0.01$; Figure 2). Although responses by both sexes at 0.1 μg were slightly greater than the control and slightly less than the control at 10 μg, these differences were not significant.

The attraction of both males and females to grandlure is similar to results obtained by other investigators in field tests (Hardee et al., 1972). Furthermore, that both sexes respond to the aggregation pheromone is further supported by electrophysiological studes indicating receptors for each pheromone component in both sexes (Gutman et al., 1981; Dickens, 1984). A previous study indicated

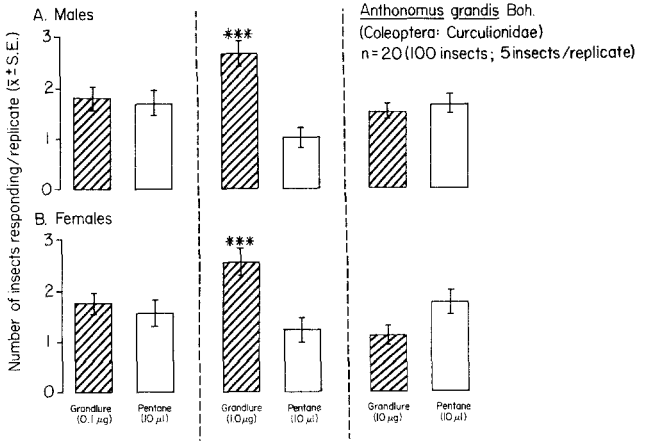

FIG. 2. Mean response of male (A) and female (B) boll weevils to serial dilutions of grandlure. Vertical bars represent standard errors. $***P < 0.01$.

that grandlure alone was unattractive to male boll weevils in laboratory bioassays, although the pheromone alone did attract males in field tests (Hedin et al., 1979). It is difficult to understand the lack of male reponse in laboratory bioassays, especially with regard to our current results. However, the lack of response of males in these earlier laboratory bioassays could be explained by the fact that: (1) males used in those studies were 4–6 days old and already producing pheromone (Gueldner and Wiygul, 1978); (2) methanol was used as a solvent in their study; and (3) a different olfactometer (Hardee et al., 1967) was used in their study.

Only the response of *A. grandis* males to the 1.0 µg dosage of β-bisabolol was significantly greater than response to the pentane control ($P < 0.05$; Figure 3). Both males and females were repelled by the 10 µg dosage of β-bisabolol ($P < 0.01$).

Male boll weevils are the first to emerge in the spring and are responsible for aggregation pheromone production. The attraction of males to β-bisabolol, the major volatile of cotton (Thompson et al., 1971), would greatly facilitate host plant location and subsequent pheromone production (Figure 3). The repulsion of both sexes by β-bisabolol at the highest dosage tested could also be significant since a high concentration of plant odor could signal previous feeding, oviposition, or other damage.

Response in Preference Experiments. Although both grandlure and β-bisabolol were attractive to males when offered versus pentane solvent (Figure 3), males preferred grandlure over β-bisabolol in preference experiments ($P < 0.01$) (Figure 4). In fact, male preference for grandlure over β-bisabolol in this experiment was similar to male reponse to grandlure vs. pentane solvent alone

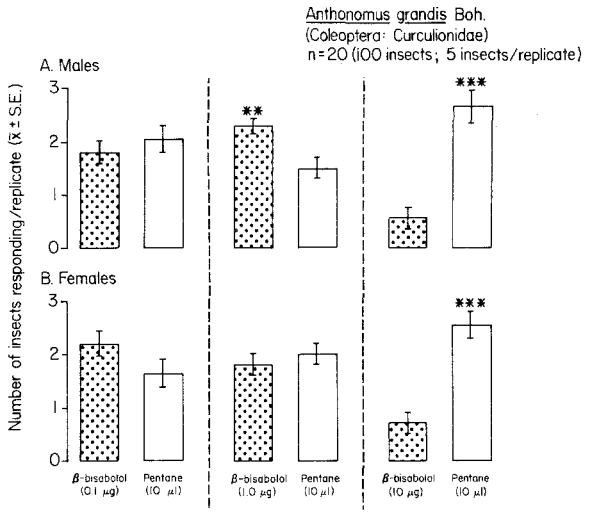

FIG. 3. Mean response of male (A) and female (B) boll weevils to serial dilutions of β-bisabolol. Vertical bars represent standard errors. $^{**}P < 0.05$; $^{***}P < 0.01$.

(Figure 2). When offered the same choice, females exhibited no significant preference for either grandlure or β-bisabolol (Figure 4).

In order to determine possible synergism between the pheromone and plant odor, both sexes were offered the choice between pheromone + plant odor vs. pheromone or plant odor alone (Figure 4). In each instance both sexes preferred the stimulus containing the most grandlure. Additionally, there was some evidence for synergism between grandlure and β-bisabolol for the females, since they preferred this combination of insect and plant odorants over β-bisabolol alone ($P < 0.05$).

Synthesis. The results obtained from the laboratory bioassay correlate well with our current knowledge of olfactory-mediated behavior in the boll weevil and help elucidate results previously considered to be enigmatic. Boll weevil populations emerging in the spring consist primarily of overwintered males, and there is some evidence that the first few weevils to emerge are males (Cross, 1983). These males must locate a host suitable for feeding and pheromone production. Both the lower threshold of the male for host odors found in electrophysiological experiments (Dickens, 1984) and its attraction to the major volatile of cotton, β-bisabolol, demonstrated here could facilitate host finding. Once the male is feeding on a suitable host and producing pheromone, then its conspecifics must choose between pheromone + plant odor vs. plant odor alone. When such a choice is offered as with grandlure + β-bisabolol vs. β-bisabolol, both sexes choose the combination of odorants.

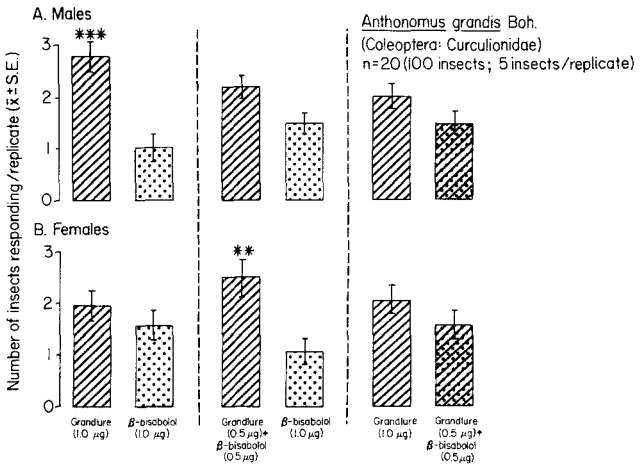

FIG. 4. Mean response of male (A) and female (B) boll weevils in choice experiments involving grandlure and β-bisabolol. Vertical bars represent standard errors. $^{**}P < 0.05$; $^{***}P < 0.01$.

URINARY SIGNALING PHEROMONE AND SPECIFIC BEHAVIORAL RESPONSE IN TREE SHREWS (*Tupaia belangeri*) I. Basic Investigations for a Bioassay

F.v. STRALENDORFF

(Received March 4, 1985; accepted May 30, 1985)

Abstract—As soon as they encounter the scent marks made by the urine of fertile male conspecifics, tree shrews of both sexes cover the scent marks with their own sternal-gland secretion by "chinning." The urine of other species, female conspecifics, or castrated male conspecifics does not elicit this behavior; that is, overmarking with sternal-gland secretion is a reaction to a specific chemical signal. The intensity of the overmarking reaction, i.e., the chinning score in response to the urine sample, decreases as the urine is diluted. The urine of different male conspecifics elicits overmarking of varying intensity; an animal's own urine is in general not overmarked. This behavioral reaction meets all the criteria for a bioassay of potential use in isolating the tree-shrew pheromone from urine.

Key Words—Bioassay, chinning, scent marking, signaling pheromone, sternal gland marking, tree shrew, *Tupaia belangeri*, urinary chemosignal.

INTRODUCTION

Tree shrews are small diurnal mammals, distributed throughout the Oriental Region (Lyon, 1913). They live in pairs, occupying territories (Langham, 1982) which they mark with urine as well as with the secretions of skin glands (Kawamichi and Kawamichi, 1979). When they are kept in enclosures, after only a few months the frequently marked branches become covered with intensely scented urine deposit, which may hang down as an orange-colored flange below the branch (Martin, 1968).

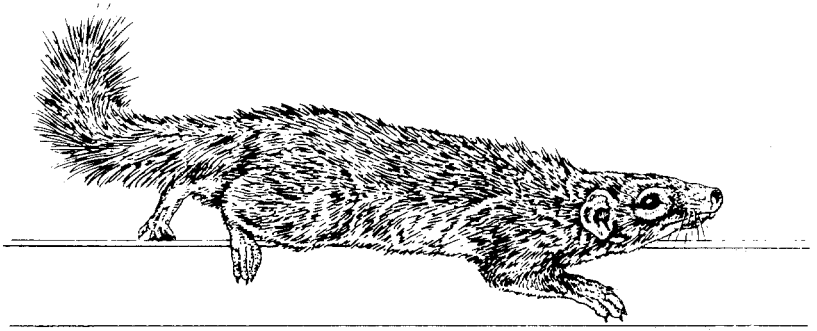

FIG. 1. Chinning response of a tree shrew to urine of a fertile male conspecific (drawn from photograph).

The marks of other animals, whether conspecifics or mammals of other species, are thoroughly sniffed by the tree shrews. After this examination, the urine marks of fertile male conspecifics are overmarked with the secretion from a patch of glands in the jugulosternal region (Figure 1). This behavior is called sternal gland marking or chinning (von Holst and Buergel-Goodwin, 1975). When chinning, an animal presses its sternal region against an object and moves the front of the body back and forth so as to rub the glandular secretion onto the object (Sprankel, 1961).

The urine marks of female conspecifics, unlike those of males, are not usually overmarked by chinning. Hence, overmarking is evidently a specific behavioral response to a specific chemical signal contained in tree-shrew urine.

Specific behavioral responses to chemical signals of conspecifics have rarely been observed in mammals (reviewed by Johnston, 1983). Often the only detectable response is general investigative behavior, and this is usually also elicited by nonspecific stimuli. Where specific behavioral responses to chemical stimuli are found, they can be used as a bioassay, a test by which behaviorally relevant signal substances can be isolated and identified.

In the experiments described here, the degree of specificity of one such behavioral response was measured—overmarking in response to chemical signals in the urine of male tree shrews. Failure of urine other than that of fertile male conspecifics to elicit overmarking would demonstrate the suitability of this behavior as a bioassay for the isolation of a male-specific tree-shrew pheromone.

METHODS AND MATERIALS

Experimental Animals. Twenty-one adult male and 15 adult female *Tupaia belangeri* were studied. Ten of them had been captured as adults in Thailand, and 20 came from our institute's own breeding colony. They were 2–4 years of age. Five of the males had been castrated as adults more than a year previously.

Each tree shrew had a wire-mesh cage to itself (floor area ca. 0.5 m^2; height 0.5 m); neighboring animals were separated physically and optically by wooden partitions. The animals lived in an artificial day/night rhythm (12:12 hr, light–dark), with light phase (activity phase) from 1000 to 2200 hr. They were housed in a climate-controlled room (temperature ca. 25 $\pm$ 1°C, relative humidity 55%; 20-fold air replacement per hour). Food (Altromin diet for tree shrews) and water were present ad libitum.

Sampling Procedures. Immediately after an object is introduced into a tree shrew's cage, the animal marks it with urine. This behavior made it possible to obtain urine without keeping the animals in special cages for metabolic studies and without disturbing them by handling. The urine was collected by placing a PVC rod with a large longitudinal groove diagonally in the cage, so that when it was marked the urine flowed down the groove to one end and, through a hole in that end, into a collecting jar. By replacing this rod with a clean one every hour, as much as 95% of the urine produced in 24 hr was collected. After use, the collecting rods were washed with hot water and dried in air.

Urine from five fertile females and from all the males was collected continuously for several weeks and stored in a deep freezer at −40°C. When the collecting period had been completed, the urine was carefully warmed to the melting point (ca. 0°C) and samples from each individual were pooled separately. In addition, three "group samples" were obtained by pooling urine collected from five fertile males, five castrated males, and five fertile females, respectively. This was done to minimize the effects of individual characteristics and provide urine samples differing only in their group-specific characteristics.

For control tests, urine was obtained from five adult fertile male gerbils (*Meriones unguiculatus*). Beginning two months before the experiments, the gerbil diet had been replaced by tree-shrew diet, to ensure that no differences between the tree-shrew and the gerbil urine would be caused by differences in the food. Urine was collected from the gerbils by putting them in a beaker twice a day; they usually urinated within 1 min, and the fluid was taken up with a pipete and deep-frozen. When 30 ml of gerbil urine had been collected, the samples were thawed (in the same way as the tree-shrew urine) and pooled.

From the pooled urine in each category, several hundred 25-μl samples were deep-frozen in small vials until they were used in the experiments.

Bioassay. The bioassay was carried out with 10 male and 10 female tree shrews. For each test 25 μl of urine was taken into a glass capillary and distributed over ca. 10 cm^2 of the screen forming the front of the animal's cage. As a rule, the animal would come to the screen immediately after this was done, sniff at the sample and, in some cases, then overmark it with the sternal region. (If the animal did not sniff at the urine sample within 30 sec after it was applied, the test was discarded.)

The intensity of the overmarking behavior was expressed in terms of the "chinning score," the number of chinning events (i.e., one forward-and-back-

ward rubbing movement) in the first 2 min after urine application. A given urine sample was tested five times on each animal, each time on a different day.

The sample was tested alternatively with a control sample at an interval of approximately 30 min. The chronological order of the presentation of both samples was changed for each test to counterbalance an eventual effect of the samples' sequence on the chinning reponses of the animals.

From the results of these five tests, the median score was selected for each animal and termed the individual chinning score; this represents the animal's individual response to the particular urine category.

Statistical Analysis. The observed differences among the reactions (i.e., the individual chinning scores) to the various urine categories were tested for significance with the Wilcoxon signed-ranks test for dependent pairs (Siegel, 1959). Differences were regarded as significant when P was less than 0.05 for two-tailed test.

RESULTS AND DISCUSSION

Reaction to Urine of Different Groups. The pooled urine from fertile male gerbils, fertile female tree shrews, and castrated male tree shrews, respectively, did not elicit chinning in most of the experimental animals. The individual chinning scores did not exceed two for each of the three urine categories (Table 1).

In sharp contrast to this result, the pooled urine of fertile male tree shrews was overmarked by 19 of 20 animals. Their individual chinning scores ranged between 1 and 37 (Figure 2). This reaction differs at a highly significant level from those to urine of the other categories ($T = 0$).

This result demonstrates that overmarking with sternal-gland secretion is triggered by a specific chemical signal present in the urine of fertile males tree shrews. The specificity of the signal is determined by taxon (*Tupaia*), sex (male), and physiological state (adult and fertile) of the animal producing it.

Reaction to Urine of Individual Male Conspecifics. Under natural conditions chinning is a response to individual urinary signals. Therefore additional tests were done to check the responses of the animals to different adult males (Table 1).

Male K88 is an animal with a darkly pigmented scrotum. The pigmentation of the scrotum is an indicator of the maturity and the fertility of male tree shrews (von Holst, 1969; Collins et al., 1982); the scrotum of immature or sterile males lacks the dark pigmentation, and the testes are often retracted into the abdominal cavity. The urine of this male elicits significantly more overmarking than does that of castrated conspecifics.

Male K69 is an adult animal of the same species differing from male K88 only in the following respects: its urine lacks the characteristic male odor, the scrotum is not darkly pigmented, and the testes are retracted into the abdominal cavity. Presumably, therefore, this animal is on a very low androgen level or

TABLE 1. MEDIAN CHINNING SCORES OF 20 TREE SHREWS IN RESPONSE TO DIFFERENT CHEMICAL STIMULI.

		Chinning score			Chinning score		
	Test sample[a]	Median[b]	Range[c]	Control sample	Median[b]	Range[c]	T^d
Urine of groups of individuals	fertile male tree shrews	13.5	0–37	fertile male gerbils	0.0	0–1	0.0

[a] Each test was done with an aliquot (25 μl) of the pooled urine collected from a group of individuals (or a single individual, respectively) over a period of several weeks.
[b] The median chinning score is the median of the individual scores of all experimental animals.
[c] The individual scores are each the median from the results of five tests on the same sample.
[d] Wilcoxon signed-rank test for dependent pairs; significance level $P < 0.05$.
[e] $N = 10$ males.

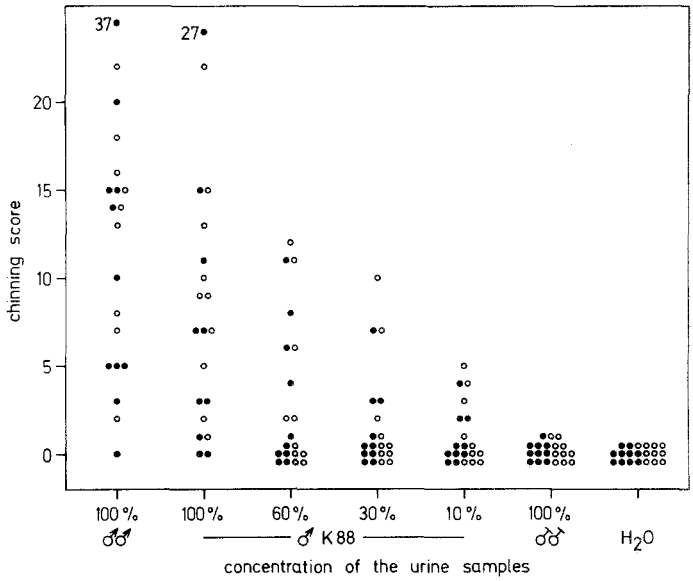

FIG. 2. Individual chinning scores of 20 tree shrews in response to urine of male conspecifics, in one case diluted to various degrees. The individual score (● male, ○ female) is the median from the results of five tests on the same sample.

even sterile. The urine of male K69 is not overmarked by conspecifics significantly more often than the urine of castrated males (Table 1).

The urines of males K88 and K69 represent only two examples of a broad spectrum of conspecific urines. Chinning responses to urine of other males may be within the range between those to the urines of the two animals or even exceed the response to urine of male K88.

Probably the response depends on the concentration of the chinning-eliciting pheromone in the urine. Since this pheromone is androgen-dependent, different pheromone concentrations may result from individual androgen levels of the males. That is, the urine of male tree shrews elicits more chinning the higher the androgen level of its producer. That this is the case has been demonstrated by von Holst and Buergel-Goodwin (1975); when they injected males with different amounts of testosterone propionate, the excretory products of these animals elicited chinning according to the administered doses of androgen.

Androgen level is not the only factor responsible for different pheromone concentrations in the urine of males. Low concentrations of urinary pheromone may be achieved as well by increased water intake and subsequent excretion of diluted urine. To investigate the consequences of urine dilution with regard to behavioral effectiveness, the following experiment was designed.

Reaction to Different Dilutions of Urine from an Individual Male. Urine from male K88 was diluted with demineralized water to give concentrations of

60%, 30%, and 10%. These were tested in order of both ascending and descending concentration. Demineralized water alone was also tested.

The intensity of overmarking decreased in relation to the progressive dilution of the urine (Table 1). Some animals gave very differentiated responses to these small changes in concentration of the pheromone.

The relation between urine concentration and chinning responses is graphed in Figure 2. Similar relations have been found in guinea pigs (Beauchamp et al., 1980) and mice (Nyby et al., 1979).

Figure 2 also illustrates a significant difference ($T = 18$) between the responses of the same animals to 100% urine of male K88 and to the mixed urine of several fertile males. The greater effectiveness of the latter might be due to a higher pheromone concentration. Whether this pheromone concentration has been caused by higher androgen levels of the males or by excretion of a more concentrated urine was not investigated.

On the other hand, the mixed urine from castrated males is even less effective in eliciting overmarking than the 10% dilution of urine from male K88 ($T = 37.5$). This difference cannot be explained by a difference in urine concentration since urine with one-tenth the normal concentration would be pathological when excreted for weeks. Clearly, the pheromone that elicits chinning is not produced by castrates or is produced only in very small amounts.

Urine samples from male gerbils, female tree shrews, and castrated male tree shrews sometimes elicit overmarking (0–2 individual scores) in a few animals. Distilled water was even less effective; it elicited no overmarking at all in 100 tests. A possible explanation is that even nonspecific odor substances trigger overmarking to some slight extent. But this effect is so small in comparison with that of the male pheromone that it is of no practical significance for bioassay.

Reaction to an Animals's Own Urine. It appears biologically plausible that animals would give differentiated responses to the chemical signals of different individual conspecifics. If male tree shrews can distinguish among the urinary signals of various male conspecifics and respond to them in different ways, they should also respond differently to their own urine than to that of fertile male conspecifics. To test this hypothesis, the overmarking reaction of each male to its own urine was observed.

Most of the fertile males failed to overmark samples of their own urine. This reaction is not significantly different from that to the urine of castrated males (Table 1). Inasmuch as the urine of a fertile male must contain its own male pheromone, the lack of a response to it is surprising; the result shows, however, that the animals can distinguish their own signal from those of conspecifics. For such discrimination to be possible, the urine of different males must differ either in qualitative composition or in quantitative composition of its components; I regard the latter as more probable.

From the results of these experiments, we conclude that overmarking with sternal-gland secretion is a specific reaction to a male-specific tree-shrew pher-

omone. A chemical analysis of tree-shrew urine, to isolate and to identify the pheromone, is now in progress.

Acknowledgments—I am grateful to Prof. Dr. D. von Holst for his support. Thanks also to Mrs. W. Deinlein for her technical assistance. The work was funded by the Deutsche Forschungsgemeinschaft Ho 443/16-4.

(Received March 7, 1985; accepted May 30, 1985)

Abstract—Gas chromatographic and mass spectral analyses were conducted on pheromone gland extracts, volatiles collected from excised pheromone glands, and volatiles collected from calling females. In addition to tetradecanal, (Z)-9-tetradecenal, hexadecanal, (Z)-7-hexadecenal, (Z)-9-hexadecenal, and (Z)-11-hexadecenal, four other compounds, tetradecanol, (Z)-9-tetradecenol, hexadecanol, and (Z)-11-hexadecenol, were also identified from gland extracts. Only the six aldehyde components were found in gland and female volatile collections. The mean percentage of components identified from volatiles collected from calling females was 13.0% tetradecanal, 18.1% (Z)-9-tetradecenal, 7.3% hexadecanal, 0.6% (Z)-7-hexadecenal, 1.0% (Z)-9-hexadecenal, and 60.0% (Z)-11-hexadecenal. Bioassays using rubber septa formulated to release the female volatile blend indicated that all six aldehyde components play major roles in close-range male reproductive behavior. Deletion of (Z)-9-hexadecenal from the six-component blend reduced the number of copulation attempts while (Z)-7-hexadecenal exerted subtle effects on all close range behaviors. Tetradecanal affected the number of times males reorient from close range. Deletion of hexadecanal from the six-component blend resulted in a significant reduction in the number of times males landed. Comparison of the six-component synthetic blend (released at somewhat less than 1 female equivalent per hour) with calling females indicated that the six-component blend was indistinguishable from the females in inducing all of the behaviors monitored.

Key Words—Volatile sex pheromone blend, behavior, chemistry, *Heliothis virescens*, Lepidoptera, Noctuidae.

INTRODUCTION

Due to the genetic propensity for rapid development of resistance to pesticides, a number of research groups have been studying alternate methods for control of *Heliothis virescens* (F), the tobacco budworm. A major effort in this direction has been to develop species-specific control techniques using the sex pheromone communication system of this insect. Consequently, the sex pheromone blend produced by female tobacco budworm moths has been under investigation for a number of years. Independent studies by Roelofs et al. (1974) and Tumlinson et al. (1975) indicated that a 16:1 blend of (Z)-11-hexadecenal (Z11-16:Al) and (Z)-9-tetradecenal (Z9-14:Al) was produced by females and was attractive to males. However, based on chromatographic and behavioral data, Tumlinson et al. (1975) suggested that the actual pheromone blend also contained other components. This hypothesis was proven correct when Klun et al. (1980) identified five additional compounds from pheromone gland rinses. The additional compounds identified were: tetradecanal (14:Al), hexadecanal (16:Al), (Z)-7-hexadecenal (Z7-16:Al), (Z)-9-hexadecenal (Z9-16:Al) and (Z)-11-hexadecimal (Z11-16:OH). Initial field studies using this blend dispensed from cotton dental wicks indicated that the seven-component blend was a significantly better lure for tobacco budworm males than was the previous identified two-component blend (Sparks et al., 1979). However, subsequent tests by Hartstack et al. (1980) indicated that the two-component blend was as efficient or better than the seven-component blend.

These results prompted Tumlinson et al. (1982) and Pope et al. (1982) to analyze volatile pheromone components released from the pheromone gland. Neither group found Z11-16:OH in the volatiles. Subsequently, Vetter and Baker (1983) critically evaluated the blend and individual components identified by Pope et al. (1982) plus Z11-16:OH in flight tunnel studies. Their results negated the behavioral function attributed to Z11-16:OH and indicated that Z9-14:Al, Z11-16:Al, and 16:Al were necessary for effective sexual signaling. However, no function could be clearly shown for 14:Al, Z7-16:Al, or Z9-16:Al. Our initial results indicated the presence of 14:Al, Z9-14:Al, 16:Al, and Z11-16:Al in the volatile pheromone blend (Tumlinson et al., 1982). However, males did not respond as well to this four-component blend as they did to virgin females in preliminary bioassays. This prompted us to reevaluate our identification. The following reports the results of chemical analyses of gland extracts, volatile pheromone components released from excised pheromone glands, and volatiles released by calling females. We also report the results of singe- and dual-selection flight tunnel studies used to assess the behavioral functions of the individual components present in the volatile pheromone blend released by females.

METHODS AND MATERIALS

Heliothis virescens used in this study were obtained as pupae from the Bioenvironmental Insect Control Laboratory, USDA, Stoneville, Mississippi. Pupae were sexed and allowed to emerge in isolation from members of the opposite sex. Newly emerged adults were collected daily and allowed to mature for 2 days prior to use in 30 × 30 × 30-cm Plexiglas cages. No insects over 5 days old were used. Both pupae and adults were maintained under a reversed 16:8 hr light–dark cycle at 26° (day) and 24° (night) and a relative humidity of 55%. All cages contained a 10% sucrose solution. Studies were conducted between hours 5 and 8 of the scotophase.

Collection of Pheromone. Gland extracts were prepared by removing the exposed terminal abdominal segments of actively calling females and dipping them in 25 μl of either ethyl ether (Fisher anhydrous reagent grade) or pentane (redistilled Fisher HPLC grade) in a conical microvial for 10–20 sec. Ten microliters of isooctane (Fisher, 99 mole %) containing 10 ng of each of the appropriate internal standards (see below) was then added and the volume was reduced to ca. 5 μl under N_2.

The technique used for collection of volatiles was essentially that described by Tumlinson et al. (1982), except that air from a compressed gas tank was pushed through the system rather than being drawn through by vacuum. Prior to entering the female holding chamber, the compressed air was passed through molecular seive and activated charcoal filters. All air lines were made of copper or Teflon tubing. The silanized glass chamber used to hold females was previously described by Cross (1980). All charcoal microentrainment filters were calibrated using 200 ng of Z9–14:Al, 14:Al, Z11–16:Al, 16:Al, and Z11–16:OH as described by Tumlinson et al. (1982), and the correction factors were incorporated into all calculations. System blanks were obtained daily by passing air through the system at 500 ml/min for a 3-hr period during the photophase immediately preceding volatile collection.

Gland volatiles were collected from the excised terminal abdominal segments of calling females during the mating period. The terminal segments were extended and removed as described previously (Teal et al., 1981a) in the dark using a dim red filtered light. The cut ends of 5–10 preparations were then placed on a 1 × 2-cm stainless-steel planchet so that the tips pointed upwards and the planchet was positioned in the collection device. Air was then passed through the system for 10 min, and the volatiles were recovered as described below. We also collected volatiles from groups of 20–50 tips over a 15- to 30-min period using the same technique.

Volatiles were collected from calling females by placing individuals in collection chambers immediately after the lights went out. Air was continuously passed through the system at 500 ml/min. Although the actual volume of air was high in comparison to that of Pope et al. (1982), the air speed in the cham-

ber was low due to its shape. Calling behavior was not visibly affected by the volume of air passed over the females. When females had entered prolonged calling bouts, the microentrainment filters were fitted onto the outports of the chambers using a Teflon sleeve. Insects were monitored throughout the calling period and, when an individual stopped releasing pheromone, the entrainment filter was removed.

Volatiles were recovered from the entrainment filters using the technique described by Tumlinson et al. (1982). The method was modified to include rinsing the walls of the receiving vessel with 15 μl of redistilled pentane and the addition of 15 ng of each of the appropriate internal standards prior to the addition of 20 μl of isooctane and volume reduction under N_2. Internal standards used for all analyses included the acetates of primary saturated alcohols from 12 to 16 carbons in length.

Chemical Analysis. Capillary gas chromatographic (GC) anslyses of natural products and synthetic standards were performed using Varian 3700 and Hewlett Packard 5792 GCs equipped with splitless injectors and flame ionization detectors. The Hewlett Packard was also equipped with a cool on-column injector. The Varian was interfaced to a Perkin Elmer CIT II system and 3600 data station while the Hewlett Packard was interfaced to a HP 3390 integrator. Capillary columns used for analysis in the Varian included a glass 35-m × 0.15-mm (ID) OV-1 column, a glass 30-m × 0.25-mm (ID) SP2340 column, and a fused silica 60-m × 0.25-mm (ID SP2330 (Supelco) column. Helium was used as a carrier gas in this instrument at a linear flow velocity of 18 cm/sec. Samples were injected at an initial temperature of 80° (injector purge at 60 sec), and the oven temperature was programmed after 2 min at 30°/min to final temperatures of 180° (OV-1). 140° (SP2340), and 165° (SP2330). Columns used in the Hewlett Packard included a fused silica 15 m × 0.15 mm (ID) cross-linked methysilicone (Hewlett Packard), a fused silica 25 m × 0.22 mm (ID) BP20 (SGE) (equivalent to Carbowax 20 M), and a 30 m × 0.25 mm (ID) SPB1 (equivalent to methyl silicone) (Supelco). Hydrogen was used as the carrier gas at 40 cm/sec. Conditions of chromatography were as follows when using the splitless injector: initial temperature = 80°, injector purge at 30 sec, temperature program after 60 sec = 35°/min, final temperature = 155°. Conditions used with the cool on-column injector were: initial oven and injector temperature = 80°, temperature program = 15°/min, final temperatures = 165° (SPB1) and 175° (BP20). In all instances, the retention times of both natural products and synthetic standards were converted to equivalent chain length units (ECL) using the acetate internal standards as the retention index (Swoboda, 1962).

Both methane and isobutane chemical ionization mass spectra were obtained using Finnigan 3200 and VG 1212F chemical ionization mass spectrometers. The Finnigan was interfaced to a Varian 1400 GC equipped with a direct injector and capillary system. Capillary GC columns used in this instrument included a 24 m × 0.25 mm (ID) glass cholesteryl *p*-nitrocinnamate (Heath

et al., 1981), a 26 m × 0.25 mm (ID) glass OV-101, and a 54 m × 0.25 mm (ID) glass SP2300 (Supelco). The VG 1212F was interfaced to a Hewlett Packard 5792 GC equipped with a cool on-column injector. A 50 m × 0.25 mm (ID) DB5 fused silica column (J&W) was used in this instrument. The total effluent from the columns was introduced directly into the ionization source. Columns used with the direct injector were operated at 155° (cholesteryl *p*-nitrocinnamate), 180° (SP2300), and 195° (OV-101). The column used in conjunction with the VG 1212F was operated at 80° until the solvent had eluted and then programmed at 15°/min to a final temperature of 220°. Spectra of peaks eluting from analyses of system blanks and natural product samples were compared with each other and with synthetic standards.

Formulation of Synthetic Blends. All synthetic chemicals used were purchased from Albany International Ltd. The compounds were purified by high-performance liquid chromatography on a 25 × 2.5-cm OD $AgNO_3$–silica column eluted with toluene (Heath and Sonnet, 1980). Hexadecanal was further purified by recrystalization from pentane. All compounds were found to be at least 99% free of isomers by gas chromatographic analyses on both the SP2330 and OV1 capillary columns.

Rubber septa (A.H. Thomas Co., 8153-D22) used as dispensers were extracted with CH_2Cl_2 for 24 hr and air dried prior to formulation. Septa were formulated by loading 500 μg of the total blend for concentration studies and 1000 μg of the blends for dual-selection tests dissolved in 200 μl of hexane into the large end of the rubber septa. Septa were aged two days prior to use, and volatiles emitted from the septa were collected and analyzed at two-day intervals at various flow rates to ensure that the percentage release of each compound and amount released per unit volume of N_2 did not change.

Blend ratios used in formulations were initially based on an empirical technique in which volatiles were collected by passing N_2 over the lures loaded with 2 mg each of 14:Al, *Z*9–14:Al, 16:Al, and *Z*11–16:Al at 500 ml/min for 1 hr as described above and analyzed. Relative differences in the amounts of each of the components released were calculated from the chromatograms of these collections and the correction factor for each compound used to formulate the test blends. Subsequently, a theoretical model of the release of components from rubber septa based on the vapor pressures of the total blend and each of the components was developed (Heath et al., in preparation). Results using the theoretical formula were consistent with the empirical technique. The theoretical model for predicting release ratios accounts for small differences in vapor pressure between *Z*7–16:Al, *Z*9–16:Al, and *Z*11–16:Al and more importantly for large differences between 14- and 16-carbon aldehydes. Therefore, this technique was used for all subsequent formulations.

Bioassays. The system used to dispense the pheromone blends into the flight tunnel consisted of the silanized glass female holding chambers linked through a flow controller to a tank of either N_2 (when comparing synthetic lures)

or air (when comparing lures with females). The outlet of the collection cage was connected via Teflon tubing to a silanized glass tube (2.5 mm ID) bent at 90° positioned in the upwind end of the tunnel. A 3 × 4-cm piece of aluminum screen positioned at the outport of the glass tube provided a landing site for the males. Gas flow through the system was precisely controlled and could be varied, thereby enabling us to precisely control the release rates of the lures.

Bioassays were conducted in a 2.0-m long × 1.0-m wide × 0.5-m high wind tunnel similar to that described by Teal et al. (1981b). The air speed through the tunnel (0.5 m/sec) was regulated by a laboratory fume hood controlled by a variable transformer and exhausted out of the building. Individual males were released at a central point in the wind tunnel 10 cm from downwind end as described by Teal et al. (1981b). The behaviors of the individual males were monitored and recorded as described previously (Teal et al., 1981b) during a 5-min test period. The behaviors used to categorize the responses of males to the blends of pheromone were those defined in mating studies. These behaviors were: directed flight upwind to the source (Tax), arrested advance and partial hairpencil exposure at 5–10 cm from the source (Hov), landing on the screen (On), hairpencil exposure on the screen (Hp), attempted copulation while on the source as indicated by bending the terminal abdominal segments and full hairpencil exposure (Cop), and reorienting after completing the close-range behaviors by moving into a hover pattern no further than 10 cm from the screen and then performing further courtship behaviors (Reo) (Figure 1). Statistical comparisons were made using a χ^2 test of independence and Yates' correction at a 0.05 probability level.

All bioassays were conducted using the volatile blend identified from calling females as the basis from which components were deleted. In initial studies a single dispenser system was positioned in the upwind end of the tunnel. This system was used to establish a concentration gradient between 0.1 and 0.5 female equivalent (FE) by passing different volumes of air over the septa for the six-component volatile blend and a four-component blend which did not contain *Z*7–16:Al or *Z*9–16:Al. Twenty individuals were flown to each treatment at each concentration. Results of the above study differed from those reported by Vetter and Baker (1983) and indicated that the minor components appear to function at close range. Therefore, a dual-selection bioassay system was developed for subsequent studies. In these studies two dispenser systems were positioned equidistant from the upwind walls and each other. The outports were angled such that the plumes formed by $TiCl_4$-impregnated cotton swabs in the holding cages merged 0.75 m downwind from the dispenser outports. The pheromone blends tested in each dual-selection test series were switched between the two dispenser systems daily and an equal number of males flown to each of the blends on each side. Thus, the behavioral sequences of 40 individual males which entered taxis after release were monitored for each pair of blends. Prior to the release of any males, compressed gas was allowed to flow through the

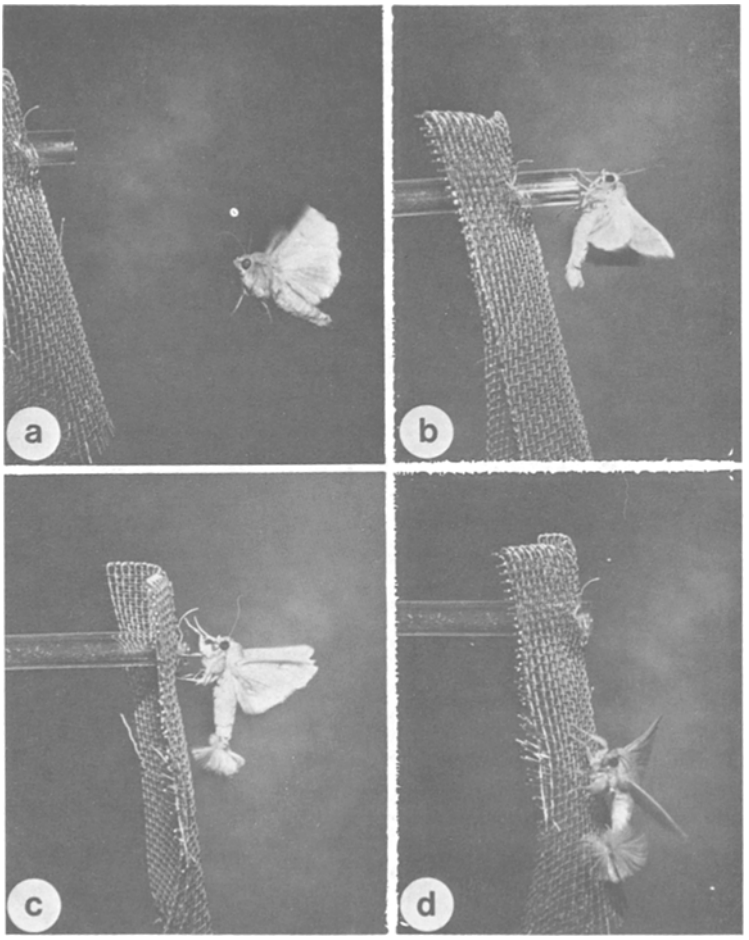

FIG. 1. Close-range behaviors monitored in bioassays. (A) Male hovering ca. 2 cm from the dispenser, note the partially exposed hairpencils. (B) Male landing on the aluminum screen. (C) Male exposing hairpencils but not attempting copulation. (D) Male attempting copulation, note the bent abdominal segments.

dispenser system for 15 min at the appropriate flow rate in order to establish equilibrium. All blends tested were permutations of the six-component blend identified from volatile collection from females and were formulated to release 4, 5, or 6 components at a 1.0 FE rate (ca. 75 ng/hr). In addition, the six- and four-component blends were compared to individual calling females in dual-selection tests. When females were used, air was passed through both dispenser systems for at least 30 min to allow the females to acclimate. Several systems

containing females were set up and, when a female ceased calling another, was immediately connected to the silanized glass outport.

RESULTS

Gland Extracts. Gas chromatographic analyses of pentane gland dips (10 sec) and extracts (30–120 sec) and ethyl ether extracts yielded distinctly different chromatographic profiles. Extracts obtained using the three techniques all contained peaks having equivalent chain-length (ECL) values coincident with 14:Al, Z9-14:Al, 16:Al, Z7-16:Al and Z9-16:Al, and Z11-16:Al (all resolved on BP20, SP2330, SP2340, and SPB1) in the ratio indicated in Table 1. Ethyl ether and pentane extracts also contained components having ECL values equivalent to tetradecanol (14:OH), Z-9-tetradecenol (Z9-14:OH), hexadecanol (16:OH), and Z11-16:OH (Figure 2A, 3A). The only alcohol peak found consistently in pentane gland dips was Z11-16:OH.

Full methane chemical ionization mass spectra (60–300 amu) were obtained using the SP2100 column for peaks corresponding to Z9-14:OH, 16:OH, and Z11-16:OH in ethyl ether extracts of 20 female equivalents (Figure 3A). Although a full mass spectrum of 14:OH was not obtained, the peak having a retention time coincident with 14:OH had fragment ions characteristic of 14:OH including 213 (M−1), and 197 (M+1−18). Additionally, GC mass

spectral analyses using the cholesteryl *p*-nitrocinnamate column and isobutane as the reagent gas indicated that the peak having an ECL value identical with Z9–14:OH had fragments indicative of a monounsaturated 14-carbon alcohol including a small 269 fragment (M+57) and a large 213 ion (M+1). The peak corresponding to 14:OH had fragments corresponding to M+57 (271), M−1 (213), and M+1−18 (197). Fragments indicative of 16:OH, including 299 (M+57), 241 (M−1), 225 (M+1−18), and 224 (M−18), were found in the natural product peak having an identical ECL value with this alcohol.

Gland Volatiles. Gas chromatographic analysis of volatiles collected from excised glands revealed the presence of five peaks on the OV-1 column and six on the SP2330 and SP2340 columns that were not present in system blanks. These peaks corresponded to 14:Al, Z9–14:Al, 16:Al, Z7–16:Al, Z9–16:Al, and Z11–16:Al. No peaks having ECL values corresponding to 14:OH, Z9–14:OH, 16:OH, or Z11–16:OH were found in any of the gland volatiles when analyzed on the OV-1 or SP2340 columns. The SP2330 column did not chromatograph Z11–16:OH under the conditions used. The mean percentages of the identified components are given in Table 1.

Female Volatiles. Gas chromatographic analyses of volatiles collected from calling females on the OV-1, SP2330, and SP2340 all indicated that the same six peaks present in gland volatile samples were released by calling females, and again there was no indication that any of the analogous alcohols identified from gland extracts were present in the volatile collections (Figure 2B). The mean percentages of the six aldehyde components are given in Table 1. As with gland volatile analyses, the percentages of Z7–16:Al and Z9–16:Al were obtained by taking the summed values on all columns and dividing by the mean proportions of each compound identified using the SP2330 (10 replicates) and SP2340 columns (8 replicates). As indicated in Table 1, there was only limited variation in the percentage of each compound released. The total amount of pheromone released per female was 1.3 ± 0.5 ng/min (N = 30).

Full mass spectra (60–300 amu) and ECL values obtained using all three columns indicated that 14:Al, Z9–14:Al, 16:Al, and Z11–16:Al were present in all of the volatile samples. Full spectra required as little as 3.5 ng of each component. None of the columns used in the GC-MS separated Z7–16:Al from

FIG. 3. Selected ion monitoring traces of major fragments obtained from methane chemical ionization mass spectroscopy of components identified from the ethyl ether extract of 20 calling females in (A), a 25 calling female hr of volatile collection obtained from (B) and the seven-component blend identified by Klun et al. (1980) (C) using the SP 2300 column in the GC mass spectrometer. Peak A = 14:Al, B = Z9–14:Al, C = 14:OH, D = 16:Ald, E = Z7- and Z9–16:Al, F = Z11–16:Al, G = 16:OH, H = Z11–16:OH. (A) *M − 1 of 14:OH, **M + 1 of Z9–14:OH, and ***M − 1 of 16:OH.

TABLE 2. PERCENTAGES OF COMPONENTS LOADED ONTO RUBBER SEPTA WITH THEORETICAL AND ACTUAL RELEASE RATES[a]

Compound	Load (%)	Theoretical release (%)	Actual release (%) (N = 20)
14:Al	3.4	13.0	13.9 (±0.65)
Z9-14:Al	4.0	18.1	17.8 (±0.62)
16:Al	9.6	7.3	6.4 (±0.16)
Z7-16:Al	0.9	0.6	0.6 (±0.21)
Z9-16:Al	1.1	1.0	0.8 (±0.10)
Z11-16:Al	81.0	60.0	60.5 (±1.12)

[a] ± standard error of the mean.

Z9–16 : Al; therefore the presence of both compounds cannot be confirmed on the basis of mass spectral evidence. Limited ion monitoring indicated the presence of a peak on both the SP2300 using methane as the reagent gas and cholesteryl *p*-nitrocinnamate columns using isobutane as the reagent gas which had ECL values coincident with Z7/Z9–16 : Al and had fragment ions characteristic of a monounsaturated C_{16} aldehyde. These ions included 239 (M+1), 221 (M+1−18), and 267 (M+29) when reacted with methane or 295 (M+57) when reacted with isobutane. As indicated in Figure 3B there is no indication that Z11–16 : OH was released as a volatile sex pheromone component.

Lure Formulations. Based on the vapor-pressure-release model developed by Heath et al. (in preparation), septa loaded with a 3.4% 14 : Al, 4.0% Z9–14 : Al, 9.6% 16 : Al, 0.9% Z7–16 : Al, 1.1% Z9–16 : Al, and 81.0% Z11–16 : Al should release the blend identified from calling females. The actual percentages released are listed in Table 2. The total amount of pheromone released per milliliter of N_2 from a septa loaded with 500 μg of the six-component blend was found to be linear and followed the equation: ng released = 1.82×10^{-4} ($\times$ ml N_2/min) + 7.68×10^{-2} (Figure 4). This correlation was consistent with values obtained using more than one septum per apparatus and when the concentration per septum was doubled. From the above equation, we calculated that four septa loaded with 1 mg each and aged for two or more days would release 1.1 ng/min at a flow rate of 690 ml/min. Although somewhat below the mean amount of pheromone released by a calling female per minute, this amount was within the range collected per female. These conditions were used in all dual-selection tests.

Bioassays. Results of concentration studies using the single dispenser system indicated that the deletion of Z7–16 : Al and Z9–16 : Al from the six-component blend had little effect on male sexual behaviors at the 0.10 and 0.25 FE levels (Figure 5). However, significantly more males ended the behavioral sequence by hairpencilling or attempting copulation when the six-component lure

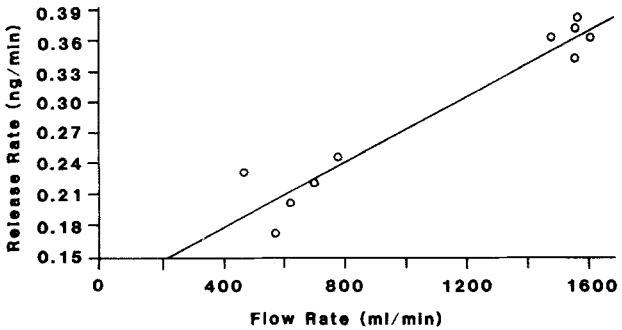

FIG. 4. Amount of the six-component aldehyde blend released from septa loaded with 500 μg at various flow rates. $R^2 = 0.96$ for equation, $y = 1.822 \times 10^{-4}x + 7.682 \times 10^{-2}$.

was presented than when the four-component lure was used at the 0.33 FE level, and all of the behaviors monitored except hovering were observed more often with the six-component than four-component lures at the 0.50 FE level (Figure 5).

Differences noted in the above study strongly suggested that Z7–16 : Al and Z9–16 : Al exert subtle effects on male sexual behaviors either alone or in combination with each other. Therefore, we developed the dual-selection test which enabled us to evaluate male responses to two different blends at the same time. Selection occurred when a male cast from side to side through the two plumes at 30–50 cm from the outports prior to moving to one of the sources. Results of these studies are given in Figure 6. Initially, we assessed the six-component volatile blend and the four-component blend that did not contain Z7–16 : Al or Z9–16 : Al. As indicated in Figure 6, males performed all of the close-range behaviors significantly more often at the six-component station, which supports the results of our single dispenser tests.

Comparison of the six-component blend and the five-component blend which did not contain Z9–16 : Al indicated that the deletion of this component resulted in a general reduction in all of the close-range behaviors with significant reductions occurring in hovering and the number of attempted copulations. Comparison of this five-component blend and the four-component blend which did not contain either Z9–16 : Al or Z7–16 : Al showed that the five-component lure was superior in all respects except selection.

Deletion of Z7–16 : AL from the six-component blend resulted in a significant decrease in the number of copulation attempts and small decreases in all of the other close-range behaviors observed. There were no differences between this blend and the four-component blend that did not contain Z9–16 : Al and Z7–16 : Al.

When 14 : Al was deleted from the six-component blend, there were no

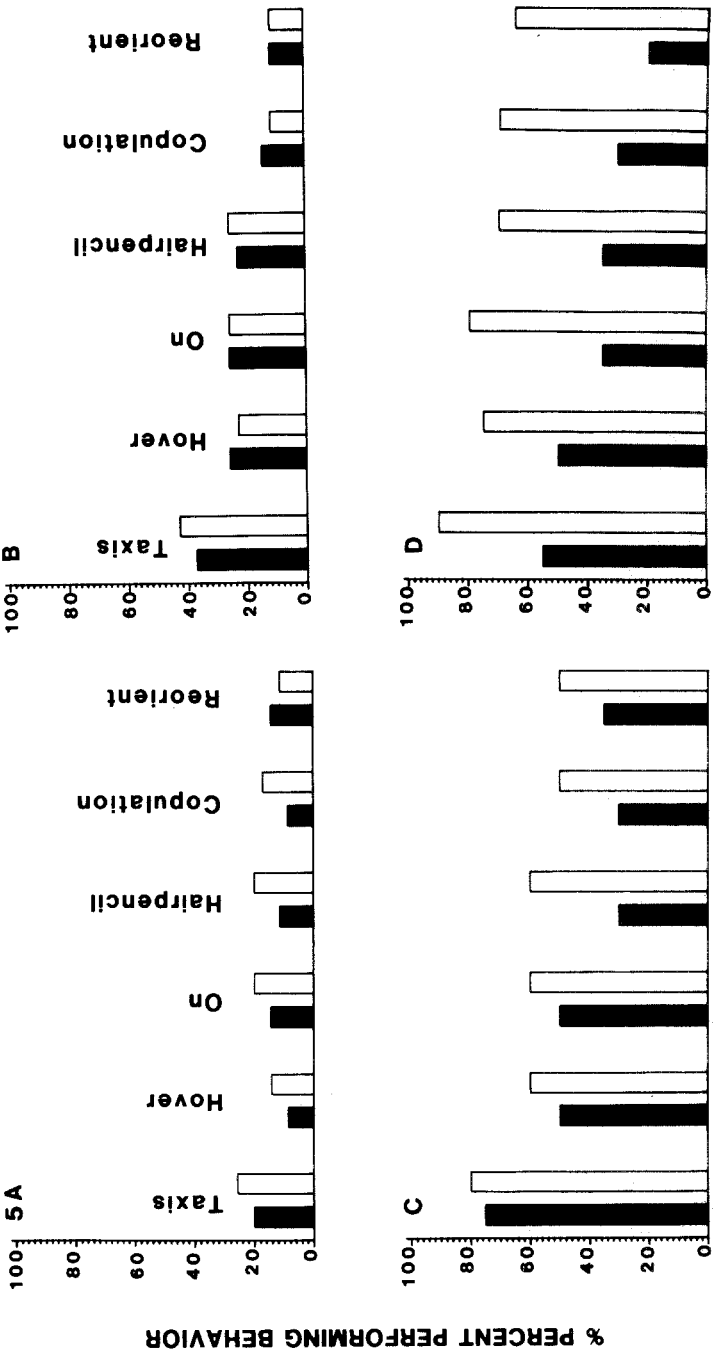

FIG. 5. Results of concentration studies using the single dispenser system. Taxis = upwind taxis, Hover = arrested advance at 5–10 cm from the source, On = landing on aluminum screen, Hairpencil = hairpencil exposure on the source, Copulation = copulation attempt at the source, Reorient = close-range reorientation. (A) = 0.10 FE/min (N = 30); (B) 0.25 FE/min (N = 30); (C) 0.33 FE/min (N = 30); (D) 0.50 FE/min (N = 20 flights to each lure). The six-compound blend (open bars) contained all six aldehydes while the four-component blend (solid bars) did not contain Z7–16:A1 or Z9–16:A1.

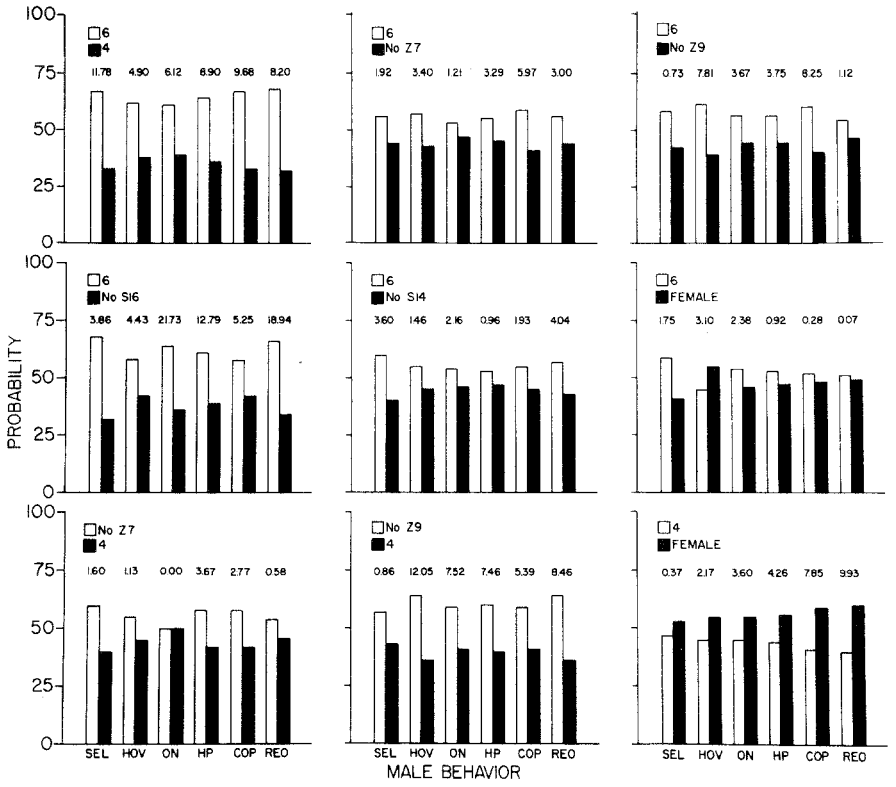

FIG. 6. Results of dual-selection studies. Numbers above figures are χ^2 values calculated using Yates' correction. SEL = selection, HOV = hover at source, ON = lands on, HP = full hairpencil exposure after landing, COP = copulation attempt at the source, REO = close-range reorientation. Four- and six-component blends are as listed in the text and in Figure 5. Blends demarked by "No Z7", "No Z9", "No S16" and "No S14" are five-component blends which do not contain *Z*7–16:Al, *Z*9–16:Al, 16:Al, and 14:Al, respectively. Probabilities are based on the number of times individual behaviors were performed in response to each blend and depend upon the performance of the previous behavior.

significant decreases in those behaviors which are requisite for successful copulation in a single attempt. However, the probability that the male would reorient at close range and perform another series of courtship behaviors was significantly reduced. Deletion of 16:Al from the six-component blend resulted in significant decreases in the number of times each behavior was performed. These overall decreases can be equated to the very low probability of landing on the source when compared to the six-component blend. No differences were found between calling females and the six-component blend released at a 1 FE level from the rubber septa. However, males performed all close-range behav-

iors except selection more often at the female station than at the four-component blend.

DISCUSSION

Results of our analyses of gland extracts support the findings of Klun et al. (1980) and Pope et al. (1982) which indicated that Z11–16:OH is present in pheromone gland extracts. The fact that neither group identified 14:OH, Z9–14:OH, or 16:OH is most probably explained by the minute amounts of these compounds present in the gland, the fact that the 14-carbon alcohols tend to cochromatograph with the 16-carbon aldehydes on high cyano phase columns, and because neither group extracted the glands for relatively long periods in polar solvents. Nonetheless the GC and GC-MS data obtained using a wide variety of columns and both methane and isobutane chemical ionization mass spectroscopy do prove that these alcohols are present within the pheromone gland. The presence of the alcohols and fact that neither Pope et al. (1982) nor we found any of the alcohols in volatile collections strongly suggests that the alcohols serve some function other than acting as pheromone components.

Our hypothesis is that the alcohols are immediate biosynthetic precursors for the aldehydes. In addition to the above features, this hypothesis is supported by the relative instability of aldehydes, ease of biochemical interconversion between alcohols and aldehydes (Snyder, 1972), and ratios between the alcohols which are similar to the aldehyde ratios. Similar ratios have been identified for fatty acids which have been shown to be pheromone precursors in other species (Wolf et al., 1981). Further, there are only limited data to support the hypothesis that Z11–16:OH functions as a pheromone component, and although this alcohol has been identified from gland extracts of all other species of *Heliothis* studied to date, it acts either as a behavioral inhibitor or causes significant decreases in trap captures when released at very low levels (Kehat et al., 1980; Teal et al., 1981a, 1984).

Percentages of the six aldehydes released from the excised glands and calling females were not significantly different when volatiles were collected for short periods. However, when large numbers of glands from both calling and noncalling females were used and the collection time increased to 15 or more minutes, the ratio of components recovered from the filters changed dramatically, becoming more similar to the gland extract (Table 1). It is interesting to note that the mean percentage for the combined short- and long-term collections of each component was very similar to that reported by Pope et al. (1982). Although the differences in the ratios reported by us and Pope et al. (1982) may reflect different geographical strains of *H. virescens*, as such have been reported by these authors, the disparate ratio reported by Pope et al. (1982) may also be

due to collecting from females which were not synthesizing pheromone for the latter part of the collection period.

Comparison of the theoretical and actual release rates from the rubber septa indicate that the release of the six aldehydes does follow the vapor-pressure-release model developed by Heath et al. (in preparation) and that the total amount released is linear over the concentrations and flow rates used. This is of significance because rubber septa can be formulated to release any blend of the six components at a specific ratio without empirical experimentation because the release ratio of these compounds is related to the relative vapor pressures of the components of the blend. It is of interest to note the similarity between the blend of aldehydes loaded onto the septa and that found within the pheromone gland (Table 2). This may indicate that the actual blend released from the surface of the pheromone gland is the result of the same vapor-pressure-release model which governs the release from rubber septa.

Results of the bioassay studies indicate that the four components tested in deletion studies are of importance for effective sexual signaling. Blends without *Z*9–14 : Al or *Z*11–16 : Al were not tested because their function as necessary prerequisites for mate location and inducing close-range courtship sequences was clearly demonstrated by Vetter and Baker (1983). Similarly, none of the alcohols identified from gland extracts were studied because no evidence for their release from the pheromone gland has been found by either us or Pope et al. (1982).

The compound which most obviously affected male reproductive behaviors was 16 : Al. This concurs with the findings of Vetter and Baker (1983) who also suggest that 16 : Al functions to provide an incentive for landing. We also noted a comparatively low probability of reorientation when 16 : Al was deleted. This reduction in reorientation may also reflect the need for 16 : Al to induce landing because, after leaving the source, there was no incentive to land again. Deletion of 14 : Al also resulted in a significant decrease in the probability that close-range reorientation would occur. Therefore, it appears that 14 : Al induces males to continue to perform close-range courtship behaviors when they are unsuccessful in their first attempt. This may account for the larger number of males which reorient to females via close-range ambulation and the higher probability of successful mating when reorienting at close range than from downwind ($P = 0.54$ close range, $P = 0.12$ downwind) (Teal et al., 1981b).

Deletion of either *Z*7–16 : Al or *Z*9–16 : Al from the six-component blend resulted in reductions in the probabilities that males would hover near the source and attempt copulation. This tends to suggest redundancy in the behavioral functions of these two components. However, while the addition of *Z*9–16 : Al to the four-component blend did not result in increases in any of the close range behaviors, the addition of *Z*7–16 : Al to the four-component lure increased the probabilities that all of the close-range behaviors except selection would be

performed. Therefore, it appears that Z7–16 : Al exerts subtle effects on all of the close-range behaviors monitored while Z9–16 : Al has a specific function in inducing the copulation attempt. Although most of the differences between the four- and six-component blends can be explained by simply adding the behavioral effects of Z7–16 : Al and Z9–16 : Al preferential selection of the six- over the four-component blends cannot. This suggests that both Z7–16 : Al and Z9–16 : Al summate to provide a cue which enables males to home in on calling females.

Our results indicate that all of the components in the *H. virescens* pheromone blend appear to exert influences on mating success for this species. While individual components appear to affect specific behaviors, in no case were behaviors eliminated from the sequence when individual components were deleted. Thus, no single compound is responsible for the elicitation of a specific behavior in the mating sequence. Similar situations have been described for both *Grapholitha molesta* (Busck) (Baker and Cardé, 1979) and *Trichoplusia ni* (Hubner) (Linn et al., 1984). In both of those studies all of the behaviors involved in the male reproductive sequence, including preflight behaviors, were affected by each component. Although we did not consider preflight behaviors in single-dispenser studies and could only consider close-range behaviors in dual-selection tests, our single-dispenser studies indicated that two minor components (Z7–16 : Al and Z9–16 : Al) do affect taxis when released at a 1 FE rate. Therefore, as discussed by Linn et al. (1984), the combination of all the secondary components appears to exert effects on all phases of the male reproductive sequence. Hence, while an individual component may influence specific behaviors more than other components, the interaction between all of the compounds is responsible for maximizing male response.

In conclusion, our study strongly indicates that only the six aldehydes previously identified by Klun et al. (1980) are released from the sex pheromone gland of actively calling females. Based on the absence of Z11–16 : OH from volatile samples analyzed by both us and Pope et al. (1982) and identification of the analogous alcohols of the three other major aldehyde components in gland extracts, we suggest that Z11–16 : OH serves as a biochemical precursor for the major aldehyde component released. Further, by developing a dispenser system which releases the same ratio and quantity of compounds released by calling females, we have demonstrated that components previously supposed to have no behavioral function are, in fact, necessary for the successful performance of close-range courtship behaviors by males. In fact, we have shown that males cannot distinguish the synthetic blend from actively calling females when released at the same rate.

(Received March 18, 1985; accepted May 30, 1985)

Abstract—A nine-step synthesis is described for a diastereomeric mixture of 15,19,23-trimethylheptatriacontane, a contact sex pheromone of *Glossina morsitans morsitans* Westwood. The compound has been synthesized by means of double alkylation of diethyl 3-oxoglutarate (DEOG) with 3-methyl-2-heptadecenyl methanesulfonate, which was readily prepared from 1-hexadecene, as the key step.

Key Words—Tsetse fly, *Glossina morsitans morsitans*, Diptera, Muscidae, sex pheromone, branched hydrocarbon, 15,19,23-trimethylheptatriacontane, diethyl 3-oxoglutarate, alkylation.

INTRODUCTION

Several workers have investigated the sex pheromones of tsetse flies, because the flies are major vectors of African trypanosomiases such as sleeping sickness and nagana. Of interest is that many insect pheromones include such compounds as alcohols, acetates, aldehydes, and hydrocarbons (Nelson, 1978; Sonnet, 1984). Carlson et al. (1978) isolated a group of sex pheromones from the

[1] This study constitutes Part XII of "Selective Alkylation of Diethyl 3-Oxoglutarate." Part XI of this series, see Naoshima et al. (1984).

cuticle of the female tsetse fly, *Glossina morsitans morsitans* Westwood and identified the most active component as 15,19,23-trimethylheptatriacontane (I), a branched hydrocarbon. Compound I was synthesized either as a diastereomeric mixture by Carlson et al. (1978) and Hoshino and Mori (1980) or as the set of four stereoisomers by Helmchen and Schmierer (1983). These methods were complicated and suffered from low overall yields. A recent report on pheromone effects (Helmchen and Langley, 1981) has showed that all of the four stereoisomers of I were equally active on *Glossina morsitans morsitans* Westwood.

A number of pheromones have been prepared from diethyl 3-oxoglutarate, DEOG, through reaction with a variety of alkylating agents (Naoshima et al., 1983, 1984). We now report a synthetic approach toward a diastereomeric mixture of I, which is based on the double alkylation of DEOG with 3-methyl-2-heptadecenyl methanesulfonate (II) derived from 1-hexadecene. Pheromone I was synthesized with an improved overall yield, compared with the value reported previously, by use of both DEOG and 1-hexadecene as the starting materials.

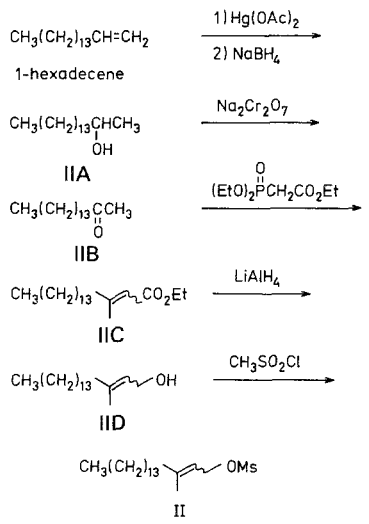
METHODS AND MATERIALS

Column chromatograpy was carried out employing 230–400 mesh silica gel (Merck Kieselgel 60 Art 9385) according to the flash technique described by Still et al. (1978). All solvent systems were expressed in ratios by volume (v/v). IR spectra were determined on a Hitachi model 260-10 spectrometer. [^{1}H]NMR spectra were obtained on a Hitachi model R-24B spectrometer in $CDCl_3$ solutions using Me_4Si as an internal standard. EI and CI mass spectra were recorded on a JEOL model JMS-D300 double-focusing mass spectrometer at 70 eV and 200 eV, respectively, using a direct insertion probe. GLC analysis for the determination of the purity of the pheromone I was made isothermally at 250°C (N_2, 60 ml/min), employing a Hitachi 163 gas chromatograph equipped with a 1-m × 3-mm glass column of 3% OV-1 on 80–100 mesh Chromosorb W AW DMCS. Sodium hydride (Aldrich Chemical Company, Inc., Milwaukee, Wisconsin) was weighed as a 60% dispersion in mineral oil and washed with dry *n*-hexane to remove the oil prior to use. Solvents were purified and dried by standard methods.

2-Hexadecanol (IIA). Compound IIA was readily synthesized from 1-hexadecene with a 97% yield by a oxymercuration–demercuration procedure (Brown and Geoghegan, 1970): mp 45–46°C (mp 41.5°C, see Messer, 1929).

2-Hexadecanone (IIB). Compound IIB was synthesized with a 96.5% yield by oxidizing IIA with sodium dichromate: mp 44–45°C (mp 43°C, see Ruzicka et al., 1928).

Ethyl 3-methyl-2-heptadecanoate (IIC). Compound IIC was synthesized by



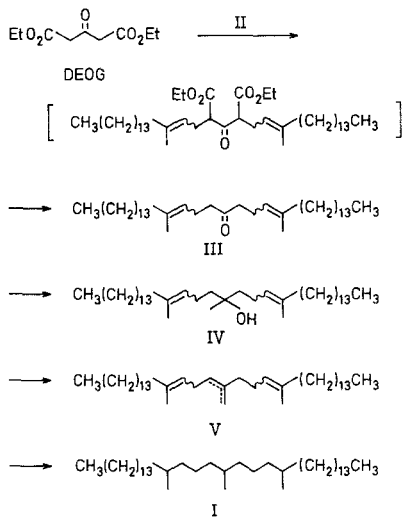
SCHEME 1.

treating IIB (24 g) with triethyl phosphonoacetate in the presence of sodium hydride. Fractionation of the product in vacuo gave IIC as a colorless liquid (29.5 g, 95%), bp 145–147°C at 0.26 mm Hg. IR (neat): 1720, 1650 cm^{-1}. [^{1}H]NMR δ: 0.87 (distorted t, 3H, J = 5 Hz), 4.04 (q, 2H, J = 7 Hz), 5.53 (broad s, 1H). EIMS *m/z*: 310 (M^+, 20), 265 (16), 128 (100). CIMS (isobutane) *m/z*: 311 [$(M+H)^+$, 100].

3-Methyl-2-heptadecen-1-ol(IID). Compound IID was synthesized by reducing IIC (28.6 g) with lithium aluminum hydride. Fractionation of the product in vacuo gave IID as a colorless liquid (21.8 g, 88%), bp 134–138°C at 0.2 mm Hg. IR (neat): 3350, 1660 cm^{-1}. [^{1}H]NMR δ: 0.87 (distorted t, 3H, J = 5 Hz), 4.08 (d, 2H, J = 6 Hz), 5.35 (t, 1H, J = 6 Hz). EIMS *m/z*: 250 (M−18, 3), 71 (100). CIMS (ammonia) *m/z*: 251 [$(M+H-H_2O)^+$, 100].

3-Methyl-2-heptadecenyl Methanesulfonate (II). Compound II was synthesized with an almost quantitative yield by treating IID (50 g) with methanesulfonyl chloride in the presence of triethylamine (Scheme 1). IR (neat): 1640 cm^{-1}. This mesylate was used directly in the next step without further characterization.

15,23-Dimethyl-15,22-heptatriacontadien-19-one (III). To a stirred suspension of sodium hydride (3.6 g, 0.09 mol) and 18-crown-6 (4 g, 0.015 mol) in dry toluene (100 ml) was slowly added a solution of diethyl 3-oxoglutarate (6.06 g, 0.03 mol) in dry toluene (15 ml) and stirring continued for an additional 1 hr at room temperature. To the solution was added a solution of 3-methyl-2-heptadecenyl methane sulfonate II (31.2 g, 0.09 mol) in dry toluene (15 ml) and the mixture was refluxed with stirring for 17 hr. After the solvent had been



SCHEME 2.

distilled off in vacuo from the reaction mixture, the residue was heated in a 15% aqueous solution of sodium hydroxide (350 ml) under reflux for 30 hr. The hydrolyzed mixture was then acidified with conc. HCl and extracted with ether. The ethereal solution was washed with brine and dried over sodium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (120 g) with petroleum ether–ether (50 : 1) followed by removal of the low-boiling impurities in vacuo, giving a colorless liquid of III (5.6 g, 33% from DEOG) (Scheme 2). IR (neat): 2930, 2850, 1720, 1460, 1380, 720 cm^{-1}. [^{1}H]NMR δ: 0.88 (distorted t, 6H, J = 5 Hz), 1.25 (broad s, 48H), 1.57 (m, 6H), 1.75–2.62 (m, 12H), 5.0 (broad s, 2H). EIMS *m/z*: 558 (M^+, 3), 81 (100). CIMS (ammonia) *m/z*: 576 [$(M+NH_4)^+$, 100], 559 [$(M+H)^+$, 70]. Analysis: calcd. for $C_{39}H_{74}O$: C, 83.79; H, 13.34. found: C, 83.48; H, 12.95.

15,19,23-Trimethyl-15,22-heptatriacontadien-19-ol (IV). To a 1.0 M THF solution of methylmagnesium bromide (60 ml, 0.06 mol) was added a solution of the ketone III (5.4 g, 0.0096 mol) in THF (30 ml) at room temperature under nitrogen, and the mixture was refluxed for 6 hr. A saturated aqueous solution of ammonium chloride was added to the reaction mixture under ice cooling, and the mixture was stirred for 1 hr. The mixture was worked up to give IV as a yellow viscous liquid (Scheme 2); column chromatography (90 g) with *n*-hexane-ether (20 : 1) gave a colorless liquid (3.8 g, 68%). IR (neat): 3330, 2930, 2850, 1480, 1375, 1120, 720 cm^{-1}. [^{1}H]NMR δ: 0.82–1.02 (m, 9H), 1.25 (broad s, 52H), 1.50–2.33 (m, 14H), 3.46 (broad s, 1H), 5.05 (broad s, 2H). EIMS *m/z*: 574 (M^+, 2). CIMS (ammonia) *m/z*: [$(M+NH_4)^+$, 68], 574 [$(M+NH_4-H_2O)^+$, 92], 557 [$(M+H-H_2O)^+$, 100].

15,19,23-Trimethylheptatriacontatrienes (V). The *tert*-alcohol IV (3.2 g, 0.0043 mol) was heated in a 20% aqueous solution of H_2SO_4 (60 ml) for 45 hr. The reaction mixture was extracted with *n*-hexane–ether (3 : 1), and the ethereal solution was successively washed with 5% aqueous sodium bicarbonate and brine, and finally dried over sodium sulfate. The solvent was evaporated in vacuo to give a brown substance. Column chromatography (150 g) with *n*-hexane gave V as a colorless liquid (2.12 g, 67%) (Scheme 2). IR (neat): 2930, 2850, 1640, 1380, 890, 720 cm^{-1}. EIMS *m/z*: 556 ($M^{\ddagger}$, 10). Compound V was hydrogenated without further characterization.

15,19,23-Trimethylheptatriacontane (I). Hydrogenation of V (0.9 g, 0.0016 mol) in a mixture of ethanol (40 ml) and *n*-hexane (40 ml) was carried out in the presence of 10% Pd/C catalyst (0.24 g). The reaction mixture was worked up to give pheromone I as a yellow viscous liquid (Scheme 2). The compound was purified by column chromatography on silver nitrate-impregnated silica gel (prepared from a 100 g of SiO_2 and 20 g of $AgNO_3$) with *n*-hexane to give a colorless liquid (0.61 g, 67% from V). IR (neat): 2925, 2850, 1465, 1380, 720 cm^{-1}. [^{1}H]NMRδ: 0.76–0.94 (m, 15H), 1.25 (broad s, 67H). EIMS *m/z*: 547 (M-15, 12), 365 (72), 295 (100), 224 (81). CIMS (ammonia) *m/z*: 579 [$(M+NH_4-H)^+$, 100].

DISCUSSION

The key step in the present approach to the synthesis of pheromone I, as shown in Scheme 2, is the double alkylation of diethyl 3-oxoglutarate, DEOG. Commercially available 1-hexadecene was chosen along with DEOG for the starting material. The alkylating agent, 3-methyl-2-heptadecenyl methanesulfonate II (mixture of *E* and *Z* isomers) was easily prepared in five steps from inexpensive 1-hexadecene with a 78% yield. To shorten the synthesis of the pheromone, DEOG was doubly alkylated with II in the presence of 18-crown-6 using sodium hydride as the base (Naoshima et al., 1981), and the product was hydrolyzed with decarboxylation in an aqueous solution of sodium hydroxide to give the symmetrical long-chain unsaturated ketone III in a 33% yield. Ketone III was then subjected to a Grignard reaction with a large excess of methylmagnesium bromide. The obtained *tert*-alcohol IV (68% yield from III) was dehydrated and subsequently hydrogenated over palladium–charcoal. The product was chromatographed on a silica gel column containing silver nitrate to give a diastereomeric mixture of I.

On a small scale, a column of silica gel coated with silver nitrate is generally used for a cleanup procedure; however, this is seemed not to be suitable for large-scale preparations, since silver nitrate is an expensive reagent. In this case, a column of silver nitrate–silica gel was useful, allowing removal of trace amounts of olefins. GLC analysis of I indicated 92% chemical purity and re-

vealed the presence of impurities which were assumed to be saturated hydrocarbons on the basis of IR and [^{1}H]NMR spectra. The purity for I may or may not be satisfactory for pheromone activities, owing to the presence of the impurities.

Thus a diastereomeric mixture of the pheromone I was synthesized, as depicted in Scheme 2, in four steps from diethyl 3-oxoglutarate, DEOG, with a 10% yield. DEOG itself is easily prepared from citric acid, a natural product. It is produced industrially by the microbiological fermentation of sugars, and thus is a readily available, renewable resource (Sperling and Carraher, 1983). The overall yield of I from 1-hexadecene was actually 7.8% in nine steps. Carlson et al. (1978) described a synthetic method for I employing a Grignard reaction with ethyl acetate, although the overall yield of I was not given. A reported value for the overall yield of I from geranyllinallol was about 0.54% in ten steps (Hoshino and Mori, 1980). The yield by our own synthesis therefore exceeded that by the reported method.

(Received February 20, 1985; accepted May 31, 1985)

Abstract—Behavioral and chemical evidence is presented for the identity of the male wing pheromone of *Ephestia elutella* (Hübner) and the role of this pheromone in courtship success is evaluated. Males with the forewing removed experienced a mating success rate less than half of that of either intact males or males that had only the wing gland area remaining of their forewings. GC-MS analysis and microchemical reactions indicated the presence of (*E*)-phytol and a series of saturated γ-lactones in a methylene chloride extract of the wings. Using an assay of female courtship behavioral response, (*E*)-phytol was found to evoke an intermediate level of response in females when presented alone, while the complete array of insect-derived γ-lactones produced no significant response. The combination of either γ-decalactone or γ-undecalactone with (*E*)-phytol in a 1:2 ratio, however, elicited a female response equivalent to that produced by the unfractionated wing extract.

Key Words—courtship pheromone, wing pheromone, male pheromone, *Ephestia elutella*, Pyralidae, phytol, γ-decalactone, γ-undecalactone.

INTRODUCTION

Behavioral studies of members of the stored-product complex of phycitine moths have revealed relatively complex courtship sequences. In addition to the long-range sex pheromone of the female, males of most species have been found to possess pheromone glands on the costal margin of the forewings (Barth, 1937;

[3]Present address: Department of Entomology, The Ohio State University, O.A.R.D.C., Wooster, Ohio 44691.

0098-0331/86/0100-0135$05.00/0

Grant, 1978) and/or the dorsal surface of the eighth abdominal segment (Dickens, 1936; Corbet and Lai-Fook, 1977). Female behavioral responses to conspecific wing pheromones have been demonstrated in three species: *Plodia interpunctella* (Grant and Brady, 1975; McLaughlin, 1982), *Vitula edmandsae* (Grant, 1976), and *Ephestia elutella* (Krasnoff and Vick, 1984). To date, however, no chemicals from these glands have been identified. We report here behavioral and chemical evidence for the identity of the male wing pheromone of the tobacco moth, *Ephestia elutella* (Hübner) and evaluate the importance of this pheromone on courtship success.

METHODS AND MATERIALS

Wing Pheromone Collection. Ephestia elutella were reared on a honey–bran–glycerol diet according to the procedure of Strong et al. (1968). Males and females were separated at the pupal stage, and adults were maintained in separate chambers on 14:10 light–dark cycles at 22–24°C. The wing pheromone was collected from 2- to 5-day-old males by excising the forewings during the period of peak sexual activity (3–6 hr into scotophase) and extracting them with methlene chloride for several hours. Wing extracts were filtered with glass wool, concentrated to 200–300 μl under a gentle flow of N_2, and stored at −15°C.

Chemical Identification. The wing gland extract was fractionated using a Waters Assoc. high-performance liquid chromatograph (HPLC), comprised of two model 6000A solvent delivery pumps, a No. 660 solvent programmer, a RCM-100 radial compression separation module, a No. 450 variable wavelength detector (190–700 nm), and a series R-400 differential refractometer. The extract was chromatographed on a silica gel RCM column using either an isocratic mobile phase of 1% methanol–99% methylene chloride or a linear solvent program of 100% methylene chloride to 10% methanol–90% methylene chloride in 10 min with a flow rate of 1 ml/min. The eluant was collected in 1-ml fractions. The mobile phases were "distilled in glass" spectral grade from Burdick & Jackson (Muskegon, Michigan). Analysis and further fractionation of the extract was carried out on a Varian model 3700 gas chromatograph with two hydrogen flame ionization detectors. A range of polarities in columns was used: 10% Silar 10C (cyanopropyl silicone) on 100–120 mesh ChW Ac (3 m × 4 mm, 4.4 g), 2% SF-96 (methyl silicone) on 100–120 mesh ChW Ac DMCS (2 m × 4 mm, 3.2 g), and Durawax-4 (polyethylene glycol stabilized with methyl silicone) fused-silica capillary (30 m × 0.25 mm, film = 0.25 μm) from J&W Scientific (Rancho Cordova, California). Carbon disulfide, used in GC analysis, was redistilled daily.

Complete mass spectra of active components were obtained using a Finnigan 4021 EI/CI capillary gas chromatograph–mass spectrometer (GC-MS) coupled to a INCOS data system. A Grob injector was used in conjunction with

the following fused-silica capillary columns (Chromatographic specialities, Brockville, Ontario): a 30-m DX-4 temperature programmed from 50°C (2 min hold) to 100°C at 30°C/min, then 10°C/min to 200°C; 30-m DB-5 held at 50°C for 1.5 min programmed at 30°C/min to 120°C, then 10°C/min to 250°C. All EI-MS and CI-MS (methane) were generated at 70 eV.

Microchemical reactions were carried out on behaviorally active HPLC fractions for confirmation of the chemical identities of pheromone components. The products of these reactions were analyzed by GC. Evidence for esters was provided by base hydrolysis (Bjostad et al., 1984). After reducing the sample to near dryness with a gentle stream of N_2, 100 μl of ethanol and 20 μl of 5% KOH were added and the solution was allowed to sit in a 1-ml reaction vial with Teflon-lined screw cap at 50°C for 1 hr. Water was then added and the aqueous solution was extracted three times with hexane. The hexane portion was concentrated under N_2 and was slowly replaced by CS_2. The presence of alcohols was established by acetylation, in which a behaviorally active fraction was taken to near dryness and 2–3 drops of acetyl chloride were added. After 1 min, the acetyl chloride was evaporated under N_2 and replaced with CS_2. For determination of double-bond position by ozonolysis (Beroza and Bierl, 1967), ozone was bubbled for 30 sec into 30 μl of CS_2 followed by the addition of 1–5 μl of the sample. Nitrogen was then bubbled through the solution for 30 sec and 1 μg triphenylphosphine in carbon disulfide was added to break up the ozonide product.

Synthetic γ-lactones were obtained from ICN-K&K Laboratories (Plainview, New York), except for γ-decalactone and (*E*)-phytol which were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin). The (*E*)-configuration of the commercial phytol was determined by 200-MHz proton NMR, GC, and GC-MS analysis. (*Z*)-Phytol was synthesized by a modification of the scheme of Burrell et al. (1966). A solution of commercial (*E*)-phytol (0.10g) in anhydrous methanol (5 ml) at −78°C was treated with ozone for 15 min. After flushing with N_2, the ozonide was discharged with dimethyl sulfide (0.5 ml) and the solvent was evaporated in vacuo. The crude product was purified by flash chromatography (Still et al., 1978) with hexane–ethyl acetate (9:1) to yield 6,10,14-trimethyl-2-pentadecanone (0.095 g). A solution of this ketone in anhydrous tetrahydrofuran (0.5 ml) was added to a mixture of ethoxyacetylene (0.12 g, 50% in hexane), anhydrous THF (0.5 ml), and *n*-butyl lithium (1.6 ml, 1.2 M in hexane) at 0°C. After 1 hr stirring at this temperature, the reaction was quenched with a saturated NH_4Cl solution (5ml) and extracted into ether (5ml).

Evaporation of the organic phase yielded 2-ethoxyethynyl-6,10,14-trimethylpentadecan-2-ol (0.12g). The acid-catalyzed rearrangement of the adduct was carried out with 10% aqueous oxalic acid (1ml) in ethanol (0.5 ml) at 22°C for 18 hr. Purification of the crude product by preparative TLC (silica gel) gave ethyl phytenoate (0.07g) as a mixture of *E*/*Z* isomers in a ratio of 50:50 as determined by GC (relative retention time *E*/*Z* = 1.19) and NMR [(*Z*)-3-methyl,

δ1.86; (*E*)-3-methyl, δ2.11]. A solution of the ester (0.07 g) in dry toluene (1 ml, distilled from sodium) was treated with Vitride (0.04 ml, 70% in toluene) at 0°C for 7 hr and at 22°C for 10 hr with additional Vitride (0.03 ml). Vitride [sodium dihydrobis(2-methoxy-ethoxy)aluminate] was purchased from Hexcel Specialty Chemicals (Zealand, Michigan). The reaction was quenched with methanol (1 ml), concentrated in vacuo, and purified by preparative TLC to give the following: recovered ester (0.028 g), (*Z*)-phytol (0.011 g), and (*E*)-phytol (0.009 g). These assignments were supported by NMR, GC, and GC-MS analysis.

(E)-*Phytol*. NMR (200MHz, $CDCl_3$): δ0.85 (12H, d, J = 6 Hz), δ1.24–1.54 (20H, m), δ1.65 (3H, s, vinylic CH_3), δ2.00 (2H, t, J = 8 Hz), δ4.14 (2H, m), δ5.40 (1H, broad t, J = 6 Hz); GC (DX-4) retention time ca. 15.4 min; MS (EI 70 eV) *m/e* 296 (M^+), 278, 196, 123, 71 (base peak).

(Z)-*Phytol*. NMR (200MHz, $CDCl_3$): δ0.85 (12H, d, J = 6 Hz), δ1.05–1.34 (20H, m), δ1.72 (3H, d, J = 1 Hz), δ2.03 (2H, t, J = 7 Hz), δ4.14 (2H, m), δ5.40 (1H, broad t, J = 6 Hz); GC (DX-4) retention time ca. 14.4 min; MS (EI 70 eV) *m/e* 296 (M^+, weak), 278, 196, 123, 71 (base peak).

Behavioral Assays. The importance of the wing pheromone in courtship success was investigated by ablation of the gland, using the procedure of Grant and Brady (1975). Within 24 hr of eclosion to the adult, males were cold-anesthetized and either the entire forewing was removed or all of the forewing except the costal wing-gland area. This procedure required that the male be anesthetized <3 min, and the two operations were alternated to control for operator experience. These males were provided sugar water and were tested during their second scotophase, at which time they were introduced into a screen cylinder containing a calling female; the ensuing courtship was video-recorded for more accurate analysis at a later time.

For determination of pheromone components, five male equivalents (ME) of each fraction were tested using a modified version of the Kransnoff and Vick (1984) bioassay, and the responses of the females were compared with those responses elicited by the crude wing-gland extract and clean-air controls. The material to be tested was placed on the inside of a 0.5 cm OD × 10-cm-long glass tube. Air, which was purified by two separated charcoal filters, was passed through this tube at 15 cm/sec. After allowing air to flow through the tube for 10 sec to evaporate the solvent, the end of the tube was presented to a calling virgin female tobacco moth. The use of a gentle airflow ensured that the chemicals were delivered to the female's head. Two- to five-day-old females, which were 3–6 hr into their scotophase, were tested either in small cylindrical cages (2 females/cage) or in a large rearing cage. The cages were backlighted by a 0.2-lux light. Females were considered to show a positive response if they exhibited either a ventral flexion of the abdomen (as described by Krasnoff and Vick, 1984) or turning without forward locomotion. Treatments were presented in a randomized complete-block design, with eight replicates of 10 females per

treatment. Statistical analyses were carried out using Duncan's new multiple-range test or Ryan's (1960) multiple-comparison test for proportions.

RESULTS

Wing Pheromone and Courtship Success. Removal of the wing gland substantially reduced the mating success of male *E. elutella* (Table 1). Males with entire forewings removed recorded a courtship success rate less than half that of either intact males or males with all of the forewing removed except the wing gland. Furthermore, the successful courtships by the glandless males were twice as long as those of males with their wing glands intact; the glandless males met with a much higher frequency of female rejection behaviors, such as turning away from the male or covering the abdomen with their wings, which made copulation more difficult to achieve. Males having all of the forewing removed except for the costal fold were as successful as intact males during courtship. Therefore, courtship success by males appears to depend primarily on the presence of intact costal-fold wing glands and not on mechanical effects such as wind generated by the entire forewings.

Wing Pheromone Identification. Preliminary bioassays (30 females/treatment) of HPLC fractions of male *E. elutella* wing-gland extract indicated that the behaviorally active components were contained in two adjacent 1-ml fractions. Activity elicited by either of these fractions was comparable to that of the complete wing extract (57% and 53% female response for the fractions, respectively, and 63% response for the extract; other fractions evoked $<10\%$ response). These two fractions were characterized by similar complex arrays of peaks on a Silar 10C GC column. Fractional collection of these HPLC fractions from Silar 10C followed by bioassay indicated that full behavioral activity was contained in two adjacent 2.5-min collections. Combining the two GC fractions

TABLE 1. COURTSHIP SUCCESS RATES AND LENGTH OF SUCCESSFUL COURTSHIPS IN MALES WITH FOREWINGS COMPLETELY REMOVED (NO WGS) OR ONLY COSTAL FOLD REMAINING (WGS ONLY) COMPARED TO INTACT MALES

Treatment	*N*	Courtship success (%)	Length of successful courtship (sec ± SD)
No WGs	34	32 b[a]	34.6 ± 10.6 b[b]
WGs only	28	75 a	14.7 ± 4.9 a
Intact males	24	83 a	17.6 ± 4.7 a

[a] Values within the column followed by the same letter not significantly different at $P < 0.05$ by Ryan's multiple-comparison test for proportions.

[b] Values within the column followed by the same letter not significantly different at $P < 0.05$ by Duncan's new multiple-range test.

produced a response of 50% (15/30 females), compared to 53% (16/30) for the combined HPLC fractions. These areas of activity were coincident with two prominent peaks at 8.9 and 11.4 min evident in GC tracings of the original HPLC fractions.

A second HPLC solvent regime (100% methylene chloride to 10% methanol–90% methylene chloride in 10 min) was utilized to fractionally resolve the active components. The component represented by the earlier GC peak was subjected to a number of chemical reagents to aid in its identification. It was unchanged when treated with KOH in EtOH; however, upon treatment with acetyl chloride, the compound (retention time 17.4 min on Durawax-4) was transformed to one with retention time 16.0 min. Base hydrolysis of the acetylated product regenerated the original GC peak. These results strongly suggested the presence of an alcohol. The retention time of this compound on both Durawax-4 and SF-96 was enveloped by those of 1-octadecanol and 1-eicosanol. Ozonolysis of the compound yielded a product with a GC retention time (Durawax-4) and MS fragmentation pattern virtually identical to those of 6,10,14-trimethyl-2-pentadecanone, which was obtained from the ozonolysis of synthetic (*E*)-phytol. Indeed, GC-MS analysis of the putative pheromone component was consistent with that of (*E*)-phytol (3,7,11,15-tetramethyl-2-hexadecenyl alcohol), with identical retention times (*E*/*Z* relative retention time = 1.08 on Durawax-4) and identical fragmentation patterns (Figure 1). (Z)-Phytol was apparently absent from the wing-gland extract. Finally, GC-MS analysis of the online hydrogenation (Beroza and Sarmiento, 1966) of (*E*)-phytol and of the natural component yielded products with matching mass spectra and identical GC retention times on SF-96, Silar 10C, Durawax-4, and DB-5 columns.

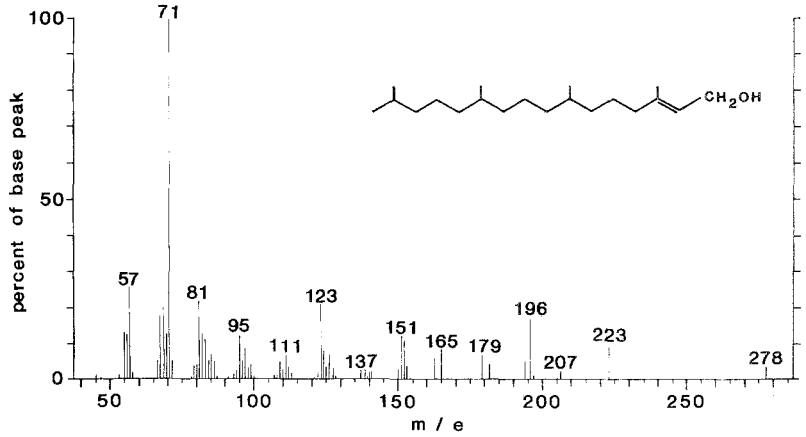

FIG. 1. EI mass spectrum of (*E*)-phytol (3,7,11,15-tetramethyl-2-hexadecenyl alcohol) isolated from *Ephestia elutella* male wing glands.

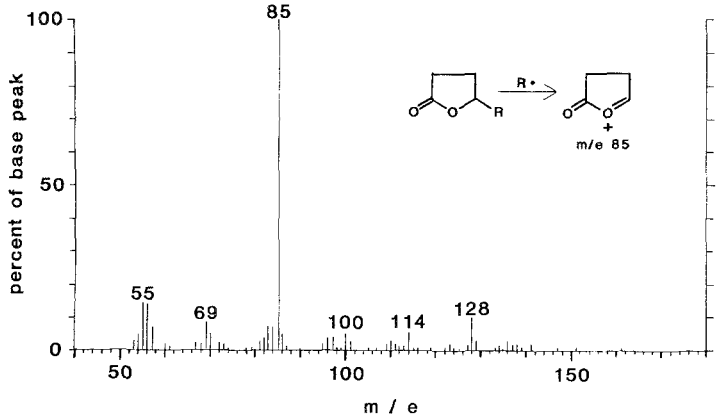

FIG. 2. EI mass spectrum of γ-decalactone isolated from *Ephestia elutella* male wing glands.

The remaining active HPLC fraction, analyzed by GC-MS, contained a series of compounds that exhibited an intense base peak of *m/e* 85 (Figure 2). This fragment is characteristic of the cleavage of the side chain from a γ-lactone (Honkanen et al., 1965). CI-MS (methane) analysis of this series did indeed produce M+1 ions consistent with those of the saturated C_9-, C_{10}-, C_{11}-, C_{12}-, C_{14}-, C_{16}-, and C_{18}-γ-lactones (Figure 3). The identities of two other compounds present with base peaks of *m/e* 85 were not confirmed, although their mass spectra suggested γ-lactones with either unsaturated or substituted side chains. The retention times of the seven wing-extract components matched those of the seven respective synthetic saturated γ-lactones on three GC columns: Silar 10C, SF-96, and Durawax-4. The retention times of C_{14}-, C_{16}-, and C_{18}-γ-lactones were determined by extrapolation of a retention time curve using synthetic C_7-, C_8-, C_9, C_{10}-, C_{11}-, C_{12}-γ-lactones for each GC column.

Behavioral Assays. In the first assay of extracted wing components (Figure 4), a blend of 25 ng each (approx. 5 ME) of synthetic γ-nona-, γ-deca-, and γ-undecalactone was found to elicit a response by females not significantly greater than that produced by clean air; however, when this blend of lactones was combined with 5 ME of the HPLC fraction containing (*E*)-phytol, female response was comparable to that evoked by either the HPLC fraction containing the full complement of natural γ-lactones combined with the (*E*)-phytol-containing HPLC fraction or the unfractionated wing extract. Since the presence of the four longer-chain γ-lactones (C_{12}, C_{14}, C_{16}, and C_{18}) did not appear to increase female response, no further work was attempted on these compounds. When presented alone, the (*E*)-phytol HPLC fraction elicited a response intermediate to that evoked by the clean-air control and the complete wing extract. When individually combined with the (*E*)-phytol fraction (Figure 5), both γ-

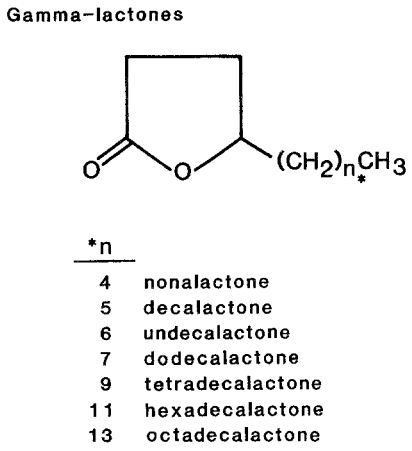

FIG. 3. γ-Lactones determined to be present in *Ephestia elutella* male wing glands.

decalactone and γ-undecalactone increased female response to a level that was significantly greater than the response to (*E*)-phytol alone and not significantly different from that to the full extract. The addition of γ-nonalactone to (*E*)-phytol, on the other hand, had no effect on female response.

Finally, female response to the synthetic (*E*)-phytol (50 ng, 5 ME) was

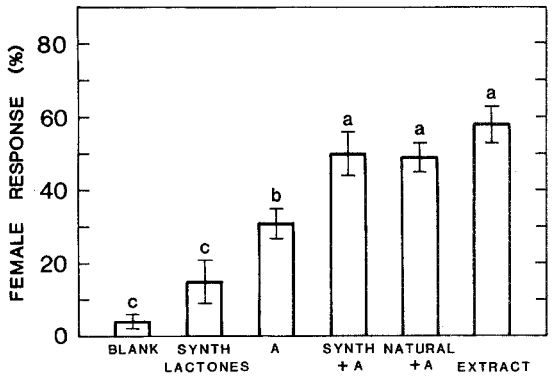

FIG. 4. Response of *Ephestia elutella* females to three synthetic lactones presented alone and in combination with an (*E*)-phytol-containing HPLC fraction (A) of *Ephestia elutella* male wing glands. Activity is compared to the complete wing extract and a recombining of A with the entire complement of lactones isolated from the wing gland (Natural). Different letters indicate significant differences at $P < 0.05$ as determined by Duncan's new multiple-range test of arcsin-transformed values. I bars indicate standard errors.

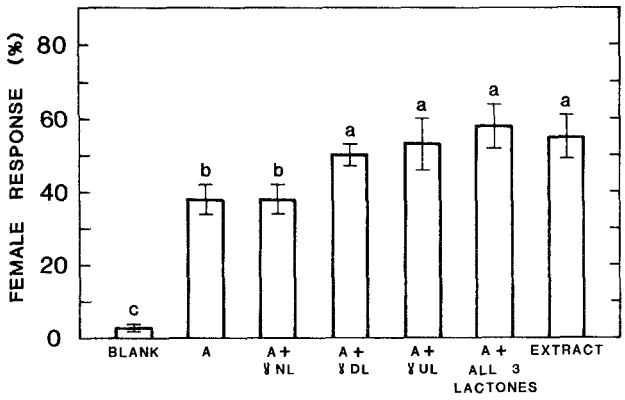

FIG. 5. Response of *Ephestia elutella* females to synthetic lactones when individually added to the (*E*)-phytol-containing HPLC fraction (A) isolated from the male wing gland. Different letters indicate significant differences at $P < 0.05$ as determined by Duncan's new multiple-range test of arcsin-transformed values. I bars indicate standard errors.

assessed (Figure 6). As in earlier assays with the insect-derived (*E*)-phytol, synthetic (*E*)-phytol evoked a response that was intermediate between the clean-air control and the unfractionated wing extract. More significantly, the combination of the synthetic compounds (*E*)-phytol, γ-decalactone, and γ-undecalactone produced a response identical to that elicited by the full wing-gland extract.

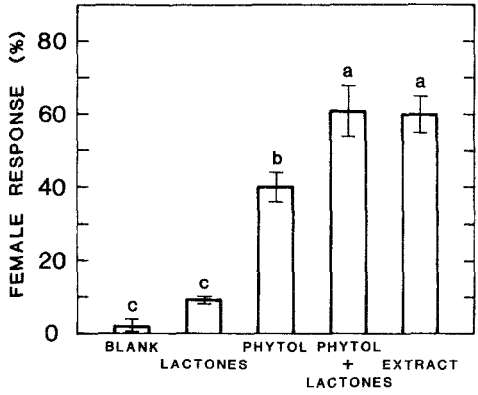

FIG. 6. Response of *Ephestia elutella* females to synthetic (*E*)-phytol alone and in combination with three synthetic lactones. Different letters indicate significant differences at $P < 0.05$ as determined by Duncan's new multiple-range test of arcsin-transformed values. I bars indicate standard errors.

DISCUSSION

We have characterized the importance of the wing pheromone to the mating success of *Ephestia elutella* males. In the past, attempts to identify male pheromones of many species of Lepidoptera have been plagued by the lack of overt behaviors on the part of the female. In *E. elutella*, however, female behaviors important in the courtship sequence are easily observed and can be elicited consistently, using chemicals in the absence of males (Krasnoff and Vick, 1984). Our chemical and behavioral data suggest that the wing pheromone of *E. elutella* consists of a blend of (*E*)-phytol, γ-decalactone, and γ-undecalactone. (*E*)-Phytol appears to be the most important component in that it was the only component that evoked a significicant level of female response when presented alone. The addition of either γ-decalactone or γ-undecalactone to (*E*)-phytol increased the response to a level not significantly different from the complete wing-gland extract. The other lactones identified from the wing glands appeared to be unimportant for female response. Females were not significantly affected by the addition of γ-nonalactone to (*E*)-phytol, and the absence of the longer-chain γ-lactones did not prevent maximum female response from being elicited.

The behavioral activity of (*Z*)-phytol, the stereoisomers of (*Z*)- and (*E*)-phytol, and the enantiomers of the γ-lactones were not studied. Full behavioral activity was evoked by the racemic synthetic compounds; therefore, it would appear that any nonpheromonal enantiomers or stereoisomers present in the synthetic mixture were not behaviorally antagonistic. Complete elucidation of the stereochemistry of this pheromone will require further chemical and behavior testing.

(*E*)-Phytol has long been known as the diterpenoid alcohol moiety of chlorophyll in plants (Willstatter et al., 1919), and both the *Z* and the *E* isomers have been isolated as unbounded molecules from the red algae, *Gracilaria andersonia* (Sims and Pettus, 1976). The present study, however, is the first report of (*E*)-phytol as a volatile component in an animal system, to our knowledge. The report of volatile γ-lactones, on the other hand, is not without precedence. Howard et al. (1983) reported the presence of γ-decalactone in anal droplets formed by the thrips, *Bagnalliella yuccae*. Wheeler et al. (1972) identified γ-dodecalactone from the defensive secretions of several species of *Bledius* rove beetles (Staphylinidae), and Dettner and Schwinger (1982) found γ-decalactone, γ-undecalactone, γ-dodecalactone, and γ-tetradecalactone in the secretions of other staphylinids. In each of these cases, however, the lactones have been found to function in a defensive role, and ours is apparently the first report of γ-decalactone and γ-undecalactone as pheromone components.

Although this bioassay proved to be a convenient method for identifying behaviorally active compounds, it measured only one set of behaviors in the courtship sequence of *E. elutella*. It is possible, therefore, that the roles of other

compounds present in the wing glands have been underestimated. Nevertheless, it seems probable from our behavioral data that these compounds would serve, at most, only a secondary role. This assertion, however, can only be verified by investigating the effect of these synthetic compounds on the complete courtship sequence and on courtship success.

Acknowledgments—The authors are grateful to Mr. R.S. Vetter for technical assistance and preparation of figures. We also wish to thank R. Mellon, K.F. Haynes, and M.A. Willis for reviewing of the manuscript.

EFFECT OF COMBINED FEEDING STIMULI ON INGESTION BY THE NEMATODE *Trichostrongylus colubriformis*[1]

KURT P. BOTTJER and LEON W. BONE

Regional Parasite Research Laboratory, ARS, USDA
P.O. Box 952, Auburn, Alabama 36830

(Received March 8, 1985; accepted May 31, 1985)

Abstract—Ingestion by the nematode *Trichostrongylus colubriformis* was stimulated by serotonin, histamine, and dopamine. Immune serum inhibited feeding by both sexes while octopamine depressed feeding by only male nematodes. However, the combined influence of these excitatory and inhibitory stimuli is unknown. Feeding in vitro by both sexes of the nematode *T. colubriformis* was similar in millimolar ratios of histamine and dopamine or histamine and serotonin, but not dopamine and serotonin. Feeding by nematodes that was stimulated by histamine, dopamine, and serotonin was decreased by subsequent exposure to octopamine. Conversely, elevated concentrations of histamine, dopamine, and serotonin decreased the inhibitory action of octopamine on helminth ingestion in vitro. Doses of immune serum also decreased the stimulated feeding of nematodes that was induced by histamine, dopamine or serotonin. However, the addition of elevated concentrations of these biogenic amines to immune serum reversed the inhibitory effect. The feeding activity of nematodes may represent a summation of the inhibitory and excitatory stimuli that occur in the chemical environment of the helminth.

Key Words—*Trichostrongylus colubriformis*, Nematoda, parasite feeding, helminth ingestion, biogenic amines, host serum, serotonin, histamine, dopamine, octopamine.

INTRODUCTION

Recent studies of ingestion by nematodes have determined that various chemical stimuli may modulate helminth feeding, based on the in vitro and in vivo uptake

[1] Mention of a trademark or proprietary product does not constitute a guarantee or warranty by USDA and does not imply its approval to the exclusion of other suitable products.

of fluorescent dye. Histamine and dopamine stimulated in vitro feeding by both sexes of *Trichostrongylus colubriformis* (Bone and Bottjer, 1985b). Octopamine reduced feeding by male helminths, but not females. Other stimuli, such as host bile or chyme, sugars, amino acids, and enzymes had no effect on in vitro ingestion by helminths. Thus, ingestion by nematodes may be regulated by chemical cues from the host rather than nutrients.

The immune status of the host may alter ingestion by intestinal helminths. Serum from an uninfected host had little influence on in vitro feeding by *T. colubriformis*, while immune serum from infected goats decreased feeding by nematodes. Suppression of helminth feeding by immune sera increased with the duration of the host's infection (Bottjer et al., 1985). Indirect immuno fluorescent studies revealed binding of immunoglobulin G_1 to the worms which was associated with an inhibition of feeding by nematodes. Other reports also indicate that serum influenced feeding by nematodes. Dog serum stimulated the in vitro uptake of glucose by *Ancylostoma caninum* (Fernando and Wong, 1964). Roberts and Fairbairn (1965) reported that dog serum was a feeding stimulus for *A. caninum*, but that rabbit serum was an ineffective stimulant of feeding by *Nippostrongylus brasiliensis*.

Nematodes in an intestinal habitat are simultaneously exposed to a variety of multiple stimuli that may alter their ingestive activity. Accordingly, this study examined the combined influences of selected biogenic amines and immune serum on in vitro feeding by *T. colubriformis*. Multiple excitatory and inhibitory stimuli may be more representative of the nematodes' chemical environment and thus provide a greater understanding of the modulation of pharyngeal pumping by helminths in response to the chemical environment.

METHODS AND MATERIALS

Trichostrongylus colubriformis was maintained in male, cross-bred goats according to previous procedures (Bone and Bottjer, 1985a). Animals were free of helminthic infection, based on fecal examination. Helminths were recovered at 21 days postinfection for experimental determination of their feeding, based on the in vitro ingestion of dye.

Triplicate samples of 250 worms of each sex were collected by mechanical pippettor, rinsed repeatedly, and placed in 2 ml of glucose-free Tyrode's solution (GFTS) at 37°C. The fluorescent dye rhodamine B was added at a final concentration of 100 μg/ml. After 30 min for feeding, the worms were rinsed repeatedly to remove the dye. Helminths were macerated in a mechanical tissue grinder prior to fluorometric analysis of ingested dye versus a series of rhodamine B standards. Background fluorescence was corrected by analyses of undyed worms. Feeding was determined as nanograms of ingested dye per microgram of dry body weight of the helminths. Cuticular uptake of dye was not

observed; thus, fluorometry determined only the oral ingestion of rhodamine B (Bottjer and Bone, 1984).

These procedures were used to evaluate in vitro ingestion by nematodes during incubation in various combinations of excitatory or inhibitory stimuli. Blood was taken from goats after 90 days of a primary infection with 50,000 larvae of *T. colubriformis*, allowed to clot, and centrifuged to obtain immune serum. Sera were pooled and frozen at −4°C until use. Biogenic amines were obtained from Sigma. The following treatments were done:

Combined Excitatory Biogenic Amines. Solutions (100 mM) of histamine (diphosphate), serotonin (creatine sulfate complex), and dopamine (hydrochloride) were prepared in Tyrode's solution. The solutions were freshly prepared and had a pH range of 4.85–6.86. The solutions were mixed to produce millimolar ratios of 100:0, 75:25, 50:50, 25:75, and 0:100. Helminths were incubated in histamine and dopamine, histamine and serotonin, or dopamine and serotonin at the above ratios. After 15 min of exposure to these stimuli, dye was added to the worms to determine their ingestion after an additional 30 min.

Combined Excitatory and Inhibitory Biogenic Amines. Helminths were incubated in 100 mM octopamine to which 0–10 mM concentrations of histamine were added. Similarly, worms were treated with 1 or 10 mM histamine that was augmented with 0–100 mM octopamine. The combined effects of octopamine and dopamine were examined by a similar protocol that used 100 mM octopamine with 0–100 mM dopamine or 10 mM dopamine with 0–100 mM octopamine. *T. colubriformis* was incubated also in 100 mM octopamine with 0–100 mM concentrations of serotonin and 100 mM serotonin with 0–100 mM concentrations of octopamine. After 15 min of equilibration in the initial stimulus, the second stimulus and dye were added to determine dye uptake after an additional 30 min for ingestion.

Combined Excitatory/Inhibitory Biogenic Amines and Immune Serum. The effect of immune serum and various excitatory biogenic amines on nematode feeding was examined also. *T. colubriformis* was incubated in immune serum (100%) with 0–500 mM concentrations of histamine, 0–250 mM concentrations of dopamine, or 0–100 mM concentrations of serotonin. Similarly, worms were placed in 10 mM dopamine, 10 mM histamine, or 100 mM serotonin to which 0–100% concentrations of immune serum were added.

The combined effect of the inhibitory stimuli, octopamine and immune serum, was examined also. Feeding by *T. colubriformis* was determined in 100% immune serum that was augmented with 0–100 mM octopamine or in 100 mM octopamine to which 0–100% concentrations of immune serum were added. These experiments allowed a 15-min equilibration in the initial stimulus before exposure of the worms to the second stimulus and dye for a 30-min period of ingestion.

Data was analyzed by linear regression and analysis of variance. The 0.05 probability level was considered significant.

RESULTS

Oral uptake of dye by male and female of *T. colubriformis* in the combined solutions of excitatory biogenic amines is shown in Figure 1. Ingestion of dye by the helminths was similar in the tested ratios of histamine–dopamine or histamine–serotonin. However, uptake of dye declined significantly in male, but not female, nematodes that were incubated in various ratios of dopamine–serotonin, when compared to their uptake in only dopamine (Figure 1A).

The effect of dosages of the feeding inhibitor octopamine on oral ingestion of dye by worms that were initially stimulated by histamine, dopamine, or serotonin is shown in Figure 2. Feeding by male *T. colubriformis* in serotonin (100 mM), dopamine (10 mM), and histamine (1 mM) was significantly reduced by the subsequent addition of 100 mM octopamine to their media. Ingestion by male nematodes in 10 mM histamine was not affected by the addition of 100 mM octopamine. Uptake of dye in vitro by female worms in dopamine, but not histamine or serotonin, was decreased significantly by the addition of octopamine (Figure 2B).

The inhibition of feeding by *T. colubriformis* males that was caused by 100 mM octopamine was reversed by subsequent addition of 100 mM serotonin, 100 mM dopamine, or 10 mM histamine to the media (Figure 3). Ingestion by female nematodes in 100 mM octopamine was increased only slightly by addition of serotonin, dopamine, or histamine to their media.

The addition of doses of immune serum to the worms' media that contained 10 mM histamine, 10 mM dopamine, 100 mM serotonin, or 100 mM octopa-

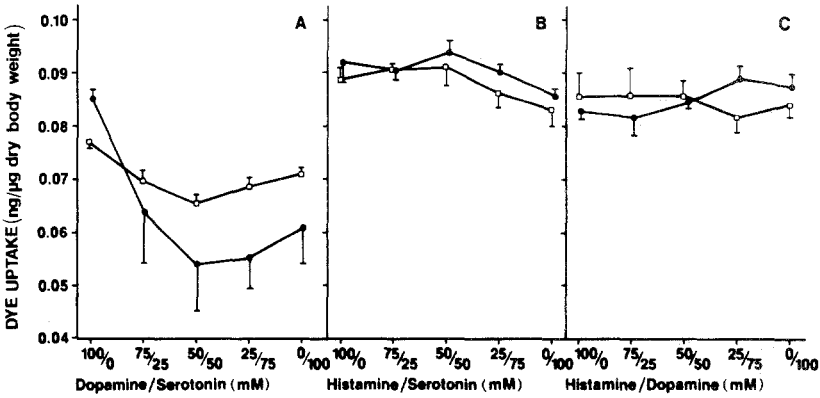

FIG. 1. Uptake of dye (ng/µg dry body weight) by males (●) and females (□) of *T. colubriformis* that were incubated in the indicated millimolar ratios of dopamine–serotonin (A), histamine–serotonin (B) or histamine–dopamine (C).

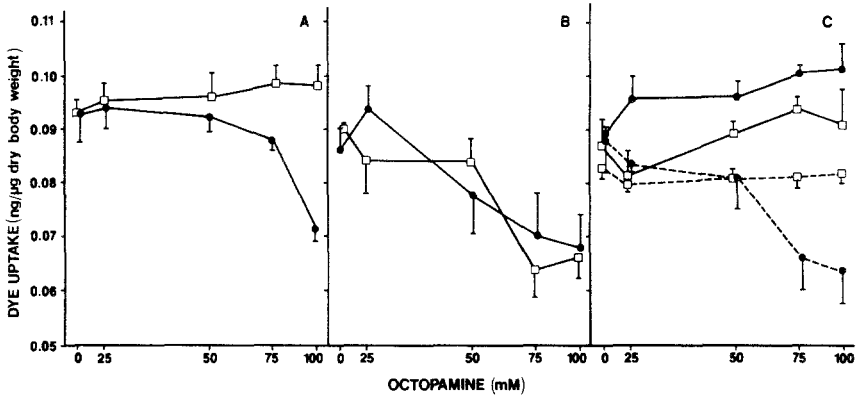

FIG. 2. Uptake of dye (ng/µg dry body weight) by males (•) and females (□) of *T. colubriformis* that were incubated in 100 mM serotonin (A), 10 mM dopamine (B), and 1 mM (---) or 10 mM (—) histamine (C) with subsequent additin of the indicated concentrations of octopamine.

mine reduced dye uptake by both sexes of nematode (Figure 4). Feeding by both helminth sexes in 100% imune serum was increased significantly after the subsequent addition of histamine, dopamine, or serotonin to the serum (Figure 5). Ingestion by female *T. colubriformis* in 100% immune serum was unchanged by the addition of octopamine to the serum, whereas feeding by the males in immune serum was decreased by addition of octopamine (Figure 5D).

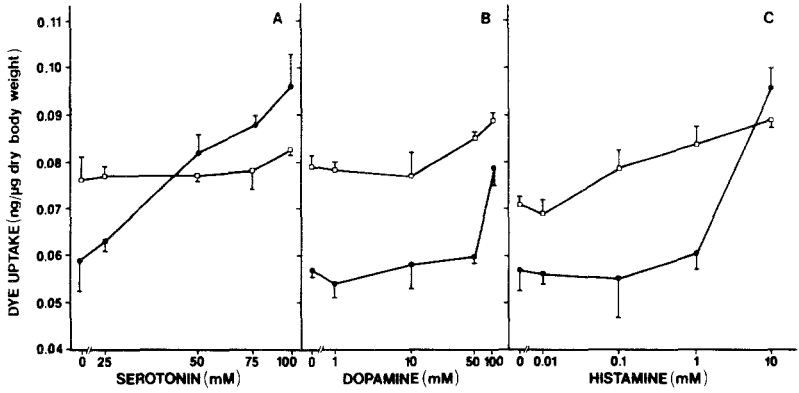

FIG. 3. Uptake of dye (ng/µg dry body weight) by males (•) and females (□) of *T. colubriformis* that were incubated in 100 mM octopamine with subsequent addition of the indicated concentrations of serotonin (A), dopamine (B), and histamine (C).

DISCUSSION

The biogenic amines dopamine, histamine, octopamine, and serotonin are reported from nematodes (Willett, 1980; Barrett, 1981). Catecholaminergic nerves occur also. Thus, alterations of neuromuscular events, such as pharyngeal pumping should be expected after exposure to these compounds. If ingestion of dye is used as an indicator of uptake from the media, the exposure of worms to a 100 mM solution in vitro results in less than a 0.09 nM internal concentration, based on the organisms dry weight. Horvitz et al. (1982) reported that pharyngeal pumping by the free-living nematode *Caenorhabditis elegans* was stimulated and inhibited, respectively, by serotonin and octopamine. Histamine was found to increase pharyngeal pumping in several free-living nematodes (Croll, 1975).

Treatment of the sexes of *T. colubriformis* with various ratios of histamine–serotonin and histamine–dopamine revealed little alteration in the helminth's ingestion. In contrast, feeding by male nematodes declined as the ratio of dopamine–serotonin was decreased. Thus, some competition between these latter biogenic amines is suggested. Absence of knowledge on the pharyngeal innervation of *T. colubriformis* makes further conjecture difficult.

Octopamine inhibited feeding by *T. colubriformis* even when ingestion was stimulated by serotonin, dopamine, and histamine. Histamine at 10 mM blocked the inhibitory effect of octopamine but failed to stimulate feeding, which suggests some level of inhibition occurred. The bases of these variations in the effects of inhibitory and stimulatory interactions of the biogenic amines is presently unknown. However, qualitative and quantitative differences in the receptors for these biologically active compounds are a likely source of the variation.

Other studies suggest that host immunity may affect feeding of zooparasitic nematodes. The intestinal cells of *T. colubriformis* and *Nippostrongylus brasiliensis* exhibit damage caused by host immunity (Rothwell et al., 1980; Lee, 1969). Alterations of feeding by nematodes may reduce their adenylate energy change as found in immune-damaged helminths (Ballantyne et al., 1978). Jones et al. (1978) reported that histamine was elevated in the host's intestine during infection and may be responsible for immune expulsion of *T. colubriformis* from the gut. Histamine, a vasodilator that facilitates leakage of immunoglobulin into the intestine, may initially cause increased ingestion by nematodes as an anticipatory response to subsequent decreases in feeding that are induced by immune serum.

This study suggests that an interaction of histamine, or other biological amines and immunoglobulin as elements of host physiology may modulate ingestion by nematodes. Histamine-induced feeding was blocked by the binding of a mannose-specific lectin to the anterior of *T. colubriformis* (Bone and Bottjer, 1985a). Thus, these amines may effect surface receptors rather than

acting directly on internal innervation of the pharynx. Bottjer er al. (1985) reported that immunoglobulin G_1 was bound to the cephalic region of the worm. Thus, the immunoglobulin may mask the surface receptors of the nematode. Consequently, higher concentrations of chemicals, as used in this study, are required to permeate the bound immunoglobulin. Zuckerman and Jansson (1984) reported that chemotaxis to a bacterial food source by free-living nematodes was inhibited by lectin blocking or enzyme obliteration of chemoreceptors. Host immunity may have a similar inhibitory influence on the chemical stimuli that induce ingestive function in zooparasitic nematodes.

CHEMICAL FRACTIONATION OF SHRIMP EXTRACTS INDUCING BOTTOM FOOD SEARCH BEHAVIOR IN COD (*Gadus morhua* L.)

O.F. ELLINGSEN and K.B. DØVING

Institute of Biology, University of Oslo
P.O. Box 1051, Blindern, N-0316 Oslo 3, Norway

(Received March 22, 1985; accepted June 3, 1985)

Abstract—The bottom food search (BFS) feeding behavior in cod (*Gadus morhua* L.), has been used in a bioassay for chemical isolation of the feeding stimulant substances present in shrimp (*Pandalus borealis*). An aqueous methanol extract of ground shrimp was separated into acidic, neutral, and amphoteric/basic fractions by ion-exchange chromatography and into single components by preparative high-pressure liquid chromatography (HPLC). Of the isolated single components, the amino acid glycine was most potent, followed by alanine. Two unidentified substances were also highly potent. There was a synergistic effect between glycine, alanine, proline, and arginine. These four amino acids were more potent than the total amino acid pool found in the shrimp extract, indicating that there may be amino acids in this pool having an antagonistic effect.

Key Words—Shrimp, *Pandalus borealis*, cod, *Gadus morhua*, food search, behavior, amino acids.

INTRODUCTION

The consumption of food in cod is composed of a series of distinct behavior patterns which add up to the total consumatory act. The behavior patterns involved in food search activity are orientation, approach, nibbling, biting, rushing, snapping, and swallowing (Tilseth and Solemdal, 1977). It seems reasonable to assume that different sensory stimuli are responsible for eliciting parts or sequences of the behavior patterns. Evidence for this assumption has become more tenable when it comes to olfactory stimuli as Døving and Selset (1980) showed that two distinct phases of the food search activity can be elicited via the olfactory system. These two behaviors are also observed in free-swimming cod (Brawn, 1969; Pawson, 1977).

0098-0331/86/0100-0155$05.00/0

During the initial phase, called orienting reaction, the fish swims around making sharp turns to the side, and up and down in the water. During the second phase, a benthic food search is displayed as an arrest of swimming close to the bottom, then the fish swims backwards using the pectoral fins and tail with the head down, trailing the barbel and the pelvic fin rays along the bottom. These behaviors are qualitatively different and can be elicited by electrical stimulation of the lateral and medial part of the lateral olfactory tract, respectively, demonstrating that the behaviors are released via different neural pathways. As the behaviors are elicited by different nervous pathways, it is reasonable to assume that the chemical stimuli must be different.

In the present study we have focused on the chemical basis for eliciting one particular component of the food search behavior, viz., the bottom food search (BFS) behavior pattern. Following a new line of chemical isolation procedures, we have isolated fractions and components releasing this behavior pattern in the cod. Chemical analysis shows that several substances with similar physical/chemical properties are involved in releasing the BFS, among them are the amino acids alanine and glycine. Two components, as yet unidentified, are also potent agents releasing BFS behavior.

METHODS AND MATERIALS

Maintenance of Fish. Cod (*Gadus morhua* L.) were caught in fish pots at Drøbak 30 km south of Oslo and transported to the aquarium facilities at the University of Oslo. The fish were 25–35 cm long and had been kept in captivity in the observation tanks for one week to two months prior to experimentation. During the test period, feeding the fish and cleaning the aquaria were regularly done on Fridays after the experimental series. The tests were performed the five first days of the week. The test fish were calm at the time of testing. They showed no signs of alarm reaction and moved quietly around in the observation aquaria. Sick or aggressive fish were removed from experiments and replaced by healthy, nonaggresive fish. A total of 28 fish were used during the period of bioassay.

Procedure. The cod were observed in four glass aquaria, 120 × 60 × 50 cm each, with a flow of 3 liters/min of seawater. The water temperature was 10 ± 2°C. Four cod marked with individual colored tags were placed in each aquarium. Test solutions were introduced at the bottom of the aquaria via two separate glass tubes (ID 1.5 mm). Teflon tubes of the same internal diameter as the glass capillaries provided connections between the delivery syringes and the glass tubes. The outlet from these glass tubes were hidden in the sand covering the bottom. The dead volume of the delivery lines was 5 ml. The stimuli were presented from syringes placed in an adjustable infusion pump. The solutions were injected into the aquarium at a rate of 2 ml/min during a period of

10 min. Stimulations were performed once a day. The test solutions were introduced in parallel with seawater blanks. Each test solution was given at five different concentrations. The aquarium seawater was used for dilution of all solutions to be tested in the bioassay.

Behavior Patterns. A benthic food search is observed in the cod when the olfactory tract is stimulated electrically and also when the fish is searching for a food source (Brawn, 1969; Pawson, 1977). Initial activity consists of an abrupt cessation of forward swimming, the cod descending to the bottom and moving backwards with the barbel and rays of the pelvic fins trailing the bottom. Each backward swim over the tube outlet was counted as a bottom food search (BFS). The number of fish doing BFS and the total number of BFS counted for the fish during a stimulation period of 10 min were used as a measure of the potency of a test solution. Other parts of the food search behavior pattern were also noted but not included in the present study. These were: orienting reaction, in the sense used by Pavlov (1927); aggression, as described by Brawn (1961); snapping, a rapid opening and closing of the jaws; and bellying, the fish making a quick swim towards the bottom, turning to its side, flashing its belly and swimming along sideways close to the bottom.

Extracts and Synthetic Solutions. Shrimp was ground twice in an electric grinder and then extracted with 3 vol of methanol–distilled water (75:25 v/v) by stirring at 800 rpm for 30 min (Franz Morat, Eisenbach, Hochschwarzwald, FRG, electrical stirrer, type R-16). The liquid phase was separated from the protein phase by vacuum filtration through a Whatman No. 1 filter. The filtrate was evaporated to dryness on a rotary evaporator at 40°C. The residue was dissolved in distilled water to a "dry-weight" content of 100 g/liter. This solution (stock solution) was used for chemical analysis, fractionation, and bioassays. Synthetic solutions were prepared with distilled water so that the concentration of each individual component was the same as that measured in the stock solution.

Chemicals. Homarine HCl was obtained from Carl Roth KG, Karlsruhe, FGR, dimethylthetine HCl from ICN Pharmaceuticals, Inc., Plainview, New York. Other chemicals were from Sigma Chemicals, St. Louis.

Characterization of Stimulants and Analytical Procedures. Analyses and characterization of the stimulants were conducted on the stock solution. Amino acid concentrations were measured on a Biotronic LC 5000 automatic amino acid analyzer. The concentration of trimethylamine was determined by a microdiffusion technique (Conway and Bryne, 1933). Trimethylamine oxide was determined as trimethylamine after reduction with titanium trichloride (Hjorth-Hansen, 1952).

Characterization and purification of stimulants are summarized in Figure 1.

By ion-exchange chromatography, the compounds were separated into three fractions: (1) acidic compounds, adsorbed on the anion exchanger and eluted

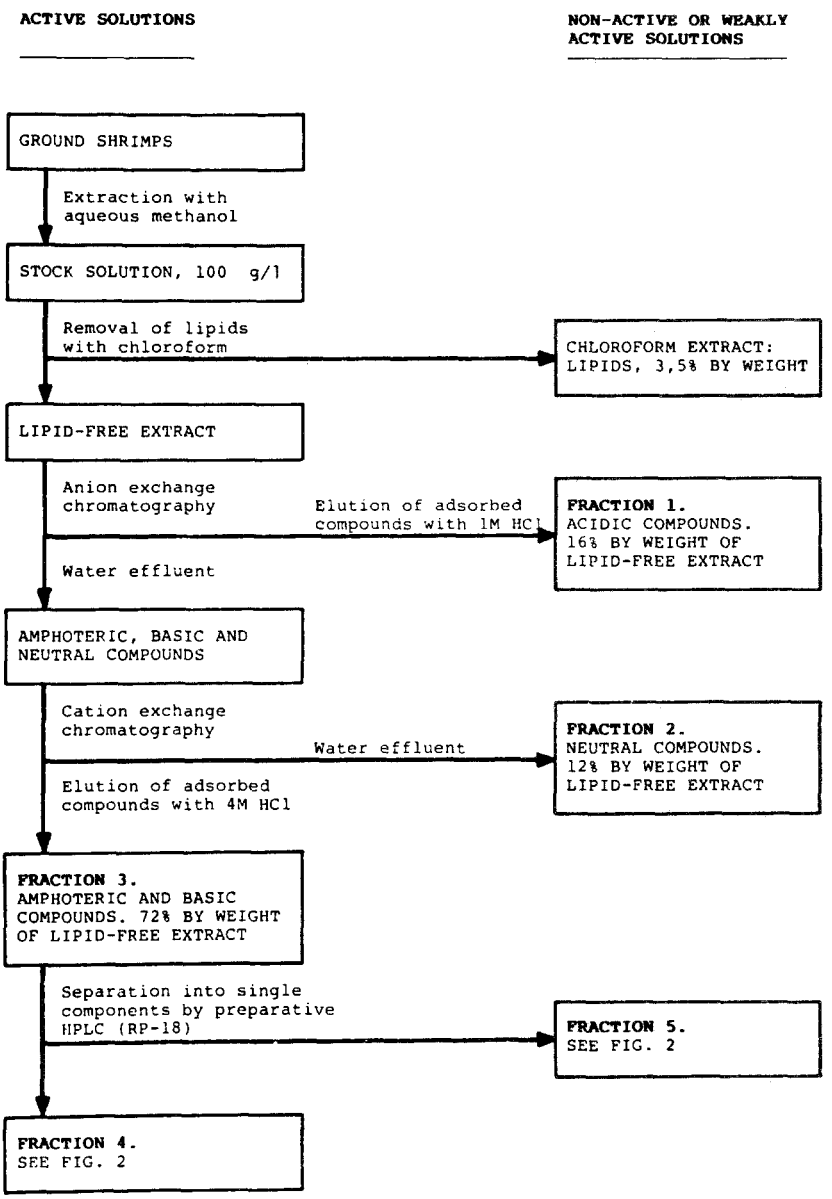

FIG. 1. Flow chart indicating the procedure followed for fractionation of food-search-inducing compounds in extract from shrimp.

with excess 1 M HCl; (2) neutral compounds, eluted from the cation exchanger with excess water; and (3) amphoteric and basic compounds, eluted from the cation exchanger with excess 4 M HCl.

Solutions with the same concentration as in the stock solution were made up from fractions 1, 2, and 3 and tested in bioassays. Test solutions made up from the stock solution and fraction 3 were also tested in equal concentrations.

Traces of fats and pigments (ca. 3.5% by weight) were removed with chloroform before chromatography. One volume of stock solution was extracted twice with two volumes chloroform. Defatted material (30 g) was dissolved in 50 ml distilled water, pH adjusted to 7.0. This solution was applied to an anion exchange column (Amberlite IRA-401, Cl^- form, 16–40 mesh, Koch-Light Laboratories, England, 2.5 × 100 cm). The column was washed with 1500 ml distilled water and adsorbed substances were eluted with excess 1 M HCl (1500 ml). The effluent and washings were combined, concentrated, and dissolved in 50 ml distilled water. The pH was adjusted to 7.0, and the sample was applied to a cation-exchange column (Dowex 50-X8, H^+ form, 16–40 mesh, Dowex, Switzerland, 2.5 × 100 cm) and rinsed with 1000 ml distilled water. The adsorbed substances were eluted with excess 4 M HCl (1500 ml).

The eluate was concentrated, dissolved in buffer, and the pH was adjusted to 4.0 before separation into single components by preparative HPLC (Perkin-Elmer, Norwalk, Connecticut, Series 3B liquid chromatograph with a Perkin-Elmer column C-18 bounded phase, 10 μm particle size, 1.8 × 25 cm). The initial eluent was 0.05 M KH_2PO_4, pH 4.0, and the final eluent methanol. Buffer was used during the first 20 min, then a linear gradient of 0–100% final eluent was used over the next 45 min. Methanol was run as a final eluent for 20 min. The flow rate was kept constant at 2 ml/min. The eluate was monitored at 210 nm (Perkin-Elmer LC 75, spectrophotometric detector).

The components separated by HPLC gave the chromatogram shown in Figure 2; they were collected in two fractions. Fraction 4 contained the substances giving rise to peaks 1–6, and fraction 5 contained all components eluted thereafter. Both fractions were tested in the bioassay at equal concentrations. Single components eluted in fraction 4 were also collected. Before testing, the buffer was removed by the following procedure: Water was removed on a rotary evaporator and the residue dried at 40°C to a constant weight. The dried, water-free material was then dissolved in excess water-free methanol, and buffer was separated from the methanol soluble components by filtration through a Millipore filter, Millipore Corp., Bedford, Massachusetts (45-μm pore size).

RESULTS

The bioassays were performed from September 1983 to September 1984. In all experiments, samples of stock solution were tested as a reference for other solutions applied to the fish (see Tables 2, 4, and 5). This control was partic-

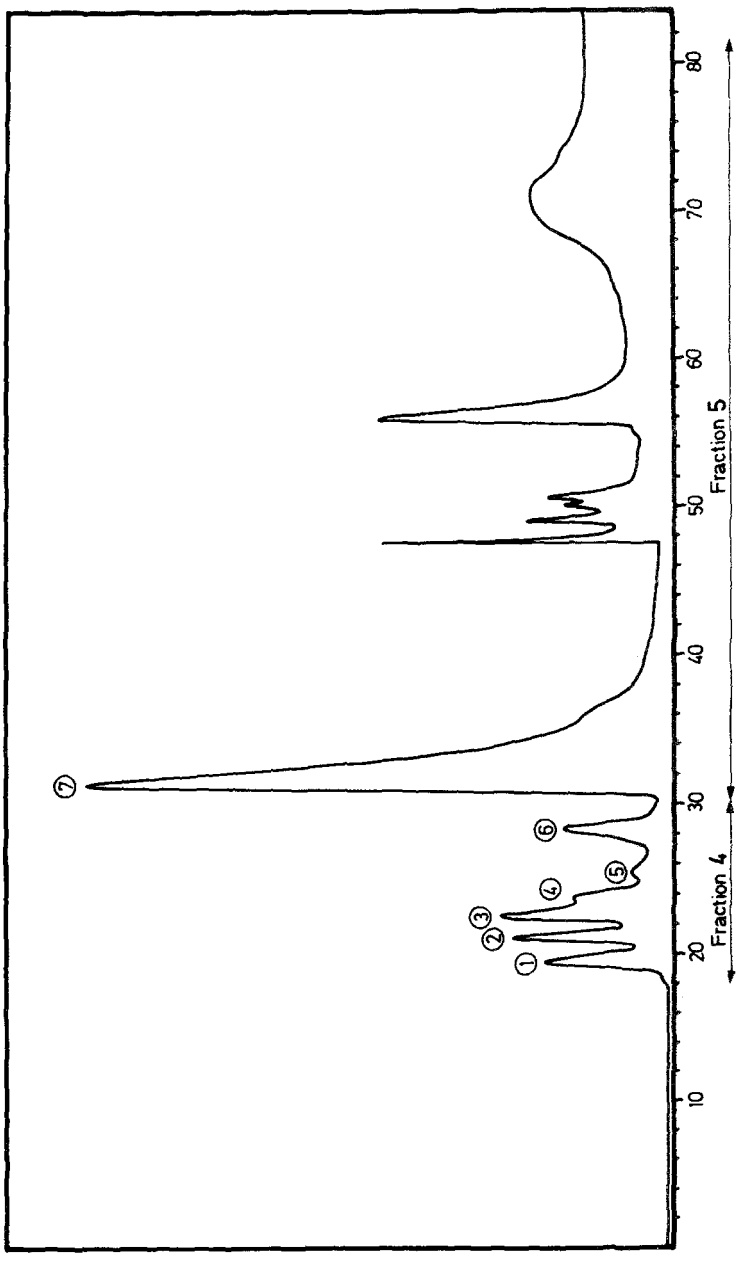

FIG. 2. Chromatogram showing the separation of amphoteric/basic components, fraction 3, by preparative HPLC. Amount injected: 50 mg. The experimental conditions are given in the text.

ularly important as the behavior and threshold for eliciting BFS varied over the year.

Comparison between Shrimp Extracts and Synthetic Solutions. The concentrations of amino acids, trimethylamine oxide, and trimethylamine found in the stock solution are given in Table 1. When a synthetic solution based on the concentration of amino acids found in the stock solution was prepared and tested, it was observed that the stock solution was 100–200 times as potent by weight as the synthetic solution (Tables 2A and B). The four amino acids (glycine, alanine, proline, and arginine) which were most abundant in the stock solution seemed more efficient in evoking the BFS behavior than the total amino acid pool (Tables 2B and C), and the results indicated that these four amino acids were only 10 times less potent than the stock solution (Tables 2A and C). Two amino acids, glycine and alanine alone, did not seem as potent as the four amino acids taken together, but were still more potent than the total amino acid pool (Tables 2B and D). When the four main amino acids were tested individually in equimolar concentrations (Table 3), glycine appeared to be most potent followed by alanine.

A solution containing the amino acids with five carbon atoms, viz., valine,

proline, methionine, and glutamic acid, induced no BFS activity when tested at the same concentrations as that found in the stock solution. A combination of the basic amino acids lysine, arginine, and histidine, scored only a few BFS patterns at the highest concentrations used (1/50 of the concentration in stock solution). The combination of methionine, the five-carbon amino acids, and the basic amino acids induced BFS activity at the same rate as did the basic amino acids.

[a] The entries give the number of fish doing BFS and the total counts of BFS performed during the injection period. Concentrations are in mol/liter of material injected. Test period: February–April 1984.

Trimethylamine oxide and trimethylamine HCl were tested in the same concentrations as found in the natural extract. They did not induce any BFS activity when tested alone. They did not affect the activity scores when tested in combination with the amino acids.

Comparison between Chemical Fractions of Stock Solution. As seen from Figure 1, the weight ratio of the adsorbed compounds was 16:12:72 for fractions 1, 2, and 3, respectively. Only the acidic fraction (fraction 1) and the fraction containing amphoteric and basic components (fraction 3) scored significantly on the bioassay tests as demonstrated in Table 4. When the stock solution and fraction 3 were compared in equal concentrations, the latter was slightly more potent (Table 5).

Further separation of fraction 3 by HPLC (Figure 2), yielded 60% by weight of the material in fraction 4, while components in fraction 5 accounted for 40%. No BFS was induced by fraction 5, while the activity induced by fraction 4 was virtually the same as the activity induced by fraction 3. Of the single components eluted in fraction 4, most of the activity was located in peaks

1, 2, and 3. Peaks 4 and 5 were less active when tested in equal concentrations (1 g/liter).

DISCUSSION

The chemicals emanating from prey induce feeding behavior in cod. In the present study we have shown that shrimp contain amino acids and substances with amphoteric/basic properties which are effective inducers of a particular part of the feeding behavior, viz., the BFS. We discuss the results of our experiments in light of previous studies on cod and attempts to isolate feeding substances for cod and other fish species. The methods developed for the chemical isolation procedure are specifically considered since they might be useful in forthcoming analyses.

The four amino acids in the stock solution, glycine, alanine, proline, and arginine, appeared to be more potent than the total amino acid pool. These results demonstrate that the amino acid pool in a shrimp extract may contain amino acids which have an antagonistic effect on BFS induction in cod. The four main amino acids (glycine, alanine, proline, and arginine) act highly synergistically. This is demonstrated from the results presented in Table 2C and 3. At a total amino acid concentration of 10.5×10^{-3}, 46 BFS were performed by 13 fish when glycine, alanine, proline, and arginine were tested in combination (Table 2C). When the same four amino acids were tested individually at a concentration of 10^{-4} mol/liter (ca. 10^{-3} g/liter), glycine induced eight BFS (performed by six fish); alanine, nine BFS (performed by three fish); proline and arginine did not induce BFS at this concentration (Table 3). Of the individually tested amino acids, glycine appeared to be most potent, this observation being in agreement with Pawson (1977). Johnstone (1980) determined detection threshold values to nine amino acids in cod by a conditioning method and found that tyrosine was most potent, followed by cysteine, phenylalanine, and glycine. The difference between threshold values was small.

Tilseth and Solemdal (1977) examined the preference of cod to a wide variety of natural baits derived from invertebrates and fish tissue. The relative effectiveness of 10 different natural baits in initiating biting of a bag indicated that unconditioned cod clearly responded best to extracts of tissue from crustaceans such as euphasids, shrimp, and deep-sea prawns. Attempts to characterize the effective components in aqueous extracts of crustacean-based baits indicated a reduction in activity at pH below 4 or above pH 10. On adjustment of pH to 11 in a diluted solution of the stock solution, we observed a similar reduction in activity. This treatment was associated with the release of dimethyl sulfide and a precipitate. Boiling of the same solution for 3 hr at pH 1 only resulted in a small decrease in food search activity.

The fractionation procedure used in this work for isolating new food-search

stimulants, other than amino acids, was a modified procedure used for isolation of quaternary bases (Abe and Kaneda, 1975; Konusu and Hayashi, 1975; Hayashi et al., 1978). These authors used the OH^- form of an anion exchanger. The anion exchanger has a higher selectivity for Cl^- than OH^-; the OH^- form is therefore more effective in exchanging acidic compounds than the Cl^- form.

In our preliminary studies, we also applied the lipid-free stock solution on a column with the anion exchanger in the OH^- form. This procedure resulted in a highly alkaline effluent, and the release of dimethyl sulfide and a precipitate. When this sample was analyzed by HPLC after passing through the cation exchanger, the chromatogram was totally different from that seen in Figure 2. Peaks 2 and 3 did not appear. Therefore, the anion exchanger was used in the Cl^- form in the fractionation procedure.

The activity associated with the acidic fraction (fraction 1) should be related to adsorbed amino acids and to nucleotides which also adsorb onto the Cl^- form of an anion exchanger. (Hayashi et al., 1978). The activity associated with the neutral fraction (fraction 2) was regarded as insignificant and was neglected in later work. Since the amphoteric/basic fraction (fraction 3) was the most potent of the three tested fractions and even had a higher activity by weight than the stock solution, further work on identification of food-search stimulants was mainly limited to this fraction.

Most of the activity induced by single components eluted by HPLC was located in substances giving rise to peaks 1, 2, and 3 in Figure 2. The substance giving rise to peak 1 was identified as the amino acid glycine, possibly containing a small amount of alanine [identical IR and mass spectra with authentic glycine, NMR (60 MHz, D_2O): δ = 3.6 ppm (s, CH_2), 1.5 ppm (d, J = 3.5, CH_3 of alanine, very weak signal, shift position and coupling constant identical with authentic alanine)].

Peaks 2 and 3 are still unidentified. These components carry the very distinctive smell of shrimp and are very labile to alkali, releasing dimethyl sulfide on treatment with cold aqueous 1 M NaOH. The presence of dimethyl-β-propiothetine (DMPT) in several species of multicellular algae is well documented (Challenger, 1959; Ishida, 1968; Noda and Horiguchi, 1975; Larher et al., 1977). The decomposition of this substance by cold alkali, yielding dimethyl sulfide, is believed to be a specific reaction (Ackman and Dale, 1965). An indirect determination of DMPT, as dimethyl sulfide, is based on this assumption. Such analyses have been carried out for marine multicellular algae (Ackman et al., 1966), for Labrador cod (Ackman et al., 1967), for brackish water algae and baltic herring (Granroth and Huttula, 1976), and for antarctic krill (Tokunaga et al., 1977). From these data it would seem possible that either peak 2 or 3 might be DMPT. The IR spectra and NMR spectra [60 MHz, D_2O, signals at δ = 3.8 ppm(s) and 3.3 ppm(s)] were not in accordance with published IR spectra (Ishida, 1968; Noda and Horiguchi, 1975) and NMR spectra (Ishida, 1968; Larher et al., 1977). Weak signals in the NMR spectrum at δ =

3.0 ppm and 3.6 ppm might suggest the presence of DMPT as a minor component in peak 3.

Due to the lack of verified structures, it is impossible to determine the concentration in the stock solution, although there are areas in HPLC comparable to glycine. The reduction in activity on alkali treatment of aqueous extracts of crustacean-based baits, as observed by Tilseth and Solemdal (1977) and in this work, obviously should be related to the alkali-labile components giving rise to peaks 2 and 3 in Figure 2. As a representative for thetines, dimethylthetine was tested in our bioassay. This compound does not occur in marine organisms, but it has been described as potent in inducing food consumption in juvenile Dover sole (Mackie et al., 1980). As demonstrated in Table 3, this compound even induced BFS when tested in our bioassay.

Peak 4, observed as a shoulder on peak 3, has been identified as glycine–betaine [superimposable IR and mass spectra, NMR (60 MHz, D_2O): δ = 3.3 (s, 9H, 3X $N-CH_3$) and 4.2 ppm (s, 2H, CH_2)]. The importance of glycine–betaine as a BFS inducer in cod is very doubtful. When glycine–betaine was tested in the same concentrations as the amino acids glycine, alanine, arginine, and proline, no BFS could be observed. The exact concentration of this compound is difficult to determine in our chromatographic system due to low concentration and lack of separation from peak 3. The concentration was determined to be approximately 0.05 g/liter in the stock solution. We were not able to show that glycine–betaine potentiated the stimulation power of amino acids when this component was included.

Components 5 and 6 are still unidentified. Compared to the substances giving rise to peaks 1, 2, and 3, they induced only a very weak degree of BFS.

The main peak in the chromatogram, peak 7, has identical retention time with homarine. No attempt has been made to identify this component by spectroscopy as neither the isolated component nor authentic homarine induced BFS-activity.

The variability of response to the stock solution could be expected due to the cyclic feeding activity of cod found in the coastal zone. Experiments were made both during the most intense feeding period and during breeding season when feeding activity is low even among juvenile cod. Variability of the seawater at the aquarium facilities could also be responsible for the changes in behavioral activity although precautions were taken to keep the water quality constant. The ordinary control routines of the water quality were unaltered during the testing period.

Acknowledgments—The authors are grateful to amanuensis Karl E. Malterud, Institute of Pharmacy, University of Oslo, for recording of spectra and for valuable discussions, and to Gro Svendsen for skillful technical assistance.

FATE OF INGESTED IRIDOID GLYCOSIDES IN LEPIDOPTERAN HERBIVORES

M. DEANE BOWERS and GILLIAN M. PUTTICK

Museum of Comparative Zoology, Harvard University
Cambridge, Massachusetts 02138

(Received March 7, 1985; accepted June 5, 1985)

Abstract—Thin-layer chromatography was used to follow the fates of iridoid glycosides ingested by four species of lepidopteran herbivores. These four species differed in their feeding strategy, ranging from generalist to monophagous specialist; and in their predator avoidance strategy, ranging from cryptic and palatable to aposematic and unpalatable. The fates of the iridoid glycosides ranged from sequestration by the unpalatable specialist, *Euphydryas phaeton* (Nymphalidae); to passage into the hemolymph and eventual elimination in the meconium by the specialists *Junonia coenia* (Nymphalidae) and *Ceratomia catalpae* (Sphingidae); to elimination of the intact compounds in the feces of the generalist feeder, *Lymantria dispar* (Lymantriidae).

Key Words—Iridoid glycoside, Lepidoptera, *Euphydryas phaeton*, Nymphalidae, *Junonia coenia*, *Ceratomia catalpae*, Sphingidae, *Lymantria dispar*, Lymantriidae, chemical ecology, insect–plant interaction, unpalatability, insect defense strategy.

INTRODUCTION

Plant allelochemicals may meet one or the other of several possible fates when ingested by an insect: (1) they may be metabolized in some way (Rosenthal et al., 1977; Brattsten, 1979; Duffey, 1980; Blum, 1983; Ivie et al., 1983; Bull et al., 1984); (2) eliminated without being metabolized (Self et al., 1964a,b); (3) used as building blocks for pheromones or defensive compounds (Schneider et al., 1975; Conner et al., 1981); (4) sequestered and used in the insect's own defense (Parsons, 1965; Teas, 1967; Brower et al., 1968; Duffey and Scudder, 1972; Rothschild et al., 1972; Roeske et al., 1976; Isman et al., 1977; Duffey, 1980; Blum, 1981, 1983). Some combination of these fates is also possible. A guild of insect herbivores feeding on plant species with a common group of

0098-0331/86/0100-0169$05.00/0

plant allelochemicals may process these compounds in very different ways (e.g., Rothschild, 1973; Isman et al., 1977; Blum, 1981).

In this paper, we compare the fates of a group of plant allelochemicals, the iridoid glycosides (Figure 1), in the various life stages of four lepidopteran herbivore species which have ingested these compounds: *Euphydryas phaeton* Drury (Nymphalidae), *Junonia coenia* Hbn. (Nymphalidae), *Ceratomia catalpae* Bdv. (Sphingidae), and *Lymantria dispar* (L.) (Lymantriidae) (Table 1). These four species show different degrees of dietary specialization, ranging from generalist to extreme specialist; as well as very different predator avoidance strategies, ranging from palatable, solitary, and cryptic, to unpalatable, gregarious, and aposematic (Table 1). The three specialist species feed only on plants that contain iridoid glycosides, while *L. dispar* is a generalist.

Butterflies in the genus *Euphydryas* specialize on plants that contain iridoid glycosides and use these compounds as larval feeding stimulants and attractants (Bowers, 1981, 1983). Feeding experiments with birds have shown that the *Euphydryas* species, in general, are unpalatable and earlier work by Bowers (1979, 1981) indicated that iridoid glycosides can play a role in this unpalatability. Larvae of the buckeye, *J. coenia*, also use iridoid glycosides as larval feeding stimulants and are restricted to feeding on plants that contain these compounds (Bowers, 1984). *Junonia coenia* is cryptic on the underside, although there are conspicuous eyespots on the dorsal surface. The catalpa sphinx, *C. catalpae* is restricted to feeding on species of *Catalpa* (Bignoniaceae), which also contain iridoid glycosides, and appears to use iridoid glycosides as feeding stimulants (Nayar and Fraenkel, 1963). The larvae have a conspicuous black and white coloration and are gregarious, whereas the adults are cryptic. In contrast to these three specialists, the gypsy moth, *L. dispar*, is a relatively generalist feeder, and the adults seem to be cryptic and palatable (Leonard, 1974).

The iridoid glycosides (Figure 1) are a group of cyclopentanoid monoterpene-derived compounds found in over 50 families of plants (Bobbitt and Segebarth, 1969; Jensen et al., 1975; Hegnauer and Kooiman, 1978; El-Naggar

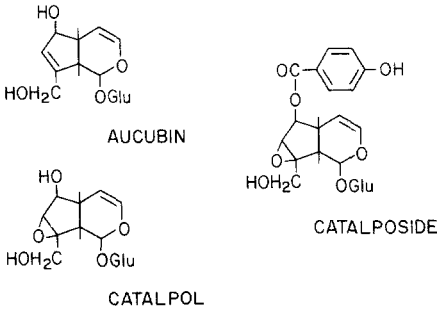

FIG. 1. Iridoid glycosides used in this study.

and Beal, 1980; Dahlgren et al., 1981; Gershenzon and Mabry, 1983). These compounds are known as "bitter substances" because of their bitter taste to humans (Thomas, 1961; Hegnauer, 1966; Kubota and Kubo, 1969; personal observation), and plants containing them have been used as natural insecticides (Hegnauer, 1966). In addition, they have been shown to be important in the interactions of insects and the plants that contain them (Nayar and Fraenkel, 1963; Bowers, 1979, 1981, 1983, 1984; Sha'aban et al., 1980; Bernays and DeLuca, 1981; Stephenson, 1981, 1982; Chang and Nakanishi, 1983).

We used thin-layer chromatography to qualitatively assay plant material, eggs, larvae, pupae, adults, and larval frass for evidence of the iridoid glycosides, aucubin, catalpol, and catalposide, which are the major identified iridoid glycosides found in the host plants we studied (El-Naggar and Beal, 1980).

METHODS AND MATERIALS

Insects and Plants. Euphydryas phaeton were reared from eggs from a wild-collected female from Leverett, Massachusetts, and during prediapause instars were fed on *Chelone glabra* L. (Scrophulariaceae) leaves, the primary host plant of this species (Bowers, 1980). In the postdiapause instars, one group of larvae were fed on *C. glabra* and another on *Plantago lanceolata* L. (Plantaginaceae), an alternative host plant (Bowers, 1980). These two plant species were chosen because adult *E. phaeton* butterflies are unpalatable and emetic to birds when fed as larvae on *C. glabra*, but are relatively palatable when larvae are fed *P. lanceolata* in the postdiapause instars (Bowers, 1980).

Junonia coenia were from a laboratory culture derived from eggs from several wild-collected females from Columbia, South Carolina. They had been maintained in the laboratory on *P. lanceolata* leaves, a commonly utilized host plant (refs. in Bowers, 1984), for only a few generations.

Ceratomia catalpae were reared from eggs derived from wild-collected females from Cape May County, in southern New Jersey. Larvae were fed in the laboratory on leaves of *Catalpa bignonioides* Walt.

Lymantria dispar larvae were reared on one of two artificial diets (Bowers, 1983): either a diet containing 3.6% dry weight catalposide or a diet containing no iridoid glycosides. These larvae were from eggs obtained from the USDA Gypsy Moth Rearing Facility at Otis Air Force Base, Massachusetts.

Thin-Layer Chromatography. Plant and insect samples were prepared using a slightly modified procedure of Wieffering (1966). Quantities of all materials were adjusted relative to the starting dry weight of the sample. For example, 100 mg dried plant or insect material is ground with an equal weight of sand. Ten milliliters of distilled water are added with 50 mg polyvinyl pyrrolidone to remove phenolics. After 15–20 min, the mixture is filtered and 50 mg sand and 50 mg kieselguhr are added. The mixture is evaporated to dryness on a rotary

evaporator. The residue is extracted overnight with 4 ml 96% ethanol, filtered, and concentrated. The concentrated samples were spotted onto prepared silica gel glass plates (Baker). The solvent system was butanol, prepared by mixing it with acetic acid and water in a ratio of 4:1:5, and then drawing off the butanol layer. The running time for these plates was about 4 hr. The spots were visualized by spraying the plates with a 1 N solution of H_2SO_4 in methanol and heating them at 105°C for 5 min (Wieffering, 1966). We have also used a *p*-anisaldehyde reagent made up of 90 ml 50% ethanol, 10 ml concentrated H_2SO_4, and 0.5 ml *p*-anisaldehyde, which produces different colors, but also identified the iridoid glycosides we are interested in. We compared the color and R_f of spots from our samples with those of standards to determine the presence or absence of particular iridoid glycosides in plants and insects.

Standards of aucubin, catalpol, and catalposide were run with the samples on each plate, and on each individual plate the R_fs of the samples and standards were virtually the same. There was minimal variation in the R_fs of the standards from one plate to another. The R_fs of the standards were as follows: aucubin: 0.35–0.39, catalpol: 0.27–0.31, catalposide: 0.55–0.58.

RESULTS

We found that *E. phaeton* larvae sequestered iridoid glycosides from both *C. glabra* and *P. lanceolata*, and that these compounds were retained through to the adult stage (Table 2). However, there were some interesting differences in the results with insects reared on these two plants. *Euphydryas phaeton* larvae reared on *P. lanceolata* produced adults that contained more aucubin than catalpol, as indicated by the size and intensity of the spots. When larvae were fed on *C. glabra*, which appeared to contain more catalpol than aucubin, the adult contained more catalpol than aucubin. Preliminary results with high-pressure liquid chromatography (HPLC) have substantiated this qualitative result: there was from six to 20 times as much aucubin as catalpol in *P. lanceolata*, and four to five times as much catalpol as aucubin in *C. glabra* (Bowers and Puttick, unpublished). The larvae, pupae, and eggs of *E. phaeton* also contained iridoid glycosides (Table 2). In addition, HPLC showed that *E. phaeton* butterflies reared as larvae on *C. glabra* have two to five times as much catalpol as aucubin. Those reared on *P. lanceolata* appear to selectively sequester catalpol, or convert aucubin to catalpol, as the butterflies contain approximately equal amounts of aucubin and catalpol, while the plants had much more aucubin. Stermitz (unpublished), using gas–liquid chromatography (GLC), found that wild-collected *Euphydryas anicia* (Doubleday and Hewitson) contained as much as 4% dry weight iridoid glycosides. We could not detect aucubin or catalpol in the frass of *E. phaeton* larvae reared on either *C. glabra* or *P. lanceolata*.

Junonia coenia, in contrast, did not sequester iridoid glycosides through

to the adult stage, although curiously, the pupa did contain iridoid glycosides (Table 2). *Ceratomia catalpae* larvae appeared to sequester selectively one iridoid glycoside, catalpol, from an array of at least five iridoid glycosides detected in the leaves of *C. bignonioides*. Although the pupa also contained catalpol, the adult did not contain any iridoid glycosides. We did not detect catalposide in either the larva or adult of *L. dispar*, although it was clearly evident in the frass. However, it is possible that our methods may not have been sensitive enough to detect the catalposide in the food material in the gut.

We were surprised to find iridoid glycosides in the pupae of *J. coenia* and *C. catalpae*, since the adults of these species did not contain the compounds. Because wastes are not eliminated during pupation but only at adult eclosion, we hypothesized that the iridoid glycosides might be in the meconium, the substance containing the waste products accumulated during pupation which is eliminated upon emergence. Nishio (1980) found that the meconium of *Danaus plexippus* L. (Nymphalidae), which fed on *Asclepias humistrata* Walt. (Asclepiadaceae), contained cardenolides. Thin-layer chromatography of the meconium of *J. coenia* revealed the presence of substantial amounts of aucubin and catalpol, the two primary iridoid glycosides found in *P. lanceolata*, and the same two which had been detected in the pupa (Table 2). Likewise, the meconium of *C. catalpae* contained catalpol (Table 2). Despite the fact that *E. phaeton* adults contained iridoid glycosides, the meconium of this species was also found to contain these compounds: catalpol if the larvae had fed on *C. glabra*, and aucubin and catalpol if the larvae had fed on *P. lanceolata*.

DISCUSSION

The fate of the ingested iridoid glycosides appears to be related to the predator avoidance strategy of the specialist herbivores. Thus, *E. phaeton*, which is unpalatable (Bowers, 1980), sequesters iridoid glycosides during larval feeding, and they are retained in the adult stage. Although we clearly need to feed pure iridoid glycosides to birds for final proof, the evidence is overwhelming that iridoid glycosides are responsible for the unpalatabilty of the *Euphydryas* (Bowers, 1980, 1981). In contrast, in *J. coenia*, iridoid glycosides are found in the larva and pupa, but not in the adult. During pupation, the iridoid glycosides pass into the meconium and are ejected at adult eclosion. The adults of *J. coenia* seem to be palatable as is suggested by their wing pattern and coloration. In addition, adult *J. coenia* were taken and presumably eaten when offered to wild birds at an outdoor feeding station and were eaten readily by a caged California scrub jay.

The pattern of sequestration in *C. catalpae* is particularly interesting. The larvae appear to selectively sequester one iridoid glycoside, catalpol, from a range of at least five iridoid glycosides which we were able to detect in the host

plant. Alternatively, they could be converting the other iridoid glycosides into catalpol. There may be other iridoid glycosides in the plant and larva that we cannot detect (see Nayar and Fraenkel, 1963). Interestingly, catalpol is one of the most bitter of the iridoid glycosides (personal observation). In addition, the results with *E. phaeton* suggest that it is catalpol that is responsible for the emeticity of adult butterflies which fed as larvae on *Chelone glabra* (Bowers, 1980) (Table 2). The larval stage of *C. catalpae* is very unlike the other species of *Ceratomia* and those of the closely related genus *Manduca* in North America. *Ceratomia catalpae* larvae are gregarious, the females laying eggs in batches of as many as 1500. The early larval stages are white with black spots, while the last three instars are usually black and yellow. There is also a predominantly yellow larval morph. In contrast, larvae of related sphingid species are solitary and cryptic. The adult of *C. catalpae* is a drab yellowish gray, very similar to the adults of related species (Hodges, 1971). Although controlled feeding experiments with birds need to be performed, anecdotal evidence from offering larvae and adults to birds at a feeding station suggests that the larvae are unacceptable to birds, while the adults are palatable (Bowers, personal observation). This suggests that utilization of *Catalpa* species as the larval host plant of *C. catalpae* with consequent unpalatability of the larvae has selected for the evolution of aposematism in this species.

We were intrigued by the presence of iridoid glycosides in the meconium of the specialist insects. This interest was piqued when we disturbed a resting *C. catalpae* and it squirted us with meconium from a distance of two feet. This suggested that the presence of iridoid glycosides in the meconium may be another line of defense against predators, a role not previously accorded to it. In general, the meconium is considered to contain the waste products accumulated during the pupal stage. Nishio (1980) found cardenolides, another group of bitter allelochemicals, in the meconium of *D. plexippus* which had fed on milkweeds. Stephenson (1982) found that iridoid glycosides were deterrent to ants when included in a sugar solution, and ants may be important predators of helpless, teneral adult lepidopterans. The meconium is usually eliminated soon after eclosion, often when the insect is disturbed. Thus it may be a defense during a very vulnerable time when the newly eclosed adult is unable to fly.

In summary, the fate of ingested iridoid glycosides differed in four species of lepidopterans fed on plants or artificial diets containing these compounds, ranging from sequestration by the unpalatable specialist, *E. phaeton*; to passage into the meconium and eventual elimination via the meconium of *J. coenia* and *C. catalpae*; to elimination of the intact compounds in the frass of the generalist feeder, *L. dispar*. These fates appeared to be related to the predator avoidance strategy of these herbivores.

Acknowledgments—We are most grateful to J. Bobbitt, University of Connecticut; A. Stephenson, Pennsylvania State University; and W. Berkowitz, State University of New York, Queens, for their generous provision of the standards of iridoid glycosides. C. Kennedy, J. Cisneros, J.

Cornell, M. Philpott, T. Becktold, M. Camerena, W. Diamond, Z. Larrin-Goodbourne, and S. Grunow provided vital and enthusiastic laboratory assistance. We particularly thank D. Lincoln and N. Welschmeyer for use of their HPLCs. D. Schweitzer collected the *C. catalpae* females for us. We appreciate the comments of J. Glyphis, B. Hölldobler, D. Lincoln, N. Stamp, F. Stermitz, and E. Wilson on a previous version of this manuscript. This work was supported by NSF grant BSR83-07353 to D. Bowers.

(Received April 2, 1985; accepted June 5, 1985)

Abstract—Reinvestigation of the pheromonal activity of anhydroserricornin, (2*S*,3*S*)-2,6-diethyl-3,5-dimethyl-3,4-dihydro-2H-pyran, showed that the magnitude of its activity was less than $1/10^3$ of that of serricornin, 7-hydroxy-4,6-dimethyl-3-nonanone, the sex pheromone of the cigarette beetle *Lasioderma serricorne* (F.). Neither a synergistic nor an inhibitory effect of anhydroserricornin addition on the action of serricornin was observed.

Key Words—Sex pheromone, cigarette beetle, *Lasioderma serricorne* (F.), *Coleoptera*, *Anobiidae*, serricornin, 7-hydroxy-4,6-dimethyl-3-nonanone, anhydroserricornin, 2,6-diethyl-3,5-dimethyl-3,4-dihydro-2H-pyran.

INTRODUCTION

The cigarette beetle *Lasioderma serricorne* (F.) is a common, destructive pest for not only cured tobacco leaves but also various foodstuffs. The sex pheromone component produced by female adults was isolated and identified as 7-hydroxy-4,6-dimethyl-3-nonanone (Chuman et al. 1979a) and named serricornin (Chuman et al., 1979b). Recently, M. Mori et al. (1982a,b) determined the absolute structure to have a 4*S*,6*S*,7*S* configuration, and the remarkable inhib-

0098-0331/86/0100-0179$05.00/0

itory action of the 4*S*,6*S*,7*R* isomer was also demonstrated (M. Mori et al., 1985).

Levinson et al. (1981) reported a second pheromone component (2*S*,3*S*)-2,6-diethyl-3,5-dimethyl-3,4-dihydro-2H-pyran, namely anhydroserricornin, isolated from solvent extracts of the female adults. Their observation in the "glass jar" bioassay using a synthetic diastereoisomeric mixture of anhydroserricornin suggested a much higher pheromonal activity than that of a diastereoisomeric mixture of serricornin. Chuman et al. (1982a), however, could not reproduce their findings using a synthetic enantiomeric mixture of anhydroserricornin in two kinds of bioassay systems. After that, Levinson et al. (1982) reported again on the high pheromonal activity of the diastereoisomeric mixture of anhydroserricornin in the "Petri dish" bioassay system, and Chuman et al. (1982b) confirmed their own earlier result using optically active anhydroserricornin. This difference between two groups on the evaluation of anhydroserricornin as the sex pheromone component has remained unresolved (Fletcher et al., 1984).

We report here the results of our recent laboratory bioassay using optically active anhydroserricornin and serricornin to solve the above question and to elucidate whether anhydroserricornin plays a synergistic or an inhibitory role to the pheromonal action of serricornin.

METHODS AND MATERIALS

Handling of Insects and Pheromonal Bioassay. The same system was adopted in the same manner as described before (M. Mori, et al., 1985.) Thus the evaluation of pheromonal activity of each test substance was achieved through the following three parameters: (1) attractiveness (accumulated number of times that males visited the source of test substance), (2) sex stimulation (accumulated number of attempted matings induced by the test substance), and (3) maximum aggregation number (maximum number of males staying simultaneously on the source of test substance).

(4S,6S,7S)-7-Hydroxy-4,6-dimethyl-3-nonanone (Serricornin). Optically active serricornin (100% EE) was synthesized by the described procedure of K. Mori and Watanabe (1985).

(2S,3S)-2,6-Diethyl-3,5-dimethyl-3,4-dihydro-2H-pyran (Anhydroserricornin). The optically pure sample of serricornin (100 mg) was refluxed in chloroform for 1 hr, followed by removing the solvent under atmospheric pressure to afford almost pure anhydroserricornin. When the dehydration of serricornin was performed by using a catalyst such as *p*-toluenesulfonic acid (Hoffman et al., 1982), many minor byproducts were revealed to be formed, some of which were difficult to remove in the subsequent purification procedure. This mild treatment with chloroform gave a satisfactorily pure sample of anhydroserricornin. Further purification was achieved by preparative GC (5% OV-1

glass column, 1 m) to obtain the pure sample (30 mg). $[\alpha]_D^{25}$ −83.1° (c = 0.42, n-hexane); lit. $[\alpha]_D^{23}$ − 53.1° (c = 0.065, n-hexane) (Chuman et al., 1982b), $[\alpha]_D^{23}$ −65.5 ± 0.5° (c = 2.28, chloroform) (Hoffmann et al., 1982), and $[\alpha]_D^{20}$ −80.7° (c = 2.54, chloroform) (Hoffman et al., 1984). High-resolution [^{1}H]NMR spectrum (500 MHz) showed that the sample was quite free from its diastereoisomer.

RESULTS AND DISCUSSION

Pheromonal Activity. The pheromonal activity of anhydroserricornin was measured with respect to the three parameters, and the data obtained were compared with those of serricornin (Tables 1–3). Small inversions of data are seen in some of these tables; however, such levels of fluctuations should be ignored because of the individual variations of insects used. As seen in Table 1, the attractiveness of anhydroserricornin is significantly lower than that of serricornin; the magnitude for anhydroserricornin is $\frac{1}{2}$ to $\frac{1}{3}$ of that for serricornin at the respective dose levels within 10^{-1}–10^{-3} μg. Table 2 shows the lower sex stimulatory activity of anhydroserricornin compared to serricornin; the accumulated number of times of attempted matings with anhydroserricornin is $\frac{1}{2}$ to $\frac{1}{3}$ of that obtained with serricornin at the respective dose levels. The third parameter, maximum aggregation number, for anhydroserricornin was also observed to be smaller than that for serricornin (Table 3); the maximum number of simultaneously responding males was $\frac{1}{2}$ to $\frac{1}{3}$ of that measured with serricornin at the same dose levels.

On the above measurements of pheromonal activities, a dose–response dependency was observed in every case. This dependency was further confirmed by measurement of the attractiveness over the range of 10^{-1}–10^{-8} μg dose levels (Figure 1). As seen in Figure 1, it is suggested that the magnitude of the pheromonal activity of anhydroserricornin is less than $1/10^3$ of that of serricornin.

TABLE 1. ATTRACTIVENESS OF ANHYDROSERRICORNIN AND SERRICORNIN TO MALE CIGARETTE BEETLES[a]

Dose (μg)	Anhydroserricornin	Serricornin	t	P
1.0×10^{-1}	44.6 (±33.6)	117.3 (±29.2)	5.16	<0.001
1.0×10^{-2}	28.0 (± 9.6)	89.5 (±48.7)	3.91	<0.01
1.0×10^{-3}	19.6 (±10.0)	82.0 (±31.1)	6.85	<0.001

[a] Accumulated numbers of times that 10 males visited the source of the test substances within 10 min. Each test was replicated 10 times, and the standard deviations are shown in parentheses.

1.0×10^{-1}	3.4 ($\pm$2.5)	8.3 ($\pm$1.7)	5.13	<0.001
1.0×10^{-2}	3.0 ($\pm$1.8)	8.2 ($\pm$2.8)	4.94	<0.01
1.0×10^{-3}	2.6 ($\pm$1.7)	7.2 ($\pm$2.3)	5.09	<0.001

[a] Accumulated numbers of times of attempted matings induced by the test substances among 10 males within 10 min. Each test was replicated 10 times, and the standard deviations are shown in parentheses.

These results agree with those which we already reported briefly for the enantiomeric mixture of anhydroserricornin (Chuman et al., 1982a) and for optically active anhydroserricornin (Chuman et al., 1982b); however, these are considerably different from those reported by Levinson et al. (1981, 1982) for a diastereoisomeric mixture of anhydroserricornin. Their "Petri dish" bioassay system (Levinson et al., 1982) is somewhat different from that applied in this study, so we further examined the pheromonal activities of anhydroserricornin and serricornin by modifications of our system, using Petri dishes of the same size used by them (75 mm ID, 30 mm height), awakened insects instead of resting insects, 30 min instead of 10 min for the observation time, and without using the filter paper screen as the source of test substance. The result is shown in Table 4, in which every number is relatively large compared with that in Table 1, mainly owing to the prolonged observation time. The data for attractiveness of anhydroserricornin in this table are essentially the same as those reported by Levinson et al. (1982) for a diastereoisomeric mixture of anhydroserricornin. But the data for serricornin in Table 4 are quite different from those obtained by Levinson et al. (1982); their value was only 20 or less at the 10^{-1} μg dose level (read from their figure), which is small compared with that obtained in this study (322, Table 4). For this reason, we consider that the serri-

cornin sample used in their bioassay contained some of the 4*S*,6*S*,7*R* isomer which is known as the inhibitory component of conventionally synthesized serricornin product (M. Mori et al., 1985).

Therefore it should be concluded that the magnitude of pheromonal activity of anhydroserricornin is $1/10^3$ of that of serricornin at the highest, and that anhydroserricornin is not an important component as the sex pheromone.

Effect of Anhydroserricornin Addition on Pheromonal Activity of Serricornin. It has been clarified above that the pheromonal activity of anhydroserricornin is very low by itself, so next we examined whether it plays a synergistic or inhibitory role to the action of serricornin. The same bioassay system was

TABLE 4. BIOASSAY RESULTS FOR ANHYDROSERRICORNIN AND SERRICORNIN AT 1.0×10^{-1} μg DOSES ACCORDING TO LEVINSON *et al.* (1982)[a]

Parameter	Anhydroserricornin	Serricornin	*t*	*P*
Attractiveness	186.5 (±40.3)	321.8 (±80.9)	4.73	<0.01
Sex stimulation	8.0 (± 2.8)	23.4 (± 6.2)	7.16	<0.001
Maximum aggregation	5.5 (± 0.7)	8.3 (± 1.5)	5.35	<0.001

TABLE. 5. ATTRACTIVENESS OF MIXTURES OF SERRICORNIN AND ANHYDROSERRICORNIN TO MALE CIGARETTE BEETLES[a]

Mixing ratio serricornin–anhydroserricornin	Dose (μg)		
	1.0×10^{-1}	1.0×10^{-2}	1.0×10^{-3}
99:1	109.0 (±30.2) a	77.2 (±31.2) a	69.6 (±11.0) a
90:10	110.3 (±30.5) a	58.3 (±30.0) ab	66.8 (±22.3) b
50:50	72.0 (±18.0) b	48.8 (±33.3) ab	69.6 (±37.0) c
10:90	66.0 (±16.5) b	47.7 (±22.5) b	37.6 (±19.3) d
1:99	44.6 (±18.5) c	17.0 (±12.1) c	15.8 (± 9.9) e

[a] Accumulated numbers of times that 10 males visited the source of the test mixtures within 10 min. Each test was replicated 10 times, and the standard deviations are shown in parentheses. Values in each column with different letters are significantly different ($P < 0.05$) by the Student's t test.

applied using 99:1, 90:10, 50:50, 10:90, and 1:99 mixtures of serricornin and anhydroserricornin as the test substances. The dose level of each test mixture was fixed at 1.0×10^{-1}, 1.0×10^{-2}, and 1.0×10^{-3} μg, respectively. The results are shown in Tables 5–7 according to the individual parameters.

As seen in Table 5, the attractiveness of serricornin was reduced with the increase of anhydroserricornin concentration. The magnitude of sex stimulation due to serricornin was also lowered with the increase of anhydroserricornin concentration as seen in Table 6. The same tendency was observed for the maximum aggregation number (Table 7). In these cases, however, the rate of activity loss never exceeded the decrease of serricornin concentration.

TABLE 6. SEX STIMULATORY ACTIVITY OF MIXTURES OF SERRICORNIN AND ANHYDROSERRICORNIN TO MALE CIGARETTE BEETLES[a]

Mixing ratio serricornin–anhydroserricornin	Dose (μg)		
	1.0×10^{-1}	1.0×10^{-2}	1.0×10^{-3}

10:90	4.2 (±1.3) c	4.8 (±1.5) b	3.8 (±1.3) c
1:99	3.4 (±1.8) c	2.8 (±1.3) c	2.8 (±1.9) c

[a] Maximum numbers of males staying simultaneously on the source of test mixtures among 10 males within 10 min. Each test was replicated 10 times, and the standard deviations are shown in parentheses. Values in each column with different letters are significantly different ($P < 0.01$) by the Student's t test.

Anhydroserricornin is thought to exist together with serricornin in nature in relatively small quantities (Levinson et al., 1981). We have also confirmed the existence of anhydroserricornin in the *n*-hexane extract of adult females by GC in the ratio of approximately 9 : 1 (serricornin–anhydroserricornin). But the results shown in Tables 5–7 do not suggest any significant effect of the anhydroserricornin addition at around this region of the mixing ratio.

These facts indicate that anhydroserricornin plays neither a synergistic nor an inhibitory role on the pheromonal activity of serricornin. Since the reversible transformation between serricornin and anhydroserricornin occurs even under mild conditions (M. Mori et al., 1984), the role of anhydroserricornin may be speculated to be a precursor of serricornin in the process of biosynthesis or an inactivated form of serricornin, although no evidence has been given yet.

Acknowledgments—The authors express thanks to Drs. M. Ono and H. Kodama and Mrs. T. Matsuki for their technical assistance.

VOLATILE FATTY ACIDS IN URINE AND VAGINAL SECRETIONS OF COWS DURING REPRODUCTIVE CYCLE[1]

PETR HRADECKÝ[2]

University of Veterinary Medicine
Department of Diagnostics
CS-61242 Brno, Czechoslovakia

(Received February 7, 1985; accepted June 13, 1985)

Abstract—Levels of volatile fatty acids (VFA) in vaginal secretions (VS) of cows were nearly independent of concentration changes of acids in the gastrointestinal tract, while levels in urine showed marked dependence. During three-week cycles, the VFA concentrations in VS increased shortly before heat and decreased to one third on days 19–22. Some cows showed an immediate increase after heat while in others the increase was slow and gradual. Moderately increased levels at midcycle were probably related to interovulatory follicle growth. Content of VFA in VS of pregnant cows was significantly above the level of the postestrus drop. Some pregnant cows in the first two thirds of gravidity had substantially higher levels of VFA than the other cows. Changes in VFA levels have a potential value for estrus detection and pregnancy diagnosis in cows. The gas chromatographic method used is too slow and tedious for practical application, but a reliable semiquantitative test for rapid proof of VFA or acetic acid in VS would be a very useful device for field use. It would have a substantial impact on the economy of cattle production by minimizing the loss of time due to delayed breeding.

Key Words—Volatile fatty acids, urine, vaginal secretion, sexual pheromones, cow, estrous cycle, estrus detection, gravidity, pregnancy diagnosis, gas chromatography.

INTRODUCTION

Recent observations associating volatile fatty acids (VFA) levels in vaginal secretions (VS) with reproductive functions in minks (Sokolov and Khorlina, 1976), monkeys (Bonsall and Michael, 1971; Curtis et al., 1971; Goldfoot et al., 1976; Michael et al., 1971), apes (Fox, 1982), and women (Bauman et al., 1982; Huggins and Preti, 1976; Michael et al., 1974, 1975; Sokolov et al., 1976; Waltman et al., 1973) have raised hopes that these compounds are mamalian reproductive pheromones. So far, this possibility has not been unequivocally confirmed or rejected, nor has any compound been identified as a true pheromone with all its predicted attributes in the above species. Regardless of whether VFA are true pheromones or not, these acids may be related to the reproductive functions and, therefore, deserve closer study both from the point of view of reproductive and pheromonal physiology and for possible diagnostic utilization (Hradecký, 1978).

Study of VFA in VS and urine of ruminants in relationship to reproduction required preliminary study of influences of acids from the gastrointestinal tract on the levels in other body fluids. Large amounts of acids are ingested with silage and are also produced by fermentation in ruminant forestomachs and large intestine. Diurnal changes in concentrations of VFA increase with grain content in the ration (Wheaton et al., 1970). Concentration in the gastrointestinal content are reflected by concentrations in portal blood due to extensive absorption of acids, but variations in peripheral blood are largely reduced due to liver uptake of acids for energetic purposes. After the relationship of gastrointestinal acids to the levels of VFA in urine and VS was ascertained, the study of VFA in relationship to reproduction was undertaken.

METHODS AND MATERIALS

For evaluation of the influence of gastrointestinal VFA levels on the acid levels in urine and VS, the samples of rumen fluid, feces, blood, urine, and VS were collected from two healthy diestrous cows in the clinic every four hr for 28 hr. For the study of VFA levels in urine and vaginal secretions during the three-week estrous cycle, samples were collected from these two cows and six cycling cows in a farm about twice a week for a period of 36 days. Cows in the clinic had been open (nonpregnant) for a long time; cows at the farm were 1–2 months after calving. Samples of urine and vaginal secretions for determination of VFA levels in pregnancy were collected at the farm from eight cows in the first trimester, seven cows in the second trimester, and six cows in the third trimester of gravidity. The cows were fed twice a day in the clinic with grass hay and grain mix and on the farm with silage (sugarbeet tops) supplemented with hay, straw, and grain mix.

VS were collected with cylindrical cellulose dental tampons 5 cm long and

1–1.5 cm in diameter wrapped in 1–2 layers of gauze. A 70-cm-long silk string with a loop was attached to one end of each tampon. Tampons were extracted with methanol, dried at 70°C, placed in 10-ml plastic vials, and weighed with vials prior to use. For sample collection, the loop was hooked in a groove made at the end of a long mare urinary catheter and the tampon was introduced into the fornix vaginae. Tampons with absorbed secretion were removed after 1 hr by pulling the strings and were placed back into original vials. The strings were cut off and the vials with tampons were weighed. After correction for the cut off string the weight of absorbed secretion in grams was determined and regarded as equal to volume in milliliters. Tampons were processed upon arrival at the laboratory or frozen until processing.

Sample processing included soaking of tampons in vials in a mixture of two volumes of acetone and three volumes of methanol for one day. Then the tampons were squeezed in a syringe and the expressed fluid was collected. Additional portions of solvent mixture were drawn through the tampon into the syringe and squeezed out until the volume of 20 ml was obtained. This extract was concentrated to 3 ml in a rotary evaporator.

The 3-ml sample was acidified with 0.5 ml of 85% H_3PO_4, mixed with one drop of antifoaming agent (silicone oil), and steam distilled until 30 ml of distillate were obtained. The distillate was adjusted to pH 10 with KOH and evaporated to dryness at 80°C in the rotary evaporator. The dry sample was transferred into 5-ml vials by washing the evaporator flask with four 1-ml portions of methanol and evaporated again at 80°C in a water bath. The resultant dry samples were dissolved in 100 μl of distilled water and 20 μl of 5 M H_3PO_4. For gas chromatographic analysis, 10 μl were used.

Blood was obtained by jugular venipuncture, urine by catheterization, and rumen fluid by a stomach tube. Samples of blood plasma and urine (3 ml) were acidified, mixed with antifoaming agent, and distilled with water vapor and further processed as samples of VS. Rumen fluid was analyzed directly after centrifugation and acidification of 80 μl of sample with 20 μl of 5 M H_3PO_4. Fecal samples were mixed with water and supernatant was treated in the same manner as rumen fluid; results were calculated on dry matter basis.

Gas chromatographic analyses were performed on CHROM 4 instrument (Laboratory Instruments, Prague, Czechoslovakia) equipped with FID and glass column (120 cm × 3 mm ID) packed with Porapak P 80–100 mesh (Waters Associates, Framingham, Massachusetts) treated with 3% *o*-phosphoric acid. Injector temperature was 190°C; column temperature was programmed from 120°C to 200°C at 6°C min, and the flow rate was 44 ml N_2/min.

Analyses separated acetic, propionic, isobutyric, butyric, isovaleric, and valeric acids. For quantitation, external standardization with a known VFA mixture in combination with recovery factors was used. Recovery factors were determined in advance by the method of standard addition of the known VFA mixture to a series of samples to eliminate the impact of extensive sample pro-

cessing on final results (Novák, 1975). Recovery factors ranged from 0.90 to 0.36 in urine and from 0.73 to 0.29 in VS for acetic and valeric acids, respectively. Reproducibility in a series of six analyses of the same sample were around 10% for urine and blood plasma, 15% for VS (six tampons inserted simultaneously into vagina of a cow), and 3% for rumen fluid. Blank processing of the tampons prepared for sample collection showed no measurable amounts of VFA contributing to the final results.

RESULTS AND DISCUSSION

Quantitative sampling of VS using the same method throughout the investigation remains an unresolved problem due to changes in the amount and viscosity of secretion. Secretion is copious and watery near estrus and very scarce and viscous during diestrus and pregnancy. Changes in technique for secretion sampling during different parts of the reproductive cycle may require modifications in subsequent sample processing and cause errors due to changes of uncontrollable factors.

The tampon technique used in this study was relatively easy. The maximum amount of fluid absorbed by the tampons at full soaking was about 5 g. Collection from 21 pregnant cows yielded an average of 1.6 ± 0.12 g secretion, while the amounts collected from cycling cows were higher and extremely variable. However, the secretion collected was not pure VS, since small amounts of secretion from vestibulum vaginae were collected during insertion and removal of tampons. Different physical properties of secretion might also cause different extractability of acids from the tampons.

Steam distillation of herbivore urine also yielded variable amounts of benzoic acid originating from microbial and acidic hydrolysis of hippuric acid (benzoylglycine). Presence of large quantities of benzoic acid in final samples to be injected for analysis was damaging since sudden crystallization in the drawn sample froze the microsyringe and might cause its destruction during injection.

VFA in rumen fluid exhibited large diurnal changes in concentrations due to microbial fermentation and content in feeds (silages). In the two observed cows, the total concentrations of VFA varied in the range 75–150 mM in rumen fluid and 0.20–0.37 mmol/g of dry matter of feces (average dry matter was $17.7 \pm 0.3\%$; $N = 16$). Fermentation in the large intestine partially compensated the effect of ruminal changes since the correlation of ruminal and fecal concentrations was $r = -0.33$ ($+0.18$ to -0.38 for individual acids).

Peripheral blood concentrations showed generally low correlations with gastrointestinal concentrations (r in the range ± 0.2) except branched-chain acids (isobutyric and isovaleric) which showed $r = \pm 0.2$ with rumen fluid and $r = -0.5$ with fecal values, and valeric acid ($r = \pm 0.2$ with rumen fluid and $r = -0.3$ with feces). These acids are used mainly by gastrointestinal microflora for amino acid synthesis, and their liver uptake is apparently less effective.

Urinary concentrations of VFA were influenced both by gastrointestinal and blood concentrations. Moderate correlations of the total VFA in urine and rumen fluid ($r = +0.67$) or blood ($r = +0.4$) indicated that any changes in urinary VFA related to reproductive functions would be obscured by dietary factors.

Concentrations of VFA in VS showed only low correlations with concentrations in other fluids (r in the range ± 0.2). With respect to the reproducibility of the sampling and processing procedure, the levels of VFA in VS could be regarded as independent of gastrointestinal production of acids and could reflect changes associated with reproduction without substantial interference of gastrointestinal acids. Table 1 gives comparative values of concentrations of the total VFA and their molar composition in the samples collected for the study of influences of gastrointestinal acids on the levels of VFA in blood plasma, urine, and VS.

Dynamics of VFA in VS of cycling cows was closely related to the estrous cycle, especially around the time of estrus (Figure 1). Several days prior to estrus, the concentrations gradually increased and then rapidly decreased to about one third. This pattern was especially clear in the two cows at the clinic (Nos. 1 and 2) that were observed daily for heat and sampled more frequently around estrus. Overall dynamics of VFA reflect to some degree the dynamics of both blood or milk progesterone (Hoffmann et al., 1976; Thibier, 1976) and estradiol (MacDonald et al., 1982) during estrous cycle and, therefore, there is probably not any simple relationship of VFA levels to a particular ovarian steroid.

The concentration decrease was observed between days 19 and 22 of the cycle, but its exact relationship to the day of estrus and optimal breeding time could not be determined because of long intervals between sample collections. The days of sampling at the farm were unrelated to the days of heat and, therefore, the results do not necessarily include maximal changes occurring during estrus. The average values obtained from samples collected before and after

TABLE 1. DIETARY INFLUENCES ON VFA IN URINE AND VS ($N = 16$)[a]

Sample	Total VFA	C-2	C-3	isoC-4	C-4	isoC-5	C-5
Rumen fluid	101.00	72.8	15.6	1.04	8.57	1.06	0.98
Feces	0.30	76.8	14.8	1.90	3.29	1.86	1.40
Blood plasma	3.08	94.0	3.30	0.49	0.43	1.19	0.55
Urine	1.97	90.6	4.55	1.01	1.32	1.85	0.70
Vaginal secretion	2.28	92.2	5.35	0.29	0.82	0.68	0.68

[a] Average concentrations of total VFA (mM, mmol/g DM in feces) and molar percentage composition (mol%) of the individual acids (C-2, acetic; C-3, propionic; isoC-4, isobutyric; C-4, butyric; isoC-5, isovaleric; C-5, valeric) in samples collected for study.

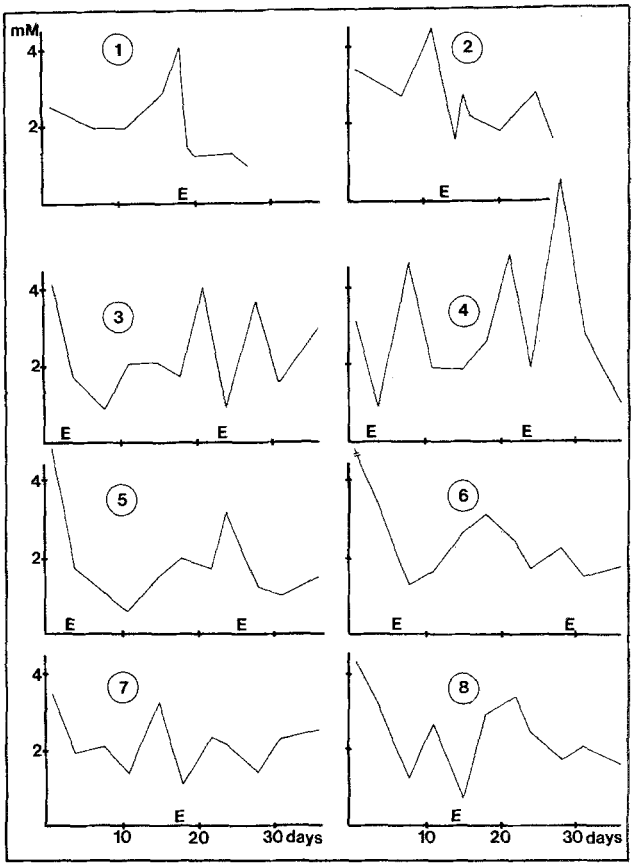

FIG. 1. Dynamics of the total VFA concentrations (mM) in VS of the eight cows during the 36-day study. E = estrus.

heat and from diestrous (all others) samples are given in Table 2. Differences among these values for VS are highly significant ($P < 0.01$, t test).

After heat, the VFA concentrations in about half the cases sharply increased while remaining low in the other half. The reason for this increase and its nearly equal distribution is so far unclear. It is interesting that a similar double peak of VFA around estrus has been observed in VS of monkeys (Goldfoot et al., 1976). Some cows exhibited increased VFA concentrations in VS also during midcycle; these might be related to the hormonal changes associated with interovulatory follicles (Schneebeli, 1984). These follicles may induce estrous behavior in cows and increase their attractivity for bulls (Hradecký et al., 1983).

Acetic acid composed 85–95 mol% of VFA in VS of cycling cows, and

TABLE 2. AVERAGE CONCENTRATIONS OF TOTAL VFA IN SAMPLES OF VS AND URINE COLLECTED BEFORE AND AFTER HEAT AND DURING DIESTRUS

Samples	N	Concentration (mM, $\bar{X} \pm s_{\bar{X}}$)	
		Vaginal secretion	Urine
Samples before heat	12	3.68 ± 0.25	6.54 ± 1.40
Samples after heat	12	1.35 ± 0.11	3.74 ± 0.60
Diestrous samples	61	2.31 ± 0.15	4.81 ± 0.43

this percentage increased slightly around estrus. Therefore, the dynamics of acetic acid closely corresponded to the dynamics of total VFA. The peak of acetic acid, the major component of VFA, lasted up to six days around estrus and was detected in all cases of heat. Peaks of the minor acids were probably of narrower duration since they were not consistently detected in every heat by the used frequency of sample collection. Dynamics observed for the minor acids is therefore less consistent than for acetic acid. In cases where the estrous peak and drop of minor acids were observed, the concentration changes were often larger than in acetic acid. In individual cases, propionic acid concentration dropped 30 times, butyric 33 times, isovaleric 14 times, and valeric 8 times. These changes approached the 20- to 30-fold changes observed in VS of minks (Sokolov and Khorlina, 1976). Another study of vaginal VFA in cows has demonstrated no cyclic variations in acid levels, but that may be due to differences in methods used or other factors not mentioned (Quinn and Simmons, 1980).

Dynamics of VFA in urine of cycling cows showed similar changes around estrus but also numerous other changes unrelated to the estrous cycle. The six farm cows had the same housing and feeding conditions, but the VFA changes in their urine were not synchronous. These changes were probably indirect consequences of dietary factors (quality of silage and hay) influencing diuresis, gastrointestinal function, and energetic status (subclinical ketosis). Some cows with large changes also had frequent positive reaction for oxidized ketone bodies in urine which can be frequently seen in high producing cows without any clinical sign of disease (Hradecký and Kudláč, 1984). Average values obtained for urinary samples from cycling cows are given also in Table 2. Urinary changes around estrus were not significant ($P > 0.05$).

Values of VFA in VS and urine of pregnant cows are given in Table 3. Of the values in VS, only the difference between the second and third trimester was significant ($P < 0.05$). The group of pregnant cows in the first and second trimester had an average concentration of total VFA in VS 4.31 ± 0.47 ($\bar{X} \pm s_{\bar{X}}$) but showed clear distribution of values into two subgroups, one with eight cows and one with seven cows. The subgroups had 5.74 ± 0.43 mM and

TABLE 3. AVERAGE CONCENTRATIONS OF TOTAL VFA IN VS AND URINE COLLECTED FROM PREGNANT COWS

Stage of pregnancy	N	Concentration (mM, $\bar{X} \pm s_{\bar{X}}$)	
		Vaginal secretion	Urine
1st trimester (47–84 days)	8	3.44 ± 0.43	3.30 ± 1.36
2nd trimester (117–170 days)	7	5.31 ± 0.73	1.25 ± 0.19
3rd trimester (210–269 days)	6	2.48 ± 0.24	2.44 ± 0.53
Total	21	3.79 ± 0.38	2.37 ± 0.56

2.67 ± 0.09 mM of VFA, respectively. All three of these values were significantly higher than post estrous values of nonpregnant cows (1.35 ± 0.11 mM). Differences in urinary values among trimesters and between pregnant and nonpregnant cows were not significant. Molar percentage of acetic acid in VS during the first two thirds of pregnancy was about 95 mol% and slightly decreased during the third trimester, while in urine it was about 90 mol% and slightly increased by the end of gravidity.

Origin of the VFA in VS as possible mammalian reproductive pheromones was discussed in relation to hormonal influences on vaginal symbiotic microflora (Bonsall and Michael, 1971; Doty et al., 1975; Hradecký, 1978; Preti and Huggins, 1975), but this possibility was not definitely proved or rejected. A possible role of microorganisms in generating VFA and other odorous compounds in VS that are related to reproduction and act as pheromones is supported by clinical experience with passing a stomach tube in ruminants. Cattle often show flehmen when the tube is being withdrawn and the rumen fluid on its surface is smeared over the sensitive area of the vomeronasal organ in the oral palate. This reaction can seldom be elicited by direct mechanical stimuli, but rubbing with rumen fluid or ingesta containing microbial products can elicit flehmen. The flehmen reaction in a bull has been shown to be related to reproductive functions and probably to pheromones in cows (Hradecký et al., 1983).

Apparent dietary influences on VFA levels in urine practically preclude use of these acids for monitoring reproductive functions in cows. However, the low dependence of the concentration changes of VFA in VS on dietary factors and their association with reproductive functions have promising diagnostic value especially in recently inseminated cows. A drop in acid concentrations around days 19–22 after breeding (natural or artificial insemination) would indicate conception failure and return into heat. Rapid determination of acid levels in VS would permit rebreeding of cows in three weeks after previous breeding with the possibility of optimal timing for insemination. On the other hand, the persistence of high acid levels would indicate probable conception. My preliminary investigation indicated that by days 20–21 after artificial insemination and

conception, the acid levels were already elevated to the gravidity values and no drop in concentration occurred. Some cows may also show behavioral signs of gestational estrus during early pregnancy (Erb and Morrison, 1958; Donoho and Rickard, 1955; Patil et al., 1982; Singal et al., 1978) and avoiding artificial insemination of these cows could eliminate probable induced embryonic death.

Gas chromatographic determination of VFA levels in VS is a valuable research tool, but it is too tedious and slow for practical application. Because all acids involved are a homologous series with similar chemical reactions and the major acetic acid represents about 90 mol%, it should be possible to develop a reliable semiquantitative test for rapid proof of VFA (or acetic acid) levels in VS for field use. This device would minimize the loss of time due to delayed breeding and conception and would have a substantial impact on the economy of cattle production.

(Received January 22, 1985; accepted June 17, 1985)

Abstract—The compositions of Dufour's gland secretions of four sympatric halictine bee species were chemically studied by combined gas chromatography–mass spectrometry. The secretion is composed of C_{16}–C_{24} macrocyclic lactones, isopentenyl esters, and hydrocarbons. Comparative analyses have revealed that the blends of compounds are species specific. Studies of individual glands belonging to bees of the species *Evylaeus malachurum* have demonstrated that each bee exhibits a specific blend in its Dufour's gland. Nestmate bees (considered as sister bees), however, are more similar to each other than nonrelated bees. The relative importance of species specificity, individual specificity, and similarities between kins are discussed.

Key Words—Halictine bees, Hymenoptera, Halictidae, *Evylaeus melachurum*, *E. carneiventre*, *E. politum*, Dufour's gland secretion, gas chromatography–mass spectrometry, macrocyclic lactones, species specificity, individual specifity, kin specificity.

INTRODUCTION

Dufour's gland, present in halictine bees, is exceedingly large and has attracted the attention of many researchers. Its oily secretion has been analyzed in many species revealing the omnipresence of macrocyclic lactones ranging from 16-hexadecanolide to 26-hexacosanolide (Anderson et al., 1967; Hefetz et al., 1978; Bergström and Tengö, 1979; Duffield et al., 1981). In all cases the secretion also contained hydrocarbons, and in a few species small amounts of isopentenyl esters accompanied them. The secretion is used to line the brood cells and tunnels of the nest (Cane, 1981; Brooks and Cane, 1984), where the

0098-0331/86/0100-0197$05.00/0

lactones, at least in part, are transformed to polyesters that create the waterproof lining.

A comparative analysis of the relative amounts of the various lactones have been conducted in 16 halictine species, demonstrating species specificity (Johansson et al., 1982). This suggests that Dufour's gland secretion may serve a more complex role, perhaps communicative, rather than merely creating a hydrophobic lining for the brood cells. Indeed, in *Lasioglossum zephyrum*, several studies suggest that odors play an important role in mate selection (Barrows et al., 1975) and nestmate recognition (Bell et al., 1974), although nothing is known of the source or the nature of the secretion involved. A communicative function of Dufour's gland secretion was demonstrated in the solitary anthophorid bee *Eucera palestinae* (Shimron et al., 1985). In this species, the secretion is utilized to mark the entrances of the nest, helping the bees to locate their own nest in a dense aggregation. Since Dufour's gland secretion is smeared at the nest entrance of at least one halictine species (Brooks and Cane, 1984), it is possible that in halctines it has a similar function in nest recognition. If the secretion produced by Dufour's gland of halictine bees indeed functions as a discriminator, then it should convey individuality. Yet in the social species, odors common to nestmates are pertinent and discrimination should take place between nests. The large size of Dufour's gland in halictine bees makes it possible to analyze individual glands and enables us to test if these characteristics hold true.

METHODS AND MATERIALS

The four species of halictine bees investigated, *Halictus resurgens*, *Evylaeus malachurum*, *E. politum*, and *E. carneiventre* nest sympatrically and were studied at Beith Elazari, on the coastal plain of Israel. Collection of the bees took place during the months April–June, 1983 and 1984, at their nesting sites. Each nest was marked, and the foraging behavior of its occupants was followed prior to their collection. The bees were collected while leaving the nest by placing a glass vial on the top of the nest. They were chilled on ice until brought to the laboratory for dissection.

All the bee species were identified by Dr. A. W. Ebmer, Linz, Austria. Voucher specimens are kept in the Entomological Collections of Tel Aviv University.

In the laboratory, the bees were dissected under cold water, and the ovarian development and the state of the spermatheca (full/empty) were recorded. Dufour's glands of the bees were placed in pentane for extraction and further analysis. In order to analyze individual glands of *E. malachurum*, each gland was put in pentane in a separate vial. Chemical characterization of the glandular exudates were carried out at the Ecological Station of Uppsala University at

Öland, Sweden, using an LKB 2091 combined gas chromatograph–mass spectrometer. The samples were run on a WG11 capillary (polar) column (0.5 mm × 25 m), temperature programmed from 150°C to 200°C at 8°C/min, then run isothermally. The different components were identified by their mass spectra.

Individual variations in the glandular components of *E. malachurum* were studied by two replicate injections of samples of individual gland extracts and comparing the relative amounts of the various components in each case. Sample analyses were carried out using an OV-1 column temperature programmed as described earlier. The data were then subjected to cluster analysis of cases based on the differences between the relative amounts of the components in each sample. An amalgamation distance between samples was determined by pseudo-nearest-neighbor algorithm. Initially each case was considered a separate cluster, then two cases with the smallest amalgamation distance were joined. This is a stepwise process continuing until all cases are combined into one cluster (Dixon, 1981). The smaller the amalgamation distance is, the more similar are the exudates involved. An example of such a clustering is depicted in Figure 2. For the statistical analysis the amalgamation distances before clustering were considered. Since the data were not normally distributed, a Wilcoxon two-sample test was used, and the results were presented as medians (Table 2). In this way nestmates and nonnestmates were compared in four nests.

Nests of *E. malachurum* were excavated and the brood cells removed. They were washed to remove adhering pollen and their cell linings were extracted with pentane. In addition, nest entrances (top 2 cm) of 12 nests were collected and similarly extracted in pentane. Both extracts were analyzed by gas chromatography using either AT 1000 or OV-1 columns programmed from 150°C to 250°C at 8°C/min. The presence of the lactones in these extracts was deduced from their respective retention times and from coinjections with Dufour's gland extracts.

RESULTS

Comparative Chemical Analysis

Dufours' gland secretion of four species of halictine bees was analyzed by combined gas chromatography–mass spectrometry. The secretions contained saturated and unsaturated unbranched macrocyclic lactones, branched macrocyclic lactones, isopentenyl esters, and saturated straight-chain hydrocarbons (Figure 1A–D). The lactones were identified by their characteristic mass spectra, including ions at M−18 (loss of water), M−60 (loss of acetic acid), a corresponding ion at *m/z* 60, and smaller ion peaks at M−43 (loss of CH_3CO) and M−46 (loss of HCOOH). These lactones were 16-hexadecanolide (mol wt 254), 18-octadecanolide (mol wt 282), 20-eicosanolide (mol wt 310), 21-hen-

eicosanolide (mol wt 324), 22-docosanolide (mol wt 338), 23-tricosanolide (mol wt 352), and 24-tetracosanolide (mol wt 366). In addition, monounsaturated unbranched lactones were present. These characteristically had a larger M^+ ion than that at M−18, and included 18-octadecenolide (two isomers, mol wt 280), 20-eicosenolide (mol wt 308), 22-docosenolide (mol wt 336), and 24-tetracosenolide (mol wt 364). No attempts to elucidate the position of the double bond or the nature of the two isomers of 18-octadecenolide were made.

Dufour's gland secretion of three of the species apparently also contained dimethyl branched lactones. This was deduced from the slightly altered mass spectra of these compounds as compared to the unbranched lactones of the same molecular weight, but mainly from their respective retention times. In *E. malachurum*, a lactone with a molecular weight of 310 corresponding to a C−20 lactone, had a retention time, under the conditions of the separation (see Methods and Materials), of 27 min. In the same analysis, 18-octadecanolide eluted 1 min earlier, while 20-eicosanolide eluted after 34 min. In addition, the compound in question had a different mass spectrum when compared to 20-eicosanolide. The compound was tentatively identified as dimethyloctadecanolide, but since we did not have any standards to authenticate this structure, this identification remains speculative. Similarly, a C−22 lactone (mol wt 338) had a retention time of 39 min while 20-eicosanolide and 21-heneicosanolide had respective retention times of 34 and 42 min. By the same line of reasoning it was assigned as dimethyleicosanolide.

The isopentenyl esters present in Dufour's gland of the species investigated were similar to those published for other halictine bees (Duffield et al., 1981) and included 3-methyl-2 (or 3)-butenyl octadecanoate, 3-methyl-2 (or 3)-butenyl eicosanoate, and 3-methyl-2 (or 3)-butenyl docosanoate. On the basis of the mass spectrum alone we could not distinguish between the two isomers. Dufour's gland secretions also contained homologous series of paraffins ranging from nonadecane to octacosane.

Species Specificity

Four sympatric species were studied: *H. resurgens*, *E. politum*, *E. carneiventre*, and *E. malachurum*, each of which produced a specific blend of chemicals in its Dufour's gland (Figure 1 and Table 1). This is demonstrated best if we inspect the various groups of compounds separately.

Lactones. H. resurgens was conspicuous in having 16-hexadecanolide and 24-tetracosenolide which were absent from the secretion of the three *Evylaeus* species. The secretion of *H. resurgens* was also the only one to be largely dominated by 24-tetracosanolide. The differences between the three *Evylaeus* species were less distinct. The major unbranched lactones were omnipresent, but *E. politum* stood out in having odd-carbon-number macrocyclic lactones including 21-heneicosanolide and 23-tricosanolide. These compounds, found

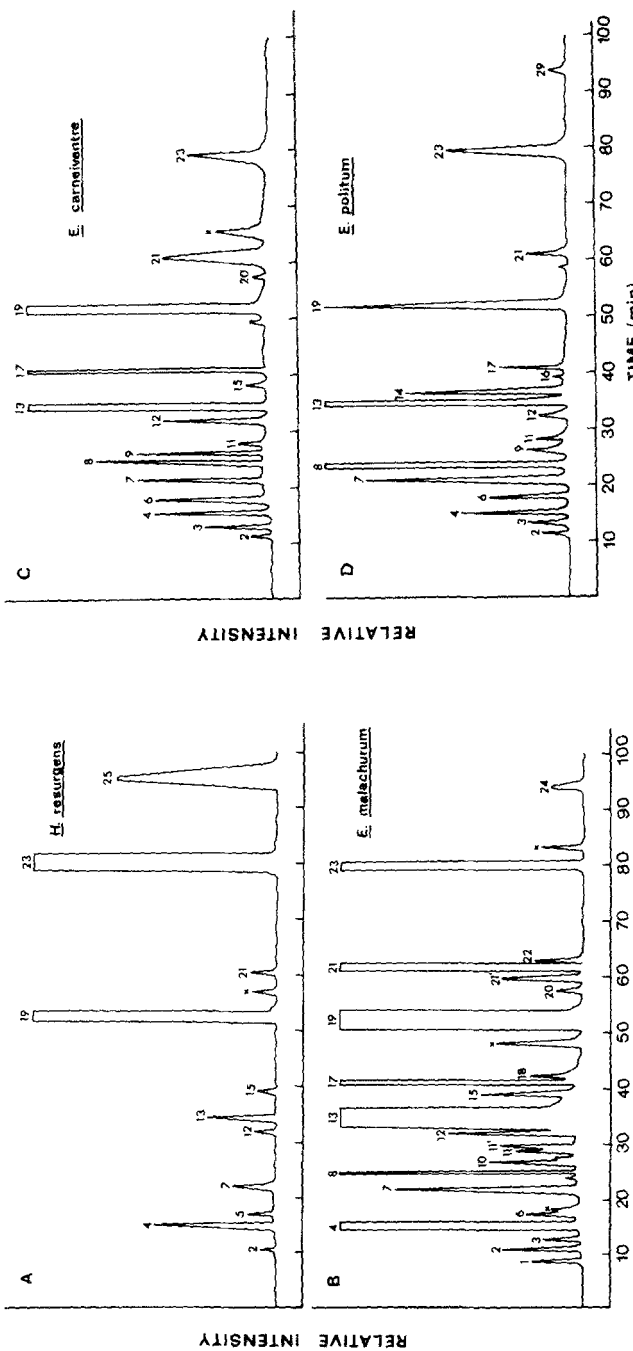

FIG. 1. Gas chromatograms of Dufour's gland extracts of four halictine species: *Halictus resurgens*, *Evylaeus malachurum*, *E. carnieventre*, and *E. politum*. Samples were run on a WG11 column programmed from 150°C to 200°C at 8°C/min, then run isothermally in an LKB 2091 combined GC-MS. The compounds identified are as follows: (1) nonadecane; (2) heinecosane; (3) docosane; (4) tricosane; (5) 16-hexadecanolide; (6) tetracosane; (7) pentacosane; (8) 18-octadecanolide; (9) hexacosane; (10) dimethyl octadecanolide; (11) 18-octadecenolide (1st isomer) (11') 18-octadecenolide (2nd isomer); (12) heptacosane; (13) 20-eicosanolide; (14) 3-methyl-2 (or 3)-butenyl octadecanoate; (15) dimethyleicosanolide; (16) octacosane; (17) 20-eicosenolide; (18) 21-heneicosanolide; (19) 22-docosanolide; (20) 3-methyl-2 (or 3)-butenyl eicosanoate; (21') 22-docosenolide; (21) 22-docosenolide (2nd isomer); (22) 23-tricosanolide; (23) 24-tetracosanolide; (24) methyl-2 (or 3)-butenyl docosanoate; (25) 24-tetracosenolide. Compounds marked with an x were not identifiable by their mass spectra.

TABLE 1. COMPARATIVE ANALYSIS OF DUFOUR'S GLAND SECRETION OF 4 HALICTINE SPECIES[a]

[a] Each sample was run on a WGll capillary column temperature programmed from 150°C to 200°C at 8°C/min then run isothermally. The relative amounts are indicated as follows: t = trace; + = small amounts; ++ = fair amounts; +++ = large amounts; D = dominant peak.
[b] Under the condition described in footnote *a*.
[c] The identity of the methyl branched lactones is only tentative.

only in trace amounts, are the first reported from the Halictidae. The differences in the apparent branched lactones is harder to depict since we do not know their exact structures. Nonetheless, *E. malachurum* posessed at least two unbranched lactones while in *E. carneiventre* only dimethyleicosanolide appeared. The latter compound was also present in the secretion of *H. resurgens* but absent in *E. politum*.

Isopentenyl Esters. The same species specificity existed when we compared the abundance of the isopentyl esters in the various species. *E. politum* was unique in having isopentenyl octadecanoate that was accompanied by isopentenyl docosanoate. In *E. carneiventre* only isopentenyl eicosanoate was present, while *E. malachurum* has, in addition to the latter compound, isopentenyl docosanoate. In Dufour's gland secretion of *H. resurgens* we could not detect any isopentenyl esters.

Hydrocarbons. Even though the hydrocarbons were present in relatively small amounts in Dufour's gland secretions, several features could be pointed out. *H. resurgens* produced only odd-carbon hydrocarbons, two of which, tricosane and pentacosane, appeared in fair amounts. In general, these two paraffins were present in fair amounts in all four species. Another distinct feature is the unique presence of nonadecane in *E. malachurum* and octacosane in *E. politum*.

Individual Variation and Genealogical Relatedness

Evylaeus malachurum was the dominant species in the study area and is a social species (Michener, 1974). We chose this species to conduct analyses of individual bees in order to assess if individual blends in Dufour's gland secretion exist. We further analyzed bees occupying the same nest as compared to randomly collected bees. The nestmates analyzed were all foragers, had undeveloped ovaries, and were unfertilized. We assume these nestmates to be sister bees. Each Dufour's extract was injected twice into the gas chromatograph, and the relative amounts of the various components were recorded by an interfaced integrator. We then compared the injections by cluster analysis of cases. Table 2 summarizes the amalgamation distances between injections of the same extracts, injections from extracts belonging to sister bees, and injections from extracts belonging to nonnestmate (= strange) bees, for four nests that were assayed. The amalgamation distance between injections of extracts belonging to nestmate (= sister) bees was significantly lower ($P < 0.001$) than that between injections of extracts belonging to nonnestmate bees and higher than that between injections belonging to the same extract. This suggests that although individual blends exist, the variation between nestmate bees is lower than that of nonnestmates.

TABLE 2. VARIATION IN COMPOSITION OF DUFOUR'S GLAND SECRETIONS OF INDIVIDUAL *E. malachurum* BEES[a]

	Median Amalgamation Distance			
Nest	Two samples of the same glandular exudate	Samples of glandular exudate from nestmate (sister bees)	Samples of glandular exudate from nonnestmates (strange bees)	*P*
1	4.99 ($N = 14$)	30.96 ($N = 8$)	54.2 ($N = 6$)	<0.001
2	4.78 ($N = 15$)	30.36 ($N = 9$)	52.02 ($N = 6$)	<0.001
3	7.68 ($N = 15$)	20.7 ($N = 9$)	52.62 ($N = 6$)	<0.001
4	6.10 ($N = 11$)	34.14 ($N = 5$)	52.26 ($N = 6$)	<0.001

[a] Samples originating from nestmates (sister bees) and nonnestmates (strange bees) were compared by cluster analysis of cases. The data of each nest are presented as median amalgamation distance calculated before the clustering of the cases.

Analysis of Cell Linings of E. malachurum

Analysis of cell lining extracts revealed the presence of the lactones at the same ratio as present in Dufour's gland secretion. During field observations, it was noted that the bee constantly smears the top of its tunnel near the nest entrance with its abdominal tip and glossae. These parts of the tunnels later became white from the material deposited by the bees. Extraction and analysis of the coated soil revealed that the secretion laid there originated from the Dufour's gland. This coating was characteristic to the top of the nest. Extraction of lower parts of the tunnel failed to demonstrate the presence of Dufour's gland compounds.

DISCUSSION

The research on Dufour's gland secretions of halictine bees has expanded over many species, making it the most studied family in this respect. This family was also extensively studied behaviorally mainly because it exhibits all known degrees of social evolution (Michener, 1974).

Most of the studies pertaining to Dufour's gland concentrated on the glandular structure (Lello, 1971) or the chemistry of its secretion (Duffield et al., 1984, and references therein). The three major groups of compounds, e.g., macrocyclic lactones, isopentenyl esters, and hydrocarbons, present in the species studied so far, are also present in the four species investigated in this study. In the present study, we show evidence of the existence of four macrocyclic lactones that were not reported earlier: 21-heneicosanolide and 23-tricosanolide

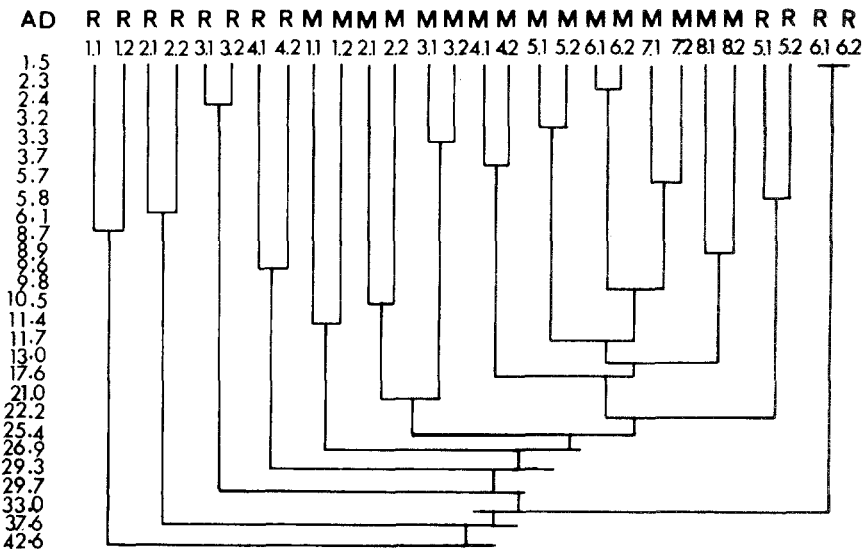

FIG. 2. Dendrogram representing the degree of similarity in the composition of Dufour's gland secretions of 14 *E. malachurum* bees. Eight of the bees were nestmates (marked by M), the other six were nonnestmates collected at random in the nesting area (marked by R). Each glandular exudate was injected twice. Accordingly, case R 1,2 is the second injection of extract of the first bee collected at random, while case M 3,2 is the second injection of the third bee collected from nest M. The amalgamation distances depicted to the left of the dendogram are calculated after the clustering procedure.

and two branched lactones, dimethyloctadecanolide and dimethyleicosanolide, all present in trace amounts only.

The chemical studies of halictine Dufour's gland secretions have largely demonstrated that the composition of the glandular secretion is species specific (Hefetz et al., 1978; Duffield et al., 1981; Johansson et al., 1982). Species specificity is also evident from the analyses of the four species presented here and, as in the other species, it is expressed usually in differences between the lactones that dominate the secretion. Our study, however, further demonstrates that individual variability exists among conspecific bees in addition to species specificity. In *E. malachurum* bees, the two lactones, 20-eicosanolide and 22-docosanolide, are always the dominant lactones conveying the species specificity, but their relative amounts with respect to the other components in the secretion varies among individuals. Thus we have a species-specific marker and demonstration of individually at the same time. Furthermore, in the social species *E. malachurum* (Figure 2 and Table 2), nestmate bees are more similar in their Dufour's gland composition than nonnestmates although individuality can also be seen among sister bees. An interesting question is how these features effect the biology and social behavior of the bees.

Several studies with *Lasioglossum zephyrum* have pointed out the importance of olfactory cues in its social behavior, mostly with respect to nestmate recognition. Nonresident bees are often recognized by the nest guard as aliens by their odor and are not allowed to enter the nest (Bell et al., 1974). Further combined behavioral and hybridization studies revealed that these individual odors are genetically controlled (Greenberg, 1979) but that learning components also exist (Buckle and Greenberg 1981). Although Dufour's gland secretion was not implicated in contributing to these individual odors, there are arguments in favor on this supposition. Dufour's gland secretion is extensively deposited in the nest walls of several halictine species including the brood cell of *Augochlora pura* and *Lasioglossum albipes* (Duffield et al., 1981; Cane, 1981) and in the nest tunnels of *Halictus hesperus* (Brooks and Cane, 1984).

In our study, we demonstrated that the upper centimeter of the nest contained extraordinarily large amounts of Dufour's gland secretion. It is thus conceivable that the glandular secretion adheres to the resident bee bodies while moving in the nest, besides the possible emission of the secretion from the gland at will. The fact that the secretion composition is species specific, as well as individual, is another argument for the suggestion that the secretion also has a communicative function. We suggest, on the basis of the data obtained, that Dufour's gland secretion is at least in part responsible for nestmate recognition. We further postulate that although individuality exists even within sister bees, the variability in this case is not large enough to be detected by the bees and that it is considered by them to be the same odor. This is also in accordance with the findings of Greenberg (1979) that related bees are more readily accepted by a nest guard than nonkin bees. Similarily, although we do not exclude the possibility of learning, we think that the acceptance of nonkin nestmates is partially due to their acquisition of Dufour's gland components from the nest lining as well as olfactory habituation by the other nonkin residents. Confirmation of these assumptions must await further behavioral studies using Dufour's gland secretions as well as its synthetic components.

Acknowledgments—Part of the chemical analyses were conducted at the Ecological Station of Uppsala University. We wish to thank the staff of the station and especially the station head, Dr. Kullenberg, for the hospitality, and Mrs. Ingela Johansson for her technical assistance. We thank Mrs. Tamar Orion and Shulamith Kronenberg from the Department of Zoology, Tel Aviv University, for their technical assistance. We also thank Dr. A. W. Ebmer, Linz, Austria, for the identification of the bees.

(Received March 21, 1985; accepted June 17, 1985)

Abstract—Root exudates of 100 cultivars of *Sorghum bicolor* L. (Moench) were screened for their ability to inhibit seed germination and seedling growth of *Amaranthus retroflexus* L. Exudates of some of the test cultivars were found to inhibit significantly seed germination and/or seedling growth of *A. retroflexus*, and most of the inhibitory activity was found in neutral and acetone fractions of root exudates. Testing of aqueous extracts and decaying residues of four selected *Sorghum* cultivars (two toxic and two nontoxic through root exudation) revealed that all four cultivars significantly reduced *A. retroflexus* growth and nitrification processes with greater inhibition achieved by the toxic cultivars. This study suggests a potential biological control of *Amaranthus* and nitrification by some *S. bicolor* cultivars.

Key Words—Allelopathy, *Sorghum*, root exudates, crop residues, water extracts, *Amaranthus*, nitrification, biological control.

INTRODUCTION

Recently, the recognized importance of allelopathy in agricultural practice has been accelerated with the main goal of using this phenomenon in biological control (Rice, 1979; AlSaadawi and Rice 1983; Putnam, 1983; Leather, 1983). One approach for utilizing this phenomenon is to screen various accessions of allelopathic crops for their ability to reduce weedy species and only a few crops have been evaluated in this aspect (Putnam and Duke, 1974; Fay and Duke, 1977; Leather, 1983).

Recently, the allelopathic potentiality of *Sorghum bicolor* has been re-

0098-0331/86/0100-0209$05.00/0

ported and well documented. Leon (1976) found that the reduction in *Sorghum* productivity under a continuous monoculturing regime was due to allelopathy. Putnam (1983) pointed out that mulches from the genus *Sorghum* provide great weed-killing capacity. Hussain and Gadoon (1981) suggested that *Sorghum bicolor* fields be rotated with other crops to maximize crop productivity. However, no work was done to test the possible differences in the allelopathic potentiality among *Sorghum* cultivars against weeds or to test the possible allelopathic effects of *Sorghum bicolor* on the nitrification process. Inhibition of nitrification is of great importance in agricultural ecosystems. Huber et al. (1977) concluded that inhibition of nitrification may markedly increase the efficiency of food production, reduce energy requirements for growing crops, decrease the incidence of plant disease, and reduce the pollution potential of nitrogen fertilizers. Inhibition of nitrification in natural ecosystems is well documented and discussed by several investigators (Rice and Pancholy, 1972, 1973, 1974; Jones and Richards, 1977; Lodhi, 1978, 1981).

With the above in mind, this project was developed to screen 100 cultivars of *Sorghum bicolor* introduced from the Institute of Forage, Plevin, Bulgaria, for their allelopathic ability against selected weeds through root exudation and to collect and characterize the allelopathic compounds in root exudates. Another aim of the study was to carry out more allelopathic studies on selected cultivars against weeds and the nitrification process.

METHODS AND MATERIALS

Collection and Biological Activities of Root Exudates. Five seeds from each *Sorghum bicolor* cultivar were soaked for 24 hr and planted in 8-cm-diameter plastic pots each containing 260 g of sterilized washed quartz sand. The pots of this and all subsequent experiments were placed in a growth room under 14 hr photoperiod (1900 ft-c) at 26 ± 2°C/24 ± 2°C day–night conditions. The pots were watered with distilled water for the first four days, followed by half strength Hoagland's solution (Hoagland and Arnon, 1950) for the remaining days. The amounts of water or Hoagland's solution were adjusted to prevent any losses of root exudates from the bottom of the pots. Pots with sand only were treated the same way and used as controls.

After 10 days, the bottom of each pot was fitted to a glass container connected to gentle vacuum to facilitate collection of root exudates. Thirteen milliliters from each collection were added to Petri dishes (10 cm diameter) containing 60 g of sterilized sand and 25 seeds of *Amaranthus retroflexus*. Seed germination and radicle and hypocotyl lengths were measured 7 days after seeding. The experiment was arranged in a randomized complete-block design with five replications.

Characterization of Biologically Active Compounds. The idea of the sys-

tem used for collection and characterization of root exudates was based on that of Tang and Young (1982) with slight modification. Five seeds of *Sorghum bicolor* cv. 219, one of the most allelopathic cultivars found from the previous experiment, were planted in sterilized cylindrical funnels containing sterilized acid-washed sand and watered with 0.2 strength sterlized Hoagland's solution. Funnel controls without sorghum plants were treated similarly at the same time.

XAD_4 resin, purchased from Fluka, cleaned with methanol, was used to pack columns of 20 cm ID × 24 cm long. The residual methanol was removed by washing the columns with distilled water several times. Each column was fixed to the cylindrical pot to receive the dripping solution. Nutrient solution was dripped from the upper reservoir to the cylindrical pot and from the latter to XAD_4 resin which then was collected by a reservoir at the bottom of the system. The nutrient solution was recycled twice a day.

Each column was detached after four days, washed with distilled water several times, and eluted with 200 ml methanol. Eluates from 18 columns were pooled, evaporated to dryness under vacuum at 40°C, and made up to 50 ml distilled water. The water extract (pH 6.8) was extracted three times with 100 ml chloroform. The chloroform fractions were pooled and concentrated to 15 ml. The water fraction was acidified to pH 2.0 with 1 N HCl and extracted three times with chloroform. The basic fraction was obtained by adjusting the water fraction to pH 12.0 and extracted three times with chloroform. The chloroform extracts at pH 12 were concentrated in vacuum separately to 15 ml. Distilled water control was run similarly to find out if toxins of microbial origin appeared in the control funnels during the experiment. The XAD_4 resin of 18 columns was removed from the columns, extracted three times with 100 ml acetone, and concentrated to 15 ml.

The biological activities of neutral, acidic, basic, and acetone fractions were determined using the Petri dish technique. From each fraction, 0.8 ml was applied separately on Whatman No. 3 filter paper (5 cm diameter). The solvent was evaporated and the filter paper was placed in a 5.5-cm Petri dish. Each Petri dish was seeded with 25 seeds of *A. retroflexus* and watered with one ml of distilled water. Seed germination and radicle and hypocotyl lengths were recorded six days after seeding. The experiment was conducted in a randomized complete-block design with three replications.

Evaluation of Allelopathic Potential of Aqueous Extracts of Selected Sorghum bicolor *Cultivars.* Aqueous extracts of *Sorghum bicolor* cultivars 219, 260, 264, and 177 were prepared following the method of Rice (1972). Ten grams of fresh weight from each cultivar were boiled separately in 100 ml distilled water for 10 min, ground in a homogenizer for 5 min, suction filtered through filter paper (15–40 μm pore size) and purified by centrifuge at 15000 rpm for 10 min. The purified solution of each cultivar was made up to 100 ml with distilled water and adjusted to pH 6.8 with 1 N HCl. Solutions for germination and growth tests were made by diluting the purified solution to 1 : 1

(v/v extract–Hoagland's nutrient solution). Control solutions were made similarly except that the extract was replaced by distilled water.

The biological activities of the extracts were determined using sand culture technique. Twenty-five seeds of *Amaranthus retroflexus* were planted per pot containing 330 g of washed, sterilized sand. Immediately after planting, 70 ml of the extract solution was added to each of the five pots making a total of 20 test pots. Controls were made similarly by adding 70 ml of the control solution to each of the five pots. After two weeks, seed germination was recorded, and the plants were thinned to the three largest per pot. Twice a month, each pot received 15 ml of appropriate solution, otherwise, they were watered when necessary with equal amounts of 0.5 strength Hoagland's solution alternated with distilled water, the amounts of solution or distilled water were adjusted to prevent any leaching from the bottom of the pots. The experiment was arranged in a randomized complete-block design with five replications.

Thirty-five days after planting, seedlings were carefully removed from each pot, washed with tap water, separated into tops and roots, and compared on the basis of oven-dry weight.

Evaluation of Allelopathic Potential of Decaying Plants from Selected Sorghum bicolor *Cultivars*. Three grams of air-dried powder form each cultivar were mixed with 500 g of loamy soil and placed in plastic pots. Twenty-five seeds of *A. retroflexus* were planted in each pot. The control was run similarly except that cultivar powders were replaced by equal amounts of peat moss. All pots were watered when necessary with tap water.

Seed germination was recorded two weeks after planting, then the seedlings were thinned to the three largest per pot, allowed to grow for another two weeks and harvested. Oven-dried biomass of roots and tops was determined. The experiment was arranged in a randomized complete-block design with five replications.

Biological Activity of Selected Sorghum bicolor *Cultivars Against Nitrification*. For the aqueous extract bioassay, the nitrification process was evaluated using a soil incubation method. A sample of a rich garden loam soil was collected to a depth of 10 cm on March 10, 1984. The soil was mixed thoroughly, air dried, and passed through a seive with 2-mm openings. One hundred grams of soil were placed into a 100-ml plastic beaker, and each plastic beaker received 12 ml aqueous solution containing 0.0944 g of $(NH_4)_2SO_4$ to make the concentration of NH_4 nitrogen added 200 ppm for the control. Treatments were run similarly except distilled water was replaced by 10% plant extracts of sorghum cultivars 219, 260, 261, and 177. The plant extracts were prepared in the same manner as mentioned previously. All beakers were incubated in the dark at 28°C. All treatments were arranged in a randomized complete-block design with five replications.

The progress of nitrification was followed every two days by measuring

the amounts of NH_4^+-nitrogen and NO_3^--nitrogen using MgO–Devarda alloy methods (Bremner, 1965).

For the residue bioassay, 1 g air-dried powder from each of the test cultivars was added to a plastic beaker containing 100 g of garden soil. An equal amount of peat moss was added to the control pot to keep the organic matter the same. Each pot received 12 ml aqueous solution which contained 0.0944 $(NH_4)_2SO_4$ the make the NH_4-nitrogen concentration 200 ppm and incubated in a growth room at 28°C under a dark condition. The experiment was arranged in a randomized complete-block design with five replications. Measurements of NH_4-nitrogen and NO_3-nitrogen were taken every two days using the same methods as mentioned previously.

RESULTS

Collection and Biological Activities of Root Exudates. All of the 100 cultivars of *Sorghum bicolor* tested differed greatly in their ability to alter seed germination and/or seedling growth of *Amaranthus retroflexus*. Seed germination was reduced by approximately 70% of control in 11 cultivars and 82% of control in 25 cultivars, the other cultivars caused no significant reduction in seed germination. The growth range was 77–113% of control. Ten cultivars, some of them economically important (cv. 219, 260) inhibited growth of *A. retroflexus* by more than 79% of control (Table 1) and 25 cultivars by approximately 85% of control. The others either did not show significant inhibition or caused no significant stimulation to seedling growth. Most of the inhibitory effects occurred in radicle growth.

Characterization of Biologically Active Substances in Root Exudates. Seed germination was slightly inhibited by the neutral fraction and slightly stimulated

[a] Significantly less than water control at 0.05 level by Student's *t* test.
[b] Significance compared to pot control at 0.05 level by Student's *t* test.

by the basic one. There was virtually no effect on germination by acidic and aceton fractions (Table 2).

All fractions, except the neutral, caused drastic inhibition to radicle growth of *A. retroflexus*. The hypocotyl length was significantly reduced by neutral and acetone fractions only. Both neutral and acetone fractions of the funnel control revealed inhibitory effects against radicle and hypocotyl growth when compared to the distilled-water control. Inhibition could be attributed to the toxins of microbial origin in the control funnels.

Bioassay of Aqueous Extracts of Selected Sorghum bicolor *Cultivars against* Amaranthus retroflexus. Aqueous extracts of all cultivars drastically reduced root, shoot, and seedling biomass of *A. retroflexus* (Table 3). However, cultivars 219 and 260 caused the maximum inhibition among all aqueous extracts of the test cultivars. No significant differences in growth were found between cultivars 219 and 260 and between cultivars 177 and 264.

Seed germination was reduced by the aqueous extracts of all test cultivars; however, the reduction is more in the aqueous extracts of cultivars 219 and 260 than in the aqueous extracts of the others.

Biological Activities of Decaying Residues from Selected Sorghum bicolor, *Cultivars against* A. retroflexus. Decaying materials of all test *Sorghum* cultivars significantly reduced growth of roots, tops, and seedlings of *A. retroflexus* (Table 4). Cultivar 219 exhibited greater inhibitory action among the test cultivars followed by the cultivar 260.

Seed germination was significantly reduced by decaying material of all test cultivars; however, no significant differences in germination percentage were recorded between the cultivars.

Biological Activity of Selected Sorghum bicolor *Cultivars against Nitrification.* In the aqueous extracts bioassay, aqueous extracts of all test cultivars significantly inhibited the nitrification process (Figure 1). The aqueous extract

[a]Average of at least 20 seedlings, means within column followed by the same letter are not significantly different at 0.05 level according to Duncan's multiple-range test.

of cultivar 219 showed greater inhibitory action than those of the others. High correlation coefficients were recorded between the ammonia remaining and nitrate produced in all treatments.

In the residue bioassay, the presence of decaying materials of all test cultivars in soil significantly reduced the nitrification process (Figure 2). However, the inhibitory effects on nitrification were stronger in cultivars 260 and 219 than

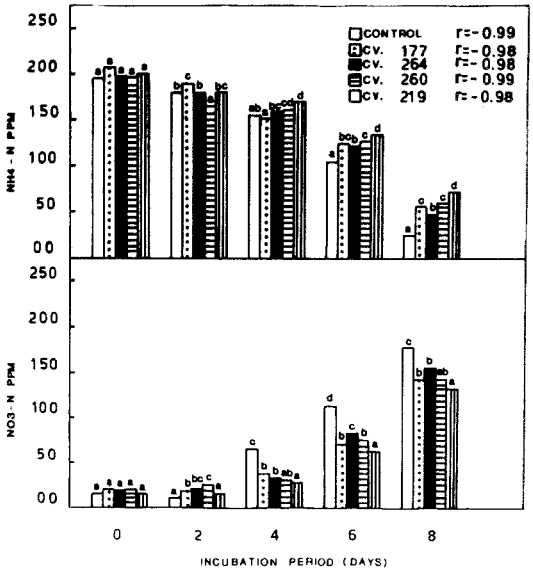

FIG. 1. Effect of aqueous extracts of selected cultivars of *Sorghum bicolor* on nitrification. Means within each sampling period sharing the same letter are not significantly different according to Duncan's multiple-range test.

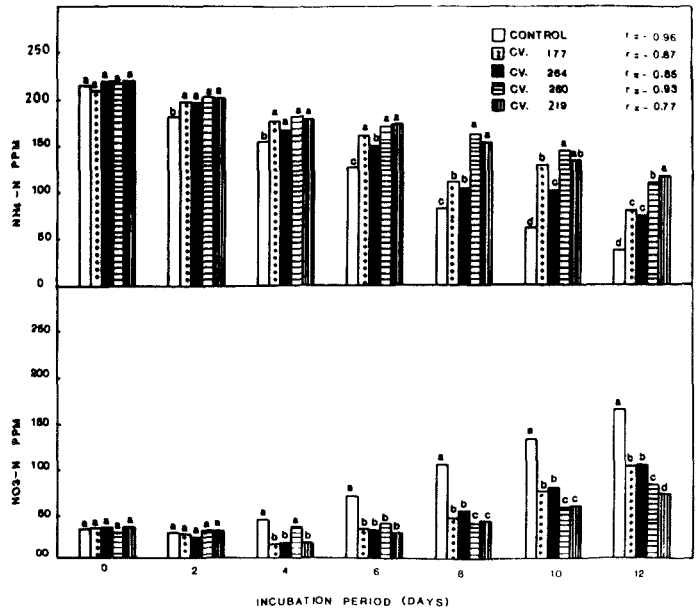

FIG. 2. Effect of decaying residues of selected cultivars of *Sorghum bicolor* on nitrification. Means within each sampling period sharing the same letter are not significantly different according to Duncan's multiple-range test.

in cultivars 177 and 264. Significant correlation coefficients between the ammonium remaining and nitrate produced were found in all treatments including the control.

DISCUSSION

The screening technique employed revealed considerable variations in the allelopathic potential of *Sorghum* cultivars. These variations could be attributed to the genetic differences between the test cultivars, since all cultivars received the same treatments during the experimental periods. Similar observations on the other crop varieties were also reported (Putnam and Duke, 1974; Fay and Duke, 1977). Moreover, the results showed that the neutral fraction of root exudates was more inhibitory than the other fractions. This result is particularly important since the pH used is similar to the pH of the soil in the fields. Tang and Young (1982) found that the neutral fraction of *Hemarthia altissima* has greater toxicity than the basic and acidic fractions.

The results also showed that the aqueous extracts of all test cultivars were inhibitory to seed germination and seedling growth of *A. retroflexus* and to the nitrification process. This suggests that the inhibition resulted from water-sol-

uble phytotoxins. This explanation was further substantiated by the *Sorghum* cultivar residue bioassay in which decaying material caused significant reduction in *A. retroflexus* growth and in the nitrification process. The results concerning the allelopathy of the test *Sorghum* cultivars against test plants agree with Guenzi et al. (1967), Abdul-Wahab and Rice (1967), Qureshi and Hussain (1980), and Lehle and Putnam (1982), who reported allelopathic effects of other *Sorghum bicolor* cultivars and other *Sorghum* species. However, the allelopathic effects of *Sorghum* against nitrification were not investigated elsewhere.

It is shown that selected cultivars, which were found to be nontoxic through root exudation, exhibited considerable toxicity through aqueous extracts and decaying materials. However, the degree of phytotoxicity is less than those which were found to be toxic through root exudation. Many reports indicated that allelopathic plant species can release phytotoxins by one or more sources of release (Rice, 1979; Horsley, 1977).

Our report indicates that some *Sorghum* cultivars reveal marked phytotoxicity, and these cultivars may prove useful in the control of some weeds and nitrification. It is premature to suggest an effective methodology; however, such developments could significantly reduce the requirements for commercial herbicides and nitrification inhibitors.

Acknowledgments—The authors wish to thank Dr. F.A. Bazzaz, the Biological Laboratories, Harvard University, for the revision of this manuscript.

(Received March 21, 1985; accepted June 17, 1985)

Abstract—This study was conducted to test the hypothesis that interfering with chlorophyll metabolism and ion uptake may be mechanisms through which some phenolic acids inhibit the growth of cowpea seedlings. Three concentrations (10^{-4} M, 5×10^{-4} M, and 10^{-3} M) of each of syringic, caffeic, and protocatechuic acids were used to test their effects using sand-culture medium. It was found that seedling growth, chlorophyll a, total chlorophyll, chlorophyll a/b ratio, and the uptake of N, P, K, Fe, and Mo were significantly reduced by most of the test concentrations of the phenolic acids. However, chlorophyll b content and the Mg uptake were not significantly affected by all the phenolic acid concentrations. Calcium uptake was significantly inhibited by 5×10^{-4} M and 10^{-3} M of caffeic acid and 5×10^{-4} M of protocatechuic acid. In most cases, the reduction in dry weight was parallel to the reduction in chlorophyll content and ion uptake, and the reduction in chlorophyll was also parallel to the reduction in ion uptake. The relationships among the inhibition of dry weights, chlorophyll content, and ion uptake are briefly discussed.

Key Words—Syringic acid, caffeic acid, protocatechuic acid, chlorophyll content, ions.

INTRODUCTION

Inhibitory effects of various chemical compounds released from plants are well documented. Rice (1974) and, recently, Putnam (1983) categorized some of these compounds and determined their ecological role in manipulated and natural ecosystems. The mechanisms through which some of these compounds

0098-0331/86/0100-0221$05.00/0

inhibit plant growth are also recognized. However, the efforts on this approach are still scarce and need further investigation (Einhellig and Rasmussen, 1979).

Allelopathic effects of *Sorghum bicolor* have been the subject of many investigators. Guenzi and McCalla (1966a,b) were able to isolate the phytotoxins ferulic, syringic, vanillic, and *o*-hydroxybenzoic acids from sorghum residues and soil from no-tillage sorghum plants. Leon (1976) demonstrated the autotoxicity of *Sorghum vulgare* in a monoculturing regime and isolated syringic, *o*-hydroxybenzoic, *m*-hydroxybenzoic, vanillic, protocatechuic, *p*-coumaric, and caffeic acids from sorghum roots. Putnam (1983) reported that sorghum residues provided significant weed-killing capacity under field conditions. In our laboratory, we screened 100 cultivars of *Sorghum bicolor* for their allelopathic potentiality and found that some of these cultivars exhibited significant inhibitory effects against *Amaranthus retroflexus* and the nitrification process (AlSaadawi *et al.*, 1986). Although the mechanisms of inhibition of some phenolic acids isolated from *Sorghum bicolor* are known, the mechanisms of some other phenolic acids such as syringic, caffeic, and protocatechuic acids were not investigated. These acids were reported to have considerable allelopathic activity and to be widely distributed in allelopathic plant species (Rice, 1974).

The aim of the present investigation, therefore, is to test the effect of the above-mentioned phenolic acids on chlorophyll content and ion uptake in plants. These two parameters are known to limit the total plant growth (Epstein, 1976; Colton and Einhellig, 1980; Einhellig and Rasmussen, 1979).

METHODS AND MATERIALS

Plant Material and Growing Conditions. Cowpea, (*Vigna sinensis* L.) was used as a test species to study the effects of phytotoxins on chlorophyll content and ion uptake. Five seeds were planted in each of 50 pots containing 650 g sterilized, washed sand. Five days after planting, the seedlings were thinned to the largest seedling per pot. The pots were divided into 10 groups with five pots each.

Three concentrations (10^{-4} M, 5×10^{-4} M, and 10^{-3} M) from each phytotoxin in Hoagland's solution (Hoagland and Arnon, 1950) were prepared making a total of nine treatments. The solution of each treatment was adjusted to pH 5.8 with N HCl and autoclaved for 15 min.

Immediately after thinning, 120 ml of a test solution was added to each pot of the appropriate group. An equal amount of sterilized Hoagland's solution at pH 5.8 was added to each pot of the control group. Two weeks later, the pots were watered again with 120 ml of appropriate solution. Between treatments and after the second treatment, the pots were watered with an equal amount of distilled water alternated with an equal amount of Hoagland's solution whenever necessary. The amounts of distilled water or nutrient solution

were adjusted to prevent any leaching from the bottom of the pots. The experiment was arranged in a randomized complete-block design and conducted in a growth room at 14 hr photoperiod (1500 ft-c) and 26 ± 2°C/24 ± 2°C day–night conditions.

Determination of Chlorophyll Content. Thirty-five days after planting, the plants were harvested and their roots washed with dilute HCl followed by deionized water. Immediately after harvesting, the first trifoliate leaf of each plant was taken for chlorophyll extraction, while the rest of the plant was oven dried for 24 hr at 105°C. The extraction procedure of chlorophyll was basically that of Knudson et al. (1977). Two grams fresh weight from the first trifoliate leaf of each plant were soaked in 30 ml of 95% ethanol for 24 hr. The ethanol–chlorophyll solution of each treatment was decanted in a container and kept at room temperature in dark conditions. The leaves were soaked again in a similar manner for two additional 24-hr periods in 30 ml of 95% ethanol. The chlorophyll–ethanol solutions of each plant were pooled, and the absorbance (A) was measured at 665 nm and 649 nm on a CE 292 Digital ultraviolet spectrophotometer. The quantities of chlorophyll a and b were measured using the following equations, respectively (Wintermans and Demots, 1965; Knudson et al., 1977).

$$\frac{\mu\text{g chloroplyll a}}{\text{ml solution}} = [(13.70)\ (\text{A } 665\text{ nm})] - [(5.76)\ (\text{A } 649\text{ nm})]$$

$$\frac{\mu\text{g chloroplyll b}}{\text{ml solution}} = [(25.80)\ (\text{A } 649\text{ nm})] - [(7.60)\ (\text{A } 665\text{ nm})]$$

Two grams of the first trifoliate leaf fresh weight were oven dried for 24 hr at 105°C and used to calculate micrograms chlorophyll per milligram dry weight.

Determination of Mineral Elements in Cowpea Plant. Oven-dried material of each plant was ground in an electrical grinder for plant analysis. Total nitrogen was determined by the macro-Kjeldahl method (Chapman and Pratt, 1961) and total phosphorus by the vanadomolybdophosphoric colorimetric method (Jackson, 1958). Calcium, Mg, K, Fe, and Mo were determined on a Perkin-Elmer model 305 atomic absorption spectrophotometer after digestion according to instructions in the analytical manual supplied with the instrument (Anonymous, 1976).

RESULTS

Effect of Phytotoxins on Growth and Chlorophyll Content. All test concentrations of all phenolic compounds, except 1×10^{-4} M syringic acid, significantly inhibited seedling growth of cowpea compared with the control (Table 1). Chlorophyll a, chlorophyll a/b ratio, and total chlorophyll were significantly

	5×10^{-4}	1.410*[a]	8.33*	8.60	0.95*	16.93*
	1×10^{-3}	1.357*	6.67*	7.57	0.88*	14.24*
Caffeic acid	1×10^{-4}	1.249*	12.85	8.43	1.52	21.28
	5×10^{-4}	1.278*	11.10*	7.79	1.42*	18.89
	1×10^{-3}	1.071*	10.20*	8.45	1.20*	18.65*
Protocatechuic acid	1×10^{-4}	1.347*	9.69*	7.96	1.21*	17.65*
	5×10^{-4}	1.303*	8.66*	7.86	1.10*	16.52*
	1×10^{-3}	1.223*	8.07*	7.33	1.10*	15.40*

[a] Values marked with asterisk are different from control at 0.05 level according to Student's t test.

reduced by all concentrations of all test phenolic acids except 1×10^{-4} M caffeic acid. However, chlorophyll b was not significantly affected by any of the concentrations of acids tested. Thus the significant reduction in the ratio of chlorophyll a to chlorophyll b was mainly due to the reduction of chlorophyll a.

Effect of Phenolic Acids on Mineral Uptake. The uptake of N was significantly reduced by all the test concentrations of phenolic acids except 1×10^{-4} M syringic acid (Table 2). All the test concentrations of phenolic acids significantly inhibited the uptake of P, Fe, and Mo in cowpea seedlings. Potassium uptake was significantly reduced by all the test concentrations of all phenolic acids except 1×10^{-4} M of syringic and protocatechuic acids. Concentrations of 5×10^{-4} M and 1×10^{-3} M caffeic acid and 1×10^{-4} M protocatechuic acid were the only concentrations that caused a significant reduction in Ca uptake. The uptake of Mg was not significantly affected by any of the concentrations of different phenolic acids.

DISCUSSION

The results revealed that growth is inhibited by all test compounds, and the degree of inhibition is correlated to the concentration of the test phenolic acids. Apparently, the concentration 5×10^{-4} M of syringic acid is the threshold level at which the growth of cowpea seedlings is significantly inhibited. However, the results could not show the threshold inhibitory level of the other phenolic acids since these acids revealed significant inhibition at the lower concentration tested (10^{-4} M).

The results also indicated that the reduction in growth is almost parallel to the reduction in chlorophyll a, total chlorophyll, ratio of chlorophyll a to chlorophyll b, and the uptake of N, P, K, Fe, and Mo. Since chlorophyll content and mineral uptake are known to limit the productivity of plants (Epstein, 1976; Buttery and Buzzell, 1977, Colton and Einhellig; 1980, Patterson, 1981), it is possible that the reduction in growth is a result due to the reduction in chlorophyll content and mineral uptake. Parks and Rice (1969) reported that several phenols caused significant reduction in chlorophyll content in blue-green algae and thus affect growth. Einhellig and Rasmussen (1978) demonstrated that the reduction in chlorophyll content is the allelopathic mechanism through which ferulic, *p*-coumaric, and vanillic acids affect soybean seedlings. Rice (1979) and Putnam (1983) reviewed the effect of several phenolic compounds on ion uptake by plants. Moreover, the results also suggest that the reduction in chlorophyll is due to the reduction in ion uptake since some of the ions tested are involved in the chlorophyll structure and/or in the metabolic pathway of chlorophyll biosynthesis.

It is noteworthy to mention that the inhibitory effects of the individual test

phenolic acids reported here are at low concentrations. The additive or synergistic inhibitory effects of such allelopathic compounds may become more detrimental than the effects of individual phenolic acids (Rasmussen and Einhellig, 1978; Einhellig and Rasmussen, 1978). Moreover, combined applications of these phenolic acids may cause significant inhibitory effects at a concentration lower than the minimum concentration used in this investigation.

Acknowledgments—We thank Drs. J.K. AL-Uqaili and H.A. Jadduo for suggestions and reviewing the manuscript.

(Received March 25, 1985; accepted June 17, 1985)

Abstract—Ten C_{16} chain-length compounds were identified from heptane extracts of ovipositors of female melonworm, *Diaphania hyalinata* (L.). The major constituents of the extracts were (*E*)-11-hexadecenal and (*E,E*)-10,12-hexadecadienal [(*E,E*)-10,12-16:Ald] and the alcohols and acetates of these olefins were found in trace amounts (<2%). Extracts also contained traces of (*E,Z*)- and (*Z,Z*)-10,12-16:Ald, hexadecanal, and 1-hexadecanol. Analysis of the behavioral responses of males to synthetic mixtures of these compounds and responses to ovipositor extracts in a flight tunnel showed that a synthetic mixture of the 10 compounds elicited a behavioral repertoire from males that was indistinguishable from that elicited by ovipositor extract. Flight tunnel studies also indicated that six of the 10 compounds probably represent the essential components of the female's sex pheromone.

Key Words—*Diaphania hyalinata, D. nitidalis*, melonworm, pickleworm, Lepidoptera, Pyralidae, sex pheromone, insect behavior, flight tunnel, 10,12-hexadecadienal, 11-hexadecenal.

INTRODUCTION

Larvae of the melonworm, *Diaphania hyalinata* (L.), feed almost exclusively upon the foliage of pumpkin and other cucurbits, and it is rarely considered a pestiferous insect. The impetus for studying the sex pheromone of *D. hyalinata* was an interest in the comparative sex pheromone chemistry of *D. hyalinata* and *D. nitidalis* (Stoll). The two species occur sympatrically and exhibit similar life cycles and habits; however, *D. nitidalis* is considered a serious pest because it feeds upon and damages the fruits of cucurbits. The results reported here define the chemistry of pheromone-like compounds from the melonworm female and male behavioral responses to synthetic mixtures of the female-borne compounds. These findings were pivotal to elucidation of the *D. nitidalis* sex pheromone (Klun et al., 1986) because compounds discovered here aided in the detection of minute amounts of similar compounds in *D. nitidalis* and the combined findings provide a basis for comparative insight into the pheromone communication systems of the two species.

METHODS AND MATERIALS

Insects. Insects used in this study were reared on pinto bean diet (Robinson et al., 1979) at the Vegetable Insects Laboratory in Charleston, South Carolina. Pupae were shipped to Beltsville, Maryland, and pupae and adults of each sex were kept in separate enviornmental chambers that were maintained under a reverse photoperiod of 16:8 light–dark, 26°C light, 20°C dark; 60% relative humidity. Adults were provided a 10% sucrose solution.

The ovipositors (terminal abdominal segments containing the pheromone gland) of 2- to 3-day-old females at 5–6 hr of scotophase (the time of their sexual activity in nature: K.D. Elsey, personal communication) were excised and transferred to heptane (ca. 5 μl/ovipositor). The tissue was soaked for ca. 30 min, and then the solvent was drawn away from the tissue using a 50-μl syringe. The behavioral response of males to the ovipositor extracts signaled the presence of female sex pheromone, and these extracts served as a resource for chemical analyses.

Chemicals and Analytical Methods. The combined extracts of several hundred melonworm ovipositors were analyzed by open-tubular capillary chromatography (OTCC) using 60 m × 0.25 mm (ID) polar and nonpolar (SE-30) columns and by OTCC–mass spectrometry using instruments and operating conditions described by Klun et at.(1982). The ovipositor extracts were derivatized by successive treatment with $NaBH_4$ and acetic anhydride–pyridine (9:1) (Klun et at., 1982), fractionated by preparative gas–liquid chromatography (Schwarz et al., 1983), and the chromatographic fractions were ozonized and

the ozonolysis products analyzed by OTCC (Klun et al., 1982) to establish sites of unsaturation in the compounds.

The monounsaturated and saturated C_{16}-chain-length compounds used in this study were purchased. All 10,12-hexadecadienes were stereoselectively synthesized in our laboratory using the methods described below.

(Z,Z)-10,12-hexadecadienal. Synthesis of this compound was patterned after the preparation of (Z,Z)-9,11-hexadecadien-1-ol reported by Svirskaya et al. (1980). Thus, 10-undecyn-1-ol was coupled in a Cadiot-Chodkiewicz reation with 1-pentyne to produce 10,12-hexadecadiyn-1-ol. The latter compound was reduced stereospecifically to (Z,Z)-10,12-hexadecadien-1-ol with dicyclohexylborane. Oxidation of the alcohol with pyridinium chlorochromate (Corey and Suggs, 1975) afforded the desired (Z,Z)-10,12-hexadecadienal.

(E,Z)-10,12-Hexadecadienal. This compound was prepared by the reaction scheme reported for the same compound by Hall et al. (1980).

(E,E)-10,12-Hexadecadienal. Pure (E,E)-10,12-hexadecadien-1-ol was obtained by low-temperature recrystallization from pentane of the equilibrium mixture of all four isomers of this alcohol obtained after treatment of (E,Z)-10,12-hexadecadien-1-ol with 0.5% thiophenol at 100°C (Henrick et al., 1975). Pyridinium chlorochromate oxidation (Corey and Suggs, 1975) then afforded the desired aldehyde.

Each of the compounds used in bioassays was purified by argentation high-pressure liquid chromatography (Klun et al., 1982), and they were >95% pure based upon OTCC.

Flight Tunnel, Test Procedures, and Experimental Design. The flight tunnel was 3 m × 60 cm, horseshoe-shaped in cross-section, and made from Plexiglas. Two air conditioners, with a combined capacity of 42,000 BTU, provided the source of air that was conditioned in a chamber (12 m^3 provided with supplemental heating and humidification) at the head of the flight tunnel. The air was blown from the chamber by a fan, driven by a 0.75 HP variable-speed motor, through a Varicel filter and cheesecloth screen into the tunnel. the downwind end of the tunnel was fitted with an 8-mesh stainless-steel screen having a 7-cm-diam. circular hole at the center of the tunnel's cross-section 16 cm from the tunnel floor. The opening was fitted with a collar that held a Plexiglas tube (20 cm long × 6.5 cm diam.) that was used for release of individual males. The release tube was fitted with a spring-mounted lid on the upwind end and a cheesecloth cover on the other. Air flow from the tunnel was directed into a hood and exhausted to the outside of the building. Three sliding windows, located along the side of the tunnel, provided access to the interior of the tunnel across its length. Overhead illumination was provided by red incandescent bulbs that were rheostat-regulated to 2.5 lux. A laminar air flow was maintained through the tunnel at 50 cm/sec and 20.5 ± 1.5°C. The position of the stimulus-plume generated in the tunnel was determined by observing the path of

smoke generated from a burning incense stick. The observation indicated that the plume traversed the length of the tunnel in a narrow band and exited the tunnel through the male-release tube at the downwind end of the tunnel.

Males, 2–3 days old, were used in the bioassays after they had been conditioned for ca. 30 min in the flight-tunnel room. Males were used once and discarded. Tests were carried out at 5–6 hr of scotophase. Each male was allowed to settle on the cheesecloth at the downwind end of the release tube, and observations were commenced when the lid was removed from the tube.

Based on previous observations of male response to the extracts of female glands and virgin females in the tunnel, six behavioral categories were chosen for quantitative analysis. These were (1) Activation (a dichotomous variable), characterized by onset of wing fanning and rapid walking, each male was allowed a maximum of 2 min to express the activation response; (2) time to activation, represented elapsed time from the removal of the lid to start of wing fanning; (3) upwind flight in plume, a dichotomous variable, represented the percentage of insects that traversed the length of the tunnel and arrived at the stimulus source; (4) flight time, the elapsed time from start of flight to arrival at the source; (5) time near source, the time a male spent hovering near the source with extended claspers and making frequent antennal and tarsal contacts with the pheromonal stimulus; (6) return to source (dichotomous), represented those males that hovered at the source, flew away, reentered the plume, and returned to the source. A male was allowed a maximum of 2 min to return to the source. The test chemicals and ovipositor extracts were applied to a 4 × 0.5-cm filter paper strip that was suspended 16 cm above the tunnel floor from a narrow clip 20 cm from the upwind end of the tunnel. The quantity of ovipositor extracts applied to the paper was adjusted so that the quantity of female-derived compounds and the quantity of synthetic compounds applied to the paper were equivalent (according to OTCC).

The experimental design for the behavioral tests was a randomized complete-block design replicated 24 times over 24 days. All the variables involving time measurements in test I were analyzed by the nonparametric M-rank procedure because the data did not meet the assumptions for homogeneities of variances. The M-rank procedure is a generalization of the Friedman's test, which can be used for unbalanced data and a randomized complete-block design (Benard and Van Elteren, 1953). The computer program used was a supplemental procedure of the Statistical Analysis System statistic programs (Sarle, 1981). The dichotomous response variables were analyzed by the analysis of variance (Cochran, 1950). Significance was tested by χ^2 analysis, and the means were ranked using Duncan's multiple-range test.

In test II, three 2-day-old, virgin females or filter paper strips treated with synthetic pheromonal components were placed in a 5-cm × 3-cm-diam. stainless-steel screen cage that was suspended by the clip at the upwind end of the

[a] Percentage composition values are averages derived from analyses of the combined extracts of 62 females on polar and nonpolar capillary columns.

tunnel. Male responses to these treatments were compared by scoring male responses in the six behavioral categories. The amount of (*E*)-11-hexadecenal in each treatment of tests I and II was fixed at 252 ng, and the amounts of other compounds in the various treatments were proportional to the percentage compositions found in the female extracts (Table 1). The test was replicated 36 times over 36 days. Data were analyzed statistically using the same procedures described for test I.

Studies of the responses of feral melonworm males to pheromonal stimuli were attempted, but field populations of the insect were too low to allow acquisition of any meaningful data. Therefore, we had to rely on the flight-tunnel assay to assess the impact of the female compounds on male sexual behavior.

RESULTS AND DISCUSSION

Chemistry. Analyses of the ovipositor extracts of the females revealed the presence of 10 pheromone-like compounds (Table 1). The identities of these compounds were deduced from the coincidence of retention times with authentic reference compounds that were fully resolved on the capillary columns and by comparison of mass spectral fragmentation patterns with the reference compounds. Reduction of the ovipositor extract components with $NaBH_4$ followed by acetylation of the resulting alcohols yielded a mixture of five C_{16} acetates. These acetates had OTCC retention times coincident with (*E*)-11-16:OAc;

16:OAc; (*E,Z*)-, (*Z,Z*)-, and (*E,E*)-10,12–16:OAc, respectively. The (*E*)-11–16:OAc and (*E,E*)-10,12–16:OAc were major components of the mixture. This result was consistent with the analyses of the underivatized extract which showed that the corresponding C_{16} aldehydes were major components of the extract (Table 1). The mixture of acetates was fractionated by preparative chromatography; *E*-11–16:OAc and 16:OAc (fraction 1) and the 10,12–16:OAc isomers (fraction 2) were collected and ozonized. OTCC analysis of ozonized fraction 1 on polar and nonpolar columns showed the presence of two compounds: unreacted 16:OAc and 11-acetoxyundecanal. Ozonized fraction 2 yielded a single compound having OTCC retention times coincident with 10-acetoxydecanal on polar and nonpolar OTCC. These results confirmed that the site of unsaturation in the monoenes of the extract was 11 and that the site of conjugation in the dienes was 10,12.

Flight Tunnel Tests. Replicated observations (24/treatment) of responses of individual males to the ovipositor extracts in the flight tunnel (Table 2, treatment M) revealed the following: Males became active within 8 sec after exposure to the pheromone and subsequently took flight. Plume-oriented upwind flight was completed by 83% of the males tested. The average flight time from the release-tube to the stimulus source was 21.3 sec. During the upwind flight, males displayed a helical-like flight pattern as they repeatedly crossed the pheromone plume over 2/3 of the flight path. The last 1/3 of the flight was most often a straight-line dash in the pheromone plume to the stimulus source. After reaching the source, the males hovered with their claspers fully extended and made repeated antennal and tarsal contacts with the paper strip. Males also landed on the strip and made copulatory strikes (abdominal curving with claspers extended) at the paper strip. The average time spent by the males near the stimulus source was 33 sec, after which they flew away downwind and then began upwind flight as they casted widely across the width of the tunnel. Seventy-five percent of the males that exhibited this behavior reentered the plume and returned to the source.

Data in Table 2 (test I) show that treatment B, which lacked 16:Ald and 16:OH, was not significantly different from treatment A in any of the behavioral categories and elicited significantly better response in time to activation category compared to female extracts. Treatments C, D, E, G, and L (blank) were significantly less effective than female extracts in two or more of the behavioral categories of the test. These treatments lacked (*E*)-11–16:Ald (*compound* 1, Table 1), (*E,E*)-10,12–16:Ald (5), (*E,Z*)-10,12–16:Ald (3), and (*E,Z*)- and (*Z,Z*)-10,12–16:Ald (4), respectively. Results showed that (*E*)-11–16:Ald (1) and (*E,E*)-10,12–16:Ald (5) were absolutely essential for pheromonal activity; male responses to treatments (C and D) lacking either of these compounds were statistically equivalent to the blank treatment. Thus, these compounds are essential pheromonal components, but they must be sensed in context with other compounds to elicit optimal behavioral reactions from the males.

[a] Compounds, designated by number, are defined in Table I. Means followed by a common letter within each test in each column are not statistically different at 0.05% level of probability. Abbreviations: Act. = activation, flt. upw. = flight upwind.
[b] N = Number of males tested against each treatment.

(*E,Z*)-10,12-16:Ald (3) proved important to maintenance of male behavioral activity in the vicinity of the pheromonal stimulus; when it was deleted from the stimulus (E) males spent less time at the source and they returned to it less frequently (E vs. A, B, or M). Deletion of (*Z,Z*)-10,12-16:Ald (4) from the stimulus (F) had a detrimental effect on percent flight upwind category in comparison to A and B, but not M. When the *Z,Z* and *E,Z* isomers were simultaneously deleted from the stimulus (G), the expected negative effects attendant with deletion of either isomer were greater than anticipated. Response scores were impacted negatively in the percent flight upwind category as well as in the time at source category. This result indicates that the two dienes have an interactive effect on male behavior and that male perception of them involves a contextual relationship.

Although results of test I indicated that compounds 1, 3, 4, and 5, (Table 1) were behaviorally important components of the female's sex pheromone, a replicated ($N = 6$) test of the four-component mixture in the flight tunnel showed that it would not elicit upwind flight in the stimulus plume. Test I data showed that treatments containing compounds 1, 3, 4, and 5 plus at least three other compounds (6, 8, 9) always produced response scores that were either equivalent to or greater than those generated by female ovipositor extracts. Inspection of data for treatments H, I, J, and K and inference led us to the conclusion that a combination of compounds 1, 3, 4, 5, 6, and 9 represented the minimum set of compounds required for elicitation of a complete repertoire of male response in all behavioral categories of the assay. Test II (Table 2) confirmed the validity of this inference. The assay showed that the 1, 3, 4, 5, 6, and 9 combination of compounds elicited responses from males that were statistically equivalent to the responses generated by female extracts or virgin females. The mixtures of the eight olefins (treatment B) identified from the female extracts was slightly less effective than all other treatments in the time to activation and percent return to source categories. This result may reflect the limits of precision for the assay, since treatment B did not differ from female extracts in Test I.

Thus, the chemical data and the behavioral studies in the flight tunnel indicate that the melonworm female sex pheromone may comprise a complex set of six compounds:(*E*)-11-16:Ald, (*E,Z*)-10,12-16:Ald, (*Z,Z*)-10,12-16:Ald, (*E,E*)-10,12-16:Ald, (*E*)-11-16:OH, and (*E*)-11-16:OAc. The copious amounts of (*E,E*)-10,12-16:Ald found in the melonworm female alerted us to the possibility that a similar compound might be found congenerically, and this cognizance proved indispensable in identification of the pickleworm female sex pheromone. The four other compounds (2, 7, 8, and 10; Table 1) identified in the melonworm female extracts did not have any detectable behavioral significance in the assay; however, they appear to be related to the pheromonally active set in a biosynthetic sense.

Acknowledgments—We thank E.D. DeVilbiss for obtaining mass spectral data, and Jenny Moy and David Bushman for help with the behavioral assays.

(Received March 25, 1985; accepted June 17, 1985)

Abstract—Heptane extracts of the ovipositors from pickleworm adults (*Diaphania nitidalis*) were found to contain (*E*)-11-hexadecenal along with proportionally smaller amounts of (*Z*)-11-hexadecenal, (*E*)- and (*Z*)-11-hexadecen-1-ol, hexadecanol, hexadecanal, and a trace amount of (*E,Z*)-10,12-hexadecadienal. Assays conducted in a flight tunnel and in the field showed that a synthetic mixture of the five unsaturated compounds elicited behavioral responses from pickleworm males that were indistinguishable from those elicited by extracts of the female or by mate-calling females. When any component was deleted from the set of five unsaturated compounds, the intensity and extent of male responses to the resulting mixtures were significantly attenuated. The female sex pheromone of the pickleworm resembles the pheromone of a congeneric species, *D. hyalinata*, but bioassays indicated that (*E,E*)-10,12-hexadecadienal, produced by *D. hyalinata* but not by the pickleworm, plays a role in pheromonal specificity.

Key Words—*Diaphania nitidalis, D. hyalinata*, pickleworm, melonworm, Lepidoptera, Pyralidae, (*E*)-11-hexadecenal, (*E,Z*)-10,12-hexadecadienal, (*E,E*)-10,12-hexadecadienal, sex pheromone, pheromonal specificity, flight-tunnel bioassays.

INTRODUCTION

The pickleworm [*Diaphania nitidalis*, (Stoll)] is distributed from Canada to South America and is particularly destructive to plantings of cantaloupe, cu-

0098-0331/86/0100-0239$05.00/0

cumber, muskmelon, and squash in the southeastern and Gulf states of the United States. Larvae of this moth bore into the ripening fruits of these cucurbits and make them unsuitable for marketing (Elsey, 1981).

Pickleworm adults are nocturnal flyers, and Elsey (1982) indicated that mating in the species was mediated by a female sex pheromone. Monitoring the migrations and population fluctuations of this pest has proven difficult because the adults are not attracted to light traps. The need of a pickleworm attractant for monitoring purposes and our interest in the comparative female sex pheromone chemistry of the pickleworm and melonworm [*D. hyalinata* (Linnaeus)] constituted the impetus for this study.

METHODS AND MATERIALS

Insects used in the research were obtained from a laboratory culture (Robinson et al., 1979) that was maintained at Charleston, South Carolina. Pupae from the culture were mailed weekly to Beltsville, Maryland, and pupae and adults of each sex were held in separate environmental chambers at the conditions described by Raina et al. (1986). The ovipositors of 2- to 3-day-old pickleworm virgin females were exised and extracted with heptane at 3–4 hr of scotophase, a time when sexual activity is maximal in the species (Esley, 1982). The extracts were analyzed (Klun et al., 1982) by open tubular capillary chromatography (OTCC) using polar (Carbowax 20 M) and nonpolar (DB-1) columns and by combined OTCC–mass spectrometry (MS). All columns were 60 m × 0.025 mm (ID). The retention times of components in extracts of the pickleworm female were compared to authentic reference compounds. All synthetic compounds used in this study were purchased or prepared and purified as described by Raina et al. (1986). The percentage composition of pheromonal components in the ovipositor extracts was estimated by replicated OTCC analyses on Carbowax 20 M of extracts from individual females and by analysis of the pooled extracts from 87 females. Field tests and flight-tunnel studies utilized synthetic mixtures of the pheromonal compounds in proportions similar to those found in the extracts.

The ovipositor extracts of the females contained several alcohols in trace amounts and the mass spectrometric detection of these was enhanced by treating the extract from 20 ovipositors with a silylation reagent. The concentrated extracts of females (10 μl) were treated with 2 μl pyridine–heptane (1 : 9, v/v) and 1 μl Sylon BTZ (Supelco, Inc., Bellefonte, Pennsylvania 16823)–heptane (1 : 9, v/v). The reaction mixture was held at room temperature (ca. 22°C) for 3 hr, treated with 2 μ1 H_2O, and the heptane layer was analyzed by OTCC-MS. Other extracts of the female ovipositors wre reduced and acetylated by successive treatment with $NaBH_4$ and acetic anhydride (Klun et al., 1982). The acetate derivatives were fractionated by preparative gas chromatography (GC) on SE30

(Schwarz et al., 1983). The acetates were analyzed by OTCC, the fraction containing unsaturated acetates was ozonized, and the ozonolysis products were analyzed by OTCC to establish the site of unsaturation. Ovipositor extracts were also fractionated by preparative GC using the SE30 column and a polar column [10% DEGS (Supelco, Inc.) on 80–100 mesh Gas Chrom Q, 2 m × 4 mm, ID] operated at 160°C using the same instrumentation and gas flows described by Schwarz et al. (1983). The chromatographic fractions from the polar and nonpolar columns were bioassayed, individually and in various combinations, to determine which sets of components in the ovipositor extracts were responsible for pheromonal activity.

Laboratory assays and quantitative analyses of male behavioral responses to compounds identified from the pickleworm female were conducted in a flight tunnel. The repertoire of behavioral responses exhibited by the pickleworm males to calling virgin females or extracts of female ovipositors in the tunnel were identical to those displayed by melonworm males in response to its female sex pheromone. Therefore, the materials, methods, experimental design, and statistical methods related to the flight tunnel assay were similar to those described by Raina et al. (1986). Three tests were conducted in the flight tunnel and five to six behavioral categories were observed and scored (see Table 2). Test I was replicated 24 times, and it involved permutations of compounds that were identified from the females. Compounds were applied to a paper strip and positioned at the upwind end of the flight tunnel. (*E*)-11-Hexadecenal (750 ng) was applied to the paper strip, and the amounts of all other compounds applied to the strip in each treatment were proportional to the percentage composition of each compound found in the pooled extracts of 87 females (Table 1). The amount of (*E*)-11-hexadecenal in each treatment was equal to the amount of (*E*)-11-hexadecenal in the female extracts according to OTCC analyses of the female extracts. Tests II and III were replicated 12 times, and they involved a study of pickleworm male responses to pickleworm synthetic female sex pheromone to which 580-, 58-, 5.8-, and 0.58-ng doses of(*E*,*E*)-10,12-hexadecadienal were added. The (*E*,*E*)-aldehyde is a pheromonal component of the melonworm female sex pheromone (Raina et al., 1986) that is not produced by the pickleworm female. Data from test III were analyzed statistically by the chi-square method; the test III data were amenable to this statistical analysis whereas test I required the M-rank procedure because of the large number of treatments in it and the variability attendant to treatments that elicited no response from males in certain behavioral categories.

Field tests using insect traps were conducted in the vicinity of Charleston, South Carolina, during August and September 1983. The insect trap was a cubical wood-framed (1 m/side) screened (6 × 16 mesh) cage that was open at the bottom. The cage opening was horizontally supported 30 cm from the ground by legs at each corner of the cage bottom. A cylindrical screened cage 8 × 3 cm, OD) containing two to five virgin females (2-day-old, reared and main-

tained in environmental chambers that were programmed in synchrony with the diurnal cycle of the field) or a rubber septum (Arthur H. Thomas, Co., Swedesboro, New Jersey, Cat. No. 8753-D22) that had been treated with 10 μl of a heptane solution containing test chemicals was positioned at the top of a wooden stake in the plane and at the center of the trap opening. Synthetic lures and females were renewed after three nights. The cubical, screened trap, baited with virgin females, proved effective in trapping pickleworm males in preliminary studies while sticky traps (Pherocon 1C, etc.) proved to be ineffective against this species (unpublished results).

Three field tests were conducted by using baited traps in a randomized complete block design with replication over nights. Traps were positioned in fields of cantaloupe with at least 30 m between traps. Test I (12 replicates) involved two virgin pickleworm females and permutations of pickleworm-female compounds that were tested in flight-tunnel assays; however, the dose of (*E*)-11-hexadecenal (75 μg) and proportional amounts of other pheromonal components (a total load of 100 μg) on the rubber septa was 100 times greater than the amount used in the flight tunnel. Test II (32 replicates) evaluated the response of males to traps baited with 1-, 0.1-, and 0.01-mg doses of the mixture of seven compounds identified from the pickleworm female (treatment A) on rubber septa versus their response to traps baited with five virgin pickleworm females. Test III (12 replicates) assayed the response of males in the field to 1 mg (A) and a 0.818-mg mixture of only the five unsaturated compounds identified from the females.

RESULTS AND DISCUSSION

Sex Pheromone Chemistry. OTCC analysis of the pickleworm ovipositor extracts initially indicated the presence of six compounds. These had retention

times, on the polar and nonpolar capillary columns, that were coincident with standard samples of (*E*)-11-hexadecenal [(*E*)-11-16:Ald], (*Z*)-11-16:Ald, hexadecanal (16:Ald), (*E*)-11-hexadecen-1-ol [(*E*)-11-16:OH)], (*Z*)-11-16:OH, and 1-hexadecanol (16:OH). Extracts that were reduced with $NaBH_4$ and then acetylated with acetic anhydride yielded three acetates that had OTCC retention times coincident with hexadecan-1-ol acetate and (*E*)- and (*Z*)-11-hexadecen-1-ol acetate. The unsaturated acetates were isolated by preparative GC and ozonized. Ozonolysis yielded a single compound having an OTCC retention time that was coincident with 11-acetoxyundecanal. This result fixed the olefinic site in the unsaturated compounds at the 11 position. Direct OTCC-MS analysis of the extracts and analysis of silanized ovipositor extracts provided confirming evidence for identity of each of the six compounds. Bioassay of a synthetic mixture of the six compounds, using proportions of compounds (Table 1) and in the amounts found in the female extracts, showed that the mixture would elicit wing fanning and rapid walking behavior from males within the release-tube of the flight tunnel, but males did not fly to the stimulus source or exhibit other behavioral responses that were elicited by extracts of the female. This result clearly indicated that the six compounds we had identified did not represent an accurate synthetic replica of the female's sex pheromone.

When the ovipositor extracts were fractionated by preparative GC on SE30, pheromonal activity was recovered only when the hexadecenal and hexadecenol chromatographic regions were collected and combined. Preparative GC fractionation of the extracts on DEGS showed that pheromonal activity could be regenerated when chromatographic regions corresponding to hexadecenal, hexadecenol, and a region preceding hexadecenol were collected and combined. A combination of the hexadecenal and hexadecenol regions alone from DEGS did not regenerate biological activity. These chromatography–bioassay results indicated that a substance responsible for biological activity in the female extracts was not a hexadecenol, although it eluted after hexadecanal and coeluted in the hexadecenol fraction on the SE30-preparative GC.

Inspection of chromatograms obtained by OTCC of the extracts on the DB-1 (a liquid phase that is chromatographically equivalent to SE30) revealed the presence of a minute component that eluted between hexadecanal and hexadecenol. The mass spectrum of this trace component was obtained by injection of the concentrated extracts from ca. 60 female ovipositors into the OTCC-MS system. Its mass spectrum was identical to the 10, 12-hexadecadienal that had previously been identified from the melonworm (Raina et al., 1986). OTCC of a synthetic mixture of the four isomers of the diene (fully resolved on both columns) showed that the trace amount of diene in the female extracts had chromatographic properties identical to (*E*,*Z*)-10,12-hexadecadienal [(*E*,*Z*)-10,12-16:Ald]. Replicated OTCC analyses of the extracts of individual female ovipositors showed that the compound comprised 0.4–0.7% of the pheromonal components in the extract and 0.2% of the pooled extracts from 87 females (Table 1). A synthetic mixture of the seven compounds was prepared with a

percentage composition identical to the pooled female extracts shown in Table 1. Preliminary assays indicated that the biological potency of the seven-component mixture was equivalent to the extracts of the pickleworm female. This result represented biological proof that the minute amount of diene in the extracts was (*E*,*Z*)-10,12–16:Ald, and it set the stage for an in-depth quantitative analysis of the behavioral responses of males to various sets of the pickleworm compounds.

Flight-Tunnel Assays. Test I results obtained with permutation of the seven pickleworm compounds (Table 2) showed that only two treatments, A and B, elicited behavioral responses from males that were indistinguishable from the responses elicited by female extracts in all behavioral categories of the assay. Treatment A represented all compounds identified from the female extracts and 16:Ald and 16:OH were omitted in B. The assay results indicated that the saturated compounds did not have any detectable communicative function in the flight-tunnel behavioral assay. Male responses to treatments E, F, and H were not statistically different from those elicited by female extracts in five behavioral categories. However, the percentages of male moths that successfully flew upwind to these treatments, lacking (*E*)-11–16:OH and/or (*Z*)-11–16:OH, were significantly smaller than those recorded for the female extracts or treatment B. Therefore, the assay results indicated that the geometrical isomers of 11–16:OH were important to maintenance of male upwind flight in the pheromone plume. Test results showed that upwind flight in the plume was even more dependent upon male perception of a trace amount (ca. 3%) of (*Z*)-11–16:Ald in combination with the four other unsaturated compounds; only 29% of the males tested flew upwind in a plume lacking (*Z*)11–16:Ald (treatment D), and the flight time to this stimulus was significantly greater than the flight time to the female extracts or the five-component mixture of unsaturated compounds (treatment B). In addition, none of the males returned to treatment D after making initial contact with it. The flight-tunnel assay results also showed that (*E*)-11–16:Ald and (*E*,*Z*)-10,12–16:Ald were each essential to elicitation of the activation behavior and upwind flight in the plume; treatments C and G, each lacking (*E*)-11–16:Ald or the trace component (*E*,*Z*)-10,12–16:Ald, were significantly different from female extracts or the five-component mixture in nearly every behavioral category of the assay.

Overall, the flight tunnel assay showed that males must sense a complete set of the five unsaturated compounds listed in Table 1 in order to exhibit a repertoire of behavioral reactions comparable to the repertoire elicited by extracts of the female. These five compounds ostensibly comprised the essence of the female's sex pheromone.

Test II (Table 2) showed that when (*E*,*E*)-10,12–16:Ald was added to a synthetic mixture of pickleworm compounds (treatment A), in a proportion equivalent to that found in the melonworm (1.3:1, (*E*)-11–16:Ald–(*E*,*E*)-10,12–16:Ald) (Raina et al., 1986), the resulting mixture was ineffective in

elicitation of behavioral responses from pickleworm males in all of the behavioral categories of the assay. Test III showed that the (*E*,*E*)-10,12-16:Ald suppressed male pickleworm responses even when the proportional quantity of the compound was reduced by two orders of magnitude from the 1.3:1 proportion found in the melonworm. These results indicate that (*E*,*E*)-10,12-16:Ald had sufficiently detrimental impact on the response of pickleworm males to its female's sex pheromone to identify it as a key substance in the specificity of pheromonal signals for the two *Diaphania* spp.

Field Studies. The results obtained in the field with permutations of the seven pickleworm compounds (Table 3, test I) were similar to the results obtained in the flight-tunnel assay inasmuch as treatments A and B proved to be as effective as the virgin females in luring males into the field traps, and all other treatments except treatment E were significantly less effective than the females. In contradiction of the flight-tunnel assay, the field-trapping results indicated that treatment E was as effective as the virgin females in causing

capture of pickleworm males. This result was somewhat perplexing because tests in the wind tunnel showed that deletion of (*E*)-11-16:OH from the mixture of five unsaturated compounds (treatment E) was detrimental to sustained upwind flight in the pheromone plume. Despite this instance of inconsistency, indications are that the five unsaturated compounds represent the minimum set of compounds required for release of a full repertoire of sexual behavior from the males. It is apparent that the flight-tunnel assay had significant utility in ethological analysis of the roles of compounds in the complex pheromonal stimulus of the pickleworm, and assay results obtained in the flight tunnel were largely in agreement with the field trial results.

Although field test I showed that 0.1 mg treatment A/septum was equivalent to the efficacy of two females in bringing males into traps, test II (Table 3) indicated that this dose or a 0.01-mg dose of A was not equivalent to five females in a trap, but a 1-mg dose of treatment A was as effective as the five females. Test III reaffirmed the comparative efficacy of 1 mg A to five virgin females and demonstrated that 0.818-mg mixture of treatment B (a mixture of the five unsaturated pickleworm compounds) was equivalently effective as a lure source when compared to either treatment A or five virgin pickleworm females. We therefore conclude: a set of five compounds, (*E*)-11-16:Ald (91.6%), (*Z*)-11-16:Ald (4.0%), (*E,Z*)-10,12-16:Ald (0.7%), (*E*)-11-16:OH (2.6%), and (*Z*)-11-16:OH (1.0%), constitutes the female sex pheromone of the pickleworm.

Table 4 shows that four of the five pheromonal components produced by the pickleworm are also components of the melonworm female sex pheromone. The chemical theme expressed by females of both species involves C_{16} chain-length compounds with sites of unsaturation at 11 and 10,12 positions. The geometry of Δ-11 double bond in the melonworm is exclusively *E*, while the pickleworm female produces both isomers. On the other hand, the pickleworm female produces only a trace amount of the *E,Z*-conjugated diene aldehyde while the melonworm produces three of the four possible geometrical isomers of the aldehyde and the *E,E* isomer of the C_{16} alcohol and acetate. Assays in the flight tunnel showed that (*E,E*)-10,12-16:Ald is an essential component of the melonworm pheromone (Raina et al., 1986); however, when it was added to the pickleworm pheromone, the response of pickleworm males was inhibited. These results provide evidence that the *E,E* aldehyde serves as a key substance in the specificity of pheromonal signals between the two species.

Table 4 also shows that both species produce 16:Ald and 16:OH; however, these compounds did not have any detectable behavior-eliciting roles for either species. Similarly for the melonworm, no behavior-eliciting roles were observed for (*E,E*)-10,12 alcohol or acetate.

Heretofore, pheromones having a 10,12-olefinic site have never been reported in the Pyralidae, and it is interesting to note that, among all the moth pheromones that have been identified, the 10,12-diene moiety is rare. Such

unsaturation has been previously detected in only four species: *Bombyx mori* (Kasang et al., 1978; Kaissling et al., 1978), *Manduca sexta* (Starratt et al., 1979), *Earias insulana* (Hall et al., 1980), and *Amorbia cuneana* (McDonough et al., 1982). It seems, therefore, that the biosynthetic processes responsible for generation of 10,12-unsaturation may be narrowly restricted to comparatively few species in the order.

SYNTHESIS OF PUNGENIN, A FOLIAR CONSTITUENT OF SOME SPRUCE SPECIES, AND INVESTIGATION OF ITS EFFICACY AS A FEEDING DETERRENT FOR SPRUCE BUDWORM [*Choristoneura fumiferana* (CLEM.)]

GEORGE M. STRUNZ, PIERRE GIGUÈRE, AND ANTHONY W. THOMAS

Maritimes Forest Research Centre, Canadian Forestry Service

(Received April 3, 1985; accepted June 19, 1985)

Abstract—Pungenin was synthesized from 3,4-dihydroxyacetophenone by a short sequence involving manipulation of protecting groups on the 3 and 4 hydroxyl functions. Bioassays indicated that the glucoside is a modest feeding deterrent for sixth-instar spruce budworm larvae, but it does not appear to retard the development of small larvae or lead to increased mortality.

Key Words—*Picea pungens*, *Picea glauca*, feeding deterrent, spruce budworm, *Choristoneura fumiferana* (Clem.), Lepidoptera, Tortricidae, pungenin, protection of OH groups, glucoside, phenolic glucoside.

INTRODUCTION

Almost 30 years ago, during an investigation of the water-soluble constituents of foliage of Colorado spruce, *Picea pungens* Engelm., Neish (1957, 1958) isolated the glucoside pungenin, in yields up to 5% of the dry weight depending on the age of the foliage. Pungenin, which was also isolated from white spruce (*P. glauca* (Moench) Voss) was characterized as 3-(β-D-glucopyranosyloxy)-4-hydroxyacetophenone (I, Scheme 1) by Neish (1957, 1958) who, in the course of the structure elucidation, synthesized its 4-monomethyl, as well as its pentamethyl ether, but not the natural product itself. The same compound, designated pungenoside was later isolated from *P. pungens*, in an independent investigation by Takahashi et al. (1960).

In a pioneering study on chemical aspects of feeding by the spruce budworm, *Choristoneura fumiferana* (Clem.), on white spruce, Heron (1965) de-

0098-0331/86/0100-0251$05.00/0

SCHEME 1.

scribed laboratory assays which indicated that pungenin behaves as a feeding deterrent for the spruce budworm. In feeding tests where fifth-instar larvae were offered a choice between disks of Japanese elder pith impregnated with a solution of the phagostimulant sucrose and identical disks also treated with the glucoside, he reported that "pungenin had a significant deterrent effect on response to 0.02 M and 0.05 M sucrose at concentrations of 0.8 and 1%, respectively." (To estimate the amount of glucoside actually present in Heron's diet disks, the concentrations of the pungenin solutions used must be multiplied by a factor reflecting the uptake of solution by the pith disks.) Noting that the new vegetative shoots of spruce, virtually devoid of pungenin, are highly acceptable to budworm larvae, while mature needles containing (in winter) up to 5% of the glucoside are not, Heron suggested that the observed feeding preference might be due, in part, to the deterrent effect of pungenin.

There appears to have been little subsequent research on pungenin, although the suggestion that it may be an important feeding deterrent for spruce budworm is still debated by entomologists (Mattson et al., 1983).

This paper reports the synthesis of pungenin, and the results of some bioassays designed to shed more light on its role in the budworm–white spruce interaction.

METHODS AND MATERIALS

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Beckman Acculab 2 spectrophotometer. Nuclear magnetic resonance spectra were run on Varian T-60 or XL-200 instruments. Optical rotations were measured using a Perkin Elmer 241 polarimeter. High-resolution and chemical-ionization mass spectra were provided by Dr. A. Hogg, University of Alberta. Microanalyses were conducted by Spang Microanalytical Laboratory, Eagle Harbor, Michigan.

3,4-Dihydroxyacetophenone

This compound [mp 116–120°, lit (Weast, 1976) 115–116°] was prepared from commercially available acetovanillone, (II), using the procedure of Lange (1962).

3-Benzoxy-4-hydroxyacetophenone

Procedure 1. A solution of 3,4-dihydroxyacetophenone (316 mg, 2.08 mmol) in pyridine (20 ml) was cooled in an ice bath, and benzoyl chloride (0.27 ml, 327 mg, 2.33 mmol) was added slowly with stirring during 5 min. The ice bath was removed, and the mixture was set aside with stirring at ambient temperature in an atmosphere of dry nitrogen for 1 hr. After addition of 4-dimethylaminopyridine (22 mg), the mixture was heated under reflux for 40 hr, cooled, and evaporated to dryness on a rotary vacuum evaporator. The residue was subjected to flash chromatography (Still et al., 1978) on a column of silica gel with chloroform–ethyl acetate (87:13) as eluent, which yielded 3-benzoxy-4-hydroxyacetophenone (378 mg, 71%), as well as the 3,4-dibenzoate (51 mg). The crystalline monobenzoate thus obtained was sufficiently pure to be used directly in the next step. A sample, recrystallized from toluene–chloroform melted at 143–156°, IR (KBr) (inter alia) 3320 (br), 1738, 1660, 1610, and 1590 cm^{-1}; NMR [60 MHz, $(CD_3)_2CO$] δ: 2.52 (3H,s), 7.00–8.27 (8H, m); mass spectrum, *m/z* 256 (M^+), 105 (base peak) ($PhCO^+$). Anal. calcd. for $C_{15}H_{12}O_4$: C 70.30, H 4.72; found C 70.11, H 4.72.

Procedure 2. Benzoyl chloride (0.78 ml, 944 mg, 6.72 mmol) was added slowly to a stirred ice-cold solution of 3,4-dihydroxyacetophenone (442 mg, 2.91 mmol) in dry pyridine (15 ml). The mixture was allowed to attain ambient temperature and was then set aside with stirring under nitrogen for 24 hr. After conventional work-up and flash chromatography on silica gel with carbon tetrachloride–ethyl acetate (92:8) as eluent, crystalline 3,4-dibenzoxyacetophenone was obtained in 96% yield. A sample, recrystallized from carbon tetrachloride had mp 118–121°, IR (KBr) (inter alia) 1750, 1735, 1687, and 1605 cm^{-1}, NMR (60 MHz, $CDCl_3$) δ: 2.61 (3H, s), 7.15–8.15 (13 H, m), mass spectrum, *m/z* 360 (M^+), 105 (base peak) ($PhCO^+$). A solution of 3,4-dihydroxyacetophenone (76 mg, 0.5 mmol) and its dibenzoate (180 mg, 0.5 mmol) in dry pyridine (12.5 ml) containing 4-dimethylaminopyridine (5 mg) was heated at reflux in a nitrogen atmosphere for 18 hr. The mixture was evaporated to dryness in vacuo, and the residue was subjected to flash chromatography on silica gel with chloroform–ethyl acetate as eluent, affording crystalline 3-benzoxy-4-hydroxyacetophenone (197 mg, 77%) and unreacted 3,4-dibenzoate (31 mg).

3-Hydroxy-4-(2-methoxyethoxy)methoxyacetophenone

To a solution of 3-benzoxy-4-hydroxyacetophenone (378 mg, 1.48 mmol) in dry methylene chloride (4 ml) containing diisopropylethylamine (0.39 ml, 289 mg, 2.24 mmol) was added slowly 2-methoxyethoxymethyl chloride (0.25 ml, 273 mg, 2.19 mmol). The reaction mixture was stirred under nitrogen at ambient temperature for 15 hr. Chloroform and brine were added and, after separation of the organic layer, the aqueous phase was extracted with chloroform. The extracts were dried and evaporated in vacuo to give crude 3-benzoxy-4-(2-methoxyethoxy)methoxy-acetophenone, sufficiently pure to be used directly for the next step.

The product, in dry tetrahydrofuran (30 ml), was stirred at ambient temperature with sodium methoxide (280 mg, 5.18 mmol) in a nitrogen atmosphere for 30 min. An aqueous solution of KH_2PO_4 was added until the pH was close to 7, and most of the tetrahydrofuran was then removed on a rotary vacuum evaporator. After addition of more water, the mixture was extracted with chloroform and the extracts were dried and evaporated to dryness in vacuo. The residue was purified by preparative layer chromatography on silica gel with ether as eluent to yield 327 mg (92%) of 3-hydroxy-4-MEM-acetophenone as a colorless oil, IR ($CHCl_3$) (inter alia) 3550, 1678, 1612, and 1590 cm^{-1}, NMR (60 MHz, $CDCl_3$) δ: 2.54 (3H, s), 3.40 (~3H, s) 3.43–3.97 (~4H, m), 5.34 (2H, s), 6.60 (1H, br s), 7.02–7.53 (3H, m), mass spectrum, *m/z* 240 (M^+).

3-(β-tetraacetylglucopyranosyloxy)-4-MEM-acetophenone

A mixture of 3-hydroxy-4-MEM-acetophenone (327 mg, 1.36 mmol), acetobromo-α-D-glucose (1.12 g, 2.72 mmol), and silver oxide (736 mg, 3.18 mmol) in dry quinoline (3.7 ml) was set aside with stirring at ambient temperature in a nitrogen atmosphere for 6 hr. The mixture was diluted with ethyl acetate and filtered through sintered glass. The filtrate was washed with 2 M HCl (3× 15 ml), water (1× 10 ml), saturated $NaHCO_3$ (2× 15 ml), dried, and evaporated in vacuo. The residue, still containing some quinoline, was subjected to flash chromatography on silica gel. The eluent was ether–hexane (4:1), ether (100%), and ether–acetone (95:5) in a stepwise gradient. The MEM-tetraacetylglucoside (770 mg) was obtained as a colorless oil, sufficiently pure to be used directly in the next step, IR ($CHCl_3$) 1756, 1748 (infl), and 1681 cm^{-1}, NMR (60 MHz), $CDCl_3$) δ: 2.05–2.08 (12 H, m) 2.54 (3H, s), 3.37 (3H, s), 3.43–4.30 (7H, m), 4.88–5.42 (6H, m), 7.08–7.78 (3H, m), mass spectrum, (CI, NH_3) m/z 588 $(M+NH_4)^+$.

3-(β-Tetraacetylglucopyranosyloxy)-4-hydroxyacetophenone

A mixture of the 4-MEM-3-tetraacetylglucoside (770 mg, 1.35 mmol) and zinc bromide (1.52 g, 6.75 mmol) in dry methylene chloride (3.0 ml) was stirred at ambient temperature under nitrogen for 24 hr. The mixture was poured into

saturated sodium bicarbonate solution (20 ml) and ethyl acetate (20 ml). The mixture was filtered through sintered glass, the aqueous phase was separated, and the organic layer was washed twice with saturated sodium bicarbonate solution and twice with brine. The ethyl acetate solution was dried and the solvent was removed under reduced pressure. The residue was subjected to preparative layer chromatography on silica gel with ether as eluent, which afforded the 4-hydroxy-3-tetraacetyl glucoside (tetraacetyl pungenin) (495 mg, 76%) as an oil, which gave crystals from ether–cyclohexane, mp 106–112°, IR ($CHCl_3$) 3525, 1755, 1675, and 1605 cm^{-1}, NMR (200 MHz, $CDCl_3$) δ: 2.06 (3H, s, $-OCOCH_3$), 2.07 (3H, s, $-OCOCH_3$), 2.12 (3H, s, $-OCOCH_3$), 2.14 (3H, s, $-OCOCH_3$), 2.55 (3H, s, $ArCOCH_3$), 3.89–3.98 (1H, 8 line m, C-5′H), 4.17–4.34 (2H, 8 line m, C-6′H_2), 5.04–5.40 (4H, m, H on C-1′, C-2′, C-3′, C-4′) 6.42 (1H, s, OH), 7.00 (1H, d, J = 8.9 Hz, C-5H), 7.66 (1H, dd, J = 2.0 Hz, 8.9 Hz, C-6H), 7.65 (1H, d, J = 1.9 Hz, C-2H), mass spectrum (CI, NH_3) m/z 500 $(M+NH_4)^+$, mass spectrum (EI) m/z 331.1027 (13%) ($C_{14}H_{19}O_9$) [cleavage at C-1′/O(C-3)], 169.0499 (base peak) ($C_8H_9O_4$), 109.0293 (96% ($C_6H_5O_2$).

Pungenin

Dry ammonia was bubbled into an ice-cold solution of the 4-hydroxy-3-tetraacetylglucoside (248 mg, 0.514 mmol) in dry methanol (10 ml) for 40 min. The solution was allowed to attain ambient temperature and was set aside with stirring for 15 hr, after which it was evaporated to dryness in vacuo. The residue crystallized from water to give pungenin (72%), first crop (65 mg) mp 190–195°, second crop (51 mg) mp 188–195° [lit. Neish (1957) 198–199°, Takahashi et al. (1960) 190–191°], mp undepressed on admixture with a sample isolated from *P. glauca* according to Neish (1957), $[\alpha]_D$-88.9° (c 0.53, water) [lit. Neish (1957) $[\alpha]_D^{25}$ − 96.8 (c 0.53 water), Takahashi et al. (1960) $[\alpha]_D^{30}$ − 85.47 (c 1.17 water)], IR (KBr) 3300 (br), 2930, 2885, 1664, 1590, 1521, 1425, 1360, 1295, 1257, 1212, 1193, 1123, 1108, 1093, 1053, 1042, and 1022 cm^{-1}, NMR [200 MHz, $(CD_3)_2CO$] δ: 2.48 (3H, s, $-COCH_3$) 2.83 H_2O ?), 3.52–3.50 (4H, m) (masked on addition of D_2O), 3.96–3.66 (4H, m) (modified on D exchange), 4.31 (1H, d, J = 3.8 Hz) (exch), 4.42 (1H, m) (exch), 4.86 (1H, d, J = 7.3 Hz, anomeric H), 5.14 (1H, br) (exch), 6.94 (1H, d, J = 8.4 Hz), 7.66 (1H, dd, J = 8.4 Hz, 2.1 Hz), 7.81 (1H, d, J = 2.1 Hz), mass spectrum (CI, NH_3) m/z 332 $(M+NH_4)^+$, mass spectrum (EI) m/z 314.0960 (0.44%) $C_{14}H_{18}O_8$, M^+), 152.0477 (100%) ($C_8H_8O_3$) 137.0242 (57%) ($C_7H_5O_3$). Anal. calcd. for $C_{14}H_{18}O_8$: C 53.50, H 5.77; found C 53.46, H 5.76.

Bioassays

Sixth Instar: Paper. Spruce budworm larvae were reared on modified McMorran diet (McMorran, 1965; Grisdale 1970), from the second instar (beginning of feeding) to the end of the fifth instar.

The bioassay procedure of Bentley et al. (1982, 1984) was followed with a few modifications. Assay disks were 1.3 cm diameter analytical paper circles (mean weight 44 mg) (Schleicher and Schuell) treated with the appropriate solution(s) of pungenin and/or phagostimulant. Pungenin was tested at levels of 1, 2, 4.3 and 5% (based on dry weight of disk plus applied phagostimulant), using 10 larvae, five of each sex, for each concentration and for the corresponding controls.

Differences in frass counts between larvae of the same sex on test and control disks were not significant at the 5% level of probability. (In this experiment male larvae produced significantly more frass pellets than females, reflecting different ages within the sixth instar.)

Sixth Instar: Diet. The meridic diet used for the major bioassay was a modification of the standard McMorran formula (McMorran, 1965), with nutrient quantities adjusted so that the weight of diet ingested would approximate more closely the weight of foliage normally consumed by spruce budworm larvae (cf. Miller, 1977). Thus, the caseine, sucrose, and salt mixture were reduced to 25% of their levels in the standard diet and the Alphacel content was increased 13-fold. The hot diet was poured into Petri dishes and allowed to cool. Disks of the diet (2 cm diam.) were cut out with a cork borer and were freeze-dried and weighed. In this manner, porous diet disks of suitable weight ($\sim$250 mg) could readily be prepared. About 1 ml of a freshly prepared aqueous solution of natural pungenin and potassium sorbate (fungicide) was added slowly to each test disk to give disks containing 4.76–4.78% pungenin and 0.19% sorbate (both dry weight), and 79% water content. Control disks received only the water and potassium sorbate.

Newly moulted, unfed, sixth-instar spruce budworm larvae were placed into separate 35 $\times$ 10-mm Petri dishes, each containing a test or control disk. The experiment involved 15 male and 15 female larvae on the test diet, and 15 larvae of each sex on the control food, all maintained at 22°C, with a 17-hr photoperiod. After the moult, pupae were removed and placed in separate vials until emergence of adults, which were killed 24 hr later.

Residual diet, frass produced, and moths were oven-dried at 60°C, and weights of diet consumed, frass produced, and adult moths were used as indices of budworm performance.

Second to Sixth Instars: Diet. Powdered lyophilized McMorran-Grisdale diet (Grisdale, 1970) (850 mg) was treated with a solution containing natural pungenin (45 mg) and potassium sorbate (1.8 mg) in distilled water (3.4 ml). Vigorous mixing produced a paste containing pungenin (5%) (dry weight) and sorbate (0.2%) which was transferred in approximately 100 mg portions to 4 ml vials. Control diet lacked the pungenin.

Newly emerged (from hibernacula) second instar larvae were placed in separate vials (32 test, 40 controls) and reared at 25°C, with a 17-hr photoper-

iod. Because the amount of pungenin available was insufficient to prepare enough diet for complete development of larvae to pupae, the experiment was terminated when the larvae moulted to the sixth instar.

RESULTS AND DISCUSSION

The aglucone of pungenin, 3,4-dihydroxyacetophenone, can be prepared in some 70% yield from commercially available acetovanillone, (II) by aluminum chloride-catalyzed cleavage of the methyl ether (Lange, 1962). It was anticipated that the greater acidity conferred on the C-4 hydroxyl group by the *para* acetyl function would enable the phenolic hydroxyl groups of 3,4-dihydroxyacetophenone to be differentiated readily. In fact, although attempts at direct protection of the C-4 hydroxyl group by a variety of procedures led predominantly to the desired products, the degree of selectivity of the process left much to be desired. This problem was overcome by the development of an indirect procedure, which allowed the 4-MEM ether of 3,4-dihydroxyacetophenone to be prepared selectively in satisfactory yield.

The ease with which acyl migration can occur in catechol monoesters (Fischer et al., 1918), and the stability of the 4-acylphenolate anion suggested that base-catalyzed acylation of 3,4-dihydroxyacetophenone under equilibrating conditions should result in derivatization of the 3-hydroxyl group in a highly selective manner. This expectation was largely realized on treatment of the diol with an equivalent of benzoyl chloride in pyridine containing a catalytic amount of dimethylaminopyridine (Steglich and Höfle, 1969). The reaction mixture, heated under reflux for 40 hr, afforded a 71% yield of 3-benzoxy-4-hydroxyacetophenone. The dibenzoate was recovered as a minor biproduct ($\sim$7%).

An alternative procedure, which gave a slightly improved yield (overall 74%), consisted in refluxing 3,4-dihydroxyacetophenone with one equivalent of its dibenzoate for 18 hr in the pyridine–dimethylaminopyridine system.

Derivatization of the C-4 phenolic hydroxyl group by means of 2-methoxyethoxymethyl chloride (Corey et al., 1976), followed by methoxide-catalyzed cleavage of the benzoate, afforded the desired 4-MEM ether of 3,4-dihydroxyacetophenone in 68% overall yield from the dihydroxy precursor.

The location of the MEM protecting group was confirmed by remethylation of the C-3 hydroxyl function with methyl iodide-potassium carbonate and zinc bromide-catalyzed cleavage of the MEM ether (Corey et al., 1976), which afforded acetovanillone identical with the starting material.

Glycosidation of the free 3-hydroxyl group was effected in excellent yield with acetobromoglucose and silver oxide in dry quinoline (Kubinyi et al., 1973). The MEM protecting group was removed by zinc bromide treatment (76%) and, finally pungenin was generated by treatment of the tetraacetyl glucoside with methanolic ammonia solution. The overall yield of pungenin from 3,4-dihydroxyacetophenone was 36.7%.

In preliminary bioassays using the method of Bentley et al. (1982, 1984), we were unable to observe significant reduction of feeding by sixth-instar spruce budworm larvae as a result of treating paper diet disks with synthetic pungenin at levels up to 5% (calculated on dry weight of paper test disk plus phagostimulant). The apparent disparity between these findings and Heron's observations undoubtedly stems from differences in the bioassay conditions used (Schoonhoven, 1982).

In a more sensitive test, sixth-instar larvae were offered a meridic diet (cf. McMorran, 1965) containing natural pungenin at a concentration of 4.76%. While in the observed sample the performance of male larvae on test and control diets, as reflected in weights of diet consumed, frass produced, and adult moths, did not differ significantly ($P > 0.05$; Student's t test) female larvae, which ate more than the males, were affected more noticeably, and the corresponding weights were some 30% lower for test insects than for controls (Table 1).

Linear relationships, with similar slopes (1.20–1.29) and intercepts, were observed on plotting dry weight of diet consumed against dry weight of frass produced for all larvae studied (test, control, male, female). The approximate digestibilities (AD) (Waldbauer, 1968) were also similar (Table 1). Both of these characteristics indicate that pungenin did not affect food digestion. Digested food is the difference between the amount of food ingested and the amount of frass egested. The ratio of food digested to moth weight gives the amount of digested food required to produce unit weight of moth. Figures for the males, 3.83 (controls) and 3.90 (test), were not significantly different. The difference for the females, 3.21 (controls) and 4.09 (test), was significant and indicates that pungenin caused conversion of the digested food to be less efficient for these larvae. The presence of pungenin in the diet did not cause any increase in mortality, and other than the reduction in size of the test females, both test and control insects appeared to develop normally to the adult stage. It is likely

TABLE 1.

Larvae	N	Diet consumed (mg, mean ± SE)	Frass produced (mg, mean ± SE)	A.D[a]	Moth weight (mg mean ± SE)
♂ ♂ Control	15	146 ± 7.4a[b]	111 ± 5.7b	23.8	9.2 ± 0.6c
♂ ♂ Test	11[c]	133 ± 8.6a	102 ± 6.9b	23.3	8.2 ± 0.7c
♀ ♀ Control	14[d]	243 ± 7.2	184 ± 5.8	24.3	18.5 ± 0.9
♀ ♀ Test	12[c]	177 ± 16.5	131 ± 12.6	26.1	12.4 ± 1.7

[a] AD = approximate digestibility (16) = 100 [(diet consumed − frass produced)/diet consumed].
[b] Within-sex means with same letter in a column are not significantly different ($P > 0.05$); Student's t test.
[c] Missing samples discarded because of fungal contamination.
[d] One pupa died ($N = 14$).

that female fecundity, which correlates with moth size, would have been affected, but this was not investigated.

To examine the effects of pungenin on smaller larvae, insects were reared from second to sixth instar on a diet containing 5% of the glucoside. Because the amount of pungenin available was insufficient to prepare enough diet for complete development of larvae to pupae, the experiment was terminated when the larvae moulted to the sixth instar.

The first moult to sixth-instar occurred on day 9 of the experiment. By day 21, 15 of the control larvae (37.5%) and 11 of the test larvae (34.4%) had died. Of the 25 control larvae alive on day 21, 15 (60%) had moulted to sixth instar, and 19 (90%) of the 21 living test insects had reached the same stage. Although the mortality in the control was higher than expected, we have found no evidence that pungenin (5%) caused increased mortality or retarded development up to the beginning of the sixth instar.

Heron's bioassays, based on choice situations, led to the suggestion that the presence of pungenin may be a contributing factor in the preference of large budworm larvae for new vegetative shoots over mature needles (Heron, 1965), and the present results are not at variance with this hypothesis. It is clear, however, that the compound does not prevent mature needles from being mined by second-instar larvae in the spring.

The present work demonstrates that spruce budworm larvae are capable of developing successfully on a diet containing pungenin at concentrations close to the highest natural levels reported, but that the resulting female insects are smaller than normal.

Acknowledgments—We thank Larry Calhoun and Ashok Patil, University of New Brunswick, for providing 200 MHz NMR spectra and optical rotation measurements, respectively.

(Received March 21, 1985; accepted June 21, 1985)

Abstract—A number of chemical compositions known to attract several synanthropic and pest fly species were tested against the Australian bush fly *Musca vetustissima*, a severe and persistent pest of man and domesticated and wild mammals. A standard composition containing small quantities of trimethylamine and indole, blended with large amounts of ammonium sulfate and anchovy meal, showed good attractancy against this fly. Deletion of ammonium sulfate did not significantly alter attractancy. Similarly, incorporation of *n*-butyric acid and linoleic acid into the formulation did not alter attractancy, nor did addition of several carbonates and bicarbonates. Skatole, a closely related compound to indole, decreased attractancy significantly. In all the tests, the attractant compositions lured greater number of females than males. The attractancy of the standard composition was studied and compared with equal amount of fresh cattle dung. Chemical attractants lured bush flies and not dung beetles, while dung attracted both flies and beetles. The dung resource was 4.6× more attractive to flies than the standard attractant composition. This suggests that there are other chemical attractants emanating from dung that warrant isolation and identification work. Nevertheless, the chemical attractants studied here provide a starting point for further investigations. The ratio of female to male flies attracted to humans was greater than the ratio of flies attracted to chemicals. The sex ratio of flies netted from human host was 3.0, while the sex ratio of flies attracted to chemical attractants was 1.8. The preponderance of females attracted to both sources was probably due to physiological requirements of the sexes.

Key Words—Bush fly, Australian bush fly, *Musca vetustissima*, Diptera, Muscidae, chemical attractants.

INTRODUCTION

Early explorers in Australia noted the pestiferous nature of the Australian bush fly *Musca vetustissima* Walker, some three centuries ago (Cleland, 1913). One of the explorers, John Lort Stokes, in 1838 related that "the flies are at you all day, crawling into your eyes, up your nostrils and down your throat" (Hooper, 1982). The nature and scope of annoyance brought about by these flies remains the same today.

This pest is widely spread over most of the continent (Hughes et al., 1972) and is especially abundant in cattle-raising areas. They breed in dung, preferring freshly deposited dung of cattle (Hughes, 1981; Hughes et al., 1972; Norris, 1966). Adult bush flies are attracted to large animals, including man, females outnumbering the males attacking or landing on hosts (Hughes, 1977, 1981; Hughes et al., 1972; Norris, 1966). We have noted that the flies can find the host in a few seconds in the field and that flies at some distance orient and move upwind toward the hosts. Chemical odors emanating from hosts or breeding medium (dung) are some of the factors providing cues for directed response by the flies. However, no definitive studies on the role of chemical attractants influencing bush fly behavior have been accomplished on this important synanthropic and synzootic fly.

The hovering and feeding behavior of bush flies approaching and attacking hosts is quite similar to that of the tiny flies known as eye gnats (*Hippelates* species, family Chloropidae) prevailing in the Western hemisphere (Mulla and Stains, 1977). Chemical attractants inducing positive responses in female *H. collusor* (Townsend) were isolated and identified from putrified chicken eggs (Hwang and Mulla, 1973; Hwang et al., 1975, 1976) and field tested by Mulla and Axelrod (1974) and Mulla et al. (1974, 1976). Some of the principal chemicals attracting *H. collusor* were also found to manifest a high level of attractancy against the common house fly *Musca domestica* (Mulla et al., 1977), and the coastal lesser house fly *Fannia femoralis* on poultry ranches (Mulla et al., 1984).

It is well known that many species of synanthropic and synzootic flies are attracted by odors emanating from putrefying proteins. *Musca sorbens*, a closely related species to *M. vetustissima*, was found to be attracted to putrefying egg and fish meat (Legner et al., 1974), and baiting of an insular population with these baits reduced populations of *M. sorbens* markedly. *M. vetustissima* has been found to be attracted to liver baits with sodium sulfide (Hughes, 1977; Norris, 1966; Vogt et al., 1981). Most recently Vogt et al. (1985) have used a mixture of putrefying liver and dung with live blow fly maggots to stir the bait for the purpose of trapping bush flies.

In view of these findings and the extensive research on the isolation and identification of chemicals showing field attractancy to a variety of pest flies, the present studies were initiated. Compositions of chemical attractants with

proven attractancy to *Hippelates*, *Musca*, and *Fannia* species were evaluated against the Australian bush fly. A simple method for field evaluation of attractant compositions was developed, where attractancy of various chemical compositions and natural attractants emanating from fresh dung was tested against field populations of *M. vetustissima*.

METHODS AND MATERIALS

Compositions of chemical attractants found attractive to the eye gnat *Hippelates collusor* (Hwang et al., 1975, 1976; Mulla et al., 1976), *Musca domestica* (Mulla et al., 1977), and *Fannia femoralis* (Mulla et al., 1984) consisted of mixtures of a carrier (anchovy meal) with one or more of the following chemicals: trimethylamine (from trimethylamine hydrochloride), ammonia (from ammonium sulfate), indole, linoleic acid, and a few lower aliphatic acids. Against the bush fly, a composition containing anchovy meal carrier (57.25%), trimethylamine hydrochloride (2.5%), ammonium sulfate (40%), and indole (0.25%) by weight was used as a standard mix with which other compositions with fewer or more chemicals were compared for luring the flies. When additional chemicals were included or deleted, the content of carrier was varied in the composition accordingly.

The composition was mixed in 1:1 ratio with Improved Golden Malrin (IGM) (Zoecon Corporation, Dallas, Texas) toxic bait. The ingredients of this bait are: 1% methomyl, 0.025% (*Z*)-9-tricosene, and 98.97% inert ingredients. Fine sand (780 g) forming a 2-cm layer was placed in a plastic bowl (18 cm diam. and 8 cm deep) and wetted with 140 ml of tapwater, bringing the moisture content initially to its field capacity level. For testing, a 5-g quantity of each mix was placed on the damp sand. In some tests, especially in testing attractancy of dung, the IGM was not mixed with the attractants, but rather it was spread on the top and around the dung or other attractant compositions.

The bowls (replicated five to six times in each experiment) containing various test attractant compositions were placed on the ground 5 m apart in paddocks infested with bush flies. They were distributed in randomized-block design in a line at right angles to the wind direction or in a circular pattern. The tests were run in two areas near Perth, Western Australia. The Serpentine area, with extensive livestock pastures, is located in the coastal plain 100 km south of Perth, while Cunderdin, a predominantly wheat growing and pasturing area, is located on the Darling plateau 150 km east of Perth.

Flies attracted to the compositions oriented toward the attractant source and crawled or flew into the bowls, walking and milling around the attractant–toxicant compositions. Because of the action of the quick-acting toxicant methomyl, the flies on contact with the bait died in the bowl within a few seconds after arrival. All flies killed in the bowls were counted with no loss due to wind

or transportation into the laboratory. The compositions were exposed in the field for a period of 4–6 hr for each experiment, depending on the activity of bush flies. After termination of each experiment, the bowls were covered with lids and brought into the laboratory where the flies were identified, sexed, and counted under a dissecting microscope.

Analysis of data was carried out using standard computer program design for randomized-block analysis. The data were transformed to log $(n + 1)$ when fly numbers were high and variable. Transformed means were compared for significant differences using Duncans's multiple-range test, letter designations for denoting significant differences are shown on untransformed means for ease of interpretation. Where there were two treatments in a given test, the transformed data were analyzed by means of t test. Significant differences between or among means are expressed in the tables.

RESULTS AND DISCUSSION

Since the attractant composition utilized fish meal as carrier and Improved Golden Malrin (IGM) as a toxicant, it was necessary to test the attractancy of these two components. Fish meal and IGM (1:1) and IGM alone were compared in the first test. The fish meal showed a low level of attractancy which was significantly higher than that of IGM alone (Table 1). When the standard composition plus IGM was compared with fish meal plus IGM, the standard composition caught significantly higher numbers than the carrier (Table 1, test II). In a third test, this comparison was repeated, and again the standard attracted significantly higher numbers than the carrier (Table 1, test II-A). On the basis of these data, it was concluded that a composition containing three chemicals, carrier, and IGM was more attractive than the carrier plus IGM to field popu-

lations of the Australian bush fly, but the carrier itself did show some attractancy also.

Compositions were prepared in which one of the three chemicals in the standard was deleted to see if deletion of each chemical would result in increased or decreased attractancy. The standard composition attracted significantly higher numbers than the compositions lacking trimethylamine hydrochloride or indole (Table 2). The composition lacking ammonium sulfate was not significantly different from the standard.

In studies on *Hippelates* eye gnats and house flies, *n*-butyric acid was found to increase the attractancy of chemical compositions (Hwang et al., 1975; Mulla et al., 1977). We deemed it desirable to study attractancy of this chemical, ammonium carbonate, and sodium carbonate in the standard composition (Table 3). *n*-Butyric acid and ammonium carbonate did not enhance attractancy. Addition of sodium carbonate, however, increased attractancy of the composition. Additionally, calcium carbonate and sodium bicarbonate were studied for enhancing attractancy, but neither one significantly increased attractancy (data not presented).

D (standard)	2.5	0.25	40.0	57.25	27.2 b

[a] $N = 6$. Means followed by same letters are not significantly different from each other at 0.05 level.

Skatole, a chemical closely related to indole, has been reported to be attractive to certain fly species and to *H. collusor* in particular (Hwang et al., 1976). This material at 0.25% concentration was added to the standard formulation. The standard composition lacking skatole attracted a mean number of 66.5 ± 18.5 flies per unit compared to 9.3 ± 2.0 flies per unit in the composition containing skatole. The means were significantly different from each other at 0.05 level. It is possible that the combined concentration of indole and skatole was too high or that skatole is acting as a repellent against the flies.

One further test was designed to evaluate the addition of *n*-butyric acid and linoleic acid to the standard composition and to delete ammonium sulfate, replacing it with *n*-butyric acid (Table 4). Addition of both linoleic and *n*-butyric acid did not significantly alter response of flies from that of the standard. However, deleting ammonium sulfate and replacing it with *n*-butyric acid significantly decreased attractancy as compared to that of the standard. Ammonium sulfate provides bulk and improves flowability and handling of the formulation. Therefore its inclusion aside from attractancy is desirable. The IGM alone attracted very few flies.

Attraction of Bush Flies and Dung Beetles to Chemicals and Dung. Bush flies and dung beetles are attracted to cattle dung. Dung beetles are employed as biological control agents to disperse cattle dung for improving pastures and to reduce bush fly production in dung pads (Ridsdill-Smith, 1981; Ridsdill-Smith and Matthiessen, 1984). Bush flies are highly attracted to freshly dropped cattle dung pads or older pads when the surface is scraped (Figure 1). During the course of our studies, we noted that large numbers of bush flies were attracted to fresh dung pads for a short period and dung attractancy declined in time as the pads crusted.

To test and compare the attractancy of dung and chemical compositions tested, fresh dung and toxicant were tested in the experimental system designed.

[b] $N = 5$. Means followed by same letter are not significantly different from each other at 0.01 level.

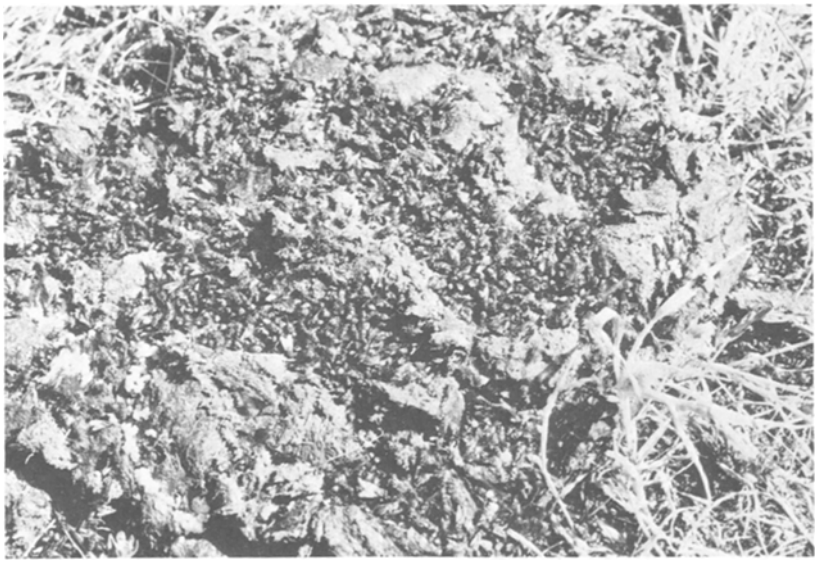

FIG. 1. Attraction of *M. vetustissima* to 1-day-old dung pad when its surface was scraped off. Flies are not attracted to such old pads; attraction ensues when the surface crust is removed. This indicates release of trapped volatiles in the pad covered with a hard crust.

Almost five times more flies were attracted to equal amounts of the dung than the chemical attractants (Table 5). The magnitude of attractancy of dung was significantly different from the chemical attractants. Dung beetles, *Onthophagus binodis* Thunberg and *Euoniticellus pallipes* (Fabricius), prevalent during the test, were not attracted to the chemical attractants but were lured to the dung in large numbers. It thus seems that bush flies and dung beetles utilize, in part, different cues for oviposition and feeding on the dung pads. Formulations of toxic chemicals and attractant compositions, if used in bush fly control programs, would not attract and harm the beneficial beetle fauna inhabiting this resource.

Relative Attraction to Chemicals and Humans and Fly Sex Ratios. Activity of bush flies is influenced by many factors, among which temperature and wind velocity play an important part. Due to variation in environmental conditions, activity patterns of bush flies are quite variable. The extent of population activity can be roughly measured by sweeping in a standard manner from human hosts (Hughes, 1970) and the numbers sampled corrected for influence of temperature.

On each day where chemical attractant compositions were exposed in the field, flies coming to a human host were netted in a 20-min sample, sexed, and counted. The data in Table 6 clearly indicate a great deal of variation in the numbers of flies either attracted to chemicals or human hosts in the different

experiments. In general, as the extent of attractancy to humans increased, so did attractancy to compositions of chemical attractants. However, there were instances where trends of attractions to the two sources did not follow the same trend.

The sex ratio of bush flies coming to human hosts was more in favor of females. The sex ratio of female to male was 3.0 for flies attracted to human

hosts, while the same ratio in flies attracted to the standard chemical attractant composition was 1.8. Since the sex ratio of flies emerging from pads is usually 1:1 (Hughes et al., 1972), the bias in sex ratio of flies attracted to hosts or attractant compositions is probably due to the physiological status of females requiring food for oogenic development and may vary with the age of flies, presence of other sources of protein, time of year, and composition of the bait (Hughes, 1981).

Measurement of quantitative responses of bush flies to chemical attractant compositions and to natural attractants emanating from fresh dung offers some interesting possibilities for further study and development of chemical attractants in bush fly control programs. It is apparent that the attractant compositions studied here are lacking one or more chemical attractants present in the dung, and isolation, identification, and evaluation of chemical attractants from dung sources warrant further studies. Nevertheless, this is the first attempt to test and evaluate chemical attractants against the widely distributed pest fly *M. vetustissima*.

It should be pointed out that the behavior of *M. vetustissima* is quite complex and variable, and is influenced by many environmental and physiological factors. Chemicals showing very low levels of attractancy will not provide a distinct separation in the behavioral response of this fly under different conditions. Further studies are warranted to work out concentration–attractancy relationships for these chemicals under various field conditions.

It is equally evident (Figure 1) that, due to the very high potency of chemical attractants emanating from dung pads, the dung pads can be used for attracting natural populations of flies and killing them on the pads with the application of suitable toxicant formulations. Addition of toxic bait to dung pads resulted in the kill of at least 1000 flies on one treated dung pad in 15–30min. In view of the low absolute density of bush flies, found to be 9000 flies/acre in one study (Norris, 1966) and less than 100 flies per acre during March in another study (Vogt et al., 1981), marked local reduction of flies could be achieved by treating dung pads in infested areas. Before such a program can be implemented, detailed studies on population dynamics and behavioral aspects of the pest are in order.

Acknowledgments—The authors would like to acknowledge the assistance of Harold Axelrod of the Department of Entomology, University of California, Riverside, California, in the preparation of attractant compositions, and of John Matthiessen of CSIRO Division of Entomology, Perth, Western Australia, for advice on bush fly sampling methods.

CHEMICAL DETECTION OF "SELF" AND CONSPECIFICS BY CRAYFISH

R.D. ROSE[1]

Department of Biology, Emory University
Atlanta, Georgia 30322

Department of Neurobiology and Behavior
The State University of New York at Stony Brook
Stony Brook, New York 11794

(Received March 11, 1985; accepted June 27, 1985)

Abstract—Stimulus waters were used to examine behaviorally chemical communication in female crayfish *Procambarus clarkii*. Animals detected conspecifics. Response to stimulus water drawn from the animal's own tank, "self" water, mimicked either response to distilled water or response to water drawn from the tank of another animal. The response to "self" water depended on the relative concentration of substance(s) in "self" water stimuli to that of the same substance(s) in the test animal's tank.

Key Words—Chemical detection, chemical communication, self, recognition, *Procambarus clarkii*, crayfish.

INTRODUCTION

Chemical communication by crayfish has been shown in a number of species (e.g., Ameyaw-Akumfi and Hazlett, 1975; Hazlett, 1985; Little, 1975; Tierney and Dunham, 1982; Tierney et al., 1984) and has spawned at least one controversy concerning sexual recognition pheromones in *Procambarus clarkii* and the methodology used to assess such pheromones' existence and extent (Itagaki and Thorp, 1981; Thorp and Itagaki, 1982; Thorp, 1984; Rose, 1982, 1984; Hazlett, 1984). Detection and recognition of "self" have been largely ignored on the behavioral level (but see Teague and Friou, 1964; McCumber and Clem, 1983, concerning recognition of immunological "self"). Indeed, "self" has recently been used as a control in studying responses to "nonself" (Hazlett,

[1] Current address: Department of Neurobiology and Behavior, The State University of New York at Stony Brook, Stony Brook, New York 11794.

0098-0331/86/0100-0271$05.00/0

1985, p. 187). The present study identifies one complication of using "self" as a control (or comparison) for chemical communication studies, i.e., that "self" can appear as either "self" or "nonself" depending on experimental conditions. Portions of this work have been reported previously in abstract form (Rose and Casper, 1980).

METHODS AND MATERIALS

Mature nongravid female intermolt crayfish (*Procambarus clarkii*; 40–60 mm carapace length; mean wet weight 31.1 g ± 7.4 SD) were obtained from commercial suppliers in Louisiana. They were housed individually in glass aquaria (20 × 40 × 25 cm high) for five days prior to experimentation. Each aquarium contained ~2 liters distilled H_2O and was aerated strongly via an airstone. Each animal was fed frozen fish daily, the uneaten tissue being removed after 30 min. If the water clouded, it was changed and the acclimation procedure started over. Temperature was maintained at 20–25° C (see Thorp, 1978; Itagaki and Thorp, 1981, concerning the effects of temperature on activity). Fluorescent overhead lighting was maintained 24 hr/day; the room was also sunlit. Experiments were performed at night (2100–0200 hr) because pilot studies indicated increased nocturnal activity. The presence of light did not appear to inhibit the activity of the test animals. In no tests were the subject animals handled or their aquaria moved or disturbed immediately prior to testing.

Behavioral variables were quantified temporally (with stopwatch and a system of alphabetic codes) with respect to resting, locomotion, and nonspecific nonlocomotory movement behaviors such as feeding and grooming. Locomotion was further subdivided into near, within 1 cm, and distant, elsewhere, with respect to the stimulus source (see below, see also Ameyaw-Akumfi and Hazlett, 1975).

Stimulus waters were obtained by gently scooping 50 ml from the source aquarium 1 hr before testing (except distilled H_2O). Stimulus waters were dripped from a burette (~0.3 drops/sec) onto the airstone during tests. This procedure precludes any response which could be due to mechanical agitation of the surface of the water. In pilot studies, both normal and blinded crayfish oriented to very slight agitations of the surface of previously calm water in their tanks.

Four treatments (described below) were used: (1) water collected from the animal's own tank ("self" water), (2) distilled H_2O, (3) "self" water–diluted test tank, and (4) water from the tank of another isolated nongravid female ("nonself" water). While treatments 2 and 4 are self-explanatory, treatments 1 and 3 are quite similar: the difference between these treatments is in the solute concentration of the environment rather than the stimulus. For treatment 1, 50 ml tank water was drawn 1 hr before testing. This water *was not* replaced.

Treatment 3 was accomplished as follows: 50 ml tank water was drawn from the test animal's tank 1 hr before testing. This water *was* replaced with 50 ml distilled H_2O which diluted the test tank by $<3\%$. This meant that the stimulus water was effectively at a higher concentration than the water currently in the tank. It is assumed that the test animal does not replenish all substances within the hour.

The rationale for each treatment is as follows: (1) "self" water represents no change in substance concentration, (2) distilled water represents an infinite dilution of virtually all substances, (3) "self" water–diluted tank represents the same stimulus as (1) but is presented in a relatively more concentrated form, and (4) "nonself" water represents the presence of a conspecific.

Test order and animals used for each test were randomized. Animals were used in a given treatment only once and only once as source or test animal on a given day. Animals were observed through a one-way screen. Test duration was 1 hr. Data were collected and analyzed in seconds. There were five to six replicates of each experiment.

RESULTS

Results are shown in Figure 1. ANOVAs of each variable show overall differences (at least $P < 0.05$). Note that female *P. clarkii* can detect conspecifics chemically (comparison of treatments 1 and 2 with 4), but appear unable

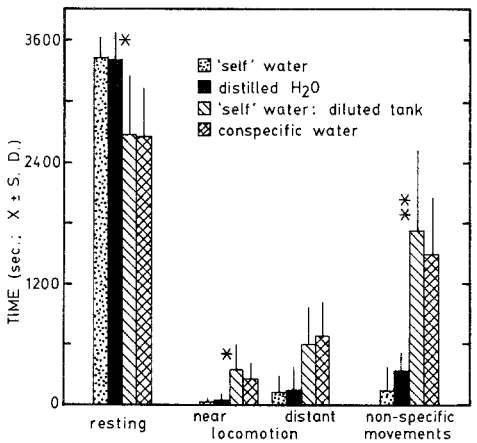

FIG. 1. Behavior of female *P. clarkii* in response to stimulus waters. Stars indicate *t*-test significance levels of the middle two means when means are rank ordered, e.g., in "locomotion, near" the means compared would be those of treatments 2 and 4. Single star, $P < 0.05$; double star, $P < 0.01$. In "locomotion, distant" significance level between 2 and 3 is $P = 0.06$; other apparent differences, e.g., 1 and 3 or 2 and 4 are $P < 0.05$.

to distinguish other individuals from themselves (i.e., the results from "non-self" and "self-diluted tank" are virtually identical, cf. treatments 3 and 4). Also, similar "self" stimuli (treatments 1 and 3) evoked significantly different responses when presented to crayfish in only slightly different environments.

DISCUSSION

Chemical recognition of "self" probably occurs widely throughout the animal kingdom. However, there is little direct evidence concerning this phenomenon. Limpets are believed to lay chemical trails when foraging that allow the individual to find its former resting position (home scar) on a rock (Cook et al., 1969; Cook, 1969). Yet I know of no evidence indicating whether these animals can distinguish their own trails from those of other limpets. Many male mammals chemically mark territories (e.g., canids, Kleiman, 1966; lorisids, Ilse, 1955). One would expect such animals to distinguish their own marks from those of conspecifics (e.g., lorisids, Seitz, 1969). Honeybees, *Apis mellifera*, a species where many consider the hive to be the individual, use "hive atmosphere" (LeComte, 1956) to chemically identify individual hives which are readily recognized by their members. Recently, two systems (salmon, Quinn and Busack, 1985; shrimp, Caldwell, 1985) have been described which should readily lend themselves to studies of chemical recognition of "self." Theoretical considerations of animal communication, in particular the biological necessity of the concept of "self" and self-recognition, are discussed in the (thoroughly entertaining) review of Markl (1985).

The behavioral variables monitored in the present study were chosen for historical reasons (see for example Ameyaw-Akumfi and Hazlett, 1975) and ease of categorization. They are not necessarily independent (see Hazlett, 1985, p. 184). The one resting and two locomotion categories are mutually exclusive and account for the entire test duration (cf. Tierney and Dunham 1982). The nonspecific nonlocomotory movement category is a subset of resting; the other subset being motionless (cf., Tierney and Dunham 1982). Present interpretations do not require such constraints as independence and exclusivity. Furthermore, Dunham's (1978) constraints for the use of novel stimuli, etc., do not apply, as this study is not concerned with the nature of the substance(s) but rather the reaction of animals to the same substances(s) under slightly different conditions (maximum possible concentration change $<3\%$ by the end of the tests).

Substance concentration in treatment 1 and 2 stimulus waters is unlikely to be greater than that in the test animal's tank. Since behavior in these two treatments was similar, and different from that in tests where substances are believed to be at a relatively higher concentration (i.e., 3, see also below), it seems that detection may be via recognition of substance at concentrations

greater than that previously in the locale. Furthermore, results from "self" water–dilute tank tests (3) and those from "nonself" water tests (4) suggest that substance(s) released may be similar for all females and again suggest that detection is somehow dependent on concentration. These results do not imply individual recognition and allow no inferences about sexual recognition. Indeed, female *P. clarkii* appear unable to distinguish "self" from "nonself" (cf., treatments 1 and 3, both "self" in reality, with 4, "nonself").

It is acknowledged that aging the stimulus may alter (e.g., deplete) the substance, but this seems unlikely (see Ameyaw-Akumfi and Hazlett, 1975; Hazlett, 1985). It is also possible that dilution of the tank somehow sensitizes the animals and that this in turn is responsible for the results observed.

(Received July 2, 1984; accepted July 1, 1985)

Abstract—Mouse urine contains a great number of volatile constituents that may be used in chemical communication. Some of these volatiles, identified in this study by combined gas chromatography–mass spectrometry and gas chromatography–Fourier-transform infrared spectroscopy, appear unique to the mouse. Certain urinary volatiles exhibit strong dependence on the sex and endocrine status of the animals, as shown through castration, treatment with an antiandrogen, and hormone supplementation.

Key Words—Urinary volatile signals, endocrinological manipulations, capillary gas chromatography–mass spectrometry.

INTRODUCTION

The common house mouse, *Mus musculus*, is widely recognized as the mammalian species most studied and best documented regarding its use of chemical signals. Several primer pheromones and a large number of releaser factors can be traced to the urine of both male and female animals. Table 1 lists the best known cases of chemical communication in *Mus musculus*; some of these are also paralleled in other rodents. The nocturnal behavior of rodents creates a strong advantage for use of these chemical signals. As discussed by Bronson and Vandenbergh, pheromones may be particularly important (Bronson, 1971,

TABLE 1. PHEROMONAL PHENOMENA IN THE MOUSE

Category	Effect	Description	Reference
Primer	Lee-Boot	Female grouping supresses estrus cycle in absence of male	Vander Lee and Boot, 1955
	Vandenbergh	Female puberty accelerated by male urine	Vandenbergh, 1969; Colby and Vandenbergh, 1974
	Bruce	Pregnancy block induced by presence of strange male	Bruce, 1959, 1965
	Whitten	Estrus acceleration and synchronization induced by male urine	Whitten, 1956
	Puberty delay	Puberty delay in young females caused by urine from grouped females	Drickamer, 1977
Releaser	Female attractivity	Estrous/pregnant urine more attractive to male	Davies and Bellamy, 1972
	Male attractivity	Male urine more attractive to estrous female	Scott and Pfaff, 1970
	Male aggression	Male urine elicits attacks between males	Chanel and Vernet-Maury, 1963
	Male fear	Urine voided under stress elicits avoidance response	Carr et al. 1970
	Male aversion	Male urine territorial marking	Jones and Nowell, 1973
	Female protection	Female urine decreases attacks by aggressive male	Mugford and Lowell, 1970; Dixon and Mackintosh, 1971
	Male ultrasound eliciting signal	Female urine elicits 70 KHz ultrasonic courtship whistle from experienced males.	Whitney et al., 1974; Nyby et al., 1979

1979; Vandenbergh, 1983) in various ecological considerations regarding *Mus musculus*, one of the most "successful" mammals on the earth.

Although many chemical signals in the mouse are now characterized biologically, chemical studies have been rare. This unsatisfactory state of affairs is partly due to the apparent complexity of the signals involved in mammalian communication, and partly due to the plasticity of response to releaser signals (Bronson, 1971). Nevertheless, chemical identification of these signals may eventually lead to an understanding of their biochemical origin, means of regulation of expression, influence of genetics, etc.

While the question of volatility of certain mouse primer pheromones remains unresolved to this date, the known releaser pheromones appear to act over a distance. Moreover, from the controversies surrounding the nature of primer pheromones (Whitten et al., 1968; Wilson et al., 1980; Bronson, 1979), it is reasonable to expect that volatile components are at least partially responsible for some of these observed effects. For example, individual recognition on the basis of airborne information appears to be an essential component of the pregnancy-block effect (Bruce, 1965) in which a strange male, or the urine of a strange male, can prevent the implantation of fertilized ova; participation of volatiles in conveying the "signature" of an individual is distinctly possible.

Mouse urine is known to possess an odor whose intensity and quality are distinctly different from those of other animals (e.g., rats), and these factors are sex-related. For the above-mentioned reasons, a significant rationale exists for the chemical identification of those urinary constituents which are unique to the mouse. In general, a search for the unusual chemicals in the urine and glandular secretions of mammals can reveal candidates for various pheromonal activities. Drawing parallels from the research on insect pheromones, it is clear that even though a pheromonal activity is not always associated with unusual compounds, the converse is very often true—structurally unique compounds are frequently associated with biological activity.

Systematic studies into the chemical nature of mouse urinary signals are, in our opinion, long overdue. The identification and subsequent synthesis of the mouse-unique constituents should permit their use in a variety of established bioassays for both primer and releaser effects. Such considerations have led us to design several experiments, employing established headspace sampling procedures (Novotny et al., 1974), capillary gas chromatography (GC), and gas chromatography–mass spectrometry (GC-MS). The complexity of mouse urinary signals and their dependency on genetic and endocrinological factors have been tentatively indicated in our previous publication (Novotny et al., 1980).

The present report describes a more complete chemical characterization of the urinary volatile fractions of male and female mice. Certain "mouse-specific" compounds have been identified here, together with the urinary constituents that show a profound endocrinological dependency, i.e., they are clearly

dependent on hormonal levels. Within the constraints of contemporary identification methodology, additional urinary volatile components are also reported. Although structurally less unusual, many of these constituents could also contribute to the overall complexity of olfactory perception in mice.

METHODS AND MATERIALS

Sample Collection and Analysis. Test animals were housed in groups of four or five in cages provided with hardwood chip bedding. Food (Purina Rat Chow, St. Louis, Missouri) and water were provided ad libitum. To collect urine, the animals were transferred to plastic metabolism cages with wire-mesh floors. The urine was collected in a polycarbonate vessel placed on Dry Ice, so that the collected samples were immediately frozen. Collection was performed in either 24- or 48-hr periods to minimize diurnal fluctuations in urine composition. At the end of a collection period, the frozen samples were thawed, filtered through a glass-wool to remove particulate matter, and refrozen in acid-washed glass vials provided with Teflon-lined screw-caps for storage prior to analysis.

Urinary volatiles were analyzed using the headspace technique referred to earlier, which employs a porous polymer (Tenax-GC, Applied Science Laboratories, State College, Pennsylvania) as a collection medium. The volatiles are sparged from 1-ml urinary samples at room temperature with purified helium gas at a flow-rate of 100 ml/min, and adsorbed onto a precolumn packed with Tenax-GC. The sample is subsequently desorbed in the heated injection port (220–240°C) of a gas chromatograph and retrapped into a cooled section of a glass capillary column. The analytical columns were glass capillaries (0.25 mm, ID) of a soda-lime type and coated statically with UCON 50-HB-2000, with benzyltriphenylphosphonium chloride added as a column deactivation agent (Franken et al., 1976).

The flame ionization detector was used for quantitative comparisons of various urinary samples. The urinary volatile constituents were identified through capillary GC-MS (Hewlett-Packard 5981 dodecapole mass spectrometer), using electron impact ionization at 70 eV. Whenever feasible, authentic samples were synthesized to verify agreement of spectral information and GC retention times. In addition, sulfur- and nitrogen-containing compounds were detected with the aid of selective flame-photometric and thermionic detectors on an instrument fitted with a three-way effluent splitter. This procedure significantly complemented the information acquired through GC-MS.

Investigations of Testosterone-Dependent Volatiles in Male Mice. Eight BALB/CWt male mice (Jackson Laboratory, Bar Harbor, Maine) were castrated at 8 weeks of age and permitted four weeks for recovery. Four males were then

implanted (Maruniak et al., 1977) with 5-mm pellets containing pure testosterone, while the other four were implanted with empty silastic tubes. Another group of males (neither castrated nor implanted) of the same age provided control urine samples.

Urines were collected daily from the individual males of the testosterone-implanted group for a total period of 20 days. The samples from blank-implanted castrates and normal males were collected at variable intervals and pooled to provide samples for comparison.

Quantitative comparisons were based on peak areas in the chromatograms obtained from the three groups. The mean integrated peak areas were plotted for different times after testosterone implantation.

Possible effects of cyproterone acetate, a well-known antiandrogen, on male urinary volatiles were also investigated. Osmotic minipumps (model No. 2002, Alzet Osmotic Minipump, Alza Corporation, Palo Alto, California) were filled with a solution of cyproterone acetate (CA) in propylene glycol (10.5 mg/ml). At an infusion rate of 0.5 μl/hr, the pumps supplied a continuous infusion of 5.3 μg/hr for two weeks in implanted animals. The 48-hr collections were started two days after implantation; in total, four samples were collected for GC analyses.

Investigation of Estrogen-Dependent Volatiles in Female Mice. In order to determine which of the mouse urinary constituents are sex-specific, female mouse urine samples were collected and analyzed. In order to control the endocrine status of these animals, mature females of three different strains (C57BL, BALB/C, and ICR) were implanted with 5-mm silastic tubes containing 17β-estradiol. Immature females (3–4 weeks old) served as controls. Occurrence of estrus in the implanted animals was verified by inspection of vaginal smears (Vandenbergh, 1967) before the urine samples were collected. Implantation induced a continuous state of estrus throughout the collection period in all investigated animals.

RESULTS

Male Urines. Figure 1 shows a typical chromatogram obtained with normal male urine. Peak numbers refer to the list of identified components in Table 2. Some of these compound identifications remain tentative at this time.

A visual comparison of the three chromatograms in Figure 2 clearly demonstrates the effects of castration and testosterone supplementation. In general, castration decreases the concentration of most volatile constituents, while androgenization of castrates restores a number of components to normal levels.

A very substantial endocrine dependency in males has been indicated for several compounds through the plots of mean peak areas during the testosterone

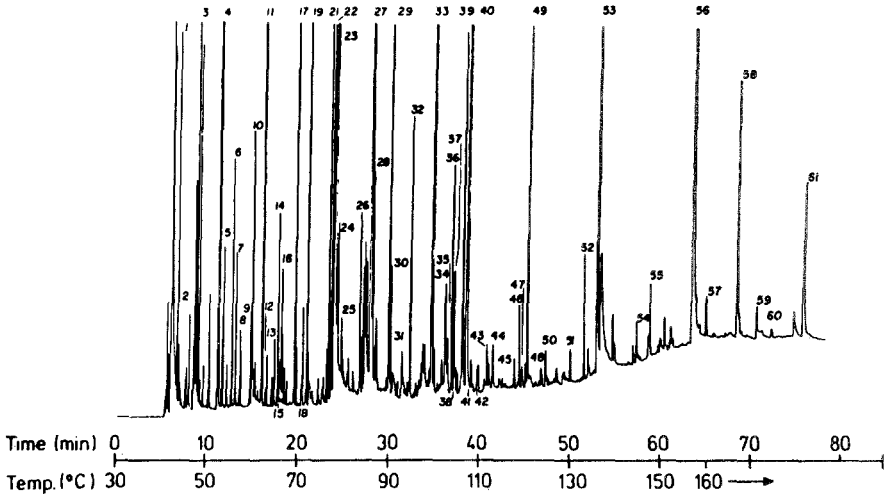

FIG. 1. Chromatogram of male mouse (BALB/CWt) urinary volatiles. Numbers refer to compound identifications in Table 2.

treatment period. For example, peak number 33 identified positively (Novotny et al., 1984) as 7-*exo*-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]-3-octene (trivially named as 3,4-dehydro-*exo*-brevicomin), is a large urinary component in normal males which is drastically decreased following castration. Testosterone treatment restores it to the original value. A similar dependency is shown by *p*-toluidine (peak 52).

Two heterocyclic compounds, 2-isopropyl-4,5-dihydrothiazole and 2-*sec*-butyl-4,5-dihydrothiazole (peaks 31 and 39) are present in normal male urine but disappear completely with castration (Liebich et al., 1977). Our observations indicated that testosterone supplementation does not readily restore these heterocyclic constituents (thiazolines) to their original concentrations. However, the distinctive odor of these unusual compounds alludes to their possible involvement in some signaling phenomena related to males.

Our recent results of behavioral testing for intermale aggression (Novotny et al., 1985) have established that 3,4-dehydro-*exo*-brevicomin and *sec*-butylthiazoline are essential components for that communication. Moreover, their attractiveness to females (Jemiolo et al., 1985a) and estrus synchronization effect (Jemiolo et al., 1986) were also verified.

While the remaining urinary constituents, as identified in Table 2, may fluctuate under different conditions, none appears to give the same pronounced endocrine dependency as the thiazolines, 3,4-dehydro-*exo*-brevicomin, and *p*-toluidine. Our previous experience with the urine samples of a number of mam-

mals strongly suggests that the above-mentioned compounds are unique to the house mouse. For example, we find no such compounds in the urine of male rats, foxes, wolves, dogs, or primates.

The GC-MS results revealed four additional compounds unique to the mouse (peaks 4, 11, 14, and 17). Mass spectra at nominal resolution (see Table 2) yield few clues to their identity other than a molecular weight of 126 and a strong structural resemblance to one another. The notion that they might be cyclic vinyl ethers (e.g., dihydrofurans or dihydrapyrans) was suggested by their early appearance in the chromatogram and the similarity of their mass spectra to those of simpler cyclic vinyl ethers found in published collections of mass spectra. This notion was reinforced by high-resolution mass spectrometry (Table 3) and Fourier-transform IR spectroscopy (FT-IR) (Figure 3). The high-resolution data were helpful in that they narrowed further consideration to molecules possessing a single oxygen atom (formula $C_8H_{14}O$), while the FT-IR data, obtained only for the compound represented by GC peak number 11, pointed to an alkyl-substituted dihydrofuran. By analogy with published spectra, it was believed that a 4,5-dihydro-2-ethylfuran moiety should account for six of the carbon atoms, with the positions of the other two carbon atoms unclear.

Synthesis of a number of such dihydrofurans was accordingly undertaken. The strategy consisted of synthesizing a γ-hydroxyketone, expected to be in equilibrium with a lactol, and subjecting that lactol to dehydrating conditions. After a number of unfruitful syntheses of γ-hydroxyketones, 6-hydroxy-6-

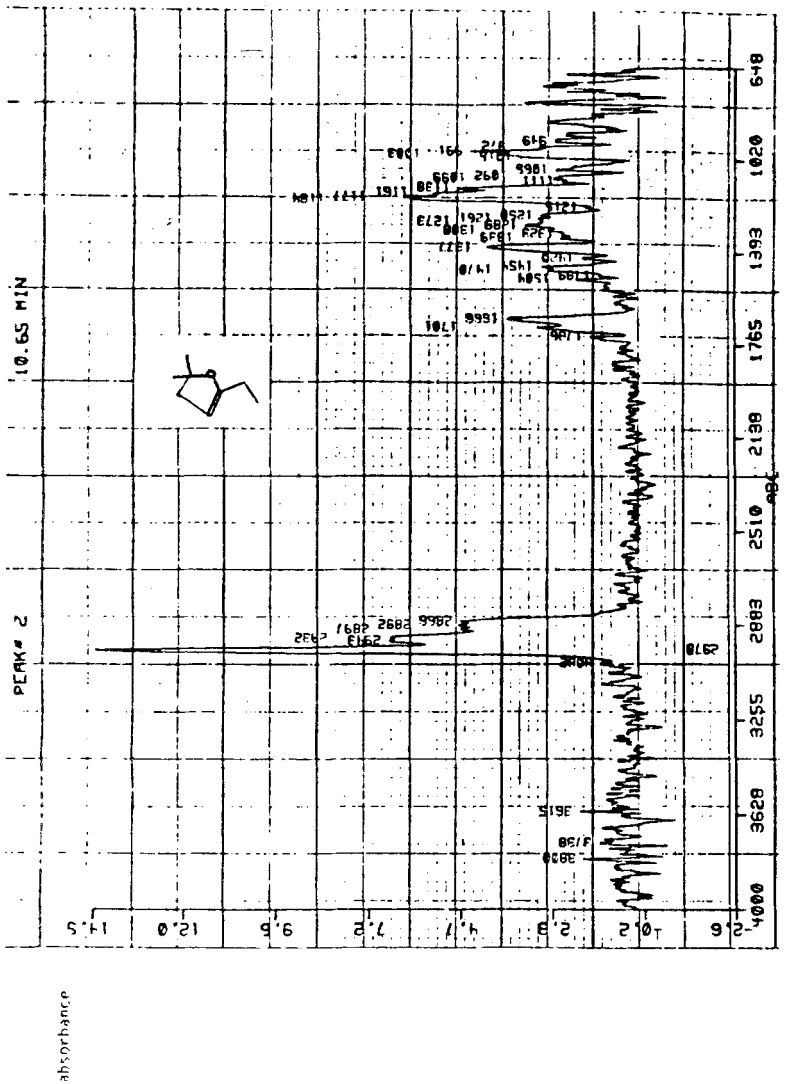

FIG. 3. IR spectrum of peak number 11, a 126 mol/wt isomer.

methyl-3-heptanone was prepared, and subsequently subjected to dehydrating conditions in the injection port of a gas chromatograph. Earlier indications, supported by the report of DiVincenzo et al., (1976), had led us to believe that the high temperature of a GC injection port should suffice to effect the desired dehydration of the lactol. Indeed, when the above hydroxy ketone was injected, three peaks appeared which agreed in both retention times and mass spectra with peaks 4, 11, and 17. Although unequivocal structure assignments have not been performed, we believe these peaks to represent 5,5,-dimethyl-2-ethyl-4,5-dihydrofuran, 5,5-dimethyl-2-(*Z*)-ethylidenetetrahydrofuran, and 5,5-dimethyl-2-(*E*)-ethylidenetetrahydrofuran. The compound represented by peak 14 remains unidentified.

It is not clear whether the urine contains the observed dehydrofurans or the γ-hydroxyketone/lactol precursor, although in light of the ease which vinyl ethers are known to undergo hydrolysis, the second possibility seems more reasonable.

The synthetic route to 6-hydroxy-6-methyl-3-heptanone was chosen partly because it includes 6-methyl-6-hepten-3-one as an intermediate, which was suspected of being a later-eluting component (peak 27), also of apparent molecular weight 126, and exhibiting a fragmentation pattern suggestive of an unsaturated aliphatic ketone. This suspicion was confirmed by a perfect match of a mass spectrum and retention time. This unsaturated ketone is surely present in the urine; it was not found upon injection of the synthetic hydroxy ketone.

A series of chromatograms shown in Figure 4 demonstrates the effect of cyproterone acetate on the excretion of mouse urinary volatiles. As the time of treatment is prolonged, the antiandrogen appears to depress the levels of all volatiles in males. This effect is similar to surgical castration.

Female Urine. Typical chromatograms of urinary volatiles for immature animals and the female with induced estrus are shown in Figure 5, while peak numbers refer again to the list of compounds in Table 2. Estrogenization of mature females produces a dramatic increase in a number of volatile compounds, indicated by an asterisk in Table 2, and causes the appearance of a compound unique to the estrus state, *n*-pentyl acetate (peak 20).

Quantitative aspects of this experiment are reported elsewhere (Schwende et al., 1984b). We have previously established that females of three different strains reacted similarly to estrogenization, while quantitative proportions of the compounds marked by an asterisk (Table 2) were somewhat different. Figure 5 shows an example of the urinary excretion by C57BL/10 females. These results are communicated here in order to contrast the major differences between male and female unique urinary constituents. None of the thiazoline compounds were observed in female urines, confirming the sex-specific nature of these substances. Likewise, only trace amounts of 3,4-dehydro-*exo*-brevicomin were encountered in female mice.

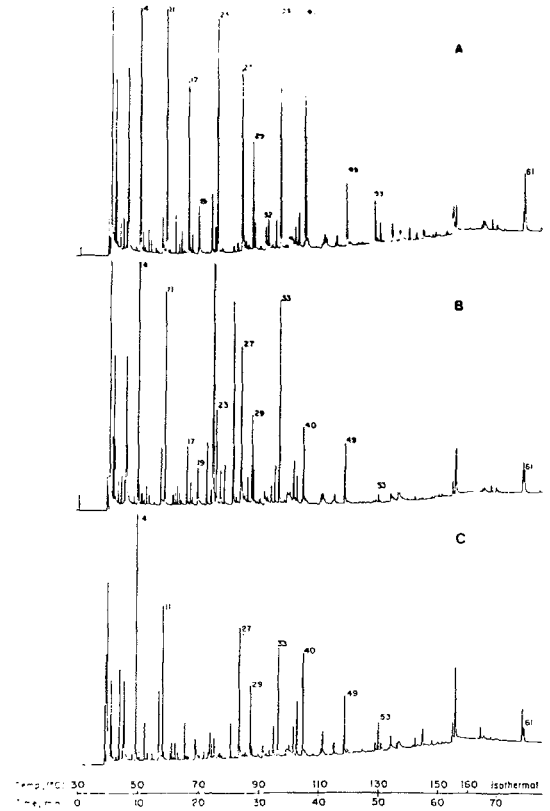

FIG. 4. Effect of cyproterone acetate on male urinary volatile profiles. Chromatograms: (A) 3 days; (B) 9 days; and (C) 13 days after implantation with continuous infusion device. Peak numbers refer to Table 2.

DISCUSSION

It is generally recognized that mammalian odors are due to complex mixtures of organic compounds. While certain specific components of those mixtures (loosely referred to as "pheromones") undoubtedly exist, less specific mixture components may also have importance for the overall chemical message perceived by the mammalian olfactory organs and interpreted by the brain. Müller-Schwarze et al. (1974) speculated that the alcohols and esters accompanying isovaleric acid in the subauricular gland of the male pronghorn antelope may act as diluents and releasing agents for the more volatile active signal components; they could also convey information regarding the individual identity. It could be reasoned that a series of structurally similar compounds, or

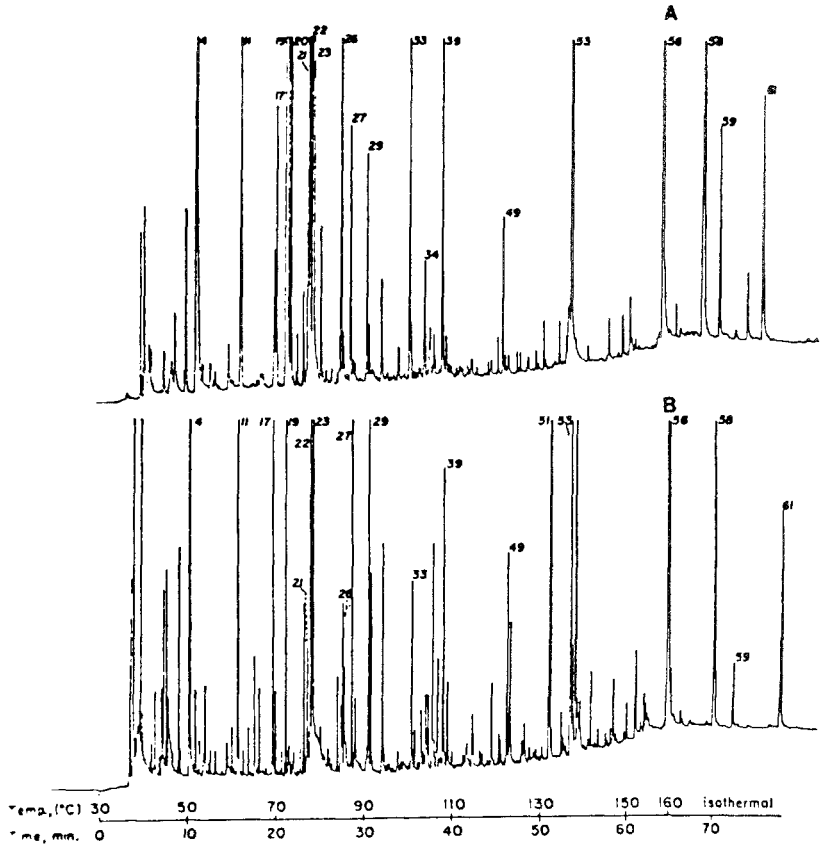

FIG. 5. Comparison of urinary chromatographic profiles for (A) mature, estrogenized female; and (B) immature female. All animals were of C57BL/10 strain. Peak numbers refer to Table 2.

members of a homologous series of odorous compounds, are likely to participate in such individual recognition of mammals. Similar functions could be operative in a number of mammals including the mouse.

Some experimental evidence indicates that the individual recognition and genetic background (including major histocompatibility genes) in the house mouse are conveyed by urinary odors. It has been shown, in restricted laboratory experiments, that mice are able to distinguish between genetically identical individuals in Y-maze tests where only volatile cues were operative (Bowers and Alexander, 1967). Although not necessarily restricted to volatile compounds, individual recognition appears to be an essential component of the pregnancy blocking effect (Bruce, 1965).

In agreement with the above biological rationale, the chemical investigations of our laboratory have demonstrated that genetic background has an observable influence over the relative concentrations of mouse urinary volatiles. While the urinary volatile profiles obtained under different circumstances are qualitatively similar (Novotny et al., 1980), strain differences can be distinguished from quantitative data. As observed recently (Schwende et al., 1984a), this holds true even for congenic mice which differ only in a small section of the major histocompatibility gene complex. Here, the influence of the major histocompatibility complex over the excretion of secondary metabolites makes the quantitative deviations discernible in spite of a great "dilution" caused by the remaining genome. A tentative molecular basis for the observations by other workers (Yamazaki et al., 1976, 1979) regarding the possible influence of the major histocompatibility complex over mating preferences is thus provided.

It is conceivable that complex mixtures of volatiles could serve as integral components of various mouse pheromones. While an active compound (or a limited number of components) may be primarily responsible for a given biological phenomenon, other components may also be essential to provide a suitable olfactory context in order to elicit a typical response. Alternatively, a chemical message may be encoded into the relative proportions and overall intensity of the entire volatile mixture. It is not unreasonable to speculate that the highly developed and integrative mammalian brain could respond in specific ways to the multivariate stimuli presented by relatively complex mixtures of organic compounds such as odors. Thus, it may not be a mere coincidence that the loss of male primer pheromone and certain releaser pheromone activities upon castration or cyproterone acetate treatment is accompanied by an overall decrease of urinary volatiles, as demonstrated in this work.

Similarly, the estrogen-dependent volatiles of female mouse urine may all be required, in specific proportions, to elicit male investigative behavior. The presence of some estrogen-independent volatiles may further be required to produce a typical male response. These possibilities are currently under investigation.

The potential significance of mouse urinary volatiles in chemical communication has led us to pursue their structural characterization. A number of unusual volatile compounds, unique to the mouse urine, have been identified here and reported for the first time. The series of related dihydrofurans is found in both male and female mice, but not in any other species observed to date. Males and females share many of the same volatile components, but their excreted amounts in different sexes vary significantly.

3,4-Dehydro-*exo*-brevicomin has shown a distinct dependency on testosterone levels in the male, suggesting its potential role as a pheromone or a pheromone adjuvant. Structurally similar compounds have sex pheromone activities in the insect world (Silverstein et al., 1968). The two thiazoline com-

pounds are also specific to male mice. We have recently verified biological activities of these substances (Novotny et al., 1985; Jemiolo et al., 1985a, 1986.)

Estrus-related compounds (Schwende et al., 1984b), except for *n*-pentyl acetate, are present in both sexes, but increase dramatically upon the estrogen treatment of females. *n*-Pentyl acetate is clearly associated with females in estrus. Our recent experiments (Novotny et al., 1985; Jemiolo et al., 1986) indicate that certain of these compounds may play an important role in puberty delay of young female mice. Their excretion seems primarily controlled by the adrenal glands, although some participation from the ovaries cannot be ruled out.

Within the scope and limitation of the techniques employed, the major volatile constituents of male and female mouse urine have been chemically characterized. Several mouse-specific compounds have been identified, including 3,4-dehydro-*exo*-brevicomin, and a series of dihydrofurans, the latter of which may all be related to a common precursor keto alcohol, 6-methyl-6-hydroxy-3-heptanone. In addition, the testosterone dependency of 3,4-dehydro-*exo*-brevicomin, the two thiazolines, and *p*-toluidine, as well as the estrogen dependencies of 2-heptanone, *n*-pentyl acetate, *cis*-2-penten-1-ol acetate, *p*-toluidine, and a series of hepten-2-ones, suggest their possible roles as important components of chemical signals.

The quantitative relationships within the complex mixture of volatile compounds in mouse urine (producing a volatile profile in our headspace sampling and chromatographic procedure) may reflect information on the individual identity and genetic background. A detailed chemical knowledge of mouse urine odor may eventually allow investigations of the signaling potential of these compounds, alone as well as in mixtures.

Acknowledgments—This research was supported by grant PHS RO1 HD 14889 from the Institute of Child Health and Human Development, Department of Health and Human Services, U.S. Public Health Service. We thank Dr. U.S. Seal, Veterans Administration Hospital, Minneapolis, Minnesota, for his generous gift of cyproterone acetate.

(Received August 31, 1984; accepted June 27, 1985)

Abstract—The volatile components of castrated male and ovariectomized female wolf urine were investigated and correlated with the administration of testosterone or estradiol and progesterone. The results indicate that testosterone induces in the castrated male the formation of some compounds typically associated with the intact male, while reducing the levels of some compounds associated with castrated male and female. The production of some of the "male" compounds was also induced in the ovariectomized female, although at lower levels. Changes in hormone levels during treatment of females are reflected in the composition of the urinary volatiles. Consequently, many of these compounds could be used to communicate gender as well as reproductive status.

Key Words—Wolf, *Canis lupus*, urinary volatiles, hormone treatment, chemoolfactory communication, testosterone, estradiol, progesterone.

INTRODUCTION

Scent-marking is a well-recognized and important aspect of mammalian communication (Johnson, 1973; Ralls, 1971). This behavior has been observed in a variety of mammals, ranging from small rodents (Bronson, 1979) to rabbits (Goodrich and Mykytowycz, 1972; Goodrich et al., 1978), ungulates (Moore and Marchinton, 1974), felids (Wemmer and Scow, 1977), and canids (Kleiman, 1966; Fox and Cohen, 1977; Peters and Mech, 1975; Rothman and Mech, 1979). All of these animals use both glandular secretions and urine as the principal means of chemical communication.

The display of marking behavior is often related to the endocrine status or seasonal changes in the hormone levels of marking mammals. Mykytowycz (1974), working with European rabbits (*Oryctolagus cuniculus*), and Thiessen (1973), studying Mongolian gerbils (*Meriones unguiculatus*), both learned that the development and use of scent glands are related to sexual maturity and the presence of gonadal hormones. The main pheromone effects observed in both male and female mice are clearly related to the endocrine status of these animals (Bronson, 1979).

Hormonal influence upon the concentrations of certain excreted chemical scent constituents can often be used to indicate those chemical substances likely to be important in communication; i.e., putative pheromones can be sought in complex biological matrices following endocrinological manipulations of the mammals. In turn, once these pheromone candidates are identified and synthesized in the laboratory, their biological testing becomes feasible. Specifically, this investigational sequence has been applied in the identification and chemical synthesis (Wiesler et al., 1984) of testosterone-dependent volatile constituents of male mouse urine (Novotny et al., 1984) and their testing in promoting intermale aggression (Novotny et al., 1985) as well as behavioral and endocrinological changes in females (Jemiolo et al., 1985). Canids have been similarly studied; characteristic red fox (*Vulpes vulpes*) urinary constituents identified by Jorgenson et al. (1978) were later shown to be attractive to the foxes in their natural habitat (Whitten et al., 1980).

We have also studied the volatile constituents of wolf (*Canis lupus*) urine during the breeding season (Raymer et al., 1984). The present study investigates the hormonal dependencies of these compounds in castrated males and ovariectomized (OVX) female wolves. Changes in the urinary profiles of volatile substances were followed after treating the animals with testosterone, estradiol, and progesterone.

METHODS AND MATERIALS

Tested Animals. For the testosterone supplementation experiment, castrated males 143 and 103 as well as ovariectomized (OVX) females 104 and

147 were used. The males were surgically altered on July 19, 1983 and April 13, 1982, respectively, while both females were altered on July 26, 1983. The experiment in which the animals were treated with female hormones utilized males 39 and 103 along with females 108 and 116. Castration dates for these animals were September 26, 1979, April 13, 1982, January 16, 1980, and January 14, 1981, respectively. All animals were postpubertal at the time of surgery.

Testosterone Treatment. Two castrated male (CM) wolves (103, 143) and two OVX females (104, 147) were given two 200-mg intramuscular injections of testosterone cypionate in cottonseed oil (Depo-Testosterone, Upjohn, Kalamazoo, Michigan), two weeks apart. Each injection resulted in a slow release of the hormone for a period of two to three weeks, based on manufacturer's information and physiological observations. Urine samples from these animals were collected weekly during the following few weeks. The collection procedure involved anesthetizing the animals with sufficient ketamine hydrochloride (Ketaset, Bristol Labs, Syracuse, New York) and promazine hydrochloride (Sparine, Wyeth Labs, Philadelphia, Pennsylvania) to provide adequate relaxation for urine withdrawal by catheter. The urines were placed into acid-washed vials with Teflon-lined caps, immediately frozen, and shipped to Indiana University for chemical analysis. Each animal served as its own control. It was obvious from the physical changes in these animals that sufficient testosterone had been administered to simulate the seasonal testosterone increase. These changes included dramatically increased secretions from the preputial area in the treated castrated males and a secretion from the clitoral fossa in the treated OVX females. These secretions apparently correlated with elevated testosterone levels (Ebling, 1977).

Clitoral enlargement was also noted in the females with the mean dimensions at week zero being 11.5 mm × 6.5 mm (length × diameter) and increasing to 16.5 mm × 10 mm after four weeks of testosterone treatment. This, too, is indicative of elevated testosterone levels (Trimble and Herbert, 1968).

Estrogen and Progesterone Treatments. Two OVX female wolves (108, 116) and two castrated males (39, 103) were treated with 17β-estradiol [E_2 (120–140 mg/implant)] and then with E_2 and progesterone [P_4 (100 mg/implant)] through the use of subcutaneous silastic implants. Hormone treatment approximated the three phases of proestrus (only E_2 elevated), estrus (E_2 and P_4 elevated), and pregnancy (primarily elevated P_4 levels) (Seal et al., 1979). Urine samples were collected as described above. Although radioimmunoassay data indicated an increase in circulating plasma levels of these hormones, the estradiol levels were below those seen in normal proestrus females. However, the OVX females displayed typical signs of proestrus, including bloody vaginal discharge.

In addition, male dogs (although not male wolves) were able to discrimi-

nate between normal anestrous females and the hormone-treated OVX females. Male dogs tried to approach the E_2- and E_2 + P_4-treated OVX wolves but, because there was some doubt as to whether or not it was safe to let them be together, the behavior of the male dogs introduced instead to anesthetized female wolves was observed. The male dogs sniffed and licked at the treated OVX females' vaginal areas, then tried to mount them, exhibiting pelvic thrusting. The male dogs also sniffed longer at treated castrated males than at untreated males. The dogs appeared somewhat confused while investigating the castrated males treated with the female hormones. It is assumed that the lack of response by intact male wolves was due to their relatively low levels of testosterone, since this experiment was conducted during the summer, that is nonbreeding season.

Due to the more complex nature of the female hormone supplementation experiment, controls consisted of urine samples collected from the same animals (with one exception) one year prior. The control animals were OVX 108, OVX 116, castrate 39, and castrate 36. Castrated male 36 served as the control for male 103 because 103 had not been castrated in time to serve as a control in this experiment.

Analytical Procedures. The volatile constituents of the urine samples obtained under the described conditions were analyzed through a headspace sampling procedure (Novotny et al., 1974a,b). Following thermal desorption of volatiles from a porous polymer (Tenax GC, Applied Science Laboratories, State College, Pennsylvania) onto a 60-m × 0.25-mm ID, glass capillary gas-chromatographic (GC) column coated with a polypropylene glycol fluid, UCON-50-HB-2000, the separations were followed with the flame ionization detector (FID) at the column temperature from 30 to 160°C at a rate of 2°/min. Compound identifications were initially aided by the nitrogen-sensitive (thermionic) and the sulfur-sensitive (flame photometric) GC detectors. Peak areas were collected and tabulated through the use of a Perkin-Elmer Sigma 10 Chromatography Data Station. Data obtained from combined capillary gas chromatography–mass spectrometry (GC-MS) provided the major information leading to a positive identification of the urinary constituents. GC-MS data were obtained with a Hewlett-Packard 5982A dodecapole instrument in conjunction with an Incos 2300C GC-MS data system. The majority of the compound identifications discussed below were verified through both retention and mass-spectral data derived from synthetic compounds.

Representative chromatograms for normal (intact) male and female urine volatiles are shown in Figures 1 and 2. The urines sampled to produce these chromatograms were pooled from many animals from November through February, a time which spanned the breeding season. Mass spectral identifications for the numbered peaks of these figures are presented in Table 1.

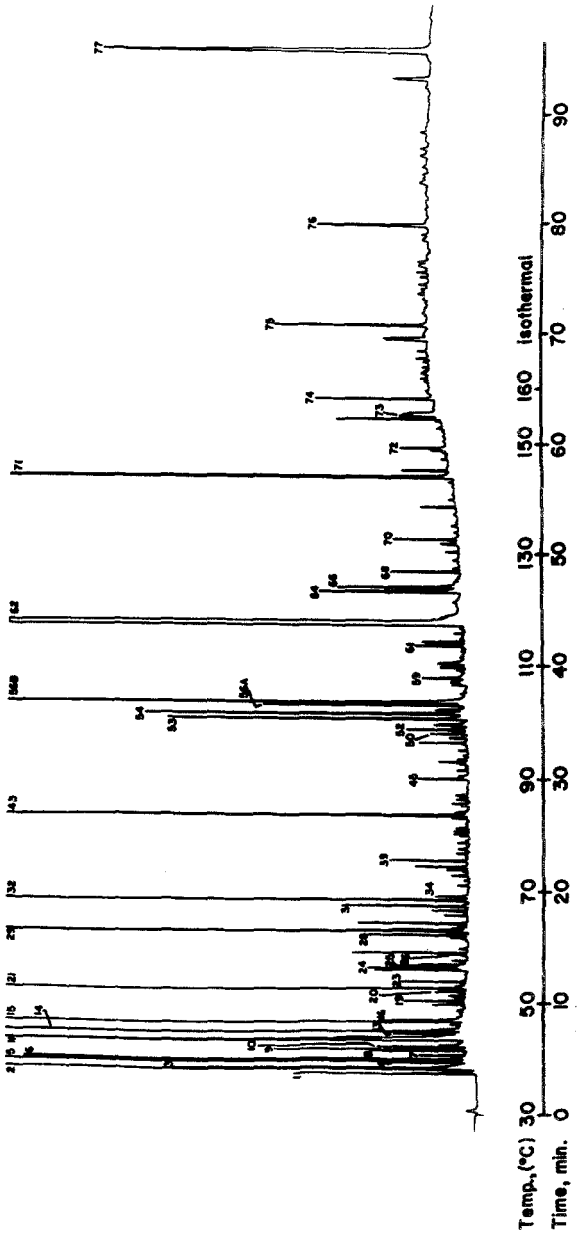

FIG. 2. Volatile profile of normal female urine followed with the flame ionization detector. Conditions as in text.

RESULTS

Testosterone Treatment

Chromatograms resulting from the separation of the volatile components of the urine were examined, and it was determined via this visual pattern recognition that of the many peaks present in each profile, 17 of them appeared to have been changing in intensity during the experiment. These peaks encompassed possible changes in both castrated males and OVX females. Subsequently, the area of each peak was plotted as a function of time in order to verify any trends apparently induced by the hormone treatment.

Male Response. Figure 3 shows the volatile profiles of the urine from an intact male wolf, a castrated male wolf, and finally a castrated male treated with testosterone. Both castrate profiles were derived from urine samples of the same animal. For the most part, this figure summarizes the results indicated by the plots mentioned in the previous paragraph. Figure 4 is a plot of peak area vs. week number following testosterone treatment for castrated male 103 for four of the ketones (numbers 33, 40, 60, and 63 in Figures 1 and 3 as well as Table 1) previously reported (Raymer et al., 1984). Similar trends were seen for castrated male 143. The delay before the increasing levels of these compounds were observed could be the result of "priming" the animal (e.g., induction of certain enzymes). A time delay may be necessary in order to induce the formation or reactivation of hormone receptor sites that have not been stimulated for some time. This testosterone dependence implies a possible importance of the four ketones in chemical communication. Indeed, behavioral testing with the wolves indicates that these compounds are of interest to the animals (C. Asa, unpublished observation).

Among the five sulfur compounds found in the urine of intact male (Raymer et al., 1984), only methyl propyl sulfide and methyl isopentyl sulfide achieved any abundance after testosterone treatment. The peak area corresponding to methyl propyl sulfide increased nearly ninefold for castrate 103 and nearly threefold for castrate 143. The increases observed for methyl isopentyl sulfide were less. However, the trend toward more elevated levels correlated very well with testosterone administration.

The levels of two compounds indicative of the normal state in females (3-ethylcyclopentanone and acetophenone), which have also been shown to become elevated in castrated animals as compared to normal males, were found to decrease somewhat after the animal had been treated with testosterone (Figure 3) (Raymer et al., 1984). Finally, 2-heptanone, a generally common mammalian urine component, which attains a slightly higher average level in normal male wolves than in normal females (unpublished observation), was found to exhibit an elevation in level in both of our castrated males after treatment with

[a] Identification of peaks numbered in Figures 1 and 2 based on 70 eV mass spectra. "A" indicates that the compound has been authenticated by retention times and mass spectra of synthetic substances. Compounds marked with an asterisk are artifacts of the methodology.

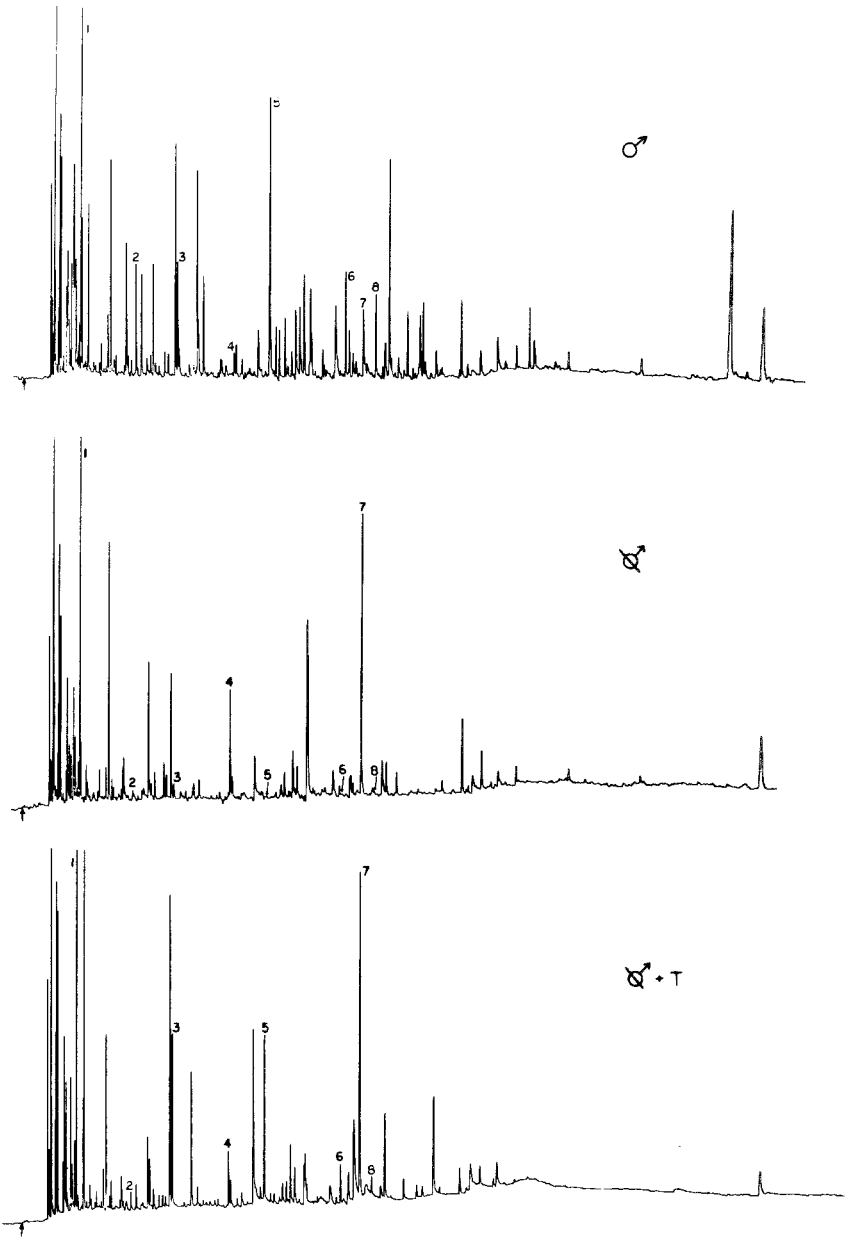

FIG. 3. Comparison of urinary volatile profiles of normal male (top), castrate male (center), and the same castrate male after treatment with testosterone. Compound identifications are: (1) methyl propyl sulfide, (2) methyl isopentyl sulfide, (3) 4-methyl-3-heptanone, (4) 3-ethylcyclopentanone, (5) 3,5-dimethyl-2-octanone, (6) 3,5,7-trimethyl-2-nonanone, (7) acetophenone, (8) 3,5-dimethyl-2-decanone.

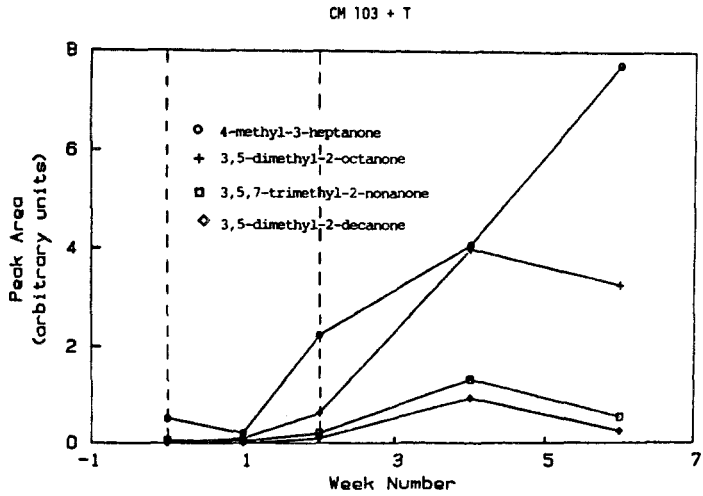

FIG. 4. Peak area vs. week number after testosterone treatment for the four carbonyl compounds induced by treatment of castrate male 103 with testosterone. The vertical dotted lines indicate when the animal was injected with the hormone.

testosterone. The same compound in the OVX females supplemented with testosterone showed no clear change.

The data presented above are entirely self-consistent since some compounds associated with intact males increased in the urine, while the compounds associated with intact females or castrate males were decreased, upon treatment with testosterone.

Female Response. The results of the experiment in which OVX females were treated with testosterone seemed, generally, to parallel the effects seen in the castrate males. The most striking change was the induction of increased urinary methyl propyl sulfide and methyl isopentyl sulfide (Figure 5). Some elevation of the ketones (for example, 3,5-dimethyl-2-decanone) was noted, although the relative amounts produced were much less than for the male. No changes were observed in the levels of 3-ethylcyclopentanone, but the acetophenone level was suppressed for at least three weeks beginning three weeks after the initial injection of testosterone. The average peak area (in arbitrary units) was 23.6 before the suppression and 0.7 afterward. These results clearly indicate that testosterone somehow inhibits the metabolic pathway leading to the formation of acetophenone.

Female Hormone Regimen

The volatile profiles for this part of the experiment were analyzed in the same manner as those above. Thirty-eight peaks were tabulated and compared to the same 38 peaks from the control data set.

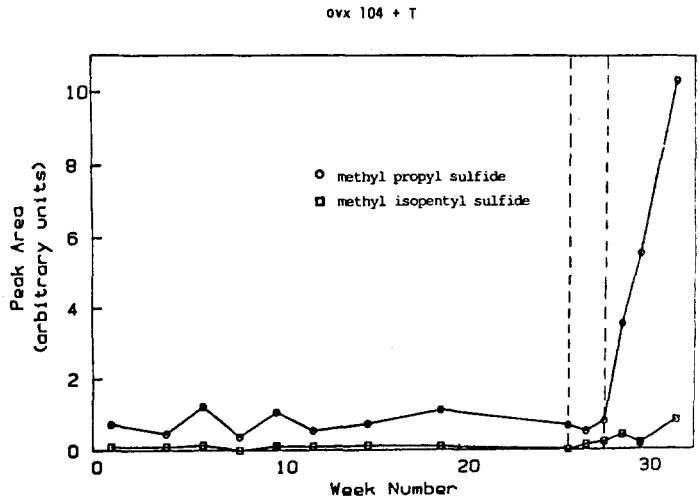

FIG. 5. Peak area vs. week number after testosterone treatment for the two sulfur-containing compounds induced by treatment of OVX 104 with testosterone. The vertical dotted lines indicate when the animal was injected with the hormone. The injections for both castrate and OVX animals took place at the same time. Therefore, week 0 of Figure 4 is not the same as week 0 here.

Female Response. Changes in the levels of various urinary compounds in treated females compared to the controls were relatively few. The compound exhibiting the most dramatic change was benzaldehyde (Figure 6). There is a clear elevation of this compound when estradiol is being released into the animals' bodies. During both E_2 and P_4 administration, regardless of which hormones were present, decreases were seen for acetophenone (although the greatest suppression was seen with progesterone alone) and peaks 11 and 29, which remain unidentified. (The mass spectrum for peak 11 suggests a $C_8H_{14}O$ ether or a $C_7H_{10}O_2$ diether. The mass spectrum for peak 29 suggests an alcohol with two positions of unsaturation). Therefore, there is evidence that the urine volatiles change as females approach estrus. This is further supported by behavioral observations that during this period of proestrus, the male wolves become very much interested in the urine of the females as evidenced by their sniffing and licking (C. Asa, unpublished observation).

Male Response. The most striking change in the castrated males treated with the female hormone E_2 was an increase in urinary benzaldehyde, as in the females (Figure 7). The fact that the response of castrated male 39 was not as clear as for animal 103 may be explained by one or both of the following. First, male 103 was castrated six months before the experiment, while male 39 had been castrated for about three years. This length of time may have altered his

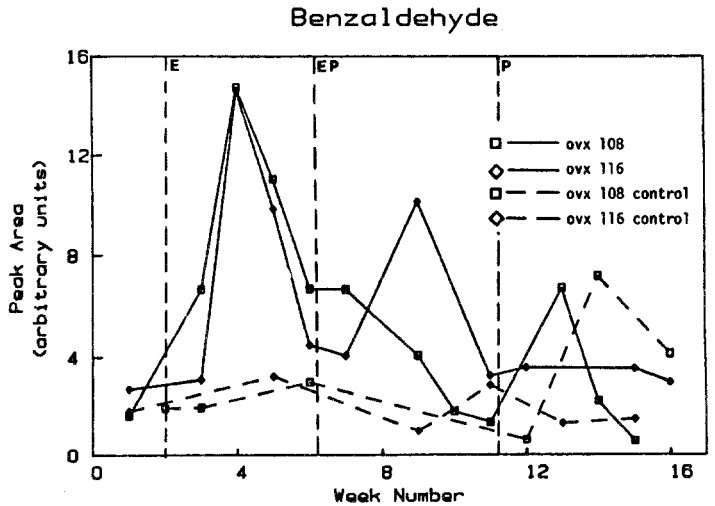

FIG. 6. Peak area of urinary benzaldehyde vs. week number for the experiment in which OVX females were treated with female hormones. The vertical dotted lines represent the time of implantation. E stands for 17β-estradiol, and P stands for progesterone. The letters indicate the hormones that were being introduced into the animal for the specified time period.

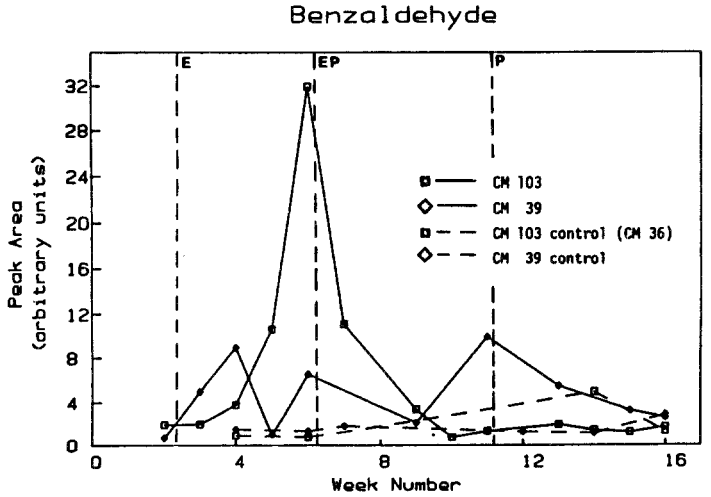

FIG. 7. Peak area of urinary benzaldehyde vs. week number for the experiment treating castrate males with estradiol and progesterone.

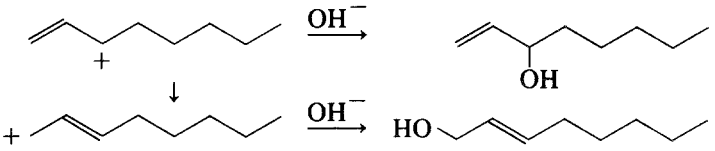
"ability" to respond. In addition, male 39 was considerably older than male 103.

Methyl propyl sulfide was generally decreased in both animals when both E_2 and P_4 were present. This observation becomes of interest when contrasted with the elevating effect of testosterone upon this compound. Finally, 1-octen-3-ol and 2-octen-1-ol were elevated in castrated male 103 (but not male 39, probably for one of the above-mentioned reasons) when both estradiol and progesterone were in the system. The fact that both alcohols follow the same trend can be explained by their common relationship to a single-resonance stabilized cation:



DISCUSSION

The testosterone dependence of a number of compounds found in the volatile fraction of normal male wolf urine, but absent or greatly diminished in castrated male urine has been demonstrated. This dependence opens the possibility that these compounds might serve to indicate to mature female wolves the degree of sexual maturity of prospective mates. The increased scent-marking that wolves perform as breeding season approaches (Peters and Mech, 1975), as well as greater frequency of marking in newly formed pairs (Rothman and Mech, 1979), is consistent with this hypothesis.

In addition, acetophenone and 3-ethylcyclopentanone, two compounds characteristically high in female urine and found to increase in male urine after castration, tended to decrease upon treatment of castrate males with testosterone. When OVX females were treated with testosterone, acetophenone decreased, and the animals began producing compounds characteristic of males. Treatment of OVX females with estradiol and progesterone caused changes in the urinary volatiles that could communicate to conspecifics their approaching estrus. The urinary volatiles of the castrate male treated with female hormones also changed but did not parallel exactly the changes observed in the female.

Treatment of animals with hormones of the opposite gender raised some questions concerning the biogenesis of the urine compounds. For example, why is benzaldehyde formation induced by estradiol treatment? The amounts seen in the urine are far too large to be explained simply as metabolites of the estrogen, indicating that a metabolic pathway common to both male and female wolves is important here. The trends elucidated in this work may help to clarify some questions about mammalian biochemistry.

Book Review

Techniques in Pheromone Research. Hans E. Hummel and Thomas A. Miller (eds.). New York, Springer Verlag, 1984. $59.00, 464 pp.

This book is published within the Springer Series in Experimental Entomology edited by Thomas A. Miller. It contains 14 chapters written by leading experts on the topic they discuss. As it focuses on the techniques used in pheromone research and its advances during the last decade, it occupies a special place among the books on pheromones and chemical ecology. It is particularly useful for the specialist wanting an up-to-date account of available methods and research equipment which could serve his purpose. The book starts with a chapter written by two pioneers who inaugurated the field of pheromone research: E. Hecker and A. Butenandt. It is entitled "Bombykol Revisited" and makes not only interesting reading for the student of the present history of science, but also mentions the more recent identification of companion compounds of bombykol, suggested routes for the biogenesis of this pheromone, the metabolism of tritium-labeled bombykol in the antenna, and its importance with respect to the molecular mechanism of action of pheromones.

The next four chapters are concerned with assays. Chapter 2, by T.C. Baker and R.T. Cardé, on techniques for behavioral bioassays, includes general considerations for conducting bioassays and contains several examples, divided into assays with and without moving air, in both cases with and without monitoring of the displacement. Chapter 3, by T.C. Baker and C.E. Linn on wind tunnels in pheromone research, and Chapter 4, by R.T. Cardé and J.S. Elkinton on field trapping with attractants, are linked in subject matter to Chapter 2. Chapter 4 also contains data of practical importance in pest management, such as trap design and trap placement. Chapter 5 by W.L. Roelofs deals with electroantennogram assays. Their importance as rapid and convenient screening procedures is well-known. The technique, pioneered by Schneider in 1957 has been developed by Roelofs and others to the present almost indispensible tool for screening, isolation, and identification of pheromones. Its broad applicability is illustrated by numerous examples in this chapter.

The three chapters that follow describe the use of electrophysical or behavioral assays as detectors in gas chromatography. Gas chromatographic separation usually preceeds EAG in the investigation of natural pheromones. In Chapter 6, on combined gas chromatography and electroantennogram record-

0098-0331/86/0100-0315$05.00/0

ing, D.L. Struble and H. Arn show how these two different techniques can be combined, using the antenna as a selective and sensitive detector (EAD) which, if desired, can be used simultaneously with an FID detector. Their paragraph on GC–single sensillum recording (GC-SSR) forshadows the discussion in Chapter 7 by L.J. Wadhams on the coupled gas chromatography–single cell recording technique (GC-SCR). These most recent aids in pheromone research, independently developed by Wadhams (1982), who worked with beetles, and Van der Pers and Löfsted (1983), working with a moth, are of particular interest in the study of some fundamental questions which arise when studying multicomponent pheromones. As GC-SSR and GC-SCR have the advantage of differentiating among responses of different receptor cells but provide information on only one type of sensillum or cell, these techniques offer a complement rather than a substitute for the GC-EAD technique.

H.E. Hummel, in Chapter 8 on the tandem gas chromatography-behavior assay, describes another coupling of two classical techniques in pheromone research. The author emphasizes the advantage of combining the virtues of the two methods, but although he does not ignore the inherent problems, he treats them as of little importance. The simultaneous presence of several compounds in a critical ratio is often necessary for activation of insects, and this is one of several factors that limits the applicability of coupling the two techniques. The others include memory effects resulting from previous runs and solvent effects.

The next five chapters deal with chemical techniques, analytical as well as synthetic. In Chapter 9, L.K. Gaston gives a brief but lucid account of techniques and equipment for collection of volatile chemicals. These techniques serve not only the identification of pheromones from natural sources but are of equal importance in developing a rational application of controlled release formulation where rates of evaporation have to be measured.

Collection of pheromones is also the subject of the much more elaborate Chapter 10 by M.A. Golub and I. Weatherston on techniques for extracting and collecting of sex pheromones. Their 52-page chapter is an extensive review containing many detailed drawings of a variety of collection apparatus and two long but conveniently arranged tables of the extraction and effluent collection methodologies as used by different authors.

Chapter 11, by R.R. Heath and J.H. Tumlinson on techniques for purifying, analyzing, and identifying pheromones, treats the processes usually following the collection of pheromones. Many of the techniques described were initially developed and are still used for much larger amounts of material and require modifications and refinements to make them useful for pheromone analyses. Without attempting to be complete, the authors give an adequate review of the present techniques and briefly give their view on future developments.

Chapter 12, by K. Mori, deals with the significance of chirality and methods for determining absolute configuration and optical purity. The wealth of

data and the many examples show how rapid the development of these methods has been and how complicated the relationship between chirality and pheromone activity can be. This chapter is not only important for pheromone scientists but for all those interested in chemistry of natural products and in structure–activity relationships.

Chapter 13, by P.E. Sonnet, tabulates selected methods of syntheses frequently employed for insect sex pheromones. It contains a rather complete survey of the relevant literature up to 1982.

The concluding Chapter 14, by D.G. Campion, surveys pheromone uses in pest control, the practical goal of most pheromone research. Although most of these uses are also found in other books or chapters on pest management by pheromones, the present book would be incomplete without this chapter.

This volume is recommended primarily to all scientists involved in pheromone research; it also contains data of general interest to ethologists, electrophysiologists, and analytical and organic chemists. Other fields of chemical ecology, such as those of microorganisms and mammals, may benefit from some of the techniques described, but it should be emphasized that the book only describes applications in the entomological field.

BIOORGANIC CHEMISTRY OF COMMUNICATION SYSTEMS

This issue arose from a symposium which I organized for the Northeastern Regional Meeting (NERM-15) of the American Chemical Society held on June 24 and 25, 1985, at New Paltz, New York. It was my intention to bring together scientists in the northeastern United States and Canada who were engaged in studying biological chemistry of sensory systems of plants, vertebrates, and insects. A prejudice for the newer subdiscipline which I call pheromone biochemistry—the study of pheromone production, reception, and removal on a molecular level—will be evident in the topics selected.

This issue is organized into three main areas: (1) pheromone chemistry, biochemistry, and perception in insects; (2) chemical blends and their perception in vertebrates; and (3) biochemical events in plant–plant and plant–insect interactions.

Pheromone biosynthesis in female moths is examined in three different ways. Bjostad and Roelofs use fatty acyl precursors multiply-labeled with stable isotopes of carbon and hydrogen to examine the origins of (*E*)- and (*Z*)-11-tetradecenyl acetates in the red-banded leafroller moth (*Argyrotaenia velutinana*). Pheromones and glandular lipids were analyzed using GC-MS, with chemical ionization and selective ion monitoring to optimize sensitivity. The importance of functional groups in pheromone specificity is explored in the spruce budworm moth (*Choristoneura fumiferana*) enzymatic studies with radiolabeled precursors by Morse and Meighen. De novo fatty acid synthesis and interconversions of acid, ester, alcohol, and aldehyde functionalities can be observed in glandular tissues by specific enzymes. As Ding and Prestwich indicate, the biosynthetic and catabolic enzymes which catalyze these functional group interconversions are broadly distributed in tissues of the tobacco budworm moth (*Heliothis virescens*). Teal and Tumlinson describe the production of nonpheromone aldheydes by topical application of exogenous fatty alcohols to pheromone glands of female *Heliothis virescens* moths. They conclude that the supply of an alcohol precursor to an oxidase system is rate-limiting for pheromone production. Finally, Bell and Meinwald describe chiral pyrrolizidine aphrodisiac pheromones of two male arctiids (*Creatonotos* spp.) and their derivation from ingested plant alkaloids. They also document new alkatrienes and a chiral C_{21} diene epoxide in females of these arctiid moths.

Enzymes which degrade pheromones are essential for clearing sensory hairs

0098-0331/86/0200-0319$05.00/0

and hydrophobically adsorbed pheromone on the integument. Prestwich, Vogt, and Riddiford describe experiments which clarify the specificity of the sensillar esterase of male wild silkworm moths (*Antheraea polyphemus*). With radiolabeled pheromone (6*E*, 11*Z*-16:Ac) and pheromone analogs of very high specific activity (58 Ci/mmol), physiologically meaningful concentrations (10 nM) were possible in these assays. In contrast to this soluble esterase found only in male antennal sensory hairs, Vogt reports that a second, cuticle-bound pheromone esterase is present in body scales of both sexes of this moth but not in unrelated species.

Pheromone processing in the aldehyde-producing moth *Heliothis virescens* is examined by Ding and Prestwich, using stoichiometrically tritiated Z9-14:Al to study tissue and subcellular location of the expected aldehyde dehydrogenase (ALDH). ALDH was highest in both male and female antennae and was also found as the most active enzyme together with alcohol oxidase (Z9-14:OH as substrate) and acetate esterase (Z9-14:Ac as substrate) in legs and glandular tissues. Similarly, Lonergan reported GC-MS evidence for the conversion of the pheromonal *E*11-14:Al to *E*11-14:Acid in all tissues of the male and female spruce budworm *Choristoneura fumiferana*. Many of the findings in these two papers were foreshadowed by related studies on *C. fumiferana* summarized by Morse and Meighen.

Pheromone reception is examined in two papers. O'Connell, Beauchamp, and Grant summarize their continuing work in characterizing electrical activity of receptor neurons in individual sensilla to single and multiple component stimuli. The neural mechanism for encoding of information from multicomponent pheromone blends is still poorly understood. Silk and Kuenen review the chemistry and behavioral responses for pheromones of the *Choristoneura species*, with specific attention to the unsaturated fatty acids in *C. fumiferana* glands. They describe the synchronized variations in Δ11-14:Acid, Δ11-14:Ac, and Δ11-14:Al, and search for additional pheromone components by screening biosynthetically related compounds for behavioral activity.

Next, two authors review work of their research groups on vertebrate chemical communication systems. Doty provides an overview of the relationships between psychophysiological measures of human olfactory perception as they are influenced by endocrine function in both sexes. Belcher presents a summary of the work in the Epple and Smith groups directed at decoding the complex information contained in scent marks of the tamarin *Saguinus fuscicollis*. Butyrate esters and squalene are found in skin glands in two subspecies and can be distinguished using chemical pattern recognition analysis of GC-MS data.

Finally, I felt that no symposium on the chemistry of communication systems would be complete without a look at selected studies on plant–plant and plant–insect interactions. Thus, Ahmad provides a review of the enzymic strat-

egies which insects and mites use to deal with phytochemicals. He offers specific data on the variation and multiplicity of MFOs in gypsy moth larvae during maturation. Finally, Lynn and Chang review the chemistry of host recognition in parasitic angiosperms, and the properties of a specific class of chemicals, the xenognosins, which induce development of the haustorium.

I hope that the readers of this *Journal of Chemical Ecology* symposium volume share vicariously in the stimulating research described in these papers. The ability to achieve a molecular-level understanding of production and regulation of communicative chemicals and the unraveling of the stepwise biochemical events involved in their reception, transduction, and catabolism are important goals for research in chemical communication in the next decade.

(Received March 18, 1985; accepted August 1, 1985)

Abstract—Sensory hair proteins from antennae of males of the wild silk moth, *Antheraea polyphemus* (Lepidoptera, Saturniidae) were incubated with radiolabeled 6*E*,11*Z*-hexadecadienyl acetate in the presence of unlabeled pheromone analogs as competitive inhibitors. The two extracellular proteins of importance, a highly active sensillar esterase and an abundant 15,000 mol wt binding protein, interact to degrade labeled pheromone less efficiently in the presence of certain unsaturated acetate analogs of the natural pheromone.

Enzymatic hydrolysis of the acetate (or diazoacetate) was also examined for three pheromone analogs: [11,12-$^3H_2$]-6*E*,11*Z*-hexadecadienyl diazoacetate, [11,12-$^3H_2$]-hexadecyl acetate, and [9,10-$^3H_2$]-9*Z*-tetradecenyl acetate. The former two are poor substrates at concentrations over four orders of magnitude. The 9Z–14 : Ac, however, is the best alternative substrate for this in vitro pheromone metabolism system. Unlabeled 9Z–14 : Ac is also the best competitive inhibitor of the hydrolysis of labeled 6*E*,11*Z*–16 : Ac. Whereas the tritiated natural pheromone shows a flat response (ca. 40% conversion) to increasing concentrations from 3×10^{-9} to 3×10^{-6} M, tritiated 9Z–14 : Ac is degraded more rapidly at higher concentrations.

Key Words—*Antherea polyphemus*, Lepidoptera, Saturniidae, wild silk moth, radiolabeled pheromone, pheromone binding, pheromone hydrolysis, antennal proteins.

INTRODUCTION

The antennae of the male giant silk moth *Antheraea polyphemus* show remarkable sensitivity and specificity in detecting the sex pheromone of this species. The pheromone of this species consists of two chemical components, 6*E*,11*Z*-16:Ac and 6*E*,11*Z*-16:Ald, with the acetate component being the more active compound (Kochansky et al., 1975). Each of the approximately 55,000 pheromone-sensitive sensory hairs per antenna possesses a pair of neurons, with one neuron of each pair being excited by only one of these pheromone components (Boeckh and Boeckh, 1979).

Vogt and Riddiford (1981), in studying the biochemical components of these sensory hairs, identified two proteins uniquely situated in the extracellular receptor lymph of these pheromone-sensitive sensory hairs: a pheromone-binding protein and a sensillar esterase. The binding protein (mol wt = 15,000 daltons) is soluble and present in a concentration of 20 mM (Vogt and Riddiford, 1981). Although this binding protein shows a low affinity for the pheromone, most pheromone is protein bound in vivo because of the extremely high concentration of binding protein (Vogt and Riddiford, 1986). The sensillar esterase, mol wt 55,000 daltons (Kaissling et al., 1985), is present at a concentration at least 10^4 lower than the binding protein (Vogt, 1984). This esterase is extremely aggressive towards the acetate component of the pheromone. We estimated that the half-life of pheromone in the presence of a physiological concentration of this esterase would be approximately 15 msec (Vogt et al., 1985). Hydrolysis of *Z*7-12:Ac by antennal esterases in *Trichoplusia ni* has been previously studied by Ferkovich (1981) and coworkers.

We have now begun to study the biochemical components of these sensory hairs utilizing a photoaffinity analog of the natural pheromone (Vogt et al., 1985, 1986). The analog 6*E*,11*Z*-16:DZA, in which the diazoacetate (DZA) group is substituted for the normal acetate moiety, showed 10% of the electrophysiological activity of the acetate (Ganjian et al., 1978). Unlabeled unsaturated 16:DZA isomers associate with varying specificity to the same proteins with which the natural pheromone associates, i.e., the sensillar esterase, the binding protein, and the putative receptor protein. Furthermore, when a DZA-protein complex is irradiated with UV light, the analog may become covalently attached to the complexed protein. Indeed, Prestwich et al. (1984a) have prepared tritium-labeled 6*E*,11*Z*-16:DZA (58 Ci/mmol), and Vogt et al. (1986) have obtained evidence for pheromone-competable, light-activated irreversible attachment of the DZA to soluble and membrane-bound proteins. Photoaffinity-labeled JH analogs have also been shown to be useful in understanding insect protein–ligand interactions (Prestwich et al., 1984b).

In this paper, we report how several pheromone analogs interact with the sensillar esterase of *A. polyphemus*. Our purpose was twofold. First, we wished to know whether the photoaffinity analog would bind to or be degraded by the sensillar esterase. It is essential to know whether or not the probe would be

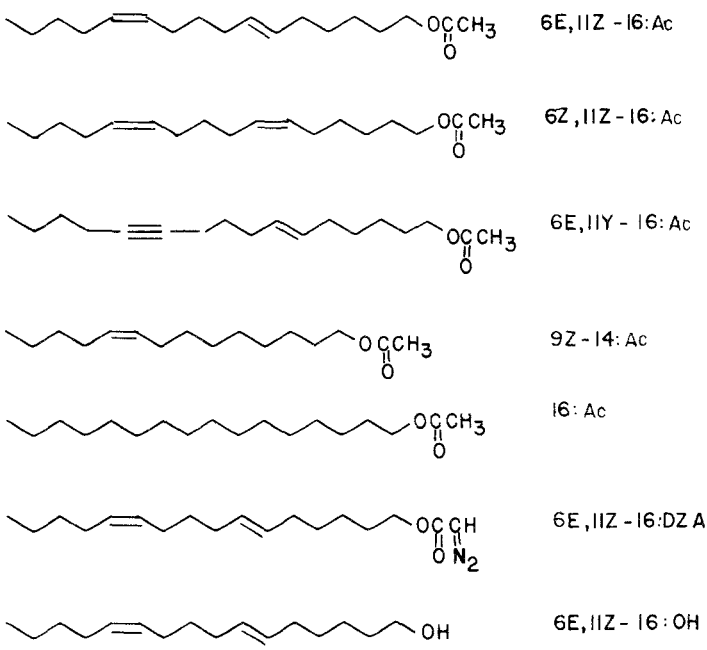

FIG. 1. *A. polyphemus* pheromone and pheromone analogs (unlabeled) used as competitors.

cleaved when complexed to a pheromone-relevant protein. Second, we wished to further examine the substrate selectivity of the soluble biochemical system responsible for pheromone transport and degradation within these sensory hairs. To these ends, a variety of unlabeled pheromone analogs were examined in enzymatic competition studies (Figure 1), and three radiolabeled pheromone analogs were synthesized and tested as alternative substrates (Figure 2).

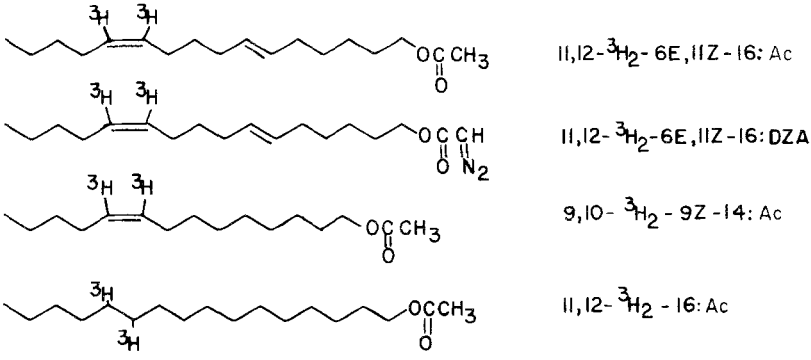

FIG. 2. High-specific-activity tritium-labeled *A. polyphemus* pheromone and pheromone analogs used as alternative substrates.

METHODS AND MATERIALS

Animal and Enzyme Sources. Antheraea polyphemus were purchased as pupae, stored in diapause at 4°C, and reared to adults at 25°C on a 18:6 light–dark photoperiod.

The enzyme preparation used in these studies was the unpurified homogenate of pheromone-specific sensory hairs isolated from the antennae of freshly emerged male moths. The technique of isolating sensory hairs was modified from Klein (Klein and Keil, 1984; Vogt, 1984, Vogt et al., 1983a,b). Branches of antennae were mixed with equal volumes 0.1-mm and 0.5-mm diameter glass beads (B. Braun, West Germany) in a lyophilization flask. The flask was lowered into liquid nitrogen and shaken violently by hand for 5–10 sec. The flask was then rechilled and the process was repeated several times. Freezing made the antennal tissue very brittle, and shaking the flask caused the glass beads to break the sensory hairs from the branches at the hair bases.

Sensory hairs were separated from glass beads and branches by repeatedly pouring the lyophilized material down a trough made of Mylar film. The sensory hairs adhered to the film, and the remaining glass beads and antennal branches were shaken away. Hairs were scraped from the Mylar film using the edge of a coverslip, and were stored in sealed microfuge tubes at −70°C. This preparation routinely required additional removal of branches using forceps under a dissecting microscope. One hundred fifty antennae would yield on the order of 20 mg lyophilized sensory hairs.

Sensory hair homogenates were prepared using an ice-cooled ground-glass microhomogenizer (Bolab), first dry and then with repeated washings with 200-μl aliquots of pH 7.2 mM Tris HCl buffer. A final concentration of 1 mg hair/ml buffer was routinely used (220 μg protein/ml). Residual hair cuticle was removed by centrifugation (12,000 *g*, 5 min, 4°C). Fresh protein solutions were prepared for each day's experiments. In addition, dilutions of the stock hair protein solutions were made just prior to a given substrate of competition assay.

Synthesis of Pheromone Analogs. [11,12-$^3H_2$]-Hexadecyl acetate was prepared by complete reduction of a partially overreduced sample of [11,12-$^3H_2$]-6*E*,11*Z*-hexadecadienyl acetate, prepared as described previously (Prestwich et al., 1984a). Thus, 5 mg of PtO_2 and several milligrams of tritium-labeled acetate (ca. 500 mCi) were stirred 16 hr in 2 ml methanol under an atmosphere of H_2. The product was purified by flash chromatography (5% ethyl acetate–hexane) (Still et al., 1978) in a disposable pipet to give TLC-homogeneous material with a nominal specific activity of 58 Ci/mmol.

[9,10-$^3H_2$]-(*Z*)-9-Tetradecenyl acetate was prepared by reductive tritiation of the 9-tetradecyn-1-yl acetate. The latter was prepared by Y.-S. Ding (Stony Brook) by alkylation of 1-tetrahydropyranyloxy-8-bromooctane with the acetylide of 1-hexyne in THF–HMPA (Henrick, 1977). Acid hydrolysis of the THP ether (CH_3CO_2H–THF–H_2O = 4:2:1), acetylation (Ac_2O, Py), and flash chromatography provided the necessary starting material.

The tritiation was carried out at the NIH Tritiation Facility at Lawrence Berkeley Laboratory. To a sample of 10 mg of 9-tetradecyn-1-yl acetate in 5 ml of hexane was added 3 mg of 5% $Pd/BaSO_4$ and 10 μl of a 100 $\mu g/\mu l$ hexane solution of quinoline. The reaction vessel was freeze-degassed and the reaction was stirred 20–30 min under 1 atm of carrier-free T_2 gas. The reaction was stopped at ca. 60% conversion. Prior experience indicated that taking the reaction to completion generated hard-to-remove overreduction products. The tritium and volatiles were removed in vacuo to reduce the volume by half, and the crude product mixture was centrifuged to remove the catalyst. The supernatant was concentrated under N_2 and chromatographed on flash silica gel with 3% ethyl acetate–hexane and then on 20% $AgNO_3$-coated flash silica gel with 6% ethyl acetate–hexane to give complete separation of the desired [9,10-$^3H_2$]-9*Z*-14:Ac (58 Ci/mmol) from the alkyne precursor.

[11,12-$^3H_2$-Hexadecadienyl diazoacetate (58 Ci/mmol) was prepared from the corresponding radiolabeled acetate by hydrolysis and diazoacetylation as described previously (Prestwich et al., 1984a).

Unlabeled analogs were available as intermediates from prior synthetic work. Thus, 6*E*,11*Z*-hexadecadien-1-ol, 6*E*-hexadecen-11-ynyl acetate, and 6*E*,11*Z*-hexadecadienyl diazoacetate were prepared as described elsewhere (Prestwich et al., 1984a). 6*Z*,11*Z*-Hexadecadienyl acetate was obtained by $AgNO_3$–SiO_2 chromatography of an 85:15 6*Z*:6*E* mixture obtained from a Wittig coupling performed by Dr. F.A. Golec (unpublished results). Unlabeled 6*E*,11*Z*-hexadecadienyl acetate and 9*Z*-tetradecenyl acetate were prepared during model studies for the tritiation experiments using H_2 in place of T_2.

All unlabeled pheromone analogs were prepared as 2.1×10^{-2} M stock solutions in heptane. For the experiments, ethanol stock solutions at 2.1×10^{-4} M were prepared by transferring 20 μl of heptane stock to a clean glass vial, blowing off solvent with N_2, and vortexing with 2.0 ml of absolute ethanol. Aqueous pheromone working solutions were prepared less than 2 hr prior to use in experiments to minimize concentration changes, since pheromones and analogs slowly adsorbed onto the glass. Preliminary experiments with labeled pheromones had indicated that this method of preparing working solutions gave stable and reproducible pheromone concentrations in the 10^{-5} to 10^{-9} M range. Thus, 50 μl of the 2.1×10^{-4} M ethanol stock was added to 1.0 ml of 10 mM Tris HCl buffer (pH 7.2) with vigorous vortexing to give a 1×10^{-5} M working solution from which serial dilutions of 1:10 (10^{-6} M), 1:100 (10^{-7} M), and 1:1000 (10^{-8} M) were rapidly prepared.

Solutions of labeled pheromone and pheromone analogs were prepared from hexane stock solutions of materials synthesized three months prior to these experiments and stored at −70°C. When necessary (i.e., when purity as assessed by TLC plate scraping was <98%), compounds were repurified by flash chromatography. Elution with 5% ethyl acetate–hexane gave radiochemically homogeneous materials which were used within three to four weeks. To prepare working solutions, an intermediate ethanol stock was prepared of each material

by evaporation of 100 μl of the hexane or heptane stock (1–3 mCi in each case) under N_2 and redissolving the radiolabeled analog in 200 μl of absolute ethanol. The ethanol stocks ($\sim 10^{-4}$ M) were stored at 4°C between daily preparations of aqueous solutions. A fresh working solution was made by addition of 10 μl into 1.0 ml Tris HCl buffer at room temperature and then prompt preparation of 1:10, 1:100, and 1:1000 dilutions. Unused solutions were discarded daily, but the vials were reused for the same analog and same dilutions to minimize adsorption problems for these 10^{-6} to 10^{-9} M solutions.

Analog Metabolism Assays. Enzyme dilution, labeled analog degradation, and competition studies were all performed following the same general protocol. First, protein solutions from sensory hair homogenates were freshly prepared and fresh aqueous pheromone analog and labeled pheromone solutions were prepared. Next, protein solutions (60 μl) were added to eight 10 × 75-mm borosilicate tubes. At 1-min intervals, 60 μl of radiolabeled pheromone solution was added. Each incubation (duplicates of four concentrations) was for 10 min at 20°C. A 3-μl aliquot (to determine [^{3}H]pheromone concentration) was removed from the aqueous solution using a calibrated, disposable glass micropipet, and 3 ml of Aquasol was added for LSC. At t = 10 min, 180 μl of ethyl acetate was added and vortexed vigorously for 15 sec. A 3-μl aliquot of the upper layer was removed to determine recovery (LSC), and a second 3-μl aliquot was spotted on a 4 × 8-cm Machery-Nagel Polygram Sil G/UV 254 plate. Plates were divided into four vertical strips and were prespotted with unlabeled 6*EZ*,11Z–16:Ac (substrate marker) and 6*EZ*,11Z–16:OH (product marker). The plates were developed in 20% (v/v) ethyl acetate–hexane; the substrate (R_f 0.61) and product (R_f 0.33) spots were visualized with I_2, and the spots were scraped into scintillation vials and counted in 3 ml Aquasol using a Beckman LS230 scintillation counter (39% efficient for tritium with minimal quenching).

The enzyme dilution experiment was performed using a 1:10 ($\sim 10^{-7}$ M) solution of [^{3}H]-6*E*,11Z–16:Ac, a fresh 1 mg/ml sensory hair preparation (220 μl protein/ml), and 1:10, 1:100, and 1:1000 dilutions of this sample. Incubation and TLC assay were performed as above.

Degradation of labeled analogs was performed with undiluted sensory hair homogenates and serial dilution (1:10 to 1:1000) of labeled analog working solutions. For these experiments no competitor was added, and 120 μl of labeled analog solution was used instead of 60 μl.

RESULTS AND DISCUSSION

Enzyme Dilution. We found that the hydrolytic activity of the sensory hair homogenates declined during the course of 8 hr of experimentation; this was most severe in diluted samples. The maximum conversion observed for a 10-

min incubation at 20°C was 76% with an undiluted fresh protein solution; the minimum was 38%. Thus, dilutions of the stock (1.0 mg sensory hairs/ml) were prepared immediately prior to a given assay.

In initial attempts to observe displacement of [^{3}H]-6*E*,11*Z*-16:Ac by the unlabeled pheromone, we observed essentially no competition at the highest concentration (3×10^{-6} M), indicating that we had not saturated the enzyme at this concentration. Since it was impossible to raise the pheromone concentration without exceeding the limits of solubility (in the absence of detergents or cosolvents), it was necessary to reduce the quantity of enzyme in the assay. A dilution series of undiluted, 1:10, 1:100, and 1:1000 gave conversions to the 6*E*,11*Z*-16:OH of 76%, 68%, 20%, and 4%, respectively. Subsequent competition experiments were run with the enzyme concentration which gave ~50% conversion, that is, a 1:30 dilution of stock. Vogt (1984) estimated that the sensillar esterase comprised less than 0.01% of total soluble protein of a sensory hair. Therefore, based on a maximum estimate of 0.1 μg enzyme/ml in stock, the enzyme concentration in the 1:30 dilution is at most 3 ng/ml or ca. 5×10^{-11} M.

Competition Studies. Using a 1:30 dilution of the stock sensory hair protein solution, the relative competitive abilities of different pheromone analogs and homologs (Figure 1) was examined. In these assays, the concentration of [^{3}H]-6*E*,11*Z*-16:Ac was held constant at 1.8×10^{-7} M and the competitor concentration varied from 3×10^{-9} M to 3×10^{-6} M. Conversions were calculated as the ratio of cpm of [^{3}H]-6*E*,11*Z*-16:OH (product) to total recovered cpm of this alcohol plus the acetate substrate. The concentration of [^{3}H]-6*E*,11*Z*-16:Ac used in this assay was below the estimated K_m of 2.2×10^{-6} M for the hydrolysis of the natural pheromone by the sensillar esterase (Vogt et al., 1985). In addition, approximately 30,000 cpm were present in the 3-μl aliquot assayed by TLC, so that our detection limit for low hydrolysis rates was on the order of a few percent. In all cases, the recovery from the TLC plates was in the range 85–95% of the cpm applied as determined by counting an equal aliquot of the applied ethyl acetate layer. All assays were performed in duplicate and are expressed as mean values normalized to maximal conversion at the lowest concentration of competitor (Figure 3).

There appear to be two main subsets among the competitors assayed. The first group consists of those analogs that possess competitive abilities equivalent to the natural pheromone. In this subset one finds the 6*Z* isomer of the natural pheromone, the diazoacetate analog of the natural pheromone, and 9*Z*-14:Ac. Each of these has a "kinked" hydrocarbon chain as well as an acetoxy or diazoacetoxy group as a terminal substituent.

The "poor" competitors include the 11-triple bond analog, the saturated hexadecyl acetate, and the product 6*E*,11*Z*-16:OH. These lack either the acetoxy group or the kinked hydrocarbon chain. It appears that the length of the chain is less important than the presence of a cisoid *Z*-linkage in the chain. This

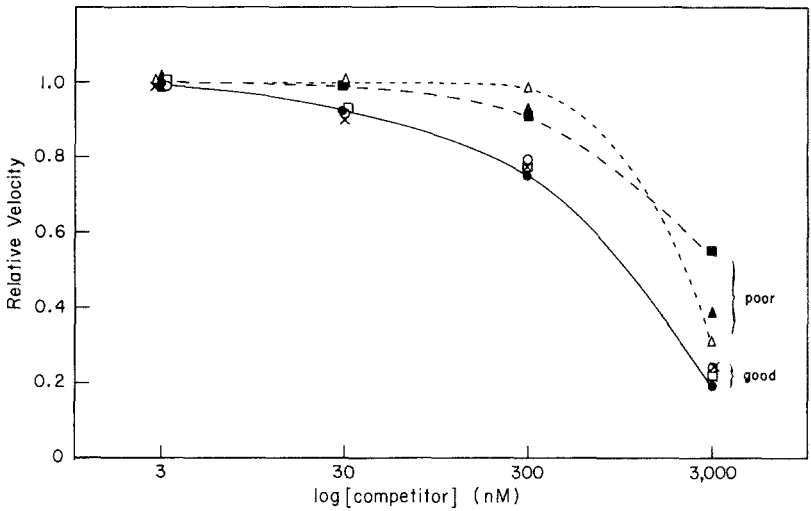

FIG. 3. Competitive displacement of [11,12-$^3H_2$]-6*E*,11Z–16 : Ac by unlabeled analogs. Percent hydrolysis (mean of two determinations) was normalized in each set to relative velocity = 1.0 for the lowest concentration of competitor to correct for fluctuations in sensillar esterase activity during a series of experiments. Good competitors: (●) 6*E*,11Z–16 : Ac; (○) 6*E*,11Z–16 : DZA; (×) 6Z,11Z–16 : Ac; (□) 9Z–14 : Ac. Poor competitors: (△) 6*E*,11-yne-16 : Ac; (▲) 16 : Ac; (■) 6*EZ*,11Z–16 : OH.

is consistent with the data of Priesner et al. (1975), which demonstrated that the pheromone analogs of highest behavioral activity are those in which the Z-alkene is correctly located relative to the methyl end of the chain instead of the acetate end.

Hydrolysis of Alternative Substrates. Using an undiluted stock sensory hair preparation, the hydrolysis rates of three pheromone acetate and diazoacetate analogs (Figure 2) were compared with that of the natural pheromone. This experiment is complementary to the competition study in that it defines the catalytic site selectivity of the sensillar esterase, while the competition study focuses on the enzyme's general preference for substrate analogs. In other words, this experiment provides direct evidence on the selectivity of the sensillar exterase in hydrolyzing substrate analogs.

Each radiolabeled substrate was examined in duplicate at three or four concentrations, and the percent hydrolysis was calculated from the ratio of product alcohol to total alcohol plus analog cpm recovered from the TLC plate. The substrates were all synthesized by reduction of an acetylenic bond with carrier-free tritium (Prestwich et al., 1984a) and have nominal specific activities of 58 Ci/mmol. Substrates were rechromatographed within three weeks of use and were examined for homogeneity by TLC just prior to incubations.

The results of the enzymatic hydrolysis of the tritium-labeled natural pheromone, the 9Z–14:Ac, the saturated hexadecyl acetate, and the 6*E*,11Z–16:DZA are shown in Table 1. In agreement with their relative competitive abilities, [^{3}H]-9Z–14:Ac is a good substrate and [^{3}H]-16:Ac and [^{3}H]-6*E*,11Z–16:DZA are poor substrates.

It is evident from Table 1 that the rate of hydrolysis of [^{3}H]-9Z–14:Ac is not constant at low concentrations, increasing from 19% to 62% (in 10 min) as the concentration increases three orders of magnitude. In evaluating these data, it is important to recall that the sensory hair preparation contains a pheromone binding protein (mol wt 15,000) at a concentration at least 10,000-fold greater than that of the enzyme (Vogt, 1984), and with an in vivo concentration of about 20 mM (Vogt and Riddiford, 1981). Unlike the very aggressive sensillar esterase (Vogt et al., 1985a), this relatively smaller binding protein apparently

TABLE 1. ALTERNATIVE SUBSTRATES FOR SENSILLAR ESTERASE

[c] This value reflects the radiochemical purity of the starting acetate.

has a very low affinity for the pheromone. Vogt and Riddiford (1986) have proposed that this sensillar binding protein buffers the pheromone against enzymatic degradation through low specific protein–pheromone interactions enhanced by the extremely high endogenous binding protein concentration. This combination of a high concentration of a low-affinity binding protein and a low concentration of an aggressive esterase could allow modulation of the amount of pheromone reaching the receptor over some six or more decades of phero mone concentration (Vogt et al., 1985; Vogt, 1984; Vogt and Riddiford, 1986). We suggest that the low rate of degradation of [^{3}H]-9Z–14:Ac at its lowest concentrations may reflect this buffering capacity of the binding protein.

CONCLUSION

Studies with analogs of 6*E*,11*Z*–16:Ac, the major component of the *A. polyphemus* pheromone, show that the sensillar esterase in male antennae has a distinct preference for substrates with conformations most similar to the natural pheromone. This is consistent with previous findings (Vogt et al., 1986; Vogt and Riddiford, 1986), and supports the hypothesis that the principal function of this esterase is to inactivate the sex pheromone.

Although the diazoacetate analog most similar to the natural pheromone proved to be a reasonably good competitive inhibitor of pheromone degradation, it proved to be a rather poor substrate for enzymatic hydrolysis. This means that, while the active site on the sensillar esterase clearly recognizes this analog, it is not capable of binding it in a manner that allows for the analogs' hydrolysis. This is a positive finding in terms of the usefulness of utilizing this probe to label pheromone-relevant proteins. However, UV irradiation of this 6*E*,11*Z*–16:DZA–sensillar esterase complex does not provide detectable amounts of labeled enzyme, although photoattachment of this diazoacetate analog to the soluble and membrane-bound protein constituents of these pheromone-sensitive sensory hairs does occur (Vogt et al., 1986).

Acknowledgments—This work was carried out during G.D.P.'s sabbatical and was partially supported by an Alfred P. Sloan Research Fellowship (1981–1985) and a Camille and Henry Dreyfus Teacher-Scholar Award (1981–1986). PHEROMONE BIOSYNTHESIS AND ROLE OF FUNCTIONAL GROUPS IN PHEROMONE SPECIFICITY

DAVID MORSE and EDWARD MEIGHEN

Department of Biochemistry, McGill University
3655 Drummond Street
Montreal, P.Q. H3G 1Y6

(Received March 25, 1985; accepted August 1, 1985)

Abstract—The sex attractants for many Lepidoptera are long-chain, monounsaturated acetate esters, alcohols, and aldehydes. In vivo metabolic studies and enzyme analysis in vitro have provided evidence that the aldehyde pheromone of the eastern spruce budworm is synthesized de novo via an acetate ester precursor. Interconversion of the functional groups (ester, alcohol, aldehyde) can explain differences in the pheromone blends used by closely related species.

Key Words—Acetate esters, alcohols, aldehydes, fatty acid biosynthesis, insect pheromones, Lepidoptera, pheromone biosynthesis, spruce budworm.

INTRODUCTION

Although the pheromone complement of a given insect is typically a complex mixture of two or more components, the building blocks, or components, of lepidopteran pheromones are relatively simple molecules with many structural similarities (Inscoe, 1982). Most pheromones of Lepidoptera are composed of a limited number of long-chain monounsaturated acetate esters, alcohols, or aldehydes, which vary with respect to chain length as well as position and configuration of the double bond.

Consideration of the lepidopteran sex attractants, listed in a recent review (Inscoe, 1982) for almost 400 species, shows that the majority (77%) of species have pheromones with monounsaturated carbon chains between 10 and 16 carbons in length. These compounds are displayed in a three-parameter diagram in Figure 1. The number of species attracted to a given compound is shown in the vertical dimension for each combination of chain length, double-bond po-

0098-0331/86/0200-0335$05.00/0

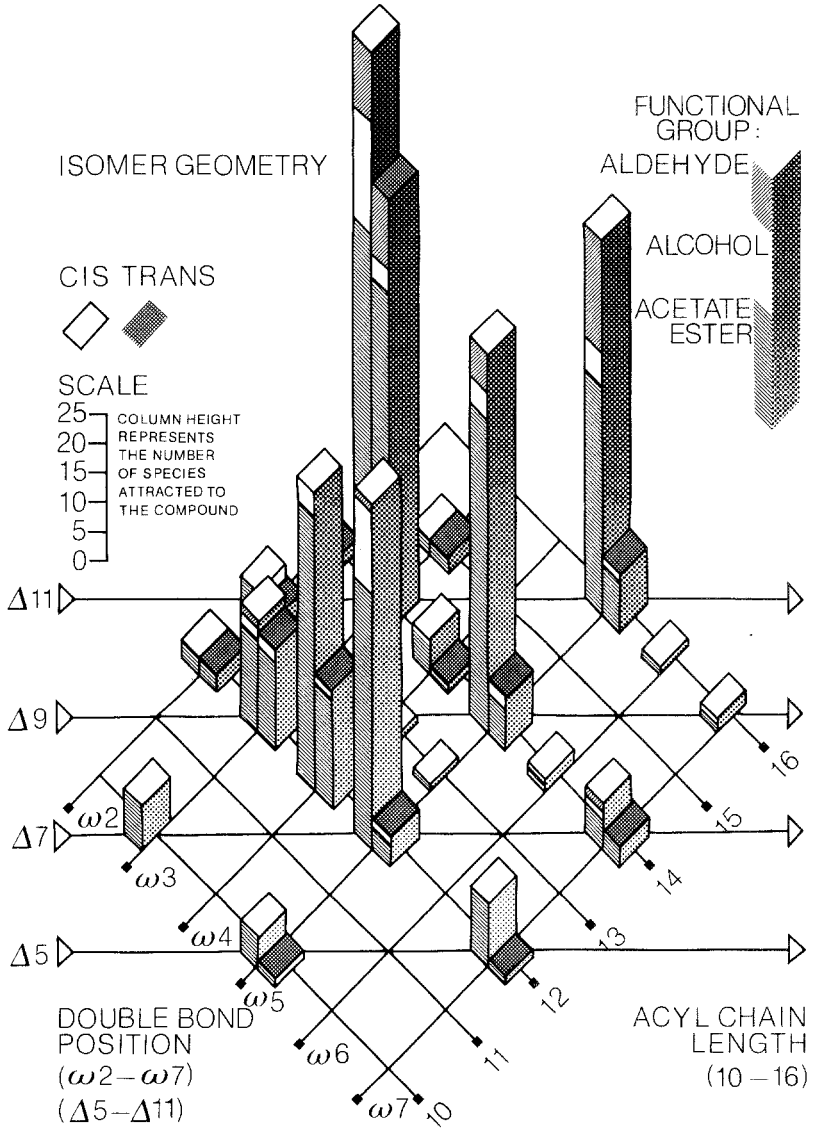

FIG. 1. Common lepidopteran sex attractants. Dependence of the number of lepidopteran species that use monounsaturated fatty acid derivatives as sex attractants on the chain length, double-bond position (ω and Δ) and configuration (*trans* or *cis*) and functional group (acetate ester, alcohol, or aldehyde). The data was compiled from a recent listing of insect sex attractants (Inscoe, 1982), and includes attractants for 293 of the 379 lepidopteran species. Saturated or polyunsaturated compounds which are the attractants for most of the remaining species were not included.

sition and configuration, and functional group. The horizontal and oblique axes define the chain length and the double-bond position with respect to either the terminal carbon atom of the chain (ω1) or the carbon containing the functional group (Δ1). This presentation emphasizes the close metabolic relationships between the different pheromones by grouping the six chemical structures resulting from two configurations at the double bond (*cis* or *trans*) and the three different functional groups (ester, aldehyde, or alcohol). These groupings are based on the assumptions that the two configurational isomers are synthesized by similar means and that the functional groups can be readily interconverted in the insect.

A strong metabolic relationship also exists between the components along each ω axis since, once the double bond is formed, its position relative to the terminal carbon (ω value) is independent of the processes of chain shortening or elongation as these occur at the functional Δ1 carbon. Consider, for example, all compounds on the ω3 axis. A Δ11-specific desaturase (Bjostad and Roelofs, 1981), active on 14-carbon acyl chains, could produce all compounds on this axis if coupled with mechanisms for chain shortening and elongation. Similarly, a Δ3-desaturase active on six-carbon acyl chains could produce the same range of compounds if coupled with a mechanism for chain elongation.

Evidence for de novo synthesis of pheromones in Lepidoptera is supported by both morphological and biochemical data (Blomquist and Dillwith, 1983). In vivo labeling studies of the eastern spruce budworm (*Choristoneura fumiferana*) have shown that an acetate ester is synthesized de novo and serves as a precursor to the aldehyde pheromone (Morse and Meighen, 1984b). The release of pheromone coincides with extrusion of the pheromone-producing gland (Sanders, 1969) which is morphologically identical to pheromone glands of other insects (Roelofs and Feng, 1968).

Recent enzyme and metabolic studies on the eastern spruce budworm have shown that the three major classes of functional groups (esters, alcohols, aldehydes) are interconverted during biosynthesis of its aldehyde pheromone, *trans/cis*-11-tetradecenal (96:4) (Morse and Meighen, 1984a, b; unpublished data). From these results, a metabolic pathway for de novo synthesis of the spruce budworm pheromone can be formulated (Figure 2) which includes those enzymes that have so far been implicated in pheromone biosynthesis. The proposed location of these enzymes is based on subcellular fractionation experiments (Morse and Meighen, 1984a; unpublished data) and ultrastructural studies of the gland (Percy, 1974) as well as information concerning the location of similar enzymes in other tissues. This biosynthetic pathway is of particular value since it can explain how distinct pheromone signals utilizing different functional moieties (ester, alcohol, and aldehyde) could have arisen for members of the budworm genus and also may explain pheromone differences in species of other genera of the Lepidoptera. The goal of this work is to summarize the evidence

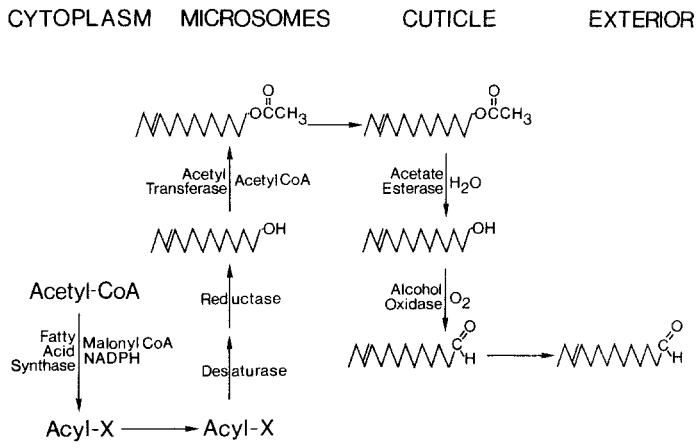

FIG. 2. Proposed pathway for pheromone biosynthesis in the eastern spruce budworm. This model incorporates the results from metabolic and enzyme studies on the spruce budworm into a framework consistent with morphological and biochemical observations in other systems. The pathway begins with fatty acid synthesis and ends with release of the aldehyde pheromone (96:4, *trans*:*cis*-11-tetradecenal) from the insect.

for specific steps in this pathway and to define more closely the role and metabolic relationship of the pheromone functional groups of Lepidoptera.

METHODS AND MATERIALS

Materials. [9,10-^{3}H]Myristic acid (23 Ci/mmol) was prepared by New England Nuclear by catalytic reduction of *cis*-9-tetradecenoic acid. [1-^{14}C]Myristate was purchased from Amersham; [^{3}H]acetyl-CoA, [2-^{14}C]malonyl-CoA, and [1-^{14}C]acetate were from New England Nuclear. Labeled tetradecanol was prepared by $LiAH_4$ reduction of labeled myristate in dry ether and purified by thin-layer chromatography. All other reagents were purchased from Sigma. Phosphate buffers were prepared by diluting appropriate amounts of 1.0 M NaH_2PO_4 and 1.0 M K_2HPO_4.

Pupae of female eastern budworms (*Choristoneura fumiferana*) were kindly supplied by Dr. Gary Grant of the Forest Pest Management Institute, Sault Ste Marie. The pupae were allowed to emerge under natural lighting. Glands were excised from the female moths and homogenized in 0.05 M phosphate, pH 7.0, with a motor-driven pestle at 500 rpm for 2 min (10 glands/ml).

In Vivo Labeling of Insects. Radioactive compounds ($\sim$1 nmol) were applied in dimethyl sulfoxide ($\leq$0.1 μl) to the glands of individual female moths (Bjostad and Roelofs, 1981; Morse and Meighen, 1984b). After 1 hr, the glands were excised and extracted with hexane.

Enzyme Assays. Acetate ester, alcohol oxidase, and aldehyde dehydrogenase assays were conducted as described previously (Morse and Meighen, 1984a). No difference in enzyme levels in extracts was observed between glands excised in the photophase or scotophase.

Thin-Layer Chromatography (TLC) and Autoradiography. Silica gel chromatography was performed on Machery Nagel Sil N-UV_{254} TLC plates, heat activated for 60 min at 110°C and developed for 90 min in hexane–ether–acetic acid (90:10:2). Argentation chromatography was performed in the same solvent on silica gel TLC plates sprayed with a 7.5% solution of $AgNO_3$ in 90% ethanol and then heated for 60 min. Reversed-phase chromatography was performed on Whatman KC18-F TLC plates, which were used without heating and developed for 20 min in CH_3CN–tetrahydrofuran–methanol (65:1:10). TLC plates containing ^3H-labeled ligands were generally treated with ENhance (NEN) prior to exposure. However, this procedure cannot be used for plates containing $AgNO_3$. Autoradiography was performed by exposing the TLC plate to Kodak X-AR OMAT film at −70°C.

RESULTS AND DISCUSSION

Fatty Acid Biosynthesis. Biosynthesis of the carbon chain backbone is the first step in the de novo formation of the pheromones in Lepidoptera. Fatty acid biosynthesis involves the stepwise addition of two carbon units from malonyl-CoA to the carboxyl functional group of an acyl derivative starting with acetyl-CoA (Volpe and Vagelos, 1973, 1976; Bloch and Vance, 1977). In animal cells, fatty acid synthase (FAS) is found in the cytoplasm (Volpe and Vagelos, 1973; 1976). Eukaryotic systems also contain two other systems believed to function in chain elongation of existing fatty acids (Bloch and Vance, 1977); a mitochondrial system which operates by reversal of β-oxidation using acetyl-CoA, and a microsomal system which appears to have a mechanism similar to the cytosolic FAS system (Khan and Kolattukudy, 1973; Sanchez and Harwood, 1981).

Fatty acid synthase activity has been measured in extracts of the budworm gland by the incorporation of [^3H]acetyl-CoA and [^{14}C]malonyl-CoA into hexane-soluble material with an isotope ratio ($^{14}C/^3H$) of approximately 8:1. The fatty acids, synthesized in vitro, appear to be saturated since chromatography on silver nitrate thin-layer plates, which resolves saturated and unsaturated fatty acids, gave only one product that comigrated with saturated fatty acid (Figure 3).

Free fatty acids have also been observed during in vivo labeling of the budworm gland with ^{14}C-labeled acetate, myristate, and tetradecanol. Analysis of the labeled fatty acids in a reversed-phase TLC system indicates that the fatty acids have chain lengths of between 12 and 18 carbons (Figure 4). This TLC

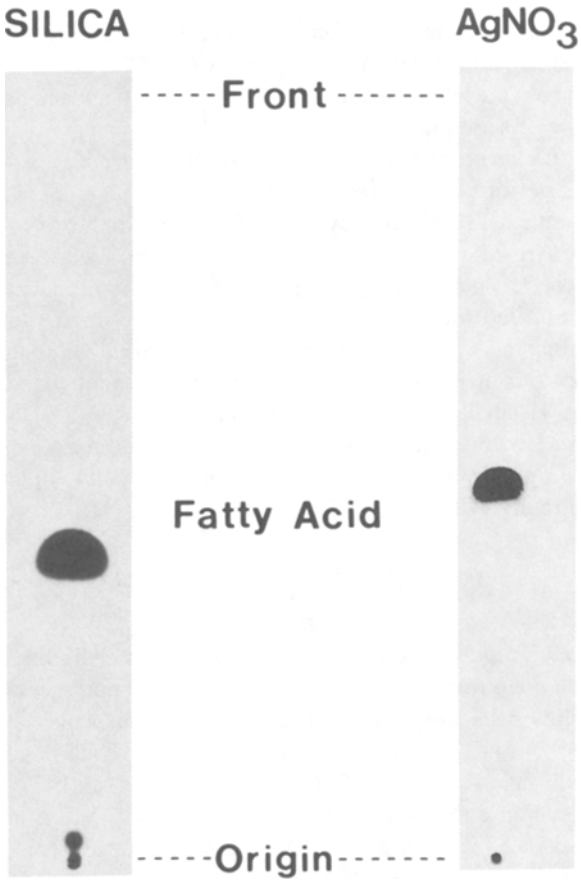

FIG. 3. In vitro fatty acid synthase activity in gland extracts. The reaction mixture (at 37°C) contained 15 μM [^{3}H]acetyl-CoA, 10 μM [^{14}C]malonyl-CoA, 500 μM NADPH and 2 μg gland homogenate in 1.0 ml 0.05 M phosphate buffer (pH 7.0), 1 mM dithiothreitol. Fatty acids, extracted into hexane after 20–60 min, were chromatographed on silica gel and silica gel plates sprayed with a 7.5% solution of $AgNO_3$. The radiolabeled product comigrates with saturated fatty acids in both systems. Minor amounts of radiolabel at or near the origin are acetyl-CoA and acetate.

system cannot distinguish between a monounsaturated acid and a saturated acid two carbons shorter. For the samples labeled with [1-^{14}C]myristate or [1-^{14}C]tetradecanol, it appears that 14:1 and not 12:0 acids are formed, as the radiolabel would be lost on direct chain shortening. Furthermore, degradation followed by de novo synthesis would not account for the apparently higher level of incorporation of label into free fatty acid (14:1/12:0) from myristate and

tetradecanol than from [1-^{14}C]acetate. Interestingly, the labeled fatty acids, released by saponification of the triglycerides, have the same distribution of chain lengths as the free fatty acids (Figure 4), suggesting that these fatty acids can be used directly in triglyceride biosynthesis in vivo.

The formation of free fatty acids has been observed in insect tissue homogenates (Municio et al., 1972; Ryan et al., 1982) as well as in mammalian systems (Bloch and Vance, 1977). In the mammalian systems, palmitic acid is the major product due to a thioesterase associated with FAS that cleaves acyl chains containing 16 carbon atoms. In several other systems, a thioesterase distinct from the FAS has been shown to produce short-chain fatty acids by cleavage of the growing acyl chains (Rogers et al., 1982; Ryan et al., 1982). Short-chain fatty acids can also be formed by limited β-oxidation of the palmitate normally formed by the FAS (Chang and Holman, 1972). Chain shortening has been implicated in the biosynthesis of the cabbage looper pheromone, as radiolabel from a ω5 16-carbon acid was found to be incorporated in vivo into the ω5 12-carbon backbone of the pheromone (Bjostad and Roelofs, 1983).

Although free fatty acids can be formed by the spruce budworm, the incorporation of label from fatty acid ([^{14}C]myristate) into the acetate ester precursor of the budworm pheromone (Morse and Meighen, 1984b) indicated that this fatty acid must first be degraded before label could be incorporated by de novo synthesis. Not only was the incorporation of label from other fatty acids into the acetate ester the same as from myristate but radiolabel incorporation from [9,10-^{3}H]myristate was fivefold less than from [1-^{14}C]myristate. The differential incorporation of the two labels provides a sensitive indicator for β-oxidation and degradation followed by resynthesis since the tritium label is preferentially lost under these conditions. It appears that the free exogenous fatty acids cannot be efficiently used in the budworm to produce the pheromone, suggesting that the fatty acyl chains may be channeled directly from the FAS system, possibly by transacylation rather than by hydrolysis (Knudsen and Grunnet, 1982). Interestingly, other work on insect systems has suggested that exogenous (dietary) fatty acids are different than newly formed acids (Keith, 1967). Furthermore, fatty acids released in an activated form (as acyl derivatives) can be used directly in desaturation or reduction steps whereas free fatty acids must first be activated (Groot et al., 1976).

Fatty Acid Desaturation and Reduction. Very little is known about the mechanisms of desaturation and reduction of fatty acids to form the unsaturated pheromones of Lepidoptera. In mammalian systems, a desaturase that acts specifically on acyl-CoAs in the presence of NADPH and molecular oxygen to introduce a double bond at the Δ9-position has been widely studied (James, 1977; Jeffcoat, 1979). All mammalian Δ9-desaturases have been localized in the microsomal fractions on subcellular fractionation.

An alternative method of desaturation is used in bacteria and involves the introduction of a double bond into a growing acyl chain (Scheuerbrandt and

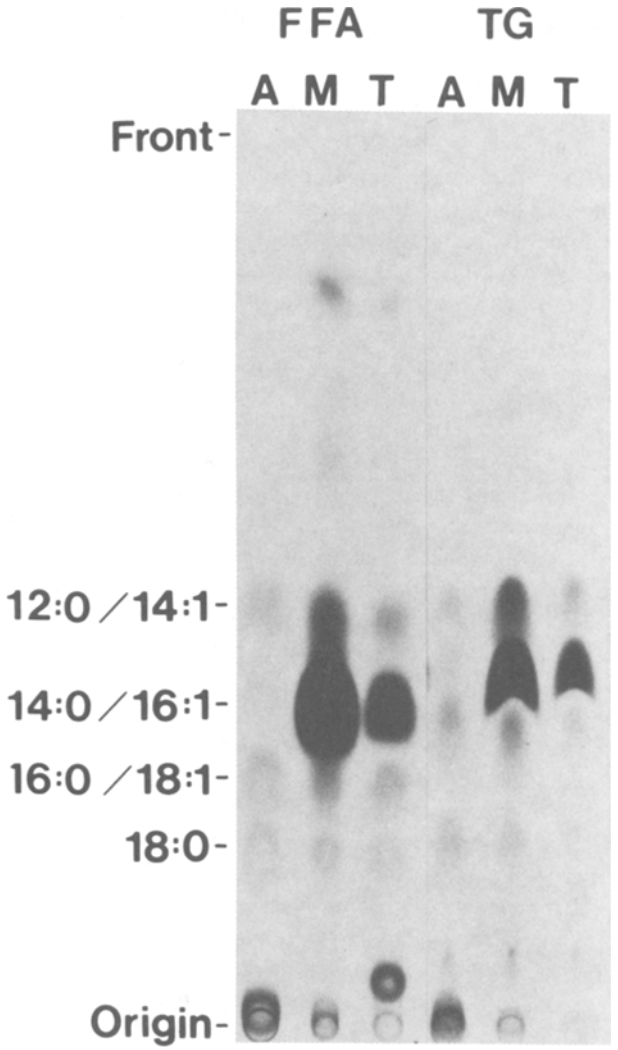

FIG. 4. Analysis by TLC of fatty acids synthesized in vivo. The glands of 20 female budworm moths were labeled with 0.8 nmol/gland [1-^{14}C]acetate (A) (56 mCi/mmol), 1.7 nmol/gland [1-^{14}C]myristate (M) (31 mCi/mmol), or 1.2 nmol/gland [1-^{14}C]tetradecanol (T) (31 mCi/mmol). After a 60-min incubation, the glands were excised, extracted with hexane, and the radiolabeled lipids separated by thin-layer chromatography (TLC) on silica gel. The free fatty acids (FFA) and the triglycerides (TG) were then extracted from the silica and rerun on a reversed-phase TLC system as shown. The positions of fatty acid standards run in parallel are indicated on the ordinate. The TG sample was saponified before reversed-phase TLC.

Bloch, 1962). A specific β-hydroxydecanoyl thioester dehydrase produces a Δ3-decenoyl derivative that can be further elongated to form palmitoleic acid (Kass et al., 1967; Brock et al., 1967).

A Δ11-desaturase has been proposed to be involved in the biosynthesis of the pheromone of the redbanded leafroller based on a higher incorporation of myristate vs. acetate label into the unsaturated pheromone, whereas other lipids were preferentially labeled by acetate (Bjostad and Roelofs, 1981). In contrast, a similar level of incorporation of label from either myristate or acetate was observed for the unsaturated ester of the spruce budworm (Morse and Meighen, 1984b). These results could reflect differences in the relative rates of desaturation and degradation in the two insects. Alternatively, the differences could be due to the shorter labeling period (2 hr) used for the budworm moth compared to that used for the redbanded leafroller moth (24 hr) which encompasses its pheromone release period. Thus, the possibility that the most stable metabolic pool (e.g., myristate) preferentially labels those lipids which are turned over at the highest rate during the labeling period cannot be excluded.

Although the reduction of fatty acids and fatty acyl-CoAs has been studied in other systems (Griffith et al., 1981; Moore and Snyder, 1982; Riendeau et al., 1982; Rodriguez et al., 1983), this activity has not been detected in extracts of insects. The reduction of fatty acids by extracts from eukaryotic cells is generally catalyzed by microsomal fractions. Fatty alcohols, and not fatty aldehydes, are the major product as aldehyde reductases appear to be associated with the fatty acid reductases (Riendeau and Meighen, 1985), presumably to prevent the accumulation of the relatively reactive, and thus toxic, aldehyde.

Aldehyde reductase, but not fatty acid reductase, activity has been detected in extracts of the gland of the spruce budworm (Table 1). In this experiment, the labeled aldehyde substrate is produced in situ by a bacterial fatty acid reductase (Riendeau and Meighen, 1981). In the presence of the gland homogenate, the aldehyde could be reduced to the alcohol with NADPH. The amounts of the different substrates and products were determined by scintillation counting after separation by thin-layer chromatography on silica gel. Unfortunately, this assay cannot be used to characterize the aldehyde reductase since the observed properties reflect those of the coupled system. An alternate coupled assay involving the conversion of the alcohol product into a labeled acetate ester with [^{3}H]acetyl-CoA has also shown that aldehyde can be reduced by gland extracts.

The specificity of the reductase system in the gland for unsaturated fatty acids will be important since it has been suggested that the ratio of unsaturated isomers (*cis* and *trans*) in the pheromone may also be controlled by this enzyme (Blomquist and Dillwith, 1983). In some species, the ratio of isomers of unsaturated fatty acids differs from the isomer ratio of the pheromone (Wolfe et al., 1981). It appears likely that the desaturase and reductase function in concert, with the reductase modifying the isomeric ratio produced by the desaturase.

TABLE 1. ALDEHYDE REDUCTASE ACTIVITY IN GLAND EXTRACTS

Added components[a]	Product (%)		
	Acid	Aldehyde	Alcohol
Reaction mixture	82	4	8
+ Fatty acid reductase (FAR)	28	56	8
+ Gland homogenate	85	4	5
+ FAR + gland homogenate	12	51	30

[a] The reaction mixture contained 0.4 μM [9,10-^{3}H]myristate (22.8 Ci/mmol), 1 mM ATP, 1 mM NADH, 1 mM NADPH, 0.1 mM CoA, and 0.1 mM $MgCl_2$ in 1 ml of 0.05 M phosphate buffer (pH 7) containing 1 mM β-mercaptoethanol. After a 60-min incubation, the aqueous medium was extracted with ether, and the products separated on silica TLC. The fatty acid reductase from *Photobacterium phosphoreum* produces significant levels of aldehyde from the acid, whereas the gland homogenate could not reduce the fatty acid directly but could reduce the aldehyde to alcohol.

Biosynthesis of Acetate Esters. The activity directly responsible for synthesis of the acetate ester has been measured both in gland extracts of the budworm moth (manuscript in preparation) and in the living insect (Morse and Meighen, 1984b). In vivo, the activity was detected by the incorporation of [1-^{14}C]tetradecanol directly into a saturated ester product. In vitro, the enzyme was found to be specific for long-chain alcohol acceptors with acetyl-CoA as the acyl donor (designated fatty alcohol: acetyl-CoA O-acetyl transferase). Activity was found only in gland extracts from the female moth, indicating that this enzyme was exclusively involved in pheromone biosynthesis. On subcellular fractionation, the acetyltransferase sedimented in the microsomal fraction with the smooth endoplasmic reticulum (SER), which is involved in lipid metabolism and is present in large amounts in the gland cells (Percy, 1974). As the SER is generally associated with the storage and secretion of material, this result is consistent with the high levels of 11-tetradecenyl acetate (96:4, *trans-cis*) in the gland and their dependence on diurnal rhythm (Silk et al., 1980) and support the proposal that the acetyltransferase synthesizes a stored acetate ester precursor that is secreted to form the aldehyde pheromone (Figure 2).

Formation of Aldehyde Pheromone. An acetate esterase, which hydrolyzes the ester to form the long-chain alcohol, and an alcohol oxidase, which catalyzes fatty aldehyde formation, have been found in extracts of the pheromone gland of the spruce budworm (Morse and Meighen, 1984a). The release of the volatile labeled aldehyde pheromone from the insect, synthesized de novo from [^{14}C]acetate, correlated with a decrease in the level of labeled acetate ester in the gland itself (Morse and Meighen, 1984b).

The acetate esterase and alcohol oxidase, in contrast to those described above, are soluble. Only water and O_2 are required for conversion of the acetate ester to aldehyde in reactions that are essentially irreversible and easily distin-

guished from the reverse pathway used for ester formation. The soluble nature of the acetate esterase and alcohol oxidase are consistent with the enzymes being physically separated in the cell from the enzymes involved in the formation of the acetate ester which appear to be associated with the endoplasmic reticulum. It is probable that the acetate esterase and alcohol oxidase are exterior to the gland cells in the cuticle since metabolic energy and cellular cofactors are not necessary for conversion of the acetate ester to the aldehyde pheromone, only water and oxygen. Ultrastructural studies of the gland cuticle have revealed the presence of pore canals (Percy, 1974; Percy and Weatherston, 1974), which in other insects have been shown to contain oxidase activity (Locke and Krishnan, 1971) and esterase activity (Locke, 1961). The location of these enzymes in the cuticle woulde be advantageous as it would clearly separate the pathways of ester synthesis and degradation, which pass through a common 11-tetradecenol intermediate.

Pheromone Degradation. Since removal of the signal molecule from the environment of the receptor is necessary for a response to new pheromone molecules, degradative mechanisms have generally been associated with the process of pheromone reception (Blomquist and Dillwith, 1983). A similar mechanism could also be associated with the biosynthetic machinery in the budworm gland in order to remove the reactive, and potentially toxic, aldehydes that are not released from the cell surface. Such a mechanism would be presumably located in a different subcellular compartment from the biosynthetic enzymes to avoid degradation of pheromone about to be released.

A NAD-specific aldehyde dehydrogenase has been found in relatively high levels in the budworm gland and is associated with the membrane in gland extracts (Morse and Meighen, 1984a). This activity was also found in homogenates of the male antennae, raising the possibility that the same enzyme is responsible for aldehyde removal in the gland and the antennae. As shown in Table 2, the levels of aldehyde dehydrogenase activity measured in gland homogenates far surpass the levels observed for the pheromone biosynthetic ac-

TABLE 2. GLANDULAR LEVELS OF ENZYME ACTIVITIES[a]

Enzyme	Product	Activity
Fatty acid synthase	Fatty acid	300
Acetyltransferase	Ester	6
Acetate esterase	Alcohol	80
Alcohol oxidase	Aldehyde	20
Aldehyde dehydrogenase	Fatty acid	400

[a] The catalytic rates of selected enzymes, given in picomoles of product per minute per insect gland, were based on standard assays and represent velocities at saturating substrate concentrations.

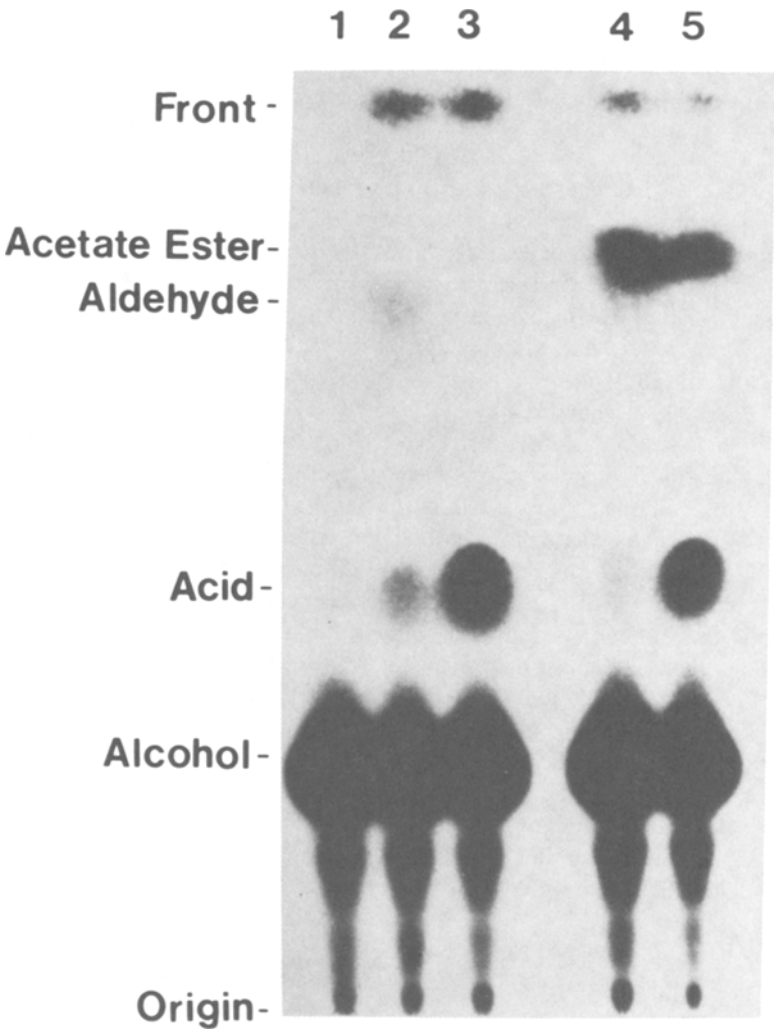

FIG. 5. Metabolism of tetradecanol by gland homogenates. The standard reaction mixture (lane 2) contained 1.2 μM [^{3}H]tetradecanol and 20 μg of gland homogenate in 1 ml of phosphate buffer, pH 7.0. Labeled compounds were extracted with hexane after a 60-min incubation and analyzed by TLC on silica gel and autoradiography. (1) Control minus gland homogenate; (3) plus 2 mM NAD; (4) plus 31 μM acetyl-CoA; (5) plus NAD (1 mM) and acetyl-CoA (31 μM). The positions of standards of tetradecanol, tetradecanoic acid, tetradecanol, and tetradecanyl acetate are indicated on the ordinate.

tivities. However, as substrate concentrations in the insect have not been measured, these activities may not reflect the rates in vivo.

A more direct comparison of the relative rates is given in Figure 5 where the radiolabeled products obtained on addition of [^{3}H]tetradecanol to a gland extract are analyzed by TLC. In the absence of other exogenous substrates, the alcohol is converted into both fatty aldehyde and fatty acid due to the presence of alcohol oxidase and aldehyde dehydrogenase activities, respectively. Addition of NAD^+ to the extract greatly stimulates the aldehyde dehydrogenase activity, as there is apparently only a low level of endogenous cofactor (NAD^+) in the extract. Consequently, the intermediate aldehyde product can no longer be detected. The large increase in the amount of fatty acid partially reflects the difficulty in extracting aldehyde from the aqueous reaction mixture compared to the other long-chain products. If acetyl-CoA is added to the extract containing tetradecanol, the alcohol is preferentially channeled into the acetate ester rather than being oxidized. Addition of NAD to the mixture containing acetyl-CoA now stimulates the oxidation pathway, and under these particular conditions, approximately equal amounts of the two products (acetate ester and fatty acid) are formed. These results illustrate that, even though a common intermediate (fatty alcohol) is being utilized in the biosynthesis and degradation of acetate esters, the relative flux in these two pathways can be regulated. Furthermore, as proposed in Figure 2, the biosynthetic and degradative pathways would be separated within the cell.

Role of Functional Groups in Pheromone Specificity. The preceding sections have summarized the evidence for a series of enzyme activities in the pheromone-producing gland of the spruce budworm based on a combination of in vitro and in vivo techniques. From these results, a biosynthetic pathway has been proposed for the spruce budworm pheromone (Figure 2) in which the final

[d] Pheromone of this genus also contains *cis*-9-tetradecenal.
[e] Pheromone of this species also contains tetradecanol.

step involves conversion of an acetate ester precursor to the aldehyde via a fatty alcohol intermediate. If the same mechanism of pheromone biosynthesis is applicable to other genera of the Lepidoptera, then it might be predicted that pheromone specificity in closely related species could be modulated by differences in their functional groups (ester, alcohol, aldehyde) rather than by alterations in the backbone chain.

Differences in pheromone specificity can easily be accomplished by alterations in the relative levels of the acetate esterase and the alcohol oxidase enzymes. Seven distinct pheromone blends of ester alcohol and aldehyde can be predicted depending on the relative activities of these enzymes (Table 3). Of course, a wide range of pheromone blends can be produced in which the relative amounts of acetate ester, alcohol, and aldehyde are different.

Support for this proposal was obtained by an examination of the insect sex attractants for different species within a genus (Inscoe, 1982). Table 4 shows that a large number of genera contain species that use attractants which differ only in their functional groups and are composed of a blend of ester, alcohol, and/or aldehyde. All seven possible combinations listed in Table 3 have at least one illustration. In some cases (i.e., in the *Platynota* species), not only does one species exclusively use a sex attractant with a different functional group than the other species, but the compound is inhibitory to the attraction of the other species.

The development in insects of a biosynthetic pathway to form acetate ester pheromones would have been greatly favored due to the high chemical stability of esters. Hydrolytic and oxidative steps to form alcohol and aldehyde pheromones could have then evolved during species differentiation. Thus specific communication systems composed of pheromones containing functional group blends would have arisen without additional energy or metabolic factors being required from the cell.

TERMINAL STEPS IN PHEROMONE BIOSYNTHESIS BY *Heliothis virescens* AND *H. zea*[1]

P. E. A. TEAL[2] and J. H. TUMLINSON[3]

(Received April 2, 1985; accepted August 1, 1985)

Abstract—In vivo application to the sex pheromone gland of *Heliothis virescens* and *H. zea* of large quantities of alcohols normally present in small amounts resulted in the preferential conversion of the alcohols to the corresponding pheromonal aldehydes. Amounts of the minor component aldehydes were increased up to 15-fold by selectively applying large quantities of the alcohol precursors. Using this technique, we have induced *H. virescens* to convert "bombykol," the sex pheromone of the silkworm, to the corresponding aldehyde, "bombykal," and have induced female *H. zea* to produce the same sex pheromone components used by *H. virescens* by applying tetradecanol and (*Z*)-9-tetradecenol to the surface of the gland. Further, treated *H. zea* females were attractive to *H. virescens* males and caused males to attempt interspecific copulation repeatedly. We have also found that the enyzme involved in this conversion is dependent on the presence of molecular oxygen, indicating that a nonspecific alcohol oxidase is responsible for the terminal biosynthetic step in pheromone production by both *H. virescens* and *H. zea*.

Key Words—Sex pheromone biosynthesis, *Heliothis virescens*, *H. zea*, Lepidoptera, Noctuidae.

INTRODUCTION

Recent developments in the collection and analysis of airborne organic molecules have enabled researchers to accurately identify the volatile pheromone blends released by a number of insect species (Golub and Weatherston, 1984).

[1] Mention of a commercial product or proprietary does not constitute endorsement by either the University of Guelph or U.S.D.A.

0098-0331/86/0200-0353$05.00/0

The volatile pheromone blends released by several species of Lepidoptera differ from those found in gland extracts not only with respect to the ratios of components but also in that extracts contain other compounds that are often closely related to the volatile pheromone components. These related compounds often lack a behavioral function, but in some instances they have been shown to have an inhibitory effect on male behavior. This is exemplified by the phermone blends released by females of the genus *Heliothis* (Lepidoptera: Noctuidae), major pests of cotton in North and South America.

Early studies by Roelofs et al. (1974) and Tumlinson et al. (1975) indicated that pheromone gland extracts of *H. virescens* contained a 16:1 ratio of (Z)-11-hexadecenal (Z11–16:AL) and (Z)-9-tetradecenal (Z9–14:AL) and that the pheromone gland of *H. zea* contained Z11–16:AL. Although these compounds were active, Tumlinson et al. (1975) suggested that the sex pheromone of *H. virescens* was more complex than that identified because the two-component blend was not as attractive as were calling females in bioassays. Subsequently, Klun et al. (1980a) identified five additional components from pheromone gland rinses of female *H. virescens*. These compounds included: tetradecanal (14:AL), hexadecanal (16:AL), (Z)-7-hexadecenal (Z7–16:AL), (Z)-9-hexadecenal (Z9–16:AL), and (Z)-11-hexadecenol (Z11–16:OH). Further, the gland of *H. zea* was found to contain the same 16 carbon aldehydes that were present in the pheromone gland of *H. virescens* (Klun et al., 1980b).

Although the above seven components were identified from *H. virescens* gland extracts, field trapping studies indicated that the 16:1 ratio of Z11–16:AL to Z9–14:AL was as efficient as the seven-component blend (Hartstack et al., 1980). Therefore, Tumlinson et al. (1982), Pope et al. (1982), and Teal et al. (1985) collected and analyzed volatiles released by sexually attractive *H. virescens* females and were able to identify only the aldehyde components. Vetter and Baker (1984) assessed the behavioral function of each of the seven components identified by Klun et al. (1980a) in laboratory flight tunnel studies and were unable to ascribe a behavioral function to Z11–16:OH. Further, analysis of gland extracts of *H. zea* calling females revealed the presence of Z11–16:OH, but field studies indicated that as little as 0.1% of this compound in pheromone lures reduced trap captures (Teal et al., 1984). Thus, although both species produce this alcohol, there was no evidence that it was released as a volatile pheromone component. A third species of this genus, *H. subflexa* (Gn.), also maintains Z11–16:OH and other alcohols in the pheromone gland (Teal et al., 1981; Klun et al., 1982) but, as occurs with *H. zea*, the incorporation of these alcohols into pheromone lures caused significant reductions in the capture of males (Teal et al., 1981). These results suggested that the alcohols produced by all three species were not released as volatile pheromone components but were involved in pheromone biosynthesis. The following reports the results of in vivo studies on the terminal steps of pheromone biosynthesis by *H. virescens*

and *H. zea* females which indicate that the identified alcohols are immediate precursors of their analogous aldehyde pheromone components.

METHODS AND MATERIALS

General. Heliothis virescens and *H. zea* females used in these studies were obtained from laboratory colonies maintained at the University of Guelph and and Insect Attractants, Behavior and Basic Biology Research Laboratory. Pupae were allowed to emerge in 30 × 30 × 30-cm clear plastic boxes under both reversed and standard 16:8 light–dark cycles at 26°C (day) 24°C (night) and 55% relative humidity. Newly emerged adults were transferred to new cages daily and were provided with a 10% sugar solution soaked onto cotton. Insects used in all studies were virgin females between 2 and 5 days old.

In all experiments, the terminal abdominal segments which contain the sex pheromone gland (Teal et al., 1983) were extended by applying pressure to the thorax and anterior abdominal segments. Ethyl ether extracts were prepared by removing the terminal abdominal segments of five females and extracting the tissue for 120 sec in 25 μl of diethyl ether (Fisher, anhydrous reagent grade). Ten microliters of isooctane (Fisher, 99 mole %) containing the appropriate internal standards (Teal et al., 1985) were then added and the volume was reduced to 5 μl under N_2 prior to gas chromatographic (GC) and GC–mass spectral analysis.

In whole insect preparations, the terminal segments were clamped in an extended position using the technique described by Bjostad and Roelofs (1983). A 0.5-μl drop of the test chemicals dissolved at various concentrations in dimethyl sulfoxide (DMSO) was then applied to the surface of the pheromone gland using a 1.0-μl syringe and allowed to penetrate for various lengths of time. In experiments conducted to assess the need for molecular oxygen by the enzyme system, the extended terminal abdominal segments were removed from the abdomens of noncalling females during either the light or dark period and placed in a 0.5-ml conical microvial under either N_2 or air. The glands were then treated with the test alcohols as described above. In these experiments the treated glands were maintained for 30 min under either air or N_2 or under N_2 for 15 min then under air for 15 min. After incubation, the terminal abdominal segments were extracted for 2 min by addition of 5 μl of isooctane containing 10 ng each of tridecan-1-ol acetate and pentadecan-1-0l acetate as internal standards. The total volume of the extract was then injected onto the capillary gas chromatographic columns.

In experiments to determine if the enzyme was present on the surface of the cuticle overlying the glands, emulsions of 200 μg of the test alcohols per milliliter of distilled H_2O were prepared by sonication on a daily basis. One

microliter (200 ng) of the emulsion was applied to the gland surface of non-calling *H. virescens* females and the preparations were allowed to incubate for 15 min prior to extraction with 10 μl of isooctane. Approximately 10 min prior to GC analysis, ca. 2 mg of granular anhydrous $MgSO_4$ was added to the extract to absorb any H_2O. Half the extract was then chromatographed on each capillary column. Experimental controls included extracts of untreated glands and extracts of 1-μl drops of the alcohol–H_2O emulsion.

Chemical Analysis. Gas chromatographic (GC) analyses were conducted using Hewlett-Packard 5792 and 5890 GCs equipped with splitless capillary injectors and flame ionization detectors. Data were recorded and processed using Hewlett-Packard 3390 reporting integrators. Fused silica capillary columns used for analyses included 30-m × 0.25-mm (ID) SPB1 and SPB10 (Supelco) and a 25-m × 0.22-mm (ID) BP20 (SGE). Conditions of chromatography were as follows: initial temperature = 80°C, splitless injector purge at 0.5 min, oven temperature increased at 25°/min after 1 min to final temperatures of 160°C or 165°C (SPB1 and SPB10) and 150° (BP20). Hydrogen was used as the carrier gas at a linear flow velocity of 38 cm/sec. Retention times of compounds eluting during the analyses of extracts were compared with those of synthetic standards and amounts of individual components were calculated.

Mass spectral analyses (MS) were conducted using VG 1212F and Finnigan 3200 chemical ionization mass spectrometers interfaced to capillary GCs having splitless injectors. Both methane and isobutane were used as reagent gases and helium was used as the carrier gas. The SPB1 column was used in the Finnigan system while a 50-m × 0.25-mm (ID) DB5 column (J&W) was used in the VG 1212F. Spectra of natural compounds were compared with those of authentic standards.

Synthetic Compounds. Saturated aldehydes including pentadecanal (15:AL), hexadecanal (16:AL), and octadecanal (18:AL) were prepared by oxidation of the corresponding alcohols obtained from the Sigma Chemical Company (St. Louis, Missouri) with pyridinium chlorochromate (Corey and Suggs, 1975). Bombykol [(*E*)-10-(*Z*)-12-hexadecadienol] (BKOH), bombykal [(*E*)-10-(*Z*)-12-hexadecadienal] (BKAL), 2-tetradecanol (2–14:OH), 3-tetradecanol (3–14:OH), and 5-tetradecanol (5–14:OH) were synthesized by R.E. Doolittle (Insect Attractants Laboratory, USDA, Gainesville, Florida). All other compounds were obtained from Albany International Ltd. (Needham Heights, Massachusetts). All saturated compounds were recrystallized from pentane while mono- and diunsaturated compounds were purified by high-performance liquid chromatography using a 25 × 1.2-cm (OD) $AgNO_3$ impregnated silica column eluted with toluene (Heath and Sonnet, 1980). GC analyses of all compounds using the SPB1 and BP20 capillary columns indicated that the compounds were at least 99% pure and were free of the corresponding alcohols or aldehydes.

Flight-Tunnel Studies. Flight-tunnel studies were conducted in the 2.0-m (l) × 1.0-m (w) × 0.5-m (h) wind tunnel used by Teal et al. (1985). Airflow

through the tunnel was 0.5 m/sec and was exhausted out from the building using a laboratory fume hood. In these experiments the terminal abdominal segments of actively calling *H. zea* females were clamped in an extended position as described earlier and the alligator claps positioned in the holes of an aluminum concentrator block so that the glands were pointing up. A 1-μl drop of a solution containing 10 ng each of 14:OH and Z9–14:OH in DMSO was then applied to the gland surface and the concentrator block was immediately positioned 1 m upwind from the male release point on a platform which raised the preparations to the middle of the tunnel. Three females were used in each test. Individual male *H. virescens* were then released in the downwind end as described by Teal et al. (1985), and the behaviors of the males were recorded over a 3-min period. Females were replaced after three males had been flown. The behaviors elicited by the volatiles released from the surface of the treated glands were compared to the male behaviors which occurred when presented with *H. zea* females which had been treated with DMSO alone.

RESULTS

Identification of Pheromone Related Alcohols. A full discussion of the identification of 14:OH, Z–14:OH, 16:OH, and Z11–16:OH is given in Teal et al. (1985). In brief, GC and GC-MS analyses using a variety of different columns, including those reported in this paper, proved that the sex pheromone gland of calling *H. virescens* females contains the above alcohols (Teal et al., 1985). The ratio of the alcohols was 83% Z11–16:OH, 7% 16:OH, 3% Z9–14:OH, 3% 14:OH.

We also conducted a study on the production of Z11–16:OH during the calling period. In this study we extracted the pheromone glands of groups of five *H. virescens* females in ethyl ether at 30-min intervals throughout the dark period. Capillary GC analysis of the extracts indicated that the amounts of Z11–16:AL and Z11–16:OH increased and peaked during the calling period and that the ratio of these compounds remained relatively constant. However, the ratio favored the alcohol in precalling females.

Application of Alcohol Pheromone Analogs. In initial studies, large amounts (0.5–1.0 μg) of 16:OH were applied to the surface of the pheromone glands of both *H. virescens* and *H. zea* ca. 1 hr prior to the onset of pheromone release (Tingle et al., 1978) and the glands were extracted 2 hr later. As indicated in Figure 1, GC analyses of the extracts on the three columns revealed that there was an average 12-fold increase in the concentration of 16:AL in *H. virescens* extracts ($N = 20$) and a tenfold increase in the *H. zea* extracts ($N = 15$) with respect to glands treated with DMSO alone. These increases were coupled with four- to fivefold reductions in the concentrations of the other aldehydes in the extracts. Application of similar amounts of Z9–14:OH, 14:OH,

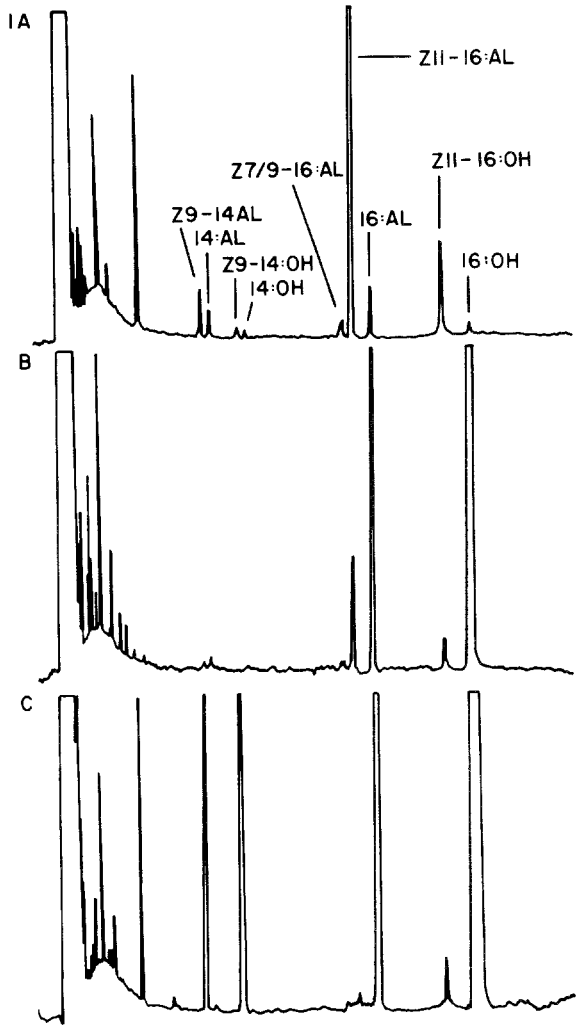

FIG. 1. Chromatograms of gland extracts of *H. virescens* on the SPB1 column. (A) Extract of untreated gland. (B) Extract of gland treated with 1 μg of 16:OH in DMSO. (C) Extract treated with a 3:1 ratio of 16:OH and Z9–14:OH.

and (Z)-7-hexadecenol resulted in 10- to 14-fold increases in the amounts of the corresponding aldehydes. Similarly, the application of a mixture of 0.5 μg Z9–14:OH and 1.5 μg of 16:OH resulted in large increases and a 1:3.5 ratio of (Z)-9-tetradecenal (Z9–14:AL) and 16:AL (Figure 1).

The initial studies had indicated that large nonphysiological amounts of the alcohols were preferentially converted to the aldehydes. However, the large

amounts applied may have disrupted the biosynthetic system within the pheromone gland. Therefore, we applied 50 ng of 16:OH to the surface of the pheromone glands of *H. zea* females and extracted them after 15 min. Extracts of the treated glands contained 8–12 ng ($N = 5$) of 16:AL while extracts of untreated glands contained 0.5–1.2 ng of 16:AL ($N = 10$).

Enzyme specificity and Functioning. Enzyme specificity was studied by applying several alcohols unrelated to any of the aldehyde pheromone components present in the pheromone glands of either *H. zea* or *H. virescens*. In initial studies, 1.0 μg of 18:OH was applied to the surface of precalling *H. virescens* glands ($N = 15$). The glands were extracted and analyzed after a 2-hr incubation period. All of the treated extracts contained substantial amounts of 18:AL as indicated by GC and GC-MS analyses. Similarly, GC ($N = 10$) and GC-MS analyses of glands treated with 15:OH indicated that this alcohol was converted to the corresponding aldehyde (Figure 2).

To assess the specificity of the enzyme system for "*Z*" configurational double bonds and for monounsaturated alcohols, glands of *H. virescens* were treated with 1 μg of either (*E*)-11-tetradecenol ($N = 10$) or BKOH ($N = 20$). As indicated in Figure 2, between 15 and 27 ng of BKAL were produced by the BKOH preparations after a 1-hr incubation period. Similarly, (*E*)-11-tetradecenal was produced when the corresponding alcohol was applied. We also studied the specificity of the enzyme for primary alcohols by applying 1-μg amounts of 2–14:OH ($N = 10$), 3–14:OH ($N = 10$), and 5–14:OH ($N = 15$)

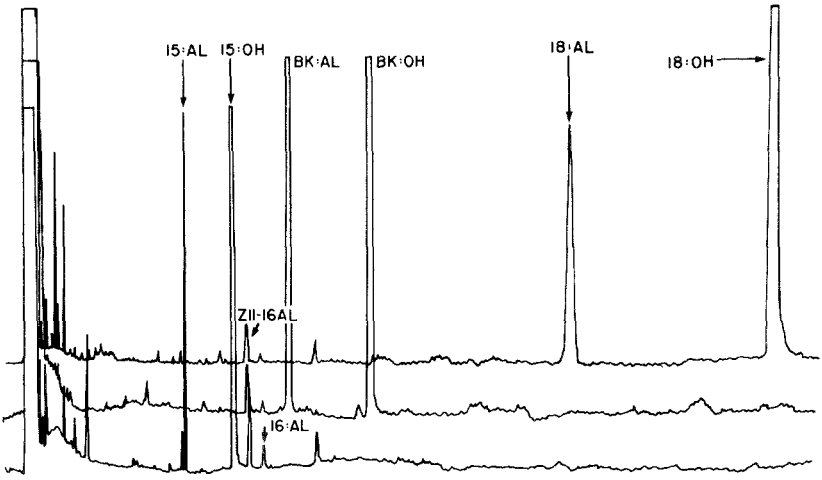

FIG. 2. Chromatograms of extracts of glands treated with octadecanol, pentadecanol and bombykol on the SPB1 column. Octodecanal = 18:AL, octadecanol = 18:OH, pentadecanal = 15:AL, pentadecanol = 15:OH, BKAL = bombykal, BKOH = bombykol.

to the glands as described above. GC analyses indicated that none of the secondary alcohols were converted to their corresponding ketones.

Studies on the effect of the circadian rhythm governing pheromone release on enzyme functioning were conducted by applying 50 ng of 16:OH in DMSO to the surface of the glands of noncalling *H. virescens* females during the photophase. Glands were removed, extracted, and analyzed after a 15-min incubation period. Results of this study indicated substantial amounts of 16:AL($\bar{x}$ = 13.3 ng, N = 5) were produced by treated glands, while control glands did not contain detectable amounts of this aldehyde.

Application of 100 ng of 16:OH to glands removed from females during the photoperiod and maintained under atmospheric conditions in microvials for 30 min prior to extraction resulted in the production of 15–30 ng of 16:AL (N = 15). However, application of 100 ng of 16:OH to glands removed during the photoperiod and maintained under N_2 for 30 min did not result in the production of 16:AL (N = 15) (Figure 3). When air was exchanged for N_2 after 15 min of incubation and the glands extracted 15 min later, substantial amounts of 16:AL (12–25 ng, N = 15) were produced.

Rate of Aldehyde Production and Release. The above studies had indicated that the alcohols were converted to the corresponding aldehydes very rapidly but gave little information about the actual rate of biosynthesis. To study this we applied 500 ng of (*E*)-11-tetradecenol to the surface of glands of *H. zea* females which had been removed and placed in microvials. Glands were extracted 1, 2.5, and 5 min after application of the alcohol. Analysis of the extracts indicated that 7.9 ng (±2.2 SE), 12.5 ng (±1.7 SE), and 18.6 ng (±2.4 SE) of (*E*)-11-tetradecenal were produced in 1, 2.5, and 5 min, respectively.

Application of 200 ng of *Z*9–14:OH in 1 μl of distilled H_2O to the gland surface of noncalling females (N = 10) resulted in the production of ca. 20 ng of *Z*9–14:AL after a 30-min incubation period. As in other experiments, little if any of the other pheromone components were detected in these extracts. This study was repeated using 16:OH (N = 15), 14:OH (N = 10), and *E*11–14:OH (N = 5) with similar results.

Flight-Tunnel Studies. In flight-tunnel studies, used to discover if the artificially produced aldehydes were released as volatiles from the surface of the pheromone gland, 65% of the male *H. virescens* entered taxis and landed on the platform which held the treated *H. zea* females and 40% attempted to copulate with these females (N = 20) (Figure 4). No males entered taxis in response to *H. zea* females treated only with DMSO.

DISCUSSION

Several studies on the actual volatile pheromone blend released by *H. virescens* have indicated that only aldehydes are released (Tumlinson et al., 1982;

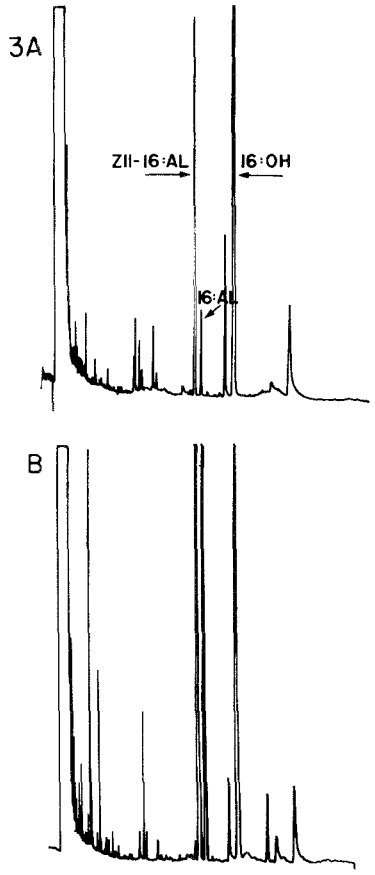

FIG. 3. Chromatograms of glands of calling *H. virescens* on the SPB1 column treated with 100 ng of 16:OH in DMSO and maintained (A) under N_2 for 30 min, and (B) under N_2 for 15 min and then air for 15 min.

Pope et al., 1982; Teal et al., 1985). However, both *H. virescens* and *H. zea* maintain significant amounts of Z11-16:OH in the pheromone glands and, in the case of *H. virescens*, 14:OH, Z9-14:OH, and 16:OH have been identified in pheromone gland extracts (Teal et al., 1983, 1985). Until now no function could be ascribed to these alcohols. Results of our study have demonstrated that the alcohols present in the pheromone gland of these species are rapidly converted to the corresponding aldehydes and are the immediate precursors of the pheromone components. The alcohol oxidase responsible for the conversion was found to be specific for primary alcohols but appears to show little specificity for either the level of unsaturation or geometric configuration of double bonds. Further, as indicated by the reduced amount of Z11-16:AL present in

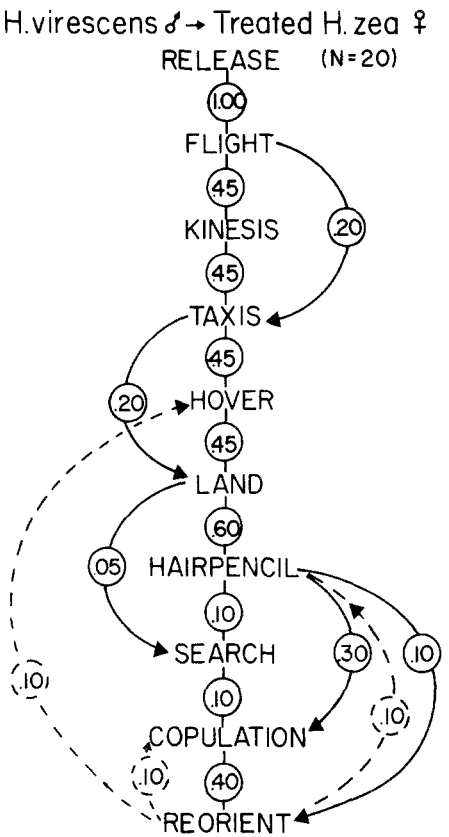

FIG. 4. Ethogram of the responses of *H. virescens* males ($N = 20$) to *H. zea* females treated with 20 ng of Z9–14 : OH and 14 : OH and placed in the upwind end of the 2-m-long flight tunnel. Numbers indicate the probabilities that each transition will occur.

extracts treated with alcohols other than Z11–16 : OH and production of a 1 : 3.5 ratio of Z9–14 : AL to 16 : AL when a 1 : 3 ratio of the corresponding alcohols was applied, substrate level competition for the enzyme regulates the blend of aldehydes produced. This is consistent with the ratio of alcohols to aldehydes in gland extracts found in earlier studies (Teal et al., 1985).

Wolf et al. (1981) documented a correlation between the ratios of unsaturated 14- and 16-carbon fatty acids present in the pheromone gland of *H. virescens* with the corresponding aldehyde pheromone components. They also found the saturated acids and suggested that the fatty acids were intermediates in pheromone biosynthesis. Subsequent work on other species indicated that the acids were intermediate precursors for the sex pheromones of those species and that double-bond position was the result of a specific Δ-11-desaturase and sub-

sequent chain-shortening step (Bjostad et al., 1981; Bjostad and Roelofs, 1981, 1983). Our hypothesis is that the free acids are converted to their corresponding alcohols which are subsequently converted to the aldehyde pheromone components by a cuticular bound oxidase. The limiting step occurs prior to the production of the aldehydes, as is indicated by the relatively constant ratios and amounts of alcohols present in the glands of calling *H. virescens* females (Teal et al., 1985). This is supported by the fact that the oxidase converts primary alcohols to aldehydes without regard to the diel periodicity of pheromone release and that the levels of the alcohols rise just prior to the onset of calling and then fall to essentially zero at the end of the scotophase.

The dependence of the enzyme on molecular oxygen demonstrated that it is a primary alcohol oxidase. This finding was supported by results of unpublished in vitro experiments conducted as described by Morse and Meighen (1984) in which various cofactors including NAD, NADP, and FAD failed to stimulate enzyme activity. A similar biosynthetic system employing an alcohol oxidase has been identified for the spruce budworm moth (Morse and Meighen, 1984), and therefore oxidases may be common among Lepidoptera species using aldehyde pheromone components.

The production of aldehydes within the first minute after application of the analogous alcohols was surprising because we anticipated that penetration into the gland would take a longer period. This suggested that perhaps the oxidase was present either within or on the surface of the cuticle. Insect cuticle contains a layer of apolar hydrocarbons which make it impermeable to water (Locke, 1974). Therefore, the alcohols would remain on the cuticular surface if applied in H_2O, and any conversion could be attributed to a cuticular bound alcohol oxidase. The fact that approximately the same amounts of the aldehydes in question were produced in these studies as when the alcohols were applied in DMSO strongly supported our hypothesis that the terminal step in aldehyde pheromone biosynthesis occurs within and on the surface of the cuticle overlying the pheromone gland. Cuticular bound enzymes have been identified from a number of insect species (Locke, 1974; Kapin and Ahmad, 1980; Ferkovich et al., 1982). Ferkovich et al. (1982) also demonstrated that cuticular esterases in the male cabbage looper [*Trichoplusia ni* (Hübner)] were involved in degradation of the female sex pheromone. However, ours is the first study indicating that cuticular enzymes are involved in pheromone production.

Although evidence pointed to the fact that a cuticular bound alcohol oxidase was responsible for the conversion of the alcohols to the actual aldehyde pheromone components in both *H. virescens* and *H. zea*, we did not know if the artificially produced aldehydes were released as volatile compounds. Therefore, we conducted flight-tunnel studies using *H. zea* females and *H. virescens* males. *H. zea* females do not produce Z9–14 : AL or 14 : AL, while *H. virescens* does, and these aldehydes have been demonstrated to be necessary for effective

sexual communication by *H. virescens* (Vetter and Baker, 1984; Teal et al., 1985). Further, these 14-carbon aldehydes appear to be responsible for semiochemically induced reproductive isolation between *H. virescens* and *H. zea* (Klun et al., 1980a,b). Therefore, by treating the *H. zea* pheromone gland with the 14-carbon alcohols, we had not only induced the production and release of 14:AL and Z9–14:AL into the air but had also eliminated semiochemically induced reproductive isolation between the two species.

The development of a cuticle-bound alcohol oxidase suggests that conversion of the alcohols to aldehydes within the pheromone gland cells is an inefficient method of aldehyde production. This is reasonable when considering the biochemical instability of aldehydes within cellular systems and ease of interconversion between aldehydes and alcohols (Snyder, 1972). It is probable that if aldehydes were produced directly from the acids within the pheromone gland cells, they would be rapidly converted to the corresponding alcohols (Reichwald-Hacker, 1983). Therefore, the aldehydes would not be available for use as pheromone components. The use of the cuticle-bound alcohol oxidase ensures that the aldehydes are available for pheromone release and that all of the alcohols are converted as they pass through the cuticle. At present, the precursor steps in alcohol biosynthesis by *H. virescens* and *H. zea* are undetermined. However, it is unlikely that alcohol biosynthesis proceeds via the production of the corresponding acetates, as occurs in the spruce budworm moth (Morse and Meighen, 1984), because none of the acetates have ever been identified in pheromone gland extracts of either *H. virescens* or *H. zea*. We are investigating the biosynthetic route responsible for the production of the alcohols at the present time.

In conclusion, our study has demonstrated that alcohols present in the pheromone glands of both *H. zea* and *H. virescens*, which have no behavioral function, are the immediate biosynthetic precursors of the aldehyde pheromone components. Further, we have demonstrated that the aldehydes produced are released as volatiles from the surface of the pheromone gland. These studies have added considerable knowledge to our understanding of the semiochemical-mediated biology of *Heliothis* species.

Acknowledgments—We wish to thank R.E. Doolittle for synthesis of bombykol, bombykal, and the secondary alcohols used in this study. We also wish to thank the Ontario Ministry of Agriculture and Food for financial support.

(Received June 3, 1985; accepted August 1, 1985)

Abstract—This paper reviews the sex pheromone chemistry and pheromone-mediated behavior of the spruce budworm and related coniferophagous (*Choristoneura*) budworms. In *C. fumiferana*, temporal changes in pheromone-gland monounsaturated fatty acids (pheromone precursors) enable the prediction of the primary sex pheromone components. This technique may also be applicable for predicting additional pheromone components. Tetradecanal (14:Ald), previously shown to enhance close-range precopulatory behavior, lowers the threshold of response by males for upwind flight to a pheromone-component source. Spruce budworm males maintain upwind flight to 95:5 (*E*/*Z*)-1,12-pentadecadiene (diolefin analog) after initiating upwind flight to a primary-component pheromone source (95:5 *E*/*Z*11-14:Ald). This is the first demonstration of apparently normal male flight responses to a pheromone analog.

Key Words—*Choristoneura fumiferana*, spruce budworm, Lepidoptera, Tortricidae, sex pheromone, behavior, flight tunnel, pheromone analog, pheromone fatty acid precursors.

INTRODUCTION

Lepidopteran female sex pheromones are, with few exceptions, multicomponent, consisting of a blend of two or more chemicals emitted at fairly consistent

[1] Lepidoptera: Tortricidae

0098-0331/86/0200-0367$05.00/0

ratios and release rates. These chemical blends elicit in conspecific males sequences of behaviors that include upwind flight which brings males to within close proximity of females. These behaviors are often readily observed in laboratory wind tunnels, and responses by males to synthetic pheromone sources can be compared to their responses to natural pheromone or females.

The existence of a pheromone communication system in the spruce budworm (*Choristoneura fumiferana* Clemens) was demonstrated by Greenbank (1963), but elucidation of the blend of chemicals comprising the female sex pheromone is still incomplete. However, recent progress has been made in defining the sex-pheromone chemistry and pheromone-mediated behavior of this insect. This paper reviews the history and some current research related to the spruce budworm pheromone communication system.

BACKGROUND

In the genus *Choristoneura* (Lepidoptera: Tortricidae), known primary sex pheromone components are comprised of Δ11-unsaturated C_{14} carbon-chain compounds. Different species' primary sex pheromone components have different oxygenated functional groups and varying blends of these components (see Inscoe, 1982). Specifically, the coniferophagous spruce budworms comprise a group of closely related (*Choristoneura*) species, native to North America (Freeman, 1967; Freeman and Stehr, 1967; Powell, 1980). Six species have been studied in terms of their pheromone specificity (Sanders, 1971; Sanders et al., 1974, 1977). The components of these female-produced sex pheromones form a group of congeneric Δ11-C_{14} aldehydes (Δ11–14 : Ald), acetates (Δ11–14 : Ac), and alcohols (Δ11–14 : OH), with blends, geometrical isomer ratios, and release rates specific to each species (Table 1).

In attempting to characterize the sex pheromone of budworm species through cross-attraction studies, Sanders et al. (1977) concluded that *C. fumiferana*, *C. occidentalis*, and *C. biennis* apparently had similar pheromones while *C. pinus pinus*, *C. orae*, and *C. retiniana* (= *C. viridis*; Powell, 1980) were mutually cross-stimulating but did not appear to have sex pheromone components in common with the former group. This was an accurate assessment; subsequent research has shown that the former group utilizes Δ11–14 : Ald's as primary sex pheromone components, whereas the latter, utilize Δ11–14 : Ac's or Δ11–14 : Ac/Δ11–14 : OH blends (Table 1). It has yet to be verified that the *C. biennis* sex pheromone is Δ11–14 : Ald, although present evidence is strongly supportive (Sanders, 1971; Sanders et al., 1974, 1977). Sex pheromone components of the remaining five species have been documented: *C. fumiferana* (Sanders and Weatherston, 1976; Silk et al., 1980) and *C. occidentalis* (Cory et al., 1982; Silk et al., 1982) have been shown to release *E*/*Z*11–14 : Ald as

primary sex pheromone components. In contrast, *C. pinus pinus* (Silk et al., 1985b), *C. retiniana* (Daterman et al., 1984), and *C. orae* (Gray et al., 1984) release *E*/Z 11-14 : Ac or *E*/Z11-14 : Ac/*E*/Z11-14 : OH blends as primary components (Table 1).

However, all species have Δ11-14 : Ac in common as the major component in the pheromone gland (in references above). In *C. fumiferana* Δ11-tetradecenyl acetate is synthesized *de novo* only in the pheromone gland, the Δ11-14 : Ac is the direct biosynthetic precursor to the aldehyde pheromone (Morse and Meighen, 1984). Morse and Meighen (1984) also found that the female diel aldehyde-emission period was synchronous with acetate production, and this supports their hypothesis that in this (coniferophagous) *Choristoneura* group a metabolic relationship exists between the aldehyde, acetate, and alcohol. It seems likely, therefore, that species specificity in pheromone production is controlled by species-specific metabolic processes, giving rise to different functional groups, ratios, and release rates from the common acetate precursor.

REVIEW OF SEX PHEROMONE CHEMISTRY OF SPRUCE BUDWORM

Among coniferophagous budworms, the spruce budworm, *C. fumiferana*, has been the most intensively studied. Early work indicated that spruce budworm females release a pheromone that "attracts" males (Greenbank, 1963). Subsequently, *E*11–14 : Ald was identified (Weatherston et al., 1971) as a pheromone component. The importance of adding the *Z* to the *E* isomer was determined upon reanalysis of female volatiles and a (96:4) *E/Z*11–14:Ald blend was shown to maximize trap captures (Sanders and Weatherston, 1976). Solvent extracts of excised pheromone glands were inactive in eliciting male response (Sanders, 1971). Reanalysis of gland extracts identified *E*11–14:OH (Weatherston and MacLean, 1974) and *E*11–14 : Ac (Wiesner et al., 1979), both of which inhibited trap capture (Sanders and Lucuik, 1972; Sanders et al., 1972; Sanders 1976).

More detailed chemical analyses (Silk et al., 1980) of pheromone gland extracts showed that Δ11–14 : Ac (20–40 ng/insect), Δ11–14 : Ald (1–3 ng/insect), and Δ11–14 : OH (1–3 ng/insect) were all present in 95 : 5 *E/Z* ratios; the saturated analogs of each functionality were also present at ca. 1% of the corresponding *E* isomer. In contrast, effluvia from "calling" females were found to contain *E/Z*11–14 : Ald (95 : 5; 10–40 ng/insect/night) and the saturated analog, tetradecanal (14 : Ald) at ca. 2% of the *E*11–14 : Ald (Silk et al., 1980). In addition, traces of (*E*)11–14 : Ac were found; no alcohols were detected.

In the same study, field testing showed that there were no significant differences in trap captures between traps baited with all four components (formulated in PVC at female effluvial ratios) compared to captures using the primary components (95 : 5 *E/Z*11–14 : Ald) alone. The reduction of trap capture by admixture of Δ11–14 : Ac with 95 : 5 *E/Z*11–14 : Ald (Sanders et al., 1972) was confirmed; however, this effect appeared to be negated by the presence of 14 : Ald, but only when all components were present in synthetic sources in female effluvial ratios (Silk et al., 1980). Pheromone release rate by "calling" females, measured by a specific and sensitive bioluminescent assay technique (Morse et al., 1982, Meighen et al., 1981, 1982), occurs mainly during scotophase in a series of "bursts" at rates as high as 50 ng/hr with considerable individual variability.

REVIEW OF PHEROMONE-MEDIATED BEHAVIOR IN SPRUCE BUDWORM

Behavioral patterns involved in mate location in feral insects generally involve upwind flight, apparent close-range orientation, and copulation (Roelofs and Carde, 1977). As in most moths, spruce budworm males locate conspecific females by flying upwind along a pheromone plume. Often, the effects of putative pheromone components on these male behaviors has been inferred from

a chemical's effect on trap capture (until recently, this was also true for spruce budworm); however, observations and quantitation of some of these behaviors can be conducted in a sustained-flight wind tunnel (e.g., Miller and Roelofs, 1978). We review here recent field and wind-tunnel work, and present some recent progress.

Sanders (1981a) showed that synthetic 95 : 5 *E*/*Z*11–14 : Alds were equivalent in "attraction" to virgin females in field trapping experiments when using a 0.03% PVC source, which releases these primary components at a rate close to that of a "calling" virgin female (Silk et al., 1980). Furthermore, in preliminary wind-tunnel work, some males demonstrated an apparent full range of precopulatory behaviors, e.g., upwind flight, courtship, and copulatory attempts in response to only these two primary components (Sanders, 1979). However, more detailed observations in the wind tunnel (Sanders *et al.*, 1981) showed that males exposed to pheromone produced by "calling" females exhibited a higher incidence of upwind flight and made more rapid upwind progress than males exposed to a similar concentration of synthetic pheromone (95 : 5 *E*/*Z*11–14 : Ald).

Sanders and Seabrook (1982) concluded that it was unlikely that other chemicals were involved in the "attraction" phase of the mating process. However, recent observations in our laboratory's wind tunnel and in the field (Alford et al., 1983) indicated an effect of tetradecanal (14 : Ald) on the behavior of male spruce budworm. A greater number of males initiated upwind flight and continued on to contact a source with ca. 5% 14 : Ald added to the Δ11–14 : Ald's than when only the Δ11–14 : Alds were present.

The addition of *E*11–14 : Ac to the Δ11–14 : Alds decreased the males' responsiveness to the aldehydes, but when present at low levels, its effect appeared to be attenuated when 14 : Ald was also present (Alford et al., 1983). This latter effect was also seen in earlier field-trapping experiments (Silk et al., 1980) and was subsequently confirmed by further laboratory wind-tunnel studies (Sanders, 1984). In addition, Sanders (1984) found that duration of sustained flights was significantly longer in response to "calling" females than to any synthetic sources (with or without 14 : Ald), implying that the synthetic blends are incomplete with respect to the female-emitted blend.

RECENT PROGRESS

It is apparent that not all the chemicals involved in the sex pheromone communication system of spruce budworm are known. In monitoring and mating disruption programs, however, it may not be essential to know every minor component although, as Roelofs has pointed out (1978), trap specificity and potency may be greatly increased as the synthetic lure more closely duplicates the natural pheromone, and it is presumed that the efficacy of mating disruption

would likewise be enhanced by a "more complete pheromone." Sanders (1984) concluded that, although single components can cause considerable mating disruption in noctuids (Campion et al., 1981), incomplete blends are considerably less effective against tortricids (Charlton and Cardé, 1981; Roelofs and Novak, 1981; Sanders, 1981b). This has led many to the conclusion that elucidation of the "complete" pheromone blend for budworm is of importance prior to further major mating-disruption tests. Recent work in our laboratory has, therefore, focused on the identification of the "complete" spruce budworm pheromone.

Previous analyses of female spruce budworm effluvia (Silk et al., 1980), using a Porapak® Q collection technique, did not indicate, at least from a chemical perspective, the presence of other components. This method, however, does introduce relatively large amounts of contamination and minor components may have been obscured by this background contamination.

The fact that, chemically, minor components are present in very low quantities in spruce budworm prompted the use of indirect techniques to ascertain component identity. Recently, Bjostad and Roelofs (1981, 1983) demonstrated that fatty acid precursors of female sex pheromone components can be identified and used to predict the presence of minor pheromone components (Bjostad and Roelofs, 1983; Bjostad et al., 1984). A technique for rapidly identifying these monounsaturated fatty acids in pheromone glands excised from female moths, using GC-MS analysis after dimethyldisulfide derivatization (DMDS) of gland extracts has been developed. A detailed analysis of monounsaturated fatty acids present in the pheromone glands of *C. fumiferana*, *C. occidentalis*, and *C. pinus*

pinus was carried out; the techniques and results are discussed in detail elsewhere (Dunkelblum et al., 1985) and are summarized in Table 2. As can be seen, the major pheromone-gland components (which have been previously identified) are readily correlated with their corresponding fatty acids. For example, in these three budworm species, the *E*/*Z*11–14:Me (*E*/*Z*11-tetradecenoic acids, methyl esters) are correlated with the Δ11-C_{14} moieties which comprise the primary pheromone components (Tables 1 and 2). The fatty acid profile is very similar for all three species. The other unsaturated fatty acids may be precursors to as yet unidentified secondary sex pheromone components in these species.

In some female moths, pheromone titer appears to be quite low on eclosion and increases to a maximum in a few days [e.g., *Trichoplusia ni* Hübner (Shorey and Gaston, 1965)]. Based on this fact, analysis of monounsaturated fatty acids in spruce budworm females by the DMDS method was repeated with the view of ascertaining whether changes in fatty acid profile occurred with moth age. Pheromone glands were obtained from groups of ca. 20 females that were in the pupal stage (just prior to emergence), 1 hr post-emergence, and 48 hr postemergence (all pupae and adults were maintained on a 16:8 light–dark cycle and glands were excised during the 2nd and 3rd hr of scotophase, coincident with mature females' peak "calling" period). Pheromone glands (three replicates) excised from these three groups were extracted with chloroform–metha-

nol (2:1) and subjected to acid-methanolysis followed by the DMDS reaction and capillary GC-MS (as in Dunkelblum et al., 1985).

The results are presented in Table 3. A large increase is seen for Δ11-14:Me (from <1% to 30–50%), and this is to be expected since this fatty acyl moiety is most likely the direct biosynthetic precursor to Δ11-14:Ac and this component to the pheromone, Δ11-14:Ald (Morse and Meighen, 1984). Perhaps more significantly, a large increase in titer occurred with two other monounsaturated fatty acids: Δ7-16:Me and Δ11-16:Me with the latter showing the largest increase. This prompted the supposition, following the corollary of Δ11-14:Me → Δ11-14:Ac → Δ11-14:Ald, that a similar sequence of events may be occurring in the pheromone gland of the spruce budworm for these Δ16 components. Although this does not preclude the other fatty acids (and certainly only monounsaturated moieties would be detected by this method), these two components were considered a suitable starting point for further chemical and behavioral analyses.

Reanalysis of female gland extracts (Dunkelblum and Silk, unpublished data) indicated that, indeed, Δ11-16:Ac is present in the spruce budworm sex pheromone gland (<0.1% of *E*11-14:Ac) but that Δ7-16:Ac could not be detected. However, neither Δ11-16:Ald nor Δ11-16:Ac was detected in effluvial material obtained by the Poropak Q collection method (Silk et al., 1980), although background contamination probably precluded detection. Because Δ11-14:Ac is the biosynthetic precursor to Δ11-14:Ald (primary pheromone components), it was assumed, as a first step, that since Δ11-16:Ac was determined as a gland component, it might be emitted as the aldehyde. However, initial wind-tunnel tests to determine the possible function of Δ11-16:Ald's were inconclusive; further tests will be warranted if Δ11-16:Ald's are found in female pheromone-gland volatiles.

The effects on behavior of putative pheromone components are usually assessed by adding them to compounds with known activity, (e.g., Linn and Gaston, 1981; Baker and Cardé, 1979). Alternatively, changes in male behavior have been measured in response to removing one or more components from the believed complete volatile blend, or by giving males a choice between two merging odor plumes (e.g., Teal et al., 1986). We have recently tested another approach relating to male response to low dosages of pheromone blends. More specifically, we hypothesized that males would have a lower response threshold to "more complete" pheromone blends, i.e., the active space (Bossert and Wilson, 1963) would become greater as the pheromone blend being tested more closely approached the natural female-emitted blend.

To test this hypothesis in our sustained-flight wind tunnel, we employed two "pheromone" sources (Figure 1). Both sources (rubber septa) were suspended, one behind the other, by thread (as in Baker and Kuenen, 1982; Kuenen and Baker, 1983) 15 cm above the center of the tunnel floor. The downwind

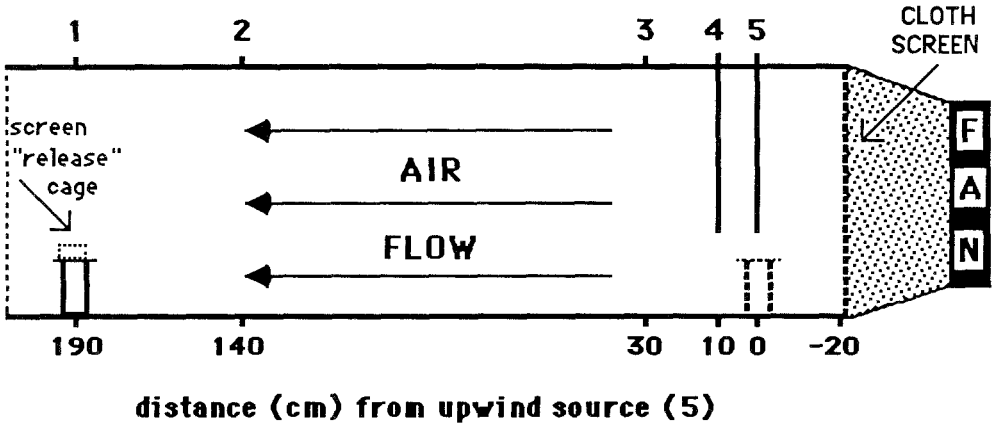

FIG. 1. Schematic side view of sustained-flight wind tunnel. In "two-source" experiments males were released from cages (at 1); as they flew upwind along the pheromone plume past (2) the downwind source (4) was pulled quickly upward, and the males' subsequent flight behaviors to the upwind source (5) were recorded.

source (DS) was constant at 3 or 10 μg 95:5 *E*/*Z*11–14:Ald, while the upwind source (US; the test source) ranged from 3 μg (95:5 *E*/*Z*11–14:Ald) down to 30 ng in half-$\log_{(10)}$ steps or the US was a blank. In a second experiment, the US contained 100 ng, 30 ng, or 10 ng Δ11–14:Ald or the same three with 5% 14:Ald added.

During the experiments, individual males were released from screen cages at the downwind end of the tunnel where some initiated upwind flight along the pheromone plume. When males, flying in or near the plume, were 140 cm from the US, the DS was quickly raised to the top of the tunnel by pulling on its supporting thread. After raising of the DS, males were observed for their up-tunnel progress and scored for whether or not they flew to within 30 cm of the US or if they continued upwind flight and contacted the US. A test flight was considered to be over as soon as males flew out of the back of the tunnel or if they touched any of the tunnel's surfaces.

Initially, we wanted to determine the threshold value for the US to which males continued to fly upwind after removal of the DS (10 μg Δ11–14:Ald). This threshold value was approximately 100 ng source dosage (Table 4). This is clearly seen by the reduction in the percentage of moths flying to within 30 cm of the US when the dosage was <100 ng (Table 4; $P < 0.05$). Additionally, the time required for males to fly to within 30 cm of the US tended to increase when the US dosage was 30 ng or 100 ng Δ11–14:Ald [Table 4; flight times were not analyzed statistically since numbers of moths flying close to the US was very low (1 or 2) when the US contained a low pheromone dose].

With the threshold value determined using Δ11–14 : Ald alone, we next tested whether this threshold would be lowered by the addition of 5% 14 : Ald to the US. Using identical procedures, we saw an apparent increased male responsiveness to low-dosage sources when tetradecanal was present. When dosage of the US was 100 ng Δ11–14 : Ald alone or plus 5% 14 : Ald, approximately the same number of moths flew to within 30 cm of the US. Most of these moths reached this source and flight times were similar. At 30-ng source loadings, however, more males continued flight to the US when 5% 14 : Ald was present ($P < 0.05$), and their flight times to both 30 cm-from-the-US and to the source were much less than flight times for males flying toward a source containing only the Δ11–14 : Ald's. (Table 5).

It appears from this data that secondary sex pheromone components, which act to increase the number of males approaching a pheromone source, also lower the response threshold for flight continuation to a similar pheromone component blend after initiation of upwind flight.

PHEROMONE ANALOGS

In some moth species, structural analogs of pheromone components have shown biological activity in terms of mating disruption (e.g., Shorey et al. 1974; Carlson and McLaughlin, 1982a,b). Activity of analogs has been predicated on the hypothesis that they are similar (isoelectronic or isosteric) to the natural compound(s) although these effects are difficult to predict. For the spruce budworm, for example, Δ9-dodecenyl formate, structurally very similar to Δ11–14 : Ald, has proven inactive in the field (Sanders et al., 1980), although formate analogs of the pheromones of the corn earworm *Heliothis zea* (Boddie) (Mitchell et al., 1975) and the tobacco budworm *Heliothis virescens* (F.) (Beevor et al., 1977) are active mating disruptants.

The response of insects to these pheromone analogs is generally difficult to assess except when examining for behaviors similar to those elicited by pheromones. Therefore, a simple and indirect assessment employing sticky traps has often been used to determine if the analogs (1) produce trap capture by themselves or (2) reduce or enhance trap capture when combined with known sex attractants, sex pheromones, or virgin females. Analogs have also been tested for their effect on mating (disruption) in field plots where analog sources have been distributed (e.g., Carlson and McLaughlin, 1982a,b).

We recently reported biological activity of a diolefin analog [95 : 5 (*E/Z*)-1,12-pentadecadiene] of Δ11–14 : Ald's (Silk et al., 1985a). Briefly, the results were as follows. Diolefin formulated in PVC vial-caps produced trap capture by itself and enhanced trap capture when combined with the Δ11–14 : Ald's. When formulated in PVC rods in a later test the same season, the diolefin produced little or no trap capture. However, when six PVCs (3.0% diolefin) were

Mean distance flown per moth flying upwind (cm)[c]	150.8 (69.90)	185 (−)	150.8 (51.16)

[a] Δ11-14:Ald = 95:5 *E*/*Z*11-14:Ald; DO = diolefin analog. $N = 25$ (five groups of five); values are means (± SD)
calculated from means of each group of five moths tested.
[b] Means in each horizontal row having no letters in common are significantly different; $P < 0.05$, Duncan's new multiple-range test.
[c] Means were not analyzed since only one moth flew up-tunnel (center column) when diolefin alone was present.

placed in a circle around traps baited with Δ11-14:Ald's, trap capture was reduced to a level not significantly different ($P > 0.05$) from traps surrounded by equally spaced PVCs containing 0.03% Δ11-14:Ald's.

From this we concluded that the diolefin had biological activity, but the trap capture data were ambiguous. We then tested the diolefin in our wind tunnel. Male spruce budworm responses to (1) Δ11-14:Ald's, (2) diolefin, and (3) 1 + 2 were examined. In measures of activation, flight initiation, flight distance, and percentage source contact, males responded similarly (Table 6; $P > 0.05$) to Δ11-14:Ald's alone and when in admixture (1:1) with the diolefin, but by itself the diolefin did not elicit upwind flight in males. [Although one male reached the upwind portion of the tunnel (Table 6), its flight path appeared random and was rarely in or near the analog plume.) In another study, male responses to the diolefin alone were not distinguishable ($P > 0.05$) from responses to a blank (control) source (Kuenen and Silk, unpublished data). Thus the diolefin did not enhance or diminish the responsiveness of males flying upwind toward a "pheromone" source.

However, we reasoned that trap capture in diolefin-baited traps (mid-season study) may have occurred after males responded to female-emitted pheromone, while no pheromone sources (virgin females) were present in our late season study where diolefin did not elicit male activity (trap capture). As a first test of this hypothesis, we allowed individual males to initiate flight to two chemical sources (see Figure 1). The upwind source contained diolefin alone or was blank, while the downwind (15 cm) source contained Δ11-14:Ald's. After males had flown to within 140 cm of the upwind source, the downwind source was quickly pulled upward by its supporting thread. Males' progress was then recorded. Most notably, males continued their normal upwind ap-

proach to the diolefin source [upwind source; mean distance flown 163.3 cm ± 45.73 (SD); $N = 24/50$ tested], while, as expected, they soon initiated cross-wind casting (Kennedy and Marsh, 1974; Marsh et al., 1978) when the upwind source was blank [mean distance flown 119.0 cm ± 29.75 (SD); $P < 0.05$; t test; $N = 30/50$ tested]. The males' flights to the diolefin source were not visually distinguishable from their flight responses to a Δ11–14 : Ald source, and 16 of the 24 moths flying upwind continued their upwind flight to reach and land on the diolefin source.

CONCLUSIONS

Progress in understanding the sex pheromone chemistry of the spruce budworm in relation to male behavior has been made in recent years. However, the sex pheromone blend of the budworm is not completely defined. Very low emission rates of additional pheromone components have made it difficult to identify these components. Identification of pheromone gland fatty acids, and particularly their temporal variation in relation to pheromone production, may become a very useful technique in identifying these additional components.

The data we have presented on male flight thresholds is not definitive at this point, but represents an approach to the study of the spruce budworm communication system. Our analyses of male responses to a pheromone analog are also preliminary; however, the demonstration of normal male upwind flight in response to the diolefin analog is, to the best of our knowledge, the first report of the observation of this behavioral response to a pheromone analog.

Acknowledgments—This research was funded in part by the New Brunswick Department of Natural Resources, and the Canadian Forestry Service. We thank Dr. C. Northcott (RPC) for synthesis of Δ11–16 : Ald and the diolefin analog from a nonaldehyde source, and Dr. G. Lonergan (UNB) for synthesis of the diolefin from Δ11–14 : Ald. We also thank Dr. E. Butterworth and M. McClure for technical assistance and L. Jewett for typing the manuscript. Special thanks go to Dr. E. Dunkelblum, for his expertise and enthusiasm during a sabbatical year from the Volcani Center, Bet Dagan, Israel during 1984–85 with PRG/RPC.

(Received April 25, 1985; accepted August 1, 1985)

Abstract—The two major components of the female sex pheromones of two *Creatonotos* species have been identified as an achiral C_{21} triene, (*Z,Z,Z*)-3,6,9-heneicosatriene, and a chiral epoxide, (*Z,Z*)-2(2,5-octadienyl)-3-undecyloxirane. The ratios of these components in the two species fall into nonoverlapping ranges. Two additional achiral minor components, (*Z,Z*)-6,9-heneicosadiene and (*Z,Z,Z*)-3,6,9-tricosatriene, were also identified in the female sex gland extracts. The male pheromone of both species consists of hydroxydanaidal, a chiral dihydropyrrolizine derived from pyrrolizidine alkaloids in the larval diet. *Creatonotos transiens* was found to convert dietary heliotrine into (*R*)-(−)-hydroxydanaidal, with inversion at the single asymmetric carbon atom. The possible biological and biosynthetic significance of the chiral pheromone components are discussed, and they are compared with known examples of chiral lepidopteran pheromones.

Key Words—Lepidoptera, pheromone, chirality, epoxide, hydroxydanaidal, biosynthesis, polyene, alkaloid, *Creatonotos transiens*, *Creatonotos gangis*, *Arctiidae*.

INTRODUCTION

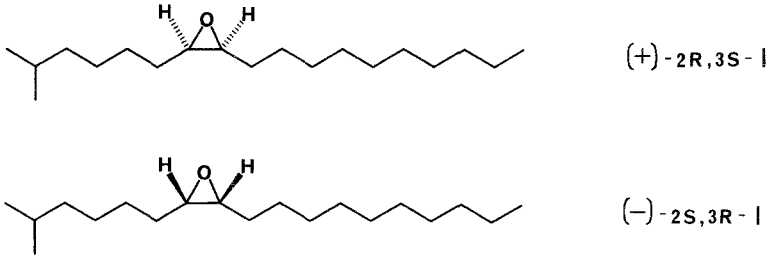
It is now generally recognized that the sex pheromones of most lepidopteran insects consist of complex mixtures of chemical components (Jacobsen et al., 1970; Roelofs and Cardé, 1974; Tumlinson et al., 1982; Schneider, 1984a,b; Boppré, 1984). Long-range attraction of male moths is usually elicited by a

0098-0331/86/0200-0385$05.00/0

blend of chemicals released by the calling female. The responding male often deploys another set of compounds in short-range interactions with the female; these "aphrodisiac" pheromones increase the likelihood of successful courtship. Female lepidopteran sex pheromones usually have simple molecular structures; they are often unsaturated straight-chain alcohols, esters, or aldehydes consisting of 10–18 carbon atoms (Baker and Evans, 1979; Baker and Bradshaw, 1981, 1983; Baker and Herbert, 1984). Contrary to earlier belief, the sex attractants produced by a particular species are not necessarily unique to that species; some components may be shared even by sympatric species with overlapping activity patterns. For the apparent purpose of species identification, hence reproductive isolation, pheromone components often occur in characteristic ratios (e.g., Roelofs and Cardé, 1974). These components frequently have closely related structures that differ only in functionality. Alternately, pheromone components may differ only in their stereochemistry. This often involves a specific mixture of *E* and *Z* stereoisomers of unsaturated components (Klun et al., 1973; Roelofs et al., 1975; Roelofs, 1979).

Most lepidopteran pheromone components have achiral structures; accordingly, they cannot exist in optically active enantiomeric forms. While many examples of chiral coleopteran pheromones are known, only a small group of lepidopteran pheromones have chiral structures (Silverstein, 1979, 1982). Chirality, then, presents an alternative basis for variation of odor components, since enantiomer discrimination (enantioselectivity) in chemoreception is well known. With respect to olfactory discrimination of enantiomeric pheromones, the first single-cell electrophysiological recordings were performed by Kafka et al. (1973). An important example of chirality in species identification is provided by enantiomer ratios in aggregation pheromones of bark beetles (genus *Ips;* Silverstein, 1982). In the following sections we describe known examples of chiral lepidopteran sex pheromones and present our study of two Asian arctiid species in which both sexes produce chiral pheromone components.

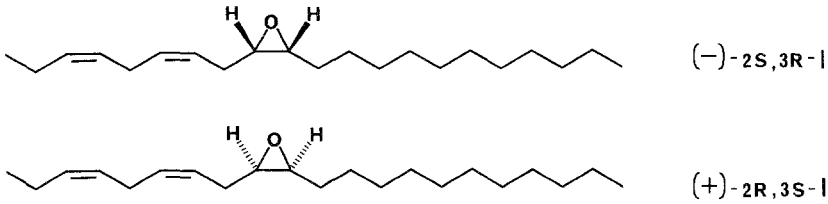
Chiral Female Pheromones in Lepidoptera. Disparlure (I) provides an interesting example of a chiral lepidopteran sex pheromone. This unsymmetrical epoxide was found to be the sex pheromone of the female gypsy moth, *Lymantria dispar* L. (Bierl et al., 1970, 1972; Beroza et al., 1971; cf. Jacobson et al., 1960, 1961). Subsequent to its isolation from the gypsy moth, disparlure was also identified as the sex attractant of the nun moth, *Lymantria monacha* L., which lives sympatrically with the gypsy moth in parts of Europe (Bierl et al., 1975). The suspicion that enantiomeric composition could be the key to species recognition led to the discovery of distinctly different enantiomer response patterns in the two species (Vité et al., 1976). More recently, single-cell and electroantennogram (EAG) recordings (Hansen, 1984; Schneider, 1984a) have suggested that the gypsy moth produces nearly enantiomerically pure (+)-2*R*,3*S*-I, whereas the nun moth pheromone contains only 10% of this (+) isomer, along with 90% of the (−)-2*S*,3*R* enantiomer. This is consistent



SCHEME 1.

with the surprising observation that both species are attracted to (+)-disparlure, whereas the gypsy moth alone, which has specialized receptor cells for both enantiomers, is inhibited by (−)-disparlure. The male nun moth has receptors for (+)-I but none for (−)-I (Scheme 1). Its attraction to the gypsy moth pheromone may be avoided in nature by the partial difference in the activity rhythms of the two species (Hansen, 1984; Schneider, 1984a). Since it is clear that insights of this sort require extremely good analytical techniques, it is unfortunate that no general methods exist for the determination of optical purity on the minute scale necessitated by most lepidopteran pheromone studies (Mori, 1984).

A second chiral epoxide, [2(2*Z*,5*Z*),3]-2(2,5-octadienyl)-3-undecyloxirane (II), is known as the major pheromone component of both the saltmarsh caterpillar moth, *Estigmene acrea* (Hill and Roelofs, 1981) and the fall webworm moth, *Hyphantria cunea* (Hill et al., 1982; Einhorn et al., 1982). Although the ranges of these two species overlap in North America, the female sex attractants used by both are blends of the same three compounds: epoxide II, (*Z*,*Z*)-9,12-octadecadienal and (*Z*,*Z*,*Z*)-9,12,15-octadecatrienal. Hill and Roelofs (1981) and Hill et al. (1982) used the EAG responses of males to the related epoxides, (+)- and (−)-disparlure, in order to probe receptor enantioselectivities in both species. In both cases, the EAG responses to (−)-disparlure exceeded those of the (+) enantiomer. By correlating the molecular structures of I and II, these investigators predicted that the active pheromones of both species would have the 2*S*,3*R* configuration. This prediction has been confirmed by EAG experiments with synthetic samples of 2*S*,3*R*-II and 2*R*,3*S*-II (Scheme 2) (Hill et al., 1982). The only assumption involved in the configurational as-



SCHEME 2.

signment is the enantioselectivity of the Sharpless epoxidation step used in synthesis of epoxide II (Mori and Ebata, 1981). In this case, enough of the natural pheromone was obtained from *Estigmene acrea* to produce a negative optical rotation, corresponding to that of synthetic 2*S*,3*R*-II. More recent work on female arctiids has uncovered this same 21-carbon epoxide in several species and a related 20-carbon epoxide occurs in one of these (*Antichloris viridis;* Meyer, 1984).

There are two known female lepidopteran pheromone components possessing a single asymmetric carbon atom. These are 10-methyldodecyl acetate (III), a minor component of the lesser tea tortrix moth, *Adoxophyes* sp. (Tamaki, 1979; Tamaki et al., 1979), and 2-butyl (*Z*)-7-tetradecenoate (IV), the major sex pheromone component of the western grapeleaf skeletonizer, *Harrisina brillians* (Myerson et al., 1982). In the case of III, neither EAG nor behavioral experiments indicated significant discrimination between synthetic enantiomers (Tamaki et al., 1983, 1984). The stereochemical compositions of natural III and IV remain to be determined (Scheme 3).

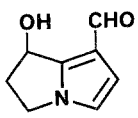
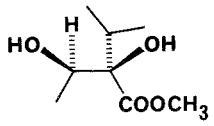
IV

SCHEME 3.

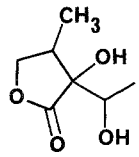
Chiral Male Pheromones in Lepidoptera. While female Lepidoptera produce chiefly fatty acid-derived pheromones (Roelofs and Bjostad, 1984), male moths and butterflies release scent chemicals having a greater variety of structures (Birch, 1974; Schneider, 1984a; Boppré, 1984). These male odor components are, in many cases, derived from natural products found in larval food sources or from compounds sequestered from plants by the adult. Perhaps the most widely distributed chiral male substance is hydroxydanaidal (V, Scheme 4), which can be derived from various pyrrolizidine alkaloids. Hydroxydanaidal has been isolated from the sex glands (abdominal hair pencils and alar wing patches) of many species of danaine butterflies (Edgar, 1975, 1982; Komae et al., 1982, 1983) and from coremata of arctiid moths belonging to the genus



V



VI



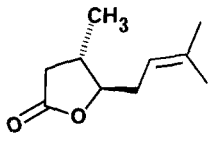
VII

SCHEME 4.

Utetheisa (Culvenor and Edgar, 1972; Connor et al., 1981). The discovery of hydroxydanaidal in the giant coremata of two other arctiids, *Creatonotos gangis* and *C. transiens* (Schneider et al., 1982) led to the first examination of optical activity in natural hydroxydanaidal. The results of this work have appeared in preliminary form (Bell et al., 1984) and are discussed later in this report. The conversion of pyrrolizidine alkaloids to dihydropyrrolizine scent components must be accompanied by removal of various esterifying acid moieties (e.g., viridifloric and trachelanthic acids). Esters derived from these acids occasionally appear as male sex organ constituents, for example methyl viridiflorate (VI) from *Euploea boisduvalii fraudulenta* (Edgar, 1982) and lactone (VII) from various ithomiine butterflies (Edgar et al., 1976) (Scheme 4).

Several chiral monoterpenes have been found as components of male pheromone mixtures and these have been summarized elsewhere (Birch, 1974; Boppré, 1984). Particularly noteworthy is eldanolide (VIII, Scheme 5), the wing gland pheromone of the male African sugar cane borer, *Eldana saccharina* (Wlk.) (Kunesch et al., 1981). This terpenoid lactone was proven to possess the 3*S*,4*R* configuration by comparison of its chiroptical properties with those of the synthetic enantiomers (Vigneron et al., 1982). Also of interest are the three chiral short-range sex attractants isolated from the hairpencils of the Oriental fruit moth, *Grapholitha molesta* (Baker et al., 1981). These were identified as (*R*)-(−)-mellein (IX), methyl jasmonate (X), and methyl 2-epijasmonate (XI) by comparison with authentic samples (Scheme 5).

We conclude this summary of chiral lepidopteran pheromones with a few unique male scent components. Particularly striking is the chiral saturated hydrocarbon, 13-methylheptacosane (XII, Scheme 6), a pheromone found on the wings of male sulfur butterflies, *Colias eurytheme* (Grula et al., 1980). The absolute configuration of this substance is apparently unknown and would be extremely difficult to determine because of the very small difference between the two enantiomers. Recently, hepialone (XIII), the major pheromonal component of the male ghost moth, *Hepialus californicus*, has been discovered as the long-range sex attractant toward the female (Kubo et al., 1985). The absolute configuration has been found to be *R*, as shown, by independent synthesis (Uchino et al., 1985). Finally, the main components of the pheromone blend



VIII

SCHEME 6.

of the male swift moth, *Hepialus hecta* L., have been identified very recently as dihydropyranone (XIV) and bicyclic ketals (XV and XVI) (Francke et al., 1985; Sinnwell et al., 1985). It is interesting to note that whereas in hepialone the chiral center bears the methyl substituent and the ethyl group is attached at the unsaturated carbon, the positions of these groups are exactly transposed in the substance produced by *Hepialus hecta* (XIV). The absolute configurations of XIV–XVI have not yet been reported.

METHODS AND MATERIALS

General. Creatonotos gangis L. and *C. transiens* (Walker) were captured mostly in North Sumatra and were reared in the laboratory (Seewiesen) as described by Wunderer et al. (1986). Details concerning the preparation of scent organs and electrophysiological assays are also given in this reference. Female scent glands (in CS_2) and male coremata (in CS_2 or ethyl acetate) were mailed in sealed ampoules to Cornell or Stony Brook for chemical analysis. Gas–liquid chromatography (GLC) of female extracts was conducted on a Varian 2100 instrument using FID detection and a Shimadzu C-R1A Chromatopac recorder. The following glass GLC columns and conditions were employed: Carbowax: 4-mm × 3.3-m column packed with 10% Carbowax 20 M on 60/80 Chromosorb W-AW-DMCS (column: 195°C; injector: 225°C; detector: 220°C). OV-1: 4-mm × 4.57-m column packed with 3% OV-1 on 60/80 Chromosorb W-AW-DMCS (column 250–280°C; injector: 250°C; detector: 290°C). XF-1150: 2-mm × 2.4-m column packed with 10% XF-1150 on 80/100 Chromosorb W-AW-DMCS.

All solvents were reagent grade; however, anhydrous pyridine was also distilled from CaH_2. Alumina for column chromatography was Woelm neutral alumina of the indicated activity grade. Machery Nagel alumina and silica sheets were employed for analytical thin-layer chromatography (TLC), and R_f values on alumina were for 95:5 CH_2Cl_2–CH_3OH (v/v). TLC visualization was achieved by exposure to I_2 or ultraviolet light. Gas chromatographic–mass spectral (GC-MS) analyses were obtained by electron impact (70 eV) using a Finnigan 3300 GC-MS instrument coupled to a System Industries 150 data system. Proton magnetic resonance (NMR) spectra (300 MHz) were recorded on a Bruker WM-300 or Nicolet NT-300 spectrometer, whereas 90-MHz spectra were obtained using a Varian EM-390 spectrometer. NMR samples were dissolved in $CDCl_3$ and data are expressed in ppm (δ) downfield from tetramethylsilane, which was an internal standard. Infrared spectra were recorded on a Perkin-Elmer model 299B spectrophotometer and optical rotations were measured using a Perkin-Elmer model 141 polarimeter with a 1-dm thermostatted cell.

Analysis of Female Lure Gland Components. Female lure gland samples were further extracted with 0.1–0.2 ml of CS_2 before GLC analysis or pre-

parative fractionation, which was performed using a splitter (10% to detector and 90% to collector). Fractions were collected using 3-mm OD glass U-tubes cooled in Dry Ice. For electrophysiological assays, preparative fractions were dissolved in pentane, hexane, or CH_2Cl_2 and sent to Seewiesen in glass ampoules. NMR samples were prepared by washing collection tubes with several portions of $CDCl_3$, directly into NMR tubes. NMR (300 MHz) and mass spectral data for (Z,Z,Z)-3,6,9-heneicosatriene (XVII, Scheme 7) and (Z,Z)-2-(2,5-octadienyl)-3-undecyloxirane (II) were recorded as follows: XVII: NMR δ5.36 (m, 6H, olefinic), 2.81 (m, 4H, doubly allylic CH_2), 2.06 (m, 4H, allylic CH_2), 1.26 (m, 18H, remaining CH_2), 0.976 (t, 3H, J = 7.7 Hz, homoallylic CH_3), 0.880 (t, 3H, J = 5.9 Hz, terminal CH_3). MS *m/z* 290 (0.7), 234 (3.4), 108 (58.4), 79 (100%). II: NMR δ5.4 (bm, 4H, olefinic), 2.94 (m, 2H, epoxy CH), 2.81 (t, 2H, J = 6.6 Hz, doubly allylic CH_2), 2.4 (m, 1H, OCHC**H**CH=CH), 2.2 (m, 1H, OCHC**H**CH=CH), 2.08 (m, 2H, allylic CH_2), 1.26 (m, 20H, remaining CH_2), 0.976 (t, 3H, J = 7.4 Hz, homoallylic CH_3), 0.880 (*t*, 3H, J = 6.2 Hz, terminal CH_3). MS *m/z* 306 (0.2), 108 (52.1), 79 (100%).

Synthesis of (Z,Z,Z)-3,6,9-Tricosatriene (XVIII, Scheme 7). This synthesis was conducted in the manner described for preparation of triene XVII (Connor et al., 1980; Jain et al., 1983). To a stirred suspension of 0.19 g of $LiAlH_4$ in 10 ml of anhydrous ether was added a solution of 1.44 g of methyl linolenate (Sigma) in 5 ml of anhydrous ether. The resulting mixture was stirred under reflux for 15 min, then cooled to room temperature. Quenching with water and aq. NaOH, followed by filtration and evaporation gave 1.20 g (92%) of linolenol as a colorless, mobile oil, pure by TLC on silica gel. A solution of 1.09 g of linolenol and 0.88 g of *p*-toluenesulfonyl chloride in 15 ml of anyhdrous pyridine was held at 5–15°C for 24 hr, then poured into 90 ml of cold water. The resulting mixture was extracted with ether, and the combined extracts were dried and evaporated. The residue was chromatographed on 100 g of Woelm silica (Act. III), eluting with 0–15% ether in hexane (v/v). Thus obtained was

XVII

XVIII

SCHEME 7.

1.22 g (71%) of linolenyl tosylate as a colorless oil which was homogeneous by TLC on silica.

A solution of *n*-pentyllithium was prepared by reacting 3.02 g of *n*-pentylbromide with 0.30 g of Li wire in 15 ml of anhydrous ether at −10° to 20°C. The resulting solution was filtered, and an aliquot was titrated with 2,5-dimethoxybenzylalcohol, giving a titer of 0.76 M. A suspension of 0.21 g of anhydrous CuI (Alfa, 99.99%) in 10 ml of anhydrous ether was stirred under N_2 at −24°C as 2.9 ml of this *n*-pentyllithium solution was added. The resulting grey solution was stirred for 15 min at −24°C; then a solution of 0.42 g of linolenyl tosylate in 3 ml of anhydrous ether was added dropwise. The dark reaction mixture was stirred at −24°C for 4 hr, then 10 ml of saturated aq. NH_4Cl was added dropwise, followed by 10 ml of ether. The organic phase was washed with saturated aq. NH_4Cl, saturated aq. NaCl, dried, and evaporated. The crude product was chromatographed on Machery Nagel silica gel 60 (70–270 mesh), eluting with hexane. Thus obtained was 0.278 g (87%) of triene (XVIII) as a colorless oil. NMR (300 MHz) δ5.36 (m, 6H, olefinic), 2.80 (t, 4H, J = 5.8 Hz, doubly allylic CH_2), 2.05 (m, 4H, allylic CH_2), 1.25 (m, 22H, remaining CH_2), 0.967 (t, 3H, J = 7.5 Hz, homoallylic CH_3), 0.870 (t, 3H, J = 6.7 Hz, terminal CH_3); IR (neat) 3010m, 2960m, 2920s, 2850s, 1650w, 1460mw, cm^{-1}; MS *m/z* 318.3286 (calc. for $C_{23}H_{42}$: 318.3286; M^+, 0.3), 262 (1.2), 108 (65.2), 79 (100%).

Although samples of XVIII were pure (TLC and GLC) after column chromatography, samples for biological testing were preparatively gas chromatographed. This was carried out on a $\frac{1}{4}$-in. OD × 6-ft glass column packed with 2.7% OV-17 on Gas Chrom Q-AW-DMCS, using a Varian 920 thermal conductivity gas chromatograph. Solutions of this and other alkenes in hexane were mailed in sealed ampoules to Seewiesen for behavioral and electrophysiological testing.

Analysis of Male Coremata (Creatonotos transiens). A sample consisting of 54 coremata was extracted with 4.5 ml of $CHCl_3$. Evaporation of the extract left 18.5 mg of a yellow glassy residue, which was chromatographed on 2 g of alumina (Act. III), eluting with 0–2% CH_3OH in CH_2Cl_2 (v/v). The following fractions were obtained: (a) R_f 0.86; 3.4 mg; colorless oil; NMR (300 MHz) 5.35 (m), 5.2 (m), 4.27 (dd, J = 4.4, 11.8 Hz), 4.16 (dd, J = 6, 11.8 Hz), 2.80 (m), 2.30 (t, J = 7.5 Hz), 2.01 (m), 1.60 (m), 1.29 (lg m), 1.24 (lg m), 0.97 (t, J = 7.5 Hz), 0.87 (bt); triglyceride mixture. (b) R_f 0.63; 0.3 mg; white solid; NMR (300 MHz) 5.34 (m), 3.51 (m), 2.26 (m), 2.1-0.9 (complex), 0.997 (s), 0.902 (d, J = 6.6 Hz), 0.854 (d, J = 6.6 Hz), 0.850 (d, J = 6.6 Hz), 0.666 (s); MS *m/z* 386 (M^+), 371, 368, 353, 275. (c) R_f 0.43–0.8, mainly 0.43; 2.0 mg; mixture. (d) R_f 0.43; 4.2 mg; hydroxydanaidal; for rotation, see Table 1, entry 3.

A second sample consisting of 81 coremata was extracted with 5 ml of ethyl acetate. Evaporation of the extract left 19.3 mg of residue, which was

TABLE 1. OPTICAL ROTATIONS OF HYDROXYDANAIDAL V: SEMISYNTHETIC AND NATURAL SAMPLES

Entry	Source	Specific rotation, $[\alpha]_D^{25}$ (ethanol)	
1	Synthesis from retronecine	−140°	(c = 0.74)
2	Synthesis from heliotridine	+137°	(c = 0.73)
3	Heliotrine-fed *C. transiens*	−122° ± 20°	(c = 0.21)
4	Heliotrine-fed *C. transiens*	−170° ± 30°	(c = 0.18)
5	Heliotrine-fed *C. gangis*	−320° ± 300°	(c = 0.005)[a]
6	Monocrotaline-fed *C. gangis*	−210° ± 70°	(c = 0.016)[a]

[a]These rotations are for crude extracts and are calculated according to hydroxydanaidal assays obtained by GLC on OV-17.

chromatographed on 4 g of alumina (Act. V), eluting with 0–1% CH_3OH in CH_2Cl_2 (v/v). The higher R_f components (13.0 mg) were rapidly eluted, affording 1.8 mg of hydroxydanaidal (for rotation, see Table 1, entry 4). The higher R_f fraction was rechromatographed on 3 g of alumina (Act. III), with 0–2% CH_3OH in CH_2Cl_2 (v/v) elution. Thus obtained were 12.1 mg of triglycerides, 0.4 mg of cholesterol, and 0.7 mg of mixed fractions.

Syntheses of (R)-(−)- and (S)-(+)-Hydroxydanaidal. The enantiomers of hydroxydanaidal were prepared from retronecine-*N*-oxide and heliotridine-*N*-oxide, as described by Culvenor et al. (1970). Activated MnO_2 was prepared by the method of Attenburrow et al. (1952).

A solution of 100 mg of retronecine (mp 117.5–118.5°C; acetone) in 2 ml of absolute ethanol containing 0.2 ml of 30% aq. H_2O_2 was stirred at ambient temperature for 1 day, then the reaction was quenched by addition of MnO_2. Filtration and evaporation left 113 mg of crystalline, white *N*-oxide, which was dissolved in 4 ml of CH_3OH and oxidized with 0.9 g of freshly prepared activated MnO_2. After the reaction mixture was stirred for 3 hr at ambient temperature, it was filtered through Celite. Evaporation left 119 mg of an amber residue, which was chromatographed on 6 g of MCB aluminum oxide 90 (70–230 mesh), eluting with 0–2% CH_3OH in CH_2Cl_2 (v/v). Thus obtained was 33.4 mg of (*R*)-(−)-hydroxydanaidal as a light yellow oil; NMR (90 MHz) 9.73 (s, 1H), 6.58 (m, 2H), 5.40 (m, 1H), 4.05 (m, 3H), 2.2–3.1 (m, 2H).

Treatment of 100 mg of heliotridine (mp 114.5–115.5°C; acetone) with hydrogen peroxide in ethanol (41 hr, room temperature), followed by activated MnO_2 in CH_3OH (2 hr, room temperature) and chromatography afforded 44.8 mg of (*S*)-(+)-hydroxydanaidal. The NMR spectrum was identical to that of (*R*)-(−)-hydroxydanaidal, described above.

Sublimation at 50–60°C (0.1 mm) furnished pure (*R*)-(−)- and (*S*)-(+)-hydroxydanaidal in 28% and 37% overall yields, respectively. The rotations of these samples are given in Table 1, entries 1 and 2.

RESULTS

Chemical Characterization of Female Lure Gland Components of Creatonotos transiens *and* C. gangis. The carbon disulfide extract of 15 *Creatonotos transiens* female lure glands was initially examined by gas–liquid chromatography (GLC) on a Carbowax column, revealing two major components (Figure 1). Following the results of electroantennogram (EAG) assays (see Wunderer et al., 1986), these two GLC peaks (at 5.1 and 14.1 min), as well as the minor peaks at intermediate retention time, were selected for chemical characterization. The more volatile major component, (5.1 min) was identified as (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene (XVII) by comparison of its spectroscopic (MS and [^{1}H]NMR) and GLC properties with those of synthetic samples (Connor et al., 1980; Jain et al., 1983). The longer retention time major component was identified as the chiral epoxide, (*Z*,*Z*)-2(2,5-octadienyl)-3-undecyloxirane (II), by comparison of its [^{1}H]NMR and mass spectra with data reported for natural (Hill and Roelofs, 1981; Hill et al., 1982) and synthetic samples of this epoxide (Mori and Ebata, 1981). The GLC properties of this second female component were also consistent with those of epoxide samples produced by oxidation of triene XVII by means of *m*-chloroperoxybenzoic acid.

Corresponding GLC analysis of *Creatonotos gangis* lure gland extracts revealed that the same two major components are present as in the case of *C.*

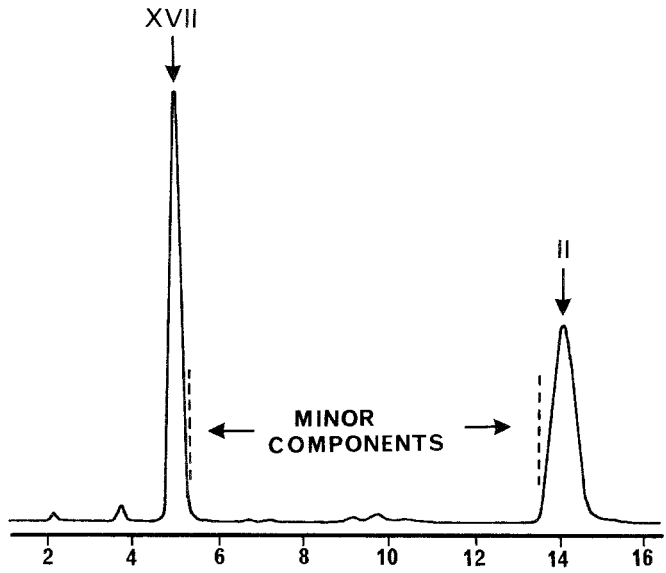

Fig. 1. Carbowax gas–liquid chromatogram of female *Creatonotos transiens* lure gland extract (retention times in min.).

transiens (see Wunderer et al., 1986). In *C. gangis* extracts, however, the ratio of epoxide II to triene XVII was found to be much larger. Thus, the ratio of II to XVII ranged from 0.9 to 2.3 for 5 *C. transiens* samples examined quantitatively, whereas this ratio ranged from 12 to 165 for 21 *C. gangis* extracts. The combined amount of volatile substances contained in each female gland was estimated to be on the order of 1–2 μg.

The minor component fraction (5.2–14 min) from the 60-gland *C. transiens* extract was further fractionated by GLC, using an OV-1 column (Figure 2). Of the four fractions produced, only the second eluted fraction, consisting of three components, showed significant EAG activity (Wunderer et al., 1986). Because this OV-1 fractionation was accompanied by substantial loss of overall activity, subsequent preparative chromatography was conducted using Carbowax.

Preparative GLC of the CS_2 extract of 82 *Creatonotos gangis* female lure glands afforded five fractions, as shown in Figure 3. The first and last fractions consisted of triene XVII and epoxide II, respectively. Of the three minor component fractions, the second (central) fraction, consisting of two components (9.5 and 10.7 min), was selected for examination. Of these two peaks, only the

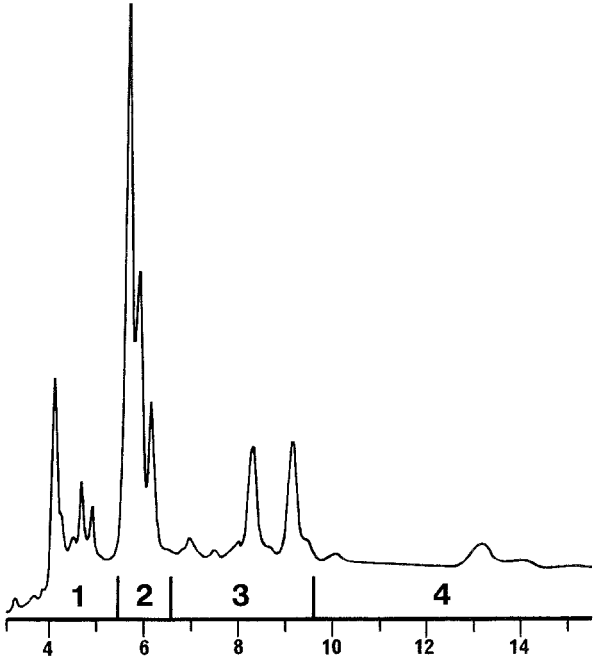

Fig. 2. OV-1 GLC fractionation of minor components obtained from Carbowax fractionation of *C. transiens* extract (retention times in min; cf. Figure 1).

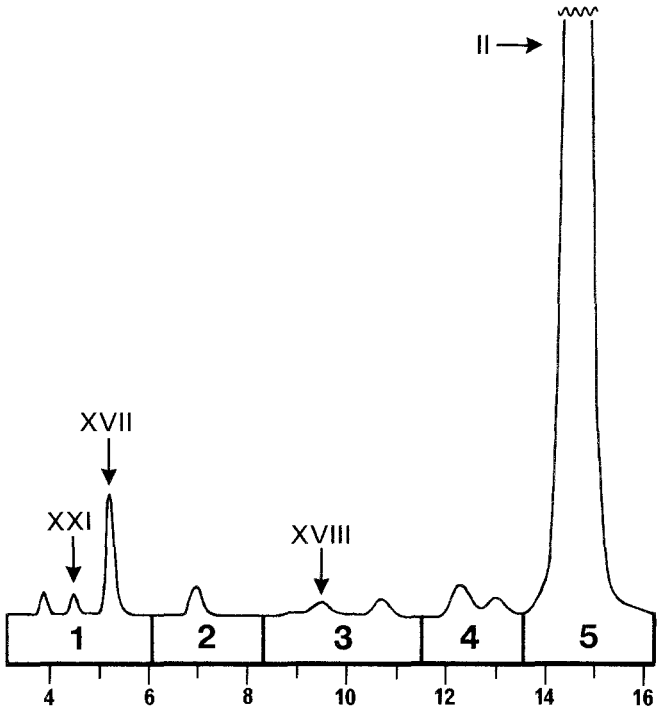

Fig. 3. Carbowax GLC fractionation of female *C. gangis* lure gland extract (retention time in min).

9.5-min peak corresponded to the active OV-1 fraction mentioned earlier (cf. Figure 2). The mass spectrum of this component (Figure 4) immediately suggested the structure (*Z,Z,Z*)-3,6,9-tricosatriene (XVIII), by comparison with the fragmentation pattern observed for triene XVII (Connor et al., 1980; Jain et al., 1983). The synthesis of triene XVIII (Figure 5) closely followed the method used to prepare XVII. Thus, XVIII was obtained in 57% overall yield from methyl linolenate, according to this three-step method. Synthetic XVIII was then shown to be identical with the 9.5-min minor component (cf. Figure 3) by GLC coinjection on Carbowax, OV-1 and XF-1150 columns and by mass spectroscopic comparison. For the relative EAG and behavioral efficacies of synthetic XVII and XVIII in *Creatonotos transiens* and *C. gangis*, see Wunderer et al. (1986).

Creatonotos female gland extracts were also examined for some of the female odor components found in other arctiid species, such as *Estigmene acrea* (Hill and Roelofs, 1981), *Hyphantria cunea* (Hill et al., 1982; Einhorn et al., 1982), and *Utetheisa ornatrix* (Connor et al., 1980; Jain et al., 1983). In particular, neither *Creatonotos* species appeared to produce (*Z,Z,Z*)-9,12,15-oc-

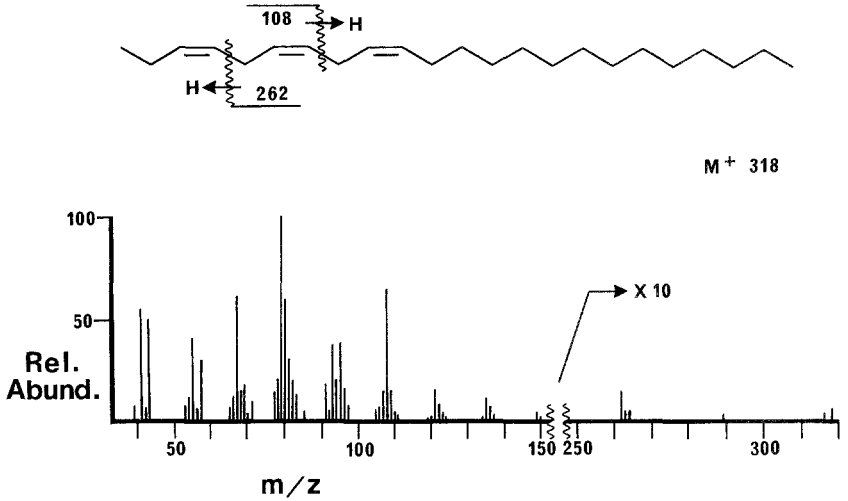

Fig. 4. Electron impact mass spectrum of 9.5-min minor component from *C. gangis* fractionation (cf. Figure 3).

Fig. 5. Synthesis of (*Z*, *Z*, *Z*)-3,6,9-tricosatriene (XVIII) from methyl linolenate. Reagents: (a) $LiAlH_4$/ether; (b) *p*-toluenesulfonyl chloride/pyridine; (c) $(n\text{-}C_5H_{11})_2CuLi$/ether.

tadecatrienal (linolenal, XIX, Scheme 8), which is found in *E. acrea*, and *H. cunea* along with epoxide II. Also absent was the tetraene component of *U. ornatrix*, (*Z*,*Z*,*Z*)-1,3,6,9-heneicosatetraene (XX). All of the *Creatonotos* extracts examined, however, did show a small peak that corresponded to (*Z*,*Z*)-6,9-heneicosadiene (XXI) on Carbowax and XF-1150 GLC columns. This diene also accompanies triene XVII in *Utetheisa* (Jain et al., 1983) and has been examined for EAG activity in *Creatonotos* (Wunderer et al., 1986).

Chemical Characterization of Male Coremata Components of Creatonotos transiens *and* C. gangis. We have already reported that the development of the male scenting organs, the coremata, is controlled by access of the larvae to pyrrolizidine alkaloids, and that large coremata may contain as much as 400 μg per insect (Schneider et al., 1982). In the present study, the corematal contents were more thoroughly examined; a preliminary report of our work on the configuration of hydroxydanaidal has appeared (Bell et al., 1984). Whereas earlier studies utilized GLC and UV-monitored HPLC to examine corematal constituents, we have now employed column chromatography in order to avoid potential problems associated with GLC of materials having low volatility or thermal stability.

Chromatographic studies were conducted on the ethyl acetate or carbon disulfide extracts of *Creatonotos transiens* coremata, excised from individuals

SCHEME 9.

which had been raised on diets containing natural heliotrine (XXII, Scheme 9) as the exclusive pyrrolizidine alkaloid. Examination of these extracts by thin-layer chromatography (TLC) showed that they consisted of three principal components: R_f 0.86 (weakly UV active), 0.63 (UV inactive), and 0.43 (UV active). Chromatography of the extracts on deactivated neutral alumina led to samples of each component that were examined by 300 MHz [^{1}H]NMR and mass spectrometry. The [^{1}H]NMR spectrum of the high R_f component (0.86) was consistent with a mixture of fatty ester triglycerides having an average of three alkene groups per glycerol unit. The next eluted component (UV inactive) was shown to be cholesterol by comparison of its mass spectrum with known fragmentations of steroids (Zaretskii, 1976) and by TLC comparison with authentic samples. The third component (UV active) proved to be (*R*)-(−)-hydroxydanaidal (V) by comparison of its physical and spectroscopic properties with material synthesized as described below. According to chromatographic recoveries, the crude extracts consisted of 18–63% glycerides, 2–8% cholesterol, and 9–23% hydroxydanaidal by weight, despite significant irreversible retention of some components: The [^{1}H]NMR spectra of crude extracts indicated only the presence of three components; UV spectra, as well as optical rotations appeared to reflect only the presence of known quantities of hydroxydanaidal (V).

Pure samples of (*R*)-(−)- and (*S*)-(+)-hydroxydanaidal (V) were required for comparison with corematal material and for electrophysiological experiments. These enantiomers were synthesized from natural retronecine and heliotridine, as shown in Figure 6. Thus, (*R*)-(−)-V was obtained from retronecine in 28% yield and (*R*)-(+)-V was obtained from heliotridine in 37%, after purification by chromatography and sublimation in both cases. The optical rotations of these semisynthetic hydroxydanaidal samples are given in Table 1, along with the data for pure and crude samples of V extracted from *Creatonotos* coremata. The purified hydroxydanaidal obtained from heliotrine-fed *C. transiens* had negative rotations (entries 3 and 4). This reflects an overall *inversion*

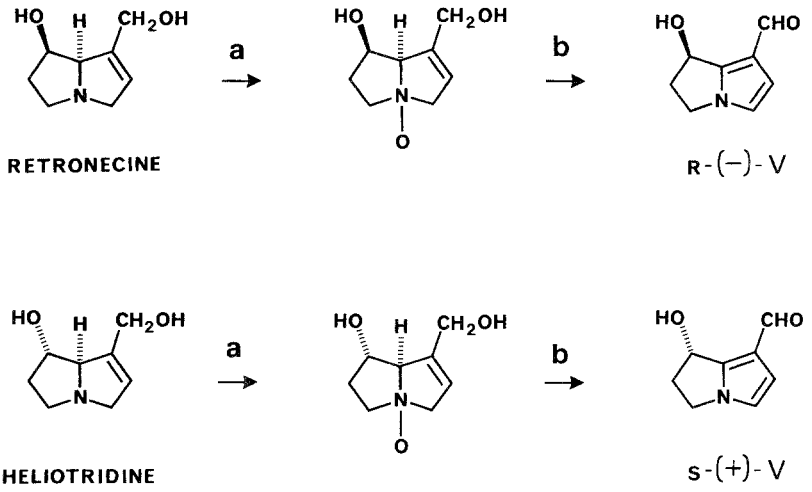

Fig. 6. Syntheses of (*R*)-(−)-hydroxydanaidal from retronecine and (*S*)-(+)-hydroxydanaidal from heliotridine. Reagents: (a) H_2O_2/ethanol; (b) MnO_2/methanol.

of configuration at the remaining asymmetric center during biosynthesis from heliotridine-derived XXII. A small number of coremata were available from groups of *C. gangis* that had been fed either heliotrine (XXII) or monocrotaline (XXIII) as the exclusive alkaloid source. In both cases, the crude extracts had weak, negative rotations (entries 5 and 6), which correlated roughly with the quantities of V they contained.

DISCUSSION

Behavioral studies of courtship in *Creatonotos* have been limited mainly to greenhouse work with *C. transiens* (Wunderer et al., 1986). These studies have shown that a dual mating and luring system is employed. Males initiate the courtship assembly by forming groups and expanding their large scenting organs, the coremata. Attracted females mate with calling males, or may at a later phase attract males by emitting their own pheromone bouquet. Trapping experiments have shown that the scent gland constituents, C_{21} triene (XVII), C_{21} epoxide (II), and C_{23} triene (XVIII), are indeed emitted by calling females. The remarkable complexity of this courtship would permit a variety of possible mechanisms for reproductive isolation between these sympatric species. In addition to potential temporal and visual factors, there are a number of possible chemical differences that could be used for species identification. Both the male and major female pheromone components are chiral, permitting differences in enantiomeric composition. Furthermore, the female pheromones of both species contain the same four components, and their ratios may be specific.

In this study we have identified four constituents of the female pheromones of *Creatonotos gangis* and *C. transiens*: C_{21} diene XXI, C_{21} triene XVII, C_{23} triene XVIII, and the chiral C_{21} epoxide II. A number of other arctiid moths are known to produce related female pheromones, as indicated in Table 2. The C_{21} polyenes are known from *Utetheisa ornatrix* and *Arctia villica*, whereas *Estigmene acrea* and *Hyphantria cunea* produce the C_{21} epoxide II as one of the female components. *Creatonotos* is unusual in that it produces both the triene XVII and the epoxide II, which may be biosynthesized by direct epoxidation of XVII (Roelofs and Bjostad, 1984). Another novel feature is the minor 23-carbon component, triene XVIII, which had not been reported previously as a lepidopteran pheromone constituent. The ratios of these three components, II, XVII, and XVIII, may carry species identifying information. Indeed, the ratio of II to XVII was consistently higher in *Creatonotos gangis* than in *C. transiens*. Electrophysiological studies indicate that the male antenna bears specialized receptor cells for II and XVII, lending a capability for recognition of this difference (Wunderer et al., 1986). Interestingly, the C_{23} triene (XVIII) has so far given EAG responses only in male antennae of *Creatonotos gangis* and not in *C. transiens*. A complete interpretation of these observations must await further investigation of: (a) behavioral effects of pheromone ratios: and (b) additional female gland constituents (see Wunderer et al., 1986). Some of the additional components are currently under identification (W. Francke, unpublished results).

The absolute configuration of C_{21} epoxide II has yet to be determined, because insufficient quantities were available for chiroptical experiments. Although a synthesis of optically active II has been reported (Mori and Ebata, 1981), an independent method is under investigation in order to provide material of extremely high optical purity (Bell and Ciaccio, unpublished results). That the chirality of II may play a role in *Creatonotos* courtship is suggested by the recent observation of enantiomer discrimination of disparlure in EAG experiments with antennae of both species (K. Hansen, personal communication). It will be particularly interesting to determine whether the enantiomer selectivities for disparlure (I) correspond to those for C_{21} epoxide II, according to the prediction of Hill and Roelofs (1981). These investigators made a straightforward correlation between the shorter epoxide substituents and the longer straight chains in the two series, predicting that (−)-(2*S*, 3*R*)-I would correspond to (+)-(2*S*, 3*R*)-II. This assumption is not necessarily valid, since the interaction of the two shorter chains with the receptor might be very different. In particular, the conformational properties of the 7-carbon, branched chain of displarlure (I) would not necessarily resemble those of the 8-carbon homoconjugated diene chain of II.

Our chromatographic examination of the extracts of male *Creatonotos transiens* coremata revealed three major constituents: lipids, (*R*)-(−)-hydroxydanaidal (V) and cholesterol. Of these, the only volatile, EAG-active compo-

nent is hydroxydaniadal. The function of the remaining materials is unknown, although it is possible that these waxy, lipophilic substances may serve as fixatives, facilitating slow and continuous release of the male "perfume." The presence of a second volatile pheromone component was suggested by electrophysiological experiments using some coremata extracts (K. Hansen, personal communication). Chromatographic fractionation always resulted in hydroxydanaidal as the only active component. A second active component, if present, would have to be unstable to GLC and mild column chromatographic conditions employed.

We have shown that *Creatonotos transiens* males convert dietary heliotrine (XXII) to (*R*)-(−)-hydroxydanaidal (V) (cf. Table 1). It is clear from the magnitudes of the observed rotations that the hydroxydanaidal produced by *C. transiens* is at least 85% pure. A more sensitive experimental method would be required to more accurately determine the optical purity. The weak rotations of crude *C. gangis* extracts imply that this species may also produce (*R*)-(−)-V from *both* heliotrine (XXII) and monocrotaline (XXIII), requiring stereochemical inversion in one case and retention of configuration in the other (cf. below). It must be emphasized, however, that these data were obtained using crude samples that may contain optically active components other than V and that no firm conclusion may be drawn regarding the enantiometric composition of hydroxydaniadal produced by *C. gangis*.

Our initial studies of *Creatonotos* coremata (Schneider et al., 1982) revealed the chiral male pheromone, hydroxdanaidal, but did not address the optical activity of this substance. A number of possible scenarios were considered at this point. If, for example, the pheromone were to consist of a single enantiomer, then potential dietary precursors might be limited to the corresponding pyrrolizidine alkaloid series. Hence, (*R*)-(−)-hydroxydanaidal might be produced only from pyrrolizidine alkaloids derived from retronecine, e.g., monocrotaline (XXIII), having the same configuration at the residual asymmetric center (C-7). Alternately, if the insect were able to convert both retronecine- and heliotridine-derived alkaloids into the male sex pheromone, then a wider variety of plant substances could be utilized. In contrast to the African monarch butterfly, *Danaus chrysippus*, in which a pyrrolizidine precursor to the dihydropyrrolizine pheromone, daniadone, is known (Schneider, et. al., 1975), the larval food plants for *Creatonotos transiens* and *G. gangis* have not been discovered.

When *Creatonotos transiens* larvae were raised on a diet consisting of heliotridine (XXII) as the exclusive pyrrolizidine alkaloid, the hydroxydanaidal (V) isolated from the adult coremata had the (*R*)-(−) configuration. Contrary to the straightforward assumption that the stereochemistry at C-7 would be retained, biosynthesis of V led to inversion of configuration. Thus a dietary alkaloid having the "incorrect" configuration (heliotridine series) is converted to

(*R*)-(−)-V, having the retronecine stereochemistry. It would be interesting to determine whether pyrrolizidine alkaloids from both series are processed indiscriminately to V, or whether a separate set of enzymes can utilize retronecine-derived precursors without performing chemical transformations at C-7.

Another biosynthetic point of interest is the mechanism for conversion of heliotrine (XXII) into (*R*)-(−)-hydroxydanaidal (V). Two reasonable mechanisms that are consistent with the observed inversion of configuration are outlined in Figure 7. In pathway "a" C-7 is oxidized to the carbonyl oxidation level at some stage in the biosynthesis. Stereoselective reduction would then introduce the correct configuration at C-7. According to pathway "b," the leaving group ability of the C-7 hydroxyl is enhanced by protonation or conversion to a suitable derivative (X). Attack at C-7 by some oxygen nucleophile would then afford the *R* configuration by Walden inversion. Mechanism "a" requires loss of the hydrogen atom at C-7, whereas in "b" this hydrogen is retained. Isotopic labeling experiments designed to distinguish these possibilities are currently in progress (J. Meinwald et al., unpublished results).

The behavioral significance of enantioselective male pheromone production in *Creatonotos transiens*, the possibly also in *C. gangis*, has yet to be determined. The antennae of both sexes respond equally well to both the (*R*)-(−) and (*S*)-(+) enantiomers of V in EAG experiments (Wunderer et al., 1986). Interestingly, a receptor cell specialized for (*R*)-(−)-V has been discovered on male antennae, whereas a separate receptor responds to (*S*)-(+)-V and weakly even to the female pheromone components (Wunderer et al., 1986). These results indicate that at least the males may be able to detect differences in optical activity. If the male pheromone enantiomeric compositions differ between *Creatonotos* species, then this could perform the function of species identification during the formation of courtship assemblies. An alternative, or supple-

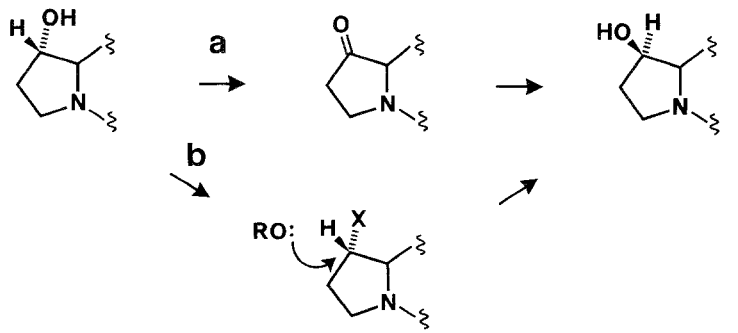

Fig. 7. Possible mechanisms for inversion of configuration at C-7 in the biosynthesis of hydroxydanaidal from heliotrine.

mental, species-specific signal might then be provided by the chiral or achiral components of the female pheromone.

Acknowledgments—The partial support of this work by the N.I.H. (AI-12020) is acknowledged with pleasure. One of the authors (T.W.B.) gratefully acknowledges the receipt of an N.I.H. Postdoctoral Fellowship (CA-06759). Professors Subhash Jain and Huang Wenkui are warmly thanked for contributing pure samples of C_{21} triene and C_{21} diene. This work was carried out in collaboration with Professor Dietrich Schneider and Doctors Micheal Boppfe, Kurt Hansen, and Hansjorg Wunderer, who reared the moths and conducted thorough electrophysiological and behavioral studies; we gratefully acknowledge their expert efforts.

METABOLIC TRANSFORMATION OF TRITIUM-LABELED PHEROMONE BY TISSUES OF *Heliothis virescens* MOTHS

YU-SHIN DING and GLENN D. PRESTWICH[1]

Department of Chemistry
State University of New York
Stony Brook, New York, 11794-3400

(Received April 26, 1985; accepted August 1, 1985)

Abstract—Unsaturated aliphatic pheromones of *H. virescens* were prepared at high specific activity (^{3}H, 58 Ci/mmol) and were employed to study tissue specificity of acetate esterase, alcohol oxidase, and aldehyde dehydrogenase in male and female *Heliothis virescens*. Thus, [9,10-$^3H_2$]Z9-14:Ac was synthesized by partial tritiation of the corresponding alkyne and was converted to the labeled Z9-14:OH and Z9-14:Al for metabolic studies. Soluble and membrane-associated enzyme activities were determined by radio-TLC assays. Esterase activity is highest in legs of both sexes, but also occurs in antennal and glandular tissues. Oxidase activity requires O_2 and is highest in female pheromone gland tissues, but it is also high in the male hairpencils. Aldehyde dehydrogenase activity was uniformly high in all tissues, but highest in antennal tissues of both males and females.

Key Words—Pheromone metabolism, tritium-labeling, acetate esterase, alcohol oxidase, aldehyde dehydrogenase, *Heliothis virescens*, Lepidoptera, Noctuidae, sensory biochemistry.

INTRODUCTION

Pheromone biosynthesis, pheromone perception, and pheromone catabolism are closely linked in terms of mate-finding behaviors of moths (review: Mayer and Mankin, 1985). In this paper, we will present experimental details on the pheromone-metabolizing enzymes of *Heliothis virescens*, using high-specific-activity, tritium-labeled Z9-14:Al (and its corresponding alcohol and acetate). First,

[1] Fellow of the Alfred P. Sloan Foundation (1981–1985) and Camille and Henry Dreyfus Teacher-Scholar (1981–1986).

0098-0331/86/0200-0411$05.00/0

however, we will survey pheromone biochemistry concisely (general review: Blomquist and Dillwith, 1983; catabolism: Ferkovich, 1981; biosynthesis: Roelofs and Bjostad, 1984). Additional recent results will be found in this symposium edition on pheromone biosynthesis (Bjostad and Roelofs, 1986; Teal and Tumlinson, 1986; Morse and Meighen, 1986) and pheromone catabolism (Lonergan, 1986; Vogt and Riddiford, 1986; Prestwich et al. 1986).

Catabolism of pheromones has been examined in only seven insects: *Bombyx mori*, *Lymantria dispar*, *Trichoplusia ni*, *Antheraea polyphemus*, *Choristoneura fumiferana*, *Heliothis virescens*, and *Reticulitermes flavipes*. The silkworm moth, *Bombyx mori*, produces bombykol (*E*10, Z12–16:OH) which is converted to "ester" and "acid" metabolites by whole male antennae exposed to labeled bombykol (Kasang, 1974). The [12,13-^{3}H]-labeled bombykol (30 Ci/mmol) and its tetrahydroisomer were prepared by partial tritiation of the 12 triple bond. At exposures of 10^{10}–10^{11} molecules/antenna, the half-life for "uptake" was 1.6 min for male and 1.0 min for female antennae. Much slower uptake was found in legs, heads, and wing scales which lack the pore tubules. Conversion from the alcohol to the corresponding labeled bombic acid and an unidentified ester, isolated by preparative TLC, showed a 4-min half-life. Chemical identifications were not performed, and no attempts to manipulate or purify the binding or catabolic proteins were reported.

The Seeweisen group also did preliminary work on disparlure biosynthesis (Kasang et al., 1974a) from the (*Z*)-[7,8-^{3}H]-2-methyl-7-octadecene (Sheads and Beroza, 1973) in female gypsy moth pupae and on racemic disparlure uptake and turnover (Kasang et al., 1974b) by male (and female) *L. dispar* antennae. In the former, aqueous ethanol suspensions of the labeled alkene were injected into female pupae two days preemergence and 34% of [^{3}H]disparlure (TLC) was recovered from female glands postemergence. There was no direct evidence of pheromone gland involvement in this conversion, however, and in view of the diel periodicity, life cycle and wild vs. lab variation of disparlure release and production (Charlton and Cardé, 1983; Richerson and Cameron, 1974), this work needs to be repeated on pheromone gland homogenates and with topical application of precursors to the gland surface. Such techniques have been used sucessfully to investigate the biosynthesis of Z11–14:Ac (Bjostad and Roelofs, 1981; Bjostad et al., 1981) in the red-banded leafroller moth and bombykol biosynthesis in silkworm moths (Yamaoka et al., 1984).

The disparlure metabolic studies are also very sketchy. At 5×10^{11} molecules/antenna of racemic [7,8-$^3H_2$]disparlure (40 Ci/mmol), about 2.5 min was required for disappearance of half the substrate and appearance of two uncharacterized polar metabolites (50%) as well as >30% of non-TLC-mobile material. Claims for specificity vs. nonspecificity of uptake and turnover are based on small differences superimposed on an exponential decay curve and are not convincing. Also, it is difficult to evaluate these data since both the attractive

(+) and inhibitory (−) enantiomers were present. It is essential to distinguish binding and catabolism of the two enantiomeric forms, since the proteins involved reside in seperate sensory cells (Hansen, 1984).

The in vivo and in vitro metabolism of *Z*7–12:Ac by *Trichoplusia ni* has been reported by Ferkovich, Mayer, and their coworkers in Gainesville (Ferkovich, 1981; Ferkovich et al., 1973; 1982a,b; Mayer et al., 1976). The acetate is converted to the corresponding alcohol by both specific and general esterases present in legs, wing scales, and antennae. The two primary roles of these esterases are to prevent sensory adaptation and to clear the body surface. The pheromone-specific catabolic proteins appear to show lower specificity for exact pheromone structures than do the receptors (measured behaviorally or by EAG or single cell), although they do show reduced susceptibility to general esterase inhibitors. This hydrolysis was demonstrated using (1) intact antennae and legs dipped in to a 10^{-3} M emulsion of pheromone in buffer; (2) in vitro homogenates of antennae, legs, cuticle, wings, and fat body; and (3) soluble proteins from the sensillum liquor of sonicated antennae. The homogenates were assayed with [^{3}H-acetate]*Z*7–12:Ac (200–800 mCi/mmol) at 10^{-6}–10^{-5} M, which is a much higher concentration (>1000×) and a much lower specific activity (300×) than for metabolic studies of bombykol, disparlure, and *E*6,*Z*11–16:Ac (see below). Nonetheless, conversion rates in the order of 6 pmol/μg protein/min in antennae were observed. Pheromone esterase activities decrease in the order of antennae > legs > wings in homogenates and wings > legs > antennae in eluates, consistent with both the postulated sensory deactivation and surface-cleaning functions.

The most thorough biochemical analysis of a pheromone binding and inactivation system is reported for *Antheraea polyphemus* (Vogt, 1984; Vogt and Riddiford, 1980, 1981, 1985; Vogt et al., 1985; Prestwich et al., 1984, 1986). Using [11, 12-$^3H_2$]*E*6,*Z*11–16:Ac (40 or 58 Ci/mmol), three electrophoretically distinct proteins were found which interact with pheromone: a nonenzymatic sensillar pheromone-binding protein (mol wt 15,000), a pheromone-hydrolyzing sensillar esterase (mol wt 55,000), and a second esterase in cuticular tissues (e.g., legs and wing scales) of males and females (Vogt and Riddiford, 1986). Oddly, an electrophoretically identical "binding protein" (mol wt 15,000) was also found in three other saturniids and a sphyngid with different pheromones, in unusually high concentrations in receptor lymph (approx. 10^5 molecules/sensillum) (Vogt and Riddiford, 1980). The sensillar esterase shows considerable specificity for acetates with *Z*-olefinic linkages and a very high V_{max} over a large concentration range.

The studies on *Choristoneura fumiferana* (Morse and Meighen, 1984a,b, 1986) show the importance of studying multiple enzyme systems in different tissues of males and females. Three activities—an acetate esterase (*E*/*Z*11–14:Ac → *E*/*Z*11–14:OH), and O_2-requiring alcohol oxidase (*E*/*Z*11–14:OH →

E/*Z*11–14:Al), and an NAD^+-requiring aldehyde dehydrogenase (*E*/*Z*11–14:Al → *E*/*Z*11–14:Acid)—were all found in glandular and other tissues using a novel bioluminescence assay (Meighen et al., 1981) and confirmed using labeled saturated analogs.

Finally, the dodecatrienol trail pheromone of *Reticulitermes* undergoes an ω-oxidation to the 1,12-diol as determined for monoene and diene analogs (Prestwich et al., 1985; G. Prestwich, C. Sack, and J.J. Brown, unpublished results). This conversion results in defluorination of (3*Z*, 6*Z*)-12-fluorododecadien-1-ol, and the monooxygenase system is currently under investigation in our laboratories.

METHODS AND MATERIALS

Animals and Enzyme Sources

Heliothis virescens were purchased from the Cotton Foundation (Memphis, Tennessee) as pupae, sexed, and reared to adult eclosion in separate 8-oz containers in a 16:8 light–dark photoperiod. At 2 hr after lights off, adults were anesthetized with CO_2 and the antennae (male and female), legs, (male and female), extruded pheromone gland (female) and extruded hairpencil–genital organ complex (male) were excised and stored in separate microfuge tubes (tissue of 5–10 animals per tube) at −90°C until required for enzyme assays.

Tissue homogenates were prepared following the procedure illustrated for antennal tissue. Twelve pairs of male (female) antennae were placed in a conical ground-glass homogenizer containing a few milligrams of glass beads (0.15 mm diameter); 100μl of pH 7.4 phosphate buffer (76 mM sodium phosphate) was added, and a motor driven pestle was used to homogenize tissue at 4°C for 5 min. Another 100 μl buffer was added, and the mixture was homogenized again. The solution and rinsings were combined in a microfuge tube to give about 12 pairs of antenna per 300 μl of buffer, and then centrifuged at 12,000 *g* for 10 min at 4°C. The soluble fraction (S) was removed and 300 μl of a detergent buffer solution (76 mM sodium phosphate, pH 7.4, 1 mM dithiothreitol (DDT), 1 mM EDTA, and 0.1% w/v Triton X-100) was added to the first pellet and sonicated for 7 min at 4°C using a Sonifer cell disrupter (model 185) operating at 50–60 W. After centrifugation at 12,000*g* for 10 min at 4°C, the supernatant (D) was removed. Finally, 300 μl of detergent buffer was added, and the pellet was resuspended by vortexing (P). Bioassays for esterase, oxidase, and aldehyde dehydrogenase were performed on each of the three protein samples (S, D, P) to account for all enzyme activity present. Protein solutions were prepared fresh for each day's experiments.

Ultrasonic hair-fracture as described by Ferkovich (1981) was also performed to obtain soluble enzymes. Thus, 50 pairs of antennae were placed in

200 μl of phosphate buffer containing 0.5 M sucrose in an ice bath and then mildly sonicated at 4°C using a Heat Systems ultrasonic cleaning bath for 60 min. These sonicates contained only soluble enzymes at 10,000*g* and were compared with homogenates for esterase and aldehyde dehydrogenase activities.

Synthesis of pheromone and metabolites

[*9,10-*$^3H_2$](*Z*)-9-*Tetradecenyl Acetate.* This was prepared by reductive tritiation of the corresponding 9-alkyne, prepared in turn by alkylation of the acetylide of 1-tetrahydropyranyloxy-8-bromooctane with 1-hexyne in THF/HMPA (Henrick, 1977). Acid hydrolysis of the THP ether (CH_3CO_2H–THF–H_2O, 4:2:1), acetylation (Ac_2O, Py), and flash chromatography provided the necessary starting material.

The tritiation was carried out at the NIH Tritiation Facility at Lawrence Berkeley Laboratory. To a sample of 10 mg of 9-tetradecyn-1-yl acetate in 5 ml of hexane was added 3 mg of 5% Pd/$BaSO_4$ and 10 μl of a 100 μg/μl hexane solution of quinoline. The reaction vessel was freeze-degassed, and the reaction was stirred 20–30 min under 1 atm of carrier-free T_2 gas. The reaction was stopped at ca. 60% conversion. The tritium and volatiles were removed in vacuo to reduce the volume by half, and the crude product mixture was centrifuged to remove the catalyst. The supernatant was concentrated under N_2 and chromatographed on 40-m ("flash") silica gel with 3% ethyl acetate–hexane and then on 20% $AgNO_3$-coated flash silica gel with 6% ethyl actate–hexane to give complete separation of the desired [9,10-$^3H_2$](*Z*)-9-tetradecenyl acetate (58 Ci/mmol) from the alkyne precursor.

[*9,10-*$^3H_2$](*Z*)-9-*Tetradecenyl Alcohol.* A solution of [9,10-$^3H_2$](*Z*)-9-tetradecenyl acetate (approx. 7 mCi) in 150 μl of 4:1 CH_3OH–3N NaOH was stirred 3 hr at 20°C. Then, 300 μl of H_2O was added, the mixture was extracted with three 200 μl portions of 1:1 ether–hexane. The extracts were dried ($MgSO_4$) and concentrated in vacuo to give radiochemically homogeneous [thin-layer chromatography (TLC) scraping, liquid scintillation counting (LSC)] alcohol (approx. 6.3 mCi, 90% yield) which was used without further purification.

[*9,10-*$^3H_2$](*Z*)-9-*Tetradecenal.* A sample of [9,10-$^3H_2$](*Z*)-9-tetradecen-1-ol of approx. 3 mCi was used for this oxidation. A total of 500 μl of CH_2Cl_2 containing the labeled alcohol was added to a solution of a small crystal of pyridinium dichromate (PDC) in 100 μl of CH_2Cl_2. The reaction mixture was stirred at room temperature under N_2 for 1–2 hr. The mixture was diluted with 5 vol of ether. This material was first chromatographed to remove the oxidant on flash silica gel with ether in a disposable pipette. After concentration in vacuo, the residue was rechromatographed on flash silica with gradually increasing percentages of ethyl acetate in hexane in a column to give radiochemically homogeneous aldehyde, using a TLC solvent system of hexane–ether–

acetic acid (90:10:2). The labeled aldehyde was particularly susceptible to chemical decomposition and was used for experiments within four days of preparation.

Enzyme Assays

Pheromone Solutions. The radiolabeled substrates used were: [9,10-$^3H_2$]Z9–14:OH for oxidase assay, [9,10-$^3H_2$]Z9–14:Al for aldehyde dehydrogenase assay, and [9,10-$^3H_2$]Z9–14:Ac for esterase assay. Hexane stock solutions were checked for purity by scraping TLC plates and counting by LSC. When the radiochemical purity was <96%, repurification by flash chromatography in a Pasteur pipet was performed. Pheromone buffer solutions were prepared fresh for a day's experiments as follows. A hexane solution (200 μl containing 30–60 μCi) of labeled substrate was evaporated under N_2 and redissolved in 500 μl of pH 7.4 phosphate buffer, which had been throughly degassed by sonication under reduced pressure followed by sparging with helium. Degassing was crucial to prevent oxidation of the labeled aldehyde to labeled acid in the pheromone buffer.

Cofactor Solutions. The oxidized cofactor nicotinamide adenine dinucleotide (oxidized form, NAD^+) (19.9 mg) was dissolved in 10 ml of pH 7.4 phosphate buffer to give 3 mM NAD^+ for use in the oxidase and dehydrogenase assays. Prior experimentation demonstrated a requirement for an oxidized cofactor as well as little difference between NAD^+ to $NADP^+$ (also at 3 mM) as the cofactor for this pheromone dehydrogenase.

Aldehyde Dehydrogenase (ALDH) Assay. Fifty microliters of [^{3}H]Z9–14:Al buffer (9×10^{-8} M) and 50 μl of 3 mM NAD^+ were added to each of eight 10 × 75-mm borosilicate tubes. At 2-min intervals, 50 μl of protein solutions (S, D, or P from different tissues) or 50 μl buffer (blank) was added. Each incubation was for 1 hr at 20°C. At $t = 1$ hr, 150 μl of ethyl acetate was added and the tube was vortexed vigorously for 15 sec. A 3-μl aliquot of the upper layer was removed to determine recovery (by LSC) and another 6 μl aliquot was spotted on 4 × 8-cm Machery-Nagel Polygram Sil G/UV 254 plates. Plates were divided into four vertical stripes and were prespotted with unlabeled Z9–14:Al, Z9–14:OH, and Z9–14:Acid. The plates were developed in hexane–ether–acetic acid (90:10:2). Spots were visualized with I_2, the TLC plate was cut into 1-cm sections, the sections were placed into 7-ml scintillation vials, and the sections counted in 4 ml of Aquasol (New England Nuclear) or Scintiverse II (Fisher). Scintillation counting was performed on a Packard TriCarb Model 3300 instrument operating at 37–45% efficiency for tritium, as determined by automatic external standardization.

Alcohol Oxidase Assay. Using [^{3}H]Z9–14:OH as substrate, the same procedure for the dehydrogenase was followed. To test for the dependence of the alcohol oxidase on the presence of oxygen, a modified assay was performed as

follows. Male legs (22 pairs) were homogenized in pH 7.4 phosphate buffer to get 2 ml of the soluble (S) fraction. An aqueous solution of [^{3}H]Z9–14:OH was made by evaporation of 100 μl (~0.15 mCi) of the hexane solution of labeled alcohol under N_2 and redissolving the residue in 2 ml of pH 7.4 phosphate buffer. Two sets of ten duplicates were prepared: one set of ten was degassed and held under N_2, and one set was exposed to air. Into each test tube, 100 μl of [^{3}H]Z9–14:OH buffer solution and 100 μl of protein solution were added at 4°C. The tubes were transferred to 30°C bath, shaken vigorously for 30 sec, and then incubated for periods of 5, 10, 15, 20, 25, 30, 35, 40, and 45 min. After 15 min, those tubes which had been flushed with N_2 were exposed to air, vortexed vigorously, and then incubation was continued. At each interval, duplicates of each set were quenched with 200 μl of ethyl acetate. A 6-μl aliquot of upper layer was spotted on TLC, developed, cut, and counted as described above.

Acetate Esterase Assay. The assays were the same as described above for the aldehyde dehydrogenase (ALDH), but using [^{3}H]Z9–14:Ac as substrate and replacing the 50 μl of NAD^+ buffer with phosphate buffer.

Autoradiography. TLC plates spotted with 6 μl of ethyl acetate layers of blank, S, D, and P enzyme incubations were sprayed with En^{3}Hance (New England Nuclear) spray, placed in contact with preflashed Kodak X-Omat XAR-5 X-ray film for 4 hr to 4 days at −80°C, and developed as usual with Kodak GBX chemicals.

Protein Concentrations. These were determined by the dye-binding method (Bradford, 1976) using bovine serum albumin as the standard.

RESULTS AND DISCUSSION

Pheromone and derivatives (Figure 1) were synthesized at high specific activity by partial reductive tritiation of 9-tetradecyn-1-yl acetate on poisoned $Pd/BaSO_4$, affording the [9,10-$^3H_2$](Z)-9-tetradecen-1-yl acetate ([^{3}H]Z9–14:Ac) at a nominal specific activity of 58 Ci/mmol. The location and extent of the tritium labels is assumed, although [^{3}H]NMR examination is in progress. Hydrolysis with aqueous methanolic sodium hydroxide on a micromole scale gave corresponding [^{3}H]Z9–14:OH. Oxidation of this alcohol to [^{3}H]Z9–14:Al was generally performed on a 3-mCi (52-nmol) scale and required careful monitoring to avoid overoxidation or conversion to other products. Several attempts with pyridinium chlorochromate (PCC) in dichloromethane led to undesired labeled materials intermediate in TLC polarity between the alcohol and aldehyde. It was not readily controlled by decreasing the amount of oxidant. However, use of pyridinium dichromate (PDC) in CH_2Cl_2 under N_2, even in >100-fold excess, gave a controlled conversion to the labeled aldehyde in 2 hr at 20°C.

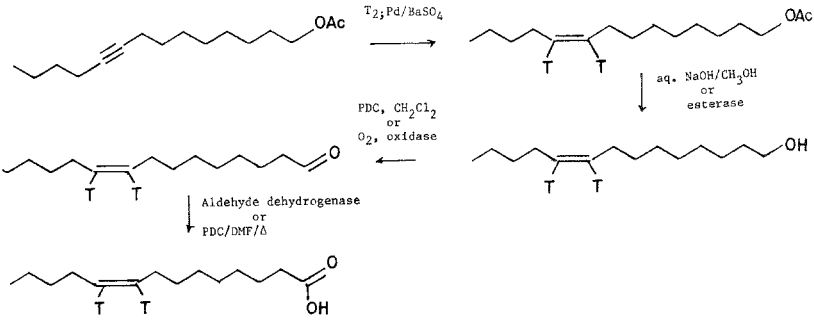

FIG. 1. Synthesis of labeled substrates and enzymic interconversions (T = ^3H).

All labeled materials were purified by flash chromatography over silica gel in a disposable pipet using hexane–ethyl acetate eluents. The labeled aldehyde was never more than one week old, and never more than 4 hr in aqueous working solutions. Failure to degas aqueous buffers used for pheromone stocks or incubations led to high "background," i.e., nonenzymic conversion to the carboxylic acid.

Tissue homogenates were prepared fresh each day from tissues stored at −90°C and used completely. This eliminated problems due to using enzyme solutions of variable age and subject to freeze–thaw sequences. The tissues were homogenized first in a phosphate buffer lacking additives, and the pellet was rehomogenized and ultrasonicated in a detergent buffer containing EDTA, dithiothreitol (DDT), and Triton X-100 to solubilize membrane-associated proteins. As discussed below, from the tissue distributions of esterase, oxidase, and dehydrogenase activities, it appears that essentially all enzyme activities are readily solubilized in buffer or in a very mild nonionic detergent. Only a small (but reproducible) residual activity of aldehyde dehydrogenase is found in the pellet fraction from female antennae.

All enzyme assays were performed with no-carrier-added substrate solutions at 10^{-8}–10^{-9} M, i.e., using a physiologically meaningful concentration of substrate. At least three repetitions per enzyme assay have been performed with separate tissue preparations and reproducible results have been obtained. The data presented in the tables and figures often illustrate a representative result as the average of duplicate subsamples for a given tissue preparation. Using the TLC assay, we could readily detect differences of 1–2% conversion (100–200 cpm out of 10,000 cpm).

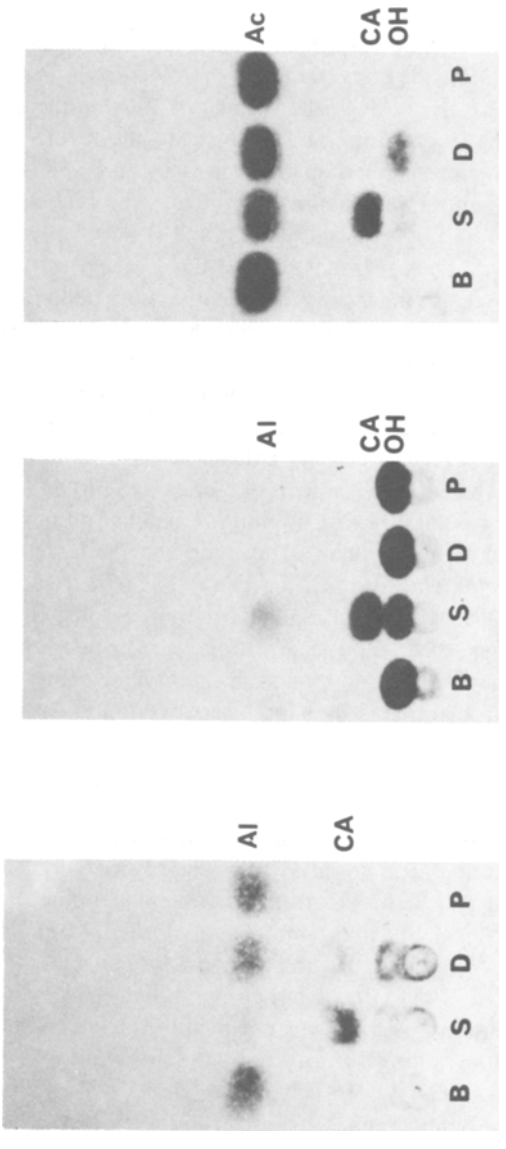
Figure 2 shows a set of autoradiograms of TLC plates to allow visualization of three enzyme activities for each of three extraction methods from both male and female leg tissue. Autoradiograms for antennal and glandular tissues appear quite similar and are omitted here; the quantative data for enzyme activ-

ity appear in Figure 3 below. The autoradiograms provide evidence for: (1) conversion of [^{3}H]*Z*9–14:Al to [^{3}H]*Z*9–14:Acid by the aldehyde dehydrogenase (ALDH), (2) conversion of [^{3}H]*Z*9–14:OH to the aldehyde by the alcohol oxidase (OX) with further transformation to the carboxylic acid by ALDH, and (3) hydrolysis of [^{3}H]*Z*9–14:Ac to the labeled alcohol by the esterase (EST) with subsequent transformations by OX and ALDH to the labeled acid. The autoradiograms demonstrate clearly the high level of radiochemical purity for each starting substrate (see blank B lanes). It also appears that the soluble aldehyde dehydrogenase is the most active enzyme in both sexes (documented below), giving nearly quantitative conversion of aldehyde to carboxylic acid. This occurs whether the aldehyde is added as substrate or is produced in vitro from oxidase on *Z*9–14:OH or combined esterase–oxidase action on *Z*9–14:Ac. Only in the detergent fraction for the esterase assay do we observe simple conversion of *Z*9–14:Ac to *Z*9–14:OH, since the OX activity has been removed and the ALDH activity is low.

As seen in Table 1, the enzymatic hydrolysis of [^{3}H]*Z*9–14:Ac to the alcohol is rapidly lost by dilution below 100 antennal equivalents (AE) per milliliter of homogenate. However, the aldehyde dehydrogenase activity was still detectable as low as 0.8 AE/ml. The oxidase activity appeared to be lower than the aldehyde dehydrogenase activity. Thus, in both male and female antennal tissues, the aldehyde dehydrogenase is the most active enzyme, consistent with its postulated importance in pheromone removal. Any aldehyde produced via oxidase action is thus rapidly converted to carboxylic acid as seen in Figure 2.

Comparison of the homogenization method and hair-fracture sonic bath method (Ferkovich, 1981) for obtaining antennal enzymes (Table 2) showed that essentially all the esterase and, indeed, a greater level of aldehyde dehydrogenase could be obtained by this milder treatment. Moreover, the quantity of cuticular material is considerably reduced. Mechanical fracture of lyophilized sensory hairs from the antennal branches used in collecting the larger (100–300 μm long) sensilla of *Antheraea polyphemus* gave protein solutions free of hemolymph and antennal branch–cuticle contamination (Vogt and Riddiford, 1981; Prestwich et al., 1986). However, this mechanical fracture/hair separation method was not readily transferred to the filiform antennae with 10 to 30-μm-long sensory hairs, such as those of male and female *H. virescens* moths. Thus, our assay results show total enzyme activity present in cuticular, hemolymph, and sensillar proteins of the antennae. The use of leg tissue is meant to control for the presence of general enzyme activities found in the cuticle and hemolymph.

Figure 3 illustrates the distribution of enzyme activities present in *Heliothis* moth tissues. The key features are : (1) Aldehyde dehydrogenase is the primary enzyme activity found in both leg and antennal tissues of males and females. (2) Oxidase activity is low in antennae, but higher in male legs and glandular



MALE

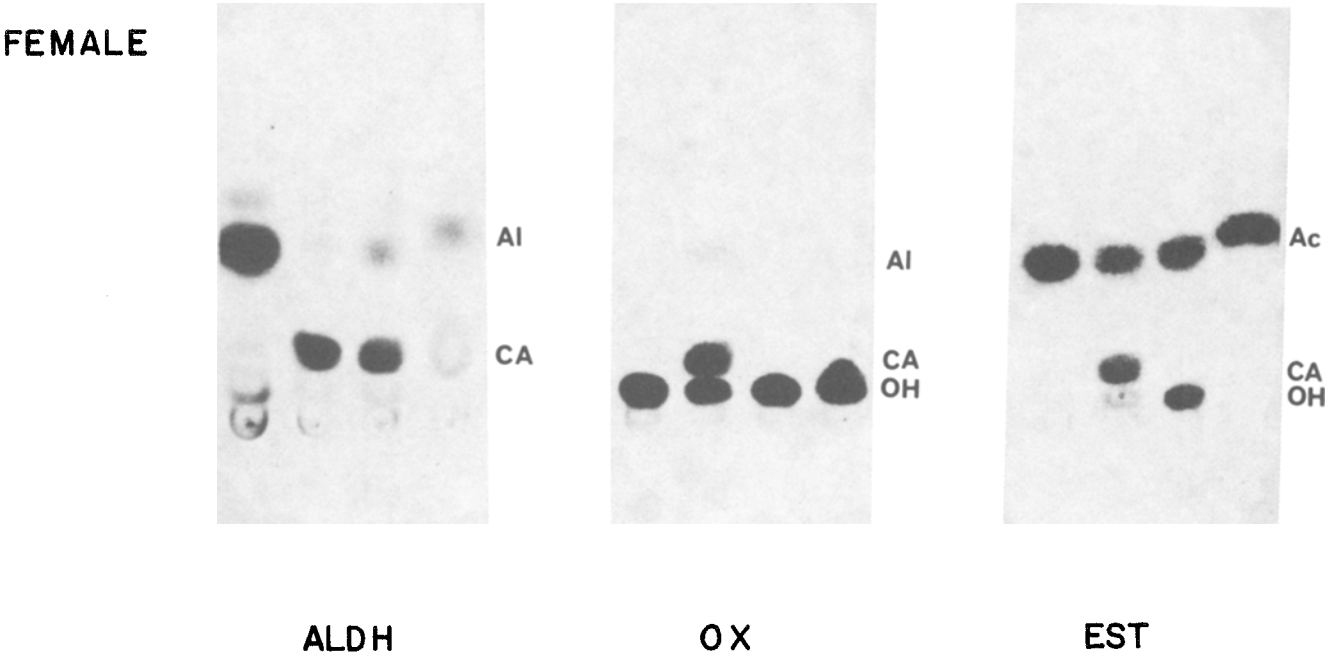


FIG. 2. Autoradiograms of TLC plates illustrating interconversions of [^{3}H]Z9–14:Ac (Ac) and the corresponding alcohol (OH), aldehyde (Al), and carboxylic acid (CA) by male (top) and female (bottom) leg tissues. The letters B, S, D, and P denote blanks, soluble, detergent, and pellet activities, respectively (see text for details); ALDH = aldehyde dehydrogenase, OX = alcohol oxidase, EST = acetate esterase.

TABLE 1. DILUTION SERIES FOR SOLUBLE ANTENNAL ENZYMES[a]

Antennal equivalent per milliliter solution[b]	Esterase (%)[c]		Aldehyde dehydrogenase (%)[d]	
	Male	Female	Male	Female
360	27	30	—	—
120	10	5	—	—

0.267	—	—	0	0

[a] Percent conversion to product, expressed as means of duplicate assays.
[b] A homogenate of male or female antennae of 350 AE/ml has 0.34 mg/ml total protein for the esterase. For the 80 AE/ml used for aldehyde dehydrogenase assays, males had 0.087 mg/ml and females 0.074 mg/ml total protein.
[c] One-hour incubation.
[d] Fifty-minute incubation.

tissues of both sexes. (3) Esterase activity is low in antennae, higher in legs, and highest glandular tissue of both sexes. (4) Males and females show all three enzymic activities in all tissues. Striking male–female differences include (a) a pellet-associated aldehyde dehydrogenase in female antennae; (b) relatively lower oxidase activity in female legs and glandular tissue, and (c) relatively higher esterase and dehydrogenase activity in female glandular tissues.

Figure 4 illustrates the results of the experiment which demonstrated that the oxidase from male legs (the highest activity source) is an O_2-requiring en-

TABLE 2. COMPARISON OF HOMOGENIZATION AND ULTRASONIC AGITATION FOR OBTAINING ENZYMES[a]

[a] Conversions expressed as percent product from duplicate assays.
[b] Fifty pair of antennae to get 200 μl of soluble fraction. Protein concentrations for homogenate: males, 0.39 mg/ml; females, 0.45 mg/ml. Protein concentrations for ultrasonicate: males, 0.47 mg/ml; females, 0.47 mg/ml.
[c] Twelve pair of antennae to get 300 μl of soluble fraction. Protein concentrations: males, 0.022 mg/ml; females, 0.035 mg/ml.

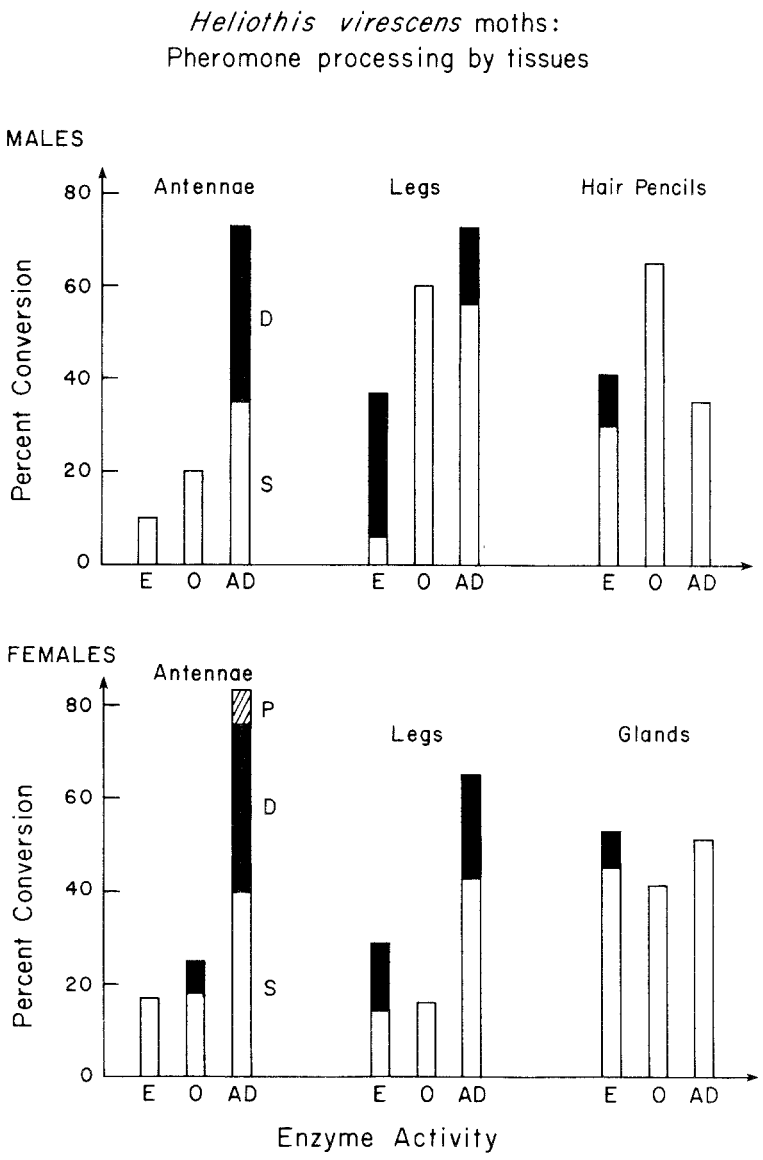

FIG. 3. Morphological distribution of acetate esterase (E), alcohol oxidase (O), and aldehyde dehydrogenase (AD) activities in adult moths (*Heliothis virescens*). All incubations were run for 1 hr at 20°C, and values shown are means of percent conversion for duplicates. Homogenates of two pairs of antennae and legs per 50 μl were used and two pheromone glands or hairpencils per 50 μl were used. Enzyme activities are shown for soluble (S, open bars), detergent-solubilized (D, solid bars), and insoluble pellet (P, cross-hatched) fractions.

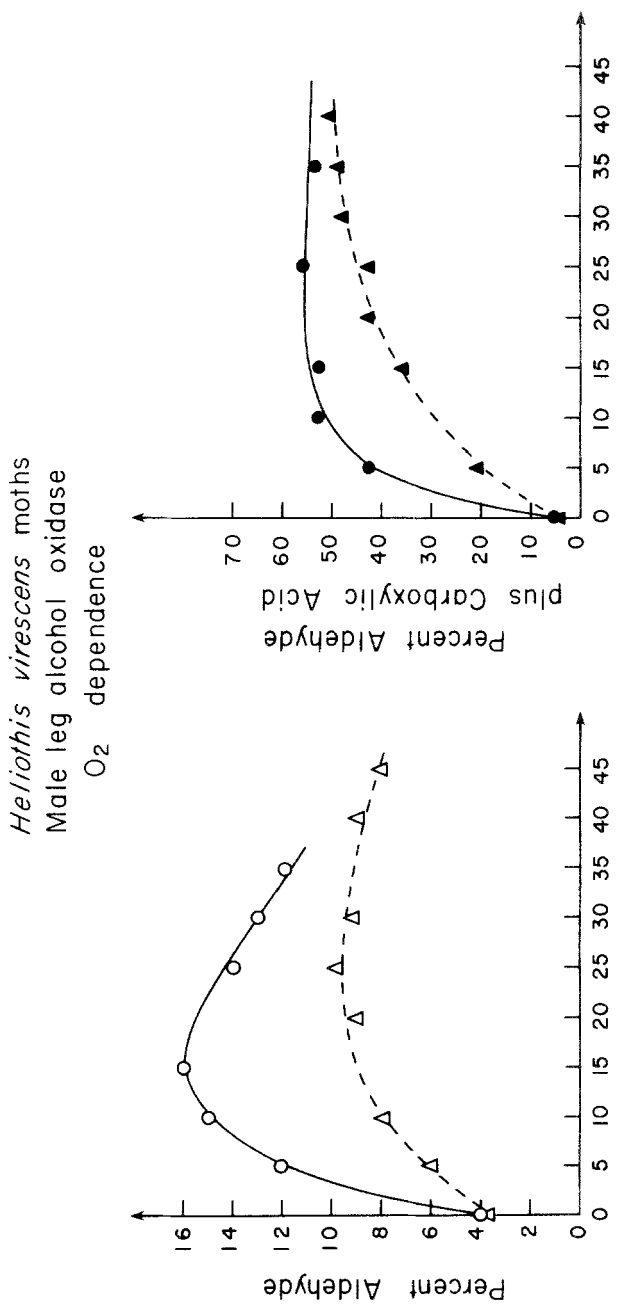

FIG. 4. Dependence of alcohol oxidase of legs of male *Heliothis virescens* moths on the presence of oxygen. Samples were incubated in air (circles) or under N_2 for 15 min followed by air (triangles). The left panel shows only conversion of [^{3}H]Z9-14:OH to the aldehyde, while the right panel shows conversion to the aldehyde plus carboxylic acid.

zyme, as opposed to being an $NAD(P)^+$-requiring alcohol dehydrogenase. This assay was conducted as described by Morse and Meighen (1984a) for *Choristoneura fumiferana* tissues. An initially lower rate of conversion of the alcohol to aldehyde (and then acid) is seen in the N_2-saturated condition, although it is difficult to reduce this rate to zero by purging the last few nanomoles of oxygen from solution. A modest increase in oxidation to the aldehyde (which is then rapidly converted to the carboxylic acid by the aldehyde dehydrogenase) is seen when air is readmitted to a N_2-saturated incubation. Failure to see a more dramatic increase may also reflect a negative effect of anoxia on the enzyme system. Cofactor deletion experiments were unsuccessful due to endogenous $NAD(P)^+$ levels.

It is important to consider the present experimental results in terms of the related metabolic conversions in *Antheraea polyphemus*, *Trichoplusia ni*, and *Choristoneura fumiferana*. For the wild silkmoth *Antheraea polyphemus*, Vogt and coworkers have described in detail the tissue localization (Vogt and Riddiford, 1981), kinetic properties (Vogt et al., 1985), and substrate specificity (Prestwich et al., 1986) of the male-specific sensillar esterase. All of these studies used freshly chromatographed, stoichiometrically labeled [11,12-$^3H_2$]-6*E*, 11*Z*-16:Ac at 58 Ci/mmol which allowed routine monitoring in the 10^{-7}–10^{-9} M range. This esterase, mol wt 55,000, shows a K_m of 2.2×10^{-6} M and V_{max} of 5.4×10^{-12} M/sec[1] for the conversion of 6*E*, 11*Z*-16:Ac to the corresponding alcohol, and the calculated half-life for pheromone under natural conditions is estimated to be 15 msec over a wide concentration range. Furthermore, the sensillar esterase showed high specificity for *Z*-unsaturated aliphatic acetates, e.g., the 6*E*,11*Z*-16:diazoacetate and saturated 16:Ac were poor substrates, while the 9*Z*-14:Ac was a good substrate. Only unsaturated 14- and 16-carbon acetates with *Z* olefinic linkages appeared to act as effective competitive inhibitors of the 6*E*, 11*Z*-16:Ac hydrolysis (Prestwich et al., 1986). Potent nanomolar inhibition was observed for 1,1,1-trifluoro-2-tetradecanone, an aliphatic trifluoromethyl ketone transition-state analog for serine esterases (Hammock et al., 1982), but not for traditional esterase inhibitors (Vogt et al., 1985). Finally, a cuticle-bound wing-scale esterase was also described for *A. polyphemus* (Vogt and Riddiford, 1986).

The key findings for the cabbage looper moth, *Trichoplusia ni*, were summarized in the Introduction. To reiterate, buffer-elutable surface esterases were found in wings > legs > antennae which degrade *Z*7–12:Ac labeled at 0.4 Ci/mmol in the acetate moiety and using concentrations in the 2×10^{-6} to 2×10^{-5} M range. These were quite reasonably postulated to serve a general cleaning role, i.e., preventing every emitting or receiving insect from becoming a pheromone source. Esterase activity in the homogenates decreased in the order antennae > legs > wings, implicating a specific receptor-clearing role for the antennal esterase in both sexes. Using unlabeled aqueous suspensions of do-

decenyl acetates at 4×10^{-3} M and monitoring hydrolysis by GC, moderate specificity for the hydrolysis of the *Z*7 isomer was found (cf. Ferkovich, 1981). In none of these experiments was it possible to follow both reactant and product at physiologically meaningful concentrations.

The spruce budworm (*Choristoneura fumiferana*) pheromone consists of >98% of a mixture of two aldehydes, *E*11–14:Al and *Z*11–14:Al in a 96:4 ratio. In an important first paper, Morse and Meighen (1984a) used novel luminescence assays to show three enzyme activities in tissues of female moths: (1) an esterase which hydrolyzes both *E* and *Z*11–14:Ac to the alcohol, (2) an O_2-dependent oxidase which converts fatty alcohols to aldehydes, and (3) an NAD^+-dependent aldehyde dehydrogenase which yields fatty acids as products. They found highest specific activity for all three enzymes in the pheromone gland and proposed the acetate as the storage form for the aldehyde pheromone. This was confirmed in later studies with ^3H- and ^{14}C-labeled saturated fatty acids, alcohols, and esters in vivo (Morse and Meighen, 1984b). In this volume, they describe in detail a new synthesis of enzymology and pheromone chemistry in which the interconversion of functional groups accounts for differences in pheromone blends used by closely related species (Morse and Meighen, 1986).

Our results with the tobacco budworm moth, *Heliothis virescens*, show also that acetate esterase, alcohol oxidase, and aldehyde dehydrogenase activities are present in all tissues of both sexes. As with the silkmoth, the substrates used in this study were all derived from [9,10-$^3H_2$]*Z*9–14:Ac, are stoichiometrically labeled, and allow studies at "physiological" nanomolar concentrations. It is also important to note that our studies used the minor aldehyde component of the ca. 93:7 blend of *Z*11–16:Al to *Z*9–14:Al which constitutes the major stimulatory cue for upwind flight. Not surprisingly, we found that the aldehyde dehydrogenase activity is by far the greatest, and it dominates the pheromone processing in both male and female antennae. Indeed, in all tissues one can readily observe (cf. Figure 2 for leg tissue) that in a 1-hr incubation, virtually all of the labeled alcohol or aldehyde resulting from esterase or oxidase activity is rapidly converted to the carboxylic acid.

An analogous result is reported in this volume by Teal and Tumlinson (1986), who show that exogenously applied "irrelevant" alcohols are converted in vivo to aldehydes by glands of female *H. virescens* and *H. zea*. This oxidase showed little specificity for alcohol chain length or unsaturation, but it did not oxidize secondary alcohols to ketones. The rapid dehydrogenase activity was not taken into account in their experiments, and this could well lead to underestimation of the real aldehyde output. They concluded from biosynthetic rates that the oxidase occurs in a cuticular-bound form in the surface of the pheromone gland. Our results, however, are more consistent with a readily soluble oxidase present in all tissues. It it is indeed cuticular, then it is readily removed by simple homogenization and is not membrane-bound.

A diel periodicity in the rise of alcohol (e.g., Z11-16:OH) and aldehyde titer occurrence (cf. Teal and Tumlinson, 1986) is triggered by the release of a brain factor in response to the onset of scotophase (Raina and Klun, 1984). On the basis of this information, the lack of acetate esters in the gland, and the abundance of Z11-16:OH in immediately precalling females, Teal and Tumlinson (1986) invoke a direct route from Z11-16:Acid (as storage form) to Z11-16:OH (as precursor) to act as a substrate for the aldehyde released during calling. This contrasts with the absence of a fatty acid reductase in gland tissues of *Choristoneura* (Morse and Meighen, 1986). Clearly, an explanation is still required for the high level of esterase found in our work in glandular tissues of males and females. The esterase level of *Heliothis* is similar to that found in *Choristoneura* (Morse and Meighen,, 1984a,b, 1986) and could be consistent with acetates as pheromones or precursors in *Heliothis* as well. However, despite careful analysis by several groups (cf. Teal and Tumlinson, 1986), acetates have not been detected in either *H. zea* or *H. virescens* female pheromone glands.

It remains to be determined what role pheromone processing enzymes play in the real sex lives of moths. Research in the area of pheromone biochemistry by enzymologists, chemists, behaviorists, and physiologists promises to provide new basic insights and potentially novel control strategies.

SEX PHEROMONE BIOSYNTHESIS IN THE RED-BANDED LEAFROLLER MOTH, STUDIED BY MASS-LABELING WITH STABLE ISOTOPES AND ANALYSIS WITH MASS SPECTROMETRY

LOUIS B. BJOSTAD and WENDELL L. ROELOFS

(Received May 9, 1985; accepted August 1, 1985)

Abstract—A technique for mass-labeling was developed to study sex pheromone biosynthesis in the red-banded leafroller moth, *Argyrotaenia velutinana*. With this technique, the pheromone components and all fatty acyl groups in the pheromone gland were analyzed for incorporation of label in the same analytic run with gas chromatography–mass spectrometry, using chemical ionization and selected ion monitoring (GC-SIM-CI-MS). Sex pheromone glands were incubated with fatty acids or triacylglycerols labeled with at least three deuterium atoms or carbon-13 atoms. The results of these incubations support an interpretation in which hexadecanoate is chain shortened to tetradecanoate, which is desaturated to produce (*E*)- and (*Z*)-11-tetradecenoate precursors for the sex pheromone components (*E*)- and (*Z*)-11-tetradecen-1-yl acetate. Labeled (*E*)- and (*Z*)-11-tetradecenoyl groups in synthetic triacylglycerols were not incorporated into the sex pheromone components, perhaps indicating that this lipid class is not a donor of the immediate fatty acyl precursors in sex pheromone biosynthesis.

Key Words—*Argyrotaenia velutinana*, Lepidoptera, Tortricidae, red-banded leafroller, biosynthesis, sex pheromone, mass-labeling, deuterium labeling, carbon-13 labeling.

INTRODUCTION

Extensive studies over the last few years on sex pheromone biosynthesis in the red-banded leafroller moth *Argyrotaenia velutinana* have provided a complete picture of the sequence of fatty acyl intermediates involved. The pathway was established principally on the basis of experiments in which sex pheromone

0098-0331/86/0200-0431$05.00/0

glands were incubated in vivo and in vitro with an array of radiolabeled fatty acids. The steps in the pathway include biosynthesis of hexadecanoate from acetate, production of tetradecanoate from hexadecanoate by chain shortening (probably by the microperoxisomes in the gland), delta-11 desaturation of tetradecanoate to generate (*E*)- and (*Z*)-11-tetradecenoate, and production of the main pheromone components (*E*)- and (*Z*)-11-tetradecenyl acetate, respectively, by reduction and acetylation of these fatty acyl intermediates. A review of this work has appeared recently (Roelofs and Bjostad, 1984).

A problem in these studies was the opportunity for radiolabeled fatty acids to be broken down in the pheromone gland and give misleading results (see Bjostad and Roelofs, 1981). For example, if sex pheromone glands are incubated with radiolabeled tetradecanoic acid, it is tempting to conclude that the appearance of radiolabel in (*Z*)-11-tetradecenoate is good evidence for delta-11 desaturation. Unfortunately, the possibility remains that the radiolabeled tetradecanoate may simply have undergone mitochondrial degradation, generating radiolabeled acetyl CoA that may have been incorporated into (*Z*)-11-tetradecenoate by some other route.

We have now analyzed this pathway with a completely different set of techniques based on the use of stable isotopes to label the fatty acyl intermediates. Incorporation of label was determined by selected ion monitoring (SIM) in conjunction with chemical ionization (CI) in gas chromatography–mass spectrometry (GC-MS). Compounds containing at least three deuterium atoms or ^{13}C atoms were synthesized or purchased for use in the present study. A similar approach has been used in studying pheromone biosynthesis in bark beetles (Fish et al., 1979; Hendry et al., 1980), and in the rice stem borer moth *Chilo suppressalis* (Arai et al., 1984).

A consequence of introducing several stable isotopes into a compound is that it becomes "mass-labeled." A convenient way to analyze a series of compounds in a GC trace for incorporation of a mass-labeled compound is to use a GC-MS program that specifies a set of mass filters in the following way. The masses and GC retention times of all compounds of interest must be known. Each GC peak can consist of a mixture of mass-labeled and unlabeled isotopes of a compound, and prior to emergence of the GC peak into the source of the mass spectrometer, the GC-MS program is changed to scan only for the masses of the (chemically ionized) unlabeled and mass-labeled compounds expected in the GC peak. Two mass-filtered GC traces are generated for each injected sample, one showing unlabeled compounds and one showing mass-labeled compounds (for the specified increment in mass). By using one of the unlabeled compounds in the sample as an internal standard, the pair of mass-filtered GC traces from pheromone glands incubated with a mass-labeled compound can be compared with the pair of traces from unincubated control glands, and degree of incorporation can readily be determined.

The recycling problem mentioned above for radiolabeled compounds is much less troublesome when multiple-labeled stable isotopomers are used instead. For example, although mitochondrial degradation of the multiple-labeled precursor [1,2,3,4-$^{13}C_4$]tetradecanoic acid would produce [1,2-$^{13}C_2$]acetyl CoA, incorporation of only one of these labeled acetyl CoA molecules would produce a molecule of [1,2-$^{13}C_2$](*Z*)-11-tetradecenoate, which would not be detected as a compound with four additional mass units (it has two additional mass units). Exactly two [1,2-$^{13}C_2$]acetyl CoA molecules would have to be incorporated in order to mislead the investigator, but the probability that two would enter the same (*Z*)-11-tetradecenoate is very tiny (the square of the probability that one would enter). It is also quite easy to detect recycling if it occurs, because the (*Z*)-11-tetradecenoate can be analyzed for incorporation of two additional mass units as well as for incorporation of four additional mass units.

Triacylglycerols comprise the most abundant lipid class in sex pheromone glands of *A. velutinana* (and of all other moth species that have been analyzed, see Roelofs and Bjostad, 1984) and contain most of the (*E*)- and (*Z*)-11-tetradecenoyl groups in the gland. The role of the triacylglycerols in sex pheromone biosynthesis is not known in any moth species. We prepared synthetic triacylglycerols with mass-labeled fatty acids at defined glyceryl positions, incubated pheromone glands with these synthetic triacylglycerols, and determined incorporation of the mass-labeled fatty acyl groups into pheromone components and into the fatty acyl constituents of all the lipid classes in the gland. These lipid classes include triacylglycerols, diacylglycerols, choline phosphatides, and ethanolamine phosphatides (Bjostad et al., 1981).

METHODS AND MATERIALS

Isotopically Labeled Compounds. [16,16,16-$^{2}H_3$]Hexadecanoic acid and [^{13}C]KCN were obtained from Stohler Isotope Chemicals (Waltham, Massachusetts). Purity of [16,16,16-$^{2}H_3$]hexadecanoic acid was greater than 99%, as indicated by GC-MS analysis of the methyl ester prepared with diazomethane (generated from Diazald, Aldrich Chem. Co., Milwaukee, Wisconsin).

[1,2,3-$^{13}C_3$]Tetradecanoic acid was synthesized by stepwise addition of [^{13}C]KCN, as follows. [1-^{13}C]Dodecanonitrile was prepared by addition of [^{13}C]KCN (10 mg) to undecyl bromide in dimethyl sulfoxide (0.5 ml) in a 4-ml vial with a Teflon-lined screw cap. After 1 hr at 25°C, water (2 ml) was added and the mixture was extracted twice with hexane (1 ml each). The nitrile was purified by Florisil chromatography in a Pasteur pipet and hydrolyzed with NaOH to form the carboxylic acid, as described by Bjostad and Roelofs (1981). [1-^{13}C]Dodecanoic acid was converted to the alcohol by adding Red-Al (3.4 M, 0.5 ml) to the neat acid in a 4-ml vial. Excess Red-Al was destroyed by

adding 2 M NaOH (2 ml) until the mild fizzing ceased, and [1-^{13}C]dodecanol was extracted with hexane (twice with 1 ml). The hexane solution was washed twice with water in a 4-ml vial (1 ml each) and evaporated to apparent dryness with a nitrogen stream.

[1-^{13}C]Bromododecane was prepared from the alcohol with triphenylphosphine dibromide, as described in Bjostad and Roelofs (1981). Further [^{13}C]KCN addition and hydrolysis produced [1,2-$^{13}C_2$]tridecanoic acid, and a final round of reduction, bromination, [^{13}C]KCN addition, and hydrolysis produced [1,2,3-$^{13}C_3$]tetradecanoic acid. Yields were nearly quantitative for the four synthetic procedures; no starting material was observed by GLC analysis at the end of any reaction.

[1,2,3-$^{13}C_3$]Tetradecanoic acid, [1,2,3,4-$^{13}C_4$]tetradecanoic acid, [1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoic acid, and [1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecanoic acid were all synthesized with the same set of reactions. The latter three compounds were synthesized, respectively, from bromodecane, (*E*)-7-decenol, and (*Z*)-7-decenol prepared by the acetylenic route described by Henrick (1977). It was possible to carry out the syntheses of the four compounds in parallel, adding aliquots of a given reagent to each of four vials at a particular step. Because the sequence of reactions was rapid and easy to work up in 4-ml vials, the average working time was 2 hr for each successive addition of a ^{13}C atom to a compound.

Two incubation experiments were conducted with triacylglycerols. For the first of these experiments, a 50:50 mixture of *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoyl, *sn*-3-oleoyl-glycerol; and *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoyl, *sn*-3-oleoyl-glycerol was synthesized by incubating a 50:50 mixture of the labeled fatty acids with *sn*-1,3-dioleoyl-glycerol in a solution of dicyclohexylcarbodiimide and 4-pyrrolidinopyridine (Hassner and Alexanian, 1978) for 4 hr at 25°C. The triacylglycerols were purified by Florisil chromatography in a Pasteur pipet (Bjostad and Roelofs, 1981), eluting successively with hexane (4 ml), 1:3 dichloromethane–hexane (4 ml), 1:1 dichloromethane–hexane (4 ml), dichloromethane (4 ml), and 1:3 ether–dichloromethane (4 ml). The triacylglycerols eluted in the dichloromethane fraction, as indicated by TLC with solvent system II (see below). Base-catalyzed methanolysis of the synthetic triacylglycerol blend was conducted, and the products were analyzed by GC-MS (see below). The expected proportions of methyl oleate, methyl [1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoate, and methyl [1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoate were observed (4:1:1, respectively). For the second triacylglycerol experiment, *sn*-palmitoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoyl, *sn*-3-palmitoyl-glycerol was synthesized and purified by similar methods.

Insect Handling. Insects were reared on a semisynthetic medium (Shorey and Hale, 1965), and sexes were separated as pupae and maintained on a 16:8

light–dark cycle. Adult females (48–72 hr posteclosion) were anesthetized with carbon dioxide gas for 5 sec, their glands were everted by squeezing the tip of the abdomen with a small clip, and a droplet (0.2 μl) of a labeled compound in dimethyl sulfoxide was applied to each gland with a 10-μl syringe mounted on a micromanipulator (Bjostad and Roelofs, 1984). The droplets were completely absorbed into the glands after about an hour, and 4 hr after the droplets were applied, the glands were excised by plucking them from the ovipositors with fine forceps. Lipids were extracted from the glands by allowing them to stand in 1 ml chloroform–methanol (2 : 1) at 4°C for 12–16 hr in a 4-ml vial with a Teflon-lined screw cap.

Chemical Derivatives. Fatty acyl groups of lipids were converted to methyl esters by base-catalyzed methanolysis. A sample in a 4-ml vial was evaporated to apparent dryness with a nitrogen stream, and a 1 M KOH in methanol (0.5 ml) was added. After 30 min, 1 M HCl (1 ml) was added, and the mixture was extracted twice with hexane (1 ml each). The hexane extract was washed once with water and evaporated to apparent dryness in a 4-ml vial with a nitrogen stream. The pheromone components are acetates, and methanolysis converts them to the corresponding alcohols. Acetyl chloride (100 μl) was added to convert the alcohols back to acetates, and after 30 min, the acetyl chloride was evaporated to apparent dryness with a nitrogen stream. The products were taken up in 1 ml hexane. Acetyl chloride does not react with the methyl esters (Bjostad et al., 1981).

Separation of Lipid Classes. Lipid classes were separated by thin-layer chromatography. Precoated 20 × 20-cm Whatman K5 thin-layer chromatographic plates (Whatman, Inc., Clifton, New Jersey) were broken into small plates (2 × 9 cm) and cleaned before use by soaking 12–16 hr in methanol in a Coplin staining jar. Plates were dried for 1 hr at 100°C in an oven, allowed to cool for 10 min, and used immediately for the separation. Solvent systems used were (I) 62 : 34 : 4 chloroform–methanol–water and (II) 80 : 20 : 2 hexane–ether–acetic acid.

Lipids on TLC plates were visualized by brief exposure to iodine vapor. Spots were lightly marked with a probe, and the iodine was allowed to evaporate. When color was no longer visible (ca. 30 min), fractions were scraped into 4-ml glass vials with Teflon-lined caps and extracted for 12–16 hr with 2 : 1 chloroform–methanol. Extracts were filtered through a small plug of glass wool in a Pasteur pipet and evaporated to apparent dryness with a nitrogen stream. Base-catalyzed methanolysis and treatment with acetyl chloride were performed as described above.

Gas Chromatography–Mass Spectrometry. Compounds were separated with a Supelcowax 10 gas chromatograph column (30 m × 0.25 mm, Supelco Inc., Bellefonte, Pennsylvania), interfaced with a Hewlett-Packard 5985 mass spectrometer. The separation was performed with temperature programming

from 40°C to 250°C at 6°C/min (3 min delay). Nitrogen was used as a carrier gas.

An essential feature of the project was the use of chemical ionization in conjunction with selected ion monitoring. Chemical ionization was performed with isobutane as a reagent gas. Because chemical ionization is much gentler than electron ionization, most of the ionized molecules of a compound remain intact, and the mass spectra obtained are very simple. The chemical ionization mass spectrum for a methyl ester consisted of a prominent M+1 peak, a much smaller M+2 peak (about 10% the height of M+1), and even smaller peaks at higher masses. The spectrum of an acetate was similarly dominated by the M+1 peak, but a peak at M−59 (loss of acetate) was also present and typically about half the height of the M+1 peak. The lack of further fragmentation also means a great increase in sensitivity in detecting the compounds of interest.

Selected ion monitoring is a technique that allows an additional increase in sensitivity, by programming the mass spectrometer to analyze for only one or a few masses, unlike the complete-spectrum mode of operation in which the mass spectrometer sequentially evaluates the abundance of each of a few hundred masses. When a complete spectrum is being obtained, the time spent analyzing for a particular mass is usually less than one percent of the total analysis time, and the sensitivity of the instrument for any one mass is reduced accordingly.

Analysis of Mass-Labeled Compounds. The mass spectrometer was programmed to scan initially for the M+1 peaks of only two compounds, the labeled and unlabeled isomers of methyl tetradecanoate (the first compound of interest to emerge from the column). For example, in glands incubated with [16,16,16-$^2H_3$]hexadecanoic acid, chain shortening would produce [14,14,14-$^2H_3$]tetradecanoic acid. The methyl ester of this labeled isomer (mol wt 243) has a mass three units greater than that of unlabeled methyl tetradecanoate (mol wt 240). The mass spectrometer was therefore initially programmed to scan for the masses 244 and 241, corresonding to the M+1 values for the two compounds (alternately scanning for mass 244 for 0.25 sec, then for mass 241 for 0.25 sec). The labeled and unlabeled isomers of methyl tetradecanoate have almost identical retention times, appearing in the GC trace as a single peak.

The first GC peak was well resolved from the second peak that emerged from the GC column, which consisted of a mixture of the labeled and unlabeled isomers of methyl (*E*)-11-tetradecenoate. Just before this second GC peak began to emerge into the source of the mass spectrometer, the program changed to scan for the masses 242 and 239, corresponding, respectively, to the M+1 values for labeled and unlabeled methyl (*E*)-11-tetradecenoate. The program changed in this way just before the emergence of each GC peak to scan for the labeled and unlabeled isomers of 12 compounds in all, which emerged from the GC column in the following order: methyl tetradecanoate, methyl (*E*)-11-tetradecenoate, methyl (*Z*)-11-tetradecenoate, 1-tetradecyl acetate, (*E*)-11-tetra-

decen-1-yl acetate, (Z)-11-tetradecen-1-yl acetate, methyl hexadecanoate, methyl (Z)-9-hexadecenoate, methyl octadecanoate, methyl (Z)-9-octadecenoate, methyl (Z,Z)-9,12-octadecadienoate, and methyl (Z,Z,Z)-9,12,15-octadecatrienoate.

For glands incubated with [16,16,16-$^2H_3$C]hexadecanoic acid, incorporation into any of the 12 compounds of interest would result in an isotopomer with three additional mass units. Sequential plotting of the most abundant ion (M+1) of the most abundant isotopomer (MAI) of each of the 12 compounds of interest allows a GC trace of the unlabeled native compounds in the glands to be generated. Alternatively, scanning for MAI+3 generates a GC trace allowing detection of mass-labeled compounds resulting from incorporation of [16,16,16-$^2H_2$]hexadecanoic acid. By alternating scanning for MAI and MAI+3 every 0.25 sec, it is possible, within a single GC run, to detect the unlabeled native compounds in the gland and also to detect any mass-labeled isotopomers of those compounds that might be formed.

It is not sufficient to demonstrate the existence of GC peaks at the correct retention times in the MAI+3 trace in order to conclude that incorporation of [16,16,16-$^2H_3$]hexadecanoic acid has taken place in glands incubated with this mass-labeled compound. In order to make a meaningful assessment of incorporation of mass-labeled compounds, it is important to compare the MAI and MAI+3 GC traces for unincubated control glands with corresponding traces for glands incubated with [16,16,16-$^2H_3$]hexadecanoic acid. Even for control glands that have not been incubated with a mass-labeled precursor, the chemical ionization–mass spectra of the 12 compounds of interest include tiny MAI+3 mass spectral peaks.

Ideally, each gland extract would be expected to contain the same overall amounts of the compounds of interest, because 20 glands were used to make each extract. In practice, handling losses (and individual female variation) can cause the overall amounts to vary. Use of an internal standard is the best way to control for this variation, a technique in which a known amount of a compound not occurring in the sample is added, so that the area of the peak for this compound in the resulting GC trace can be compared to the areas of the sample peaks and allow them to be quantified. A variation of this technique was used to allow comparison of the MAI and MAI+3 GC traces from an extract of unincubated control glands with the MAI and MAI+3 GC traces from an extract of glands incubated with [16,16,16-$^2H_3$]hexadecanoic acid. The most abundant of the 12 compounds derived from the sex pheromone glands is methyl oleate (methyl (Z)-9-octadecenoate), and this compound was a convenient internal standard to use in quantifying the MAI and MAI+3 compounds in a given extract. The amount of oleate in the gland is reasonably constant with respect to the other fatty acyl groups in the gland (for examples, see the four chromatograms in the right-hand column of Figure 2, or the three chromato-

grams in the top row of Figure 3). By representing the amounts of the MAI and MAI+3 compounds in the gland in proportion to the amount of MAI methyl oleate, the MAI and MAI+3 traces for unincubated control glands and for glands incubated with a mass-labeled precursor could be directly compared with one another.

RESULTS

Sex pheromone glands incubated with [1,2,3,4-^{13}C]tetradecanoic acid were able to incorporate this compound into the three pheromone components 1-tetradecyl acetate, (*E*)-11-tetradecen-1-yl acetate, and (*Z*)-11-tetradecen-1-yl acetate (Figure 1, peaks D, E, and F, respectively). This incorporation is apparent in comparison of the MAI+4 GC trace for control glands with that for glands incubated with [1,2,3,4-^{13}C]tetradecanoic acid; the MAI GC traces for the two extracts were nearly identical. Incorporation into the three fatty acyl biosynthetic precursors of the pheromone components, tetradecanoate, (*E*)-11-tetradecenoate, and (*Z*)-11-tetradecenoate, was also observed (peaks A, B, and C, respectively). A small amount of incorporation into the saturated fatty acyl groups hexadecanoate (peak G) and octadecanoate (peak I) was observed, presumably due to chain lengthening. None of the unsaturated fatty acyl groups in the gland other than (*E*)-11-tetradecenoate and (*Z*)-11-tetradecenoate incorporated [1,2,3,4-^{13}C]tetradecanoic acid.

Sex pheromone glands were incubated with different amounts of [1,2,3-^{13}C]tetradecanoic acid (Figure 2). Comparison of Figures 1 and 2 illustrates that the GC peaks were smaller in the MAI+4 control trace for [1,2,3,4-^{13}C]tetradecanoic acid than in the MAI+3 control trace for [1,2,3-^{13}C]tetradecanoic acid. For this reason, it is apparent, in comparison of these two figures that compounds labeled with four additional mass units allow a better assessment of incorporation than compounds labeled only with three additional mass units. As glands were incubated with increasing amounts of [1,2,3-^{13}C]tetradecanoic acid, the amount of labeled (*E*)- and (*Z*)-11-tetradecenoate increased slightly, but the amount of labeled tetradecanoate increased greatly, in direct proportion to the amount added initially. This indicates that biosynthesis of (*E*)- and (*Z*)-11-tetradecenoate was near its maximum even at 100 ng labeled tetradecanoate per gland. An unexpected observation was that the ratio of *Z* to *E* increased as the initial amount of labeled tetradecanoate increased. The amounts of the pheromone components produced were approximately the same for all three amounts of topically applied labeled tetradecanoate, indicating that the rates of biosynthesis of these compounds were also near maximum.

The products of glands incubated with [1,2,3-^{13}C]tetradecanoic acid or with [1,2,3,4-^{13}C]tetradecanoic acid were analyzed with a series of mass-selective filters to verify that incorporation was apparent only in the expected mass window (Figure 3). Glands incubated with [1,2,3-^{13}C]tetradecanoic acid dif-

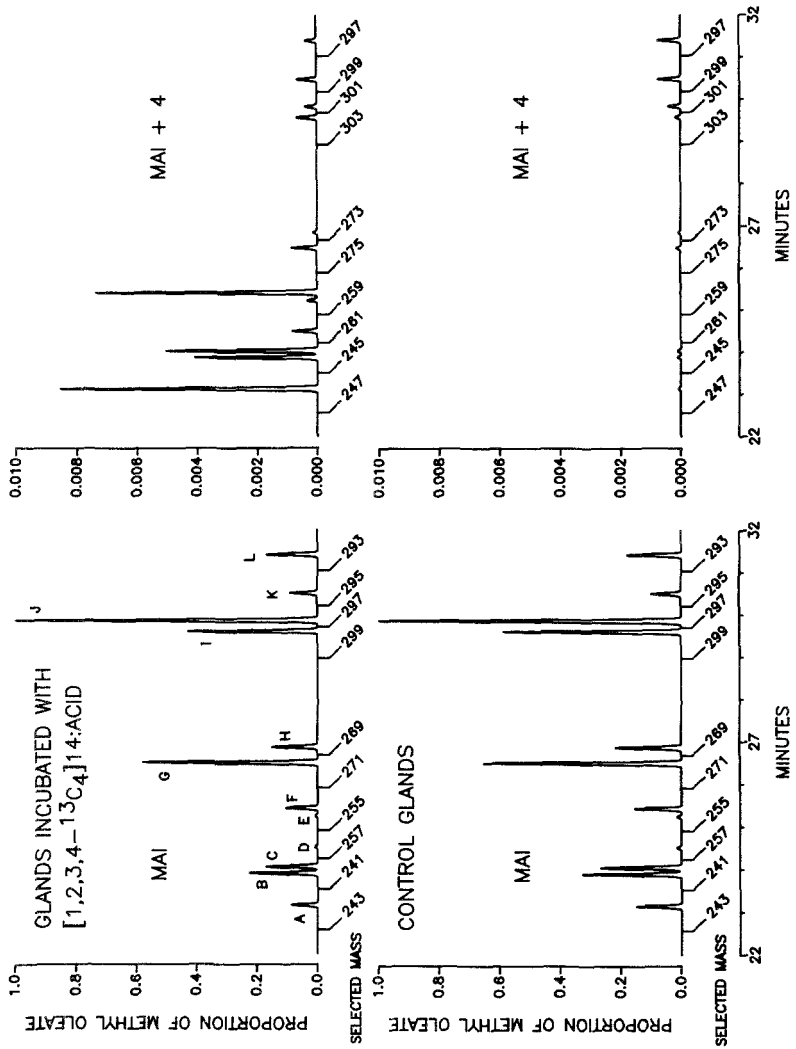

FIG. 1. Incorporation of [1,2,3,4,-$^{13}C_4$]tetradecanoic acid into pheromone components and fatty acyl groups in sex pheromone glands of *A. velutinana*. A = methyl tetradecanoate, B = methyl (*E*)-11-tetradecenoate, C = methyl (Z)-11-tetradecenoate, D = 1-tetradecyl acetate, E = (*E*)-11-tetradecen-1-yl acetate, F = (Z)-11-tetradecen-1-yl acetate, G = methyl hexadecanoate, H = methyl (Z)-9-hexadecenoate, I = methyl octadecanoate, J = methyl (Z)-9-octadecenoate, K = methyl (Z,Z)-9,12-octadecadienoate, L = methyl (Z,Z,Z)-9,12,15-octadecatrienoate (oleate). MAI = most abundant ion of most abundant isotopomer.

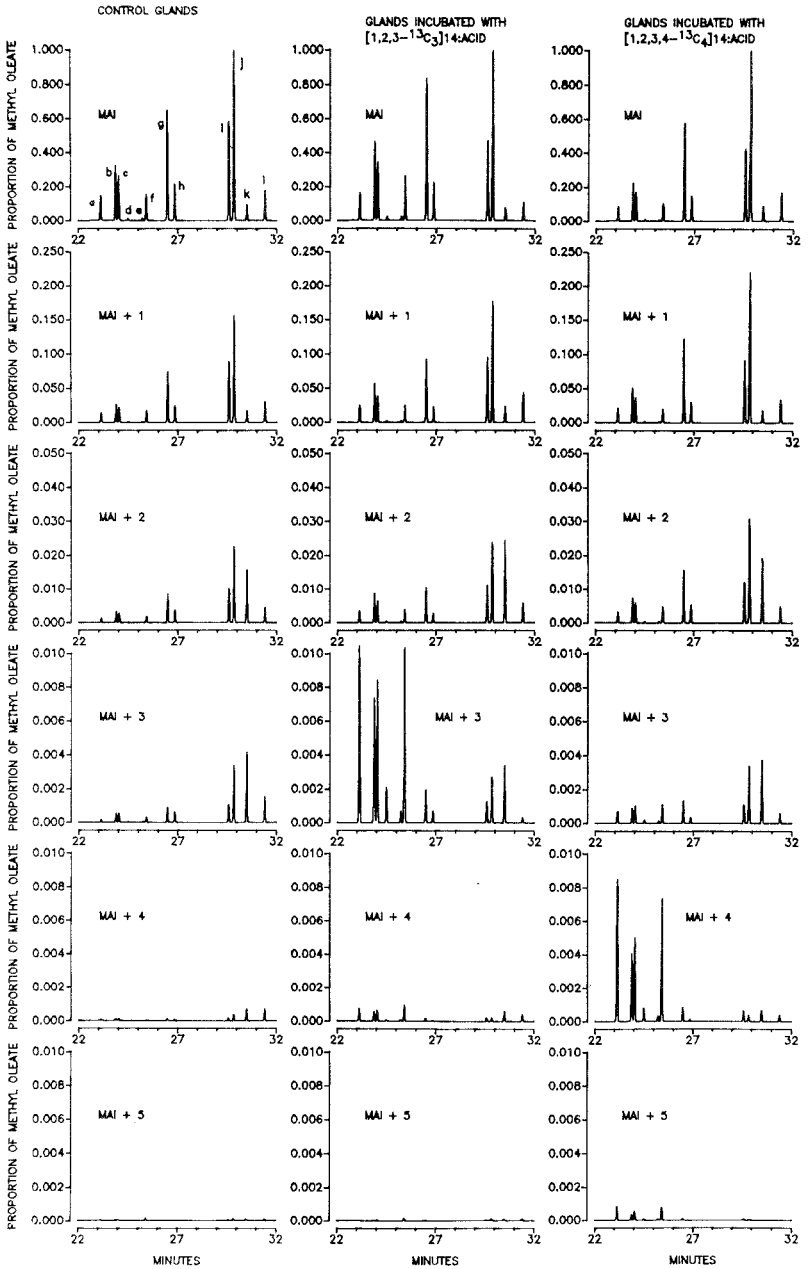

FIG. 3. Analysis with different mass filters of glands incubated with [1,2,3,4-$^{13}C_4$]tetradecanoic acid, glands incubated with [1,2,3-$^{13}C_3$]tetradecanoic acid, and control glands. Abbreviations as in legend for Figure 1.

fered from control glands almost exclusively in the MAI+3 window (but very slightly in the MAI+4 window). Glands incubated with [1,2,3,4-^{13}C]-tetradecanoic acid differed from control glands almost exclusively in the MAI+4 window (but very slightly in the MAI+5 window). The slight differences in the mass windows one unit higher are due to the small M+2 peaks (about 10% the amount of the M+1 peaks) in the chemical ionization mass spectra of the compounds of interest.

Glands incubated with [1,2,3,4-^{13}C](*Z*)-11-tetradecenoic acid were analyzed with a filter for MAI+4 compounds, and incorporation into the expected product [1,2,3,4-^{13}C](*Z*)-11-tetradecen-1-yl acetate was observed, but into no other compounds in the gland (Figure 4). Similarly, glands incubated with [1,2,3,4-^{13}C](*E*)-11-tetradecenoic acid showed incorporation into (*E*)-11-tetradecen-1-yl acetate, but into no other compounds in the gland (Figure 5).

Incubation of sex pheromone glands with [16,16,16-$^{2}H_3$]hexadecanoic acid

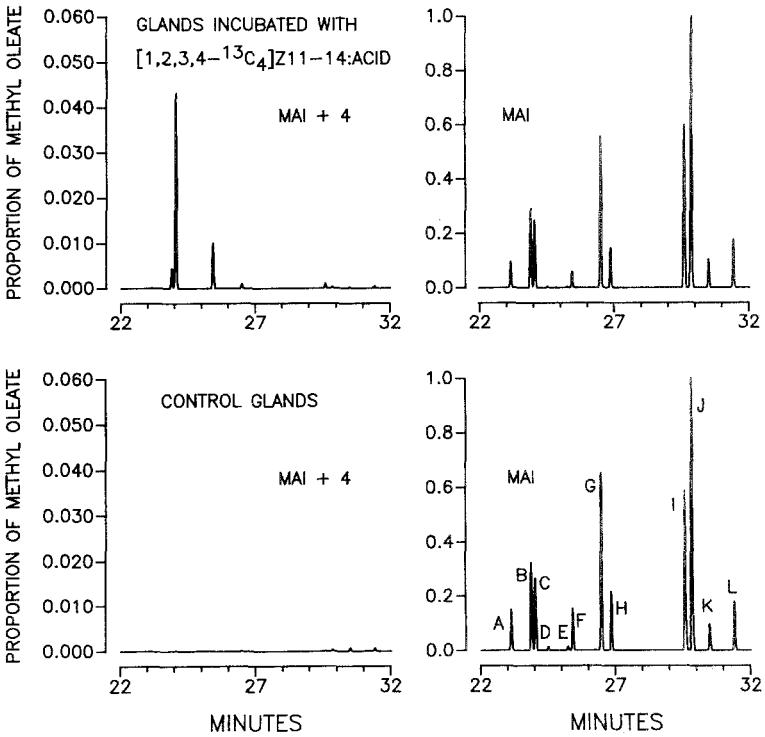

FIG. 4. Incorporation of [1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoic acid into pheromone components and fatty acyl groups in sex pheromone glands of *A. velutinana*. Abbreviations as in legend for Figure 1.

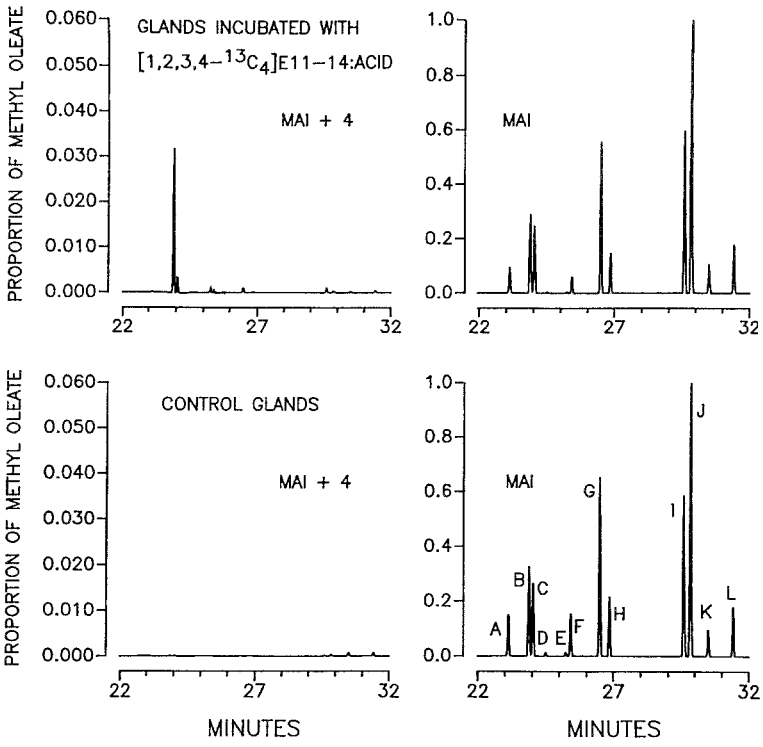

FIG. 5. Incorporation of [1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoic acid into pheromone components and fatty acyl groups in sex pheromone glands of *A. velutinana*. Abbreviations as in legend for Figure 1.

(Figure 6) resulted in the appearance of mass-labeled pheromone components (peaks D, E, and F) and the mass-labeled immediate fatty acyl precursors (peaks A, B, and C). A small amount of incorporation in octadecanoate was also observed, presumably due to chain-lengthening. Incorporation into unsaturated fatty acyl compounds other than (*E*)-11-tetradecenoic acid and (*Z*)-11-tetradecenoic acid was not observed.

Glands incubated with synthetic triacylglycerols did not incorporate the mass-labeled (*Z*)- or (*E*)-11-tetradecenoyl groups into the sex pheromone components, nor were these fatty acyl groups incorporated into choline phosphatides or ethanolamine phosphatides. Results for the 50:50 mixture of *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoyl, *sn*-3-oleoyl-glycerol; and *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoyl, *sn*-3-oleoyl-glycerol are shown in Figure 7. The experiment with *sn*-1-palmitoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoyl, *sn*-3-palmitoyl-glycerol gave similar results.

DISCUSSION

Incubation of sex pheromone glands of *A. velutinana* with fatty acids mass-labeled with several atoms of deuterium or ^{13}C in the present set of experiments produced results completely consistent with our previous work with radiolabeled fatty acids (Bjostad and Roelofs 1981). We concluded previously that hexadecanoate was the first fatty acyl intermediate in the biosynthesis of the sex pheromone components. Incubation with [16,16,16-$^2H_3$]hexadecanoic acid (an MAI+3 mass-labeled compound) in the present study resulted in the production of MAI+3 mass-labeled pheromone components and of the structurally analogous fatty acyl intermediates, but fatty acyl groups that were found not to be intermediates in the biosynthesis of the sex pheromone components in previous studies with radiolabel (Bjostad and Roelofs, 1981; Bjostad and Roelofs 1984) were found not to incorporate three extra mass units in the present experiment (peaks H, I, J, K, L, Figure 6). Biosynthesis of these other fatty acyl groups takes place entirely before adult emergence, and only the fatty acyl intermediates involved in pheromone production are biosynthesized in the adult female (Bjostad and Roelofs, 1981).

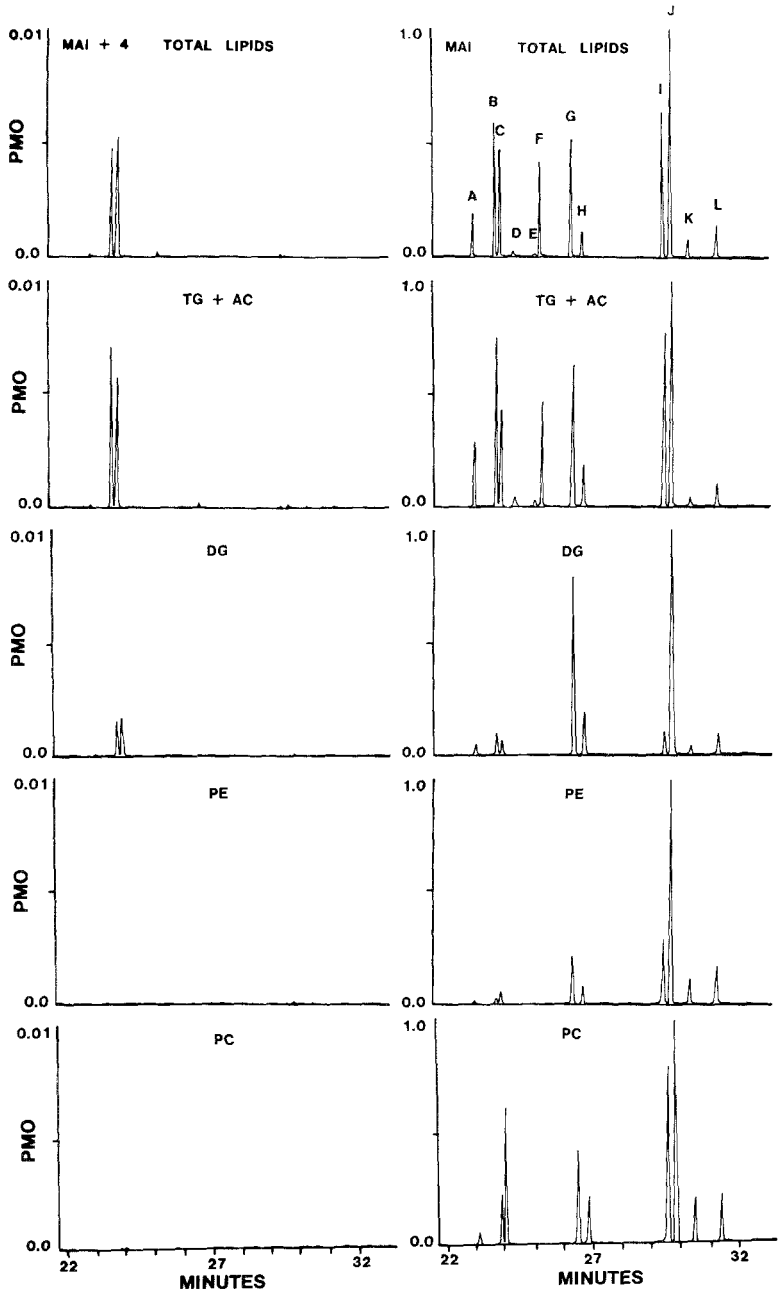

FIG. 7. Incorporation of a 50:50 mixture of *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*Z*)-11-tetradecenoyl, and *sn*-3-oleoyl-glycerol; and *sn*-1-oleoyl, *sn*-2-[1,2,3,4-$^{13}C_4$](*E*)-11-tetradecenoyl, and *sn*-3-oleoyl-glycerol into pheromone components and fatty acyl groups in sex pheromone glands of *A. velutinana*. TG = triacylglycerols, AC = acetates, DG = diacylglycerols, PE = ethanolamine phosphatides, PC = choline phosphatides, PMO = proportion of methyl oleate in the control glands. Other abbreviations as in legend for Figure 1.

Incubation of glands with MAI+3 or MAI+4 mass-labeled tetradecanoic acid resulted in mass-labeled pheromone components and their structurally analogous fatty acyl precursors, but did not result in mass-labeled hexadecanoate. This is consistent with our previous conclusion that tetradecanoate is the second fatty acyl intermediate in the pathway.

Glands incorporated MAI+4 mass-labeled (*E*)- or (*Z*)-11-tetradecenoic acid only into the corresponding pheromone component and not into the other geometric isomer. This supports our previous conclusion that geometric isomerases do not occur in the gland. The incorporation of the *E* isomer was only 9% that of the *Z* isomer, despite the fact that glands were incubated with the same amount of each precursor, indicating that selection of the *Z* precursor for reduction and acetylation to the analogous pheromone component occurs at 11 times the rate of conversion of the *E* precursor. The lack of incorporation into tetradecanoate or hexadecanoate is consistent with our previous conclusion that each of the 11-tetradecenoates is a third fatty acyl intermediate in the pathway to each of the respective pheromone components.

Incubation with different amounts of [1,2,3-$^{13}C_3$]tetradecanoic acid showed that the rate of pheromone production was near maximum even for the smallest amount tested (100 ng/gland). Of the MAI+3 label in the gland after incubation with this amount, most was in the pheromone components and their immediate fatty acyl precursors, implying excellent conversion of MAI+3 mass-labeled tetradecanoate to mass-labeled (*E*)- and (*Z*)-11-tetradecenoate and subsequent conversion to the pheromone components. This is puzzling in light of the overall loss of [1,2,3-$^{13}C_3$]tetradecanoic acid that must have taken place, because 100 ng of methyl [1,2,3-$^{13}C_3$]tetradecanoate would produce a GC peak approximately 0.4 units in height on the scale shown (proportion of methyl oleate). The MAI+3 mass-labeled compounds only account for a total of about 0.04 units, indicating 10% recovery of mass-labeled material. The remaining 90% was presumably degraded in the gland or was eliminated from the gland.

The relative abundance of peaks K and L (methyl linoleate and methyl linolenate, respectively) was surprisingly high in mass-filtered chromatograms for MAI+2, MAI+3, and higher mass compounds, even for control glands (for example, see Figure 3). We initially suspected that compounds other than methyl linoleate and methyl linolenate isotopomers may be present with the same retention times, but higher molecular weights. If this were true, the increased relative abundance of peaks K and L should be apparent only in one of the higher mass-filtered chromatograms, but the increase is actually seen in chromatograms for MAI+2, MAI+3, MAI+4, and MAI+5 compounds (higher masses were not examined). An alternative possibility involves differential incorporation of isotopes of carbon. Insects can biosynthesize some fatty acids themselves, but rely on dietary sources of linoleate and linolenate (Downer, 1978), which was of plant origin for the insects used in this study. Insects can either deplete or enrich their body tissues in ^{13}C with respect to the

^{13}C content of their food (DeNiro and Epstein, 1978). If the insects used in this study were able to biosynthesize fatty acids that were depleted in ^{13}C relative to their dietary linoleate and linolenate, this carbon isotope fractionation may account for the increased relative abundance of linoleate and linolenate in several of the higher mass chromatograms rather than one alone.

The use of multiple-labeled stable isotopes as markers for biosynthetic studies has some advantages over the use of radiolabeled compounds. First, the likelihood of misleading results because of recycling of acetyl CoA from mitochondrial degradation is greatly reduced, as mentioned earlier in the introduction. A second advantage of mass-labeled compounds is the ability to distinguish alternative biosynthetic pathways in the same experiment. For example, chain-lengthening of (*Z*)-9-dodecenoate can be postulated as an alternative path to (*Z*)-11-tetradecenoate. The relative importance of this route could be tested by incubating sex pheromone glands with a mixture of [1,2,3,4-$^{13}C_4$](*Z*)-9-dodecenoic acid and [1,2,3,4,5,6-$^{13}C_6$]tetradecenoic acid at the same time. Mass spectral analysis for MAI+4 incorporation and for MAI+6 incorporation would establish the contributions of each pathway. It is advisable to use mass-labeled compounds at least two mass units apart; the CI mass spectrum of a compound labeled with four extra mass units (MAI+4) includes a small peak at MAI+5 (about 10% the abundance of the MAI+4 peak).

The (*Z*)- and (*E*)-11-tetradecenoate groups in the gland occur in four lipid classes: triacylglycerols, diacylglycerols, choline phosphatides, and ethanolamine phosphatides. Although hexadecanoate, tetradecanoate, and the (*Z*)- and (*E*)-11-tetradecenoates are known to be successive fatty acyl intermediates in the biosynthesis of the pheromone components (*Z*)- and (*E*)-11-tetradecenyl acetate, the role of each of the glycerolipid classes that carry these fatty acyl groups is not yet known. Most of the (*Z*)- and (*E*)-11-tetradecenoate groups in the gland occur in the triacylglycerols (Bjostad et al., 1981). Surprisingly, the pheromone components did not incorporate any labeled (*Z*)- or (*E*)-11-tetradecenoate when glands were incubated with the synthetic triacylglycerols tested in the present study.

These results contradict our earlier conclusion that the triacylglycerols are a source of (*Z*)- and (*E*)-11-tetradecenoate for the biosynthesis of the corresponding pheromone components. We found previously that in glands incubated with radiolabeled acetate for different time intervals, there were significant changes in the triacylglycerols in the relative proportions of radiolabel in tetradecanoate, (*Z*)-11-tetradecenoate, and (*E*)-11-tetradecenoate (Bjostad and Roelofs, 1984). Because the relative proportion of radiolabeled tetradecanoate decreased with time of incubation, we concluded that triacylglyceryl tetradecanoate was being used to make triacylglyceryl (*Z*)- and (*E*)-11-tetradecenoate. We further concluded that the increase in the relative proportion of radiolabeled (*E*)-11-tetradecenoate with time of incubation could be explained in terms of a 10:1 difference in the respective rates of conversion of triacylgly-

ceryl (*Z*)- and (*E*)-11-tetradecenoate to the corresponding pheromone components.

The incubations of glands with synthetic triacylglycerols in the present study were an attempt to demonstrate more directly that the triacylglycerols were acyl donors for the biosynthesis of the sex pheromone components. The complete lack of incorporation that we observed has several possible explanations. One possibility is that the results are an artifact and that the synthetic triacylglycerols were simply unable to enter the pheromone gland cells despite the fact that labeled fatty acids were readily incorporated. The triacylglycerols are larger and less polar than the fatty acids, and this may have resulted in such exclusion.

If the results are not an artifact, then they indicate that triacylglycerols are not acyl donors for pheromone biosynthesis and that there is a different explanation for the temporal change we observed previously in the relative proportions of radiolabeled tetradecanoate, (*Z*)-11-tetradecenoate, and (*E*)-11-tetradecenoate (Bjostad and Roelofs, 1984). The explanation must also take into account the related observation in the present study (Figure 2) that incubation of glands with increasing amounts of [1,2,3-$^{13}C_3$]tetradecanoic acid resulted in an increase in the amounts of (*Z*)- and (*E*)-11-tetradecenoate produced and also an increase in the proportion of *Z* to *E*.

One such explanation can be constructed in terms of the following scenario. Delta-11 desaturation of tetradecanoate may initially produce twice as much (*Z*)-11-tetradecenoate as (*E*)-11-tetradecenoate. This is the ratio we have observed in the choline phosphatides and in the ethanolamine phosphatides (Figure 7), and there is evidence that desaturation actually takes place on fatty acyl groups of phospholipids (Pugh and Cates, 1979). As (*Z*)-11-tetradecenoate is produced, some is converted to the pheromone component (*Z*)-11-tetradecenyl acetate and some is incorporated into triacylglycerols that may be a metabolic dead end. Only a tiny proportion of the (*E*)-11-tetradecenoate is converted to the corresponding pheromone component, and most of this isomer is incorporated into triacylglycerols. A fresh supply of (*Z*)- and (*E*)-11-tetradecenoate in a 2 : 1 ratio is continually made available to the enzymes that produce (*Z*)- and (*E*)-11-tetradecenyl acetate, and disposal of the unused portion is accomplished by incorporating it into triacylglycerols. In this interpretation, the triacylglycerols are not acyl donors for the pheromone components and may serve instead as a "dumping ground" for tetradecanoate, (*Z*)-11-tetradecenoate, and (*E*)-11-tetradecenoate that are not used in pheromone biosynthesis. If this is true, a reasonable alternative explanation for the observed temporal change in proportion of these three fatty acyl groups in the triacylglycerols can be proposed in terms of differences in the rate of pheromone biosynthesis at different times of day. The rates of biosynthesis of the pheromone components relative to those of their fatty acyl precursors may be higher in the latter part

of the dark period. Because the amount of (*E*)-11-tetradecenoate used for pheromone biosynthesis is only one tenth that of the *Z* isomer, the proportion of unused (*E*)-11-tetradecenoate relative to that of the *Z* isomer would be higher in the latter part of the dark period.

This scheme may also account for the results in the present study involving incubations of glands with different amounts of [1,2,3-$^{13}C_3$]tetradecanoic acid (Figure 2). Approximately equal amounts of labeled (*E*)-11-tetradecenoate, (*Z*)-11-tetradecenoate, and (*Z*)-11-tetradecen-1-yl acetate were observed in glands incubated with 100 ng [1,2,3-$^{13}C_3$]tetradecanoic acid. The rates of biosynthesis of labeled pheromone components and 11-tetradecenoates were near maximum even at this lowest amount tested. By greatly increasing the amount with which glands were incubated, presumably it was possible to increase slightly the amounts of (*Z*)- and (*E*)-11-tetradecenoate produced by desaturation (in a 2 : 1 ratio). Because the rates of biosynthesis of the corresponding pheromone components remained about the same (and in a 9 : 1 ratio of *Z* to *E* isomers), unused (*Z*)-11-tetradecenoate may have accumulated at an increased rate with respect to unused (*E*)-11-tetradecenoate. Incorporation of these unused *Z* and *E* isomers into triacylglycerols would result in an increase in the *Z* to *E* ratio.

Acknowledgments—We thank Kathy Poole for rearing the insects. We are particularly grateful to Robert Butz and Terry Acree of the Food Science Department, NYS Agricultural Experiment Station, Geneva, New York, for their generosity in making the mass spectrometer and other laboratory facilities available for this project, and for many hours of discussion and assistance in making this approach possible. (Received April 20, 1985; accepted August 1, 1985)

Abstract—Multicomponent pheromone systems are common in many insect species. As our knowledge about the number of different chemical compounds actually involved in a particular communication system increases, so too does the need for an efficient neural mechanism for the encoding of behaviorially relevant odor compounds. Here we consider the electrical activity of olfactory receptor neurons in a subset of the individual pheromone-sensitive sensilla on the antennae of male cabbage looper moths (*Trichoplusia ni*). Responses to single- and multiple-component stimuli, drawn from seven behaviorally active compounds, were obtained at several different intensities. Some blends elicited electrical responses which were not readily predicted from a knowledge of the receptor neuron's response to individual components.

Key Words—Cabbage looper, *Trichoplusia ni*, Lepidoptera, Noctuidae, insect attractant, electrophysiology, olfactory receptor, pheromone blend.

INTRODUCTION

The chemical communication system of *Trichoplusia ni*, the cabbage looper moth (CL), is now known to involve at least seven behaviorally relevant odor compounds, six of which are produced by the female (Bjostad et al., 1984). As has been the case in a wide range of species, the number of components identified in the female gland of *T. ni* has increased over the years, keeping pace with technical developments in modern chemistry. In particular, the recent advances in microanalytical procedures have made it possible to monitor the composition of the effluvia from a single behaviorally active female (Baker et al., 1981; Guerin et al., 1981; Löfstedt et al., 1982). This contrasts with the sac-

0098-0331/86/0200-0451$05.00/0

rifice of 500,000 virgin females required in Butenandt's original identification of bombykol in the domestic silkworm (Butenandt, 1963).

As our awareness of the behavioral and chemical complexity of an insect's pheromonal communication system expands, so too should our appreciation for the demands made upon its nervous system (Cardé and Baker, 1984; Dethier, 1971). For example, it would be reasonable to postulate that the insect olfactory system would be characterized by: extreme specificity at the molecular level, so that exceedingly small changes in the chemical structure of pheromone compounds can be discriminated; a reasonable amount of neural plasticity, so that the molecular diversity that is to be processed can continue to increase as other organisms, including organic chemists, synthesize new behaviorally relevant compounds; enormous gain, so that very dilute, but evolutionarily important, chemical signals, like those emanating from willing but remote sexual partners, can be detected; considerable resolving power, so that these signals, which are likely to be buried in a sea of other nonsignificant compounds, can be discriminated; wide dynamic range, so that small differences in local concentration gradients may be used to locate the sources of distant chemical signals; and, finally, all of these requirements must be packed within the space allocated to the nervous system and fueled within the limited energy budget imposed by the overall metabolic cost of existence.

The sensory processing of complex chemical signals by the insect olfactory system has often been postulated to involve a set of narrowly tuned, highly specific olfactory receptor neurons, one for each of the behaviorally relevant component compounds in the pheromone blend (Priesner, 1979a,b, 1980, 1983). In experiments where individual components of a pheromone blend are used as stimuli for single olfactory receptor neurons, many of the behaviorally relevant components do seem to have their own, narrowly tuned specialized receptor neuron type, each apparently dedicated to detecting and signaling its presence (Löfstedt et al., 1982). Even in those instances where several additional compounds may stimulate the same single-receptor neuron, the concentrations required for threshold electrophysiological responses are often so large that a behaving animal would likely never encounter them in sufficient amounts to elicit meaningful neural activity. Thus, each behaviorally relevant component of a complex pheromone blend is thought to have its own private channel of communication with the central nervous system. There the composition of a particular stimulus mixture may be unambiguously decoded by simply noting which of the separate input channels are activated.

From a theoretical point of view, this type of system is an efficient neural encoder, only in those cases where the pheromone blend consists of only a few compounds. That is, as the number of compounds in the communication system increases, so too does the requirement for additional private input channels (O'Connell, 1975, 1981). Moreover, in any system where all of the primary receptor neurons are very narrowly tuned, the ability to respond to small amounts

of other compounds, including those produced by potential competitors, is severely restricted and can include only those chemicals with nearly identical structural and chemical properties to those which are already in the stimulus set. Thus, a system which relies on highly specialized, narrowly tuned receptors to encode information about pheromones is less adaptive than other arrangements in the sense that it imposes a form of odor blindness on the nervous system which restricts its ability to process the pheromonal signals emanating from other sources.

In contrast, efficient encoding of a very large number of different odor compounds can be accomplished, on theoretical grounds, by a relatively small number of different olfactory receptor neuron types if each group is uniquely responsive to a range of different odors (Erickson, 1982; O'Connell, 1981). The identity of a particular stimulus may then be unambiguously decoded by the central nervous system if it evaluates in parallel the relative amounts of neural activity elicited across the whole population of receptor neuron types. It is important to note that the relative breadth of tuning among the different classes of olfactory receptor neurons need not be constant in this type of encoding mechanism. Thus, some fraction of the available input channels could be more narrowly tuned than others.

Although highly specific olfactory receptor neurons, apparently tuned to individual behaviorally relevant pheromone components, are observed in many species, it is common to find systems in which behaviorally relevant compounds are processed in the absence of such tuned receptor neurons (Löfstedt et al., 1982; O'Connell, 1972, 1975). There are also insects in which olfactory receptor neurons exist in males that are apparently tuned to compounds that are not produced by the species female (Löfstedt et al., 1982; O'Connell, 1985c; Priesner, 1979a,b). Given the chemical complexity of many pheromone systems and the well founded desire to use them as ecologically sound methods of insect pest control, it is absolutely necessary that the neural mechanisms underlying, and responsible for, pheromone perception become the objects of intensive study.

One of the basic problems to be evaluated may be stated quite simply: given that the olfactory communication systems of insects are, in nearly all cases, sophisticated (with multiple chemical signals conveying a variety of interrelated messages each of which ultimately results in a series of integrated, context-specific behavioral responses), how does the insect nervous system detect, encode, and process these messages unambiguously and still cope with the range of theoretical restraints enumerated earlier? An initial step toward answering this admittedly global question involves a consideration of the specific response properties of particular classes of insect olfactory receptors when they are each presented with behaviorally relevant components of the pheromone blend.

The earliest component identified from female CL (Ignoffo et al., 1963;

Berger, 1966), and the major volatile component of the gland is (Z)-7-dodecenyl acetate (Z7–12 : Ac). This compound is essential for flight initiation in males and was originally thought to be entirely responsible for the biological activity obtained with female gland extracts. Subsequently, (Z)-7-dodecenol (Z7–12 : OH) was shown to significantly arrest upwind flight in males exposed to either calling females or to sources of synthetic Z7–12 : Ac (Toba et al., 1970; Tumlinson et al., 1972; McLaughlin et al., 1974). Although this compound has occasionally been found in gland extracts, it is generally considered to arise artificially in the process of chemical separation or analysis (Linn et al., 1984). It is thus classified in common with other behaviorally active compounds which are not components of a female's pheromone blend, as an interspecific compound, perhaps one involved in some speciation mechanism which includes the CL (Fletcher-Howell et al., 1983; Leppla 1983).

A saturated 12-carbon acetate, dodecyl acetate (12 : Ac) was next identified in female glands and was shown to modulate several of the close-range search behaviors of males, including landing frequency and total time spent on the pheromone source (Bjostad et al., 1980). Recently four additional compounds were found in the female gland. They have been identified chemically and implicated behaviorally as important components of the pheromone blend (Bjostad et al., 1984). These compounds include: (Z)-5-dodecenyl acetate (Z5–12 : Ac); 11-dodecenyl acetate (11–12 : Ac); (Z)-7-tetradecenyl acetate (Z7–14 : Ac); and (Z)-9-tetradecenyl acetate (Z9–14 : Ac). Although the exact roles of these latter four compounds in modulating normal male behavior is still being evaluated, there is little doubt that, in wind-tunnel assays, the two previously identified CL female components elicit only about 25% of the close-to-source behaviors observed when animals are exposed to the total complement of the six female-produced components (Bjostad et al., 1984; Linn et al., 1984). Moreover the more complex six-component synthetic blend elicits behavioral responses which are quantitatively equivalent to those elicited by excised virgin female pheromone glands, both in terms of the number of males responding and the amount of time required for the full behavioral sequence.

The experiments and discussion reported here continue our attempts to unravel blend perception in the peripheral olfactory system of the cabbage looper moth. We had previously focused on the three original compounds whose behavioral import was known (O'Connell, 1985b,c). There we focused especially on the quantitative response characteristics of a selected subset of pheromone-receptor neurons (HS sensilla) which had earlier been shown to be very responsive to Z7–12 : Ac and Z7–12 : OH (O'Connell et al., 1983). Here we expand these studies in HS sensilla by considering the alterations in neural discharge engendered in these receptor neurons by the addition of the four recently identified pheromone components to the various blends previously considered. The effect of adding the behavioral inhibitor Z7–12 : OH to some of these mixtures

was also examined. The number of stimulus combinations was kept manageable by fixing the intensity and composition ratios of the various components at levels near those found in female gland extracts. Since we have explored only a limited portion of the available behaviorally relevant stimulus domain, in only one of the two recognized classes of pheromone-sensitive sensilla, it is not yet possible to provide a thorough description of potential coding mechanisms. However, we hope to show here additional instances where olfactory receptor neurons are responsive, in novel ways, to multiple-component stimuli even in those cases where an individual behaviorally relevant pheromone component is not processed by a separate unique class of receptor neuron.

METHODS AND MATERIALS

Animals. All of the adult moths used in this study were derived from the laboratory-reared stock maintained by the Insect Attractants, Behavior and Basic Biology Research Laboratory, USDA, Gainesville, Florida. Eggs were collected from filter papers placed in laying cages, washed in dilute sodium hypochlorite solution, and rinsed with distilled water. After hatching, larvae were supplied with ad libitum Velvetbean Caterpillar Diet (#9795, Bio-Serve Inc., Frenchtown, New Jersey 08825). Newly pupated animals were sexed, and experimental males were isolated from further contact with females. Virgin adult males had access to 5% sucrose solution and were used as subjects when 2–5 days of age. All animals were maintained at 23°C, 70% relative humidity, and exposed to a 14 : 10-h light–dark cycle.

Recordings. Animal preparation, tungsten microelectrode construction, extracellular recording conditions, odor cartridge placement, and their control were as described elsewhere (O'Connell, 1975, 1985c; O'Connell et al., 1983). Briefly, males were restrained and fixed in a recumbent position on a Plexiglas holder. One of their antennae was held in place with transparent adhesive tape and then viewed at 600 power with the long working distance objectives of a light microscope. Transillumination of the antennae revealed the shafts and bases of individual olfactory sensilla and allowed the positioning of electrolytically sharpened recording microelectrodes. In general, we found that stable recordings were routinely obtained with these techniques and that odor-induced responses could be monitored for considerable time periods, apparently limited only by the gradual dehydration of the animal over a 24- to 96-hr interval.

The electrical signals generated by the two olfactory receptor neurons found in each sensillum were processed with an AC-coupled amplifier (bandpass 0.3–3.0 kHz), displayed on an oscilloscope, and then sorted and timed by an online digital computer (O'Connell et al., 1973). For each stimulus application the computer produced: (1) an event–time histogram; (2) a reconstructed spike

record; and (3) the total number of action potentials elicited in the prestimulus, stimulus, and poststimulus intervals for both receptor neurons in a sensillum. All the data were obtained from sensilla whose morphological and physiological properties classified them as HS sensilla (O'Connell et al., 1983).

Stimulation. All the compounds used here are found in the female cabbage looper pheromone gland or are known to modulate male behavior. Both Z7-12:Ac and Z7-12:OH were obtained from Farchan Chemical Co., Columbus, Ohio. The saturated compound, 12:Ac was a gift from Dr. W. Roelofs, New York State Agricultural Experiment Station, Geneva, New York. The purity of these materials was evaluated prior to use by Albany International, Controlled Release Division, Needham Heights, Massachusetts. Based upon gas chromatographic retention times on polar (SP-2340) and nonpolar (SPB-1) columns (60M, WCOT), each calibrated against authentic standards, the level of cross-contamination among these three compounds was negligible (detection limit, <0.1%). Absolute purity was 87% for Z7-12:OH (+8% *E*7-12:OH), 93% for Z7-12:Ac (+5% *E*7-12:Ac), and 98% for 12:Ac. The remaining female produced compounds, 11-12:Ac; Z5-12:Ac; Z7-14:Ac, and Z9-14:Ac, were a gift from Dr. M.S. Mayer, Insect Attractants, Behavior and Basic Biology Research Laboratory, USDA, Gainesville, Florida.

A range of stimulus intensities for each compound was produced by serial dilution with light mineral oil (Aldrich Chemical Co., Milwaukee, Wisconsin). The dilution series varied in decade steps from 0.1 μg/μl to 0.0001 μg/μl and were known to span the range of physiologically effective intensities typical for HS sensilla. The relative amount of each compound present in a synthetic mixture was matched to those observed analytically in extracts of female glands except for Z7-12:OH which, although behaviorally active, seems not to be a natural glandular constituent. This latter compound was evaluated in mixtures at a proportion equal to that used with mixtures containing Z7-12:Ac. The various single and multicomponent stimuli were produced by spotting, in turn, 0.5 μl of the appropriate individual dilution series onto a filter paper (160 mm^2) held in individual glass odor cartridges. Make-up mineral oil, where required to equalize the evaporative surface area, was added to each filter paper so that total liquid volume for each cartridge was 1.5 μl.

This method of stimulus preparation results in single cartridges that evoke responses equivalent to those that are obtained when the individual components of a blend are kept in separate cartridges and mixed in the air space surrounding a single sensillum. Thus, within our ability to measure differences between these two modes of stimulation, a single-odor cartridge delivers multiple-component stimuli with individual release rates equivalent to those obtained with cartridges containing only a single pheromone component. Most mixtures were evaluated at a single concentration and composition ratio. The concentration level normally selected was one which would, on average, result in a half-

maximal action potential discharge. This allowed us to detect both increases and decreases in the neural activity evoked by mixtures. For the principal component of the female pheromone blend, Z7–12 : Ac, the 0.005 μg/cartridge was routinely used. The six female-produced compounds were made up as a single stock solution at the composition ratios observed in extracts of female glands (Table 1) to minimize the total volume involved when these compounds were evaluated.

Completed odor cartridges were sealed with Teflon plugs and caps and stored in individual Teflon-capped glass vials which were, in turn, stored in an opaque container continuously purged with dry nitrogen (1.6 liters/min). Between experiments this container was purged and stored at 4°C. These are necessary precautions for pheromone storage and handling and are designed to prevent cross-contamination between individual samples.

Individual stimuli were 2 sec in duration and applied, under computer control, by passing purified, oxygen-free nitrogen (60 ml/min) over the filter paper contained in each glass odor cartridge. The outlet of the odor cartridge was positioned 8 mm from the antennal surface. In the interstimulus interval (usually 5 min), the antenna was bathed by an opposed, humidified pure air stream (Ultra Zero grade; Matheson, Gas Products, East Rutherford, New Jersey), at a flow rate of 120 ml/min. Each stimulus was presented in duplicate to each olfactory receptor neuron. The order of stimulus presentation proceeded from cartridges containing only single compounds through to those containing all seven compounds. All the responses reported here were obtained with a single set of odor cartridges. Control odor cartridges, which contained only 1.5 μl of mineral oil on filter paper, were interspersed with odor stimuli on a random basis to monitor for inadvertent contamination of the odor line connections. In the few cases where contamination was revealed by measurable responses to control car-

TABLE 1. COMPOSITION OF SIX-COMPONENT *Trichoplusia ni* PHEROMONE BLEND

Compound	Relative proportion[a]	Composition ratio (%)	Amount in the 0.005-μg dilution
Z7–12 : Ac	100.0	81.6	0.00408
Z5–12 : Ac	9.1	7.4	0.00037
12 : Ac	8.2	6.7	0.00034
11–12 : Ac	2.8	2.3	0.00012
Z7–14 : Ac	1.5	1.2	0.00006
Z9–14 : Ac	0.9	0.7	0.00004

[a] Average proportion (relative to Z7–12 : Ac) measured in the gland extracts of six individual females (Bjostad et al., 1984).

tridges, replacement of the relevant Teflon fittings eliminated subsequent responses to controls. In these cases, all of the response data since the preceding control cartridge presentation were discarded and the individual stimuli were repeated. Thus, there was no need to correct any of the response measures reported here for background responses associated with the mechanics of stimulus application.

Data Analysis. The response measure reported here was derived by subtracting the number of action potentials produced by a particular receptor neuron during the 10 sec immediately preceding the 2-sec stimulus pulse from the number of action potentials which occurred in the succeeding 10 sec. The duplicate responses obtained with each odor cartridge were averaged to provide the data set for individual neurons. Because of the large number of possible stimulus combinations among the seven relevant compounds, the range of effective stimulus concentrations likely to be appropriate for each, and the range of potentially interesting composition ratios among the constituents of a particular mixture, the number of individual stimuli evaluated in a single recording session (2 hr) was necessarily only a small fraction of the available stimulus set. In each case, the responses to multicomponent stimuli were compared to the algebraic sum of the responses elicited in the same receptor neurons by the appropriate intensities of their single components. The resulting pairs of expected and observed values were compared statistically with the Wilcoxon matched-pairs signed-ranks test or with the sign test (Siegel, 1956).

RESULTS

Response Characteristics. Action potentials were recorded extracellularly from sensilla (HS) on the male CL antenna which contains receptor neurons that are highly sensitive to the major pheromone component, Z7-12:Ac. The neurophysiological and morphological characteristics of this class of sensilla have been described and contrasted with the properties of the other class of pheromone-sensitive sensilla on the antenna (O'Connell et al., 1983; Grant and O'Connell, 1985). Each HS sensillum is innervated by two spontaneously active receptor neurons that produce action potentials which can be reliably differentiated from each other by their amplitudes and waveforms. By convention, the receptor neuron producing the larger amplitude action potential is designated the A neuron and that producing the smaller is designated the B neuron. The mean number of spontaneous action potentials ($\pm$ SEM) in this sample of 26 individual sensilla was 0.28 $\pm$ 0.05 impulses/sec for the A receptor neurons and 0.33 $\pm$ 0.06 impulses/sec for the B receptor neurons. In addition to this typical range of spontaneous activity, individual HS sensilla were also characterized by their length, shape, and responsiveness to low doses (0.0005–0.005 μg) of Z7-12:Ac and Z7-12:OH.

Responses to Individual Components. Five of the seven behaviorally relevant compounds have been evaulated as individual stimuli. Their intensities were adjusted to approximate those measured in female pheromone glands (Table 1), except for Z7–12:OH which is not produced by the female and thus was evaluated at an intensity equal to that used for Z7–12:Ac. As demonstrated in previous studies (Grant and O'Connell, 1985; O'Connell, 1985a–c; O'Connell et al., 1983) and illustrated here in Figure 1 (taken from O'Connell, 1985c), the average A receptor neuron in HS sensilla is reliably responsive to low doses (0.005 μg) of Z7–12:Ac whereas the average B receptor neuron is responsive to comparable amounts of Z7–12:OH. Neither receptor neuron is particularly responsive to 12:Ac, even when larger intensities are evaluated (Figure 1). Similarly, we show in this sample of olfactory receptor neurons that neither Z5–12:Ac (0.0005 μg) nor Z7–14:Ac (0.00005 μg) alone, elicited consistent amounts of electrical activity in either receptor neuron (Figure 2).

Responses to Mixtures. The average magnitude of the electrical response obtained from individual receptor neurons to stimulation with the various mixtures is displayed in Figure 2. The response obtained in each receptor neuron to stimulation with a particular mixture was compared to the response expected if the responses to individual components were additive. The observed and expected response values for each receptor neuron were then compared to each other with the Wilcoxon matched-pairs signed-ranks test. In general, the direction of the statistically significant trends observed in the responses elicited by

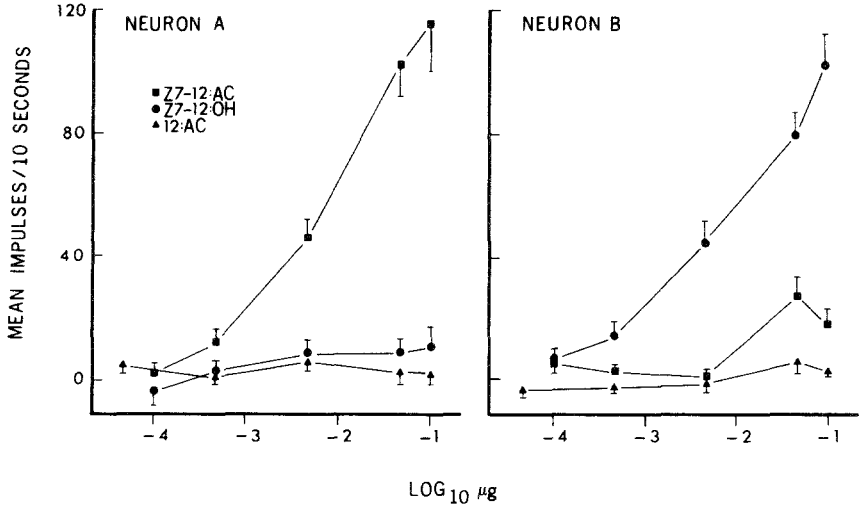

FIG. 1. The average (mean ± SEM) dose–response functions for both A (left) and B (right) receptor neurons ($N = 35$) in response to stimulation with graded doses of each of three behaviorally relevant compounds (from O'Connell, 1985c).

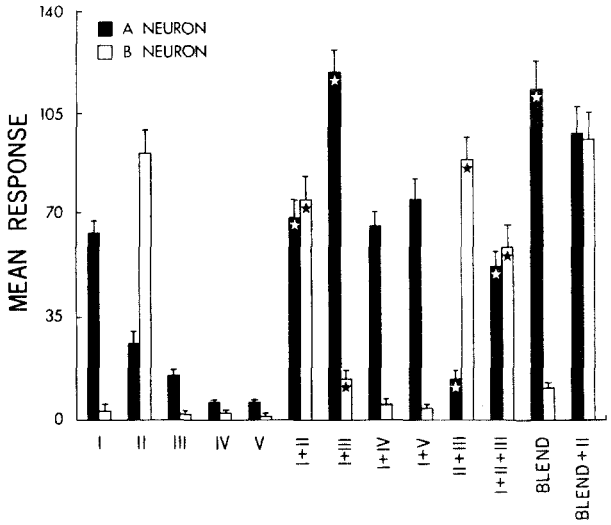

FIG. 2. The average (mean ± SEM) response (in impulses/10 sec) to the indicated single- and multiple-component stimuli. In all cases, a minimum of 12 pairs of A and B receptor neurons contributed to each mean (range 12–26). The compounds and their doses are: I = Z7-12:Ac (0.005 μg); II = Z7-12:OH (0.005 μg); III = 12:Ac (0.0005 μg); IV = Z5-12:Ac (0.0005 μg); V = Z7-14:Ac (0.00005 μg); blend = all of the compounds listed in Table 1. Statistically significant differences ($P < 0.02$, two-tailed, Wilcoxon matched-pairs signed-ranks test) between the observed and expected responses to multicomponent stimuli are starred. Cartridges containing mineral oil were on average ineffective stimuli for both A (1 ± 1 impulses/10 sec) and B (2 ± 1) receptor neurons.

mixtures was similar in both the average A and B receptor neuron. Of the five binary mixtures evaluated in this sample of HS sensilla, three elicited responses which were significantly different from the expectations of the additive model (starred bars in Figure 2). We previously demonstrated in another sample of 47 sensilla that 12:Ac has a significant synergistic effect on the magnitude of the responses elicited by Z7-12:Ac in both the A and B receptor neuron of the average HS sensillum (O'Connell, 1985b,c). We show in this sample of sensilla, similar levels of synergy and note that 12:Ac seems unique in this regard because the other two minor pheromone components examined (Z5-12:Ac and Z7-14:Ac) did not significantly alter the responses elicited in either receptor neuron when they were individually combined with Z7-12:Ac. The responses elicited in both receptor neurons, by a blend containing all six of the identified female-produced compounds, were, on average, indistinguishable from those elicited by the binary mixture containing only Z7-12:Ac and 12:Ac. In addition, the average magnitude of the A receptor neuron discharge elicited by this blend is significantly larger than would be expected from the additive model.

The responses elicited by mixtures which contain Z7–12 : OH are, on average, reliably smaller than those predicted by summing the responses obtained with the individual components of the mixture. The three-component blend (I + II + III, see Figure 2 legend) elicited responses which were, on average, smaller than those obtained with the most effective single component. The one exception observed here involved the mixture containing all seven behaviorally active compounds. In this case both receptor neurons produced responses to this complex blend which were, on average, equal to those expected from the additive model (Figure 2). The alterations in average discharge magnitude evoked in the receptor neurons by addition of Z7–12 : OH to stimuli containing various components of the pheromone blend were examined in more detail by computing a series of average response histograms. These histograms were obtained by averaging the response histograms obtained from 12 individual sensilla, each stimulated with the indicated compounds. They display the average number of impulses which occurred in successive 100-msec bins for the 5 sec immediately following stimulus onset and provide a convenient summary of the average pattern of discharge evoked by a particular stimulus.

On the left of Figure 3 we show the average responses evoked by several single and multicomponent stimuli in this sample of twelve A receptor neurons. On the right are the responses obtained in the same set of neurons for these mixtures, now with the inclusion of 0.005 μg of Z7–12 : OH. Although these response histograms are averages of the activity elicited in these 12 neurons by the indicated components, it is clear that they retain characteristic differences in both the amount of neural activity evoked and its temporal distribution from one stimulus to another. In part, these observations are in agreement with those of Grant and his colleagues who showed that individual receptor cells tend to have unique temporal patterns of discharge. Some receptor neurons respond to stimulation with a fixed dose of a selected pheromone component by producing a reasonably steady tonic level of discharge which may persist for the duration of the stimulus exposure. Others will respond to the same stimulus with an initial phasic burst of activity followed by a more prolonged tonic level of discharge even in situations where it is known that rectangular pulses of pheromone are being provided (Grant et al., 1985).

The histograms of Figure 3 also reinforce our earlier observation that the addition of 10% 12 : Ac to Z7–12 : Ac (Figure 3B) greatly enhances the amount of neural activity elicited in A receptor neurons especially when compared to the amount of activity ascribable to the presence of Z7–12 : Ac alone (Figure 3A). This increase is even more impressive in light of the relatively narrow tuning of A receptor neurons previously demonstrated in this species and the general failure of 12 : Ac to be an effective single stimulus for the two receptor neurons in HS sensilla (O'Connell et al., 1983). This ability to synergize the responses elicited in A receptor neurons is unique to 12 : Ac since the addition

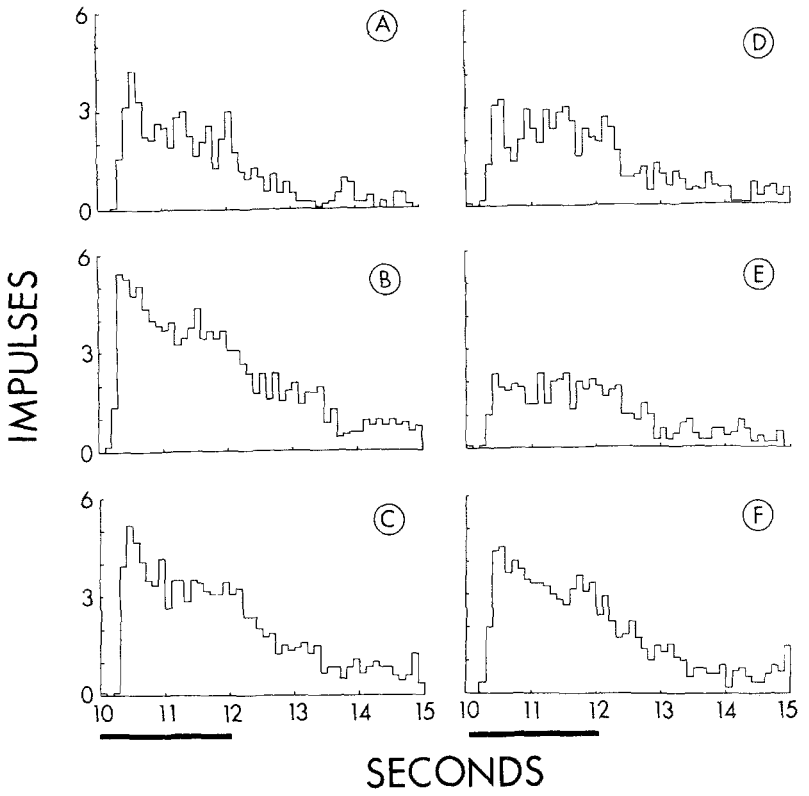

FIG. 3. Response histograms averaged across 12 individual A receptor neurons. The 2-sec stimulus period is indicated by the bars at the bottom. The stimuli evaluated include: (A) Z7-12:Ac; (B) Z7-12:Ac + 12:Ac; (C) blend (in Table 1); (D) Z7-12:Ac + Z7-12:OH; (E) Z7-12:Ac + 12:Ac + Z7-12:OH; (F) blend + Z7-12:OH.

of the remaining four female-produced compounds to the blend (Figure 3C) did not elicit an additional increase in the amount of discharge obtained when compared to that evoked by stimulation with the binary mixture (Figure 3B). However, these additional materials are not without impact on neural activity because they clearly prevent the significant reduction in discharge expected when Z7-12:OH is added to the total blend (Figure 3F). That is, the addition of Z7-12:OH to the binary mixture containing Z7-12:Ac and 12:Ac normally results in a net reduction in the response evoked by the trinary mixture (Figure 3B and E). However, the response elicited by stimulation with the total blend plus Z7-12:OH (Figure 3F) remains equivalent to that obtained with the total blend alone (Figure 3C).

The effects of these alterations can be more easily appreciated by subtract-

ing the appropriate average response histograms from each other to produce difference histograms as shown in Figure 4. Again we see that there are two significant interactions, one involving the increase elicited by the addition of 12:Ac to Z7–12:Ac (Figure 4B) and a second involving the large reduction elicited by the addition of Z7–12:OH to this binary mixture (Figure 4E). In both cases the total amount of neural discharge and its temporal pattern have been substantially altered. There is also a tendency for the alterations observed to be larger in the earlier portions of the neural discharge. It is also clear that the newly identified female-produced pheromone components do not add substantially to the response obtained with the binary mixture (Figure 4C), yet they do prevent the reduction in response expected subsequent to the addition of Z7–12:OH to the female blend (Figure 4F).

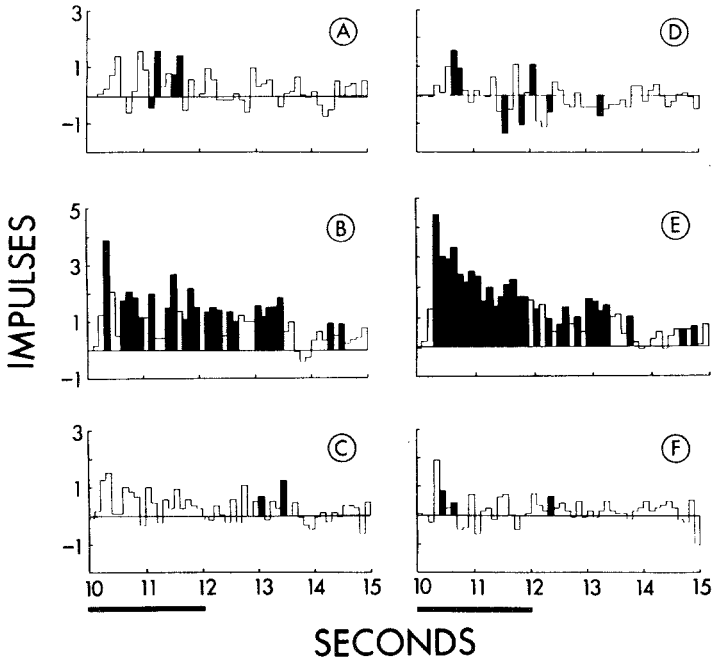

FIG. 4. Difference histograms which plot in 100-msec bins the number of action potentials remaining after two average response histograms (shown in Figure 3) have been subtracted from each other. Each of the bins with statistically significant difference scores ($P < 0.05$, one-tailed, sign test) are indicated in black. The response histograms subtracted are: (A) Z7–12:Ac + Z7–12:OH − (Z7–12:Ac + Z7–12:OH + 12:Ac); (B) Z7–12:Ac + 12:Ac − (Z7–12:Ac); (C) Z7–12:Ac + 12:Ac − (blend); (D) Z7–12:Ac − (Z7–12:Ac + Z7–12:OH); (E) Z7–12:Ac + 12:Ac − (Z7–12:Ac + 12:Ac + Z7–12:OH); (F) blend − (blend + Z7–12:OH).

DISCUSSION

Given the high level of specificity encountered historically in individual insect pheromone-receptor neuron studies, most researchers seem to assume that an *N* component pheromone blend is processed by *N* different specialized receptor neurons. Although the interactive aspects of blend perception have not often been considered in detail, multicomponent stimuli, when they have been used, usually fail to evoke unique responses in single receptor neurons beyond those which can be accounted for from a knowledge of their responses to individual components of a blend. A potential contributing factor to this failure to observe interactions among multicomponent stimuli may be the natural tendency to examine only those single-pheromone compounds which are clearly responsible for a well-defined component of male sexual behavior, are known to produce a large summated neural discharge (EAG), or are processed by specialized olfactory receptor neurons. Nearly every species so far examined produces a large number of pheromone-like compounds whose collective behavioral and electrophysiological properties are not explored in the context of a multicomponent pheromone blend because they individually fail to elicit specific behavioral responses or discriminable units of electrical activity from peripheral olfactory receptor neurons.

The four pheromone components, recently described in the female cabbage looper gland, provide a good object lesson which demonstrates the rapid increases in the chemical, behavioral, and electrophysiological complexity of pheromone communication systems. As individual stimuli, these compounds fail to elicit any of the normal components of male sexual behavior (Linn et al., 1984). They are also completely inactive when mixed together at intensities comparable to their abundance in extracts of the female pheromone gland. However, addition of the originally identified pheromone component Z7–12 : Ac to these compounds results in a five-part blend which is fully competitive with calling virgin females. Addition of the sixth female-produced compound 12 : Ac, does not elicit further significant increases in the amount of male behavior observed. If individual single components are removed from the total blend, only Z7–12 : Ac can be associated with a specific component of male behavior. As the complexity of the blend is further reduced, decrements in male behavior begin to occur in a graded fashion. The close-to-source behaviors are more affected than are those further downwind. However, it is still not possible to ascribe the absence or reduction of a particular behavioral sequence with the removal of a specific compound (Linn et al., 1984).

It is possible that the behavioral results obtained by Linn and his colleagues (1984) in the CL may represent an isolated case in which the pheromone communication system is unusually complex. However, the ever-growing list of compounds identified in individual female pheromone glands suggests that their

results may be the norm (Baker and Cardé, 1979; Baker et al., 1976; Bjostad and Roelofs, 1983). Although we have only begun to evaluate the physiological responses elicited in one of the two subsets of pheromone-sensitive sensilla by stimulation with only a few of the possible blends among the seven behaviorally active compounds, six of which are female-produced pheromone components, it is clear that our conceptualization of the neural basis for pheromone discrimination must be greatly expanded. Mixture interactions of the sort described here, at the level of primary olfactory receptor neurons, provides appropriate grist for a system in which more complex coding mechanisms may occur.

SCALE ESTERASE: A Pheromone-Degrading Enzyme from Scales of Silk Moth *Antheraea polyphemus*

RICHARD G. VOGT[1] and LYNN M. RIDDIFORD

Department of Zoology
University of Washington
Seattle, Washington 98195

(Received May 30, 1985; accepted July 29, 1985)

Abstract—Body scales of the silk moth *Antheraea polyphemus* contain an esterase which can degrade the female sex pheromone of this species. This esterase, which appears to be stabilized to the scale cuticle, is present in both sexes, but is species specific. The enzyme may play a significant role in the behaviors associated with sex-pheromone attraction, helping to filter out stimulus noise by degrading adsorbed pheromone, thus preventing adsoptive body surfaces from becoming uncontrolled pheromone sources.

Key Words—Insect, pheromone reception, sex pheromone, molecular behavior, cuticular proteins, *Antherea polyphemus*, Lepidoptera, Saturniidae.

INTRODUCTION

During their sexual flight, male moths display rapid (< 1 sec) behavioral responses to fluctuations in the ambient pheromone concentration (Kramer, 1975; Marsh et al., 1981). This temporal sensitivity suggests the presence of processes acting to maintain an overall low level of background stimulus noise. Such a process exists within the lumen of the pheromone-sensitive sensory hairs of the silk moth *Antheraea polyphemus*, where there is a potent pheromone-degrading enzyme, the sensillar esterase (Vogt and Riddiford, 1981a,b, 1985; Vogt et al., 1985). This enzyme rapidly metabolizes residual pheromone within the sensory hair, ensuring that the neuron is stimulated predominately by new, incoming pheromone.

Lipophilic pheromone molecules adsorb to the general body surface as well

[1]Current address: Department of Chemistry, SUNY, Stony Brook, NY, 11794.

0098-0331/86/0200-0469$05.00/0

as to the sensory hairs (Kasang, 1971; Mayer, 1975). Several studies have suggested the presence of enzymatic processes near the surfaces of moth bodies, which might degrade adsorbed pheromone, thus preventing the moth's body from becoming an uncontrolled pheromone source (Kasang, 1971; Mayer, 1975; Vogt and Riddiford, 1981b; Ferkovich, et al., 1982). However, none of these studies was successful in isolating the source of this "surface" enzymatic activity.

We now report that the scales covering the body surface of *A. polyphemus* possess a potent pheromone-degrading enzyme and that this enzyme can function to inactivate adsorbed pheromone. The process is present in both male and female *A. polyphemus*, but is species specific. This enzyme exists in such a manner that it may contribute significantly to preventing an individual male moth from becoming his own pheromone source or a source for other males, and it may function in the female in the control of pheromone release.

METHODS AND MATERIALS

Animals. Antheraea polyphemus, Actias luna, Hyalophora cecropia, Samia cynthia (all Fam. Saturniidae, subfam. Saturniinae), and *Automeris io* (Fam. Saturniidae, subfam. Hemileucinae) were purchased as pupae, stored in diapause at 4°C, and allowed to develop to adults at 25°C on a 18:6 light–dark cycle. *Manduca sexta* (Fam. Sphingidae, subfam. Sphinginae) were taken from our colony.

Scale Collection and Preparation. Scales were removed, using forceps, from appropriate body surfaces of recently emerged moths (1–3 days old). Care was taken not to remove underlying tissues. Scales were weighed and, for aqueous assays, suspended in detergent buffer (10 mM Tris HCl, pH 7.2, 0.1% Triton X-100). Inclusion of detergent was required to wet the otherwise highly hydrophobic scales. In general, amounts of scales processed per batch ranged from 0.5 to 20 mg, depending on species and surface of origin. To remove any soluble contaminants, scales were washed with several milliliters of detergent buffer by first suspending in 1 ml of buffer, then collecting scales on a 0.22-μm Millipore filter. Scales were rinsed with at least 2 ml of additional detergent buffer, and subsequently scraped from the filter and stored in detergent buffer in sealed vials. Scales were either stored frozen, or unfrozen at 0°C, as indicated.

Preparation of Substrates and Inhibitors. Substrates were either [11,12-^{3}H]-6*E*,11*Z*-hexadecadienyl acetate (58 Ci/mmol; prepared by Prestwich according to Prestwich et al., 1984), the major component of the *A. polyphemus* sex pheromone (Kochansky et al., 1975) or alpha-naphthyl acetate (alpha-NA). [^{3}H]Pheromone was stored in hexane at −70°C. When purity, as assessed by TLC, was <98%, the pheromone was repurified by flash chromatography (Still

et al., 1978). The pheromone was prepared for use by drying an aliquot of hexane solution under N_2 and redissolving in EtOH. An aqueous assay solution of 3×10^{-8} M pheromone was prepared by diluting 10 μl of EtOH stock (3×10^{-6} M pheromone) into 1 ml of detergent buffer using a vortex mixer. An aqueous assay solution of alpha-NA was prepared by diluting 100 μl of EtOH stock (10^{-1} M alpha-NA) into 10 ml of detergent buffer, using a vortex mixer.

Esterase inhibitors, 1,1,1-trifluoro-2-tetradecanone (TFT) (Hammock et al., 1982; Vogt et al., 1985) and *O*-ethyl-*S*-phenylphosphoramidothiolate (EPPAT) (Sparks and Hammock, 1980; Vogt et al., 1985) were supplied by Dr. T. Sparks in EtOH stock solutions (10^{-1} M inhibitor). Aqueous assay solutions were prepared by diluting 30 μl of EtOH stock into 5 ml of detergent buffer using a vortex mixer (6×10^{-4} M inhibitor).

Enzyme Assay: Pheromone. Pheromone metabolism by isolated scales was studied either in aqueous suspension (detergent buffer) or in air. Scale concentrations were as indicated in figure legends. For all assays, pheromone concentration was 10^{-8} M.

For aqueous assays utilizing endpoint kinetics (Figure 3), 100 μl of scale suspension (0.54 mg/ml) was incubated with 50 μl of aqueous [^{3}H]pheromone. Incubations were performed in 10 × 75-mm borosilicate tubes at 23°C on a rotary mixer. Four incubations were run together: three with scales and the fourth with buffer (control). At 1-min intervals, 50 μl of pheromone was added to each tube, and reactions were quenched after 5 min by addition of 150 μl of ethyl acetate (EA), mixing the contents of each using a vortex mixer for 10 sec. One EA aliquot (3 μl) was assayed for radioactivity, and two aliquots (3 μl) were chromatographed (Macherey-Nagel, Polygram SIL G/UV254, 4 × 8 cm, coated plastic). TLC plates were developed using 25% EA in hexane. Plates were loaded with unlabeled pheromone (6*E*,11*Z*-16:OAc) and pheromone product (6*E*,11*Z*-16:OH) and, after development, spots were made visible using iodine vapor (R_f 0.61 and 0.33, respectively). Spots were cut out and associated radioactivity was measured in Aquasol in a Beckman LS230 scintillation counter. Controls routinely showed $< 1\%$ radioactivity at product R_f. Velocities were determined by multiplying the alcohol/(alcohol + acetate) ratios (from TLC) by the substrate concentration. To study the effect of boiling, scales were boiled 30 min, then stored on ice for 24 hr prior to the assay.

For the aqueous assays examining pheromone degradation over time (Figure 1), the above assay was modified such that each of three borosilicate tubes initially contained 1.5 ml of scale preparation in detergent buffer and one contained detergent buffer alone (control). At $t = 0$, 0.75 ml pheromone was added. At 5, 13, 21, 31, 38, and 46 min respectively, 100 μl from each tube was transferred to 200 μl of EA and mixing was performed using a vortex mixer. One 3-μl aliquot of EA was assayed for total radioactivity and two aliquots were chromatographed as described above. At 13 min, the reaction was slowed by transferring 1.5 ml of incubation mixture to a microfuge tube and centrifug-

ing 3 min. The relatively scale-free supernatant was assayed at 21 and 31 min, respectively. At 31 min, the scale pellet amd supernatant were remixed using a vortex mixer, and the reaction was continued at full strength in the microfuge tube. The volume of the pellet was approximately 10% of the total incubation volume, such that the pellet could account for the majority of degradation which occurred during this separation period.

To study degradation of pheromone adsorbed onto wing scales from air (Table 1), scales were packed into cartridges made from the protective tips of 1 ml disposable syringes, with a pin hole at the end of each tip. A filter paper odor source containing approximately 10^{-8} g of pheromone (4 μCi) was inserted into a 1-ml syringe connected to bottled air. Cartridges containing scales and empty control cartridges were sequentially attached to the syringe for 5 min, with airflow maintained at 300 ml/min. Evaporated pheromone passing through the cartridge could adsorb either onto the scales or the walls of the cartridge. At the end of pheromone application, each cartridge was washed with 50 μl of toluene, and this wash was analyzed via TLC as described above.

Enzyme Assay: alpha-NA. Degradation of alpha-NA (Figure 2) was monitored spectrophotometrically (Varian Superscan II) at 321.5 nm (product, alpha-naphthol). Two-hundred microliters of scale suspension (0.54 mg scales) were preincubated (1 hr) in a microfuge tube (1.5 ml) with 1.2 ml of inhibitor (TFT or EPPAT, 10^{-4} M) in detergent buffer or with detergent buffer alone. The suspension was centrifuged (Beckman microfuge), and 1 ml of supernatant removed. At $t = 0$, 1 ml of alpha-NA (containing inhibitor as indicated) was added, and the contents were mixed using a vortex mixer. The final scale concentrations were 0.38 mg/ml, the initial alpha-NA concentrations were 7×10^{-4} M, and the total incubation volume was 1.4 ml. Incubations were done at 23°C on a rotary mixer. At indicated times, tubes were microfuged 2 min, and 1 ml of supernatant was transferred to a quartz cuvette and the amount of product present was measured. After measurement, the supernatant was transferred back to the microfuge tube, and scales were resuspended by vortexing. The time between initiation of a centrifugation and resuspension of scales was 12 min. At 60 min, the reaction mixture was microfuged for 4 min, the supernatant was removed and assayed, and held isolated from scales through the 90-min reading. To study the effect of freezing, scales were frozen on Dry Ice and thawed just prior to the experiment. To study the effect of boiling, scales were boiled 30 min, just prior to the experiment.

Gel Electrophoresis. Scales (1.84 mg) were washed as described above, and homogenized (BOLAB ground glass homogenizer, 0°C) in 400 μl detergent buffer. Branches of six male antennae (10.3 mg) were homogenized (200 μl). Pieces of male forewing (33.02 mg) were homogenized (400 μl). All homogenates were microfuged for 2 min, and 30-μl aliquots of the supernatants as well as of the first 1 ml of scale wash were subjected to electrophoresis on a

nondenaturing polyacrylamide slab gel (Figure 4) (0.7 mm thick, 5% stacking, 10% running, 4°C, 20 mA constant current) (Vogt and Riddiford, 1981a). After electrophoresis, the gel was reacted with alpha-NA and beta-NA in the presence of fast blue RR (Shaw and Prasad, 1970; Vogt and Riddiford, 1981a) to reveal esterase bands.

Histochemistry. Unfixed, frozen sections (16 μm) of male wings were dried (1 hr, 50°C) and reacted with the same enzyme stain used to identify esterase bands from electrophoresis. Sections were preincubated for 10 min in phosphate buffer (0.1 M, pH 7.2) or in the presence of esterase inhibitor (TFT, 2×10^{-4} M phosphate buffer). Sections were then reacted (1 hr) with the same esterase stain described above for electrophoresis, in the absence (Figure 5A) or presence (Figure 5B) of TFT (2×10^{-4} M). After staining, sections were transferred to a drop of distilled water on a microscope slide, allowed to air dry, and mounted in glycerol–gelatin. Sections were photographed under identical exposure settings on a Leitz photomicroscope using tungsten-balanced Ektachrome slide film. Figures (Figure 5) were taken from black-and-white negatives made from these slides.

RESULTS

Degradation of Air-Adsorbed Pheromone. When pheromone was blown through a cartridge of *A. polyphemus* scales (male, dorsal forewing), about 25% of the adsorbed pheromone was metabolized to the alcohol in 5 min (Table 1). In both the control cartridges and those containing scales, the residual amount of undegraded pheromone was similar (Table 1), suggesting that most of the undegraded pheromone was adsorbed to the walls of the cartridge, the airflow

TABLE 1. DEGRADATION OF AIR-ADSORBED PHEROMONE BY WING SCALES[a]

Experimental conditions	Weight scales (mg)	Total dpm recovered	% converted to alcohol

[a] Cartridges containing either scales or no scales were exposed to an airstream blown over a filter paper source containing 4 μCi of pheromone (approx. 10^{-8} mol) for 5 min, then a toluene wash of the cartridge was analyzed by TLC.

having channeled between the scale plug and the cartridge wall. Therefore, the rate of metabolism of pheromone adsorbed to the scales was probably much higher.

Degradation of Solubilized Pheromone. When *A. polyphemus* scales (male, dorsal fore-wing) were suspended in detergent buffer (0.1% Triton X-100), they were able to degrade both pheromone (Figure 1) and alpha-NA (Figure 2) to their corresponding alcohols (Vogt et al., 1985). Initial studies utilizing alpha-NA as well as beta-NA as substrates demonstrated a substrate preference for alpha-NA. Incubation of scales (0.38 mg/ml) with 10^{-4} M beta-NA (upper solubility limit) showed no degradation over 1 hr. Under otherwise identical conditions, incubations with alpha-NA at concentrations exceeding 5×10^{-5} M were required to observe degradation over 1 hr. Therefore, the highest obtainable concentration of 7×10^{-4} M alpha-NA was chosen for these assays.

This degradative process occurred within an insoluble fraction and was strongly associated with the scales, as there was a substantial reduction in activity when scales were removed from the substrate by centrifugation (Figures 1 and 2). Degradative activity was unaffected by a single freezing and thawing

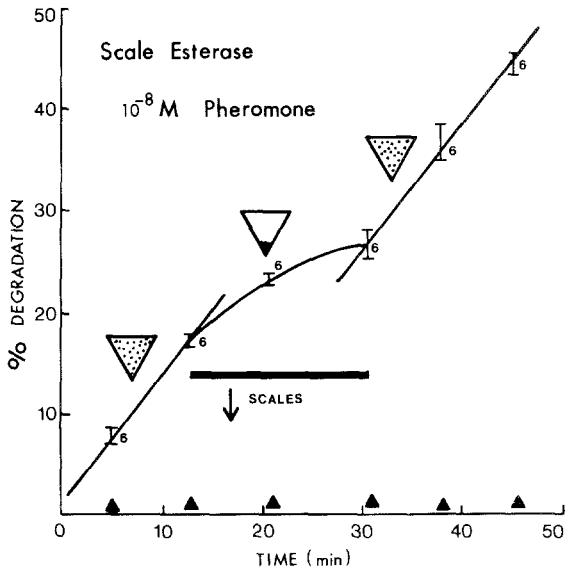

FIG. 1. Degradation of pheromone (10^{-8} M) by scales (0.9 mg/ml) of the dorsal fore-wing of male *A. polyphemus* (percentage degradation as alcohol/alcohol + acetate). At 13 min, scales were centrifuged to pellets in the bottoms of respective incubation vessels and remixed with supernatant at 31 min. The large open triangles indicate the state of dispersion of scales in the microfuge tubes during the three phases of the experiment. The small filled triangles represent control levels of radioactivity at the alcohol R_f. Data bars indicate range of data values at each time point. Each data bar represents six assays.

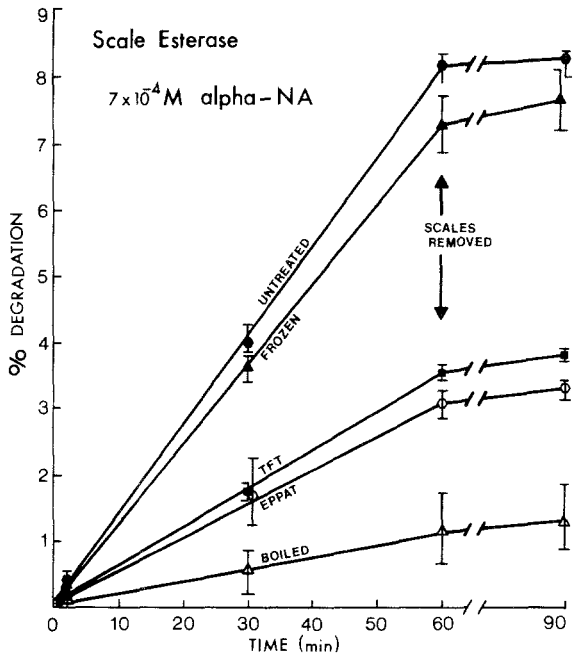

FIG. 2. Degradation of alpha-NA (7×10^{-4} M) by scales (0.36 mg/ml) of dorsal hindwing of male *A. polyphemus*. Untreated: scales were fresh, receiving no pretreatment. Frozen: scales were frozen at −20°C and thawed at room temperature prior to the assay. TFT and EPPAT: scales were preincubated in these inhibitors (10^{-4} M) for 1 hr before the assay. Boiled: scales were boiled 30 min prior to the assay. In all assays, after 60 min incubation, scales were removed from substrate by centrifugation, and the supernatant was then assayed at 90 min. The data time points are not corrected for the time required (12 min) for each set of spectrophotometric readings. Data bars indicate spread of data values at each time point. Each data bar represents the range of three assays.

(Figure 2), but was reduced by two known esterase inhibitors, TFT and EPPAT (Figure 2). Activity was also reduced by boiling for 30 min, although residual activity persisted through this treatment (Figure 2), returning to about 50% after 24 hr at 0°C (Figure 3).

Source Specificity. Degradative activity was present in scales collected from a variety of body surfaces of *A. polyphemus* (Figure 3), with the long scales of the dorsal thorax having the most activity and those of the ventral abdomen having the least. Activity was not sex specific in *A. polyphemus* (Figure 3), but did show a distinctly species-specific pattern (Figure 3). No observable esterase activity was detected from the scales of *Hyalophora cecropia*, *Actias luna*, or *Manduca sexta*, although low levels of activity (approximately 10% that of *A. polyphemus*) were detected from the scales of *Samia cynthia* and *Automeris io* (Figure 3).

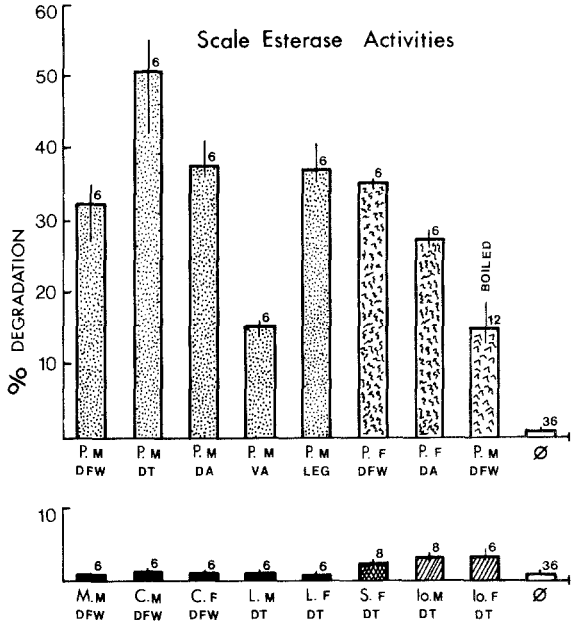

FIG. 3. Comparison of pheromone (10^{-8} M) degradation by scales (0.36 mg/ml) collected from various sources [percentage degradation over 5 min as alcohol/(alcohol + acetate)]. Species sources: P = *A. polyphemus*; M = *Manduca sexta*; C = *Hyalophora cecropia*; L = *Actius luna*; S = *Samia cynthia*; Io = *Automeris io*; "Ø" = controls (no scales). Sex is indicated by M (male) or F (female). Scale sources: DFW = dorsal forewing; DT = dorsal thorax; DA = dorsal abdomen; VA = ventral abdomen; LEG = leg. Data bars indicate range of data with accompanying numbers indicating the number of assays per data bar. The histograms represent the mean of the data. BOILED scales were previously frozen, were boiled 30 min, then stored unfrozen at 0°C for 24 hr prior to assay.

Histochemical Studies. Vogt and Riddiford (1981a) had previously reported an integumental esterase, suggesting that it might be present to degrade pheromone adsorbing to the body surface. This integumental esterase was abundant in all cuticularized tissues, including antennae and wings (Figure 4) (Vogt and Riddiford, 1981a). It was the major soluble esterase present in wings (Figure 4), degrading beta-NA and alpha-NA with comparable vigor (Vogt and Riddiford, 1981a; Vogt, unpublished). No soluble esterases from scale washes or scale homogenates were detected by gel electrophoresis (Figure 4), suggesting that the integumental esterase was not responsible for the scale-associated pheromone metabolism.

In an attempt to localize this soluble integumental esterase within the wing tissue, we reacted frozen sections of male adult wing (Figure 5) with the same

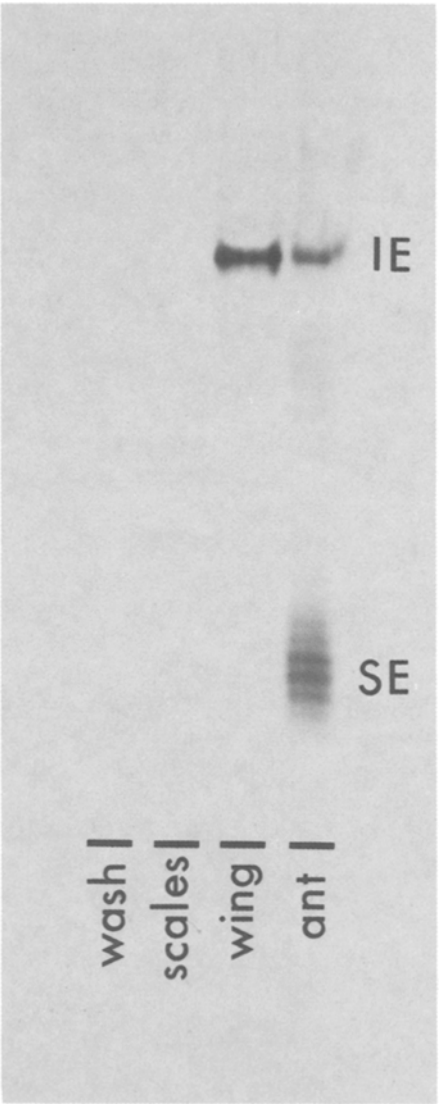

FIG. 4. Electrophoretic gel of soluble esterases released from homogenates of antennal branches (ant), forewings (wing), scales of dorsal forewing (scales), and an initial wash of these scales, all from male *A. poplyphemus*. Tissues were homogenized in detergent buffer at 0°C, and then microfuged to remove particulate matter. IE indicates integumental esterase, and SE indicates sensillar esterase (Vogt and Riddiford, 1981a). Tissue amounts per lane were: ant, 1.54 mg; wing, 2.47 mg; scales, 0.138 mg; wash, 30 μl of a 1-ml detergent wash of 1.84 mg scales. No soluble esterase activity was detectable in the scale and wash lanes.

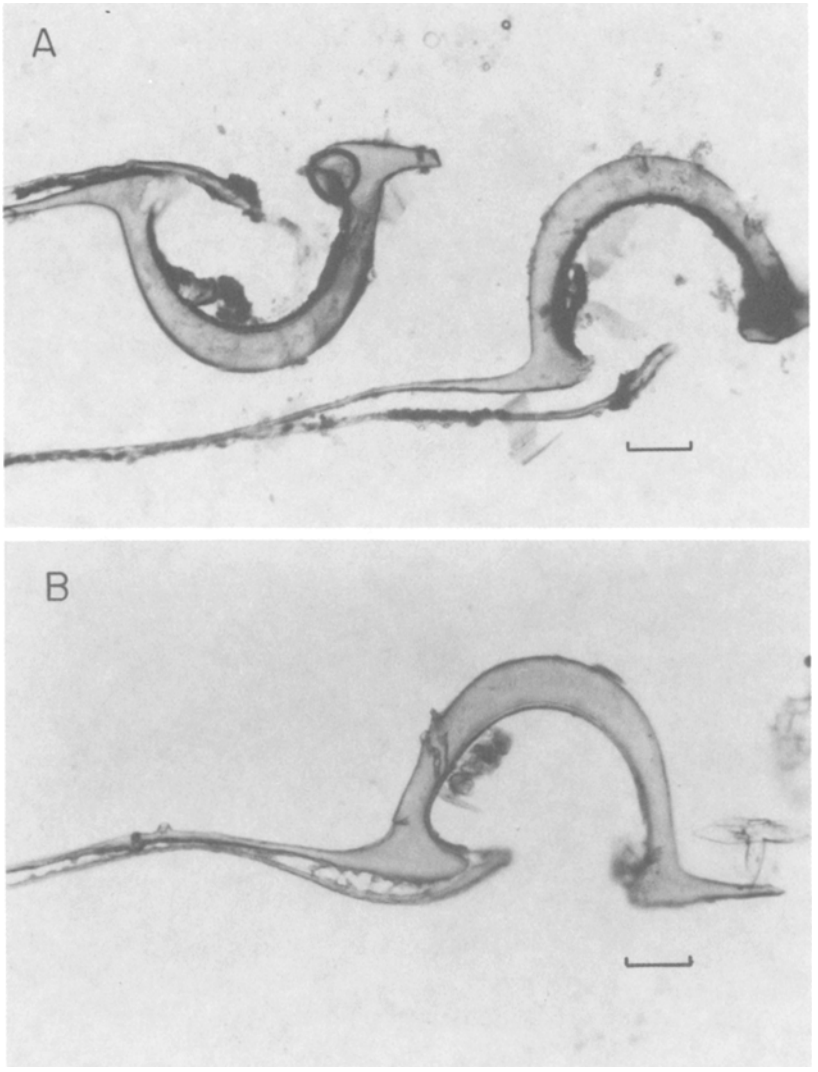

FIG. 5. Frozen sections of forewings of male *A. polyphemus*, through a wing vein. In these sections, the thin cuticle on the dorsal side of the wing vein appears broken. Figures 5A and 5B were both stained with the same esterase stain used to stain the gel in Figure 4. The section in Figure 5B was preincubated with the esterase inhibitor TFT (2×10^{-4} M, 10 min) prior to coincubation with substrate plus TFT. Esterase activity appeared as a noticeable darkening along the inside surface of the cuticle, the site of the wing epithelial cells. The size bars indicate 50 μm.

esterase stain used to stain gels (Figure 4). The stain reaction was carried out in the presence and absence of the esterase inhibitor TFT. These studies showed the presence of strong esterase activity associated with the wing epidermis (Figure 5). No definitive staining could be observed in the scales, although the pigmentation of the scales made such staining difficult to observe.

DISCUSSION

The data presented above clearly demonstrate that there is an esterase associated with the scales of *A. polyphemus* that degrades the major component of the female sex pheromone. This esterase is sensitive to specific inhibitors and to boiling, and it demonstrates substrate specificity. These findings support our earlier studies which showed that pheromone applied to the unbroken wing surface was rapidly degraded (Vogt and Riddiford, 1981b).

Previous studies have shown that homogenates or sonicates of general body parts of moths could degrade pheromone (Kasang, 1971; Mayer, 1975; Ferkovich et al., 1982). Kasang (1971) suggested that this degradation was due to surface enzymes acting to degrade adsorbed pheromone, thus preventing the animal from acting as a false pheromone source. Ferkovich et al. (1982) went so far as to suggest that enzymatic activity associated with the legs of the cabbage looper moth, *Trichoplusia ni*, might act as an antennal cleaning mechanism, where leg-associated esterases would degrade residual pheromone combed from the antenna by the legs. None of these studies, however, demonstrated the site of observed enzymatic activity.

In order for enzyme to have access to adsorbed pheromone, the enzyme must be located near the adsorptive surface of the animal. The major adsorptive surface is undoubtedly the scales, which cover the entire animal similar to shingles on a house. Considering the tremendous surface area provided by the scales, any pheromone drifting near the body surface is far more likely to adsorb onto a scale than onto the cuticle of the integument (Figure 6) (Futrelle, 1984). Our finding of a pheromone-degrading enzyme associated with the body scales of *A. polyphemus* satisfies this requirement.

This scale esterase appears to be cross-linked to the scale cuticle, presumably having been secreted with the other cuticle proteins at the time of scale formation (Greenstein, 1971). There are apparently no cellular structures present in adult scales (Greenstein, 1971). The esterase was quite stable in detergent buffer (Figures 1–3), with no activity being liberated after homogenization in Triton X-100 (Figure 4). Although activity was severely reduced by prolonged boiling (Figure 2), much of the activity returned after 24 hr at 0°C (Figure 3), suggesting that the enzyme's association with other cuticle elements may have helped to stabilize and protect it.

This insoluble scale esterase is clearly different from the soluble integumental esterase that we previously obtained from various *A. polyphemus* tissues (Vogt and Riddiford, 1981a). The histochemical studies show that the soluble esterase is restricted to the wing epidermis. This latter esterase is likely a more general esterase associated with cytoplasmic functions, and only happens to degrade the pheromone. Of course, it could also degrade any pheromone which happened to penetrate through the cuticle.

Does this scale esterase truly have a role in pheromone processing prior to mating? Certainly the esterase shows a strong substrate preference in favor of pheromone over alpha-NA. Wing scales degraded greater than 30% of 10^{-8} M pheromone in 5 min (Figure 3), while requiring in excess of 5×10^{-5} M alpha-NA to generate any observable degradation. Technically, alpha-NA degradation is easily monitored at concentrations well below 10^{-5} M (Vogt et al., 1985). The species specificity of the esterase also argues in favor of its role in phero-

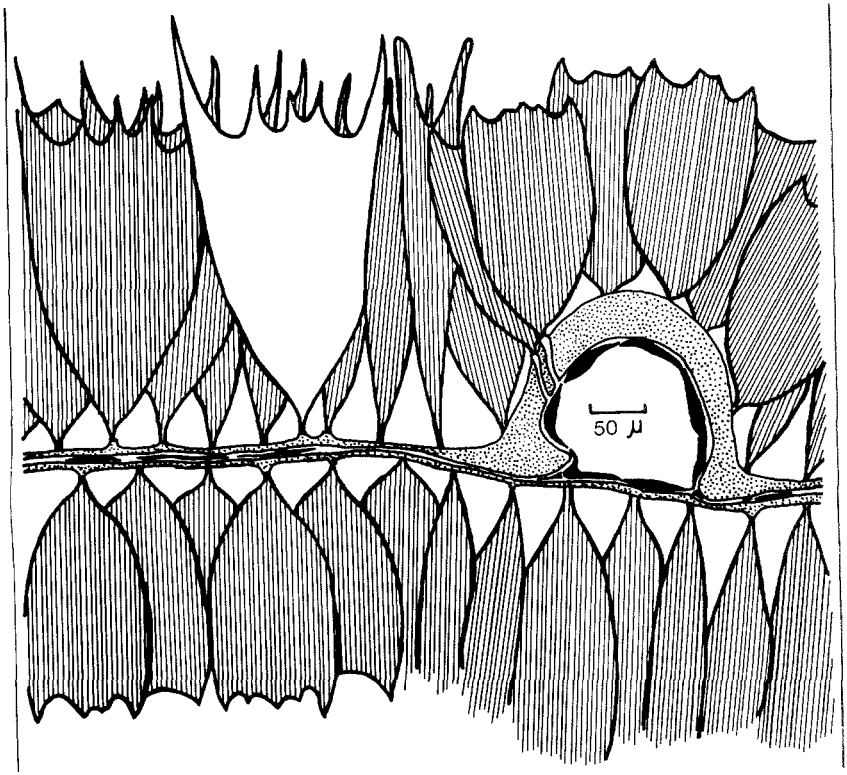

FIG. 6. Schematic diagram of a wing of *A. polyphemus*, showing the density and size relationships of scales to wing cuticle. Scales normally lie flat, overlapping each other such that there are two layers of scale covering the integumental cuticle.

mone processing. Esterase activity was either extremely low or completely absent in scales of *A. luna*, *H. cecropia*, and *S. cynthia*, all closely related species of the same subfamily as *A. polyphemus*, as well as *A. io* and *M. sexta*, somewhat more distantly related species. This pattern of species specificity suggests that the esterase does not have some general role in scale cuticle formation or pigmentation.

However, even if the esterase does have a function other than degrading pheromone, we have shown that if pheromone adsorbs to esterase-containing scales, it is degraded. Clearly then, the esterase can function in reducing background noise. How significant is this contribution in noise reduction to the precopulatory behaviors of these animals? If one considers the importance of the precopulatory sex-attractant behaviors of both males and females in terms of the selection of gene form, even the slightest contribution by the scale esterase could be quite significant. Certainly, in the present study the scale esterase was examined at a pheromone concentration (10^{-8} M) that was well within the physiological range of pheromone-sensitive sensory hair function, and nearly four orders of magnitude above the physiological threshold of these same sensory hairs (Vogt et al., 1985).

Furthermore, realizing the differences between the male and female precopulatory behaviors, the esterase may serve the sexes differently. For the male, the enzyme could function behaviorally to prevent an individual moth from becoming his own pheromone source. To other males, the enzyme could function to ensure that the local attractant source is indeed a female. And to the female, the enzyme could function to ensure control of pheromone release, allowing only pheromone from the secreting gland to leave the female undegraded. It should be noted, however, that for different moth species, the degree of control over such parameters may differ as a function of the selective pressures placed on the evolution of the relevant behavioral strategies.

It seems possible that, in the evolutionary design of the behaviors associated with sex-pheromone attraction, a single biochemical reaction may have assumed a role in more than one aspect of this sexually selected behavior. Recalling the noise-reducing role of the sensillar esterase of the pheromone-sensitive sensory hairs (Vogt et al., 1985), our findings suggest that, in the evolutionary design of the sex-pheromone attraction/reception process, multiple biochemical reactions have become optimized to maintain an overall low signal-noise level in order to maximize the efficiency of response during pheromone-elicited flight orientation.

Acknowledgments—We thank Profs. J. Edwards and J. Truman and Drs. G. Kasang and R. Preiss for their helpful discussions, Dr. T. Sparks and Prof. B. Hammock for supplying the esterase inhibitors, and especially Prof. G. Prestwich for isotopes, assays, and his ever-enthusiastic support and encouragement. METABOLISM OF PHEROMONE COMPONENTS AND ANALOGS BY CUTICULAR ENZYMES OF *Choristoneura fumiferana*

GREG C. LONERGAN

Department of Chemistry
University of New Brunswick
Fredericton, New Brunswick, Canada

(Received May 30, 1985; accepted August 1, 1985)

Abstract—In vivo incubation of *Choristoneura fumiferana* with (*E*)-11-tetradecenal, the major pheromone component, resulted in adsorption followed by transformation to (*E*)-11-tetradecenoic acid, the only observed metabolite. Antennae, legs, and wings from both sexes were investigated for enzyme activity. Specificity studies with the aldehyde dehydrogenase system showed that the enzyme prefers aldehydes of 14-carbon chain length or shorter.

Key Words—*Choristoneura fumiferana*, Lepidoptera, Tortricidae, pheromone components, pheromone metabolites, aldehyde dehydrogenase.

INTRODUCTION

There have been several studies undertaken in recent years aimed at elucidating the mechanisms involved in insect pheromone perception. However, this has proven not to be a simple and straightforward task. Although substantial progress has been achieved towards this goal and a framework has been established on which future research will undoubtedly be based, there are still many aspects of these processes that must be clarified.

The sequence begins with the biosynthesis and release of volatile components from within the pheromone-producing gland (usually female). These components are normally transported by air currents to the vicinity of a recipient moth, then are adsorbed onto antennae and body tissue. The sequence culminates in the transduction process and finally degradation and deactivation of the active components occurs to complete the cycle. Some of these processes have been studied in several insect species, particularly *Antheraea polyphemus* (Vogt

0098-0331/86/0200-0483$05.00/0

and Riddiford, 1981; Kanaujia and Kaissling, 1985), *Trichoplusia ni* (Ferkovich *et al.*, 1982) and *Choristoneura fumiferana* (Percy, 1974; Silk *et al.*, 1980; Morse *et al.*, 1982), yet our understanding of them still falls short, particularly in the area of transduction (Villet, 1978).

The eastern spruce budworm moth (*Choristoneura fumiferana*) (Lepidoptera: Tortricidae) inhabits most forests of Canada and the northeastern United States; it is one of the most economically devastating insect pests, feeding on and eventually destroying spruce and fir in these areas. The primary pheromone components were initially identified (Weatherston et al., 1971; Sanders and Weatherston, 1976) and shown to consist of a mixture of 96:4 *E/Z* 11-tetradecenal. This pheromone system was later reevaluated (Silk et al., 1980; Alford et al., 1983) and shown to contain the additional minor component, tetradecanal as 2% in the blend. As for the biosynthesis and release of these pheromone components, some aspects have been investigated by Morse and Meighen. They report the identification of biosynthetic and degradative enzymes in the gland, and the evidence suggests the presence of an acetate ester precursor to the aldehyde pheromone components (Morse and Meighen, 1984a,b).

The findings reported in this paper result from an examination of the interaction of pheromone components with the cuticular surfaces after intial contact with the recipient moth. The first event is the adsorption of pheromone molecules onto all the surface tissues. Some of the molecules adsorbed on the antennal sensilla are transported through pore openings to the interior of the hairs. A percentage of the molecules will reach the vicinity of the receptor proteins associated with the dendritic portions of the sensory neurons which innervate these sensilla hairs (Kaissling, 1974). Presumably after inducing transduction, the stimulant molecule is inactivated by complexation with binding proteins, by enzymatic degradation, or both.

The first problem to be addressed concerns the fate of the pheromone molecules that do not participate in the transduction process; that is, those molecules that do not enter the pores. If the pheromone components bound to the cuticular surfaces readily desorb, this would provide false sensory information, whereas if they accumulate and remain bound indefinitely, this could lead to system inefficiency and overload in high-density populations. The most reasonable consequence would be enzymatic degradation of the components to inactive compounds.

This study identifies the primary degradation product of the major pheromone component (*E*)-11-tetradecenal, as (*E*)-11-tetradecenoic acid. The metabolic transformation is consistent with the presence of a dehydrogenase system on all the cuticular tissues examined—antennae, legs, and wings (Morse and Meighen, 1984a). The study also indicates that the enzyme system is active in female tissues as well as in the male, but to a lesser degree. An estimate of the rate and turnover capabilities to the various tissues are examined and compared.

Experiments have also been designed to determine the metabolic selectivity of the enzyme system towards the aldehyde pheromone components and several other aldehyde analogs. In addition to the aldehyde metabolism studies, bioassays have been carried out with (*E*)-11-tetradecenol and (*E*)-11-tetradecenyl acetate (previously shown to be behaviorally and electrophysiologically active) (Sanders et al., 1972; Sanders and Weatherston, 1976; Priesner, 1979), to determine if oxidase and esterase enzyme systems are present on the cuticular surface.

METHODS AND MATERIALS

Insects. Second-instar spruce budworm larvae from Great Lakes Forestry Research Laboratory, Sault Ste. Marie, Ontario, were reared on a synthetic diet (Harvey and Gaudet, 1977). The pupae were sexed and placed in separate rearing rooms. The adults were maintained on a 17:7-hr light–dark cycle (5.1–8.4 lux at 23–25°C, relative humidity 60%) and were collected daily.

Tissue. Moths 2–3 days old were used for both the in vitro and in vivo experiments. For in vitro studies, the moths were anesthetized by freezing at −15°C for 10 min. The leg and antenna tissues were removed with forceps, while the wings were excised with a razor blade and were used for bioassay immediately after their removal. For the in vivo tests, on the other hand, upon completion of the bioassay, the moths were anesthetized by freezing, and the tissues were removed and analyzed.

Pheromone Components. (*E*)- and (*Z*)-11-Tetradecenal were prepared by the following procedure. 1,10-Decane diol was treated with HBr (50%) at 95°C, and the monobrominated product was continuously extracted from the reaction medium with heptane (Pattison et al., 1956). The 10-bromodecanol was protected with dihydropyran in the presence of *p*-toluenesulfonic acid catalyst and subsequently alkylated with butyne in THF/*n*-butyllithium at 0°C (Hendry et al., 1975). The tetrahydropyranyl protecting group was removed in aqueous acidic methanol, and the resulting 11-tetradecyne-1-ol was hydrogenated under 40 lb/in^2 of hydrogen with the catalyst palladium on barium sulfate (10%) poisoned with pyridine in methanol (Su et al., 1973). These hydrogenating conditions produced the 11-tetradecen-1-ols with a *E*/*Z* ratio of 60:40, respectively, as indicated by gas chromatography. These *Z* and *E* isomers were separated on a silver nitrate-impregnated acidic resin column by elution with methanol (Houx et al., 1974). Compounds with greater than 99.5% isomeric purity were obtained as determined by GC analysis on a SP1000 capillary column. (*E*)- and (*Z*)-tetradecenols were oxidized to the corresponding aldehydes with pyridinium chlorochromate (PCC) in methylene chloride (Corey and Suggs, 1975). Tetradecanal was prepared by the oxidation of tetradecanol (Aldrich) with PCC in methylene chloride buffered with sodium acetate.

Analogs. 13-Tetradecenal was obtained as follows. Bromododecanol was prepared from 1,12-dodecane diol using the described HBr procedure, and the alcohol moiety was protected as the pyranyl ether. The bromide was then alkylated using a lithium acetylide–ethylene diamine complex in DMSO to give 13-tetradecynol (Dear and Pattison, 1963). Then deprotection of the alcohol, as above, followed by hydrogenation with 1 atm H_2 catalyzed by palladium on carbon (10%) in methanol produced 13-tetradecenol. Finally oxidation with PCC yielded the 13-tetradecenal. Hexadecanal, pentadecanal, tridecanal, and dodecanal were all prepared from the respective alcohol precursors (Aldrich) by the PCC oxidation procedure. (*E*)-11-Hexadecanal was obtained from 1,12-dodecane diol by a procedure similar to that described for the preparation of 11-tetradecenal. (*Z*)-11-Hexadecenal was obtained from Aldrich. (*E*)-11-Tetradecenol was obtained as an intermediate in the synthesis of 11-tetradecenal as described above. (*E*)-11-Tetradecenyl acetate was prepared by acetylation of (*E*)-11-tetradecenol with acetic anhydride–pyridine.

The intermediates and final products were purified by flash column chromatography (Kieselgel 60, 230–400 mesh) (hexane–ethyl acetate gradient solvent system) (Still et al., 1978). Nuclear magnetic resonance analysis was performed on either a Varian T60 or Varian XL200 instrument. The infrared spectra were obtained from a Perkin-Elmer 598 spectrophotometer. GC analyses were carried out using a Varian 6000 gas chromatography/capillary system and the GC-MS analyses were performed with a Finnigan 4021 EI-CI system coupled with an INCOS data system.

Pheromone Component and Analog Assay Solutions. Organic stock solutions of pheromone components and analogs were prepared by dissolving 10 mg of the compound in 1000 μl of hexane. The aqueous solutions to be used for in vitro bioassays were obtained by placing 10 μl of the organic stock solution in a 3-ml glass vial, evaporating the hexane under dry nitrogen flow, adding 1000 μl of distilled water and, finally, vortexing for 5 min at room temperature. The aqueous samples were immediately utilized in the assay. The components used for the in vivo bioassay were applied in neat form to filter paper.

Buffer–Cofactor Solutions. The phosphate buffer pH 7.4 was prepared by mixing 2.9 ml of 0.5 M NaH_2PO_4 and 12.4 ml of 0.5 M Na_2HPO_4 and diluting to 100 ml. A solution of 3 mM NAD^+ was prepared by dissolving 100 mg NAD^+ in 50 ml of phosphate buffer solution. The buffer solutions were stored at 2°C.

In Vivo Assays. The incubations were performed in crystallizing dishes 150 × 75 mm. A circle of filter paper (Whatman quality No. 1) was placed at the bottom of the container, and the assay component was spotted on the paper in neat form. A wire screen was positioned 2 cm above the filter paper (to prevent direct moth contact with the applied test component), and the dish was topped

with a large watch glass. After 5 min of equilibration, the moths were quickly placed in the assay chamber and the glass lid replaced. The experiments were run from 0.25 to 8 hr, after which time the moths were anesthetized and the tissue removed and washed several times with ether. The extracting solvent was concentrated under N_2 flow to 200 μl in the cases of both the antenna and leg extracts and to 1000 μl in the case of the wing extracts. Then 50 μl of diazomethane solution (Fieser and Fieser, 1967) was added to each of the concentrated extracts to convert the free acids to GC-detectable methyl esters. Two control assays were run: one in which the assay chamber contained moths and no substrate, the other in which the chamber contained substrate and no moths. The extracts were analyzed by the GC techniques described in the analysis section.

In Vitro Assay. In the bioassays utilizing intact tissue, the antennae, prothoracic legs, and metathoracic legs from 10 moths were placed in 10 × 75-mm culture tubes. To these tubes were added solutions of NAD^+ phosphate buffer (150 μl) and the aqueous substrate (150 μl, 10 μg). A fourth tube in which the tissue was omitted was used as a control. These assays provided a substrate concentration of $\sim 6 \times 10^{-5}$ M. The culture tubes were vortexed at 10-min intervals during the 1- and 2-hr incubation periods. At the end of these periods, the assay mixture was extracted with 3 × 500 μl portions of ether, then the solvent was concentrated to 200 μl under a slow stream of dry N_2. A diazomethane solution (150 μl) was added, and the extract was analyzed by GC-MS and GC.

Bioassays of homogenized tissue were employed to compare the activity of homogenized versus intact tissue. These bioassays differed from the intact tissue bioassays only in that the prothoracic legs were not assayed. The tissue was homogenized with a ground-glass hand homogenizer (3 ml), and the incubation was performed in the homogenizing tube.

Selectivity studies were carried out to determine if the dehydrogenase enzyme system displayed substrate specificity. The pheromone components and the analogs were assayed in a 1 : 1 concentration ratio with (*E*)-11-tetradecenal. The bioassays were performed with homogenized and intact tissues from 10 pairs each of antennae and metathoracic legs from 10 moths. The duration of the assays was 1 hr in the case of intact tissue and 15 min for the homogenized tissue. The shorter bioassay period for the homogenized tissue was necessary because of its higher rate of metabolism, and it was desired that only 50% of total substrate be metabolized. At 3×10^{-5} M concentration, 85% of the (*E*)-11-tetradecenal substrate was converted to the corresponding (*E*)-11-tetradecenoic acid during the incubation periods. Therefore a 2×10^{-5} M concentration each of both the analog and (*E*)-11-tetradecenal was employed.

In vitro bioassays with (*E*)-11-tetradecenol and (*E*)-11-tetradecenyl acetate were employed to determine if oxidase or esterase enzyme systems, respec-

tively, were operating on or within the antennae and legs. Antennae and legs from 20 moths were excised for these bioassays. Both homogenized and intact tissues were incubated for 1 hr at a substrate concentration of 6×10^{-5} M.

Bioassay Analysis. All bioassays were performed in triplicate and controls were run simultaneously for all experiments. The crude ether extracts were treated with a diazomethane solution to methylate the free acids prior to GC analysis. As a check for solvent efficiency, the tissue was additionally extracted in several runs with hexane and methylene chloride; however, these solvents were not superior to the ether normally used for the extractions.

The GC analyses were performed on a Varian 6000 gas chromatograph equipped with a flame ionization detector; helium was used as carrier gas at an inlet pressure of 0.9 kg/cm^2 (3 ml/min). An SP1000 (50 m $\times$ 0.5 mm) capillary column was used in conjunction with a split injection mode (1 : 5). Temperature 120°/2 min/Rate 8°/150°. Detection limits: 1 ng. The GC-MS analyses were carried out on a Finnigan 4021 EI-CI-INCOS system using a DB5 (30 m $\times$ 0.32 mm) capillary column. Helium was used as the carrier gas with injections via a Grob injector. Temperature 50°/2 min/Rate 10°/150°/Rate 20/220. Detection limits: 1 ng.

The GC peaks were identified and quantitated by a comparison of peak heights with those from internal (pentadecanoic acid methyl ester) and external [(*E*)-11-tetradecenoic acid methyl ester] standards. GC injections of each assay were replicated at least twice. The GC-MS analyses were not necessarily replicated.

RESULTS

In Vivo Metabolism. In order to investigate the metabolism of the primary pheromone components (95 : 5, *E*/*Z* 11-tetradecenal), an in vivo bioassay was designed in which the air surrounding the moths was permeated with these components. It was desirable to look for the formation of degradation products under natural conditions. Although the quantity of applied pheromone was unnaturally high, the moths were unrestricted in their movement within the assay chamber. These conditions avoided the use of an aqueous environment which could alter the adsorption and metabolism of the pheromone components.

Initially the bioassay was performed with ten 2-day-old male moths and with a filter paper source concentration of 100 mg of pheromone. The bioassay was run for 2 hr after which time the moths were anesthetized and the tissues removed and analyzed for degradation products. Under these conditions, only one metabolized product was detected by GC-MS analysis, (*E*) 11-tetradecenoic acid (Figure 1).

Experiments were then carried out to quantitate the activity of the enzyme responsible for the observed degradation. To accomplish this, bioassays were

run for 0.25, 0.5, 1, 2, 3, and 8 hr duration, with a saturating source concentration of pheromone. [Saturating concentration of pheromone = the maximum amount (mg) that could be employed without anesthetizing the moths; thus, a source concentration of ca. 400 mg was maintained during the assay period.] At higher pheromone concentrations the moths were anesthetized by the pheromone. The quantity of 11-tetradecenoic acid metabolite recovered from each incubation period was found to increase exponentially with time for both the male and female tissues (Figures 2 and 3). In addition, it appears that the acid

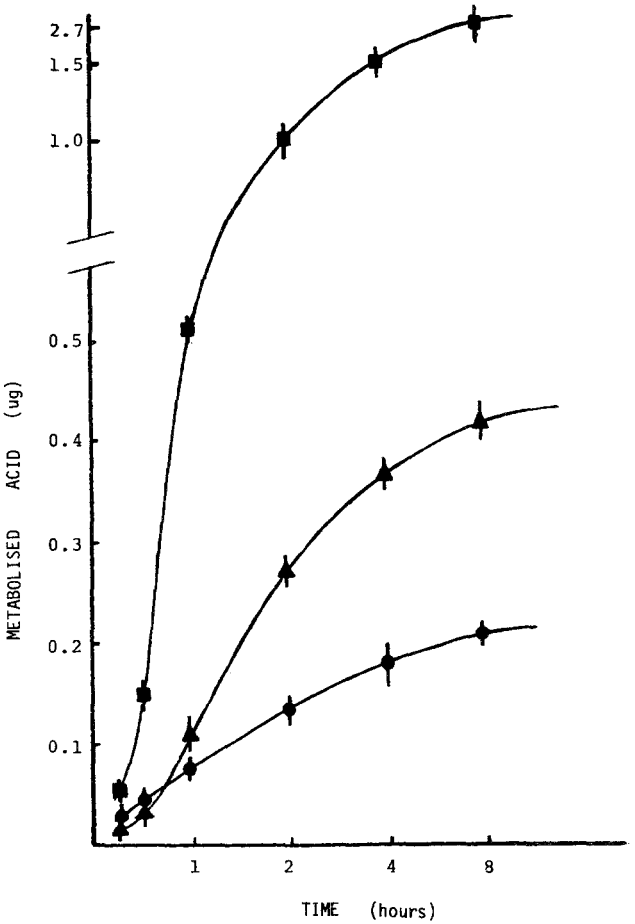

FIG. 2. In vivo formation of 11-tetradecenoic acid metabolite by male tissue. The data represent the mean value (μg) of acid obtained from 20 antennae ●, 20 metathoracic legs ▲, and 20 forewings ■. The curves fit a true exponential as determined by linear regression calculations. Bars represent standard deviation.

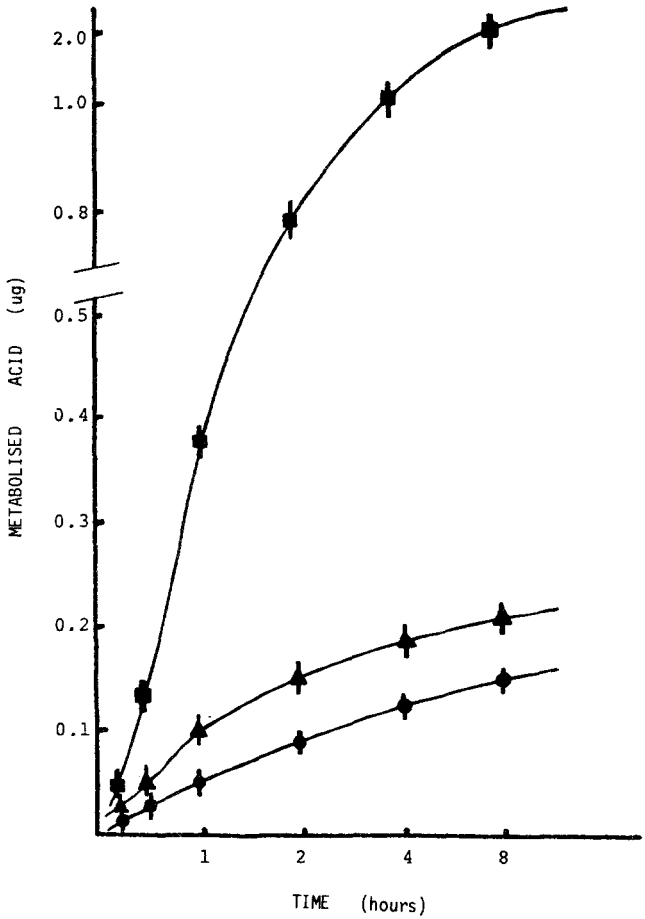

FIG. 3. In vivo formation of 11-tetradecenoic acid metabolite by female tissue. The data represent the mean value (μg) of acid obtained from 20 antennae ●, 20 metathoracic legs ▲, and 20 forewings ■. Bars represent standard deviation.

is either desorbed or converted to as yet unknown metabolite(s) (Figure 4). A study to determine whether this acid metabolite is biologically or behaviorally active or if it is further metabolized is now underway.

From the curves in Figures 3 and 4, it is evident that the decrease in amount of the acid does not entirely account for the exponential degradation of the aldehyde. It is possible that the enzyme responsible for aldehyde metabolism is restricted by the large quantities of aldehyde and acid present on the tissues.

The metabolic rates for the enzyme of the various tissues examined were calculated for the first 30-min incubation period. In the bioassays of these du-

rations, it appears (Figure 4) that the acid catabolism is not a significant factor. The following rate values are estimates made from the curves in Figures 2 and 3: (1) 1.0×10^{-13} M/sec/male metathoracic leg (350 μg), (2) 1.2×10^{-13} M/sec/male antenna (25 μg), (3) 4×10^{-13} M/sec/male forewing (490 μg), (4) 9.5×10^{-14} M/sec/female metathoracic leg (340 μg), (5) 8×10^{-14} M/sec/female antenna (20 μg), and (6) 3.4×10^{-13} M/sec/female forewing (500 μg).

Despite the fact that the metathoracic legs are 15× heavier and have a surface area ~10× greater than the antennae, the rate of metabolism of the aldehyde is very similar for both these tissues. This result may be accounted for if the antenna either has a greater number of dehydrogenase enzymes per unit area or if the antennal enzyme is more active. Whichever the case, it is

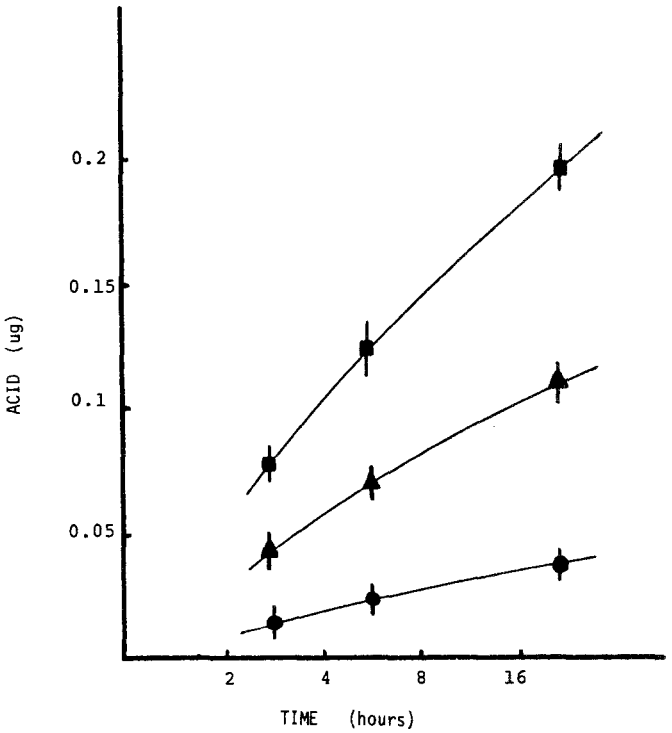

FIG. 4. 11-tetradecenoic acid removal from male tissue. The values represent the mean value (μg) of acid lost from 20 antennae ●, 20 metathoracic legs ▲, and 20 forewings ■. Standard deviations represented by bars. 40 male moths were incubated with pheromone (400 mg) for 2 hr at which time 10 moths were removed and the acid metabolite quantitated (initial acid concentration). Also at 2 hr, the remaining 30 moths were transferred to a clean chamber. After 3 hr, 10 moths were removed and the acid metabolite quantitated. This was repeated at 6 and 20 hr.

probably a reflection of the need for a quicker and more efficient removal of excess aldehyde from the antenna.

The above consideration may explain the slightly slower rate of metabolism by the female tissues as compared to the male. The female *Choristoneura fumiferana* perceive their own pheromone as determined by electrophysiological and behavioral studies (Palaniswamy and Seabrook, 1978). However, the removal of excess pheromone may not be as crucial to females versus males, since the females do no fly upwind in pheromone plumes. Perception of their own pheromone may be useful in monitoring the density of calling females in the area and may affect their calling behavior and emigration.

In Vitro Metabolism—Intact versus Homogenized Tissues. Aqueous incubations of antennae and pro- and metathoracic legs were carried out with pheromone concentrations of 6×10^{-5} M. The activities of intact and homogenized tissues were compared (Table 1). It was found, as in the case of the in vivo studies, that the intact antennae and intact metathoracic legs displayed similar enzymatic activity under aqueous conditions. The prothoracic legs produced slightly less metabolite than the metathoracic legs: perhaps a reflection of their smaller size.

When homogenized tissue was bioassayed, the quantity of recovered metabolite increased substantially, particularly in the case of homogenized antennae (from 28% to 75% conversion for a 1-hr incubation period). This increase in enzymatic activity is probably due to the release of enzymes from within the interior of the antenna upon homogenization. As additional supportive evidence that the degradation taking place with the intact tissue is the result of cuticular enzyme activity, the following additional experiments were conducted. First, scales (2 mg) from male wings were incubated with (*E*)-11-tetradecenal for 1 hr, and a 22% conversion of aldehyde to acid took place. Secondly, following several intact tissue bioassays (antennae and legs) and subsequent ether extraction, the tissue was homogenized and additionally extracted with ether. However, no significant increase in acid metabolite was observed.

TABLE 1. IN VITRO PHEROMONE METABOLISM[a]

				Metathoracic	
	Intact	Homogenized	Prothoracic, intact	Intact	Homogenized
1	28 ± 5	75 ± 6	24 ± 6	30 ± 5	40 ± 7
2	53 ± 5	90 ± 8	45 ± 6	59 ± 9	70 ± 4

[a] Values expressed as percentage conversion of (*E*)-11-tetradecenal to (*E*)-11-tetradecenoic acid (mean ± SD). Three replicates of 10 moths for each bioassay bioassayed at pheromone concentration of 6×10^{-5} M.

In Vitro Metabolism—Competitive Analog Assay. To determine whether the dehydrogenase enzyme displayed selectivity for the pheromone components, a number of 12- to 16-carbon analogs were competitively assayed with the (*E*)-11-tetradecenal standard. The percentage conversions of aldehyde to acid for intact and homogenized tissues are presented in Table 2. At a concentration of 2×10^{-6} M, the 12-, 13-, and 14-carbon analogs were equally good substrates as (*E*)-11-tetradecenal. On the other hand, the enzyme showed less discrimination for the 15-carbon substrate with only a 25% conversion to acid after 1 hr with intact tissue as compared to a concurrent 70% conversion of (*E*)-11-tetradecenal. In the case of the 16-carbon analogs, the enzyme showed complete selectivity for the 14-carbon standard. It appears that the presence or position of the double bond in the substrate is not a factor influencing metabolism, whereas the addition of one carbon creates a serious disadvantage. Two extra carbons in the chain renders the analog an inactive substrate.

When the bioassays were conducted with homogenized tissue, the rate of

[a] Values expressed as percentage conversion to acid metabolite (mean ± SD). Three replicates of 10 moths for each bioassay.

[b] Analogs were bioassayed at 2×10^{-5} M concentration in the presence of (*E*)-11-tetradecenal, also at 2×10^{-5} M.

[c] Intact tissue bioassay duration = 1 hr at room temperature.

[d] Homogenized tissue bioassay duration = 15 min at room temperature for antennae, 30 min at room temperature for legs.

[e] At 2×10^{-5} M in presence of analog; the average of 28 bioassays with the five "good" competitive substrates. At 2×10^{-5} M, (*E*)-11-tetradecenal alone was 85% converted to the acid.

[f] Controls were simultaneously run for all the subtrates.

[g] Tissue heated at 80°C for 20 min prior to bioassay to determine at what temperature the enzyme is heat labile.

metabolism increased by a factor of three, but the selectivity trends were similar to those found for the intact tissues.

Other Enzyme Systems. Bioassays were carried out to determine if other enzyme systems were operating on the tissues studied. The existence of oxidase and esterase enzymes has been found in the pheromone-producing gland and other tissues of the female (Morse and Meighen, 1984a). Esterase, alcohol dehydrogenase, and oxidase enzymes have been found in the antenna and leg tissues of male *Heliothis virescens* whose pheromone consists in part as a 97 : 3 blend of (*Z*)-11-hexadecenal and (*Z*)-9-tetradecenal (Ding and Prestwich, 1985; Klun et al., 1980). However, in bioassays in which homogenized male antennae and legs were incubated with (*E*)-11-tetradecenol and (*E*)-11-tetradecenyl acetate, respectively, only unreacted substrate was recovered in 90% yield. It appears that the sensitivity of the methods employed was not adequate to enable the detection of small quantities of metabolites. A more extensive search for these enzyme systems using radiolabeled substrates is now under investigation.

CONCLUSIONS

The primary degradation product formed by enzymatic metabolism of 11-tetradecenal on cuticular surfaces, including antennae, legs, and wings, is the corresponding 11-tetradecenoic acid. This enzyme system undoubtedly serves a clearing function, to keep the body tissue free of excess pheromone. Whether this same enzyme is found in the interior of the antenna, where its function would be connected with the transduction process, is not clear. The bioassays utilizing homogenized antenna tissue do suggest that this enzyme may be operating inside the sensilla or antenna or both.

Acknowledgments—Dr. W.D. Seabrook is acknowledged for supplying the spruce budworm moths used in this study. Thanks to Dr. Colleen Northcott for technical assistance.

REPRODUCTIVE ENDOCRINE INFLUENCES UPON OLFACTORY PERCEPTION: A Current Perspective[1,2]

RICHARD L. DOTY

Smell and Taste Center, Department of Physiology, and Department of Otorhinolaryngology and Human Communication School of Medicine, University of Pennsylvania Philadelphia, Pennsylvania 19104

(Received May 16, 1985; accepted August 1, 1985)

Abstract—An overview of relationships between psychophysical measures of olfactory function and reproductive neuroendocrine processes is presented. Human studies are emphasized, and the influences of gender, menstrual cycle phase, pregnancy, and injected gonadal hormones upon olfactory perception are discussed in detail.

Key Words—Pregnancy, olfactory threshold, odor preferences, hormones, estrous cycle, menstrual cycle, pheromone, UPSIT, sex differences.

INTRODUCTION

Hormones and other neuroendocrine factors influence not only the nature and deposition of biological secretions used in mammalian social communication, but also the sensory systems involved in detecting such materials and extracting information from them. Despite this fact, the anatomic, physiologic, or chemical substrates of neuroendocrine influences upon chemosensory function are largely unexplored. Such influences have been particularly difficult to establish in nonhuman mammals, since rather complex equipment and painstaking operant conditioning is required to accurately assess basic aspects of sensory function. Thus, most behavioral olfactory research involving animals has focused upon odor preferences, rather than upon olfactory sensitivity or other psychophysical measures requiring exacting stimulus control. The opposite is true with

human olfactory research, where olfactory thresholds are the most common measure. Unfortunately, human endocrine-olfactory studies are somewhat limited in terms of the information they can provide, in that critical invasive endocrine or physiologic manipulations cannot be performed.

Despite such limitations, human studies form the backbone of our current understanding of relationships between the endocrine system and olfactory perception and provide us with important clues as to the underlying mechanisms. Furthermore, the results of such studies are inherently compelling, given our own speciocentric predilections and the important role of the sense of smell in (1) warning us of airborne hazards and (2) determining the flavor and palatability of foods and beverages. For these reasons, and because the animal literature on this topic is extremely limited, the present review focuses mainly upon human studies. Since much of this literature has been reviewed in detail previously, an attempt has been made to summarize the current state of knowledge, rather than to be comprehensive. The interested reader is referred elsewhere for more detailed accounts of this topic (cf. Doty, 1976, 1981, 1986a,b).

SEX DIFFERENCES IN OLFACTORY FUNCTION

Several human studies report women have lower thresholds (i.e. greater sensitivity) than men to a number of odorants, including camphor, the artificial musk Exaltolide, citral, and amyl acetate (Le Magnen, 1952; Schneider and Wolf, 1955; Koelega, 1970; Koelega and Köster, 1974; Toulouse and Vaschide, 1899). Such sex differences do not appear to be particularly robust, however, since they are not seen by all authors (e.g., Venstrom and Amoore, 1968; Punter, 1983) and, in some cases, appear to require relatively large sample sizes to be observed.

Similarly, women have been shown to outperform men on various odor identification tasks, such as the University of Pennsylvania Smell Identification Test (UPSIT; cf. Doty et al., 1984a,b). Again, the differences are not large over most of the age range, although greater female performance is clearly evident at the older and younger ages (Figure 1). This sex difference in odor identification ability is quite general, since it is present to about the same degree in American whites, American blacks, American Koreans, and native Japanese (Doty et al., 1985).

The origin of the sex difference in human olfactory sensitivity or odor identification ability is not known. A limited body of data suggests, however, that girls before the age of puberty perform better than boys on both types of tests, implying that adult differences in gondal steroid levels are not its basis. For example, prepubescent girls evidence greater basal sensitivity (i.e., lower thresholds) than prepubescent boys to amyl acetate (Koelega and Köster, 1974), in addition to obtaining higher scores on the UPSIT (Figure 1). Interestingly, while young girls outperform the boys on nearly all of the UPSIT test items, a

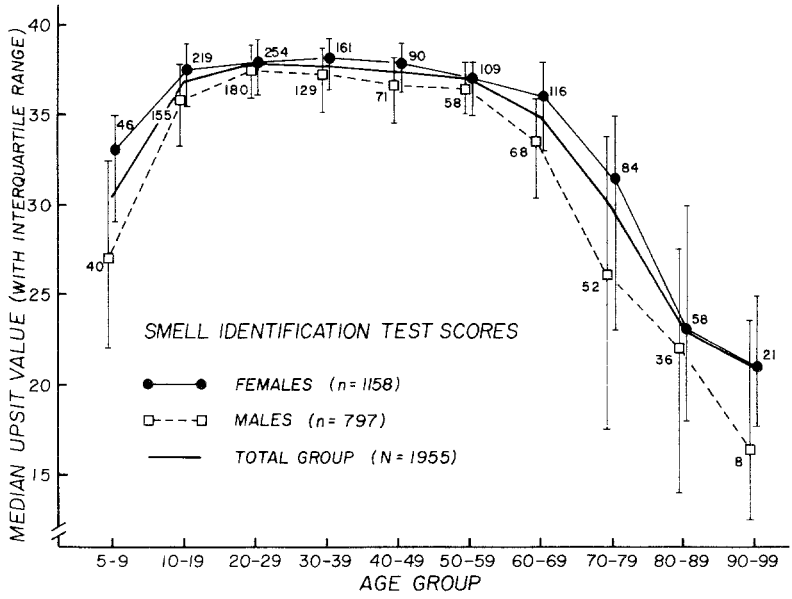

FIG. 1. University of Pennsylvania Smell Identification Test (UPSIT) scores as a function of age and gender. Numbers by data points indicate sample sizes. Reprinted with permission from Doty et al. (1984b). Copyright 1984 by the American Association for the Advancement of Science.

recent item analysis has revealed that 4- to 5-year-old boys outperform their female counterparts on the odors of motor oil and gasoline, suggesting that early cultural learning may influence the test scores. The girls outperform the boys on even these items, however, after this time (Doty, unpublished observations).

Sex differences in the rating of the pleasantness of odors have also been noted. For example, Griffiths and Patterson (1970) had 156 men and 145 women rate the pleasantness of a suprathreshold concentration of 5-androst-16-en-3-one. On the average, women rated the odor as less pleasant than did men. For both sexes, the lower a subject's threshold for the odor, the greater was his or her dislike. For subjects with the same threshold value, women rated the odor as more unpleasant than did men. Analogous sex differences have been seen for a number of odorants, including common sources of human body odor. Thus, women rate the odors of human breath, axillae, and vaginal secretions as more intense and less pleasant than do men (Doty et al., 1975, 1978, 1982b).

Although, sex differences in olfactory sensitivity have not been carefully examined in animal studies, there is some indication that the development of the olfactory system may be influenced by gondal hormones and that sex differences exist at the morphological level in at least some sectors of the chemosensory pathways (see Segovia et al., 1984). In addition, sex differences in odor

preferences are well established, and often are indicative of complex relations between experiential and physiologic factors, including endocrine state. Such relations are exemplified by the early work of Mainardi and associates (1963) which found that adult estrous female house mice (*Mus musculus domesticus*), normally reared by both parents since weaning, preferred odors from males of the same strain to those from *Mus musculas bactrianus*. Estrous *Mus musculus domesticus* females, reared only by their mothers in the absence of adult males, showed no sexual preferences and were attracted indifferently to *M. m. bactrianus* and *M. m. domesticus* male odors. Such preferences were not observed in the males. More recently, Brown (1983) noted that female rats reared with both their dam and sire strongly preferred the odor of male bedding over that of clean shavings. However, female rats reared with the dam alone did not show such a preference. The specific mechanisms underlying these preferences have yet to be elucidated.

INFLUENCE OF MENSTRUAL CYCLE ON OLFACTORY PERCEPTION

Although there have been numerous studies of olfactory function across the phases of the menstrual cycle, in many cases the sensory measures were collected too infrequently during the cycle to determine the specific nature of the fluctuations. With rare exceptions, circulating hormone levels have not served as the basis for categorizing the cycle phases. As noted elsewhere (Doty, 1979), the procedure for characterizing cycle phases can significantly alter the conclusions. Despite such problems, however, it is now clear that cyclical alterations occur in olfactory sensitivity to a number of odorants (including xylene, furfural, phenyl ethanol, and Exaltolide), with peak sensitivity occurring a day or two before the midcycle LH surge (Doty et al., 1981; Köster, 1965, 1968; Le Magnen, 1952; Vierling and Rock, 1967).

Despite the fact that circulating levels of gonadal hormones have been suggested to be the basis of the fluctuations in olfactory sensitivity across the menstrual cycle phases, only one menstrual cycle/olfactory study has measured circulating levels of the major reproductive hormones concurrently with sensory testing (Doty et al., 1981). In this work, a signal detection paradigm was used to evaluate odor detection performance to furfural across 17 menstrual cycles of normally cycling women, six menstrual cycles of women taking oral contraceptives, and six equivalent time periods of three men. During the 2- to 3-hr test periods (which occurred every other day throughout the cycles), measures of blood pressure, heart rate, body temperature, nasal airflow, and respiration rate were established, along with radioimmunoassay-determined serum or plasma levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estrone (E_1), estradiol (E_2), progesterone (P), and testosterone (T). In general,

peaks in average sensitivity were observed midcycle, midluteally, and during the second half of menses in both women taking and not taking oral contraceptives. The serendipitous finding of systematic alterations in the detection performances of women taking oral contraceptives suggested the fluctuations are not directly dependent upon circulating levels of gonadal hormones or hypophyseal gonadotropins (Figure 2). The basis of these fluctuations is not yet known.

To determine if the fluctuations observed in sensory sensitivity across the pill cycles were present in a modality other than olfaction, we measured puretone auditory thresholds and evoked potential auditory brainstem responses every other day across two complete cycles of a 28-year-old woman taking an oral contraceptive. In addition, measures of olfactory sensitivity (d′) to phenyl ethanol, body temperature, heart rate, and circulating levels of LH, total estrogens, and progesterone were also established (Doty et al., 1982a). The results of this study (Figure 3) suggest that a number of the dependent measures fluctuated in similar fashion across the time periods examined, although the peaks in olfactory sensitivity during the second half of the cycles were relatively large compared to those observed in the average data presented in Figure 2 (possibly reflecting the use of a different odorant or an individual difference). In addition, slight differences in the times of maxima and minima were present across the variables. Since these data were collected from only one subject and because each point in Figure 3 represents a moving average with equal weights attached to three adjacent time points, some of the lack of correspondence among the variables may be due to the multiple averaging of noise, rather than to a difference in underlying rhythms. The degree to which these rhythms are related to one another requires additional study.

Cyclical changes in odor detection performance are also observed in mice and rats, with peak performance occurring during either estrus or proestrus. Such cyclicity is eliminated by ovariectomy, suggesting the hypothesis that they are due to fluctuations in circulating levels of gonadal hormones (Pietras and Moulton, 1974; Phillips and Vallowe, 1975; Schmidt, 1978). Such dependence on ovarian hormones would be in congruence with electrophysiological studies noting that estrogen augments, and progesterone depresses, evoked potential activity within olfactory-related areas of the forebrain in several species (see Kawakami and Sawyer, 1967; Oshima and Gorbman, 1969). However, it is also possible that the estrous-related sensitivity fluctuations are a primary manifestation of cyclic neuroendocrine events higher in the system than the ovary, and that removal of the gonads simply eliminates "permissive" levels of gonadal hormones necessary for their expression.

Several examples of the likely "permissive" role of ovarian estrogens in the expression of nonovarian, but estrous-related, rhythms are available from the rat literature. For example, recurrent vaginal estrus occurs in gonadectom-

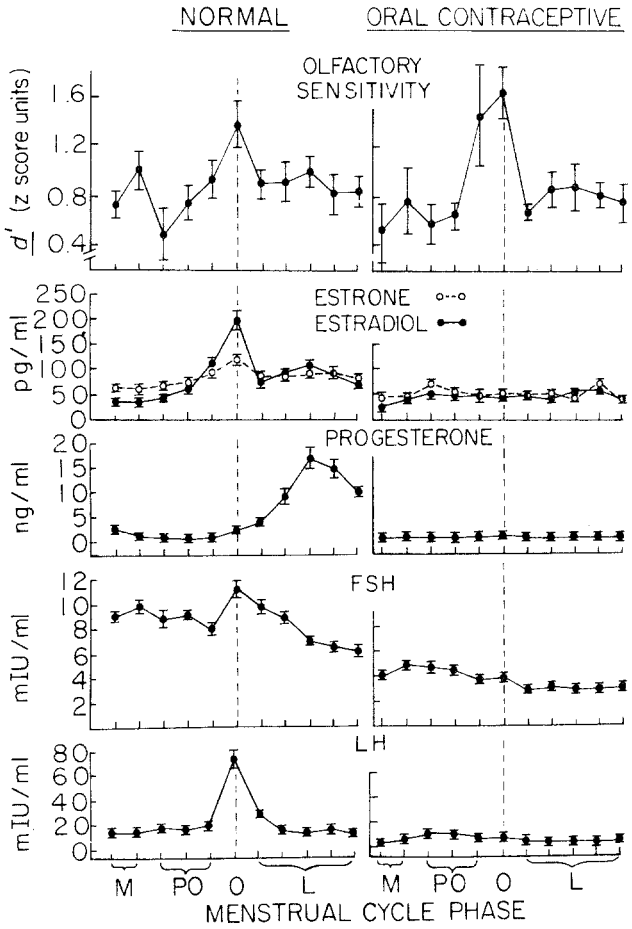

FIG. 2. Patterns of changes in signal detection measures of olfactory sensitivity and plasma or serum levels of five reproductive hormones across cycle phases of women taking and not taking oral contraceptives (data modified from Doty et al., 1981). Data are normalized and assigned to cycle phases using the Doty (1979) procedure, where M = menstrual phases 1 and 2, PO = preovulatory phases 1–3, O = "ovulatory phase" (day of LH surge or day before LH surge in normally cycling group, day 13 or 14 in oral contraceptive group, where day 1 = 1st day of menses), and L = luteal phases 1–5. Note clear fluctuation in olfactory sensitivity in both groups, and the lack of correlation between these changes and circulating levels of pituitary and gonadal hormones in the oral contraceptive group. From Doty et al. (1982a), with permission.

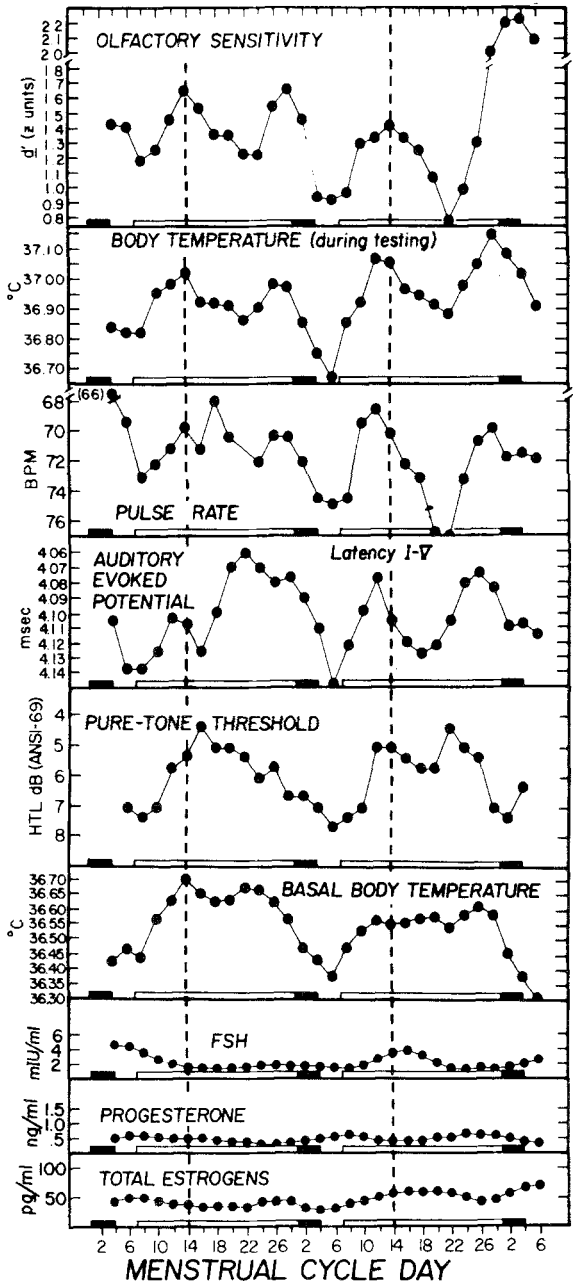

FIG. 3. Changes in nine variables across two consecutive menstrual cycles of a woman taking oral contraceptives. To diminish noise, a moving average with equal weights attached to three adjacent time points was applied to each series. Dark rectangles on the abscissae signify periods of menstrual bleeding, open rectangles days during which the oral contraceptive medication was taken. Testing took place from 9:30 AM to 12:00 PM on each test day. Pure-tone thresholds are averaged across a wide range of frequencies. From Doty et al. (1982a), with permission. Copyright 1982 by IRL Press Limited.

ized rats injected daily with a constant low dose of estrone (Bourne and Zuckerman, 1941a). The periodicity of this phenomenon is indistinguishable from that of nonovariectomized females. This cyclicity is not markedly altered by hypophysectomy, although it is eliminated or greatly affected by adrenalectomy. Interestingly, this cyclicity is related to a 4- to 5-day rhythm in adrenal weight which is present in castrated females given a constant daily injection of a low dose of estrone (Bourne and Zuckerman, 1941b). The rhythm in adrenal weight and volume is due mainly to hypertrophy of cells within the zona fasciculata of the cortex, although adrenal medullary cells were noted to increase in size as a result of estrogenic stimulation. Since adrenal insufficiency is related to enhanced odor detection performance, it is not inconceivable that rhythmic activity of the adrenal may relate to the cyclic changes in olfactory sensitivity (see Henkin and Bartter, 1966; Sakellaris, 1972).

Another example of the possible "permissive" role of estrogens in estrous-related rhythms comes from the work of Terasawa and Timiras (1968). These authors noted that estrous-related cyclic changes in electrically induced seizure thresholds in the hippocampus and amygdala, although eliminated by ovariectomy, were briefly restored, in dampened fashion, following a single injection of estradiol. That this phenomenon may be influenced by some type of early hormonal "organization" process is suggested by the finding that such restoration was most marked in rats ovariectomized in early adulthood and was not present in rats ovariectomized in infancy.

Currently, research in our laboratory is being performed to ascertain whether or not the cyclical fluctuations in olfactory sensitivity of rats can be established in the absence of the gonads when low levels of estrogen are provided on a tonic basis. If so, caution must be exercised in assuming that the rhythmic fluctuations in olfactory sensitivity of these animals is due solely to alterating levels of gonadal hormones from the ovaries.

CHANGES IN OLFACTORY FUNCTION DURING PREGNANCY

Despite the widespread incidence of cravings and aversions in many women during the time of pregnancy (cf. Dickens and Trethowan, 1971; Hook, 1978), a relationship between episodes of such phenomena and alterations in chemosensory function has yet to be experimentally established. Although the literature is inconsistent regarding alterations in smell perception during pregnancy, the few studies in which longitudinal measures were taken suggest that olfactory sensitivity is decreased during late pregnancy (Doty, 1986a). Anecdotal reports of hypersensitivity have received no strong support, although there is some suggestion that such hypersensitivity, if present, occurs during the earlier stages of pregnancy. In mice, a slight increase in olfactory sensitivity has been reported a few days prepartum, with a marked increase occurring during the postpartum week (Schmidt et al., 1982).

INFLUENCES OF CASTRATION AND/OR ADMINISTRATION OF GONADAL STEROIDS UPON OLFACTORY SENSITIVITY

To date, only a few human studies have examined the influences of oophorectomy, orchidectomy, or hormonal replacement therapy upon olfactory function. Unfortunately, double-blind procedures and rigorous statistical and methodological controls (e.g., controls for the effects of repeated testing) have been lacking in a number of these studies, so it is difficult to establish whether such manipulations influence olfactory function.

Several investigators suggest that decreases in circulating estrogen titer are associated with decreased olfactory sensitivity, and increases with increased olfactory sensitivity. In 1952, Le Magnen obtained odor detection thresholds for the musk Exaltolide in seven ovariectomized women and found them to be approximately two log units higher than normal. Five of these women were subsequently administered estradiol. Thresholds were found to drop by over two log units in two of these subjects, and by less than a log unit of the others. No change was seen in the fifth subject. In subsequent studies, Le Magnen administered estradiol to himself and noted an increase in sensitivity to trimethylamine and pyridine, and a decrease in sensitivity to safrol.

Six years after Le Magnen's study, Schneider et al. (1958) measured citral thresholds in two hypogonadal women, aged 30 and 84 years, once a week for periods extending over six months. The subjects received daily injections of either placebo or Equilin SO_4, Premarin, or estradiol interspersed in 1- to 2-week-long treatment intervals within the test period. The average thresholds were reported to be lower during the estrogen treatment periods than during the times of placebo administration, although the differences were not marked and the ranges of the daily thresholds overlapped considerably.

More recently, Good et al. (1976) evaluated olfactory sensitivity for nine days via a signal detection procedure in a woman who was reportedly anosmic to Exaltolide. The percentage of hits (reports of the presence of the odor on odor trials) and false alarms (reports of the presence of odor on blank trials) were both zero on the two pretreatment days, implying that detection was not reported on any trial. During the initial treatment days the percentage of hits and false alarms rose to about the same level, whereas during the later ones the percentage of hits rose even higher and the false alarm rate dropped somewhat.

While the aforementioned studies are cited in support of the positive influences of estrogen on olfactory function, other studies claim that testosterone decreases olfactory sensitivity. Le Magnen (1952) self-injected large doses of testosterone and found decreased sensitivity to several odors tested, including Exaltolide. Schneider et al. (1958) injected a 69-year-old woman periodically with androgen and found that during the periods of injection the thresholds for citral were higher than during the periods of noninjection. In contrast, rat studies suggest that exogenous testosterone increases, rather than decreases, odor

detection performance (Pietras and Moulton, 1974). Since supraphysiological doses of testosterone were used in the rat work, it is not clear whether this phenomenon is due to the conversion of the hormone to estrogenic metabolites.

The few animal studies available suggest that orchidectomy, per se, has little or no influence upon odor detection performance. Thus, Carr and Caul (1962) found no alteration in the ability of prepubertally castrated rats to learn a water-reinforced discrimination between the odors of receptive vs nonreceptive female conspecifics. Carr et al. (1962) found no effect of prepubertal castration on detection thresholds for estrous urine in male rats. Recently, we established odor detection performances of six postpubertally castrated rats and six sham-operated controls to ethyl acetate using a computer-controlled olfactometer and a go/no-go operant response procedure [Doty, unpublished data; see Marshall et al. (1981) for a description of the general test paradigm]. Despite the extreme sensitivity of our procedure to subtle alterations in odor detection ability, we similarly found no short-term influence of adult castration

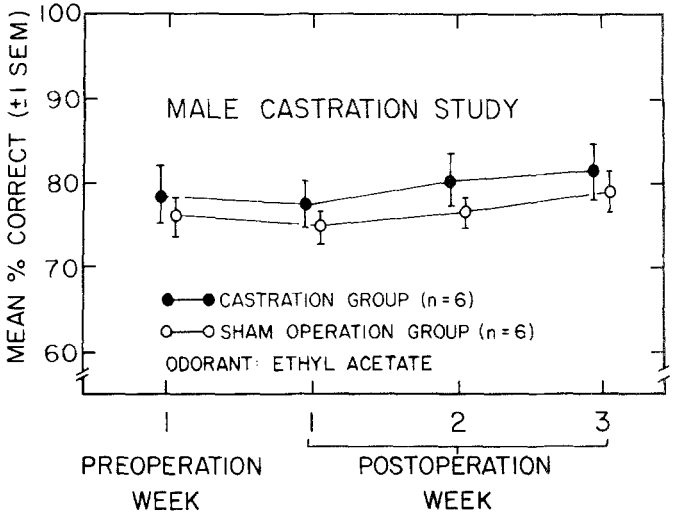

FIG. 4. Percent correct detection of ethyl acetate in a go/no-go operant task for six castrated and six sham-operated Long-Evans male rats (Doty, unpublished data). Each data point represents an average of 10,920 trials (260 trials/day/rat). Within each subject's daily test session, 60 trials were run at $10^{-4.5}$ log concentration (percent saturation) and 50 trials at each of the following log concentrations: $10^{-5.0}$, $10^{-5.5}$, $10^{-6.0}$, and $10^{-6.5}$. The concentrations were presented in a series of descending and ascending 10-trial same-concentration blocks in which half of the trials were blank. Two adjacent blocks of 10 trials were run at the beginning of the test session for the $10^{-4.5}$ concentration and at the second ($10^{-6.5}$), third ($10^{-4.5}$), fourth ($10^{-6.5}$), and fifth ($10^{-4.5}$) reversal points of the staircases. The order of presentation of the odorant and blank trials were from a quasirandom series within each of the 10 trial blocks.

on odor detection performance (Figure 4). Whether long-term castrates evidence alterations in odor detection performance requires futher study.

In contrast to the minor or nonexistent effects of orchidectomy on smell function, ovariectomy reportedly eliminates fluctuations in olfactory detection performance associated with the rat's estrous cycle (Pietras and Moulton, 1974; Phillips and Vallowe, 1975). Specifically, the peak noted in odor detection performance during estrus is not present. Interestingly, baseline performance appears to be slightly elevated in the ovariectomized animals (Pietras and Moulton, 1974). Injection of estradiol reportedly increases odor detection performance, whereas injection of progesterone decreases such performance, with latencies for the peak effects being 12 and 18 hr, respectively (Phillips and Vallowe, 1975).

CONCLUSIONS

It is becoming increasingly apparent that complex relations exist between olfactory function and neuroendocrine factors in mammals. Previous notions of a simple relationship between measures of olfactory function and circulating concurrent levels of gonadal hormones appear no longer tenable, at least in the human, and a concerted effort to understand the mechanisms underlying endocrine/olfactory interactions is sorely needed. However, even basic questions regarding human olfactory/endocrine relationships have not been answered at the psychophysical level, as pointed out in a recent review (Doty, 1985a). Questions yet to be answered include: Does olfactory sensitivity (and/or other measures of olfactory function) change systematically during pregnancy and, if so, are such changes related to factors such as nutritional needs, food intake, cravings, or aversions? Are the fluctuations in olfactory sensitivity noted across the reproductive cycle closely coupled with fluctuations in other sensory systems? If so, which ones? Are fluctuations in olfactory sensitivity present in prepubscent girls whose brains have not yet experienced cyclic changes in blood levels of reproductive hormones from the ovary? Are sex differences or endocrine-related changes in olfactory sensitivity specific to only some types of odors? If so, what are the physiochemical parameters most closely related to these changes? In a double-blind situation, what influences, if any, do exogenously administered hormones have on olfactory function? If such hormones influence olfactory sensitivity, by what means do they exert their influence?

As indicated in the present paper, most human studies have focused upon sex differences or upon naturally occurring time periods associated with hormonal alterations, such as pregnancy, menopause, or stages of the menstrual cycle. While such studies shed considerable light on possible endocrine/sensory interactions, observations from such studies need to be followed up by incisive animal studies in which the mechanisms responsible for the phenomena can be more fully elucidated. For example, a sex difference in human olfactory func-

tion could be due to factors as diverse as differences between the sexes in (1) the nasal architecture (which conceivably influences the number of odorant molecules reaching the olfactory neuroepithelium), (2) sniffing strategies or patterns, (3) the anatomy or physiology of the olfactory system proper (including subtle hormone-dependent alterations in vascular and secretory processes within the neuroepithelium), (4) the frequencies of certain habits among male and female populations (e.g., dieting); (5) attention or arousal; (6) familiarity and/or experience with odorants; and (7) acquired alterations in the olfactory system, such as neuroepithelial damage from industrial pollutants or viruses. While the relative influence of some of these variables can be assessed statistically or determined experimentally in the human, others are not amenable to such measurement and require the use of suitable animal models for their estimation.

Le Magnen, in his pioneering and classic studies of endocrine/olfactory interactions, suggested the hypothesis that the perception of only certain odorants, such as Exaltolide, is influenced by alterations in endocrine factors. More recent studies suggest, however, that alterations in sensitivity across estrous or menstrual cycles are rather general, being observed for a number of compounds (see Doty et al., 1981; Pietras and Moulton, 1974). Although the degree of such changes may vary across odorants, it is difficult at the present time to ascribe any functional significance to them, as they could simply reflect such factors as the number of receptor sites, receptor site types, or fibers recruited for each of the odorants. Furthermore, such differences might have an experiential basis, in that exposure to an odorant may alter subsequent responsiveness to it. For example, Coopersmith and Leon (1984) have demonstrated that rats, preexposed to the odor of peppermint, evidence a higher level of radiolabeled 2-deoxy-D-glucose uptake in the olfactory bulb (a measure of functional neural activity) than rats not similarly preexposed. It is also noteworthy that olfactory imprinting can occur for substances of no apparent biological relevance (e.g., cinnamon and cumin; cf. Porter and Etscorn, 1974, 1975) and that the olfactory system, per se, is exquisitely sensitive to substances never before encountered in either ontogeny or phylogeny, such as perfluorocarbons (Marshall et al., 1981). Such complexity and plasticity serves as a never-ending challenge to investigators interested in understanding endocrine/olfactory interactions in mammalian forms.

(Received May 17, 1985; accepted August 1, 1985)

Abstract—Scent marking with specialized skin glands is a common behavior in the tamarin, *Saguinus fuscicollis*. The scent marks identify species, subspecies, gender, and individual, and they also contain information on the social position and hormonal condition of an animal. The marks are chemically complex, containing a large number of compounds. Analysis by means of gas chromatography–mass spectrometry has identified 16 major components (squalene and 15 esters of butyric acid). These compounds are present in the marks of males and females of two subspecies, *Saguinus f. fuscicollis* and *Saguinus f. illigeri*. Application of computerized pattern recognition techniques has shown that concentration patterns of some of the butyrates are diagnostic of the two subspecies while concentration patterns of other butyrates are diagnostic of males and females regardless of subspecies. Behavioral studies have shown that the concentration patterns of butyrates and squalene alone do not encode information on subspecies and gender. It is, however, likely that this information is partially encoded by these specific butyrate–squalene concentration patterns but that yet unidentified compounds in the scent marks serve as necessary synergists.

Key Words—Chemical communication, scent marking, pattern recognition, *Saguinus fuscicollis*, GC-MS, primate, tamarin, skin secretions, *n*-butyrate esters, concentration profiles.

INTRODUCTION

In comparison with many other mammalian groups, primates (including man) have traditionally been classified as microsmatic. This classification has been based on a progressive reduction from prosimians to monkeys, apes, and man in the complexity of the nasal chamber, the extent of the olfactory epithelium, the development of the vomeronasal organ, and the relative sizes of the main and the accessory olfactory bulbs (Epple and Moulton, 1978; Wysocki, 1979; Epple, 1986; Maier, 1981). These findings have often been taken as indication of a poorly developed chemosensory system in infrahuman primates and humans. Questioning the validity of this judgment, Keverne (1983) has pointed out that neural projections from the olfactory system have access to the neocortex via the thalamus and that primates, with their well developed neocortex, have a more sophisticated neural backup for recognition and evaluation of olfactory sensory input patterns. "Primates do not therefore have a poorly developed sense of olfactory perception, and the ways in which this is employed may well be the most evolved of all species" (Keverne, 1983). Indeed, during recent years, evidence has accumulated suggesting that the olfactory system serves as an important sensory mediator of signals in sociosexual communication and that many primates make extensive use of chemical signals in these areas of behavior (Epple, 1974a, 1976, 1986; Schilling, 1979). Moreover, the vomeronasal system may also mediate chemical signals important in communication among conspecifics (Epple, 1986).

Much of the evidence for the use and function of chemical signals in primates is based on the fact that many species possess specialized scent-producing skin glands in various body regions, show scent marking behavior, and investigate conspecifics and their scent marks by sniffing and licking. The literature on the occurrence of specialized scent glands and scent marking behaviors and on other observational and experimental evidence for the behavioral functions of chemical signals within the order of primates has been reviewed in detail by Epple (1974a, 1976, 1986) and by Schilling (1979). According to the studies reviewed by these authors, one widespread function of chemical signals appears to be the communication of information on the identity of the species, subspecies, gender, and individual, and on the reproductive condition and social and emotional state of the individual. In addition, chemical signals play a role in a variety of behavioral contexts. Functions associated with spacing behavior and territoriality, with aggressive behavior, with reproduction, and with mother–infant interactions have either been suspected or have been demonstrated experimentally in a number of prosimians, in some New World monkeys, and in a few Old World monkeys (reviews: Epple, 1974a, 1976, 1986; Schilling, 1979).

The chemical composition of scent signals has been studied in several spe-

cies of primates (see reviews by Epple, 1986, Albone, 1984). However, characterizing the biological activity of chemical compounds of suspected communicatory function by means of bioassay experiments has proven to be very difficult. In many species the sources of chemical communicatory signals are highly complex. In most mammals, including some primates, scent gland secretions contain numerous compounds (Albone, 1984). Moreover, the scent marking behavior of some primates involves elaborate mixing of scent gland secretions with other body products such as urine or vaginal discharge (Epple, 1986). In these complex mixtures, communicatory messages may be encoded by quantitative as well as qualitative patterns (Albone, 1984; Johnston, 1983; Preti et al., 1977), which increase the difficulty of identifying the specific compounds or patterns of compounds with which particular behavioral responses are associated. Moreover, most species of primates live in societies in which not only the physiological condition of the individual but also its social status and numerous experiential factors have a profound influence on its responses to communicatory signals. Therefore, the way in which chemical and other social signals influence behavior depends on the context in which they are perceived. This fact greatly complicates the design of experiments for the evaluation of biological activity of specific chemical constituents.

Our own studies on the behavioral functions and chemical composition of scent signals in South American tamarin monkeys have certainly been confounded by the complexities described above. We review here some of the difficulties we have encountered and the progress we have made in the course of this work.

Of all monkeys and apes, the marmosets and tamarins (Callitrichidae) may rely most heavily on chemical communication. Callitrichids are the only family of monkeys in which specialized epidermal scent glands are developed to as great a degree as in some of the prosimians, a group which makes extensive use of such glands in chemical communication (Schilling, 1979). The saddleback tamarin (*Saguinus fuscicollis*), the species on which our studies have concentrated, possesses an apocrine chest gland above the sternum and a large pad of sebaceous and apocrine glands in the circumgenital–suprapubic area (Perkins, 1966) (Figure 1). Males and females routinely scent mark with the circumgenital–suprapubic gland, depositing glandular secretions which are mixed with urine and possibly genital discharge. The sternal gland is used less frequently, sternal marking occurring predominantly in situations of high arousal. Investigation of the scent deposits by all members of a group includes sniffing and occasionally licking, both of which result in contact between the chemical stimulus and the muzzle.

The high frequency of circumgenital–suprapubic marking during daily routine activities of a group and the large amount of investigatory behavior shown by all group members indicate that the chemical signals deposited in the marks

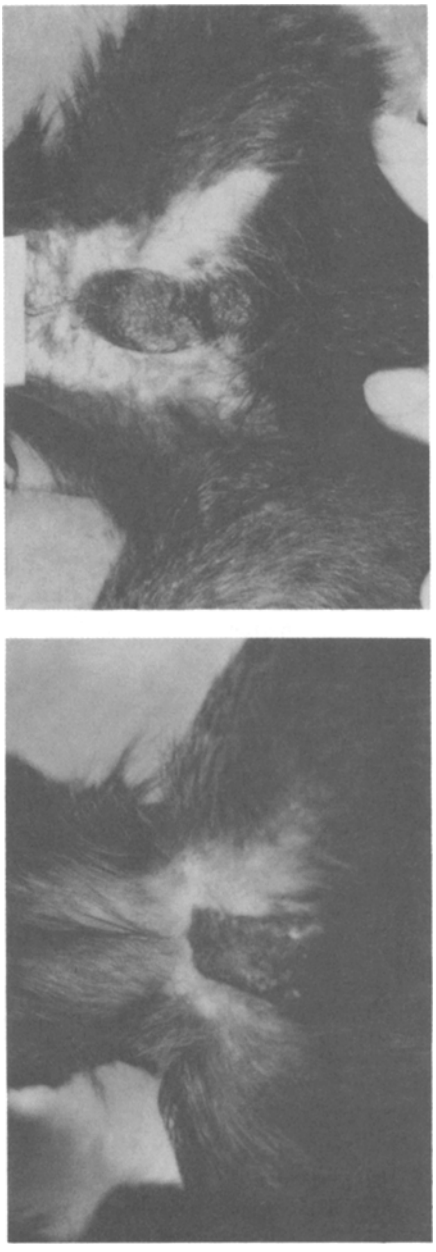

FIG. 1. Scent glands of *Saguinus fuscicollis* male (left), female (right).

are of considerable importance in social and sexual behaviors of saddle-back tamarins. During recent years, therefore, our work has been concerned with an analysis of the informational content of the circumgenital–suprapubic scent marks, their chemical composition, and the way in which the chemical constituents encode the various messages.

BEHAVIORAL STUDIES

Methods

Adult *Saguinus fuscicollis* males and females served as subjects and as donors of scent marks. The spontaneous responses of subject monkeys to scent marks produced by donor monkeys or to samples of voided urine were recorded quantitatively, measuring their investigation of novel stimulus objects of standard size which were scented with the material to be tested. Under laboratory conditions, the tamarins readily investigate novel objects placed into their cages. Therefore, it was important to evaluate the monkeys' response to "odorless" novel objects and to objects carrying control odors vis-à-vis their response to identical objects carrying the odor of conspecifics. Aluminum plates or perches of white pine (61 × 5 × 0.6 cm) were used as stimulus objects, and the investigatory responses measured were contacting, sniffing, and scent marking of the stimulus object. Wooden perches were discarded after one use but aluminum plates were reused after thorough cleaning. The results of the experiments reviewed below have been published, and detailed descriptions of all methods can be found in these reports (Epple, 1971, 1974b, 1978; Epple et al., 1980). We therefore only summarize the testing procedures here.

Single Plate Tests. These tests were used to assess the responses of the tamarins to differently scented, single-stimulus objects. For each test, the subject was isolated from its group mates in one compartment of their double-unit home cage. A stimulus plate was placed in the center of the cage floor for a period of 5 min. The 5-min test was divided into 60 intervals of 5 sec. Contacting, sniffing, and scent marking on the stimulus plate were scored in the following way: For each behavior a score of 1 was given for every interval during which it was shown, regardless of its actual frequency of occurrence. After a series of tests, the mean contacting, sniffing, and marking scores of each subject were computed, and differences in responses to the different stimuli were analyzed statistically (Siegel, 1956). Significant differences in response intensity were interpreted as evidence that the subjects discriminated between the stimuli.

Choice Tests. Most of our behavioral testing employed choice tests. This method allows the animal to investigate simultaneously two stimulus plates, each carrying a different type of scent. Some of our earlier tests lasted for 15

min (Epple, 1971, 1973, 1974b). More recently, 5-min tests have been used since the response of the animals in 5-min tests did not differ from that in 15-min tests. In all tests, the left/right positions of the stimuli are counterbalanced to avoid a reflection of side preferences. All test periods were divided into 5-sec intervals, and scoring was done in the same manner as in single-plate tests. The occurrence of a statistically significant difference in the intensities of contacting, sniffing, and marking the stimulus plates was interpreted as evidence that the animals are able to discriminate between them. Discrimination among the following scent types was tested.

1. Genus, species, subspecies
   (a) *Saguinus* versus *Callithrix*
   (b) *Saguinus fuscicollis* versus other *Saguinus* species
   (c) *S. fuscicollis fuscicollis* versus *S. fuscicollis illigeri*
2. Gender
   (a) Males versus females
   (b) Intact males versus castrated males
   (c) Castrated males versus intact females
3. Individuals
   (a) Male A versus male B
   (b) Female A versus female B
4. Rank
   (a) Dominant males versus subdominant males

Habituation Tests. These tests (Halpin, 1974) were used when animals did not show a spontaneous preference for one sample over another. A subject was presented with a single plate carrying one type of scent for 5 min. The plate was then removed, and a 5-min test, presenting a choice between a second sample of the previous type and a novel scent, was given. It was expected that animals who can discriminate between the samples will investigate the novel scent more frequently than the sample to which they have been habituated.

Collection and Preparation of Scent Material

Natural scent marks were collected by placing a clean stimulus plate into the home cage of a donor monkey. If several donors were required, the plate was placed with each one in succession. The tamarins scent marked the stimulus plates readily. The marked plates then were transferred to the cage of the subject to be tested without manipulation of the marks. In some experiments, scent marks from several donors were collected on glass plates and processed into methanol as described in Chemical Methods (see below). In these cases, the methanol solution of three scent mark equivalents was applied to aluminum plates, and the plates were placed into the cage of the subject immediately after all solvent had evaporated. When urine samples were tested, uncontaminated

urine was aspirated from plastic sheeting placed under the home cage of a donor and samples of 1 ml or 0.4 ml were placed on a stimulus plate.

Behavioral Results

Control Experiments. Because of the interest of the tamarins in all novel objects which are introduced into their environment, a number of control tests were performed. These tests compared their responses to novel objects carrying conspecific scent material with their responses to either unscented novel objects or to objects scented with control odors.

In choice tests offering two clean aluminum plates identical to those used as substrates for scent presentation, the animals did not discriminate between the plates. Their responses to these plates were much lower than to plates carrying scent marks (Epple et al., 1980). In tests offering a choice between a plate scented with exaltolide (a synthetic musk), and a clean plate, no preference was shown (Epple, unpublished). In tests offering a single plate at a time, sniffing and scent marking did not differ in response to clean plates, plates scented with exaltolide, and plates scented with synthetic mixtures of squalene and those butyrates which are among the components of natural scent marks (see below). Plates scented with natural scent marks, on the other hand, elicited significantly more sniffing and marking than any of the controls (Epple et al., 1980). These results show that, although novel objects and arbitrary novel odors elicit sniffing and scent marking, conspecific odors do so at a significantly higher level.

Signal Content of Natural Scent Marks and Urine. The responses of the tamarins to natural scent marks and urine suggest that the scent marks and, to a much lesser degree, voided urine, contain a number of communicatory messages. When *S. fuscicollis* were presented with choices between scent marks or urine samples of their own species and equivalent material from other species of callitrichids (*Callithrix jacchus*, the common marmoset, and *Saguinus labiatus*, the red-bellied tamarin), they sniffed and scent marked the material from conspecifics significantly more frequently (Epple et al., 1979). Furthermore, when given a choice between the scent marks of two subspecies maintained in our colony (*S. f. fuscicollis* and *S. f. illigeri*), the former subspecies preferred its own scent over that of *S. f. illigeri* (Epple et al., 1979).

When test animals were presented with choices between marks of males and marks of females, they sniffed and scent marked samples from males more frequently than those from females under a variety of conditions. The response appears to be largely independent of the relative amounts of the presented material. This response was shown when each stimulus plate was scent marked by a single donor male or female (Epple, 1971), and when two donors marked each plate (Epple, 1974b, and unpublished). When one plate carried the marks of two females and the other plate carried the marks of only one male, male scent was preferred. This response was also shown when a plate marked by two

males was offered as an alternative to a plate marked by only one female (Epple, 1974b). Preference for material from males was also shown when a choice between scent marks of eight males and eight females, pooled in solvent, was presented (Epple, 1974b). When given a choice between a mixture of male and female marks, and female marks alone, the test animals sniffed both with equal frequency. However, the scent marked the plate carrying the mixture more frequently than the plate carrying female marks, suggesting that a signal for maleness was contained in the mixture (Epple, 1978).

When marks from males and females were presented under a screen which made it impossible for the monkeys to contact the samples directly, the same behavioral responses were observed. This indicates that the male–female discrimination can be made on the basis of volatile constituents of the mark alone (Epple, 1978). When voided urine alone was presented, female subjects preferred urine from males over urine from females, but male subjects did not discriminate between the samples (Epple, 1978). Moreover, the complex scent marks were highly preferred over voided urine from the same individual when a choice between marks and urine was given (Epple, 1978). In another experiment, marks from intact males were preferred over those from castrates, implying a discrimination of hormonal state (Epple, 1979). Marks of castrated males, on the other hand, were not preferred over those of intact females (Epple, unpublished).

The ability of the tamarins to discriminate between scent marks of unknown male individuals was demonstrated by means of habituation tests (Epple et al., 1979). An additional experiment showed that the animals actually utilize the scent to identify known individuals. The tamarins were allowed to interact with either a strange male or female for 10 min, during which they exchanged aggressive displays with the stranger. It was expected that this interaction would motivate the animals at a later time to be particularly interested in their opponent's marks. Each encounter was followed by a choice test, offering marks from the recent opponent versus those of a familiar donor of the same sex. The subjects preferentially investigated the recent opponent's marks. This response was shown even when the tamarins were tested several days after they had encountered the opponent (Epple, 1974b). However, subjects did not discriminate between urine samples of two individuals presented under the same conditions (Epple, 1978).

Social status also appears to be encoded in scent marks, either by the amount of scent deposited or perhaps by a difference in scent quality between dominant and subdominant animals. When the monkeys received a choice between marks of unfamiliar dominant and subdominant males, the scent marks of the dominant males were preferred (Epple, 1973).

The stability of the chemical signal over time has been investigated. In series of single-plate tests and choice tests, freshly marked plates were sniffed and marked more frequently than unscented plates, plates carrying control odors

(butyrate–squalene mixtures or exaltolide), and plates carrying scent marks which had been aged at room temperature for various periods of time. Depending on the conditions of testing, aging scent marks remained attractive to the monkeys for 1–3 days. Signals identifying gender also appeared to persist for this period of time. The animals discriminated between scent marks from males and scent marks from females on the basis of fresh material, and 1- and 2-day-old material, but not on the basis of 3- and 4-day-old marks (Epple et al., 1980).

In summary, the results of the behavioral studies reviewed above demonstrate that the complex scent mark material of *S. fuscicollis* is an important vehicle for communicating the identity of species, subspecies, gender, and individual; its social status and hormonal condition; as well as the age of the material. Urine alone contains information on species and gender, but not on individuality, and is behaviorally much less attractive than scent marks.

CHEMICAL STUDIES

Methods

Our findings that the scent mark material, and not urine, is the important vehicle for communication via chemical signals led us to an investigation of the chemical nature of the scent marks. Initially, gas chromatography (GC) together with mass spectrometry (GC-MS) was used as the analytical method of choice. Most of these results, together with experimental details, have been published. We present here a brief description of the procedures employed in the chemical analysis of the scent material. The reader is referred to the original publications for further descriptions (Smith et al., 1976; Yarger et al., 1977; Golob et al., 1979).

Preparation of Scent Material

Scent marks from one or more donors were obtained by allowing the animals to mark frosted glass plates (61 × 5 × 0.6 cm) attached to aluminum plates of the same size. The deposited material was removed by rinsing with 30 ml nanograde methylene chloride–methanol (3 : 1, v/v), and the resulting solutions stored at −76°C. Prior to analysis, the solvent was removed by careful rotary evaporation at reduced pressure. For analysis, the residue was dissolved in nanograde hexanes and further reduced in volume (15–20 μl) under nitrogen. When used for bioassay, the residue was taken up in nanograde methanol or hexanes (0.5 ml per three scent marks).

Analytical Procedures

The identification of the major volatile components of the hexane-soluble material was accomplished using GC and GC-MS as the primary tools. Both

packed columns and high-resolution glass capillary columns were employed. Additionally IR, NMR, and total synthesis of each component established the structures (Smith et al., 1976; Yarger et al., 1977; Golob et al., 1979).

Quantitative analysis of the volatile constituents of scent material for individuals of different donor types (i.e., males or females of different subspecies) was performed on a Perkin-Elmer gas chromatograph interfaced to a Perkin-Elmer PEP-II computer. High-resolution SF-96 coated open tubular glass capillary columns were employed for fractionation. Quantification of the major components was accomplished by integration of their GC peak areas. These values were expressed as an area percentage of the total eluate of all these components.

Chemical Results

Analytical studies employing gas chromatography and combined gas chromatography–mass spectrometry demonstrated that the major volatile constituents of hexane-soluble material extracted from natural scent marks are squalene and a number of saturated and unsaturated alcohols esterified with butyric acid (Figure 2). Under our conditions of analysis, these components constituted approximately 96–98% of the volatile material of the scent mark (Smith et al., 1976; Yarger et al., 1977). The structures of these naturally occurring butyrates were confirmed by comparison of their IR, NMR, and mass spectra with the respective spectra of the butyrates obtained by total synthesis (Golob et al., 1979). Approximately 0.5 g of each butyrate was prepared. The availability of synthetic samples of each butyrate (99.9% pure) permitted the formulation of synthetic butyrate–squalene scent marks.

All of the butyrates and squalene were found to be present in the scent marks of males and females of all subspecies of *S. fuscicollis* investigated and of their hybrids. No qualitative differences between the marks of males and females or between different subspecies and hybrids could be detected in the retention time area of these compounds.

The remaining 4% of the volatile scent mark components are generally of higher volatility, eluting by GC before the first butyrate ester. The composition of the highly volatile region is quite complex, containing numerous compounds, among them aldehydes, esters, ketones, and acids. Analytical work on the chemical constituents of higher volatility is presently in progress. A few compounds other than the butyrates and squalene, among them some additional acids, are also present in the butyrate–squalene region and may be of some importance to the communication system. The scent marks also contain a number of constituents of high molecular weight, the presence of which can be demonstrated by other techniques such as UV absorption, gel electrophoresis, and thin-layer chromatography (Belcher, unpublished). Little is known currently about the composition of the low volatility compounds.

As mentioned above, no qualitative differences in the butyrate–squalene area (the area of the major volatile constituents) were detectable in the scent marks from different subspecies and from males and females. Therefore, we tested the hypothesis that differences in the concentrations of these compounds are responsible for encoding some of the communicatory signals which our behavioral studies have indicated to be present. The relative concentrations of all butyrates and of squalene in a series of scent marks of individual donors were determined as described in Chemical Methods. The concentration profiles

of these compounds in the scent marks of a number of males and females of *S. f. fuscicollis*, *S. f. illigeri*, and of some hybrids were monitored in this way over extended periods of time.

The concentration profiles in the scent marks of these males and females remained remarkably constant. Figure 3, showing the "scent print" of a hybrid male (♂100) over a period of three years, documents this finding. The "scent prints" of the two subspecies appeared to differ from each other, and those of hybrids were different from those of each purebred subspecies (Epple et al.,

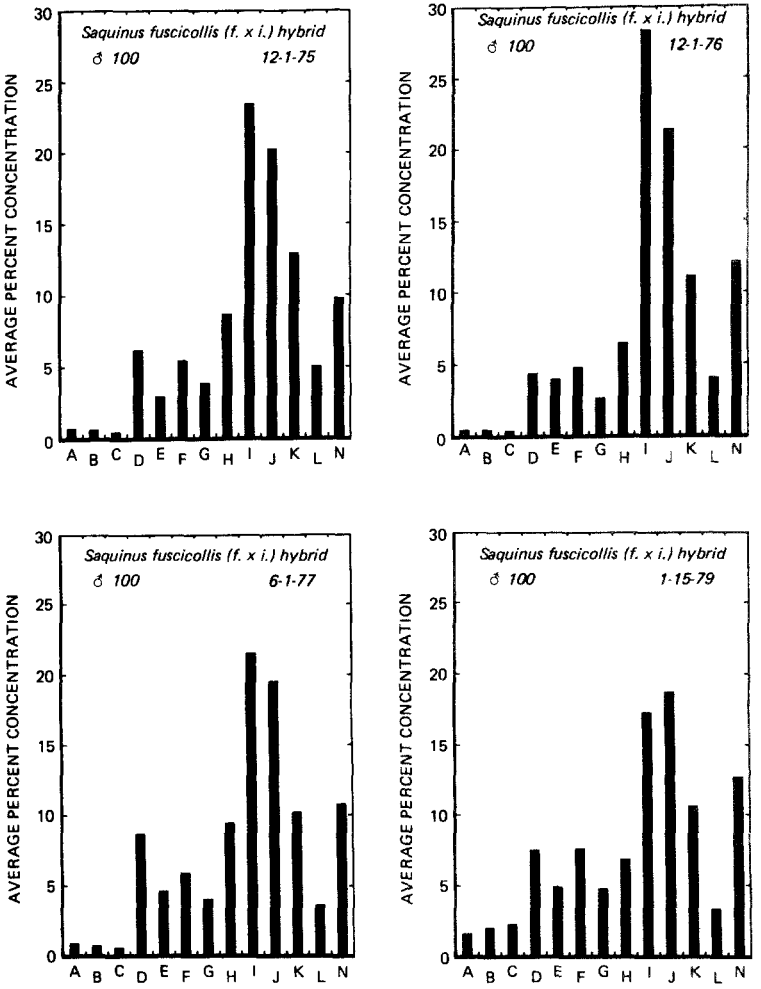

FIG. 3. Scent prints of *Saguinus fuscicollis* male over time.

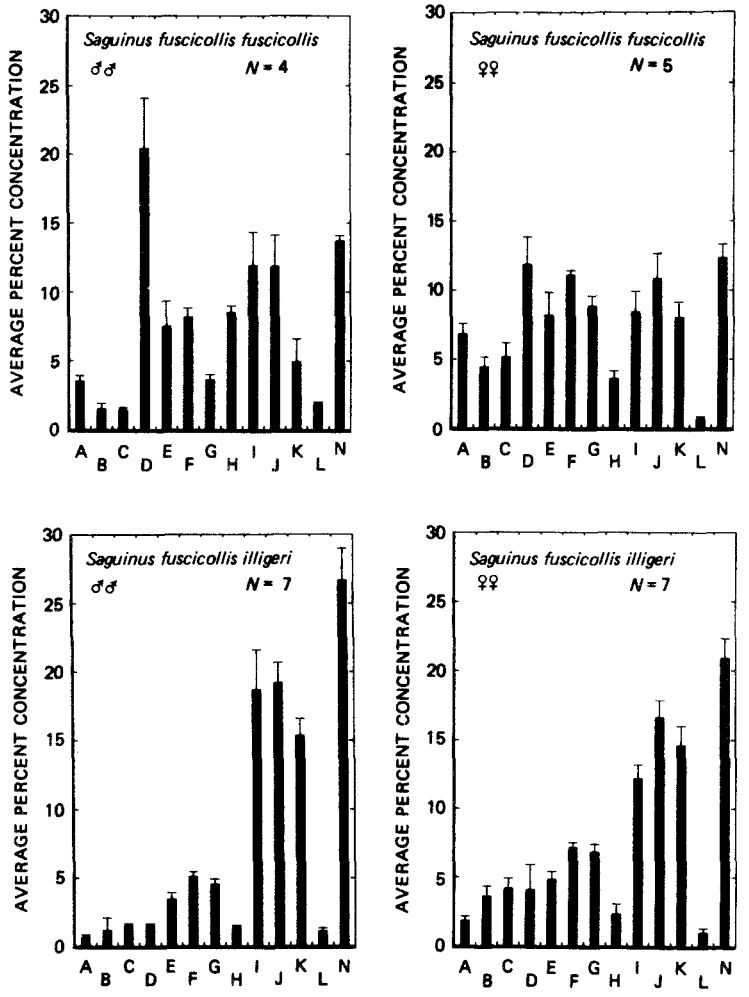

FIG. 4. Average concentration profiles of *Saguinus fuscicollis* males and females of two subspecies. Reprinted with permission from Smith, A.B. III et. al. (1985). *Science* 228:175–177. Copyright 1985 by the AAAS.

1979). Moreover, there also appeared to be differences in the concentration of some of the butyrates between males and females. Figure 4 shows average concentration profiles for males and females of both subspecies. Differences in profiles are apparent. In an attempt to examine more rigorously these differences, computerized pattern-recognition analyses were used to classify the concentration profiles of the scent marks as to gender and subspecies (Smith et al., 1985).

PATTERN RECOGNITION STUDIES

In general, pattern recognition methods are employed to classify samples or patterns according to a particular set of measurements or descriptors. The sample or pattern is represented as a point in *n*-dimensional space where the axes of this space are defined by the set of measurements used to describe the pattern. Ideally, for a binary classification problem, the patterns will cluster in two different regions of space and meaningful differences between the two groups will be reflected by this clustering.

In our study, pattern recognition techniques were employed to classify the individual scent prints according to a particular set of descriptors, i.e., the relative concentrations of 13 major volatile components of the scent marks. (The three latest eluting components were not included, as integration of their relatively broad peaks gave inconsistent results.) Means and standard errors for the relative concentrations of 12 butyrate esters (A–L) and squalene (N) (see Figure 2) were calculated for the scent print of each individual, and these data were submitted to pattern recognition analysis. Classification was done in two different studies, one on the basis of gender (male and female), and the other on the basis of subspecies (*Saguinus fuscicollis fuscicollis* and *Saguinus fuscicollis illigeri*).

For the gender study, 48 donors (25 females and 23 males) of both subspecies, including hybrids, were used. Forty of these individuals were used as a training set, and their descriptors used to generate classification schemes (discriminants). The remaining eight individuals comprised a prediction set, whose descriptors were used to test the validity of the discriminants. Members of these sets were determined by random lot. The data were standardized by autoscaling and examined by standard pattern-recognition techniques. Using linear discriminant analysis (Jurs and Isenhour, 1975), a classification scheme was developed from descriptors B and C. The SIMCA pattern recognition method (Wold, 1976), which develops an individual mathematical model for each class to which patterns are to be assigned, developed a principal component model for each class based on compounds B, C, and H.

The subspecies study used 23 individuals (9 *Saguinus fuscicollis fuscicollis* and 14 *Saguinus fuscicollis illigeri*). Due to the small number of donors available, a prediction set was not used. Principal component analysis (Jackson, 1983) was performed on all 13 descriptors to develop a classification scheme from the first principal component. Additionally, using the SIMCA method, a one-principal-component model was developed for each class from seven compounds (A, D, F, G, H, K, and N).

Pattern Recognition Results

The pattern recognition studies statistically document the differences in the concentration profiles between males and females and between the two subspe-

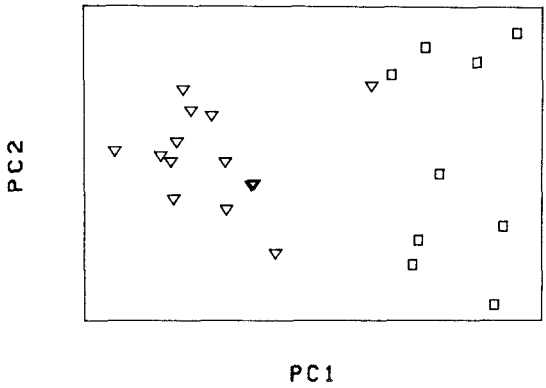

FIG. 5. A principal component representation of the pattern space defined by A, D, F, G, H, K, and N. Squares represent *S. f. fuscicollis*, the triangles represent *S. f. illigeri* individuals. cies. In the gender identification study, the classification scheme based on descriptors B and C (butyrates B and C, Fig. 2) correctly classified 38 of the 40 members of the training set. When tested on the prediction set, it was 100% successful. Additionally, the SIMCA method correctly classified 36 members of the training set and all members of the prediction set. The subspecies study also produced good results. Both principal component analyses and the SIMCA method produced discriminants that correctly classified 22 of 23 animals. Figure 5 displays a two-dimensional representation of the clustering pattern for the subspecies study.

These results demonstrated that information derived solely from the concentration patterns of the major volatile components of scent material can be used mathematically to classify an animal as to gender and subspecies. Furthermore, it appears from the gender study that some components are more important than others in providing this information. However, the limited number of animals available in the subspecies study did not allow this point to be examined.

DISCUSSION

Pattern recognition has provided us with a new method for evaluation of complex chemical signal mixtures. The demonstration of mathematical classification of the butyrates and squalene concentrations into subspecies and gender categories does not necessarily imply that this information is utilized by the animals for the same purpose. The existence of such categories, however, suggests that they may be involved in structuring communicatory messages.

We have attempted to evaluate further the behavioral significance of the butyrates and squalene (Belcher et al., unpublished). A number of studies were carried out in which we altered the scent mark secretion by adding synthetic butyrates in concentrations sufficient to change the total butyrate–squalene profiles. In general, the scent prints of *S. f. illigeri* males differed from those of females of the same subspecies in the relatively lower concentrations of the first eight eluting butyrates. Those butyrates implicated by pattern recognition to be important for gender classification [B, C, and G (an earlier pattern recognition analysis included descriptor G as well)] were tested in the following manner.

Scent mark material was collected from male *S. f. illigeri* donors and to half of it was added synthetic butyrates B, C, and G sufficient to mimic the concentrations found in scent material from female *S. f. illigeri* donors. The spiked and unspiked samples were then presented to test animals in two-choice preference tests. Those butyrates implicated in subspecies discriminations (A, D, and H) had higher concentrations in material from *S. f. fuscicollis* than from *S. f. illigeri*. Therefore, in like manner, another pool of scent-mark material from *S. f. illigeri* male donors was divided, and to one half was added synthetic butyrates, A, D, and H sufficient to mimic the concentrations found in material from *S. f. fuscicollis* male donors. Again, the spiked and unspiked samples were subjected to standard two-choice preference tests. In neither bioassay did the subjects show a significant preference for one sample over the other. One explanation for these results is that other components in the scent mark which are essential for complete biological activity informed the subjects about the true identity of the donor type.

In another study, synthetic mixtures of squalene and all butyrates were prepared from compounds synthesized in our laboratory. These mixtures were formulated so that their gas chromatographic profiles mimicked the profiles of four individual males, two *S. f. fuscicollis* and two *S. f. illigeri*. Behavioral tests were then conducted, offering the monkeys a choice between synthetic formulations mimicking the squalene–butyrate areas of both subspecies. In these tests, the subjects showed significantly more scent marking in response to synthetic *S. f. fuscicollis* mixtures, while sniffing and contacting both formulations with equal intensity (Epple et al., 1979). The differences in scent marking behavior, although significant, were small, and a replication of this experiment did not yield significant differences in response to the two formulations.

Additional studies have evaluated the behavioral significance of fractions of scent mark material (Epple, unpublished). Scent marks collected in methylene chloride–methanol were evaporated and the residue dissolved in either hexane or methanol. Bioassay choice tests were conducted both with scent material dissolved in hexane and with material dissolved in methanol. In both cases, fractions of material from males were preferred over fractions of material from females, a response identical to that given to natural marks. However, when

fractions of the marks of individual donors were tested against the chemically untreated marks placed on the plates by the same donors, untreated marks were preferred over the hexane fractions from the same individual. Methanol fractions, on the other hand, appear to retain full activity. No discriminatory response was shown when plates carrying such fractions were tested against plates carrying natural marks from the same individual. The difference in activity between methanol and hexane fractions is not due to the presence of solvent since scent marks to which these solvents had been added and then allowed to evaporate were not discriminated from untreated scent marks.

Behavioral analysis of gas chromatographic fractions of the hexane-soluble scent material was also performed. [For preparative work, the scent material was chromatographed through packed columns (SE-30, Carbowax, or Dexsil on solid supports) and trapped via a Brownlee-Silverstein thermal gradient collector (Brownlee et al., 1969).] Earlier in our work, we encountered technical problems created by the use of methanol in gas chromatography and therefore used the hexane fraction in our further analytical and fractionation procedures. (Chemically-bonded fused silica columns now make possible the use of methanol as a solvent.) This was done with the understanding that, although biological activity was somewhat diminished, hexane fractions still contained the information concerning gender. This information was retained after preparative GC when the total eluate was collected as one fraction. However, GC fractionation of scent marks from males and from females into fractions containing the highly volatile compounds fixed in squalene, and into fractions containing only the butyrates and squalene, resulted in a loss of biological activity in both fractions (Epple, unpublished). These results suggest that neither the highly volatile compounds by themselves nor the butyrates and squalene alone contain all of the information. It is therefore likely that compounds from both regions work in concert to encode gender.

SUMMARY

The results of our behavioral studies are consistent in suggesting that compounds from both areas of volatility are necessary to encode messages on subspecies and on gender. It may well be that what is required for transmission of these messages is an elaborate pattern of chemicals which presents a total "chemical image" (Albone, 1984). Beauchamp et al. (1976) has compared the search for "the pheromone" to the search for "the note" of a song. However, we may find that certain "phrases" in the chemical profile identify the message and its donor as certainly as we identify a musical composition and its composer from a fragment or excerpt.

Defining these key phrases will require a multidisciplinary attack, and new avenues of analysis doubtless will be required. Our novel approach, using the

statistical methods of pattern recognition, has proven of immense value in targeting potentially significant chemical components. We expect that further use of this technique will be important in reconstructing significant phrases in complex chemical communication codes.

(Received June 6, 1985; accepted August 1, 1985)

Abstract—A variety of oxidases, reductases, esterases, epoxide hydrolases, and group transferases in herbivorous insects and mites detoxify and facilitate the excretion of toxic phytochemicals (allelochemicals). Current theory indicates that the cytochrome P-450-dependent mixed-function oxidases (MFOs) are by far the most important enzymes because they have many attributes that are essential for an effective detoxification system. Data presented here on the midgut microsomal MFO activity of larvae of the gypsy moth, *Lymantria dispar*, are discussed in the light of previous work and support the theory. In the gypsy moth, the MFO levels exhibit a parallel trend with changes in specific feeding rates, and changes in the specific activity of the enzyme appear to be regulated ontogenetically and by inductive effect of chemicals in the diet. The specific activity of the MFOs rises more sharply on leaves of a highly preferred type-1 plant, the pin oak, than on an artificial wheat germ diet; the increase from mid-second instar to mid-fifth is 4.5- and 1.8-fold, respectively. The relationship of food consumption rate to increase in body mass (W) was slightly in excess of a 1 : 1 ratio for both pin oak and the artificial diet, indicating that the feeding rate surpasses the increase in W (a rare phenomenon in insects). Moreover, the surface-to-volume ratios are fairly constant for combined data of gut lumen and epithelium in second to fifth instars, because the volume occupied by the epithelial cells is much larger than in older ones. Thus, it is concluded that greater specific activity of the MFO is necessary with larval advancement to higher instars in order that they may process dietary allelochemicals with an efficiency comparable to younger larvae. Additional data suggest that MFO level increases reflect further adaptation to: (1) normal, seasonal changes in plants' allelochemical composition and concentration; (2) increase in allelochemical concentration in response to leaf damage; and (3) the risk faced by dispersing larvae of

encountering a greater amount and variety of allelochemicals on suboptimal/less suitable plants. Evidence also has emerged recently for MFO-catalyzed metabolism/deactivation of numerous plant allelochemicals, including compounds that induce the enzyme. MFOs are further adapted for participation in the biogenesis of substances physiologically important to insects. Moreover, the catalytic center of the MFO system, cytochrome P-450, occurs in multiple forms; the significance of this important feature is discussed.

Key Words—AK-reductases, arginase, cytochrome P-450, enzyme induction, esterases, epoxide hydrolases, *Lymantria dispar*, Lepidoptera, Lymantriidae, mixed-function oxidases, rhodanese, transferases, urease.

INTRODUCTION

Herbivores have been subject to an astonishing array of toxins and other slow-acting but nevertheless fitness-reducing secondary chemicals produced by plants; these phytochemicals are commonly called allelochemicals. Consequently, herbivores have adapted to deal with chemical defenses, and the present day relationships reflect an ongoing evolutionary process termed "coevolution" (Ehrlich and Raven, 1964). Recent studies have revealed great complexity and diversity in insect–plant relationships, particularly in mechanisms of host recognition and nonhost rejection (reviews in Ahmad, 1983a; Bell and Cardé, 1984). After the initial search has brought an insect in close proximity with potentially favorable plants, it must then make a critical assessment of host suitability for feeding and/or oviposition on the basis of its behavioral and biochemical adaptations to avoid or neutralize the deleterious effects of allelochemicals present in the food plants (Brattsten and Ahmad, 1986).

Biochemical adaptations to plant allelochemicals include penetration barriers, special excretion, temporary binding with carrier proteins, storage in adipose tissues, sequestration of allelochemicals in specialized organs or body spaces for defensive purposes, modification of target sites, and enzymatic detoxifications (reviews in Rosenthal and Janzen, 1979). Five major enzyme systems particularly suited for the deactivation and elimination of plant allelochemicals are: cytochrome P-450-dependent monooxygenases, commonly called mixed-function oxidases (MFOs); reductases; esterases; epoxide hydrolases; and glutathione-*S*-transferases. Several other group transferases also are important.

These enzymes can be grouped conveniently into primary (phase I) and secondary (phase II) metabolic processes. Generally, the MFOs, reductases, esterases, and glutathion-*S*-transferases are considered phase-1 enzymes because they can attack the lipophilic compound directly. Glutathione-*S*-transferases are also phase-II enzymes, e.g., they attack epoxide intermediates of phase-I reactions. The resulting product of a phase-I reaction is usually innocuous or less toxic and more hydrophilic than the parent compound. Metabolites of phase-

I reactions often are rendered more polar for excretion by conjugation with amino acids, glutathione, sugars, phosphate, and sulfate by specific group transferases (reviewed by Brattsten, 1979a; Ahmad et al., 1986).

In insects, carbohydrate conjugates of alcohols, phenols, aromatic carboxylic acids, amines, and sulfhydryls are formed by UDP-hexosyltransferase. Phosphotransferase (a kinase) and sulfotransferase reactions are known in insects and other arthropods but to a lesser extent. Acyl (*N*-methyl and *N*-acetyl) conjugations and amino acid conjugations have not been studied in insects. The epoxide hydrolases (previously called epoxide hydratases or hydrases) are important inactivating enzymes of arene oxide (epoxide) intermediates of phase-I reaction catalyzed by the MFOs. The enzymatic action is that of a hydrolase except that the catalysis does not dissociate the parent compound, but involves conversion of epoxides to diols by stereospecific addition of a molecule of water (Brattsten, 1979a). Epoxide hydrolases occur in many phytophagous insect species, and in the two-spotted spider mite, *Tetranychus urticae*, and also are inducible by plant allelochemicals (Mullin et al., 1982; Mullin and Croft, 1984; Yu, 1986). Further, these studies suggest enzyme multiplicity, the *trans*-epoxide hydrolase being more commonly associated with anthropod herbivory than the *cis*-epoxide hydrolase. Glutathione-*S*-transferases are of wide occurrence in insects. In the fall armyworm, *spodoptera frugiperda*, they are highly inducible by many allelochemicals and by plants that are widely different in their secondary chemistry (Yu, 1986, and refs. therein). There is no direct evidence for allelochemical metabolism by these enzymes, but the induction suggests transferase–allelochemical interactions and hence, by inference, metabolism. As discussed later, a glutathione-*S*-transferase may be involved in detoxification of the epoxide of precocenes in insensitive insects.

Regarding phase-1 enzymes, of the many specific reductases, the cytosolic aldehyde ketone (AK) reductases are of special interest as they are capable of attacking a broad range of aldehydes and ketones, two structures which are common to many toxic or repellent allelochemicals (reviewed by Brattsten, 1979a). They have been shown to reduce naturally occurring benzaldehyde, daunorubicin, and many synthetic substrates.

The esterases, arylesterase (Mn^{2+} and Co^{2+}) and carboxylesterase, differ in their rate of substrate hydrolysis and in their sensitivity to organophosphates (arylesterases being insensitive). Their endogenous roles are poorly understood, except for JH-specific esterase (Sparks and Hammock, 1979), and a pheromone-deactivating enzyme in receptors of the cabbage looper moth *Trichoplusia ni* (Ferkovich et al., 1982). These esterases occur in both the cytosol and microsomes and are of wide occurrence in mammals, insects, and mites. Together, the two esterases can hydrolyze a variety of aliphatic, phenolic, polycyclic, and heterocyclic esters and lactones. Esters of benzilic acid, chlorobenzilate, chloropropylate, and bromopropylate were found to be hydrolyzed by microsomal carboxylesterase of the rat liver (Knowles and Ahmad, 1971). Syn-

thetic pyrethroid insecticides were also metabolized by microsomal esterase, but the MFO-catalyzed oxidation of naturally occurring pyrethrins was more predominant in insects (Abernathy and Casida, 1973; Jao and Casida, 1974). The pyrrolizidine alkaloid esters can be hydrolyzed by the carboxylesterase and thus detoxified. MFO attack produces an active toxin, a pyrrole derivative, in mammals. In danaid butterflies, the speculation is that the MFOs' action on these compounds produces male courtship pheromones (see Brattsten, 1979a, and refs. therein).

The esterases are induced by various plant allelochemicals. Feeding on celery, potato, and parsley induced the enzyme in larvae of the fall armyworm (Yu, 1986). In two-spotted spider mites, esterase activity is elevated more when fed umbellifers such as celery and carrot, compared with snap bean (Mullin and Croft, 1983). In polyphagous Lepidoptera, the activity of midgut carboxylesterase is correlated with a wide host range (Turunen and Chippendale, 1977). In larvae of gypsy moth, *Lymantria dispar*, the postmitochondrial fraction of the midgut exhibited 91.5% of the total carboxylesterase activity of all tissues (Kapin and Ahmad, 1980). In herbivorous insects, a lipase is known to be involved in the utilization of triglycerides during embryogenesis, but after hatching the "true lipase" is not detected (Kapin and Ahmad, 1980, and refs. therein). Perhaps the function of carboxylesterase is in the utilization of lipids by hydrolysis to substrates suitable for energy-generating metabolism, but an additional outcome of this process may be that toxic lipids are deactivated. Since plants produce many toxic esters and lactones, including JH-like compounds, the role of esterases in the deactivation of plant allelochemicals deserves thorough investigation.

The phase-I enzymes have the potential of working in concert with phase-II enzymes to bring about deactivation of lipophilic molecules. This renders them highly water-soluble to facilitate their excretion. Recent work has also unravelled specific detoxification enzymes. In the bruchid beetle, *Carydes brasiliensis*, the arginase level is high, accompanied by an exceedingly active urease (rare in insects). Thus appreciable amounts of L-canavanine, a nonprotein amino acid, are converted to canaline and urea by arginase action, and the urease further metabolizes urea to CO_2 and NH_3; the latter is recycled as a source of primary nitrogen (Rosenthal et al., 1982). Long and Brattsten (1982) and Beesley et al. (1985) demonstrated that the enzyme rhodanese, is present in small amounts in insects that feed with impunity on plants containing cyanogenic compounds. This enzyme can convert cyanide to less toxic thiocyanate. However, Long and Brattsten (1982) concluded that rhodanese is not important in cyanide detoxification. A better possibility would be its incorporation into β-cyanoalanine by a specific synthetase known from plants only. This enzyme is under investigation for its presence in insects (Beesley et al., 1985).

The cytochrome P-450-dependent MFOs are by far the most important enzyme system because they detoxify a wide range of foreign chemicals (e.g.,

drugs and pesticides), and also because phase-II reactions depend on the primary oxidative attack of this phase-I enzyme system. Tissue/cell distribution, enzyme components, catalytic events, and reactions catalyzed by the MFO system were thoroughly reviewed (Ahmad, 1979; Brattsten, 1979a). The catalytic center, cytochrome P-450, requires for oxidative activity reducing equivalents from NADPH (supplied via a reductase, NADPH cytochrome P-450 reductase), and molecular oxygen. The basic reaction that results in the formation of alcohols and phenols is:

$$RH + O_2 + NADPH + H^+ = ROH + NADP^+ + H_2O$$

where RH is the substrate and ROH the hydroxylated metabolite. The monooxygenation reaction, however, gives rise to several other biotransformations, depending on substrate structure and stability of the intermediate metabolite. Well-known reactions are: aliphatic and aromatic hydroxylations, arene oxide or epoxide formation, *O*-, *S*-, and *N*-dealkylations, and thiophosphate oxidation. The oxidation of sulfides (thiothers) to sulfoxides and sulfones previously considered to be a cytochrome P-450 reaction, is apparently catalyzed by a FAD monooxygenase (Brattsten and Ahmad, 1986).

In 1971, the current MFO theory came into focus, indicating for the first time deactivational interactions of plant allelochemicals with MFOs (Krieger et al., 1971). Gut enzyme level was found to be significantly higher in polyphagous Lepidoptera than in oligophagous and monophagous species. The need for higher MFO level was in agreement with the greater risk for generalists in contacting plants potentially richer in allelochemical diversity and concentration compared with specialists which usually are well-adapted to the host's specific defensive chemicals (Feeny, 1976; Rhoades and Cates, 1976). The theory received impetus with the discovery, six years later, that the gut MFOs of larvae of the southern armyworm, *Spodoptera eridania*, a polyphagous lepidopteran, were induced rapidly by a variety of allelochemicals and that, following induction, the larvae became more tolerant of the alkaloid, nicotine (Brattsten et al., 1977). Brattsten (1979b) found significantly greater induction of southern armyworm's gut MFOs when larvae fed on umbellifers such as carrot, parsley, coriander, and *Spananthe*, than when they fed on their favored food plant, the legume, lima bean.

In another lepidopteran, the variegated cutworm *Peridroma saucia*, feeding on peppermint induced the larval gut MFOs more than on another plant, snap bean (Yu et al., 1979). In the gypsy moth, *Lymantria dispar*, the MFO titer was found to increase both ontogenetically and by induction, indicating an increase in biochemical defense congruent with larval development and concomitant increase in food consumption (Ahmad, 1982). In the polyphagous Japanese beetle, *Popillia japonica*, the gut MFO was induced rapidly and attained maximal levels within 24 hr of feeding on sassafras, phlox, and broccoli (Ahmad, 1983b). The induction was highest in field polyphagous beetles, moderate

in laboratory-simulated polyphagy, and lowest on single-plant feeding. As in gypsy moths, MFO activity was reduced throughout all nonfeeding developmental stages, but was maintained at high levels in active feeding stadia. Mullin et al. (1982) reported that the MFO level was higher in the phytophagous two-spotted spider mite than in the predatory mite, *Amblyseius fallacis*.

The MFO theory has been recently criticized, however. Dowd et al. (1983) provided many examples of MFO-catalyzed metabolism of allelochemicals by insects, but as discussed later, they questioned the broader implications of the "MFO–plant–toxin" relationship. Gould (1984) claimed that "evidence presently available does not offer strong support of the theory, because key pieces of information are lacking."

Presented in this paper are new data on the gypsy moth's MFOs which, along with previous published work and new findings by other researchers, provide a better assessment of the overall role of MFOs in herbivory in insects and answer most, if not all, of the recent criticisms. Areas requiring future investigation are discussed. Also briefly discussed is the role of MFOs in the biogenesis of substances physiologically important to insects.

METHODS AND MATERIALS

Insects. Gypsy moth larvae used to monitor growth, feeding rates, and MFO activity were hatched in the laboratory from field-collected egg masses and reared at 23° ± 1°C, 55% relative humidity, and 14:10 light–dark photocycle, on a wheat-germ based artificial diet or on leaves of pin oak, *Quercus palustris*, a preferred (type I) food plant of the larvae (Doane and McManus, 1981).

Larval Development and Feeding Rates. Control diet blocks, 1.5 × 1.5 cm, and pin oak leaves were first weighed to obtain fresh (wet) mass and then dried at 90°C for 6 hr and reweighed to obtain dry mass. The water content of the diets was thus determined. The uneaten portion of the diet block or pin oak leaf was weighed after drying at 90°C for 6 hr to determine dry mass. Dry mass of food consumed was then calculated using the ratio of wet to dry mass as mentioned.

Measurement of Gut Surface Area and Volume. The mid-instars of first to fifth stadia were dissected and the guts removed and fixed in Bouin's fluid. Fixed tissues were embedded in paraffin, and 15-μm serial sections were prepared and mounted on slides. Although the lepidopteran gut is a long undifferentiated tube (Berridge, 1970), the midgut could easily be distinguished from the much thinner and more transparent foregut and the constriction at the junction with the hindgut (Figure 1). The sections and a piece of 1-cm^2 paper were placed in a photographic enlarger and their outlines were traced onto sheets of white paper. Areas of these enlarged sections were measured using a Houston

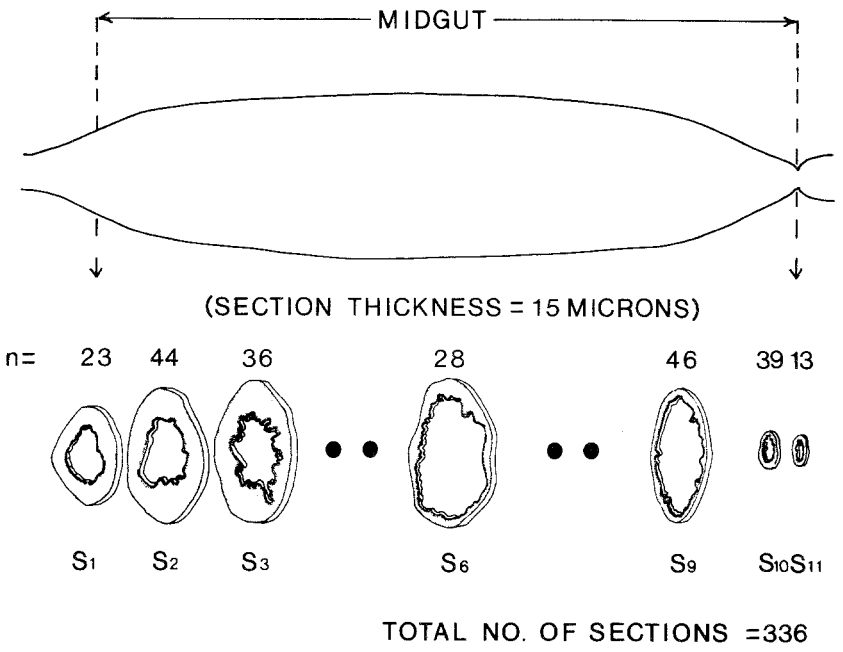

FIG. 1. Simple graphic presentation of gypsy moth's 3rd-instar gut indicating the position the midgut was excised from between fore- and hindgut. Midguts of other larval stages were similarly dissected and 15-μm thick sections were prepared. S and n denote slide numbers and number of serial sections on slides. Area occupied by epithelial cells is depicted in gray.

Instruments Highpad digitizer attached to a MINC laboratory computer (Digital Equipment Corp., Maynard, Massachusetts).

The digitizer was programmed to transform the circumference of an irregular circle (due to villi or folding of the epithelial layer) to an equivalent completely round circle. This permitted the calculation of the radius from circumference of each section from the measured flat surface area. The section thickness (h) being a known constant (15 μm), the surface areas and volumes were computed using a program utilizing the three related equations: (1) circumference = $2\pi r$ (mm), (2) surface area = $2\pi rh$ (mm^2), and (3) volume = $\pi r^2 h$ (mm^3). Summation of measurements of all sections from a midgut provided its total surface area and the volume enclosed. These two parameters were computed for gut lumen, lumen plus gut epithelium, and gut epithelium alone. The total surface area in each case was divided by total volume to obtain the surface-to-volume ratios. Number of sections (n) measured in this manner for a single midgut of each instar was: first, 159; second, 292; third, 336; fourth, 459; and for fifth instar, 1023.

Assessment of Food Intake Increases with Body Mass. The food intake is correlated to body mass, setting a limit to the size of the gut and to the rate at which food can be processed. This is an exponential function represented by the general form:

$$y = b \cdot a^x \tag{1}$$

The logarithmic form of this equation is:

$$\log y = \log b + x \log a \tag{2}$$

Using equation (2), feeding rate and body mass relationship was plotted as a linear function between $\log_e$ of y (feeding rate) plotted againt $\log_e$ of x (body mass). The scaling factor between body mass (W) and feeding rate (exponent of W = slope of the regressed line) was established according to Islam (1981; in Crawley, 1983).

Leaf Moisture. The moisture content of pin oak leaves (from a tree that had been free of any infestation over the past 10 years) of various ages from newly flushed to the time larvae reached mid-fifth instar was determined by subtracting dry weight from wet weight; dry weight was obtained by drying leaves at 90°C for 6 hr, cooling in a desiccator overnight, and then reweighing.

In another experiment designed to determine changes in water content upon herbivory, leaves from another pin oak tree that was partially infested in 1983 with gypsy moth larvae were used. Water content in undamaged leaves was determined as described above. Larvae from infested leaves were prevented from moving onto undamaged leaves as described by Schultz and Baldwin (1982).

Assay of MFO activity. Optimal assay conditions for gypsy moth microsomal gut MFO activity had previously been investigated using the substrate *N,N*-dimethyl-*p*-nitrophenyl carbamate (DPNC) (Forgash and Ahmad, 1974). In this investigation, I used *p*-chloro-*N*-methylaniline (PCNMA), which produced higher turnover than did DPNC and provided essentially the same flat bell-shaped enzyme activity–pH profile, as reported for DPNC. Maximal activity occurred at 33–34°C (instead of 35–36°C for DPNC), with only ca. 3–4% less activity at 32°C. Addition of BSA, which was found to enhance DPNC activity by 24.5%, had no effect on *N*-demethylation of PCNMA. The reaction rate was linear up to 30 min. All conditions of the MFO assay were the same as in similar work on the southern armyworm (Brattsten et al., 1977), and the Japanese beetle (Ahmad, 1983b).

Clean midguts obtained by dissecting the larvae were homogenized and centrifuged to obtain microsomal pellets (cf. Ahmad, 1983b); 500 midguts of second- and third-instar larvae, 350 midguts of fourth-instar larvae, and 250 midguts of fifth instars were used. After suspension of microsomes in isotonic KCl (Ahmad, 1983b), the protein concentration was determined by the method

of Miller (1959). Immediately after protein determination, the MFO activity was assayed. Upon termination of the reaction, chromogenic reagent was added and the clear supernatant was read for absorbancy at 450 nm against an appropriate blank in the double-beam mode in a Beckman spectrophotometer (model 35). The specific activity of the MFO-catalyzed *N*-demethylation was obtained and the activity expressed as picomoles per milligram protein per minute (at 32°C).

RESULTS

Larval Body Mass and Feeding Rate. Studies of gypsy moth development on the two diets were completed up to the eclosion of adults. However, in Table 1, the data are provided only up to mid-fifth instar, commensurate with MFO activity measurements to this developmental stage. The following trends are evident: (1) increase in mass on leaves of pin oak and the artificial diet was the same until the third instar ($P > 0.05$ by t test), (2) a dramatic increase in mass occurred by the mid-fourth instar, (3) mass of fourth and fifth instars was greater ($P < 0.05$ by t test) when larvae were reared on artificial diet than when reared on pin oak, and (4) food consumption rates (dry mass/48 hr) followed closely the increase in larval mass. Fifth instars that developed into male pupae (data not included in Table 1) continued feeding for additional 4–5 days and greatly increased their mass by 2.5-fold on pin oak leaves and by 2.0-fold on the artificial diet. Gut clearance and pupation followed. Fifth instars that developed into sixth-instar larvae (females) exhibited a great surge in food consumption and nearly doubled their mass relative to the terminal fifth-instar males. Despite differences in mass gain and increase in food intake between the two diet groups, mass of male and female pupae, sex ratio, and days for adult eclosion were the same for larvae reared on either food. Therefore, gypsy moths fared equally on both diets, and the developmental synchrony must be due to intrinsic regulation (most likely hormonal), especially at the time of pupation.

In both diet groups, relative feeding rates dropped as larvae approached the next molt (Table 1). Larvae from 12 to 24 hr of apolysis had less food in their gut than larvae in mid instars; all late-instar larvae were characterized by retraction of the head capsules. Moreover, relative feeding rates (dry mass/1.0 g body mass/48 hr) increased from first-mid instar to the fifth-mid instar, the trend being more pronounced in pin-oak fed larvae than in the artificial-diet group. The rate of feeding as larvae advanced in age was increased more than the increase in body mass. This finding has important implications vis-à-vis increase in the specific activity of gut MFO enzyme, as discussed later.

Gut Surface Area and Volume Relationship. Surface area-to-volume ratio of the gut is an important factor when studying the amount of food that can be taken up into the gut lumen, subsequent passage of food materials through the

gut epithelium, and associated gut enzymes that are not secreted. The smaller midguts of early instars have more surface relative to volume than the midguts in later instars (Table 2). Surface area of midgut lumen of first to fifth instars increased greatly in larvae reared on pin oak; volume increases were even greater, giving rise to a decrease in the surface-to-volume ratio from 185.8 in mid-first instar to only 19.8 in the mid-fifth instar (Table 2). However, when surface area and volume were considered for gut lumen in combination with gut epithelium, this trend was not obvious; surface-to-volume ratios were fairly constant in second to fifth instars. This pattern is evident from the data on gut epithelium only, which indicates that the volume occupied by epithelial cells, on a relative scale, is much greater in younger larval stages than in older stages (Table 2). Thus, the gut epithelium of later instars is much thinner (by volume; relative to lumen volume) than that of younger larvae. This result has implications in better understanding of the need for greater specific activity of midgut MFOs in later instars than in younger larvae, in order to process dietary allelochemicals with comparable efficiency.

TABLE 2. COMPUTER-GENERATED MEASUREMENTS OF SURFACE AREAS, VOLUMES, AND SURFACE-TO-VOLUME RATIOS OF GUT LUMEN, GUT LUMEN + GUT EPITHELIUM, AND GUT EPITHELIUM ONLY IN MID-1ST TO MID-5TH INSTARS OF GYPSY MOTH REARED ON PIN OAK

Food Intake and Body Mass. In insects, food intake generally increases with $W^{0.8}$ where W is body mass; by comparison, mammalian food intake scales to about $W^{0.7-0.75}$ (Crawley, 1983, and refs. therein). Food intake in the gypsy moth increased by about the same scaling factor on both diets, $W^{1.09}$ for pin oak and $W^{1.15}$ for the artificial diet (Figure 2), indicating an ability to process much more food than hitherto reported, except for cinnabar moth, *Tyria jacobaeae*, where the scaling factor is 0.88 (Crawley, 1983). This relationship, established by regression analysis, was highly significant ($r^2 = 0.99$ for pin oak and 0.98 for artificial diet). Despite greater mass for fourth and fifth instars in the artificial-diet batch, the scaling of W to rate of food intake is nearly the same ($P > 0.05$; comparisons of slopes) as in the larvae reared on pin oak. Although the gut volume of the bigger and heavier artificial-diet-reared larvae was not measured, the data suggest that the gut volume may be increasing proportionately with W. Clearly this finding deserves further study as it has implications in understanding the overall energetics of the gypsy moth.

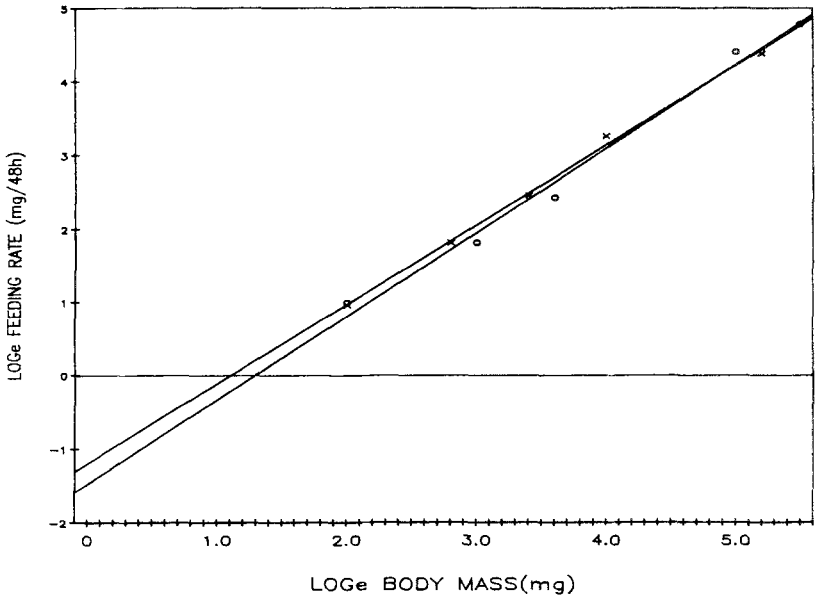

FIG. 2. The relationship of specific feeding rates to body mass (W) of first to fifth instars of the gypsy moth. Open circles and crosses denote data from artificial-diet- and pin-oak-reared larvae, respectively. The data were transformed to natural logs ($\log_e$) for regression to obtain a linear relationship. The regression revealed scaling factors of $W^{1.09}$ and $W^{1.15}$ for pin oak and artificial diet groups of larvae, respectively. Both regressions are highly significant ($r^2 = 0.99$ for pin oak and 0.98 for artificial diet). However, comparison of slopes indicated that the difference in the two scaling factors was not significant.

TABLE 3. CHANGES IN LEAF MOISTURE OF GYPSY MOTH'S HOST PLANTS[a]

Plant species	Leaf moisture (%, $\bar{X} \pm$ SE)[b] Newly flushed leaves	Mature leaves	References
Free of insect feeding/defoliation			
Sugar maple	74	60	Hough and Pimentel (1978)
White oak	75	60	Hough and Pimentel (1978)
Red oak	74	59	Hough and Pimentel (1978)
	66.8 ± 4.9	57.3 ± 0.9	Schultz and Baldwin (1982)
Pin oak[c]	73.1 ± 2.6	53.0 ± 1.6	Ahmad, unpubl. data
Following feeding/defoliation			
Red oak	66.3 ± 1.9	55.1 ± 5.9	Schultz and Baldwin (1982)
Pin oak[c]	73.0 ± 1.9	49.9 ± 1.9	Ahmad, unpubl. data

[a] Data are condensed to reflect overall changes from newly flushed leaves (concurrent with appearance of hatchlings) to mature leaves (when larval development is completed). The time of bud break and appearance of hatchlings is sychronized; however, the date when ths event occurs in the northeast differs from state to state because of differences in climatic conditions.
[b] Hough and Pimentel data did not provide standard deviations or errors of the means.
[c] Means are derived from 10 replicates. The difference between newly flushed and mature leaves is significant ($P < 0.05$ by t test).

Leaf Moisture. The drop in moisture content in pin oak was greater (20%) than in other hosts (10–15%) (Table 3). Moreover, the reduction was slightly higher (23%, but not significant) in pin oak leaves as a result of larval feeding on the plant. The relationship of changes in water content to allelochemical concentration and its implication to MFO activity is discussed below.

MFO Activity. The following trends are evident (Figure 3): (1) the enzyme level in all late instars (when feeding decreases, then ceases) is always lower than in the corresponding mid instars; (2) a progressive increase occurs in late-instar enzyme level, the rise is gradual and not different in the larvae of both diet groups, either in titer or in the slope ($P > 0.05$ by t test); and (3) in the actively feeding mid instars, MFO activity rises sharply from second to fifth stage: the rise was significantly higher ($P < 0.05$ for differences in the slopes) in larvae reared on pin oak (slope = 36.04) than those reared on the artificial diet (slope = 24.88), and the difference between mid-fifth and mid-second instar was much greater (4.5-fold) on pin oak than on the artificial diet (1.8-fold). Figure 4 clearly shows a parallel trend in the MFO specific activity and specific feeding rates of larvae fed leaves of pin oak.

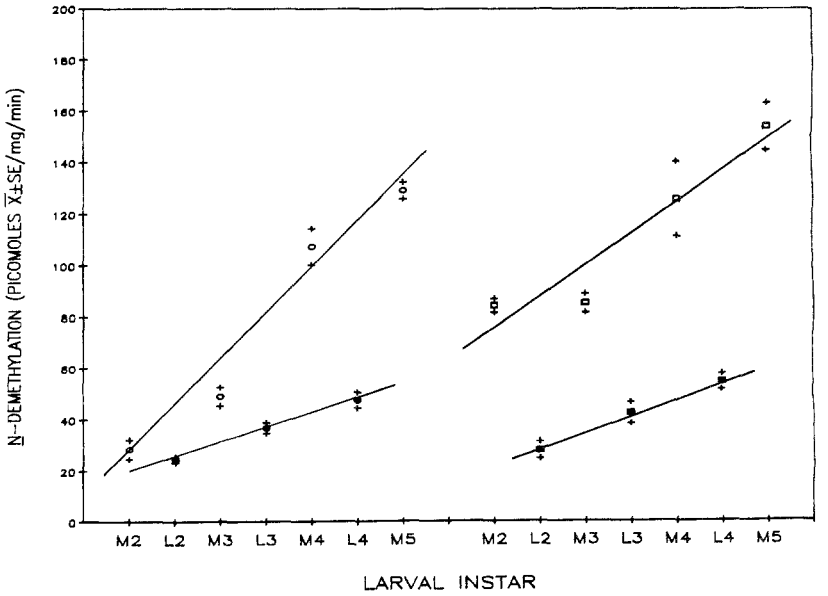

FIG. 3. MFO-catalyzed *N*-demethylation specific rates for the substrate PCNMA of midgut microsomal preparations of second to fifth instars of the gypsy moth. Data to the left are for larvae reared on pin oak; open and closed circles denote data for actively feeding (mid instars) and in reduced feeding stages (late instars), respectively. Data to the right are for larvae reared on wheat germ artificial diet; open and closed squares denote data for active and reduced feeding stages, respectively. All data are means derived from four replicates; plus symbols denote ±1 SE.

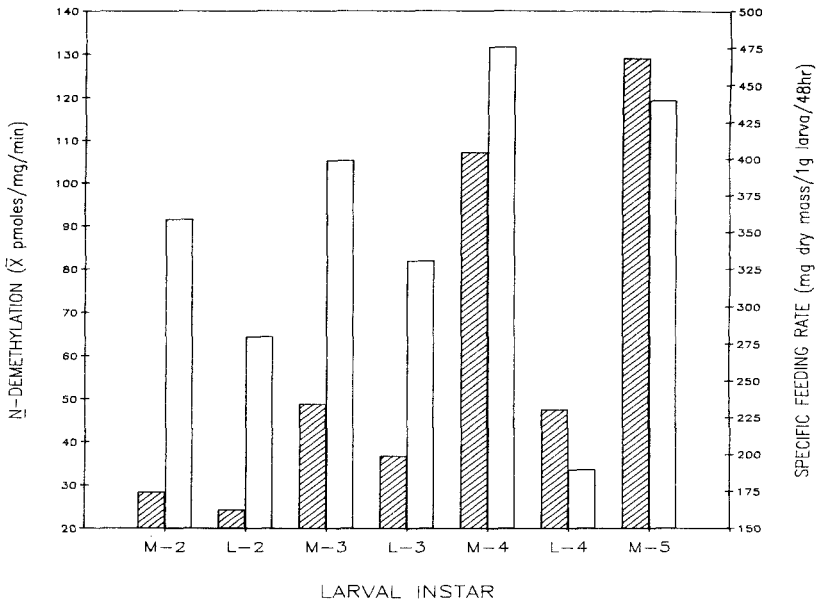

FIG. 4. Patterns of MFO activity and specific feeding rates of mid (M) and late (L) second- to fifth-instar larvae of the gypsy moth. MFO activity is high in all mid instars, rising with larval advancement and concomitantly with increases in specific feeding rates. Preecdysial depression in MFO activity coincides with the preecdysial suppression of specific feeding rates in late instars. Striped bars represent MFO activities, and open bars the specific feeding rates.

DISCUSSION

Results presented in this paper are discussed in light of the criticisms of the MFO theory by Dowd et al. (1983), and Gould (1984). The criticisms found in the above papers can be categorized in six specific statements.

1. Variation in MFO Specific Activity with Insect Development. Patterns of variation in MFO activity exist among developing stages in insects, e.g., southern armyworms (Brattsten, 1979b), gypsy moths (Ahmad, 1982), and Japanese beetles (Ahmad, 1983b), indicating that the activity is highest in feeding stages, is lowered during the molting process, and kept low during nonfeeding quiescent developmental stages. Gould (1984) stated that although the fifth instars of the gypsy moth consume ca. 10 times more food (artificial diet) than third instars, they are ca. 10 times heavier than the thirds; therefore the relative consumption rate for the two instars is equal. However, no data were provided on larval mass. Data in the present paper (Table 1) show that body mass difference between the mid-fifth and mid-third instars is only 6.65-fold. The difference in consumption rate per larva is 10.67-fold, however. Gould further

stated that changes in MFO specific activity were related to diet consumption on a per larva basis rather than on per unit larval mass, which is a common measure of relative feeding rate (Scriber and Slansky, 1981). Here I provide a clear relationship between relative consumption rates (mg dry mass of food eaten/1.0 g larva/48 hr) and the specific activity of larval gut MFO (Figure 4).

2. *Problem of Scaling Gut Volume/Surface Area to Enzyme Level.* The finding (Ahmad, 1982) that larger gypsy moth larvae (i.e., fifth instars) had higher specific activity than smaller stages (i.e., third instars), was contradicted by Gould (1984), because he speculated that higher specific activity existed in smaller larvae, since their volume-to-surface ratio is smaller (or conversely, surface area-to-volume ratio is higher, as per this report) than in larger older instars. Assuming that plant toxin molar concentration remained unchanged in the diet, the dose of plant toxin(s) expected to contact the gut wall of smaller larvae would be relatively higher. Gould is correct in pointing out this "geometric" aspect; however, he overlooked the fact that MFOs are not associated with membranes of epithelial cells but are distributed throughout the cell's network of endoplasmic reticulum, being membrane-bound to that structure. Thus, any consideration of gut volume/surface area (and the amount of food it can hold and process) must be viewed in the context of cellular volume.

In agreement with Gould, I found that larvae reared on pin oak leaves show a 480-fold increase in gut lumen volume from mid-first to mid-fifth instar; consequently, the surface-to-volume ratio dropped from 185.8 in the first instar to 19.8 in the fifths (Table 2). However, because the volume of the gut epithelium increased only 13.05-fold between the first and fifth instars, the surface-to-volume ratio showed a reverse trend as larvae developed, increasing from first- to fourth-instar larvae (Table 2). Schmidt-Nielsen (1979) had pointed out that organs may not scale in the same proportion as the animal size.

In the gypsy moths reared on pin oak, body mass and relative feeding rate scales to $W^{1.09}$ (Figure 2). This is a reflection of great increases in gut lumen volume that can hold greater amounts of food in older larvae and, also, to enhanced feeding rates. However, the large amount of food in the guts of larger larvae must pass through a volume-wise thinner layer of epithelial cells than in smaller larvae. Therefore, it is logical to predict that larger larvae cope with plant toxins with an efficiency at least comparable to that in smaller larvae because the specific activity of MFOs in their midgut epithelium is higher.

In support of his criticism, Gould (1984) further stated that "there have been no successful demonstrations of any MFO activity in first and second instars of Lepidoptera." In the present study MFO activity was quantified in second-instar larvae of the gypsy moth, and the data support earlier predictions (Ahmad, 1982; Ahmad, 1983b) of an increase in MFO specific activity with feeding-stage development (Figure 3). Although enzyme levels of first-instar larva remain to be investigated, the data for first instars most likely will fit the profile presented in this report.

3. Induction and Subsequent Metabolism of Inducers. One of the most significant features of the gut microsomal MFO system is its ability to respond rapidly via induction by allelochemicals (Brattsten et al., 1977). Dowd et al. (1983) and Gould (1984) claimed that, following induction, subsequent metabolism of an inducer has never been shown. However, as documented in the following examples, recent work in large measure alleviates their concern: (1) (+)-Limonene is hydroxylated as well as epoxidized in herbivorous mammals (Brattsten, 1983, and refs. therein). (2) The mint monoterpene, pulegone, is transformed in vitro to 9- and 10-hydroxypulegone by southern armyworm midgut microsomes (Trammell, 1982). (3) α-Pinene and other cyclic terpenes have been shown to be metabolized in rats and bark beetles; in the latter, some oxidized products are used as pheromones (Brattsten, 1983). (4) Xanthotoxin, a linear furocoumarin, is metabolized by MFOs of the fall armyworm and larvae of the black swallowtail butterfly, *Papilio polyxenes*; metabolic rates are different in the two species, however (Ivie et al., 1983). (5) In a thorough study discussed in more detail below, Yu (1986) demonstrated MFO-calalyzed turnover of many other structurally diverse allelochemicals in the fall armyworm.

One of several inducers which is not metabolized is the organochlorine compound, mirex (Barker *et al.*, 1972). Natural products tend to be more biodegradable than synthetic compounds, e.g., pyrethroids (Abernathy and Casida, 1973; Jao and Casida, 1974). Plant enzymes must be able to detoxify allelochemicals (therefore allelochemicals must be biodegradable) when injury occurs, in order to escape autointoxication (Rosenthal and Janzen, 1979; Harborne, 1982). Moreover, plants translocate allelochemicals during early growth and at the time of leaf senescence when they are broken down and recycled. The synthetic insecticides, especially the chlorinated hydrocarbons, on the other hand, often are less biodegradable, a desirable attribute for persistent insecticidal activity. High acute toxicity of such compounds makes it extremely difficult to demonstrate induction of the insect cytochrochrome P-450. Recent work on the mechanism of dioxin induction and gene expression shows that induction is of a specific form of cytochrome P-450 (Jones et al., 1985; Jaiswal et al., 1985). Dioxins are polychlorinated compounds (in studies cited here, the compound is TCDD, 3, 4, 7, 8, tetrachlorodibenzo-*p*-dioxin), and like mirex, they induce cytochrome P-450 but are not metabolized. The compounds are extremely toxic; the LD_{50} is in the microgram per kilogram range. As we learn more about the nature of the binding site on the cytosolic receptors of other substrates in relation to that of cytochrome P-450s, we will be able to better understand why mirex and dioxin have such a high affinity for the cytosolic receptor but not for the enzyme they induce. Other acutely toxic substrates (e.g., pyrethroids) that are metabolized by the MFOs apparently do not induce the enzyme activity at nonlethal dose levels.

4. Ineffectiveness of MFOs against Specialized Allelochemicals. It has been emphasized by many researchers (Feeny, 1976; Rhoades and Cates, 1976;

Brattsten 1979a) that enzymatic detoxification represents only one of many other biochemical adaptations against plant allelochemicals. It is not surprising then, that plant toxins such as cardiac glycosides (of milkweeds; family Asclepiadiceae) are tolerated by nonenzymatic means (e.g., insensitivity of target site) by larvae of the monarch butterfly *Danaus plexippus*, which sequesters cardenolides for defense against vertebrate predation (Blum, 1978). Other insects which rarely or never eat cardenolide-containing food (e.g., *Periplaneta americana*) may also not be harmed as cardenolides are not absorbed by the gut (Scudder and Meredith, 1982).

Nicotine is tolerated by both metabolic deactivation and by specialized excretion (Brattsten, 1979a, and refs. therein). The extent to which one insect species uses one mode of tolerance more than the other probably represents selection of genetic variables for the two attributes that differed in populations of different insect species. Nicotine tolerance like that of cardenolides represents a highly specialized historically established relationship between chemically well-defended plants and their equally well-adapted feeders. These examples are improper in nullifying the MFO theory which had never claimed that all allelochemicals are subject to attack by the MFOs. On the contrary, the theory assigned a greater role for MFOs in generalists that need to detoxify a broad range of lipophilic allelochemicals than in specialists that encounter specific toxin(s).

Gould (1984), using the two cases discussed above, reached the conclusion that (in reference to enzymatic detoxification of allelochemicals) "metabolism seems unimportant." Discussion so far has provided a firm basis for a major role for enzymatic deactivation of allelochemicals in herbivores. Even in cases such as the antimetabolite L-canavanine, previously thought to be tolerated only because of a modified tRNA synthetase, Rosenthal et al. (1982) demonstrated enzymatic detoxification. Marty and Krieger (1984) have provided evidence that in the larvae of the monarch butterfly, uscharidin, a cardiac glycoside, undergoes enzymatic metabolism in the fat body and midgut by enzymes other than MFOs. Thus enzymatic involvement is indicated even where we thought other defense mechanisms were solely operative in imparting insect tolerance to plant allelochemicals.

5. Lethal Biotransformations by MFOs and MFO Inhibitors. Some plant compounds, instead of being detoxified, are activated to more potent toxins. In the argument that MFOs do not necessarily deactivate allelochemicals, Gould (1984) cited two examples of potentiation of pyrrolizidine alkaloids (Mattocks, 1972) and aflatoxins (Tilak et al., 1975). Recently, lethal bioactivation of plant and synthetic precocenes to reactive epoxides by MFOs in the corpora allata (CA) of sensitive insects (e.g., *Locusta migratoria*) also has been shown (Ellis-Pratt, 1983). The CA is the organ of synthesis of hormonal epoxides (juvenile hormones). The epoxide of precocenes spontaneously rearranges to a carbonium

ion, and in this form it is a potent alkylating agent reacting with CA's macromolecules, culminating in complete necrosis of the organ. In nonsensitive species, precocenes are ineffective due to metabolic deactivation and excretion. Precocenes can undergo MFO-catalyzed *O*-demethylation or epoxidation. The epoxide is toxic, but not if attacked either by an epoxide hydrolase and then conjugated or by a glutathione-*S*-transferase; in both cases (and also *O*-demethylation), the result is detoxification, presumably occurring in the gut, fat body, or other tissues with a full and sufficiently active enzyme complement, but apparently not (sufficiently) in the CA. (Ellis-Pratt, 1983; Bowers, 1983; Dowd et al., 1983). Clearly this requires work on MFOs of the CA, gut, and fat body to better understand why precocenes are activated and persist in toxic form in sensitive insects but not in insensitive ones.

Vertebrate herbivores generally avoid eating toxic plants, although mistakes occasionally occur. Insects avoid such plants altogether. Exceptions are several species of danaid butterflies, where the males are strongly attracted to certain pyrrolizidine-containing plants. For example, feeding on nectar of *Crotalaria* sp. (Fabaceae) provides monocrotaline, a pyrrolizidine alkaloid that is converted to male courtship pheromone(s) (Boppré, 1978). Interestingly, the biotransformation of monocrotaline to the pheromones may be MFO-catalyzed (Brattsten, 1979b). It is not known whether this occurs in the gut, integument, or a specialized organ. The nature of this MFO requires study. In vertebrates, oxidation produces a highly toxic and carcinogenic metabolite in the liver, and the hepatotoxicity is fatal (Brattsten, 1979a).

Aside from toxic substrates (to which at least some insects are refractory), plants also are known to produce methylenedioxyphenyl compounds called lignans that inhibit MFO activity. Some examples are sesamin and sesamolin from sesame oil, myristicin in parsnip, and apiol from parsley leaves (Brattsten, 1979a; Bowers, 1983). A synthetic lignan, piperonylbutoxide has been commercially used as an insecticide synergist. Studies with piperonylbutoxide show that it is essentially an inhibitor, ultimately undergoing degradation by the MFOs (Brattsten, 1979a, and ref. therein).

The above examples of toxin sythesis or enzyme inhibition are predictable by the coevolutionary scenario (Ehrlich and Raven, 1964). Accordingly, insects and plants are engaged in an evolutionary arms race. As insects have developed enzymatic adaptations to neutralize toxic allelochemicals, plants in turn have developed countermeasures to offset the insects' responses. We have seen that some of the plant's countermeasures have been breached by some insects, a further indication of ongoing coevolution. In my opinion, therefore, the relatively few examples of lethal biotransformations or MFO inhibitors do not negate the generalization that the MFOs act, in large measure, as a detoxification system for a great majority of plant toxins.

6. Enzyme Multiplicity and Method of Assay. Until 1979, cytochrome mul-

tiplicity had been shown for the mammalian system and in insecticide-susceptible and -resistant house flies. Ahmad (1979) stated that in the immediate future research will be directed to resolve the question "whether the insect gut-MFO system is dependent on a single form or on multiple forms of cytochrome P-450." Recent evidence involving differential induction and metabolism showed that the order of induction of MFO-catalyzed epoxidation in the fall armyworm was indole 3-carbinol > flavone > indole 3-acetonitrile; the order for biphenyl hydroxylation was flavone > indole 3-carbinole > indole 3-acetonitrile, and for parathion desulfuration the order was indole 3-acetonitrile > flavone > indole 3-carbinole (reviewed by Yu, 1986). Ivie et al. (1983) showed that xanthotoxin is substantially metabolized by the gut MFO of larvae of the black swallowtail butterfly, but the enzyme in the fall armyworm larva metabolized only a very small amount of xanthotoxin. Gunderson et al. (1986) have shown the existence of cytochrome P-449 and P-450 (CO-complex peaks) in larvae of the southern armyworm. Moreover, the spectral form P-449 was found to hydroxylate pulegone at the C-10 position three times faster than the P-450 form in vitro.

Gould (1984) suggests that despite multiplicity, MFO activity has been measured mainly by epoxidation of dieldrin to aldrin as per Krieger et al. (1971). The following are some examples of different substrates and biotransformations used to assess MFO activity: (1) hydroxylation of aniline in gypsy moth larvae (Forgash and Ahmad, 1974) and in southern armyworm larvae (Brattsten et al., 1976); (2) hydroxylation of dihydroisodrin in six species of saturniid larvae (Krieger et al., 1976), in black cutworm (*Agrotis ypsilon*), and in cabbage looper larvae (Thongsinthusak and Krieger, 1976); (3) overall NADPH oxidation (inhibited by CO and SKF-525A) in gypsy moth larvae (Ahmad and Forgash, 1973, 1978); (4) allelochemical-dependent NADPH oxidation (inhibited by CO and piperonylbutoxide) in the fall armyworm (reviewed by Yu, 1986) and southern armyworm (Brattsten, 1983); (5) *O*-demethylation of *p*-nitroanisol in the housefly (Hansen and Hodgson, 1971), in gypsy moth larvae (Forgash and Ahmad, 1974), and in fall armyworm larvae (Yu, 1986, and refs. therein); (6) *O*-demethylation of methoxyresorufin in southern armyworm larvae (Brattsten et al., 1980); (7) *N*-demethylation of *N*,*N*-dimethyl-*p*-nitrophenyl carbamate in the house fly (Hansen and Hodgson, 1971) and in gypsy moth larvae (Forgash and Ahmad, 1974; Ahmad and Forgash, 1978); and (8) *N*-demethylation of *p*-chloro-*N*-methylaniline in saturniid larvae (Krieger et al., 1976), larvae of the southern armyworm and black swallowtail butterfly (Brattsten et al., 1977; Brattsten, 1979b), and the Japanese beetle (Ahmad, 1983b). These examples refute Gould's (1984) comment that MFO activity has been assessed mainly by one method.

The most powerful evidence of a major allelochemical-detoxifying role for the MFOs is an impressive list of allelochemicals that are now known to be metabolized by this enzyme system. The following allelochemicals are metab-

olized by insect gut MFOs: phytoecdysones (cf. Bowers, 1983), oxidative metabolism of precocenes (cf. Bowers, 1983; Ellis-Pratt, 1983), metabolism of the monoterpene, pulegone (Brattsten, 1983; Gunderson et al., 1986), and metabolism of three indoles, safrole, flavone, *trans*-anethole, estragole, a cardenolide (digitoxin), three coumarins, a phenylpropane (eugenol), alkaloids (atropine, strychnine, caffeine), 13 monoterpenes, two sesquiterpenes, a diterpene (phytol), stigmasterol, sitosterol, ergosterol, squalene, and β-carotene (Yu, 1986). A number of cyclic terpenes are also oxidized, some of which are used as pheromones (cf. Brattsten, 1983).

Further Interpretations of Results on Diet and Age-Related Changes in Gypsy Moth Gut MFOs. The MFO activity was higher on artificial diet than on pin oak leaves using the *N*-demethylation assay of the substrate PCNMA. This may be because pin oak (closely related to red oak and a type-1 plant) is a highly preferred host plant for the gypsy moth. In the southern armyworm (also by the same assay) larval enzyme level on artificial diet was 0.70 nmol (Brattsten et al., 1977); whereas on lima bean it was 0.29 nmol/mg protein/min (Brattsten, 1979b). In the Japanese beetle also, the induction of MFOs was lower on sassafras (2.59 nmol), a highly preferred host plant, than on less preferred broccoli (2.93 nmole/mg protein/min) (Ahmad, 1983b). Conceivably, the gypsy moth's MFO occurs at higher levels on less preferred/nonhost plants as, for example, has been shown for the southern armyworms (MFO activity was 2.73, 1.92, and 1.24 nmol on carrot, *Spananthe*, and parsley, compared to only 0.29 nmol on lima bean; Brattsten, 1979b). This interesting possibility needs experimental validation. Higher induction of MFOs by the artificial diet fed to gypsy moths could be due to the presence of many potential inducers such as components of wheat germ and agar, cholesterol, antibiotics, and antifungal compounds (ODell and Rollinson, 1966).

Nonetheless, data in Figures 3 and 4 reinforce the conclusion reached earlier (Ahmad, 1982) that MFO titers in the gut of the gypsy moth increase ontogenetically and by induction during feeding stages (Figure 3), suggesting an increase in biochemical defense commensurate with larval development and concomitant increase in food intake. Analysis of leaf water content as a function of leaf-aging and herbivory has shown a marked drop (Hough and Pimentel, 1978; Schultz and Baldwin, 1982; and data on pin oak leaves as per this report); the molar concentration of leaf allelochemicals will therefore increase. Moreover, leaves' phenolics and tannins also increase with time (Baldwin and Schultz, 1983). Other allelochemicals have not been analyzed from this perspective, but it is possible that similar increases occur in ubiquitously present "general green leaf" compounds (e.g., various hexenals, hexanols, hexanylacetate, etc.); this increase in concentration is probably the result of degradation of leaf constituents with aging and senescence (cf. May and Ahmad, 1983, and refs. therein). Some of these compounds have been shown to be inducers of MFOs and also metabolizable (Brattsten et al., 1977; Yu, 1986). An example

is the compound *trans*-2-hexenal, which is so highly reactive that it is used along with *p*-benzoquinone and methacrylic acid as a defensive substance in some insects (Blum, 1978). These compounds inactivate macromolecules such as proteins by reacting with nucleophilic groups such as NH_2 and SH. Simpler phenolics that are present in most leaves (and give rise to more complex flavonoids, e.g., rotenone; and polyphenols, e.g., tannins) also may be metabolized by the MFO system. The phenolics increase in concentration in oak leaves with time and as a result of plant response to herbivory (Baldwin and Schultz, 1983).

The leaf tannin content significantly increases as leaves mature and in response to leaf damage (Schultz and Baldwin; 1982; Baldwin and Schultz, 1983), and this lowers the availability of primary nutrients, nitrogen and sugar. At the same time, allelochemical concentration increases as a consequence of decrease in leaf water. Futher, as the larvae disperse seeking other hosts, the risk of encountering plants poor in nutritional quality and well-defended by toxic allelochemicals increases. From this I conclude that the gypsy moth is able to complete development by its ability to maintain high food consumption rates on nutritionally poor diets and to cope with allelochemically adverse plants by its remarkable ability to increase MFO levels. Similarly, high food consumption rates as compensation for poor diets is known for the polyphagous larva of the southern armyworm (Scriber, 1984). My conclusion is supported by (1) correlation of MFO activity with increase in specific rate of dietary intake with larval advancement, (2) by the nearly 1 : 1 relationship of food consumption rates to increase in body mass (Figure 2) and (3) the sharper rise in MFO activity on pin oak leaves, 4.5-fold from second to fifth instar, an indication that more allelochemicals that need to be detoxified are increasing in the plant concomitant with the insect development. The comparatively smaller increase, 1.8-fold, seen when larvae were fed artificial diet perhaps merely reflects a response of the MFO enzymes to greater total amounts of inducers as a result of an intrinsically increased specific rate of food consumption, rather than the molar concentration of inducers which remained unchanged.

Future Directions. The data suggest that MFOs in herbivorous insects have all the necessary attributes to act as a major enzymatic defense mechanism to allelochemicals. Moreover, specific multiple forms seem to have been elaborated, enabling some insects to deal more efficiently with specific allelochemicals of their particular hosts. However, a great deal remains to be investigated. Particularly interesting studies involve (1) some inducers that are not metabolized, (2) more thorough studies of cytochrome P-450 induction and multiple forms, (3) how efficient the system is in metabolizing relatively less innocuous but lipophilic allelochemicals in contrast to potent toxins in various species, (4) the full identity of MFO-metabolizable allelochemicals present in preferred and nonpreferred/nonhost plants of the gypsy moth and other insects, (5) further work on phytophagous mites which have been shown to possess higher activi-

ties of MFOs and *trans*-epoxide hydrolase than in a predacious mite, and (6) the interesting observation (C. A. Mullin, personal communication, 1984) that sucking phytophagous arthropods have lower levels of MFOs and other detoxification enzymes than chewing arthropods.

Aside from gut MFOs, sizable microsomal MFO activity is associated with the fat body and Malpighian tubules of insects. In some species, such as the gypsy moth and the Japanese beetle, the fat-body-specific microsomal MFO activity is 55 and 85%, respectively (Ahmad and Forgash, 1973; Ahmad, 1983b). In the cabbage looper and the American cockroach, *Periplaneta americana*, microsomal MFO activity in the fat body surpasses that in the gut (Brattsten, 1979, and refs. therein). Ahmad (1982) hypothesized that the fat body–MFO system may "provide insects with a secondary line of defense from toxic allelochemicals." Recent work suggests that in some insects precocenes are deactivated in the gut, fat body, and Malpighian tubules by MFO-catalyzed *O*-demethylation and/or by dihydrodiol formation and subsequently conjugated and excreted (Ellis-Pratt, 1983). The fat body microsomal MFOs are inducible enzymes, unlike the mitochondrial system, which is noninducible and whose function is to carry out hydroxylation of molting prohormone α-ecdysone to the active β-ecdysone (Bollenbacher et al., 1977). Whereas Ahmad's (1982) hypothesis requires clarification, a complicating factor requiring resolution is the evidence that steroid hydroxylation is not always mitochondrial, but is also carried out by the microsomal systems of the peripheral organs, e.g., the fat body and Malpighian tubules (Feyerseisen and Durst, 1978, and refs. therein).

Finally, enzymatic adaptations, especially the MFO system, may also enable herbivorous insects to utilize phytosterols in the biogenesis of cholesterol (Ahmad, 1979), cyclic monoterpenes, and plant olefins to produce sex attractants (Brattsten, 1979b, 1983) and to convert pyrrolizidine alkaloids to male courtship pheromones (Boppré, 1978; Brattsten, 1979b). Also, as discussed above, the MFO system in the corpora allata functions in the synthesis of juvenile hormone (JH) from farnesoate (Ellis-Pratt, 1983) and in regulating the JH titers along with expoxide hydrolase and also an esterase (cf., Brattsten, 1983).

The site of cholesterol synthesis from phytosterols is the insect gut. An intermediary reaction in the dealkylation of C_{28-29} phytosterols, e.g., sitosterol, to C_{27} cholesterol is the formation of an epoxide (fucosterol epoxide), and the entire conversion is dependent on NADPH and oxygen. This hypothesis, first advanced by Ahmad (1979), requires experimental support. This biotransformation has its root in the inability of de novo biosynthesis of the cyclic steroid nucleus in insects. In fact, insect association with plants has lead to complete dependence by insects on cyclic compounds of plant origin, as an evolutionary answer to costly ring closure reactions. Thus it is not surprising that cyclic monoterpenes through MFO oxidation also are utilized as pheromones. The same can be said with regard to cyclic oxidative derivatives of toxic pyrrolizi-

dine alkaloids in serving as male courtship pheromones in danaid butterflies. However, future investigations should resolve whether these "biogenesis" reactions of the microsomal MFOs are catalyzed by specific forms of the cytochrome P-450 and, also, the tissue and organ where pheromonal synthesis occurs, especially in the danaids which release monocrotaline-derived pheromones from their hair pencils.

Brattsten (1979b) hypothesized that the gypsy moth's sex attractant, disparlure, an epoxide of an olefin, is synthesized by an MFO system. However, it remains to be seen if this conversion is effected in the pheromone gland or the midgut. Unpublished results (L.B. Brattsten, C.F. Wilkinson, and T. Taylor, cited in Brattsten, 1979b) show that gut microsomal MFO of the armyworm can catalyze the epoxidation of the olefin. Therefore, it is possible that disparlure may also be synthesized in the midgut and then sequestered in the pheromone gland. This possibility awaits experimental investigation.

Compounds such as disparlure and many other epoxide pheromones may be inactivated by *trans*-epoxide hydrolase, known to be present in many tissues such as midgut and fat body, but so far this enzyme has not been found in pheromone glands. Earlier, it was pointed out that a pheromone-specific esterase is present in the cabbage looper's receptors, which would deactivate the esterpheromone after it has elicited a response in the male. Likewise, there is the need to study existence of AK-reductases in pheromone receptors for their role in deactivating (after elicitation of a response is over) a large number of aldehyde and ketone pheromone molecules of insects.

From the foregoing, it is clear that MFOs have been harnessed by insects in allelochemical deactivation and also in the utilization of substances physiologically important to insects. Both detoxification and biosynthetic roles of these enzymes should be considered in the future investigations of the MFOs and other allied allelochemical-interacting enzyme systems.

Acknowledgments—I thank Dr. G.D. Prestwich for inviting me to present this paper at the 15th NERM ACS Symposium on "Bioorganic Chemistry of Communication Systems." I am grateful to Dr. S. Govindarajan for help in preparing serial sections of the gypsy moth's larval midguts, Ms. Sule Oygur for enlarging thousands of gut outlines, Dr. T.M. Casey for providing his expertise in measurements of surface-to-volume ratios of guts and for placing at my disposal his computerized digitizer for area measurements, Dr. Y.-S. Ng for preparing computer-drawn figures and regression analyses of data, and the many student helpers who performed several hundred dissections of larvae for the assessment of MFO activity. The manuscript has been greatly improved thanks to the valuable criticisms and useful suggestions of Dr. T.M. Casey, Dr. C. Schal, and Dr. G.W. Wolfe. Dr. H.T. Streu is thanked for his moral and material support. This is a publication of the New Jersey Agricultural Experiment Station, Publication No. D-08130-07-85. Supported by state funds, United States Hatch Act funds, and other gifts and grant-in-aid monies.

THE HAUSTORIUM AND THE CHEMISTRY OF HOST RECOGNITION IN PARASITIC ANGIOSPERMS

MAYLAND CHANG and DAVID G. LYNN

Searle Chemistry Laboratory
The University of Chicago
Chicago, Illinois 60637

(Received July 6, 1985; accepted August 1, 1985)

Abstract—Two parasitic angiosperms, *Agalinis purpurea* (Scrophulariaceae) and *Striga asiatica* (Scrophulariaceae), are compared as to the chemical recognition events involved in host selection. *Agalinis* is a hemiparasite which can mature to seed-set without a host, whereas *Striga* is a holoparasite and survives for only a very limited time without a host. Both parasites, however, attach to a host through a specialized organ known as the haustorium and regulate the development of this organ through the recognition of chemical factors from host plants. We now describe the discovery of 2,6-dimethoxy-*p*-benzoquinone (2,6-DMBQ) as an haustoria-inducing principle from *Sorghum* root extracts. Our investigation of this compound has led us to suggest that one level of host recognition in these parasitic plants is mediated through their enzymatic digestion of the host root surface. Degradation of surface components liberates quinonoid compounds, such as 2,6-DMBQ, which in turn trigger haustorial development.

Key Words—*Agalinis*, *Striga*, parasitic angiosperms, 2,6-dimethoxy-*p*-benzoquinone, haustoria, organogenesis, laccase, phenol oxidase, parasite-host recognition.

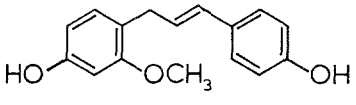
INTRODUCTION

The viability of an organism depends on its ability to recognize and respond to events occurring in its environment. An efficient and specific recognition system is particularly critical for organisms that have evolved as parasites dependent on a specific association with a host. Parasitic plants, being sessile organisms, respond to potential hosts through processes of growth and development. These responses are readily observed and quantified, and therefore

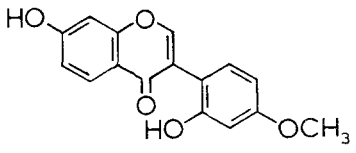
0098-0331/86/0200-0561$05.00/0

these organisms represent a simplified system for investigating the chemistry of such recognition events.

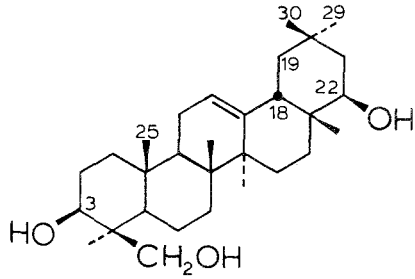
At present, there are tens of thousands of plant species which have evolved the ability to parasitize other plants. Some of these parasites have a narrow host range and must have developed methods for selecting between host and non-host. The parasitic angiosperm *Agalinis purpurea* responds to the presence of host plants by controlling the development of an organ specialized for host attachment termed the haustorium (Kuijt, 1969; Riopel, 1979; Riopel and Musselman, 1979). Preliminary experiments suggested that materials exuded from host plants induced the development of the haustorium in *Agalinis*. In fact, by screening fractions from a commercially available plant exudate, gum tragacanth, for the ability to induce haustoria in axenic cultures of *Agalinis*, the first



1



2



3

haustorial inducers, xenognosin A(1) and B(3), were isolated and characterized (Lynn et al., 1981; Steffens et al., 1982). Several synthetically prepared analogs of the xenognosins (Kamat et al., 1982) established the *m*-methoxy phenol functionality and the propene double bond as structural features critical for biological activity (Steffens et al., 1982). Work in other laboratories (Bell, 1981; Carlson and Dolphin, 1981; Dewick, 1975) has shown the xenognosins to be phytoalexins and plant-stress metabolites. Taken together, these findings have led us to suggest that the xenognosins are stable constitutive antibiotics necessary for host-plant defenses and therefore likely recognition cues of a suitable host. The identification of the xenognosins, then, provided the first experimental support that parasitic angiosperms mediate host selection through the identification of specific molecules present in and potentially exuded by their hosts.

Isolation of the triterpene soyasapogenol B(3) exuded from the *Agalinis* host, *Lespedeza sericea* (Leguminosae), was quite unexpected in light of the strengths of the arguments in favor of the phenylpropanoid recognition cues identified in gum tragacanth (Steffens et al., 1983). However, many of the find-

ings which support the phenolics also favor 3 as a recognition cue. The haustoria-inducing activity of 3 is dependent on certain structural features. Neither the 22-keto derivative, soyasapogenol E, nor a series of other olean-12-ene triterpenes possessed any detectable activity. The soyasapogenols have been found exclusively in the Leguminosae and therefore may have restricted occurrence, but their chemotaxonomic usefulness is not as well established as that of the flavanoids. The soyasapogenols have also been attributed with defensive roles. In their glycosylated form, they are toxic and reduce herbivory in leguminous seeds (Langenheim, 1981). A group of more highly oxidized oleane triterpenes, the averacins, are found in oat roots and are potent resistance factors to "take all" disease caused by the fungus *Gaeumannomyces graminis* (Crombie et al., 1984).

Measurements of the levels of root exudation of these triterpenes and a single flavanoid, genistein, from *Lespedeza* suggested that terpenoid exudation is under active metabolic control and that phenolic exudation is extremely low. (Steffens et al., 1986; Lynn, 1985). If this low exudation level of phenolic compounds from *Lespedeza* can be taken as representative of potential hosts, then it seems unlikely that quantities of these phenolics sufficient for the induction of haustorial development would be exuded. Therefore, the structural specificity, the stable and specific metabolic production, and the metabolic control over the exudation of the soyasapogenols by *Lespedeza* suggest that the terpenoids may be more appropriate substances for these parasites to use as recognition cues.

The haustoria-inducing activity of soyasapogenol B is, however, much weaker than that of xenognosin A. In a filter paper disk assay, 20 nmol of soyasapogenol B is the lowest quantity which will induce haustoria, whereas xenognosin A will induce large numbers of haustoria at 1 nmol. Haustoria are not induced when soyasapogenol B is presented as a 10 μM solution, but xenognosin A is quite active at this concentration. Measurements of the rate of exudation of 3 from 2-week-old seedlings suggest that, without any environmental alteration or microbiological metabolism, sufficient amounts of soyasapogenol B for haustorial induction would not accumulate. Unlike the xenognosins, which constitute virtually all of the activity of gum tragacanth, the soyasapogenol B activity represents only a portion of the activity of *Lespedeza*. While there is a very real possibility of synergism occurring with the multiple components from *Lespedeza*, it is clear that the complete story of the interaction between *Agalinis* and *Lespedeza* root exudation has not been defined.

Agalinis purpurea, while a much larger and more vigorous organism when attached to a host, is a hemiparasite capable of maturing to seed-set without host attachment. Host recognition would, therefore, be expected to be less critical for *Agalinis* than for a holoparasite, such as *Striga asiatica*, which is incapable of survival for more than 10 days without a host. *Striga* has a host range that is restricted to grasses, such as wheat, corn, and *Sorghum*, and has

been commonly called "witchweed" because of its damaging effects on grain crops. It is now clear that *Striga* has at least two levels of host recognition, one at the level of germination and one associated with the development of the haustorium. *Striga* initiates its commitment to a host through germination. A sesquiterpenoid, strigol, has been found to be exuded by cotton roots as a potent *Striga* germination stimulant. However, cotton does not serve as a host for *Striga* and, in fact, is used as a trap crop to reduce *Striga* infestation. Both corn and *Sorghum* serve as hosts for *Striga* and have been shown in our laboratory to produce separate stimulation factors for both germination and haustorial development.

Haustorial development is also very tightly regulated in *Striga*, and it has been shown that the induction of the haustorium is not possible four to five days postgermination (Riopel and Baird, 1986). Perhaps of even more importance is that *Striga* forms only a terminal haustorium (Figure 1) and radicle elongation ceases with the induction of haustorial development. For successful host attachment, this induction must occur within a 50-μm distance of the host. Germination must occur within a distance where the growing radicle can reach the host's surface within five days postgermination. Therefore, not only must *Striga* carefully select a suitable host, but it must also be able to determine the distance between itself and its host. The chemical challenge with *Striga*, then, is to explain not only how it recognizes its host, but how it recognizes the distance from its host. In this paper we will attempt to lay the groundwork for the explanation of both aspects of this biological recognition.

METHODS AND MATERIALS

Seeds. Striga asiatica seeds were obtained from R.E. Eplee, U.S.D.A. Witchweed Methods Development Laboratory, Whiteville, North Carolina, and handled under USDA quarantine at Charlottesville, Virginia. *Agalinis purpurea* seeds were obtained from L.J. Musselman, Old Dominion University. *Sorghum bicolor* (Var. Sudan) seeds were grown in vermiculite under greenhouse conditions.

Bioassays. Haustorial induction was determined by first germinating *Striga* seeds in distilled water with strigol (Nickrent et al., 1979). The 24-hr-old seedlings were then transferred and exposed to selected extracts in distilled water. Haustoria were counted 24–48 hr later.

Isolation of Haustorial Inducer from Sorghum Roots. Two-month-old vermiculite-grown *Sorghum* roots (600 g fresh weight) were exhaustively extracted with CH_2Cl_2–MeOH (4:1), and the extract was filtered and dried in vacuo. This material was extracted with $CHCl_3$ and the washings were concentrated to yield 174 mg of a dark green oil. The oil was applied to a Sephadex LH-20 column (2.5 × 37.1 cm, CH_2Cl_2–MeOH, 40:60), and following 125 mL of

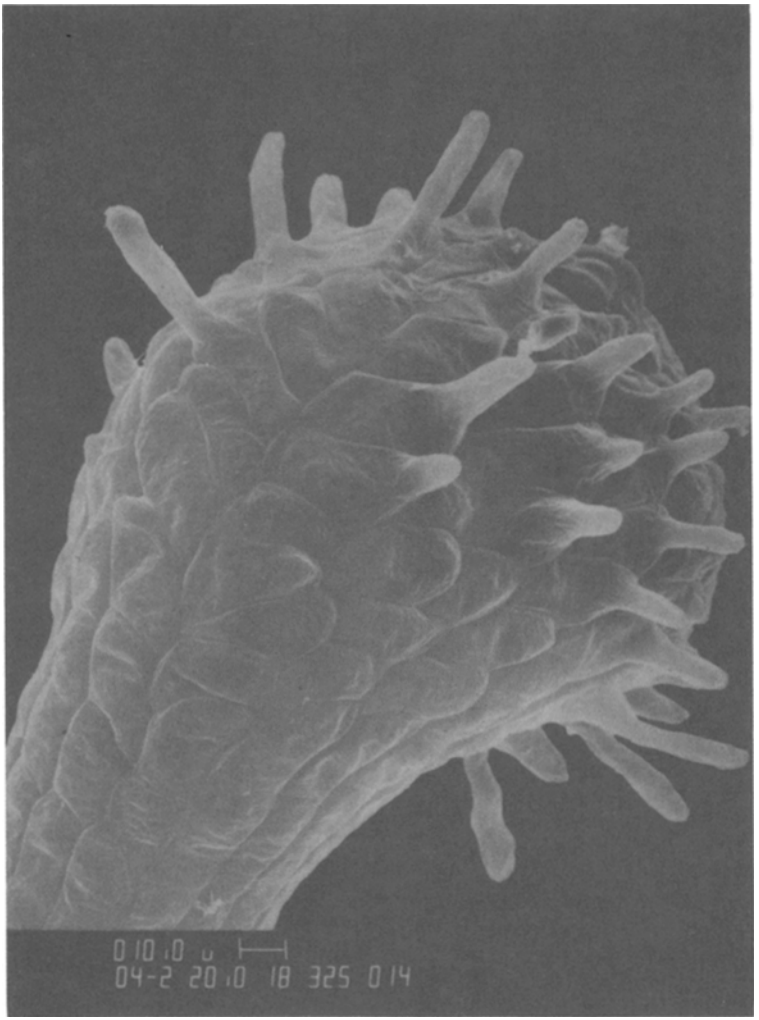


FIG. 1. Electron micrograph of the developing haustorium of *Striga asiatica*. The haustorium forms at the meristematic tip and radicle elongation is halted. (Courtesy of Dr. Vance Baird).

eluant, a biologically active red-colored band was collected and dried (38 mg). Further purification on a reverse-phase C18 flash column (1.1 × 2.1 cm, 40% MeOH–H_2O) gave an early eluting orange fraction (7.9 mg), which was subsequently chromatographed on SiO_2 (0.55 × 6.1 cm, CH_2Cl_2) to yield a yellow sample (1.1 mg). Final HPLC purification on Waters Radial Pak (SiO_2, 5 μm, 8 mm i.d. × 10 cm, 92% hexane–6% CH_2Cl_2–2% MeOH) gave 100 μg of a

crystalline solid capable of haustorial induction. This procedure was repeated four additional times throughout the process of the structural characterization and yielded a total of approximately 600 μg of material.

Chromatography. Gel filtration chromatography was performed using Sephadex LH-20-100 (25–100 μm particle size) obtained from Sigma Chemical Co. Reverse-phase chromatography was performed by using octadecylsilane-bonded silica gel (40 μm particle size) supplied by J.T. Baker Chemical Co. Silica gel 60 (230–400 mesh) obtained from EM Reagents, Inc., was used for SiO_2 column chromatography. High-pressure liquid chromatography (HPLC) was performed both analytically and preparatively on 5 μm Waters Radial Pak SiO_2 columns. Solvents were blended in a Dupont series 8800 four-solvent pump operated by a Dupont series 8800 gradient controller. Effluent was monitored at 284 nm with a Dupont series 8800 Spectro variable wavelength detector.

Syntheses of Compounds 2,6-Dimethoxy-p-*benzoquinone* (4), was synthesized by the method reported earlier (Bolker and Kung, 1969).

For *2,5-Dimethoxy*-p-*benzoquinone* (5), to a stirred solution of 2,5-dihydroxy-*p*-benzoquinone (50 mg, 0.36 mmol) in 3 mL methanol, diazomethane (0.72 mmol) was added at room temperature, and the stirring was continued for 2 hr. Solvent was evaporated in vacuo, the residue dissolved in CH_2Cl_2, and washed with 5% Na_2CO_3 (2×) and H_2O (2×). Concentration of the organic layer gave 5 (40.8 mg, 68%).

2,3-Dimethoxy-p-*benzoquinone* (6), was prepared by oxidation of 1,2,3-trimethoxybenzene with hydrogen peroxide and potassium ferricyanide (Matsumoto and Kobayashi, 1985).

2-Carboxymethoxy-6-methoxy-p-*benzoquinone* (7), was prepared by nitric acid oxidation (Bolker and Kung, 1969) of 1,2-dimethoxy-3-phenoxyacetic acid (synthesized from 2,3-dimethoxyphenol by the method of Burgstahler and Worden, 1973). [^{1}H] NMR ($CDCl_3$), δ 3.81 (s, 3H), 4.60 (s, 2H), 5.72 (d, J = 2Hz, 1H), 5.84 (d, J = 2 Hz, 1H). FT-IR (CH_2Cl_2), 1756, 1697, 1644, 1595 cm^{-1}.

2-Ethoxy-6-methoxy-p-*benzoquinone* (8). A solution of 2,3-dimethoxyphenol (15.8 mg, 0.103 mmol) in ethyl bromide (2 mL) and K_2CO_3 (19.9 mg) was refluxed for 9 hr. The solvent was evaporated in vacuo, the residue dissolved in ether and washed with saturated $NaHCO_3$ (3×), then H_2O (3×). The organic layer was dried over anhydrous $MgSO_4$, concentrated in vacuo, and purified on SiO_2 (0.55 × 6.3 cm, benzene–MeOH, 98:2) giving 1,2-dimethoxy-3-ethoxybenzene (2,3 mg, 13%). Subsequent oxidation with nitric acid as above, gave VIII. [^{1}H] NMR ($CDCl_3$), δ 1.46 (t, H = 7 Hz, 3H), 3.79 (s, 3H), 3.97 (q, J = 7 Hz, 2H), 5.27 (s, 2H). FT-IR (CH_2Cl_2), 1697, 1644, 1593 cm^{-1}.

2-Methoxy-p-*benzoquinone* (9) was prepared by the reaction of *p*-benzoquinone with methanol at room temperature for 24 hr. Purification on SiO_2 column (1.6 × 9.5 cm, benzene–ether, 90:10) gave IX. [^{1}H] NMR($CDCl_3$), δ

3.73 (s, 3H), 5.84 (s, 1H), 6.60 (s, 2H). FT-IR (CH_2Cl_2), 1679, 1658, 1622, 1589 cm^{-1}. UV (CH_2Cl_2), λ_{max} 358 nm (log ϵ 1.20), λ_{max} 254 nm (log ϵ 2.18).

Histochemical Assay for Detection of Phenol Oxidases (Harkin and Obst, 1973). *Sorghum*, peas, and lettuce seeds were surface sterilized with 50% commercial bleach for 20 min. *Agalinis* seeds were surface sterilized as reported earlier (Riopel and Musselman, 1979). Treated seeds were then rinsed with sterile distilled water and grown on a modified Murashige and Skoog (1962) medium under a 12 hr photoperiod at 27°C. Seedlings were transferred from the agar to microscope slides, and a solution of 0.1% syringaldazine in ethanol (1–2 drops), followed by 0.3% H_2O_2 (1–2 drops) was added to the roots. The red-purple color developed immediately and tended to fade after 15 min.

Spectroscopy. [^{1}H] NMR data were recorded with a home-built console interfaced with an Oxford 500-MHz magnet, a 1280/293C data system, and NMCFT software. FT-IR spectra were performed on a Nicolet 20SXB with 1 cm^{-1} resolution. The spectrum was stored and solvent background was computer subtracted. UV data were obtained using a Perkin-Elmer Lambda 5 UV/VIS spectrophotometer. High- and low-resolution mass spectral data were obtained with a VG 70-250 spectrometer.

RESULTS

A general screen for materials which are able to induce the development of haustoria in *Striga* has been developed (Nickrent et al., 1979). The use of this screen to direct the purification of compounds from *Sorghum* roots is shown in Scheme 1. This purified haustorial inducer proved to be the only active fraction in *Sorghum*. The bright yellow compound was slightly soluble in H_2O and very soluble in organic solvents, and possessed a strong long-wavelength UV chromophore with λ_{max} 284 nm (log ϵ 4.01) and 376 nm (log ϵ 2.65). [^{1}H] NMR ($CDCl_3$, 500 MHz) indicated only two signals at δ 5.83 and 3.75, with a relative integrated ratio of 1:3, respectively. EI-MS (70 eV, 200°C) showed a molecular ion at *m/z* 168, and this assignment was supported by DCI-MS (isobutane, M + H ion at *m/z* 169). Exact mass measurements established a molecular formula of $C_8H_8O_4$ (*m/z* 168.0389, calc. 168.0422).

These data uniquely support a dimethoxy-*p*-benzoquinone structure. Orthoquinones are generally dark red in color and possess a considerably higher redox potential than the para isomers. This redox chemistry is readily observed as an intense $(M + 2)^+$ ion in the mass spectrum (Patai, 1974). The three isomeric

SCHEME 1. The schematic representation of the isolation procedure followed for the purification of the haustorial inducer from *Sorghum* root extract. The activity of each fraction is represented as the concentration of the extract necessary to induce 75% of the seedlings to develop haustoria. @Minimum concentration required to induce 75% haustoria. *Swelling only, no viable haustoria observed. All other fractions were inactive.

p-benzoquinones 4–6 are not readily distinguishable by the data thus far presented.

The 2,3-substituted quinone, (6), reflects the symmetry observed in the system by NMR, but the quinonoid protons would be expected to resonate farther downfield (δ 6.3–7.3) than those observed in the haustorial inducer. The electronic spectrum of the unsubstituted *p*-benzoquinone has three absorptions:

an intense $\pi \rightarrow \pi^*$ transition at 246 (log ϵ = 4.42), a medium intensity $\pi \rightarrow \pi^*$ band at 288 (log ϵ = 2.50), and a weaker $n \rightarrow \pi^*$ absorption at 439 nm (log ϵ = 1.35) (Patai, 1974; Morton, 1965). Introduction of a methoxy substituent produces a small bathochromic shift of the first band (< 10 nm), but the second band undergoes a more noticeable red shift of the order of 69 nm (Patai, 1974; Thomson, 1971, and references therein). The third band is little affected and is obscured by the second maximum. Introduction of a second substituent has much less effect on the second band than the first, and is the greatest for the 2,3-disubstituted derivative (Patai, 1974). The observed bands in the haustorial inducer at 284 and 376 nm do not fit with the expected transitions of the 2,3-dimethoxy isomer (6). In addition, neither the favorable retro-Diels-Alder fragmentation, nor the $(M + 2)^+$ ion expected for 6 are observed in the mass spectrum (Bowie et al., 1966). The mass spectrum of the natural product shows ions at *m/z* 112 and 80 which could arise from the retro-Diels-Alder cleavage of either 4 or 5 (Figure 2).

Of the two possible isomers remaining, the 2,5-isomer would be expected to give two different electronic transitions of equal intensity around 280 nm. In addition, the carbonyl stretching frequencies in the 2,5-isomer should be of the same frequency. FT-IR (CH_2Cl_2) of the haustorial inducer showed intense bands

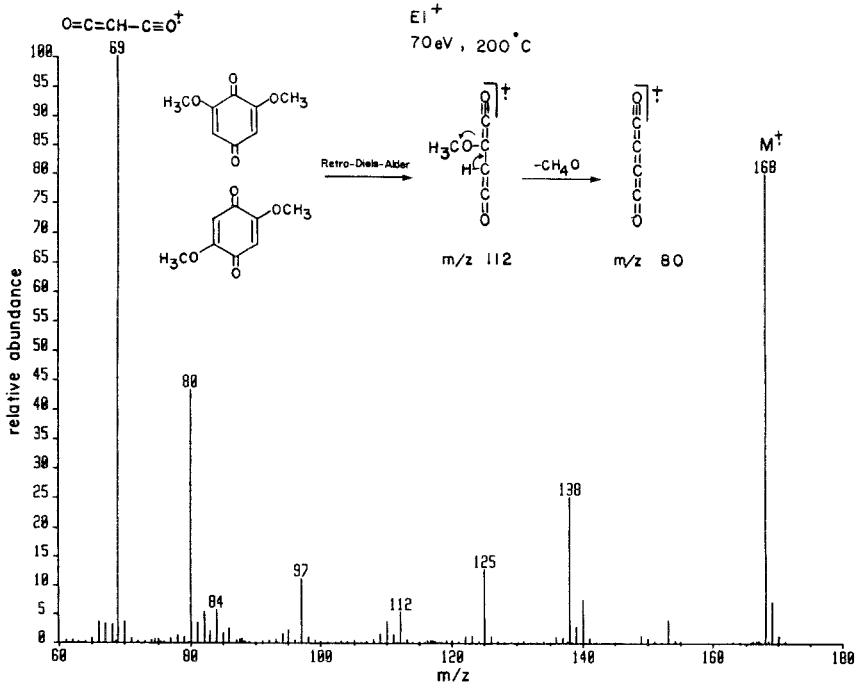

FIG. 2. Electron impact mass spectrum (70 eV, 200°C) of the haustorial inducer from *Sorghum*. The sample (ca. 3 μg) was volatilized from a solid probe on a VG 70-250.

at 1698 (νC = 0), 1646 (νC = 0), and 1597 cm^{-1} (νC = C) (Figure 3). These electronic and vibrational transitions uniquely established the haustorial inducer as 2,6-dimethoxy-*p*-benzoquinone (4 2,6-DMBQ).

Synthetic studies have finalized the assignment. Nitric acid oxidation of 1,2,3-trimethoxybenzene gives 4 in reasonable yields (Bolker and Kung, 1969), whereas oxidation with hydrogen peroxide and potassium ferricyanide gives 6 and 4 in a 3 : 1 ratio, respectively (Matsumoto and Kobayashi, 1985). The commercially available 2,5-dihydroxy-*p*-benzoquinone can be efficiently methylated with diazomethane to give 5. These synthetic samples gave the anticipated spectral data (Table 1) and confirmed the assignment of 2,6-dimethoxy-*p*-benzoquinone as the haustorial inducer.

By similar synthetic methods, several benzoquinone analogs have been prepared. These studies reveal a strict structural requirement for biological activity. Figure 4 compares the haustoria-inducing activity of the monomethoxy (9), and ethoxymethoxyquinones (8), both of which show reduced activity when compared with 4. Unexpectedly, replacement of the ethyl substituent of 8 with the corresponding carboxy methylene (7), increases the analog's activity to a level comparable to 2,6-DMBQ. More drastic structural alterations completely abolish activity (Table 2). Like the xenognosins, a methoxy functionality ap-

pears to be critical, and the unsubstituted benzoquinone, as well as the dimethyl and 2,5-dihydroxy derivatives, are totally inactive.

The active quinones also show a distinct concentration for maximal activity, and at high concentrations they inhibit haustorial induction. This inhibition may be related to the broad spectrum of toxic effects documented for these quinones (Bundenberg de Jong et al., 1955; Hausen et al., 1972; Jones et al., 1981; Kodaira et al., 1983; Redfearn and Whittaker, 1962; Schultz et al., 1979), however, there is no necrosis or obvious growth inhibition at high concentrations. 2,3-DMBQ and 2,6-DMBQ are both inhibitors of mitochondrial respiration (Chappel and Hansford, 1972; Redfearn and Whittaker, 1962) and are capable of inducing haustoria. In contrast, the 2,5-isomer shows no such inhibition of respiration and does not induce haustoria. The connection between the inhibition of respiration, the general toxicity, and haustoria-inducing activity of these quinones is still not clear.

Recognizing that pathogenic fungi secrete phenol oxidases to catalyze the breakdown of lignins to various phenolics including 2,6-DMBQ (Umezawa et al., 1982), we investigated whether parasitic angiosperms produced the same enzymes. The addition of syringaldazine (Figure 5) and hydrogen peroxide to

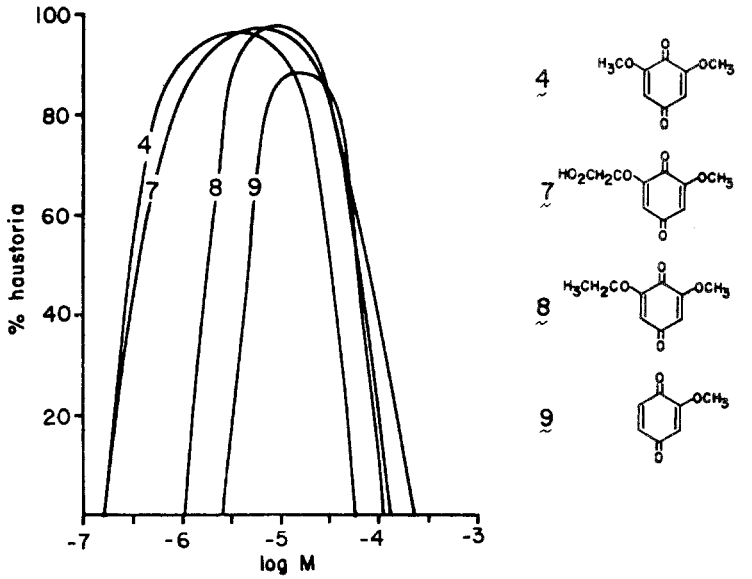

FIG. 4. Logarism of the concentration of the haustorial inducer plotted against the percentage of 2-day-old *Striga* seedlings that are induced to develop haustoria. The assay is performed on 20–50 *Striga* seedlings in 1 mL of distilled H_2O and the number of haustoria are counted after 24–48 hr exposure time. The striking inhibition at high concentrations of the analogs does not appear to be due to insolubility nor are there any visible toxic effects on the seedlings.

the roots of lettuce, pea, and *Sorghum* seedlings immediately turned the root hair zone of these plants a dark reddish purple. By contrast, this dye is oxidized at the meristematic root tip in *Agalinis* seedlings. None of the potential host plants, thus far tested, show evidence for any phenol oxidase activity at the root tip.

DISCUSSION

Striga asiatica responds through the development of the haustorium to only a single compound in *Sorghum* extract. This specific response is much simpler than the chemical responses seen between *Agalinis* and *Lespedeza*. *Striga*, being an obligate parasite, has a far more restrictive time frame in which to identify its host than does *Agalinis*. This limitation in time means that *Striga* must germinate at a distance where the growing radicle can reach the host root within five days, about 0.3–0.4 cm. Likewise, haustorial induction, which stops radicle elongation, must occur well within 50 μm of the host root, or the parasite will not attach or survive. So *Striga*, much more critically than *Agalinis*, must

TABLE 2. COMPARISON OF THE BIOLOGICAL ACTIVITY OF DIFFERENT BENZOQUINONE ANALOGS[a]

	ED_{50}		ED_{50}

	$0.6\text{-}3.0 \times 10^{-6}$ M		

[a]The ED_{50} represents the concentration of the analog necessary to induce haustorial development in 50% of the *Striga* seedlings.

utilize host chemistry to signal not only the presence of a suitable host, but also to serve as a cue that the host is within the required distance for attachment. How then can the exudation of stable phenolic compounds account for this host and distance selection given that such materials would be expected to accumulate very differently depending on the soil, weather, and microbial conditions?

Work over the last 40 years has focused on the identification of the germination factor for *Striga* from natural host plants. This work has not been successful primarily because of the reported physical instability of the germination stimulants. Strigol was identified from a nonhost, cotton (Cook et al., 1972); this stimulant is quite stable and can accumulate around the root of the cotton plant. *Striga's* ability to respond to a physically unstable compound could eliminate any buildup around the host root and may provide a mechanism for

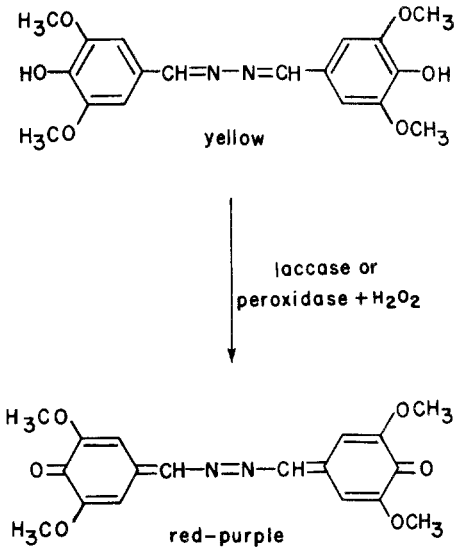

FIG. 5. Oxidation of syringaldazine to the red-purple pigment used for the histochemical detection of laccases or peroxidases.

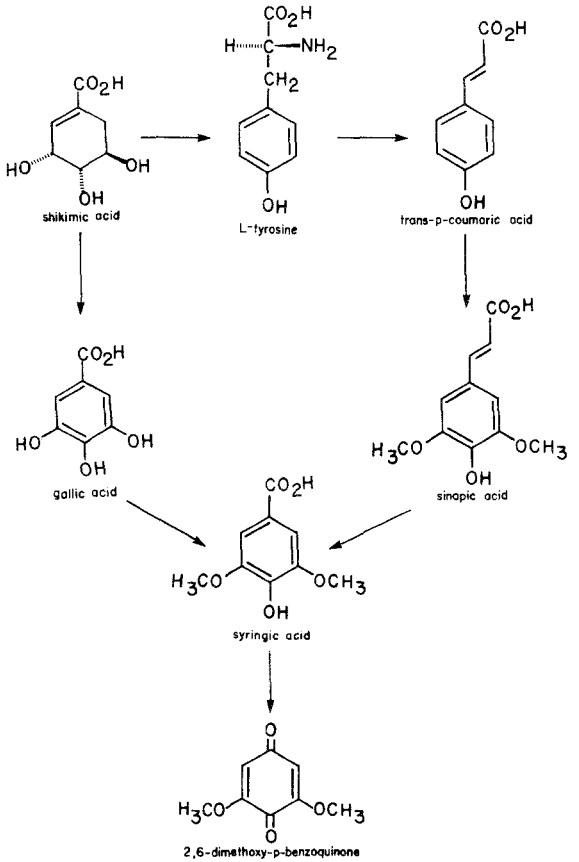
measuring distance. 2,6-DMBQ is chemically stable, so that under appropriate conditions it could accumulate at distances far from the root surface.

2,6-DMBQ is broadly distributed in the plant kingdom, occurring in 48 genera within 29 different families (Handa et al., 1983). The benzoquinones are biosynthesized through two independent pathways, both branching from shikimic acid (Scheme 2). Direct dehydrogenation gives rise to benzoic acid derivatives, such as syringic acid. Alternatively, oxidative removal of the propene side chain of phenylpropanoids, such as sinapic acid, gives the same benzoic acid which is oxidatively decarboxylated to the quinone (Harborne, 1977; Haslam, 1974). Both of these pathways are found in large numbers of plants and the widespread occurrence of 2,6-DMBQ is not surprising. However, all our efforts to identify 2,6-DMBQ in the root exudate of *Sorghum* have failed, and in fact, carefully collected exudate from healthy *Sorghum* seedlings does not induce haustorial development in *Striga*.

Xenognosin A, which induces haustoria in *Agalinis* and *Striga*, is structurally similar to 2,6-DMBQ. Both compounds contain the same metamethoxyphenol functionality, differing only in oxidation state. Structural modifications altering this functionality dramatically affect the activity of both compounds. Our report (Lynn et al., 1981) of phenolic compounds inducing haustorial development in *Agalinis* led MacQueen (1984) to study the activity of other phenolic compounds. Ferulic and sinaptic acids are active on *Striga hermonthica* at 10^{-6} M, whereas syringic acid shows half maximal activity at 10^{-7}

M. The level of haustorial induction by these phenolic acids is comparable to those observed by the similarly substituted quinones. Our studies have shown that 3,4-dihydroxycinnamic acid and 1,2,3-trimethoxybenzene, both of which either lack the methoxy or free hydroxy groups, show no activity whatsoever in *Striga asiatica*. These results suggest that the activity of all of these phenolics is mediated through a similar mechanism in *Agalinis* and *Striga* species, but it does not explain how these compounds are being detected by the parasite.

Umezawa et al. (1982) have shown that pathogenic fungi are capable of degrading lignin model compounds, such as 12, to 2,6-DMBQ by the action of phenol oxidases (Figure 6). In fact, simple syringic and sinapic acid derivatives give 2,6-DMBQ when treated with laccases or peroxidases (Caldwell and Steelink, 1969; Ishihara and Ishihara, 1976). A specific dye, syringaldazine, has been developed to test for the presence of these enzymes (Figure 5). The com-



SCHEME 2. Biosynthetic pathways for the production of 2,6-DMBQ.

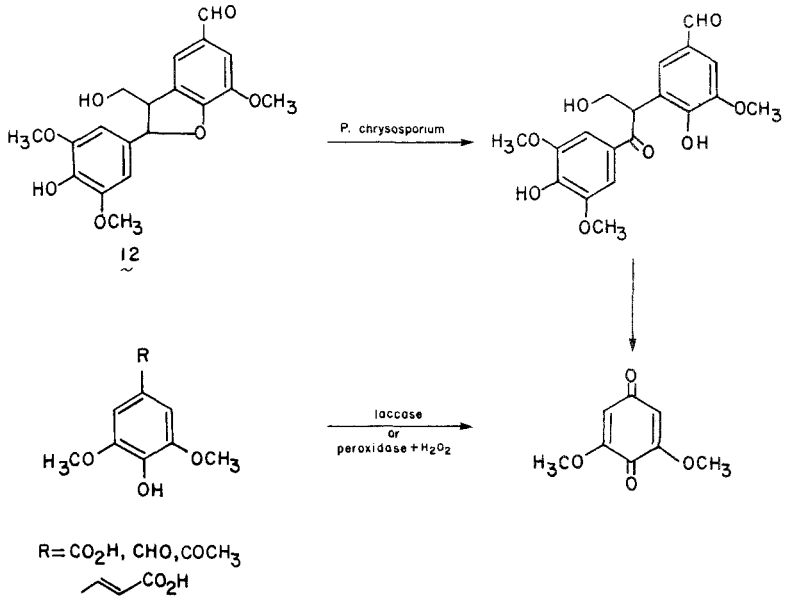


FIG. 6. Enzymatic breakdown of a lignin model compound by the pathogenic fungi *Phanerochaete chrysosporium*. Oxidation of alkyl phenols is possible with laccases or peroxidases to give compounds similar to 2,6-DMBQ.

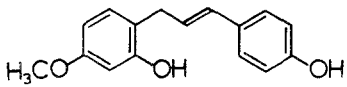
pound, which is yellow in its reduced form, is oxidized to the red–purple quinone methide in the presence of laccases or peroxidases (Harkin and Obst, 1973).

Harkin and Obst used this dye to screen large numbers of fungi for phenol oxidases and were able to obtain a correlation between plant pathogenic fungi and excreted phenol oxidases. This correlation supported the specific use of these enzymes by the fungi to digest host-plant cell walls. Our results have shown that *Agalinis* has similar enzymatic activity apparently localized at the meristematic root tip. While the identification of this enzymatic activity says nothing about its specificity, the differential location of these enzymes in the parasite appears to be significant.

The presence of such activity would allow these parasites to oxidatively degrade phenylpropanoid surface components from proximal root surfaces. If a root surface with the proper phenylpropanoid is enzymatically degraded to the appropriately substituted quinone, such as 2,6-DMBQ, then the parasite responds by initiating the development of the host attachment organ. Most importantly, the strategic localization of these enzymes at the meristematic tip would guarantee proper distances being established between host and parasite before haustorial development is initiated. Structural modifications of xenognosin A that would be expected to effect this oxidation, such as reduction of

the propene double bond or the methoxy regioisomer (11), drastically reduce the biological activity. These other phenylpropanoids could be active as a result of their conversion into the active quinones. Such a theory of surface component degradation to the appropriate quinones would unify the mechanism of distance regulation and host selection in *Agalinis* and *Striga* and may be widespread among the Scrophulariaceae. Efforts are currently underway in our laboratory to further substantiate this mechanism of biological recognition.



11

What we hope to have demonstrated is that plants, like animals, have evolved very specific recognition systems that allow them to respond to and regulate their environment. It is critical that parasitic angiosperms regulate and respond to environmental cues, and they have provided a very fruitful system for study. Such plant–plant interactions may prove to be far more prevalent and highly evolved than we ever dreamed possible. Through a better definition of the control of plant growth and development, we hope it will be possible to define more precisely the communication occurring between members of the plant kingdom.

Acknowledgments—We thank Professor Glenn Prestwich and the other organizers of this symposium for the invitation to present this paper and for their organization of such a conference. The collaborative effort between this laboratory and the laboratory of Professor James Riopel at the University of Virginia is gratefully acknowledged. Mary Beth Hetz' performance of many of the bioassays and much of the *Sorghum* production was an invaluable contribution. We also thank Professor Fred Ruddat at The University of Chicago for valuable advice and help; the Frasch Foundation, USDA Competitive Research Grant 5901-0410-9-0257 and USDA Cooperative Agreement 58-7B30-0-196 for support. D.G.L. also acknowledges support from the Alfred P. Sloan Foundation and The Camille and Henry Dreyfus Foundation, Inc.

(Received December 21, 1984; accepted July 3, 1985)

Abstract—*Hylurgopinus rufipes* male and female beetles were attracted to American elms infected with Dutch elm disease, and to American elms killed by injection of cacodylic acid. *H. rufipes* was also attracted to solvent extracts of elm, or to Porapak Q-trapped volatiles from elm. The major components of attractive fractions of Porapak Q-trapped volatiles were isolated, identified, and tested in field bioassays. Several artificially compounded mixtures of sesquiterpenes were attractive to *H. rufipes*, although no bait tested was as attractive as diseased tree controls. Laboratory bioassays with *H. rufipes* were marginally successful. In laboratory bioassays, nine of 14 sequiterpenes identified from active fractions of Porapak extracts elicited significant response from *Scolytus multistriatus* male and female beetles: δ- and γ-cadinene, α-cubebene, γ-muurolene, and β-elemene were most active. However, in field tests, none of the sesquiterpenes alone or in combination significantly attracted *S. multistriatus*, nor did they significantly enhance the attraction of *S. multistriatus* to female-produced pheromone components (4-methyl-3-heptanol [H] and α-multistriatin [M]). In other field tests, α-cubebene (C) significantly enhanced response of *S. multistriatus* to H plus M, but foliage, logs, or chips of healthy elm did not enhance trap catch to HMC.

Key Words—*Hylurgopinus rufipes*, *Scolytus multistriatus*, Coleoptera, Scolytidae, sesquiterpenes, host attractants, Dutch elm disease, kairomone, pheromone, elm bark beetles, *Ulmus americana*.

INTRODUCTION

Dutch elm disease has ravaged elm populations in North America and Europe. In North America, the principal vectors of the disease are two scolytids: the European elm bark beetle [*Scolytus multistriatus* (Marsham)] and the native elm bark beetle [*Hylurgopinus rufipes* (Eichhoff)]. *S. multistriatus* is the dominant species in most of the United States, and it has been studied extensively (for review, see Gardiner, 1976). In the mid-1970s, the aggregation pheromone complex for *S. multistriatus* beetles was reported (Pearce et al., 1975), and synthetic pheromones are now registered for detection and mass trapping of this beetle (e.g., O'Callaghan et al., 1980; Lanier, 1981; Peacock et al., 1981).

H. rufipes beetles are the principal vector of Dutch elm disease in the northern United States and Canada, where winters are too severe for *S. multistriatus* to survive in significant numbers. To date, attempts to demonstrate the use of pheromones by *H. rufipes* have failed (Peacock, 1979; Gardiner, 1979), and it has been suggested that this insect may aggregate using only host volatiles (Gardiner, 1979; Lanier, 1983). Indeed, several groups have reported, and we have confirmed, that both sexes of *H. rufipes* are attracted to cut elm wood (Martin, 1936), wounded elms (Landwehr et al., 1981), naturally moribund elms (Gardiner, 1979), and especially trees killed with the arboricide cacodylic acid (Gardiner, 1979).

There have been a few reports of volatile compounds produced by the genus *Ulmus* (e.g., Rowe et al., 1972; Rowe and Toda, 1969; Pearce et al., 1975; Peacock et al., 1975; Blight et al., 1978; 1983; Blight, 1981) and of volatiles produced by microorganisms associated with *Ulmus* (French et al., 1984). However, there has been no systematic attempt to isolate and identify the principal volatiles released by elm trees; most previous work with volatile compounds has been directed towards the identification of pheromones produced by *S. multistriatus* and *S. scolytus* (Fab.) (Pearce et al., 1975; Peacock et al., 1975; Lanier et al., 1976; Blight, 1981). Since the pheromone components in these cases were found to be much more powerful attractants than host volatiles, only the sesquiterpene α-cubebene, which synergized the pheromone of *S. multistriatus*, was of more than passing interest. However, Peacock et al. (1984) recently showed that elm logs enhanced attraction of *S. multistriatus* to multilure, and this effect could not be duplicated by increasing levels of α-cubebene. In the case of *H. rufipes*, where no pheromonal activity has been demonstrated, host volatiles are of paramount interest as potential attractants.

The aims of this research were: (1) to isolate and identify the attractive host volatiles produced by moribund elm trees, (2) to test artificially compounded mixtures of attractive chemicals as baits for *H. rufipes*, and (3) to determine whether additional host compounds are involved in the aggregation of *S. multistriatus*.

METHODS AND MATERIALS

Field Bioassays. Experiment 1 (Table 1) tested the hypothesis that *H. rufipes* beetles aggregate on wood suitable for breeding in response to pheromones. *H. rufipes* reared from our laboratory colonies were induced to bore into elm bolts (30 cm long and 15 cm diameter) to produce the following treatments: 20 females in log, 20 males in log, 10 males plus 10 females in log, and log without beetles. The logs were placed on the ground in sticky $\frac{1}{4}$-in. mesh hardware cloth cylinders closed at both ends by plywood squares. Experimental details are as follows: From May 24 to July 30, 1978, three replications were exposed near Ohio, Herkimer County, New York; from July 21 to September 8, 1978 and from September 5 to October 6, 1978, single replications were exposed near Manlius, Onondaga County, New York. *H. rufipes* were collected from the sticky traps at irregular intervals and at the end of the experiment. The Ohio test site was an open grassy area, whereas the Manlius sites were densely wooded with elms and other broad-leaved trees.

Experiment 2 (Table 2) was a field bioassay to measure the relative attractiveness of healthy, diseased, and cacodylic acid-killed trees. White, plastic-coated, 20 × 45-cm paper sheets treated with Stickum Special® remained wrapped around test trees at heights of 1–2 m above ground in Oswego County, New York from April 30 to July 6, 1979. At the end of the test period, the number of beetles caught on each sticky panel was counted. In addition, we assessed the number of beetle attacks on the various trees as measured by the number of insects reaching the xylem per square decimeter of bark surface area.

Experiment 3 (Table 3) employed two bioassay methods to ascertain

TABLE 1. EXPERIMENT 1: FIELD RESPONSE OF *Hylurgopinus refipes* TO BEETLES IN LOGS AND LOGS ALONE[a]

	Test 1	Test 2	Test 3	Total[b]
Log + 20 males	9	29	20	58
Log + 20 females	5	23	21	49
Log + 10 males and 20 females	7	22	13	42
Log	10	14	5	29
Total	31	88	59	178

[a] Test 1, Ohio, New York, May 24–July 30; test 2, Manlius, New York, July 21–September 8; test 3, Manlius, New York, September 5–October 6, 1978. Each test consisted of three replications of each treatment.

[b] Combined catches for three tests differ significantly from equality among treatments ($\chi^2 = 10.09$; $P < 0.05$). The sex ratio for beetles captured was 1:1.2 (♀ : ♂), and there were no significant differences in sex ratios among treatments.

Healthy	8	17.38a	3	0 a
Diseased	4	190.25b	3	1168b
CA-killed	9	259.69b	3	277c

[a]Means followed by the same letter are not significantly different (Student's t test, $P < 0.01$).

TABLE 3. EXPERIMENT 3: FIELD ATTRACTION OF *Hylurgopinus rufipes* TO ELM EXTRACTS

	Date/place	Treatment	Beetles caught
Test 1	May 8–14, 1981	Ethanol extract, 20 μl	71
	Oswego Co., New York	Ethanol	13
Test 2	June 6, 1981	Porapak-Q extract, 20 μl	86
	Syracuse, New York	Hexane, 20 μl	0
		Ethanol extract, 20 μl	3
		Ethanol, 20 μl	0

whether *H. rufipes* was attracted to either an ethanol extract of the bark of cacodylic acid-killed elms or to a pentane extract of Porapak-Q-trapped volatiles from bark of killed elms. In the first test, blower olfactometers (Gara and Vité, 1962) were used to bioassay extracts dispensed from 2-ml polyethylene vials with a pinhole in the cap. In the second test, 10 μl of the extracts were pipetted onto Masonite panels that were fastened immediately above sticky traps (45 × 22 cm white cardboard sheets) placed 1–2 m above ground on healthy elms. The Masonite panels were rebaited and rotated among trap positions at 30-min intervals.

Experiment 4 (Table 4) field bioassayed the response during May to July 1984 of *H. rufipes* to compounds identified from elm. Three test plots were used: one was in a level swampy area in Rutland, Vermont, and the other two were outside Tinmouth, Vermont, on gently sloping hillsides. On all sites, elms were present but were not the most abundant hardwood species. Two replicates of each bait were tested in each plot. Traps were 50 × 25-cm cardboard panels coated with Stickem Special, wrapped around and stapled to trees about 1.5 m above ground level. Traps with baits were placed at least 8 m apart on species

Bait[b]	Beetles/trap observation[a]	
	Number	Mean ± SE
Diseased elm	12	31.33 ± 7.85a
3	12	11.83 ± 2.72b
4	12	8.16 ± 2.55bc
5	12	7.83 ± 2.23bc
6	12	4.25 ± 1.16cd
2	12	2.58 ± 0.68d
1	12	2.25 ± 1.32de
7	12	1.33 ± 0.62de
Healthy elm	12	0.58 ± 0.26e
8	12	0.42 ± 0.19e

[a] Three plots each with two replications observed twice (May 31, June 16) for 12 trap observations. Means followed by the same letter were not significantly different ($P > 0.05$, Student's t test).
[b] Baits were as follows: 1, β-elemene; 2, α-cubebene; 3, β-elemene, α-cubebene, α-copaene, α-gurjunene, allo-aromadendrene, thujopsene, and β-caryophyllene; 4, same as 3 less β-elemene and α-cubebene; 5, same as 3 less β-elemene; 6, same as 3 less α-cubebene; 7, δ-cadinene; 8, calamenene, γ-muurolene, α-humulene, α-selinene, and α-circumene. Later tests of β-elemene + α-cubebene and other combination yielded no data. Lack of beetles on traps on diseased elms indicated that few beetles were moving to breeding material after late June.

of trees other than elms and on healthy and diseased elm trees (controls). Baits were prepared by absorbing hexane solutions of compounds into grey rubber GC septa (Supelco, 9 mm). Each septum was loaded with 1 mg of each component of the bait. Baits were impaled on a large metal paper clip bent into a U-shape, and the paper clip was hooked over the top edge of the trap panel so that the bait was positioned about 4 cm from the trap surface. The bait was covered with a 2-dr glass shell vial to keep off rain and wind-blown debris. Baits were assigned to trees by randomly drawing vials of baits from a bag.

The same sticky traps were used throughout the test period, but the baits were replaced when the trap catches were counted. All *H. rufipes* were removed when the trap catches were counted at two-week intervals. Traps were examined twice; thus there were 12 observations of each bait (3 plots × 2 replicates/plot × 2 observation periods). Testing was discontinued when the trap catch on diseased control trees fell to less than $\frac{1}{10}$ of the peak season catch.

Experiment 5 (Table 5) examined the effects of elm volatiles on the enhancement of attraction of *S. multistriatus* to its synthetic pheromone, multilure. Multilure was dispensed from Conrel® hollow fibers (Albany International, Needham Heights, Massachusetts) at nominal daily release rates of 274 μg 4-methyl-3-heptanol, 126 μg α-multistriatin, and 369 μg α-cubebene (Cuth-

TABLE 5. EXPERIMENT 5: ATTRACTION OF *Scolytus multistriatus* TO PHEROMONE AND HOST ODORANTS IN THE FIELD, SYRACUSE, NEW YORK

Bait[a]	Beetles/trap observation		Index (mean ± SE)[c]
	Number[b]	Mean	
A. May 25–August 25, 1980

22 ♀ ♀ + log	22	58.1	4.88 ± 2.00b
Log	22	41.9	2.97 ± 1.26b
B. June 1–August 14, 1981			
HMC + chips	16	365.5	33.0 ± 2.47a
HMC	16	310.4	25.9 ± 2.67ab
HMC + log	16	265.9	22.2 ± 2.59bc
HMC + foliage	16	200.1	18.8 ± 1.97c

[a] HMC 4-methyl-3-heptanol, α-multistriatin, and α-cubebene dispensed from Conrel hollow fibers.
[b] A, two replications observed 11 times; B, four replications observed four times. Logs, chips, and foliage were changed at each observation.
[c] Catches on each trap were indexed as a percentage of the total catch on a replicate. Total catch 1980, 18,270 beetles; 1981, 40,183 beetles.

bert et al., 1983). Beetles were trapped on white 46 × 66-cm poly-coated cardboard sticky traps affixed 2.5 m above the ground to utility poles at least 40 m apart on streets where there were no elms in a residential section of Syracuse, New York.

In 1980, treatments were: (1) multilure, (2) multilure plus an elm log (25 cm long, 8–10 cm diam), (3) 20 female *S. multistriatus* beetles with an elm log (as a source of natural pheromone), and (4) an elm log alone. Each treatment was represented once on two experimental replicates on different streets. Beetles on traps were counted and logs were changed at weekly intervals from May 25 to August 25. Logs were wrapped in fine mesh copper screening during the experiment and examined for beetle attacks when they were replaced.

In 1981 treatments were: (1) multilure, (2) multilure plus elm log, (3) multilure plus 180 g elm wood and bark chips (produced with a chain saw), and (4) multilure plus 120 g fresh elm foliage. The logs were as described for the 1980 experiment; elm foliage and chips were held in copper wire screen baskets affixed to utility poles. Each treatment was represented once in each of four replicates. Fresh elm materials were provided, and treatments within replicates were rotated at the beginning of four 21-day observation periods between June 1 and August 14.

Experiment 6 (Table 6) investigated the possibility that limonene could be substituted for α-cubebene as the host component of multilure. Methods of bee-

TABLE 6. EXPERIMENT 6: ATTRACTION OF *Scolytus multistriatus* TO PHEROMONE AND COMBINATIONS OF PHEROMONE PLUS α-CUBEBENE OR LIMONENE; SYRACUSE, NEW YORK, AUGUST 1–SEPTEMBER 3, 1980

Bait[a]	Beetles/trap observation		Index (mean ± SE)[c]
	Number[b]	Mean	
HMC	20	511.4	33.10 ± 3.57a
HML−	20	353.0	23.74 ± 3.49ab
HM	20	302.4	21.92 ± 2.92b
HML+	20	290.3	20.99 ± 2.72b
Blank	20	3.5	0.27 ± 0.08c

[a] H = 4-methyl-3-heptanol; M = α-multistriatin dispensed from Conrel hollow fiber; C = α-cubebene; L+ = (+)-limonene; L− = (−)-limonene dispensed from polyethylene vials.
[b] Four replicates observed five times (weekly intervals).
[c] Catches on each trap were indexed as a percent of the total replicate catch during each observation interval. Total beetle catch for the experiment was 29,214 beetles. Means followed by the same letter were not significantly different ($P > 0.05$, Student's t test). The probability level for the difference between HMC and HML− was $<0.10 >0.05$.

tle trapping and release of 4-methyl-3-heptanol and α-multistriatin were the same as those used in experiment 5. Limonene was released from heat-sealed 2-ml polyethylene vials with 2 mg of (+)- or (−)-limonene loaded into each vial. α-Cubebene was released from grey rubber GC septa (9 mm, Supelco) which had been impregnated with 1 mg α-cubebene in hexane solution. Actual release rates of limonene and α-cubebene were not determined. Baits were placed in a cardboard shelter and stapled to the trap substrate. Each of four treatments and a blank was replicated four times and observed at weekly intervals between August 1 and September 3, 1980.

Insects and Laboratory Bioassays. H. rufipes were from colonies maintained as described by Gardiner and Roden (1977). *S. multistriatus* adults used in laboratory bioassays emerged from naturally infested elm wood and were conditioned in glass Petri dishes under 12 hr fluorescent light at 23°C and ambient humidity (Lanier et al., 1977). In early bioassays of host extracts with *S. multistriatus*, the males and females were tested separately, but when no significant differences in response were evident, the sexes were not separated.

The bioassay device used was the Moeck (1970) olfactometer, in which beetles were induced by positive phototaxis to cross an air flow that bore a narrow odor stream. Beetles that turned and walked 2 cm toward the odor source or made at least one 360° turn within the odor stream were judged to have responded positively. Beetles that did not respond to the odorant on the first trial were released once more; the response for the group was the sum of the two trials. This is one of the assays used in the isolation of *S. multistriatus*

pheromone components (Pearce et al., 1975) and in subsequent laboratory tests (Lanier et al., 1977; Lanier and Burns, 1978; Elliott et al., 1979). A walkway olfactometer (Jantz and Rudinsky, 1965) and a dual-choice device (White and Richmond, 1979) were also tried but found unsuccessful for bioassays with *H. rufipes*.

For all laboratory bioassays with *S. multistriatus*, a 5 beetle-hour equivalent of multilure (the synthetic pheromone of *S. multistriatus*) was the standard against which responses to other volatiles were indexed (5 beetle-hour equivalents = 12.5 ng 4-methyl-3-heptanol, 1 ng α-multistriatin, and 25 ng α-cubebene).

Experiment 7 (Table 7) assessed the laboratory response of *S. multistriatus* to the same ethanolic and Porapak extracts of moribund elm tested for the field response of *H. rufipes* (experiment 3).

Experiment 8 (Table 8) bioassayed response of *S. multistriatus* to fractions and subfractions of one of the Porapak extracts (EB43). A pentane extract of Porapak was made following aeration (2 liters/min) from July 16 to 25, 1980, of 5.5 kg bark stripped from a 30-cm-diameter American elm that had been killed by cacodylic acid treatment on June 20. The fractionation procedures are described in the section "Isolation and Identification of Compounds from Elm" (below).

Experiment 9 (Table 9) tested the laboratory response of *S. multistriatus* to compounds (5 ng in 1 μl hexane on filter paper) isolated from the most attractive host extract fractions (1 and 2, Table 8).

Experiment 10 (Table 10) tested individual sesquiterpenes as possible synergists to H + M in attracting *S. multistriatus*. Bioassays were run from

1 + 3 + 4	5	25.2 ± 2.87d
1 + 2 + 4	5	46.6 ± 6.02c
Air control	16	12.1 ± 3.82c

[a] Fractions 1–4 were collected at 0–24, 24–40, 40–74, and 74–126 min, respectively; 1.5 m × 7 mm ID, 10% Carbowax 20 M on chromosorb W 50/80 N_2 80 cc/min, 100° for 24 min, 100–190° at 6°/min. Fraction 2 was cut into five subfractions collected at 0–22, 22–29, 29–40, 40–47, and 47–66 min, respectively; 2.4 m × 4 mm ID, 4% Apiezon L on chromosorb G 60/80, N_2 60 cc/min, 150°. Indices of response to five subfractions of fraction 2 ranged from 8.5 to 20.5 for individual subfractions and from 11.0 to 22.0 for the various combinations of four of the five subfractions.

[b] Response to each stimulus was indexed as a percent of the response to the pheromone standard during a series of tests. Letters indicate significant differences ($P < 0.05$, t test of pairwise comparisons).

[c] 12.5 ng 4-methyl-3-heptanol, 1 ng α-multistriatin, and 25 ng α-cubebene in 5 μl hexane.

August 15 to September 12, 1984, in residential Syracuse, New York. Traps were set up as described in experiment 7. H + M were released from Conrel fibers (experiment 7), and sesquiterpenes were released from grey rubber GC septa (Supelco, 9 mm) loaded with 1 mg of test compound. Each of six sesquiterpenes, α-cubebene, β-elemene, thujopsene, α-copaene, allo-aromadendrene, and α-gurjunene, were tested alone and in combination with α-multistriatin and 4-methyl-3-heptanol (HM).

Traps with large number of beetles were removed and replaced to facilitate counting the trap catch. When trap catches were large (>500 beetles, estimated) beetles in 10 circles (4.5 cm diam) printed on the trap were counted, and the total catch was estimated by the regression equation $y = 41.8 + 12.5x$, where y is estimated total catch and x is the number of beetles on the circles.

Experiment 11 (Table 11) tested mixtures of sesquiterpenes as possible synergists to H + M in attracting *S. multistriatus*. Traps and baits were prepared as described in experiment 9. Sesquiterpene treatments were prepared with 1 mg of each sesquiterpene per septum. All *S. multistriatus* on the traps

[a] 5 ng/μl hexane on filter paper.
[b] Twenty-five unsexed *S. multistriatus*/replicate.
[c] Response to each stimulus was indexed as a percent of the response to the pheromone standard during a series of tests. Letters indicate significant differences ($P < 0.05$, t test of pairwise comparisons).
[d] 12.5 ng 4-methyl-3-heptanol, 1 ng α-multistriatin, and 25 ng α-cubebene in hexane solution totaling 5 μl.

were counted four times at weekly intervals. The experiment was run from July 6 to September 6, 1984, in residential Syracuse, New York.

Isolation and Identification of Compounds from Elm. American elm logs (wood + bark) were obtained from an urban area of Syracuse, New York. Logs were either sawn into thin disks or chipped with an industrial chipper. When required, logs were peeled so that wood and bark could be extracted separately. Ethanol extracts were made by steeping macerated bark (25 g) in 200 ml of 95% ethanol at room temperature. The resulting solutions were filtered and concentrated by removal of ethanol through a fractional distillation column.

For preparation of Porapak-Q extracts, an aeration apparatus was made from a thoroughly cleaned 55-gallon steel drum, fitted with a charcoal trap at the inlet, and a Porapak-Q trap (20 cm × 2.5 cm ID) at the outlet. A vacuum pump was used to pull air through the apparatus (2–9 liters/min). Aerations were continued for a period of one week, after which the material being aerated and the Porapak-Q trap were changed. Porapak-Q traps were stripped of volatiles by percolating 100 ml of glass-distilled pentane through the trap. The re-

[a] Individual sesquiterpenes were presented in two replications, observed three times. Other baits were presented in each replicate with each of the five sesquiterpene (two replicates × three observations × five experiments = 30).

[b] H, 4-methyl-3-heptanol; M, α-multistriatin dispensed from Conrel hollow fibers. The following sesquiterpenes were dispensed from rubber septa: E, β-elemene; T, thujopsene; Co, α-copaene; A, allo-aromadendrene; Cu, α-cubebene; G, α-gurjunene; XS_i are sesquiterpenes that were presented individually but pooled in this table.

[c] Catches on each trap were indexed as a percentage of the total catch on traps in each replicate during each observation interval. Total beetle catch for the experiment was 70,725.

[d] Means followed by the same letter were not significantly different ($P > 0.05$, Student's t test).

sulting solution was concentrated to 200–300 μl with a fractional distillation column.

The crude extract was then fractionated with a series of preparative GC columns (Table 12). Preparative GC was done with a Varian 1700 Aerograph GC, equipped with an FID detector, and using nitrogen carrier gas. GC fractions were collected with a thermal gradient collector (Brownlee and Silverstein, 1968), using 1.7- or 3-mm OD glass capillaries. All preparative columns used were glass, packed with 60/80 mesh AW-DMCS Chromosorb G or W. Generally, injector and detector temperatures were 170° and 200°, respectively. A Varian 3700 capillary GC equipped with an FID detector and using helium carrier gas was used for analytical GC work in the splitless mode. Fused silica columns used were FFAP (50 m × 0.21 mm ID, 35° for 1.67 min, programmed at 4°/min to 170°, held for 30 min) or OV-101 (50 m × 0.21 mm ID, 35° for 1.67 min, programmed at 4°/min to 190°, held for 30 min), with injector and detector temperatures of 150° and 210°, respectively. A Finnigan 4000 capillary GC-MS was used in splitless mode with EI (70 eV). Columns were fused silica FFAP (50 m × 0.21 mm ID) and DB-1 (30 m × 0.21 mm ID) temperature programmed from 50° to 150° at various rates. Proton NMR spectra were

[a] H, 4-methyl-3-heptanol; M, α-multistriatin dispensed from polyethylene vials. S 13–18 are combinations of sesquiterpenes dispensed from rubber septa. Sesquiterpene baits were as follows: 13, β-elemene, α-cubebene, α-copaene, α-gurjunene, allo-aromadendrene, thujopsene, and β-caryophyllene; 14, baits 13 + 17; 15, baits 13 + 18; 16, baits 17 + 18; 17, γ-cadinene, δ-cadinene, α-muurolene; 18, α-selinene,*trans*-calamenene, α-humulene, α-curcumene, α-calacorene.

[b] Sesquiterpenes were initially presented twice with HM and twice without HM (except HMS 13 appeared thrice). HM and blank were presented four times. During the fourth and final observation period HM was added to previously unaccompanied sesquiterpene and blanks. Two traps (blank and HMS 15) were down during one observation period.

[c] Each treatment was indexed as a percent of the total catch during an observation period. Means followed by the same letter are not significantly different ($P < 0.05$, Student's t test).

obtained with a Varian XL-100 spectrometer, using 5-mm or cavity tubes. In cases where high resolution was required, 360 MHz spectra were recorded on a Bruker WM-360 spectrometer. Solvents used were $CDCl_3$ (100% D, Sigma Chemical Co.) for nonaromatic samples, and CD_2Cl_2 (100% D, Sigma Chemical Co.) for aromatic samples. Optical rotations were measured on a Perkin-Elmer model 141 polarimeter, using a 1 ml cell (1 dm path length) and chloroform solvent at 589 nm (Na "D" line).

Individual compounds were isolated from the crude pentane extracts of Porapak-Q-trapped volatiles by using the sequences of columns shown in Table 12. Isolated compounds were identified by comparison of their spectra, and Kovats indices with published data (Davies and Bignall, undated; Pearce, 1975; Andersen and Falcone, 1969; Swigar and Silverstein, 1981; Heller and Milne, 1978; Yukawa and Ito, 1973) and with those of authentic samples (Table 13). Confirmation of structures was obtained by coinjection of our isolated compounds with authentic compounds on capillary columns. Where the quantity of isolated material permitted, the sign of the optical rotation and, in two instances, the specific rotation were determined.

Authentic samples of compounds were obtained from a variety of sources. Monoterpenes, with the exception of sabinene (Firmenich, S.A., Geneva), and 2-methylnaphthalene were obtained from Aldrich Chemical Co. Sesquiterpenes were obtained from sources listed in Table 13.

Isolation of individual sesquiterpenes from essential oils was in general carried out as follows. The fraction with a boiling point of 81° at 15 mm Hg to 150° at 0.1 mm Hg was separated. The hexane-soluble portion of this material was loaded onto a slurry-packed (hexane) column of alumina (neutral, activity I, 60/80 mesh; 1 g hexane-solubles per 25 g alumina) and eluted with three column volumes of hexane under gravity flow. The eluate was concentrated under reduced pressure and loaded onto a flash chromatography column of 15% $AgNO_3$ on silica gel (230/400 mesh) with a loading of no more than 1 g of material to 50 g of silica. Columns were eluted with hexane followed by increasing concentrations of ether in hexane. Where necessary, final purifications were done by preparative GC, using a 4-m × 1-cm-OD glass column packed with 20% FFAP on AW-DMCS Chromosorb G (60/80 mesh).

β-Elemene was prepared by dehydration of elemol. Since several attempts to purify crude elemol by fractional crystallization failed, the crude material (a viscous syrup), was used directly. Crude elemol (Firmenich, SA) refluxed with a fivefold excess of acetic anhydride for 48 hr gave a 9:1 ratio of β-elemene and an unidentified sesquiterpene olefin. Pure β-elemene was isolated in approximately 50% yield by concentration of the crude reaction mixture followed by fractional distillation through a 30-cm × 1-cm-ID column of glass helices, using a distillation head with a split ratio of 20:1, bp 28–32° at 0.05 mm Hg.

Racemic α-curcumene was synthesized by cuprous iodide-catalyzed reaction of the Grignard reagent of *p*-bromotoluene with the tosylate of 5-hepten-1-ol (Aldrich) in THF. Racemic calamenene, as a mixture of the *cis* and *trans* isomers (30:70 *cis–trans*), was synthesized by treatment of racemic α-curcumene with polyphosphoric acid at 80–90°, as previously described (Anderson et al., 1972).

α-Cadinene was prepared as a minor product of the dehydrohalogenation of cadinene dihydrochloride with $AgNO_3$ in DMSO (Mehta, 1971). Cadinene dihydrochloride was itself prepared from treatment of cubeb oil distillation fractions rich in α-copaene and δ-cadinene with dry HCl in ether at 0° (Herout and Sykora, 1958), followed by recrystallization of the crude product from ether at −70°.

RESULTS

Biology. The numbers of *H. rufipes* captured on traps baited with beetle-infested logs were low (Table 1) in spite of considerable beetle activity in the test areas; for example, unbaited sticky bands on utility poles and elms in the

general area of test 1 caught 366 *H. rufipes*, while the hardware cloth sticky traps containing elm logs with or without *H. rufipes* boring in them caught an aggregate of only 31 beetles. During the spring, when *H. rufipes* beetles were colonizing elm for breeding, uninfested logs were as attractive as material that contained boring *H. rufipes*. However, in the late summer and fall, when new adults move to live elms in which they feed and overwinter, the beetle-infested log treatment (summed for tests 2 and 3) attracted significantly more *H. rufipes* than the uninfested log.

H. rufipes were clearly more strongly attracted to diseased elms, and to elms killed with cacodylic acid than to healthy elms (Table 2). This confirmed Gardiner's (1979) observations and indicated that volatile chemical attractants were produced by the dead or dying elm tree. Even through more *H. rufipes* were captured on cacodylic acid-killed elms, a significantly greater number of beetles bored into the bark of diseased elms. Treatment with cacodylic acid had

obviously rendered the trees less acceptable for breeding than trees dying naturally, as had also been noted with *Scolytus scolytus* and *S. multistriatus* in England (O'Callaghan et al., 1984).

Ethanol extracts of elm bark and pentane extracts of Porapak-Q-trapped volatiles from elm logs proved to be more attractive than solvent controls (Table 3). In the second test, a Porapak-Q extract was more attractive than the ethanol extract. In this test, one of us (GNL) observed flying *H. rufipes* following the Masonite panel to which the Porapak-Q extract had been applied as the treatments were being carried for rotation among trap positions. Due to the apparent potency of the Porapak extract, and because only volatile materials were obtained from Porapak-Q aerations, this type of extract was chosen for GC fractionation and isolation of attractive components.

In the laboratory, *H. rufipes* exposed to a variety of conditioning treatments gave no indication of response to elm extracts presented in a walkway olfactometer (Jantz and Rudinsky, 1965) or in a dual-choice device (White and Richmond, 1979). A few *H. rufipes* beetles gave a classic klinotactic response to stimuli presented in a Moeck (1970) forced-air olfactometer. However, the overall percent response was very low (4.9% and 8% to Porapak and ethanol extracts, respectively), and it was not deemed feasible or reliable to test individual isolated compounds for activity by this method.

Having no laboratory bioassay to test possible attractants for *H. rufipes*, all further bioassays were conducted in the field. Faced with a considerable number of identified compounds to bioassay, it was decided to test initially several combinations of compounds and, with nothing else to guide us, we decided to prepare mixtures based on the results of laboratory bioassays of the isolated compounds as attractants for *S. multistriatus* (Tables 7–9). We do not mean to imply that *H. rufipes* and *S. multistriatus* beetles are necessarily attracted by the same compounds, but *S. multistriatus* was attracted in lab assays to the extracts that attracted *H. rufipes* in the field, and it seemed possible that they might have some host attractants in common. Several points emerge from the field bioassays (Table 4). First, no bait tested was as attractive as a diseased elm tree. However, five of the eight baits tested were significantly more attractive than the healthy elm controls. In particular, a seven-component mixture (bait 3) was the most attractive bait in most of the replicates and its overall catch was approximately 40% of that of a diseased tree. Deleting α-cubebene (bait 6), β-elemene (bait 5), or both of these compounds (bait 4) appeared to reduce response to the residual mixture. α-Cubebene alone (bait 2) was more attractive than a healthy elm while β-elemene (bait 1) was not. Very low attraction to δ-cadinene (bait 7) and the combination of calamenene, γ-muurolene, α-humulene, α-selinene, and α-curcumene (bait 8) indicated that these compounds were of little interest to *H. rufipes*.

With these preliminary data in hand, different combinations of the sesquiterpenes were made up and tested. Unfortunately, by early July when new baits

were placed in the field, beetle flight to breeding material had virtually ceased (very low trap catches even on diseased trees), and no further useful data were obtained.

The first bioassays with *S. multistriatus* were designed to detect enhancement of pheromone baits by host plant material, but no evidence was found to indicate that the attractiveness of multilure (4-methyl-3-heptanol + α-multistriatin + α-cubebene) dispensed from Conrel fibers was enhanced by odors from plant material (Table 5). Experiments that extended through most of the *S. multistriatus* flight seasons in 1979 and 1980 caught more than 18,000 and 40,000 beetles, respectively, but no treatment caught significantly more beetles than the multilure bait alone. In fact, beetle catch on traps baited with multilure plus wilting foliage was significantly lower than that on multilure alone. Surprisingly, virgin females boring in logs (1980, Table 5) did not significantly enhance the attraction to logs. Removal of the bark revealed sterile (no larvae) beetle tunnels in all logs with which 20 female *S. multistriatus* were confined ($\bar{x}$ = 11.8 tunnels/log); no feral beetles had attacked the untreated logs.

Bioassays to test limonene as a substitute for α-cubebene, as had been reported by Blight et al. (1983), were inconclusive despite the large numbers of beetles caught. Addition of α-cubebene to a mixture of 4-methyl-3-heptanol (H) and α-multistriatin (M) significantly increased trap catches, but no significant differences could be demonstrated between either HM and [HM + (−)-limonene] or [HM + α-cubebene] and [HM +(−)-limonene]. Addition of (+)-limonene to HM baits had no discernible effect.

The pattern of response by *S. multistriatus* to Porapak extracts and ethanol extracts of elm tissue in laboratory bioassays (Table 7) was similar to that of *H. rufipes* in field tests (Table 3). The aeration-collected volatiles were clearly more active than the solvent extract, but both evoked response above the level of the air control in all tests.

A Porapak extract of elm bark was divided into four fractions by preparative GC (1, monoterpenes; 2, sesquiterpenes; 3 and 4, longer-retention-time compounds). Laboratory bioassays of individual GC fractions with *S. multistriatus* showed that the sesquiterpenes (fraction 2) could account for 74% of the response to the whole extract (Table 8). When fractions were presented in combinations, deletion of the sesquiterpene fraction significantly reduced response. Bioassay of subfractions of the sesquiterpene fraction evoked only low responses from *S. multistriatus;* recombining subfractions increased responses, but the interaction seemed additive rather than synergistic. Since further fractionation and bioassay seemed impractical, we proceeded to identify the principal components in the active fraction and to bioassay synthetic or purified samples of these compounds. Results of the chemical analysis are given in the following section.

When 14 sesquiterpenes isolated from the most attractive fraction of the elm extracts were bioassayed with *S. multistriatus* in the Moeck olfactometer,

nine compounds evoked a response significantly higher than the blank (Table 9). These were 20–65% as attractive as the pheromone standard. The most attractive compounds were δ-cadinene, γ-cadinene, α-cubebene, γ-muurolene, β-elemene, and calamenene. Of these, only α-cubebene had been previously identified as an attractant component for *S. multistriatus* (Pearce et al., 1975).

In field bioassays, traps baited with sesquiterpenes, either individually or in combinations, did not catch significantly more *S. multistriatus* than blank traps (Tables 10 and 11). Mean catches on traps baited with *S. multistriatus* pheromone components H and M plus sesquiterpenes were not significantly different from those with HM alone. Despite lack of significance of differences, some field activity of sesquiterpenes is suggested because combinations of sesquiterpenes with HM generally attracted more beetles than HM alone (Table 11), and the ranked order of attractiveness of HM plus individual sesquiterpenes (Table 10) was similar to the order projected by laboratory bioassays (Table 9).

Chemistry. As was the case with similar aerations of *Ulmus americana* logs infested with *S. multistriatus* (Pearce et al., 1975; Peacock et al., 1975), and with extracts of several species of elm infested with *S. scolytus* (Blight et al., 1983), our Porapak-Q extracts consisted primarily of mono- and sesquiterpene hydrocarbons. A representative chromatogram is shown in Figure 1. The total amount of material obtained from any one large-scale aeration in the 55-gallon drum varied from 3 to 20 mg. The maximum amount of any one compound obtained was 4 mg for sesquiterpenes, and 10 mg for monoterpenes. The major portion of the volatiles of debarked and chipped or intact elm logs was sesquiterpenoid, while bark volatiles were primarily monoterpenes. Compounds isolated from the Porapak-collected elm volatiles are listed in Table 12 and

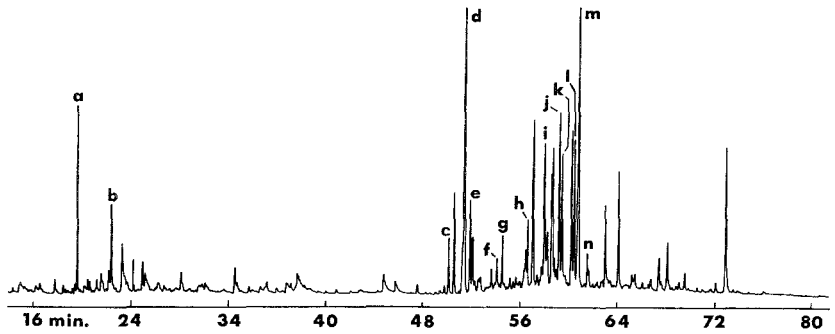

FIG. 1. Gas chromatogram of Porapak-Q-trapped volatiles from an elm log (0V-101 column 50 m × 0.21 mm ID, initial column temp. 35° for 1.67 min then programmed at 2°/min to 190°. He flow rate = 3 ml/min, detector 250°, injector 150°C): a, α-pinene; b, β-pinene; c, α-cubebene; d, cyclosativene; e, α-copaene; f, α-gurjunene; g, β-caryophyllene; h, α-huumulene; i, γ-muurolene; j, α-selinene; k, α-muurolene; l, γ-cadinene; m, δ-cadinene; n, *trans*-calamenene.

structural formulae of the principal compounds are illustrated in Figure 2. There was considerable variation in the relative and absolute amounts of compounds obtained from different extracts. This is not surprising, as no attempts were made to standardize the age, season, or condition of elm logs used for aerations; all of these factors could affect the secondary metabolite composition of the elm tree.

Because of the small amount of each compound isolated, it was not feasible to measure accurately the optical rotation; thus the sign of the rotation was the only value recorded (Table 12), with the exception of α- and β-pinene. These two monoterpenes were isolated in multimilligram quantities from several combined bark extracts. Isolated α-pinene gave a specific rotation of $[+25.2°]_D^{21}$ (c 5.5, $CHCl_3$), while a standard sample (Aldrich) gave $[+45.5°]_D^{21}$ (c 3.0, $CHCl_3$). The specific rotation of isolated β-pinene was $[-15.2°]_D^{21}$ (c 3.0, $CHCl_3$), lit. value $[-21°]_D^{21}$ (neat).

Authentic samples of sesquiterpenes that were not commercially available were isolated from essential oils or synthesized (Table 13). In particular, it was

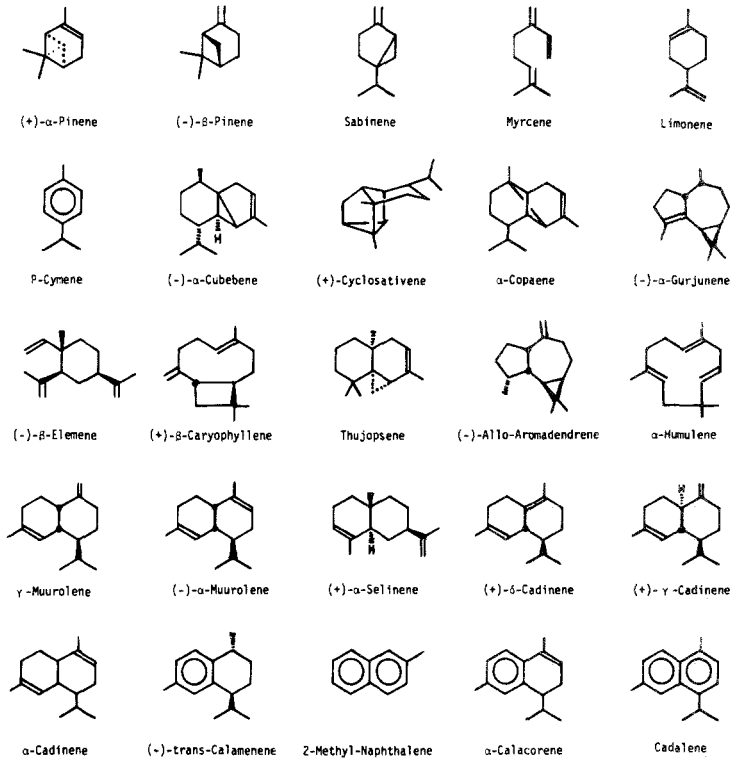

FIG. 2. Structures of terpenes and sesquiterpenes identified from elm volatiles.

found that flash chromatography of essential oil distillation fractions on silica gel–15% $AgNO_3$ that had been activated by heating to 80° under high vacuum for 12 hr was very effective, providing excellent separations of double-bond isomers on a several-gram scale on elution with stepwise gradients of hexane–ether. There was no detectable isomerization even of such acid-labile compounds as α-cubebene, as had been reported in the older literature.

The dehydration of elemol to β-elemene has been previously reported (Thomas, 1974). However, since the published method gives a 3:2 mixture of β- and δ-elemene, respectively, other dehydration methods were surveyed. It was found that refluxing crude elemol in acetic anhydride for 48 hr gave a 9:1 mixture of β-elemene and an isomer that could be cleanly separated by fractional distillation under reduced pressure.

α-Curcumene was synthesized in moderate yield. A major by-product was 4,4′-dimethylbiphenyl, the dimerization product from the Grignard reagent used. It is recommended that a published one-pot procedure giving a 90% yield be followed instead (Hall et al., 1975). α-Curcumene was then cyclized to calamenene by polyphosphoric acid treatment (Andersen et al., 1972).

Dehydrohalogenation of cadinene dihydrochloride gave a mixture of predominantly δ- and β-cadinene, with α-cadinene present as a minor component. The three isomers were separable in milligram amounts by careful preparative GC on a Carbowax 20 M column.

DISCUSSION

The literature has established that several types of elm materials are attractive to the two North American vectors of Dutch elm disease, *S. multistriatus* and *H. rufipes*. Before this study, the only host compound actually implicated as an attractant was the *S. multistriatus* pheromone synergist, α-cubebene (Pearce et al., 1975; Gore et al., 1977; Lanier et al., 1976). The results presented here strongly support the hypothesis that *H. rufipes* beetles locate moribund elms in which to breed principally by attraction to host volatiles. Several sesquiterpenes, including α-cubebene, appear to play a role in host-finding by *H. rufipes*.

Like Gardiner (1979) and Peacock (1979), we found no indication that *H. rufipes* beetles use a pheromone to aggregate on breeding material. Nevertheless, during the late summer and fall, when newly emerged adults were moving to healthy elms in which to overwinter, beetle-infested material seemed to be more attractive than logs alone. However, our data do not permit distinction among possibilities that this enhancement was produced by a pheromone, an increased release or different blend of host compounds, or a combination of these factors.

Moribund elms have a sweet and spicy apple-like odor that, to humans, is

quite distinct from the odor of healthy elms. Whether the difference is mainly qualitative or quantitative remains to be determined, but a previous investigation (Gore et al., 1977) found that the quantity of α-cubebene released by elm increases as the tissues degrade. The important point is that *H. rufipes* beetles seem to have little difficulty in finding moribund elms among a background of odors, and therefore no pheromone seems to be required for aggregation. Like dung flies and carrion beetles, *H. rufipes* can be quite assured of finding mates and breeding sites by following odor trails to decomposing elm trees. The fact that most studies of scolytid chemical ecology have focused on aggressive tree-killing species of bark beetles (see Borden, 1982) probably has created a biased impression of the importance of aggregation pheromones in the family as a whole. The majority of the scolytid species are scavengers that, like *H. rufipes*, may rely on host volatiles alone to locate breeding sites.

The most attractive sesquiterpene mixture caught only 40% of the number of *H. rufipes* (Table 4) as did the diseased elm controls. However, several important points must be made. First, since ratios varied from one extract to another, the sesquiterpene mixtures were arbitrarily made up with equal amounts of each sesquiterpene (1 mg/bait), so that the ratios in which the compounds occur naturally in elms were not duplicated. Thus, the attractiveness of baits might be increased by varying the ratios of the components in the most attractive bait. Secondly, there are probably other components, which, when added to the currently most attractive mixture, may increase the attractiveness of the baits either additively or synergistically. In addition, the compounds listed in Table 12 that were not identified in time for field trials in 1984 will be evaluated as attractants in the next series of bioassays.

It should also be borne in mind that there is a tremendous difference between using a whole diseased tree as a source of attractants and a point source of attractants that a septum bait represents. This may well account for much of the difference between trap catches of diseased trees versus sesquiterpene baits.

There is obviously a great deal more work to be done in refining bait mixtures. The data already in hand clearly demonstrate that *H. rufipes* beetles will respond to sesquiterpene baits and that it should be possible to use sesquiterpene-baited traps as a monitoring tool for *H. rufipes*, even with the nonoptimized baits used to date. In fact, sesquiterpenes could probably be added to multilure baits so that the same bait and trap could be used for the two North American vectors of Dutch elm disease.

H. rufipes and *S. multistriatus* beetles behaved quite differently toward sesquiterpenes in bioassays; *H. rufipes* responded poorly in the laboratory but well in the field, whereas *S. multistriatus* was attracted in the laboratory but not in the field. The problem with our laboratory bioassay of *H. rufipes* may be that this insect does not readily display the type of klinotaxis developed as a criterion of response in bioassays of *S. multistriatus* and *Ips* species. On the other hand, our field experiments on attraction of *S. multistriatus* always included the pher-

omone components 4-methyl-3-heptanol and α-multistriatin in some of the positions. The pheromone may have overwhelmed the beetles' propensity to respond to host compounds. One of our experiments (Table 6) strongly corroborates previous work (Pearce et al., 1975; Lanier et al., 1977) that showed α-cubebene to be a synergist of the pheromone components H and M, but other experiments provided only equivocal support for the host–synergist hypothesis. There are several factors (position effects, inappropriate release rates) that might be invoked to explain the apparent lack of enhancement by host volatiles on attraction of *S. multistriatus* to HM, but low beetle catches are not among them since over 250,000 *S. multistriatus* beetles were caught in these experiments. Our results (Table 5) do not corroborate the enhancement of HMC by host material as was reported by Peacock et al. (1984), but enhancement might have been confounded by the high concentration of pheromone released by the commercial baits used in our tests.

Blight et al. (1978) presented equivocal evidence that (−)-limonene synergized response of *S. scolytus* to 4-methyl-3-heptanol in Europe. Our data (Table 6) demonstrate that this is not the case with *S. multistriatus*, and we would not recommend substitution of (−)-limonene for α-cubebene in baits for *S. multistriatus*. Limonene and other monoterpenes were present in crude extracts from aerations, but the GC fraction containing them was only slightly attractive to *S. multistriatus* in laboratory bioassays.

Finally, specific rotations obtained for α- and β-pinene that were considerably less than those of pure enantiomers indicate that the trees produce enantiomeric mixtures. This also suggests that some of the other compounds isolated may not be enantiomerically pure, which could, of course, introduce a whole new dimension of complexity into the bioassay of artificially formulated baits. At present, there does not seem to be a simple solution to determining the chiral purity of the 20 or so hydrocarbon compounds obtained in small amounts.

Acknowledgments—We gratefully acknowledge support from the National Science Foundation. Technical assistance was provided by Alison Baker, Ellen Gallagher, Alan Grant, and Alan Jones. We also thank the companies and individuals listed in Table 13 for gifts of essential oils and compounds. The NIH NMR Resource at Syracuse University, Dr. George C. Levy, director, furnished the 360-MHz spectra. We are indebted to Francis X. Webster for helpful discussions and for assistance in obtaining the 100-MHz spectra. GC-MS spectra were provided by Hazel S. Jennison and Robert B. Woznikaitis. The many revisions characteristic of a multiauthored manuscript were typed most patiently and competently by Ms. Catherine Bellinger.

(Received February 14, 1985; accepted July 9, 1985)

Abstract—In laboratory bioassays, males of *Matsucoccus resinosae* from *Pinus resinosa* in New York and *Matsucoccus* n. sp. from *Pinus thunbergiana* in Korea were strongly attracted to crude hexane extracts of *M. resinosae* females, and *M. resinosae* males responded strongly to extracts of *Matsucoccus* n. sp. females. Males of the two species responded similarly to gas chromatographic fractions and subfractions of a pentane extract of *M. resinosae* females. Sex pheromones of these two species appear to be the same or very similar.

Key Words—Sex pheromone, interspecific attraction, red pine scale, *Matsucoccus resinosae*, *Matsucoccus* n. sp., *Pinus resinosa*, *Pinus thunbergiana*, Homoptera, Coccoidea, Margarodidae.

INTRODUCTION

Scale insects of the margaroid genus *Matsucoccus* (about 30 known species) feed exclusively on pines (genus *Pinus*) (Ray, 1982). *M. matsumurae* (Kuwana), the type species for the genus, was first described from Japan. It was also reported from Korea (Kanda, 1941), and currently devastates pine forests of eastern mainland China (McClure et al., 1983). *M. resinosae* Bean and Godwin (red pine scale) attacks *P. resinosa* (red pine) in the northeastern United

[1] Homoptera: Coccoidea: Margarodidae.

States, where it is presumed to have been imported (Bean and Godwin, 1955; Anderson et al., 1976; Grimble and Miller, 1976).

M. matsumurae was also known as *M. liaoningensis* Tang in China until Young (1979) proposed synonymy based on similarities in morphology and life histories of the two species. McClure (1983) suggested that *M. resinosae* was a junior synonym of *M. matsumurae*. This opinion was reiterated by Young et al. (1984), but synonymy has not been formally proposed.

M. resinosae was the first coccoid for which evidence of a female-released sex attractant pheromone was reported (Doane, 1966). Young and Qi (1983) used reduced cross-attractiveness and asynchrony of life cycles of *M. matsumurae* and *M. massonianae* Young and Hu to support the validity of these species. Conversely, strongly cross-attractive sex pheromones, along with similarity of morphology and life history, suggested synonymy of *M. resinosae* under *M. matsumurae* (Young et al., 1984).

An apparently undescribed *Matsucoccus* species has recently been damaging forests of *Pinus thunbergiana* (Japanese black pine) on the southeastern Korean peninsula, about 200 km west of the nearest known *M. matsumurae* infestation. This previously unknown entity is morphologically distinct, although it closely resembles *M. matsumurae* and *M. resinosae* (Miller, personal communication) and is univoltine rather than bivoltine as are *M. matsumurae* and *M. resinosae*.

We report experiments on the cross-attractiveness of sex pheromones of the unnamed species from Korea and *M. resinosae* from New York. We also report isolation of the principal active components of the *M. resinosae* sex pheromone.

METHODS AND MATERIALS

Insect Sources and Laboratories. M. resinosae used for pheromone preparations and bioassays were collected in Putnam County, New York. *M. resinosae* female pheromone extracts were fractionated and bioassayed with *M. resinosae* males at Syracuse, New York. Laboratory rearing and tests with males of the Korean *Matsucoccus* n. sp. were performed at the Forest Research Institute in Seoul, and field collections were made in Posung-gun of Chollanam Province.

Preparation of Crude Pheromone Extracts for Bioassay and Fractionation. M. resinosae were obtained by beating infested branches of sapling red pines between 7 AM and 1 PM on September 11 and 12, 1982, late August 1983, and on June 4, 1985. Adult females were collected with forceps from a white cotton drop cloth. A crude hexane extract was prepared from the 1982 collection by placing 100 female adults into a screw-cap glass vial (ca. 1 cm in diameter, 3.5 cm in height, fitted with a Teflon gasket) containing 300 μl of hexane at 9

AM on September 11, 1982. After three days at 25°C, the crude pheromone extract was serially diluted with hexane to 1%, 0.1%, 0.01%, and 0.001% of the original concentration. The crude pheromone extract dilutions (CPEDs) were stored in glass vials with screw caps lined with Teflon gaskets. All CPEDs were stored at -8 ± 3°C. Crude extract of *Matsucoccus* n. sp. was made from females collected from Korea in April 1984. Extract of 400 females in 1 ml of hexane was diluted 100 times for bioassay of attractiveness to *M. resinosae* males.

In 1982, an extract was prepared for GC fractionation from 3500 female *M. resinosae* placed in five vials; four contained 200 μl pentane and one contained 200 μl hexane. After three cycles of freeze-sonication, each with replacement of fresh pentane, the combined extracts were dried over Na_2SO_4 and concentrated to 0.4 ml through a 20-cm packed (glass beads) column. The concentrated extract was fractionated on a 1.5 m × 7 mm ID glass column, 10% Carbowax 20 M on Chromosorb W, 50–80, N_2 80 cm^3/min, 150° isothermal. Three fractions were collected: F1, 0–42 min, F2, 42–60 min; and F3, 60–132 min. Each fraction was diluted to 0.1 female equivalent/μl hexane for bioassays. F3 (the most active fraction) was further fractionated on a 3-m × 4-mm-ID glass column, 3% OV-101 on Chromosorb G, 60–100, N_2 60 cm^3/min, 150° isothermal: F3-1, 0–6 min; F3-2, 6–18 min; F3-3, 18–24 min; F3-4, 24–42 min; and F3-5, 42–90 min. Each fraction was diluted to 0.1 female equivalent/μl hexane. F3-5 (the active fraction) was further fractionated on the same OV-101 column under the same conditions into four fractions: F3-5-1, 0–42 min; F3-5-2, 42–54 min; F3-5-3, 54–62 min; and F3-5-4, 62–94 min.

Similar procedures were used to isolate the principal compound in F3-5-4 from 17,000 *M. resinosae* females collected during August 1983 in Putnam County, New York.

Preparation of Males for Testing. In the United States branches of red pine containing cocoons of *M. resinosae* were collected in the field and put into an emergence cage at 23 ± 2°C under natural photophase. The emergence cage consisted of a cardboard box with a glass jar (ca. 300 ml) attached at one side. Because the males are positively phototactic, they moved into the glass jar, from which they were easily removed.

In Korea, saplings (5–8 years) of Japanese black pine infested by *Matsucoccus* n. sp. were transplanted into vinyl pots and were reared in the laboratory at 20 ± 3°C under natural photophase. Newly spun cocoons were removed from the saplings with forceps. They were stored in Petri dishes, and the males emerging therein were used for bioassay.

General Bioassay Background and Procedures. Doane (1966) stated that the males of *M. resinosae* emerge during the night and fly most actively in the early morning hours. He also said that by 10 AM many males were able only to walk about or make uncoordinated attempts to launch themselves in flight, but that they were able to mate with the adjacent females and fertilize them.

We found that, after the flight period, the males of both species of *Matsucoccus* began to walk about continuously, moving at random in the absence of the pheromone. A few hours thereafter, they became sluggish and weak-legged and walked erratically with a limping motion. Males that walked continuously were more consistently attracted by pheromone than those that showed an erratic limping motion or those that made intermittent unsuccessful attempts at flight in tests we conducted by puffing very dilute pheromone vapors at them as they walked on a sheet of white paper. Males that stopped moving or paused to groom their antennae did not respond well to pheromones, so the bioassay was delayed until walking resumed.

Bioassays were done under fluorescent light (700 lux) at 25 ± 2°C and 60 ± 10% relative humidity between 9 AM and 1 PM. Bioassays of the CPEDs and fractions with *M. resinosae* males were run in September 1982, on the 20th for the CPEDs and from the 22nd through the 26th for the fractions. For the males of *Matsucoccus* n. sp., tests of the CPEDs were run on February 1, 1984, and tests of the fractions were run on February 7 and 8. Bioassays of *M. resinosae* male response to CPED of *Matsucoccus* n. sp. and purified pheromone of *M. resinosae* were conducted from June 6 to 16, 1985. Each male was kept under a numbered, inverted, transparent plastic cup (ca. 20 ml) on a piece of white paper until he was tested. After each test, the male was covered with the same cup and kept for the next test.

Attraction of males was tested by puffing pheromone vapors from a medicine dropper with an inside diameter of ca. 1.7 mm at the tip. Micropipets were used to place 1 μl of CPED or fraction inside a medicine dropper, about 1 cm from the tip. To expel the evaporating hexane, the rubber bulb of the medicine dropper was pressed 10 times in 10 sec. Then the tip of the dropper was positioned 8 ± 2 mm from the male and pointed at his antennae. Puffs of air were then forced from the medicine dropper by gently pressing the bulb at 1.5-sec intervals; about 1 ml of air was expelled at each puff.

If a male turned toward the dropper tip and began to move toward it, the tip was moved so that its distance from the advancing male would remain roughly constant. If a male followed the retreating medicine dropper tip, the latter was moved in a straight line for 4 cm, and then the direction of its course was altered by 120° for a second 4-cm distance. If the male followed the dropper tip for another full 4 cm, the direction was again altered by 120° so that it was moving toward the starting point. Thus, the path of the dropper tip and the following male would have described a 4-cm-sided equilateral triangle. Altering the path of the dropper tip in this manner precluded its haphazard coincidence with the path of the male. For each test, males completing one or more sides of the test triangle were given scores from 1 to 3, equal to the number of triangle sides completed; males responding to the pheromone but following the dropper tip for less than 4 cm were given a score of 0.5, and males that failed to respond to the point of following were given a score of 0.

Bioassays of Crude Pheromone Extracts. The order for testing CPEDs was: control, 0.001%, 0.01%, 0.1% and 1%. Ten males were used in successive tests in a standard order (i.e., 1–10) so that each male would rest the maximum interval between tests.

Bioassays of Pheromone Extract Fractions. The males of both *Matsucoccus* species have a very short life-span (less than 24 hr), and they move towards the pheromone source for only a few hours. Therefore, in order to give males the maximum resting time between each test, and to minimize the effect of senescence of the males, the sequence in which the males were tested was set as a Latin square matrix. Because the fractions inside the medicine dropper continuously evaporate during the experiment, each fraction was newly applied to the medicine dropper every 5 min. A new medicine dropper was used at each additional application to avoid accumulation. In each experiment, hexane was used as control, and the 1% CPED was used as the standard unfractionated pheromone extract.

RESULTS AND DISCUSSION

Males of both *M. resinosae* and *Matsucoccus* n. sp. were attracted by the CPED of *M. resinosae* at dilutions of 0.1% and 1% (Table 1). Every male tested was attracted by the 0.1% CPED, but attraction was strongest to the 1% CPED. Males of *M. resinosae* were attracted to the CPED of *Matsucoccus* n. sp., although significantly less than to purified pheromone from *M. resinosae* females (Table 2).

Males of both *Matsucoccus* species responded to the third of three fractions (F3) of the *M. resinosae* extract (Table 3). Bioassays of five subfractions of F3 showed clearly that all biological activity resided in F3-5. This fraction, further divided into four parts, produced two equally active fractions, F3-5-3 and F3-

[d]Concentration of fractions of F3 = 875 females in 150 μl hexane.
[e]Concentration of fractions of F3-5 = 300 females in 15 μl hexane.

5-4. Another test with *M. resinosae* using the original three fractions at tenfold lower dilutions (i.e., more concentrated solution) showed that F2 also had biological activity. Bioassays of subfractions of F2 showed that F2-4 was active. Comparisons by GC showed that the activity in F2-4 probably corresponded to that in F3-5.

Since patterns of response for *Matsucoccus* n. sp. and *M. resinosae* males are identical, we believe that the pheromones are also largely or entirely identical. The slight, but significant, difference in response of *M. resinosae* to materials from conspecific and *Matsucoccus* n. sp. was probably a result of the difference in the nature of the stimuli (purified pheromone of *M. resinosae* vs. CPED of *Matsucoccus* n. sp.).

Pheromones of coccoids studied prior to *Matsucoccus* had proven to be species specific, as with pairs of closely related citrus scales within the genera *Aonidiella* (Moreno et al., 1972) and *Planococcus* (Rotundo and Tremblay, 1975). Even reciprocal hybrid *Planococcus citri* (Risso) × *ficus* (Singoret) males reacted positively only to the pheromone of the maternal species (Rotundo and Tremblay, 1982); this is in contrast to bark beetles in the genus *Ips* for which Lanier (1970) reported abolition of pheromone specificity in species hybrids. Tremblay and Rotundo (1976) speculated that pheromonal specificity might be a mechanism for sympatric speciation in scale insects.

Young et al. (1984) suggested that strong cross-attractiveness between *M. matsumurae* and *M. resinosae* supports their conspecificity, but they are studying other characteristics before formally proposing synonymy. While lack of pheromone specificity is clearly a valid criterion for taxonomic decisions, our tests, together with moderate cross-attractiveness between *M. matsumurae* and *M. massonianae* reported by Young and Qi (1983), indicate that cross-attraction does not necessarily demonstrate conspecificity in the genus *Matsucoccus*.

There is evidence that the pheromone of *M. resinosae* females is attractive to flying males. Males were caught in the field by sticky paper flight-traps to which crushed *M. resinosae* females had been attached (Park, unpublished data), and, in flight chamber tests, Doane (1966) observed flying *M. resinosae* males being attracted to females. Although testing the walking males with a medicine dropper was an ideal way of bioassaying fractions available only in extremely small amounts, further studies with crude pheromones and larger amounts of pheromone fractions would be needed for determining what components of the pheromonal system effect male flight behavior or if other components are involved besides those that affect walking behavior.

In a personal communication cited by Doane (1966), Kring stated that some aphids must go through a preliminary flight period before they become attracted to colored panels; it is conceivable that an analogous behavior will be found in newly emerged *Matsucoccus* males. Inbreeding would be discouraged if *Matsucoccus* males take flight and become attracted by the pheromone only after a preliminary period of sustained flight.

The host range of most *Matsucoccus* species is rather narrow. All *Matsucoccus* species feed only on pines; of the 31 named species of *Matsucoccus*, none is known to feed on more than one subgenus of *Pinus*. Rieux (1975) stated that there is a close relationship between certain groups of *Pinus* and those of *Matsucoccus*, which suggests concomitant speciation in *Matsucoccus* and hosts. Rieux also devised a classification of *Matsucoccus* based on host preference. Because both *Pinus resinosa* and *P. thunbergiana* belong to the subsection *Sylvestres* (Critchfield and Little, 1966) and they appear very similar, the relationship between *M. resinosae* and the Korean *Matsucoccus* n. sp. may be equally close. It might be expected that cross-attraction would not be shown by species of *Matsucoccus* with hosts in more distantly related groups of pines. If so, cross-attraction experiments with *Matsucoccus* species could prove to be an effective way of studying the phylogeny of the genus.

STEREOSELECTIVE SYNTHESIS OF (*Z*,*E*)-3,5-TETRADECADIENYL ACETATE: Sex Attractant for Carpenterworm Moth, *Prionoxystus robiniae* (Peck) (Lepidoptera: Cossidae) and Effect of Isomers and Monounsaturated Acetates on Its Attractiveness[1]

R.E. DOOLITTLE and J.D. SOLOMON[2]

Insect Attractants, Behavior, and Basic Biology Research Laboratory, Agricultural Research Service, U. S. Department of Agriculture, Gainesville, Florida 32604

(Received May 9, 1985; accepted July 8, 1985)

Abstract—A new efficient stereoselective synthesis for (*Z*,*E*)-3,5-tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) a potent male sex attractant for the carpenterworm, *Prionoxystus robiniae* (Peck), was developed. The effects of the other three isomers (*Z*,*Z*; *E*,*Z*; *E*,*E*) on the field attractiveness of the *Z*,*E* isomer toward male *P. robiniae* were determined. The *Z*,*Z* isomer inhibited attraction, the *E*,*E* isomer synergized attraction, and the *E*,*Z* isomer had no effect on attraction. Seven monounsaturated 14-carbon acetates were evaluated for their effect on the attractiveness of *Z*3,*E*5–14 : Ac. (*E*)-3-Tetradecenyl acetate enhanced attraction and (*Z*)-9- and (*E*)-5-tetradecenyl acetate reduced trap captures. (*Z*,*E*)-3,5-Tetradecadien-1-ol also reduced the attractiveness of *Z*3,*E*5–14 : Ac.

Key Words—*Prionoxystus robiniae*, Lepidoptera, Cossidae, Carpenterworm, sex attractant, (*Z*,*E*)-3,5-tetradecadienyl acetate, inhibition, synergism.

INTRODUCTION

The sex pheromone of the adult female carpenterworm, *Prionoxystus robiniae* (Peck), a destructive borer in the trunks of southern hardwood trees, was first

[1] Mention of a commercial or properietary product does not constitute an endorsement by the USDA.
[2] Current address: Southern Forest Experiment Station, Forest Service, USDA, Stoneville, Mississippi.

reported by Solomon and Morris (1966) and partially characterized by Solomon et al. (1972). (*Z,E*)-3,5-Tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) was found to be a powerful attractant for male carpenterworms (Doolittle et al., 1976a) through a combination of electroantennogram (EAG) investigations of standard chemicals and synthesis of candidate chemicals possessing the biologically active functionalities. Although this chemical is a strong field attractant, its presence in the insect has never been established.

The original synthesis (Doolittle et al., 1976b) involved a Wittig condensation between (*E*)-2-undecenal and the phosphorane prepared from 3-hydroxypropyltriphenylphosphonium iodide and two equivalents of strong base. Unfortunately this reaction produces a mixture of the *E,E* (*E*3,*E*5–14 : Ac) and *Z,E* (*Z*3,*E*5–14 : Ac) isomers in a ratio of about 3 : 1 *E,E/Z,E* along with a small (<2%) amount of *Z,Z* isomer. Under carefully controlled conditions, it is possible to increase this ratio to about 1 : 1. Commercial preparations are commonly the 3 : 1 ratio (Doolittle).[3] The *Z,E* isomer content can be increased to about 90% by spinning band distillation, but this is a tedious process and a large amount of the *Z,E* isomer is lost. Initially formation of the *E,E* isomer was advantageous because this isomer is a powerful attractant for another destructive cossid, the aspen carpenterworm, *Acossus centerensis* (Litner) (Doolittle et al., 1976b). Interestingly, neither isomer inhibited the attraction of either species to the other isomer and, indeed, there seemed to be some indication that the attraction of *P. robiniae* to the *Z,E* isomer was enhanced by the *E,E* isomer (Solomon et al., 1978). This did not overcome the inherent inefficiency of the original synthetic procedure when applied to the commercial production of this attractant.

The initial EAG experiments (Doolittle et al., 1976a) indicated the presence of a second active component in female extracts. Based on its gas chromatographic retention time, this component was most likely a monounsaturated 14-carbon acetate. With this in mind and in consideration of the necessity of developing a new, more efficient synthesis for the *Z,E* isomer, we investigated the stereoselective synthesis of all four isomers of 3,5-tetradecadienyl acetates and the effect of the *E,Z*; *Z,Z*; and *E,E* isomers and the *Z*- and *E*-3, *Z*- and *E*-4, *Z*- and *E*-5, and *Z*-9 tetradecenyl acetates (*Z*3–14 : Ac, *E*3–14 : Ac, *Z*4–14 : Ac, *E*4–14 : Ac, *Z*5–14 : Ac, *E*5–14 : Ac, and *Z*9–14 : Ac) on the attractiveness of *Z*3,*E*5–14 : Ac. These monoenes had given the strongest responses in the initial EAG investigations. In light of the reported (Tumlinson et al., 1972) inhibitory effects of alcohols, the diene alcohol *Z,E*-3,5-tetradecadien-1-ol (*Z*3,*E*5–14 : OH) was also tested for its effect on the attractiveness of *Z*3,*E*5–14 : Ac toward male *P. robiniae*. The results of this investigation are the subject of this report.

[3] Farchan Laboratories, Gainesville, Florida has attempted commercial preparation of this compound and has produced ratios of from 4 : 1 to 2 : 1 *E,E/Z,E*.

METHODS AND MATERIALS

Instrumentation. Instrumentation used in the chemical synthesis included a Perkin Elmer model 1420 infrared spectrophotometer (infrared spectra were recorded as 2% w/v solutions in CCL_4), Varian Aerograph models 1400 and 2100 gas chromatographs equipped with user-designed all-glass capillary split-inlet systems with carrier gas (He) linear flow velocities of 18 cm/sec and a split ratio of 100:1. Four columns were used: (A) 50 m × 0.20 mm ID coated with SP-1000 (175°C); (B) 15.2 m × 0.20 mm ID coated with 0.1% cholesteryl-*p*-chlorocinnamate (Heath and Doolittle, 1983) (when this column was operated below 150°C, it was in a supercooled state); (C) 14 m × 0.20 mm ID coated with 0.15% cholesteryl-*p*-nitrocinnamate (170°C) (Heath and Doolittle, 1983); and (D) 14 m × 0.25 mm ID fused silica (Quadrex Corp. "007" series) coated with 0.25 μm of SP2340 (140°C).

High-performance liquid chromatography was done at a flow rate of 9.9 ml/min using a Waters Associates M6000 solvent delivery system, a Rheodyne 905-19 injector for sample introduction, and a Waters Associates R401 differential refractometer detector. Mass spectra were recorded on a Finnigan 1015S chemical ionization mass spectrometer using isobutane as reagent gas. [^{1}H]Magnetic resonance spectra were recorded in $CDCl_3$ on a Nicolet 300-MHz spectrometer. Chemical shifts are in parts per million from tetramethylsilane and the coupling constants are in Hertz.

Chemical Synthesis of Z*3,*E*5-14:Ac and* E*3,Z5-14:Ac.* The synthetic routes used are outlined in Figure 1, scheme A. This method of synthesis is a modification of that described by Zweifel and Backlund (1978) with details as follows for the *Z,E* isomer: a 1 M solution of diborane in THF (0.1 mol, 100 ml) was added dropwise to 80 ml of a 2.5 M solution of cyclohexene in THF (0.200 mol) held at −15°C. Tetrahydrofuran (THF) was dried by distillation from lithium tetrahydroaluminate. Alternatively, borane methyl sulfide (10 ml, 0.10 mol) was diluted to 100 ml with THF to generate the borane solution, after which the solution was stirred at 0–5°C for 1 hr. Then a solution of 1-decyne (14 g, 0.10 mol) in 25 ml of THF was added dropwise at 0–5°C, and the mixture stirred at 0–5°C for 2 hr during which time the white slurry dissolved. The tetrahydropyranyl ether of 3-butyn-1-ol, prepared from 3-butyn-1-ol and dihydropyran by the method of Miyashita et al. (1977), bp 96°C/23 mm, had spectral characteristics (IR, NMR, MS) consistent with its chemical structure.

This ether (15.4 g, 0.10 mol) was placed in a flask with 80 ml of THF and treated dropwise at −60°C with 0.10 mol (77 ml of a 1.3 M soln) of ethereal methyl lithium. After addition of the methyllithium, the solution was brought to −15°C for 0.5 hr and then was transferred via cannula to the borane reagent which was held at −25°C. The solution was allowed to warm to room temperature, held there for 1 hr, and chilled again to −15°C at which time 30 ml (0.11 mol) of distilled tri-*n*-butyltin chloride was added. The reaction mixture

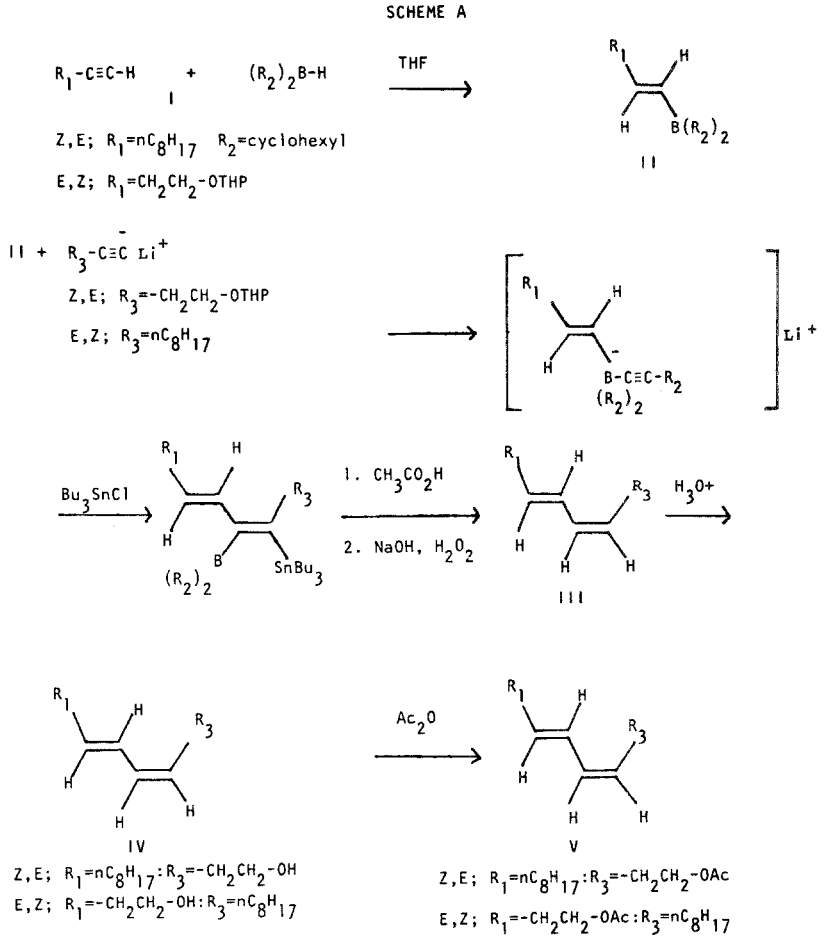

FIG. 1. Synthesis of three of the four isomers of 3,5-tetradecadienyl acetate.

was brought to room temperature over 15 min and stirred for 1 additional hr, then 23 ml of glacial acetic acid was added and the mixture was heated at 50–60°C for 1 hr. The reaction was cooled to about 30°C, 100 ml of methanol and 80 ml of 6 N sodium hydroxide were added, and the mixture was oxidized with 24 ml of 30% H_2O_2 at 35–40°C. After stirring for 1 hr at room temperature, the mixture was diluted with water and extracted several times with ether and hexane.

The combined organic extracts were washed several times with water, saturated brine, and dried over Na_2SO_4. After removal of the drying agent and evaporation of the solvent, the residual oil was chromatographed on a column of Florisil to remove the $Bu_3SnOSnBu_3$. For this scale reaction, a minimum of

SCHEME B

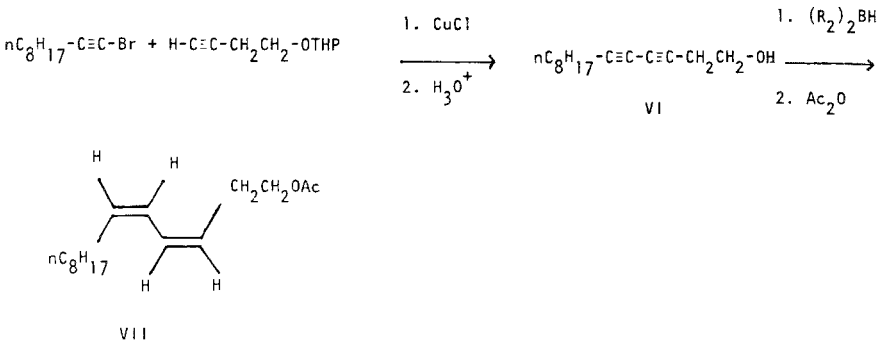

FIG. 1. Continued.

400 g of Florisil was used and the product eluted with 3% ethyl acetate in hexane. Hydrolysis by stirring overnight in 100 ml of methanol containing 1 ml conc. HCl; dilution with water; extraction several times with ether; washing the combined ether extracts with water, saturated $NaHCO_3$, and saturated brine; drying over Na_2SO_4; and removal of drying agent and solvents produced crude alcohol IV, $R_1 = nC_8H_{17}$; $R_3 = CH_2{-}CH_2OH$, containing approximately 1% *E,Z* isomer and 1.5% *E,E* isomer (col B). This alcohol was recrystallized from pentane at Dry-Ice temperatures to yield 16.84 g (76% yield) of 98% pure alcohol which was acetylated with acetic anhydride and triethylamine in either in the usual fashion and vacuum distilled (bp 107°C/0.03 mm) to give V, $R_1 = nC_8H_{17}$, $R_3 = -CH_2CH_2OAc$ containing <2% *E,E* and <1/2% of the other two isomers (cols B, C, and D).

The spectral data are as follows: IR cm^{-1} 3020 (olefinic C-H), 1745, 1235, 1035 (acetate), 980, and 947 (*Z,E* conjugated diene); [^{1}H]NMR 0.88 (3H, t), 1.27 (12H, m), 2.04 (3H, s), 4.09 (2H, t), remaining proton assignments in Table 1. MS *m/z* (rel. abundance) 193 (100) (M+1−60), 252 (11) (M), 253 (45) (M+1).

E,Z Isomer. The *E,Z* isomer V, $R_1 = CH_2CH_2OAc$; $R_3 = nC_8H_{17}$ was synthesized in an analogous fashion by reversing the order in which the acetylenic starting materials were used. It was prepared in 75% yield and from 97 to 99% isomeric purity after recrystallization and acetylation. The spectral data are as follows: IR cm^{-1} 3020 (olefinic C-H), 1745, 1235, 1032 (acetate) 980, and 950 (*E,Z* conjugated diene); [^{1}H]NMR 0.88 (3H, t), 1.27 (12H, m), 2.05 (3H, s), 4.11 (2H, t), remaining proton assignments in Table 1. MS *m/z* (rel. abundance) 193 (100) (M+1−60), 252 (2) (M), 253 (47) (M+1).

Synthesis of Z3,Z5-14:Ac, VII. This synthesis is outlined in Figure 1, scheme B, and consists of a (Chodkiewicz and Cadiot, 1955) type of reaction followed by reduction with dicyclohexylborane (Zweifel and Polston, 1970) as

[b]The signals of all protons gave correct integration values. Signals were all AA'B_2XY patterns.

follows: 3-butyn-1-ol (0.1 mol, 7.0 g), *n*-propylamine (0.17 mol, 14 ml), CuCl (1 mmol, 0.1 g), hydroxylamine hydrochloride (7 mmol, 0.5 g), and 125 ml of methanol were placed in a flask under nitrogen and chilled to 15°C. 1-Bromodecyne (0.1 mol, 21.72 g), prepared by the method of Brandsma (1971) dissolved in 25 ml of methanol was added dropwise, maintaining the temperature between 15 and 22°C. After addition, the reaction was stirred at this temperature range for several hours, adding small amounts of hydroxylamine hydrochloride whenever the mixture turned blue or blue-green. When the reaction mixture remained yellow and any tendency for the temperature to rise ceased, it was poured into water and extracted several times with ether.

The combined ether extracts were washed with water, saturated brine, and dried over Na_2SO_4. After removal of the drying agent and solvent, the residual oil was vacuum distilled (bp 132–136°C/0.001 mm). The distilled product was chromatographed on a column of 150 g of silica gel to remove the C_{20} diyne hydrocarbon that gas chromatography–mass spectrometry indicated was present. This is a common impurity in Cadiot coupling reactions, arising from self-coupling of the bromoalkyne. The diyne alcohol eluted with 10% ethyl acetate–hexane to give 10.9 g (53%) of pure product VI. The diyne alcohol was converted to its tetrahydropyranyl (THP) ether by the aforementioned procedure used for 3-butyn-1-ol, and the crude ether was reduced to the diene as follows: a 0.55 molar solution of dicyclohexylborane (0.04 mol) in THF was prepared as described (Zweifel and Polston, 1970), 4.36 g (0.015 mol) of the THP ether

in 20 ml of THF was added at 0°C, and the mixture was stirred at room temperature overnight.

Acetic acid (9 ml) was added, and the mixture was heated at 65°C for 5 hr, cooled to room temperature and 31 ml of 6 N NaOH was added. It was then oxidized at 35–40°C with 9.5 ml of 30% H_2O_2, stirred at room temperature, diluted with water, extracted and dried in the usual fashion, and the residual oil remaining after removal of the solvent was hydrolyzed with 50 μl of conc. HCl in 100 ml of methanol for 2 hr. The diene alcohol isolated from the hydrolysis by the usual extraction procedure was treated with acetyl chloride in ether with triethylamine as acid scavenger, worked up in the usual fashion, and vacuum distilled (bp 108–109°C/0.01 mm) to yield 2.11 g (55.4%) of *Z,Z* acetate VII which contained <1% each of the *Z,E* and *E,Z* isomers and no detectable amount of *E,E* isomers by GC analysis on column C.

The spectral data are as follows: IR cm^{-1} 3020 and 3005 (olefinic C-H), 1745, 1235, 1035, (acetate); [^{1}H]NMR 0.88 (3H, t), 1.27 (12H, m), 2.04 (3H, s), 4.09 (2H, t), remaining proton assignments in Table 1. MS *m/z* (rel. abundance), 193 (100) (M+1−160), 252 (14) (M), 253 (52) (M+1).

E*3*, E*5–14:Ac. Pure E,E* isomer was obtained by saponification of material that had been synthesized by the original route (Doolittle et al., 1976a) and purified via spinning band distillation to 95% *E,E* content, followed by low-temperature crystallization of the alcohol from pentane to >99% purity (determined on columns A and B) and reacetylation. This gave the *E,E* isomer in >99% isomeric purity. Spectral data were as follows: IR cm^{-1} 3010 (olefinic C-H), 1745, 1235, 1020 (acetate), 985 (*E,E* conjugated diene); [^{1}H]NMR 0.88 (3H, t), 1.26 (12H, m), 2.04 (3H, s), 4.09 (2H, t), remaining proton assignments in Table 1. MS *m/z* (rel. abundance) 193 (100) (M+1−60), 252 (17) (M), 253 (43) (M+1).

Z*3–14:Ac,* E*3–14:Ac,* Z*4–14:Ac,* E*4–14:Ac,* Z*5–14:Ac,* E*5–14:Ac, and* Z*9–14:Ac.* These monoene acetates were either purchased from commercial sources or synthesized via established well-documented routes (Sonnet, 1984; Mori, 1979, 1981; Henrick, 1978; Rossi, 1977) and were purified by high-performance liquid chromatography (HPLC) on silver-nitrate-impregnated silica gel as described by Heath et al. (1977). Gas chromatographic analysis on columns A, B, and C gave isomeric purities >99%.

Field Tests. Field studies were conducted during the carpenterworm flight season from mid-May to mid-July of 1982 and 1983 in the Delta Experimental Forest, Stoneville, Mississippi (a mixed hardwood forest). In 1982, the diene acetates *E*3,*Z*5–14 : Ac, *Z*3,*Z*5–14 : Ac; and *E*3,*E*5–14 : Ac; the monoene acetates *Z*3–14 : Ac, *E*3–14 : Ac, *Z*4–14 : Ac, *E*4–14 : Ac, *Z*5–14 : Ac, *E*5–14 : Ac, and *Z*9–14 : Ac; and the diene alcohol *Z*3,*E*5–14 : OH were tested alone and in blend with the active diene acetate *Z*3,*E*5–14 : Ac to determine their effects upon attractiveness to male *P. robiniae*. The *Z,E* isomer was prepared by dis-

solving 350 μg $Z3,E5$–14 : Ac (the active isomer) in 200 μl nanograde hexane. A 10 : 1 ratio of Sustane 6 was added as an antioxidant/preservative. Each of the three diene acetates, seven monoene acetates, and diene alcohol was blended with the Z,E isomer ratios of 0, 1, 3, 10, and 25%.

In 1983, additional field tests were conducted to further define the effects of the diene acetate, $E3,E5$–14 : Ac, and the monoene acetate, $E3$–14 : Ac, upon the active isomer, $Z3,E5$–14 : Ac. Test samples were prepared in the same manner as in 1982, except that ratios of 0, 0.5, 2, 5, 12, and 15% of E,E isomer and ratios of 0, 0.5, 1, 2, 3, and 5% of $E3$ isomer to Z,E isomer were tested.

Each test sample was micropipetted onto a cotton dental roll (2 × 1 cm) dispenser. After the solvent evaporated, charged dispensers were placed in platform sticky traps (Solomon et al., 1978). Traps were suspended from tree branches 1.5 m above the ground and randomly assigned to sites 110–160 m apart in the forest. Traps were rerandomized weekly to new sites, and male catches were recorded daily except weekends, for as long as the baits remained attractive. The total catch for each trap over the entire test period was recorded. There were four replications (baited traps) per treatment in 1982 and eight replications per treatment in 1983. The data from the acetate mixtures (Figures 2–6) were subjected to regression analysis (Steel and Torrie, 1960), and the data from the mixtures of $Z3,E5$–14 : Ac and $Z3,E5$–14 : OH were subjected to analysis of variance and Duncan's new multiple-range test at the 0.05 level.

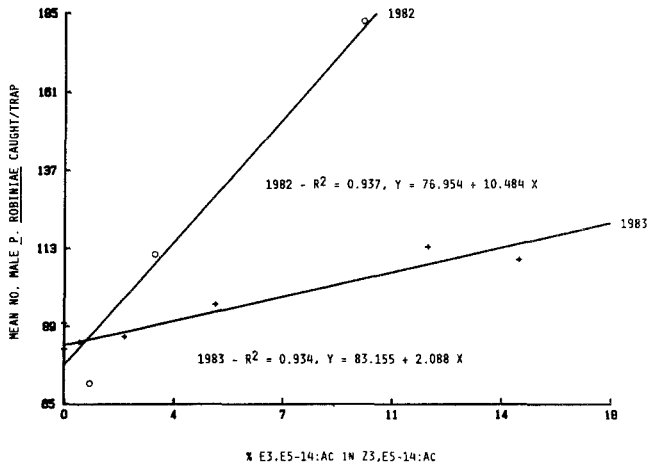

FIG. 2. Attraction of mixtures of (E,E)- and (Z,E)-3,5-tetradecadienyl acetates ($Z3,E5$- and $E5,E5$–14 : Ac) toward male carpenterworms (*P. robiniae*) in 1982 and 1983, Stoneville, Mississippi.

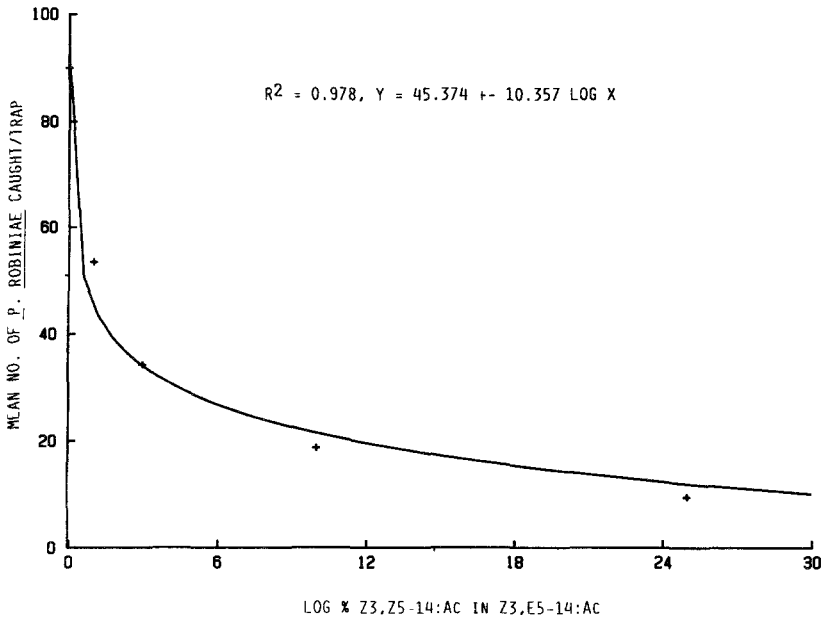

FIG. 3. Effect of (*Z*,*Z*)-3,5-tetradecadienyl acetate (*Z*3,*Z*5–14 : Ac) on the attractivenss of (*Z*,*E*)-3,5-tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) toward male *P. robiniae* in 1982, Stoneville, Mississippi.

RESULTS AND DISCUSSION

Chemical Synthesis. The *Z*,*E* and *E*,*Z* isomers of 3,5-tetradecadienyl acetate were synthesized stereoselectively via scheme A of Figure 1. This procedure produced these isomers in high stereopurity and good yield. Traces of isomeric impurities could be conveniently removed by low-temperature crystallization of the alcohols from hydrocarbon solvents. For example, this technique is especially efficient at removing the *E*,*Z* and *Z*,*Z* isomers from a sample of *Z*,*E* since the *E*,*Z* and *Z*,*Z* isomers are the more soluble ones. Recrystallization was very efficient for the removal of isomers from a sample of *E*,*E* alcohol, since this isomer is the least soluble of the four, but would not be as effective for the removal of the *E*,*E* isomer from one of the other three since it would have a strong tendency to cocrystallize.

Allowing the reaction mixture to remain at room temperature overnight after the addition of the *n*-Bu_3SnCl but before addition of the acetic acid (see Methods and Materials) produced some startling results. In the case of the *E*,*Z* isomer, varying conditions in this fashion in three preparations produced from

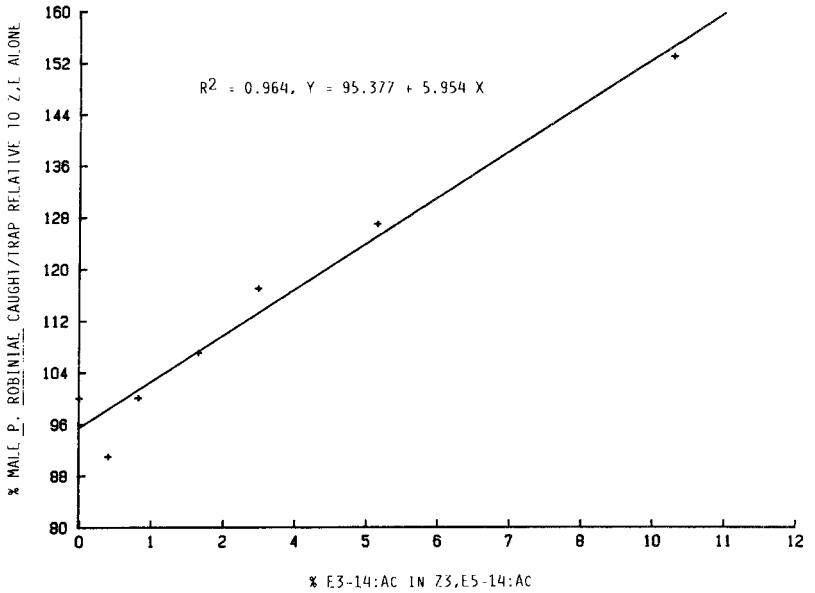

FIG. 4. Attraction of mixtures of (*E*)-3-tetradecenyl acetate (*E*3–14 : Ac) and (*Z*,*E*)-3,5-tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) toward male carpenterworms (*P. robiniae*) in 1982 and 1983, Stoneville, Mississippi.

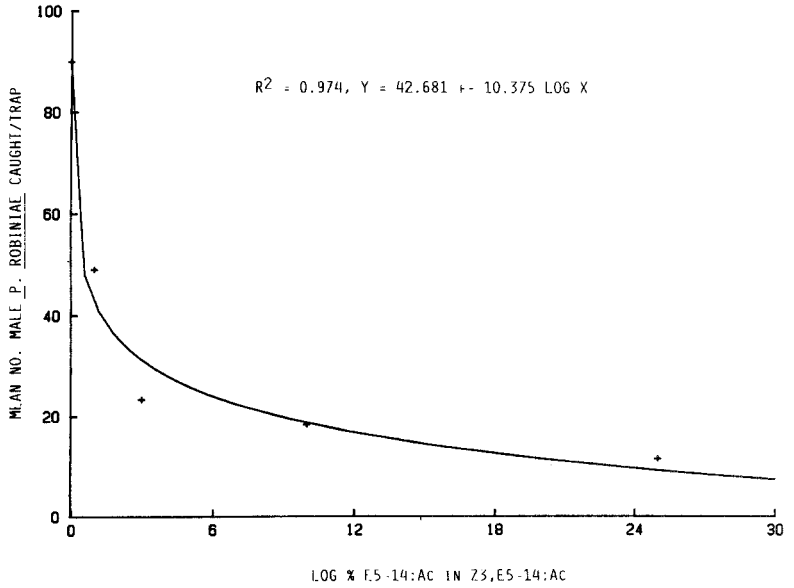

FIG. 5. Effect of (*E*)-5-tetradecenyl acetate (*E*5–14 : Ac) on the attractiveness of (*Z*,*E*)-3,5-tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) toward male carpenterworms (*P. robiniae*) in 1982, Stoneville, Mississippi.

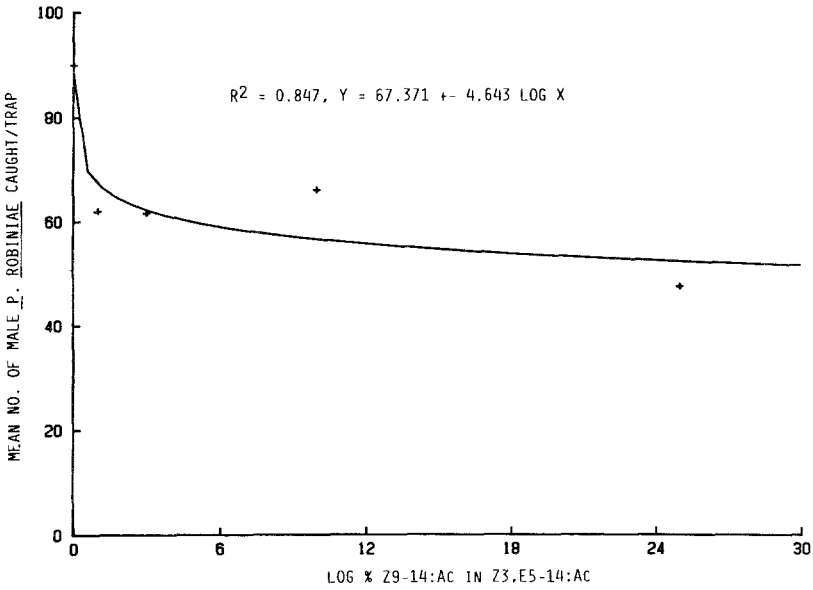

FIG. 6. Effect of (*Z*)-9-tetradecenyl acetate (Z9–14 : Ac) on the attractiveness of (*Z*,*E*)-3,5-tetradecadienyl acetate (*Z*3,*E*5–14 : Ac) toward male carpenterworms (*P. robiniae*) in 1982, Stoneville, Mississippi.

10 to 37% of the *Z*,*E* isomer but <6% of the *E*,*E* isomer and only traces of the *Z*,*Z* isomer. Allowing the mixture to remain at room temperature the prescribed 1 hr produced the *E*,*Z* isomer containing <2% of the *Z*,*E* isomer. In one preparation of the *Z*,*E* isomer, 19% *E*,*Z* was produced when the reaction mixture was allowed to stand at room temperature overnight. This reversal of stereochemistry of both bonds is unprecedented and emphasizes the drastic changes that can occur in stereochemistry with a rather minor change in reaction conditions.

The *Z*,*Z* isomer of 3,5-tetradecadienyl acetate was synthesized by the route outlined in Figure 1, scheme B, which produced this isomer in good yield with high stereoselectivity. The stereochemically pure *E*,*E* isomer was prepared by repeated recrystallization of a sample of the *E*,*E* alcohol available from previous work, followed by acetylation. The stereopurity of these isomers was assessed by capillary gas chromatography on a variety of columns. Chromatograms of all four isomers on liquid crystal and isotropic phases are presented in Figure 7. Resolution between the *Z*,*E* and *E*,*Z* isomers is the smallest, but it is sufficiently high on the liquid crystal column (col C) for the determination of small amounts of one isomer in the presence of the other. Note the reversal of the elution order for the *Z*,*E* and *E*,*Z* isomers on the two columns.

The [^{1}H]NMR chemical shift values for the olefinic and allylic protons as

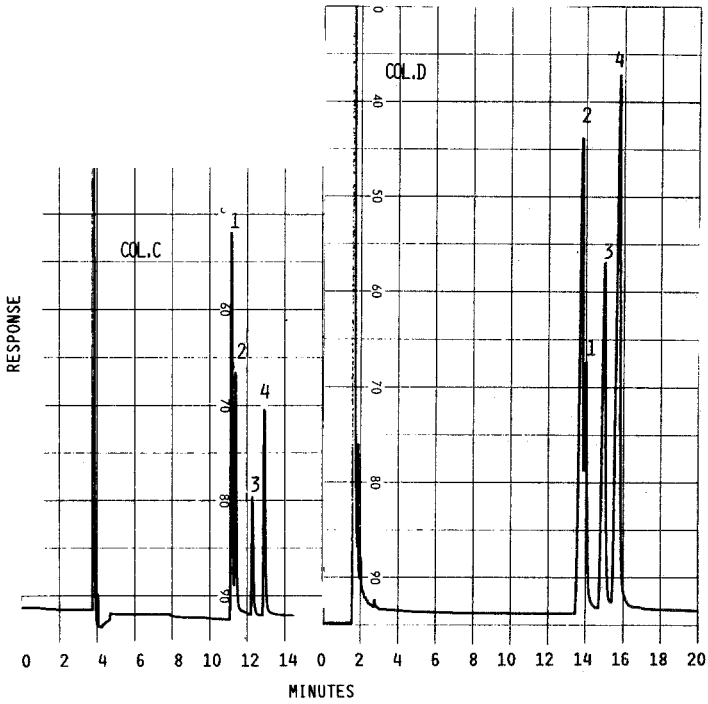

FIG. 7. Chromatograms of the four isomers of 3,5-tetradecadienyl acetate. 1 = *E,Z*; 2 = *Z,E*; 3 = *Z,Z*; 4 = *E,E*. Col. C:40 m × 0.20 mm ID fused silica capillary coated with 0.15% cholesteryl-*p*-nitrocinnamate (180°C). Col. D: 14 m × 0.25 mm ID fused silica capillary coated with 0.25 μm SP 2340 (140°C).

determined by a series of spin–spin decoupling experiments is presented in Table 1. The monounsaturated acetates were purified and analyzed as described in Methods and Materials.

Field Tests. The *E,Z*; *Z,Z*; and *E,E* isomers of 3,5–14 : Ac, as well as the seven monoene acetates when tested alone, did not attract male *P. robiniae*. *E*3,*Z*5–14 : Ac, *Z*3, *Z*4, and *E*4 and *Z*5–14 : Ac had no significant effect on the attractancy of *Z*3,*E*5–14 : Ac toward male *P. robiniae*.

Addition of *E*3,*E*5–14 : Ac to the *Z,E* isomer did increase the attractiveness of the *Z,E* isomer to male *P. robiniae* (Figure 2) as had been reported (Doolittle et al., 1976a; Solomon et al., 1978). The intensity of response of male moths to the mixtures appears to be somewhat different for the two years. However, data for 1983 should be considered the more reliable because of the large number of replications. In any case, there is a pronounced positive effect from the *E,E* isomer.

*Z*3,*Z*5–14 : Ac has a pronounced inhibitory effect on the attractiveness of *Z*3,*E*5–14 : Ac toward male *P. robiniae* (Figure 3). Addition of *E*3–14 : Ac to *Z*3,*E*5–14 : Ac resulted in increased trap captures similar to the effect of the *E*3,*E*5–14 : Ac (Figure 4).

Both *E*5 and *Z*9–14 : Ac caused a reduction in the number of male carpenterworms captured by *Z*3,*E*5–14 : Ac when added to this attractant (Figures 5 and 6). The effect of the *Z*9–14 : Ac is not as marked as with the *E*5–14 : Ac, but nonetheless reduction in trap captures did occur. The effect of *E*5–14 : Ac was similar to that of the *Z*3,*Z*5–14 : Ac.

It was found that the diene alcohol *Z*3,*E*5–14 : OH had a moderate inhibitory effect on trap captures by *Z*3,*E*5–14 : Ac (Table 2).

These results confirm and further define the effect that *E*3,*E*5–14 : Ac has on the attraction of *Z*3,*E*5–14 : Ac toward male *P. robiniae*. The presence of small quantities (up to 10%) of this isomer in samples of the attractant is not only acceptable but desirable. When designing a synthetic route to the *Z*,*E* isomer, those reactions that tend to produce the *Z*,*Z* isomer or the free alcohol as an impurity should be avoided. The synthesis herein described produced no detectable amount of *Z*,*Z* isomer and, when carefully controlled, produces only very minor quantities of the *E*,*Z* and *E*,*E* isomers, one of which is innocuous and the other desirable.

The inhibitory effects of the *E*5 and *Z*9–14 : Ac are difficult to explain and attempts to do so would be speculative. The enhancement of attraction caused by *E*3–14 : Ac strongly indicates that the pheromonal system probably consists of a blend of chemicals which is apparently becoming the rule rather than the exception with lepidopterous sex pheromones (Steck et al., 1980, 1982; Klun et al., 1979).

TABLE 2. RESPONSES OF MALE *P. Robiniae* TO MIXTURES OF (*Z*,*E*)-3,5-TETRADECADIEN-1-OL AND (*Z*,*E*)-3,5-TETRADECADIENYL ACETATE (STONEVILLE, MISSISSIPPI, 1982)

Ratio of *Z*3,*E*5–14:Ac to *Z*3,*E*5–14:OH	Mean number males captured per trap[a]
100:0	203.8a
99:1	113.0b
97:3	65.0b
90:10	97.5b
75:25	62.8b
0:100	0.5

[a]Means followed by the same letter are not significantly different at the 0.05 level as judged by Duncan's new multiple-range test.

CONCLUSION

The new stereoselective synthesis of $Z3,E5$-14:Ac herein described provides an economical route for the efficient production of reasonably large quantities of this attractant free of deleterious isomers. The synthesis should make possible field investigations into the possible application of this chemical for monitoring and control programs.

The data from the effects of monounsaturated acetates on the attractiveness of $Z3,E5$-14:Ac should provide some starting points for the unraveling of the pheromone system of this insect and perhaps other members of the family Cossidae.

Acknowledgments—We thank E.R. Mitchell for his invaluable assistance with the statistical analysis of the field data.

DETOXIFICATION FUNCTION OF GEOPHAGY AND DOMESTICATION OF THE POTATO

TIMOTHY JOHNS[1]

Division of Biological Sciences and Museum of Anthropology
University of Michigan
Ann Arbor, Michigan 48109

(Received April 30, 1985; accepted July 8, 1985)

Abstract—Detoxification as the adaptive function of geophagy is demonstrated from field and historical data associating clay consumption with the domestication of potentially toxic potatoes. In vitro analyses showed that the glycoalkaloid, tomatine, was effectively adsorbed by four classes of edible clays over a range of simulated gastrointestinal conditions. These results, in conjunction with reports of geophagy by nonhuman primates, suggest geophagy as a solution to the impasse chemical deterrents pose to the process of domestication and to chemical constraints on plant exploitation by non-fire-using hominids. The inorganic component of the chemical environment deserves increased attention from chemical ecologists.

Key Words—Geophagy, hominid, primate, detoxification, glycoalkaloids, tomatine, domestication, potatoes, clay-organic interactions.

INTRODUCTION

Selection for changes in secondary chemical constituents has been an essential aspect of the domestication of food plants (Rindos, 1980). However, it is problematic as to how the wild progenitors of staple cultigens with appreciable levels of toxins would have been acceptable initially for human consumption, and therefore subject to genetic manipulation. Cooking has been suggested as the major technological mechanism for making plant foods available to humans (Stahl, 1984; Leopold and Ardrey, 1972). However, heat-stable toxins would remain serious deterrents to foragers, including those with controlled fire. The heat-stable, water-insoluble glycoalkaloids of the potato, which are considered

[1] Current address: Department of Entomological Sciences, University of California, Berkeley, California 94720.

0098-0331/86/0300-0635$05.00/0

in the present study, are not destroyed by cooking. I present evidence associated with the domestication of the potato to show that geophagy was crucial to this process.

I suggest that geophagy is the most basic human detoxification technique with behavioral antecedents that are prehominoid. Soil consumption has been observed in many animals, including invertebrates (Shachak et al., 1976) and reptiles, birds, and mammals (Marlow and Tollestrup, 1982; Smith 1979). Although clays may (or may not) be important nutritionally, they may at least have a detoxification function in mammals. Geophagy in rats has been interpreted to have evolved in relation to the gastrointestinal illness that occurs after eating toxic substances (Mitchell et al., 1976; Burchfield et al., 1977).

The role of geophagy in the detoxification of alkaloids, tannins, and quinones is suggested by several cases of geophagy recorded in the anthropological literature (Laufer, 1930; Anell and Lagercrantz, 1958). In nonhuman primates, the nature of geophagy has led primate ecologists to suggest that a detoxification function in relation to plant secondary compounds is being served (Hladik, 1977).

Interpretation of the adaptive significance of geophagy associated with potato consumption and domestication is decidedly less problematic than with other cases where geophagy and organic toxins have been linked, in that detoxification is the explicit intent of those who practice it. Indians of the American Southwest and adjacent Mexico consume clays with the wild potato species, *S. jamesii* Torr. and *S. fendleri* Gray (Laufer, 1930; Whiting, 1939). The expressed reason for the consumption of specific clays is their effectiveness in eliminating bitterness and in preventing stomach pains or vomiting that result from eating large quantities of these foods without clay. Similar reports of Andean native consumption of specific clays with potatoes date from the 16th-century chroniclers (Weiss, 1953). Specific clays are still consumed with frost-resistant potato cultigens (*Solanum* × *juzepczukii* Buk. and *S.* × *curtilobum* Juz. et Buk.) by the inhabitants of the Central Andean altiplano, with the stated rationale of eliminating the bitter taste characteristic of these potatoes.

Clays are obtained from locally well-known sites in both North and South America. In Peru and Bolivia, I have seen excavations for edible clays extending two or three meters below the surface. Edible clays may be used medicinally, but they are distinguished from clays used for other purposes such as pottery making and for whitewash. Remnants of the historical trade in edible clays persist among the Quechua and Aymara of southern Peru and Bolivia (Rowe, 1946; Tschopik, 1946). Andeans distinguish quality of edible clays largely on the basis of texture. Of the two Peruvian clays, *ch'aqo* and *p'asalla* (Table 1), the former is judged superior because of the relative ease with which it breaks up in water. Andeans consume unseasoned potatoes as the sole or dominant constituent of a meal. Bitter potatoes are dipped in a thick slurry of

P'asalla (Aymara, Quechua)	Tincopalca, Prov. San Roman, Dept. Puno, Peru; July 14, 1981; purchased in Mercado Mancocapa, Juliaca, Prov. Puno.
Ch'aqo (Aymara, Quechua)	Acora, Prov. Puno, Dept. Puno, Peru; July 15, 1981; purchased in Puno, Prov. Puno.
Dleesh (Navajo)	Chinlee area, Navajo Reservation, Arizona, U.S.A.; July 1, 1981; collected by Wendy Wolfe.

clay. Indians of the American Southwest consumed potatoes both cooked and raw. Clays were reportedly added during cooking (Bailey, 1940) or were taken with each mouthful of potato (Whiting, 1939).

Solanine, the bitter glycoalkaloid common in most potatoes, is considered to be toxic to humans in quantities above 20 mg/100 g fresh weight (Gregory, 1984; Jadhav et al., 1981), although cases of solanine poisoning are rare. Glycoalkaloid poisoning involves gastrointestinal and neurological disturbances similar to those caused by the related classes of steroid glycosides, saponins and cardiac glycosides (Jadhav et al., 1981). Tuber-bearing species of *Solanum* vary in the identity and quantity of the glycoalkaloids contained (Gregory et al., 1981; Osman et al., 1978; Johns, 1985). The pharmacokinetics of clay–organic interactions have been studied under gastrointestinal conditions (White and Hem, 1983), and adsorption is generally either through ion-exchange and/or physical adsorption (Theng, 1974). Naturally occurring alkaloids have been shown to be effectively bound by clays (Hendricks, 1941; Wai and Banker, 1966; Ridout, 1967; Barr and Arnista, 1957). The degree of binding depends on reaction conditions (White and Hem, 1983) and on the nature of the clays (Barr and Arnista, 1957; McGinity and Hill, 1975).

In this study the detoxification potential of geophagy was estimated by measuring the adsorptive capacity for tomatine of four potato clays that were recognized as distinct by native practitioners. Qualitative mineral composition was determined with X-ray diffraction.

METHODS AND MATERIALS

Materials. All of the four clays used with potatoes (see Table 1 for sources) were obtained as dry solid pieces. In preparation for adsorption assays, clays obtained from the field were pulverized in a mortar. Field samples and standards were elutriated with 15 times their weight of deionized water for 1 h. Samples were decanted to remove large particles of clay and sand. The decanted portion was centrifuged at 15,000*g* for 10 min, and the pellet was dried at 80°C, repulverized, and stored in a desiccator until used. Kaolin and bentonite were purchased from Sigma Chemical Co.

X-Ray Diffraction. Clays were characterized by powder pattern X-ray diffraction. Air-dried and glycolated preparations were analyzed by M. Cosca, Department of Geology, University of Michigan.

Determination of Adsorptive Capacity. Adsorption of alkaloids on well-characterized clays such as kaolin has been shown to follow an isotherm represented by the Langmuir equation (Barr and Arnista, 1957; Ridout, 1967). The adsorption of a representative and commercially available glycoalkaloid, tomatine, by four sample clays, *ch'aqo*, *p'asalla*, *p'asa*, and *dleesh*, and by commercially available clays, kaolin and bentonite, was determined using the linear form of the Langmuir adsorption isotherm:

$$\frac{C}{X/M} = \frac{1}{ab} + \frac{1}{\mathrm{b}}C$$

where C is the equilibrium concentration of tomatine in solution, and X/M is the amount of tomatine adsorbed per gram of adsorbant. Constants are designated as a and b, with b being equal to the monolayer capacity of the adsorbant.

Adsorptive capacity was determined by stirring 6-mg samples of clay with tomatine (concentration 2–10 mg/10 ml) in 10 ml of buffer (ammonium acetate, pH 5.5) at room temperature for 1 hr. Equilibrium concentrations (C) of tomatine were determined. All tubes were centrifuged for 10 min at 14,500*g*, and a 5-ml aliquot of the supernatant was freeze-dried. The aglycone, tomatidine, was obtained by hydrolyzing samples in 10 ml of 2 NH_2SO_4 heated at 100°C for 2 hr. Aglycones were precipitated with concentrated NH_4OH and were extracted with benzene. Known amounts of tomatine in four concentrations were taken through the lyophylization, hydrolysis, and extraction procedures in each experiment, and served as standards. The quantity of tomatidine present was determined using a titration method (Fitzpatrick and Osman, 1974). The inverse of the slope ($1/b$) of a linear regression of $C/(X/M)$ on C for each clay sample was used to determine the adsorptive capacity (b).

Adsorptive Capacity under Physiological Conditions of pH and Ionic Strength. The effect of pH on tomatine adsorption was determined for *p'asa* and bentonite using the method described above. Solutions were buffered over

a pH range of pH 5.5–1.5, using 0.1 M ammonium acetate (pH 5.5 and 4.5) and 0.1 M ammonium formate (pH 3.5 and 1.5). Adsorptive capacities under stomach conditions were simulated at pH 2.0 and 0.075 M for *p'asa*, bentonite, and *dleesh*.

Determination of the adsorptive capacity at reduced ionic strength was not possible at pH 5.5 or above because of the limited solubility of tomatine (cf. pK_a of α-solanine = 6.6 (Windholz, 1976)). The effect of ionic strength on the adsorption of tomatine was determined at pH 4.5 for *p'asa* and bentonite using concentrations of ammonium acetate varying from 0.15 to 0.01 M. Adsorption under unbuffered conditions was determined for *p'asa* and bentonite using a starting pH of 2.5. Determinations at pH 5.5 and ionic strength of 0.15 were used to approximate sorption in the intestinal tract for *p'asa*, bentonite, and *dleesh*.

RESULTS AND DISCUSSION

Adsorptive Capacities of Potato Clays. Qualitative characterizations of the four field-collected clays are recorded in Table 2. The sample of *p'asa* showed high interlayer swelling in water. Many of its properties were similar to those of bentonite.

Values of the adsorptive capacities for tomatine for each of the clay samples at pH 5.5 and 0.1 M ammonium acetate are shown in Table 2. These determinations are representative of binding under oral conditions. Significant differences ($P < 0.05$) in slopes are seen between all clays tested (analysis of covariance). Assays with kaolin showed experimental variation that was difficult to correct with the experimental methods used. The steep slope of the Langmuir isotherm for kaolin as compared to those of montmorillonite clays such as bentonite and *p'asa* is consistent with the weak cation-exchange capacity of kaolin (Barr and Arnista, 1957; Meshali, 1982).

The adsorption of tomatine by the six clay samples and standards follows a pattern consistent with the known cation-exchange capacities and intercalation properties of different clay groups (Theng, 1974). With an adsorptive capacity of 0.50 g/g (pH 5.5, 0.1 M ammonium acetate), the Bolivian clay, *p'asa*, is superior to bentonite (adsorptive capacity: 0.37 g/g), one of the best commercially available adsorbants of organic compounds. At pH 4.5 and 0.01 M buffer concentration, *p'asa* and bentonite have capacities of 0.68 and 0.65 g/g, respectively. For unbuffered samples, adsorptive capacities of 0.61 g/g and 0.64 g/g, respectively, were recorded for the two clays. Under these conditions of low ionic strength, tomatine adsorption by bentonite is comparable on a milligram basis to that of previously studied pharmaceutical agents (Wai and Banker, 1966).

Of the four clay samples, the weakest adsorption was shown by *dleesh*,

TABLE 2. CHARACTERIZATION OF CLAYS AND COMPARISON OF DETOXIFICATION POTENTIALS AS REPRESENTED BY ADSORPTIVE CAPACITIES FOR TOMATINE

Clay	Characterization	Adsorptive capacity [g/g (r^2)]
P'asa	Predominantly smectites, mixed-layered with illite; quartz. High interlayer swelling.	0.50 (0.99)
P'asalla	Mixed-layer of smectites and illite; quartz.	0.28 (0.94)
Ch'aqo	Predominantly illite, mixed-layered with smectites, chlorite, kaolinite; quartz.	0.19 (0.98)
Dleesh	Predominantly illite, mixed-layered with smectites, kaolinite, chlorite; quartz	0.14 (0.97)
Bentonite		0.37 (0.98)
Kaolin		0.05 (0.77)

obtained from the Navajo reservation. Its adsorptive capacity of 0.14 g/g is, nonetheless, approximately three times greater than Kaolin under similar conditions.

Effects of pH and Ionic Strength on Adsorptive Capacity. The adsorptive capacities of tomatine by *p'asa* and bentonite show no significant ($P > 0.05$) differences between pH 5.5 and 1.5 (Table 3). The lack of appreciable effects due to increasing proton concentration is consistent with other studies that have considered the adsorption of organic bases onto clays (Meshali, 1982; Browne et al., 1980). The pK_as of the alkaloid portion of glycoalkaloids favor the protonated form under experimental conditions.

The increased binding of tomatine as ammonium acetate concentration is decreased from 0.15 to 0.01 M is highly significant ($P < 0.0001$) for both *p'asa* and bentonite (Table 4). The nature of the competition for negatively charged sites between tomatine and other cations will depend on the exchangeable cations present on the surface of the clays and the particular cations present in solution (McGinity and Hill, 1975).

Sorption of high-molecular-weight cations has been shown to involve both ion-exchange and physical adsorption and to reach adsorption levels that exceed the cation-exchange capacity of the clays (Wai and Banker, 1966). At low ionic strength, 0.66 meq/g of tomatine were adsorbed per gram of *p'asa*, while ben-

TABLE 3. EFFECT OF pH ON ADSORPTIVE CAPACITY OF P'ASA AND BENTONITE

pH	Ionic strength (M)	Adsorptive Capacity [g/g (r^2)]		
		P'asa	Bentonite	Dleesh
5.5	0.10	0.50 (0.99)	0.37 (0.98)	
4.5	0.10	0.45 (0.98)	0.41 (0.96)	
3.5	0.10	0.50 (0.97)	0.42 (0.97)	
2.5	0.10	0.50 (0.99)	0.46 (0.98)	
1.5	0.10	0.48 (0.99)	0.44 (0.98)	
2.0	0.075	0.49 (0.97)	0.43 (1.00)	0.11 (0.93)

TABLE 4. EFFECT OF IONIC STRENGTH ON ADSORPTIVE CAPACITY OF P'ASA AND BENTONITE

Ionic strength (M)	pH	Adsorptive Capacity [g/g (r^2)]		
		P'asa	Bentonite	Dleesh
0.15	5.5	0.40 (0.99)	0.30 (0.98)	0.03 (0.98)
0.15	4.5	0.45 (0.97)	0.33 (0.99)	
0.10	4.5	0.45 (0.98)	0.41 (0.96)	
0.05	4.5	0.58 (0.99)	0.46 (1.00)	
0.01	4.5	0.68 (0.99)	0.65 (0.99)	
Unbuffered	2.5 (initial)	0.61 (0.99)	0.64 (0.99)	

tonite adsorbed 0.63 meq/g. On a molar basis, the measured values of tomatine are, in fact, less than the average meq/g reported for montmorillonite clays (0.8–1.5 meq/g). The failure of tomatine to occupy all sites available for cation exchange most likely represents a "cover-up effect" (Hendricks, 1941). The large size of the tomatine molecule (mol wt 1034) exceeds the area available per exchange site.

Detoxification under Physiological Conditions. Adsorption studies over the range of conditions encompassing gastrointestinal pH and ionic strength (Lentner, 1981) demonstrate the ability of these edible clays to bind tomatine and hence neutralize the bitterness and eliminate the gastrointestinal irritation associated with glycoalkaloid ingestion (Jadhav et al., 1981). The quantities of clay necessary to reduce glycoalkaloids from a level of 100 mg/100 g fresh weight, typical of wild potatoes (Gregory, 1984), to a recognized nontoxic level of 20 mg/100 g (Gregory, 1984) are minuscule in comparison to the amounts that are consumed at an actual meal (Whiting, 1939). Culinary practices of

Andeans and the Hopi, as described above, should facilitate glycoalkaloid adsorption.

The determinations of adsorptive capacity made at pH 5.5 and 0.1 M ammonium acetate account for the decrease in bitterness reported by native peoples. Soluble molecules of glycoalkaloids available to interact with oral receptors are also those available for clay adsorption.

The overall detoxification of the clays is most dependent on adsorption in the stomach. Determinations of adsorptive capacity at pH 2.0 and 0.0075 M monovalent cation concentration (ammonium ion) reflect binding during the gastric residence period. Under these conditions, only 271 mg of the least adsorbant of the clays, *dleesh*, would reduce a toxic level of 50 mg tomatine in 100 g of potatoes to the recognized nontoxic level of 20 mg/100 g TGA. *P'asa*, the most effective adsorbant would provide the same detoxification with only 60 mg of clay.

Desorption at the increased pH and ionic strength of the intestines could reduce the effective detoxification of clays. At pH 5.5 and 0.15 M ammonium acetate, the adsorptive capacities of *p'asa*, bentonite, and *dleesh* are the lowest in comparison to all the conditions tested. The reduced solubility of glycoalkaloids at pHs above 5.5 would be expected to reduce adsorption under normal intestinal pHs of 6–8 (Lentner, 1981). Previous work (White and Hem, 1983) has shown that in vivo, in the presence of clays, pK_as are effectively higher. Such an effect would facilitate clay–tomatine binding in vivo. Even if clay adsorption of glycoalkaloids is reduced in the intestine, their insolubility under basic conditions should minimize adsorption by the intestine and decrease the resultant toxic effects.

Evolutionary Significance of Geophagy by Humans. Wild potatoes, as weedy annuals occurring in abundance on sites of human disturbance, meet the classic criteria for a domesticable plant (de Wet and Harlan, 1975). However, weakly toxic glycoalkaloids, while not eliminating the possibility of consumption, would limit the use of potato tubers to a casual occurrence or as an emergency food. Geophagous practices associated with the gathering of potatoes from the wild (Laufer, 1930), and with the cultivation of wild potatoes (Whiting, 1939; cf. Pennington, 1963) and primitive domesticates (Weiss, 1953) link this detoxification phenomenon with the process of human-directed evolution leading to plant domestication. Association of the detoxification function of geophagy with stages in the domestication of the world's premier vegetatively propagated cultigen (FAO, 1983) has important implications, as well, for the domestication of many crops where wild relatives contain toxic levels of secondary compounds.

The clay–potato association provides insight into the general phenomenon of geophagy. Potato clays are used habitually with a resource which otherwise is only modestly exploitable because of the presence of weak but quantitative

toxins. The use of clays in this situation corresponds to geophagous practices of at least eight species of primates which include at least some leaves in their diet (Hladik, 1978; Wrangham, personal communication). Nonlethal quantities of secondary compounds limit the exploitation of particular abundant resources by generalist herbivores (Freeland and Janzen, 1974) and constrain primate food choice (Clutton-Brock, 1977; McKey et al., 1981). Specific clays, often from termite mounds, are eaten daily, sometimes seasonally, by chimpanzees (Uehara, 1982; Wrangham, 1977; Hladik and Gueguen, 1974).

If early human foraging was analogous to the feeding of modern nonhuman primates, then food procurement by humans must have been subject to the constraints imposed by plant defensive compounds. Geophagy is a behavior with antecedents that are certainly prehominoid, and higher primates, including humans, have apparently maintained it as a mechanism for dealing with naturally occurring toxins.

Rats consume clay when subjected to chemical toxins in laboratory settings (Mitchell et al., 1976, 1977a). Mitchell et al. (1977b) demonstrated that if a rat develops a conditioned taste aversion to a novel (and nontoxic) flavor, it will respond to this conditioned stimulus by consuming clay, even if clay was not administered during the original conditioning episode.

The conditioned aversion response has been extensively studied in rats and other animals (Garcia et al., 1974; Riley and Baril, 1976) and has provided a model for considering human taste aversions and preferences (Garb and Stunkard, 1974; Garcia et al., 1974; Bernstein, 1978). The well-studied model linking toxicosis and conditioned responses, mediated through gastrointestinal upset, can be extended to include geophagy as part of an integrated "psychological" response to environmental toxins. This model may be extended to include geophagy as an adaptive behavioral response for generalist primates as well as rats.

Widespread medicinal uses of clays by humans to treat diarrhea (Vermeer and Ferrell, 1985) and other gastrointestinal ailments may relate to the detoxification function of geophagy either directly or indirectly via the "psychological" response to gastrointestinal upset.

Periodic deficiencies in food availability are a fundamental stress facing humans and other primates (Stahl, 1984). Wild potatoes are typically exploited by humans during famines or periods of seasonal scarcity (Laufer, 1930; Whiting, 1939). Geophagy accompanying the use of famine foods is a widely documented behavior of traditional agriculturalists around the world (Laufer, 1930; Solien, 1954). Here geophagy is a response to gastrointestinal stress in the form of hunger (Solien, 1954) or poisoning by ingestion of barely tolerable wild plants or bacterially contaminated foods. The most appropriate responses to this stress are maintained and transmitted through human culture and institutions. Modern cultural attitudes towards geophagy are clearly important in encour-

aging or restricting this behavior. Maintenance of geophagy as a cultural trait may be a relic of its historical significance (Laufer, 1930; Anell and Lagercrantz, 1958; Hunter, 1973).

Crises in food production are an inherent component of many models of the development of agriculture (Rindos, 1980). The transition of geophagy from a general response to toxin-related stress to a more specialized detoxification technique can be interpreted as an important step allowing expanded resource exploitation and the domestication of particular plants. Wild potatoes were presumably a minor dietary constituent or a famine resource under primitive conditions of exploitation, but eventually provided a subsistence base for complex prehistoric civilization in the Central Andes. By analogy, wild plants were probably more available to early hominids than has been previously supposed (Leopold and Ardrey, 1972).

The functional significance of geophagy suggests that the interaction of animals with the inorganic component of the chemical environment deserves increased attention from chemical ecologists. Animals ingest exogenous substances for nutritional, digestive (Martin and Martin, 1978), defensive, and communicative purposes (Harborne, 1982). Clearly they ingest exogenous substances for their detoxification properties as well.

Acknowledgments—This paper is dedicated to the late Prof. Volney H. Jones. I thank M.M. Martin, S.F. Osman, H.V. Kuhnlein, M. Cosca, W.L. Merrill, and C.I.P. (Lima) for technical support; W. Wolfe for the sample of *dleesh*; and A. Camino, R.I. Ford, R.W. Wrangham, and S.L. Keen for their comments. This research was supported by a NSERC Canada Postgraduate Scholarship and a NSF Dissertation Grant (DEB-8208298).

Abstract—Infection of ryegrass (*Lolium perenne*) by an endophytic fungus (*Acremonium loliae*) confers resistance against the Argentine stem weevil (*Listronotus bonariensis*). Extracts from ryegrass clones, infected and uninfected with *A. loliae*, were compared in a feeding choice bioassay, and several fractions were identified which affected stem weevil feeding behavior. One stem weevil feeding deterrent, peramine $C_{12}H_{17}N_5O$, has been isolated from infected ryegrass and partially characterized as a basic indole derivative. Extracts from cultured *A. loliae* had no effect on stem weevil feeding behavior nor was peramine detected in the fungal cultures examined. Peramine and the other active substances are hydrophilic in contrast to the lipophilic properties reported for the neurotoxic lolitrems also isolated from ryegrass infected with *A. loliae* and associated with causing ryegrass staggers disorder in livestock. It is suggested that ryegrass staggers and stem weevil feeding deterrency may arise by different biochemical mechanisms.

Key Words—Perennial ryegrass, *Lolium perenne*, Gramineae, Argentine stem weevil, *Listronotus bonariensis*, Coleoptera, Curculionidae, *Acremonium loliae*, *Acremonium coenophialum*, endophyte, bioassay, induced resistance, feeding deterrent, peramine.

INTRODUCTION

Perennial ryegrass (*Lolium perenne L.*), the dominant New Zealand pasture grass, can be severely damaged by Argentine stem weevil [*Listronotus bonariensis* (Kuschel), Coleoptera: Curculionidae]. In the spring, diapausing adults respond to increasing daylength and begin laying eggs in the leaf sheath at the

0098-0331/86/0300-0647$05.00/0

base of ryegrass tillers. The larvae penetrate the stem and develop through four instars during which time they mine and kill up to four tillers. There are two generations per year, with populations peaking in the spring in the South Island and in the summer in the North Island. The adult weevils feed on the tips of leaves but do little damage to mature plants.

Perennial ryegrasses resistant to stem weevil have been identified (Kain et al., 1982a,b), and this resistance has been linked to the presence of an endophytic fungal infection in the resistant plants (Prestidge et al., 1982). The resistance of endophyte-infected ryegrass derives in part from selective feeding by the adult weevils. Gaynor and Hunt (1983) showed that there was less feeding by adult weevils on plants infected with endophyte, and this led to fewer eggs and larvae and to less damage. The endophytic fungus associated with stem weevil resistance of ryegrass, *Acremonium loliae* Latch, Christensen and Samuels, is seed transmitted and closely related to *Acremonium coenophialum* Morgan-Jones and Gams, found in tall fescue, *Festuca arundinaceae* (Schreber) (Morgan-Jones and Gams, 1982; Latch et al., 1984). A second, less common, *Gliocladium*-like endophyte has also been isolated from ryegrass (Latch et al., 1984) but, when ryegrass was artificially infected with this fungus, no resistance to stem weevil was detected (Gaynor et al., 1983).

Endophytic infection of ryegrass has been reported to be associated with resistance to eight species of sod webworms (*Crambus* spp.) (Funk et al., 1983a), to billbugs (*Sphenophorus* sp.) (Funk et al., 1983b) in the United States, and to pasture mealy bug, *Pseudantonina poae* (Mask.), in New Zealand (W.D. Pearson, DSIR, Lincoln, personal communication). Tall fescue infected with *A. coenophialum* has been shown to be resistant to stem weevil (Barker et al., 1983) and to oat aphid, *Rhopalosiphum padi* (L.) (Latch et al., 1985). Endophyte-infected ryegrass, however, is not resistant to *R. padi*. Endophytic fungi have also been reported from Chewings fescue (*F. rubra* L. *sensu lato*), Bermuda grass [*Cynodon dactylon* (L.) Pers.] and a number of other species (Latch et al., 1984). However, only for Chewings fescue are there indications of endophyte-associated insect resistance (Funk et al., 1983b).

The presence of *A. loliae* in ryegrass is also associated with a specific livestock disorder known as ryegrass staggers (Fletcher and Harvey, 1981). This disorder occurs sporadically in stock grazing ryegrass pasture infected with endophyte and is characterized by tetanic muscle spasms and a hypersensitivity to external stimuli. Ryegrass staggers is of considerable importance to agriculture in Australia and New Zealand (Cunningham and Hartley, 1959; Gallagher et al., 1984). The presumed causative agents of ryegrass staggers, a series of tremorgenic neurotoxins named lolitrems, have recently been isolated from extracts of "toxic" pasture and seed (Gallagher et al., 1981, 1982). The lolitrems are structurally similar to the other known tremorgenic mycotoxins such as the penitrems and the janthitrems (Gallagher et al., 1984). Infection of tall fescue

pasture with *A. coenophialum* in the United States is also associated with a complex of stock disorders referred to as fescue foot, fat necrosis, and summer slump or fescue toxicity (Johnson, 1983).

Recent research suggests that endophyte-infected ryegrass and tall fescue is less palatable and may also adversely affect growth and reproduction of stock (Johnson, 1983; Fletcher, 1983; Fletcher and Barrell, 1984). We decided to identify the biochemical mechanisms by which endophytic infection confers stem weevil resistance to the infected plant. This should indicate the feasibility of producing insect-resistant ryegrasses which have no associated animal toxicity and also suggest possible approaches to this goal, e.g., via plant selection or reinfection with mutant endophytes.

METHODS AND MATERIALS

The preference of adult weevils for endophyte-free plants, coupled with the consequent increase in larval damage, led us to develop a bioassay sufficiently sensitive to detect adult weevil feeding preferences between extracts from endophyte-infected and uninfected ryegrasses. "Grasslands Nui" perennial ryegrass was used throughout, and clones free of *A. loliae* were obtained by treating infected ryegrass with benomyl fungicide using the method of Latch and Christensen (1982). The plants were repotted several months prior to testing and checked for endophyte infection microscopically and by an ELISA technique (Musgrave, 1984). For large-scale extraction, the plants were subdivided and grown in the field for several months as spaced plants.

Feeding Choice Bioassay. Ryegrass from either infected or uninfected clones was harvested using an electric sheep-shearing handpiece to collect all material above ground level and stored at −20°C until required. Frozen grass was chopped into 2-cm lengths, blended twice in 95% ethanol, and the resulting extract filtered through Celite and evaporated to dryness under reduced pressure. This extract was redissolved in chloroform–ethanol–water (5:2:1), and a known volume was added to cellulose powder (Whatman CC31) to give a concentration of 2.5 g extract/4 g of cellulose powder. The cellulose powder was dried on a rotary evaporator at 40°C and then on a vacuum pump at 40°C for 1 hr.

Four grams of this cellulose powder was stirred rapidly into a hot mix made from agar (4 g), sucrose (5 g), and water (90 ml). After cooling, 35–40 agar disks were cut with a cork borer (1 cm diameter × 3 mm thickness) and used in a feeding choice bioassay to determine the feeding preference of adult weevils. Subsequent fractions isolated after solvent partitioning or chromatography were assayed at concentrations proportional to their concentration in the 95% ethanol extract.

For the feeding choice bioassay, one adult weevil in an 8-cm-diameter Petri dish was presented with two agar disks, one containing extract from an endophyte-infected ryegrass and the other extract from an uninfected clonal replicate. Dishes were replicated a minimum of 35 times and maintained at 16°C with 16 hr daylength for 72 hr. The amount of feeding on each disk was assessed by scoring blind on a 0–3 scale the amount of frass produced by the weevil (0, having no frass; 1, having 1–2 small clumps of frass; 2, having 4–10 clumps of frass; 3, having large areas of the disk covered in frass). The difference in feeding scores between the two agar disks of each Petri dish was calculated and the significance of the deviation of these differences from zero (i.e., no difference in feeding) was tested using the Wilcoxon signed rank test (Siegel, 1956). The mean difference in feeding scores (MFS) was determined for all the Petri dishes in the test. A positive MFS value indicates more feeding on the disks containing extract from uninfected ryegrass, while a negative MFS value indicates more feeding on the disks containing extract from infected plants.

Feeding Deterrent Bioassay. Activity in the feeding choice bioassay could be the result of either the presence of a feeding deterrent in the extract from the infected ryegrass or higher levels of some feeding stimulant in the extract from uninfected ryegrass. To distinguish between these possibilities, a change was made in the preparation of the cellulose powder used in the feeding choice bioassay. The 95% ethanol extract from uninfected ryegrass was partitioned between 80% ethanol and petroleum ether. The 80% ethanol phase was evaporated to dryness, weighed, redissolved in chloroform–ethanol–water (1 : 1 : 1), and adsorbed onto cellulose powder at 2 g of extract/4 g of cellulose powder. To this cellulose powder was added either sufficient purified extract of an active fraction from an infected plant to give a normal plant concentration (plus solvent, 15 ml total volume), or just solvent (15 ml). The resulting two suspensions were evaporated to dryness and the two portions of cellulose powder used to prepare the two agar disks for the feeding choice bioassay. This was then used to determine whether the previously active fraction still deterred feeding when incorporated back into the ethanolic extract, thus suggesting the presence of a feeding deterrent. To check whether an imbalance of feeding stimulants was involved, the above procedure was repeated but using instead the corresponding extract from a clonal plant uninfected with *A. loliae*.

Phase Partitioning. The 95% ethanol extract, prepared as previously described, was partitioned between chloroform–methanol–water (1 : 1 : 1), then further partitioned between *n*-butanol–water (1 : 1), or petroleum ether–80% ethanol (1 : 1) following the sequences outlined in Figures 1 and 2. All phases were backwashed with the appropriate solvents. The backwashes were partitioned against each other and recombined with their parent phases.

Chromatography. The fractions obtained from the above partitioning were further separated by chromatography following the sequences outlined in Fig-

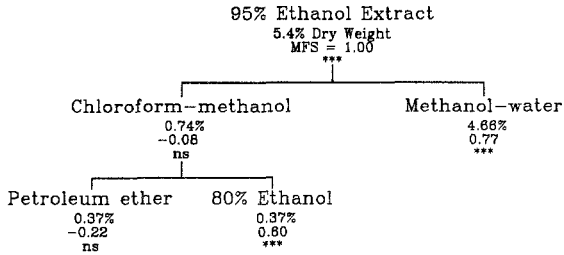

FIG. 1. Phase separation of ryegrass extract showing partitioning of mass (% dry weight), mean difference of stem weevil feeding scores when offered a choice of extracts from infected or uninfected ryegrass (MFS), and the significance of the difference (ns = not significant, *** = $P < 0.001$). A positive MFS value indicates more feeding on the agar disks containing extract from uninfected ryegrass.

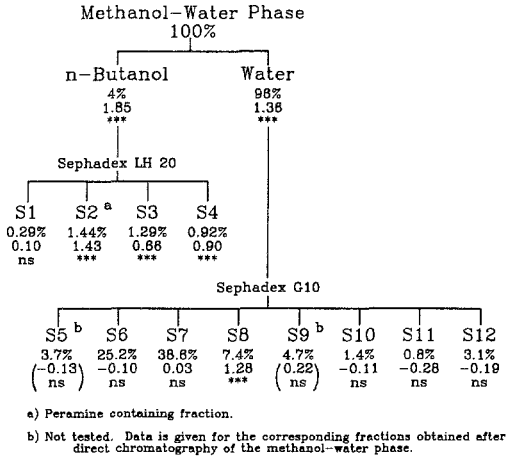

FIG. 2. Phase separation and chromatography of the methanol–water extract showing for each fraction: partitioning of mass (as a % of methanol–water extract), mean difference of stem weevil feeding scores when offered a choice of extracts from infected or uninfected ryegrass (MFS), and the significance of the differences (ns = not significant, *** = $P < 0.001$).

ures 2 and 3. Chromatographic fractions were routinely examined by silica gel thin-layer chromatography (TLC) using a vanillin–sulfuric acid spray reagent, and fractions containing similar components were bulked together for the bioassay. Extracts from both infected and uninfected plants were chromatographed separately, under, as far as possible, identical conditions.

For Sephadex G-10 chromatography (Figure 2), the sample (2.8 g) was eluted from a 25 × 920-mm column of Sephadex G-10 (V_0 180 ml) using 1%

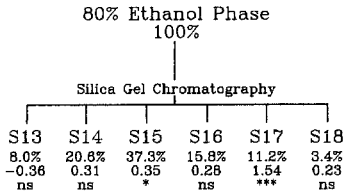

FIG. 3. Fractionation of 80% ethanol extract showing for each fraction: partitioning of mass (as a % of 80% ethanol extract), mean difference of stem weevil feeding scores when offered a choice of extracts from infected and uninfected ryegrass (MFS), and the significance of the differences (ns = not significant, * = $P < 0.05$, *** = $P < 0.001$).

n-butanol–water. The flow rate was 60 ml/hr, and 10-ml fractions were collected. Fractions eluting between 160 and 200, 200 and 330, 330 and 450, 450 and 580, and 580 and 1000 ml were bulked on the basis of their UV adsorption at 280 nm.

For Sephadex LH-20 chromatography (Figure 2), a ratio of 1 g sample to 55 g Sephadex LH-20 was used. The column was eluted with 80% ethanol.

For silica gel chromatography (Figure 3), a sample of the 80% ethanol phase (12.2 g) was applied to a column of silica gel (400 g) packed in 50% petroleum ether–chloroform. The column was eluted successively with chloroform (1.3 liters), chloroform–ethanol (9:1) (6.3 liters, two fractions collected); chloroform–ethanol (8:2) (3.5 liters); chloroform–ethanol–95% ethanol (7:3:3) (3 liters); then (1:2:2) (2.3 liters); then 95% ethanol (1.5 liters).

Isolation of Peramine. The stem weevil feeding deterrent, which we have named peramine, was detected in fraction S2 (Figure 2) as a blue staining spot ($R_f \sim 0.3$) after TLC and spraying with Ehrlich's reagent (*p*-dimethylaminobenzaldehyde–hydrochloric acid). TLC was performed on aluminum-backed silica gel-60 using the lower phase of a chloroform–methanol–water (7:13:8) partition.

Fraction S2 was rechromatographed on Sephadex LH-20 with 80% ethanol until no significant further purification could be achieved. Further chromatography on Sephadex LH-20 (100:1 w/w) using 95% ethanol–dichloromethane (1:9) was used to remove pigments. Fractions containing peramine were eluted using a gradient of 95% ethanol–dichloromethane (2:8 to 1:1). This material was dissolved in 0.01 M ammonium bicarbonate buffer, pH 7.8, containing 2% *n*-butanol and applied to a column of CM-Sephadex in the same buffer. The column was washed with ammonium bicarbonate buffer until the last yellow band had eluted. Peramine was then eluted with 1% acetic acid, pH 4.6, containing 2% *n*-butanol.

Purification of peramine by high-performance liquid chromatography (HPLC) was achieved on a 5-μm C-18 Rad-Pak 8 × 100-mm column fitted with a RCSS C-18 Guard-Pak insert. A linear solvent gradient from 60% to

90% methanol–water over 20 min was used. Both solvents were 0.005 molar in sodium *n*-heptanesulfonate. The flow rate was 1 ml/min with UV detection at 230 and 280 nm. Peramine eluted as the single major peak after 27 min. To remove the bulk of the sodium *n*-heptanesulfonate prior to mass spectrometry, the material was partially desalted using G-10 Sephadex, eluting with water. Subsequent elution with methanol gave peramine.

Flatbed paper electrophoresis was run at pH 10.8 using a 0.1 M sodium carbonate buffer and 5-hydroxy- and 5-methoxytryptamine as standards.

Acetylation of Peramine. Peramine (~0.5 mg) was dissolved in acetic anhydride (0.5 ml) and pyridine (0.5 ml) and kept at room temperature for 6 hr until TLC indicated no peramine remained. Excess reagents were removed with toluene under reduced pressure, and the residue was taken up in dichloromethane and filtered. Preparative silica gel TLC using acetone–dichloromethane (1:3) gave diacetyl-peramine as the major product: electron ionization mass spectrometry (EIMS) *m/z*: 331(M^+), 272, 247, 230, 213, 205, 188, 175 (100%).

Bioassay with Cultured Endophyte. Mycelium from a liquid potato–dextrose culture of *A. loliae* endophyte was blended in 95% ethanol, filtered, evaporated, and made up as a standard solution as for the plant extracts. The hyphal extract was added to cellulose powder onto which had been adsorbed extract from endophyte-free ryegrass as described for the feeding deterrent bioassay above. Agar disks containing hyphal extract plus extract from endophyte-free ryegrass were compared with disks containing only extract from endophyte-free ryegrass. Bioassay concentrations corresponded to 0.7, 4, 7, and 28 mg fungal mycelium/g agar.

RESULTS

Crude Extracts. When adult stem weevils were presented with a choice of agar disks containing 95% ethanol extract either from ryegrass infected with *A. loliae* or from an uninfected clonal replicate, there was significantly less feeding (MFS = 1.00) on the disks containing the extract from infected ryegrass (Figure 1). When this extract was solvent partitioned with chloroform–methanol–water, activity was found in the more polar methanol–water phase (MFS = 0.77). When the inactive chloroform–methanol phase (MFS = −0.08) was further partitioned between 80% ethanol and petroleum ether (Figure 1), activity was found in the 80% ethanol phase (MFS = 0.60), suggesting a masking effect by inactive petroleum-soluble substances.

Isolation of Peramine. The methanol–water phase was partitioned between *n*-butanol and water (Figure 2), and activity was found in both phases. The *n*-butanol phase was chromatographed on Sephadex LH-20 and yielded three active fractions S2, S3, and S4. Fractions from both infected and uninfected plants

were compared by TLC using a variety of spray reagents. The only observed difference between the extracts from infected and uninfected plants was a blue-staining compound detected with Ehrlich's reagent only in fraction S2 from infected ryegrass. This blue-staining material, which we have named peramine, was purified by repeated Sephadex LH-20 chromatography and further purified on Sephadex LH-20 using a gradient of 95% ethanol in dichloromethane. This purified material was active in the feeding choice bioassay of 10 ppm (MFS = 1.13; $P < 0.001$) and 1 ppm (MFS = 0.50; $P < 0.001$). It was also tested in the feeding deterrent bioassay and was found to deter weevil feeding at 10 ppm (MFS = 0.49; $P < 0.001$). The concentration of this fraction in fresh plant tissue from infected plants was estimated to be approximately 8 ppm.

Peramine, homogeneous by TLC and essentially pure by HPLC, was obtained from the partially purified material by ion-exchange chromatography using CM-Sephadex. This material was tested in the feeding choice bioassay by incorporation into agar–cellulose powder disks containing sucrose as the only stimulant (sucrose agar) and was active at 1.3 ppm (MFS = 1.45, $P < 0.001$, concentration based on UV adsorption at 285 nm; ϵ taken as 10,000 based on indole). Ammonium acetate, a coeluant with peramine from the CM-Sephadex column, was also tested at a nominal 18 ppm against sucrose agar in the feeding choice bioassay and was inactive (MFS = 0.18).

A final purification of peramine was achieved by reversed-phase HPLC which removed a number of minor UV adsorbing impurities. A phase modifier, sodium *n*-heptanesulfonate (0.005 M), was added to the mobile phase in order to obtain retention of peramine on the C-18 stationary phase. The phase modifier proved difficult to separate from the small quantities of peramine present, reducing the preparative value of this separation step. Peramine, obtained after HPLC, was desalted on Sephadex G-10 and showed identical UV, low-resolution mass spectra, and chromatographic behavior on TLC to material obtained after CM-Sephadex chromatography.

Peramine showed UV maxima at 232 and 285 nm, suggestive of a 2,3-disubstituted indole (de Jesus et al., 1983). Paper electrophoresis indicated peramine was a strong base, retaining a positive charge at pH 10.8. Peramine gave a positive reaction with Dragendorff's reagent (1-μg sample on TLC) but no reaction with ninhydrin (8-μg sample size). High-resolution electron ionization mass spectrometry (EIMS) established $C_{12}H_{17}N_5O$ as the formula for the highest mass ion (*m/z* 247.1404, $C_{12}H_{17}N_5O$ requires 247.1432). A second high mass ion, measured as $C_{11}H_{15}N_3O$ (*m/z* 205.1214, $C_{11}H_{15}N_3O$ requires 205.1214) corresponded to the product of a cyanamide loss. Attempts made to obtain the FAB-mass spectrum of peramine gave only ions arising from the matrix used (glycerol, glycerol HCl, thioglycerol, PEG). The molecular formula of peramine was confirmed as $C_{12}H_{17}N_5O$ by acetylation which gave a diacetyl derivative *m/z* 331 (M^+, $C_{16}H_{21}N_5O_3$). Characteristic acetamide (*m/z* 272) and ketene (*m/z* 247, double ketene) losses were also observed.

Activity of Water Phase. The water phases from both infected and uninfected plants were chromatographed on Sephadex G-10, and the fractions obtained compared in the choice bioassay (Figure 2). Fraction S8, from within the included volume of the Sephadex column, was the only active fraction. Fractions from both infected and uninfected plants were examined by TLC, but no differences were observed under UV irradiation or with ninhydrin, vanillin, Ehrlich's, fast blue, or sulfuric acid as spray reagents. No peramine was observed. When methanol was added to aqueous solutions of S8, inorganic salts were precipitated. The remaining methanol-soluble components were predominantly glucose and fructose as determined by ^{13}C nuclear magnetic resonance spectroscopy ([^{13}C]NMR). No major differences in the [^{13}C]NMR spectra were observed for samples obtained from either infected or uninfected plants. Samples of S8 were consistently inactive in the feeding deterrent bioassay. The activity in the choice bioassay may result from a higher concentration of feeding stimulants in the extract from uninfected ryegrass. In light of these bioassay results and since no chemical differences were detected between extracts from infected and uninfected plants, this fraction was not further examined.

Activity of 80% Ethanol Phase. Silica gel chromatography of the 80% ethanol phase yielded two active fractions (S15 and S17) (Figure 3). Fraction S15 appeared to have marginal activity and was not further investigated. Fraction S17, obtained from endophyte-infected ryegrass, was an active feeding deterrent (MFS = 0.83, $P < 0.001$), while the corresponding fraction from an uninfected plant was inactive (MFS = −0.07). Fraction S17 from the infected plants was further purified by silica gel, Sephadex LH-20 (80% ethanol) and CM-Sephadex ion-exchange chromatography. TLC revealed the presence of peramine, suggesting that the activity of the 80% ethanol phase may be due to the same components as occur in the *n*-butanol phase, indicating an incomplete initial chloroform–methanol–water partition.

Bioassay of Cultured Acremonium. Extracts of mycelium of *A. loliae* grown in culture did not affect weevil feeding in the feeding deterrent bioassay at concentrations corresponding to 0.7, 4.0, 7.0, and 28.0 mg hyphae per gram of agar. The MFS values were, respectively, 0.03, −0.10, 0.19, and −0.10.

DISCUSSION

The results obtained with the feeding choice bioassays show that ryegrass infected with *A. loliae* contains extractable substances which affect the feeding behavior of adult Argentine stem weevil. Activity is concentrated in the more polar phases and can be further resolved by chromatography. A comparison of chromatographic fractions from plants infected and uninfected with *A. loliae* revealed an active feeding deterrent in the *n*-butanol phase. This feeding deterrent, which we have named peramine, was only found in extracts from ryegrass

infected with *A. loliae*. It was not detected in extracts from uninfected plants or in liquid cultures of *A. loliae* (D.D. Rowan, unpublished results). Peramine, $C_{12}H_{17}N_5O$, has been isolated and shows UV adsorptions and chromogenic reactions typical of a substituted indole derivative. Peramine deterred feeding by adult Argentine stem weevil at 1.3 ppm.

Peramine is chemically different from the tremorgenic lolitrems also isolated from ryegrass infected with *A. loliae* and which are suspected of causing sporadic outbreaks of ryegrass staggers in livestock. The molecular formula of lolitrem A ($C_{42}H_{55}NO_8$) and the structures of lolitrems B ($C_{42}H_{55}NO_7$) and C ($C_{42}H_{57}NO_7$) have been published (Gallagher et al., 1981, 1984). Lolitrems are nonpolar, neutral compounds containing a highly substituted indole ring system and are structurally related to the known aflatrem, penitrem, and janthitrem mycotoxins (Gallagher et al., 1984). Their biological activity against insects has not yet been reported. Based on the solvent partitioning studies of Gallagher et al., (1977) and on the HPLC retention data for lolitrem B (Gallagher et al., 1985), we would expect lolitrems to elute in fractions S13 or S14 (Figure 3). Fractions S13 and S14 were not active in the stem weevil choice bioassay, nor could the characteristic mass fragments for lolitrems (*m/z* 348) (Gallagher et al., 1981) be detected in either of the active fractions, S15 and S17. We therefore suggest that the neurotoxic lolitrems, if present in our extracts, are not important as feeding deterrents.

The amount of endophyte in ryegrass varies between 5 and 200 mg/g, with typical concentrations ranging from 30 to 50 mg/g (Musgrave, 1984). Extracts from cultured *A. loliae* were not active against Argentine stem weevil at concentrations corresponding to 28 mg hyphae/g agar. However, as bioassays on ryegrass extracts show activity even at one tenth the natural concentration of plant material, any feeding deterrent activity in the cultured endophyte should be detectable at the levels used in these tests. Neither peramine nor the lolitrem neurotoxins (R.T. Gallagher, personal communication) have yet been detected in liquid cultures of *A. loliae*. This suggests that peramine, the lolitrems, and other stem weevil active substances are not constitutive in the fungal mycelium. However, they might still be produced by *A. loliae* when growing endophytically or under as yet undefined culture conditions. Alternatively, they may be plant metabolites produced in response to the endophyte.

As peramine and the other stem weevil active fractions appear to differ chemically from the lolitrems, it may be possible to produce an endophyte-infected ryegrass resistant to stem weevil but which does not produce ryegrass staggers in livestock. An understanding of the mechanisms whereby endophytic infection of ryegrass confers resistance to infected plants may also be relevant to research on the insect resistance of other grasses infected with endophyte. Finally, the stem weevil resistance of ryegrass infected with endophyte can be seen as another example of a plant resistance to a pest arising from the effects of a previous fungal challenge.

Acknowledgments—We thank Dr. G.C.M. Latch and Mr. M.J. Christensen of Plant Diseases Division, DSIR, for preparing clonal plants and endophyte cultures, and Professor R. Hodges, Massey University, for the mass spectra. The biometrical assistance of Dr. J.R. Sedcole of Grasslands Division, and the technical assistance of M.B. Hunt and S.M. Pilkington of Applied Biochemistry Division and of V.A. Hunt of Entomology Division, DSIR, Palmerston North is gratefully acknowledged.

(Received March 29, 1985; accepted July 11, 1985)

Abstract—In the present study male redbanded leafroller (*Argyrotaenia velutinana*), cabbage looper (*Trichoplusia ni*), and Oriental fruit moths, (*Grapholita molesta*), were tested in a flight tunnel to (1) the major pheromone component, (2) the *Z/E* pheromone component mixtures for Oriental fruit moth and redbanded leafroller, (3) and the female-released blends, over a series of dosages. Experiments were designed to test the hypothesis that male response downwind of a female is initiated by the major component and that minor components function only to elicit behaviors close to the female during close-range approach and courtship. The results did not support this hypothesis, but rather showed that males initiated upwind flight in significantly higher percentages to the complete blends of components, at all dosages, compared to single components or partial blends. Addition of minor components also signficantly enhanced male perception of the major component at lower dosages, resulting in completed flights to dosages of the major component that alone did not elicit any upwind flight. Our results support the concept that minor components function to enhance male sensitivity to the pheromone, and the specificity of the signal. Our results also support the hypothesis that the active space of the pheromone is a function of the upper and lower concentration thresholds for the blend of components, and not simply for the major component.

Key Words—Sex pheromone, active space, *Trichopulsia ni*, Lepidoptera, Noctuidae, *Argyrotaenia velutinana*, *Grapholita molesta*, Tortricidae, multicomponent pheromones, sustained-flight tunnel.

INTRODUCTION

Recently, in our lab, the sex pheromone of the cabbage looper (CL), *Trichoplusia ni* (Hubner), and the redbanded leafroller (RBLR), *Argyrotaenia velutinana* (Walker), were reinvestigated (Bjostad et al., 1984a,b; Linn et al., 1984), as part of a series of studies concerned with sex pheromone biosynthesis (Roelofs and Brown, 1982; Bjostad and Roelofs, 1983; Roelofs and Bjostad, 1984). Several new compounds were identified for each species from sex pheromone gland extracts and airborne collections, as predicted from the proposed biosynthetic routes. Subsequent behavioral tests in a sustained-flight tunnel revealed two important points: the female-released blend was superior to the previously identified pheromones (Roelofs et al., 1975; Bjostad et al., 1980), and the blend enhanced all aspects of the male response, both quantitatively and qualitatively. The results of these tests indicated that previously characterized behavioral functions of the components were artifacts (Baker et al., 1976; Linn and Gaston, 1981a,b), the result of analysis based on observations of male behavior with partial or incorrectly identified blends. Our results were also in agreement with those reported previously for the Oriental fruit moth (OFM), *Grapholita molesta* (Busck) (Baker and Cardé, 1979).

The present work was initiated to expand on the results of the studies with OFM, CL, and RBLR. We tested male moths in the sustained-flight tunnel to a dosage series of the major (or most abundant) pheromone component, of the *Z/E* mixture for OFM and RBLR, and of the full blend for each species. Our objective was to determine if males are significantly more responsive to the female-released blend of components, and if they are more sensitive to the full blend compared to only the major component(s) at low dosages, simulating conditions downwind from a female. The results are discussed with respect to current ideas concerning male perception and the active space of the pheromone.

METHODS AND MATERIALS

Insects. RBLR and CL were reared on semisynthetic diet (Shorey and Hale, 1965), and OFM were reared on small green thinning apples, at 25°C, 16:8 light–dark photoperiod. The sexes were separated as pupae, and adult males were segregated daily by age and kept under conditions similar to those during rearing, in chambers separated from females.

Chemicals. For RBLR, the (*Z*)-11-tetradecenyl acetate (*Z*11–14:OAc) isomer (Farchan) was collected by GLC [2m × 2mm glass column packed with 10% XF-1150 (50% cyanoethyl methyl silicone) on 100–120 mesh chromosorb W-AW-DMCS], to ensure purity and was found to be > 99.9% pure. The *E*11–14:OAc isomer (Farchan) was added to the *Z* isomer to make a 92:8 *Z/E* mix,

as shown by capillary GLC (45-m Carbowax 20 M column). The ratio of components in the seven-component blend (Bjostad et al., 1984a) was as follows: 12:OAc (7.5), Z9-12:OAc (1.2), E9-12:OAc (2.5), 11-12:OAc (3.6), 14:OAc (4.6), Z11-14:OAc (100), E11-14:OAc (8.1). The ratio was checked by capillary GLC with all components $\pm 1\%$ of the desired blend.

For OFM the Z8-12:OAc isomer (Farchan) was purified by HPLC (Baker et al., 1981) and shown by capillary GLC to be $> 99.9\%$ pure. The mixture of Z8- and E8-12:OAc (6% E) was prepared and checked by capillary GLC, as was the three-component blend (6% E in Z8-12:OAc with 10% Z8-12:OH added, Cardé et al., 1979; Linn and Roelofs, 1983).

For CL the Z7-12:OAc isomer (Farchan) was shown by capillary GLC to be $> 98\%$ pure with no detectable E7-12:OAc or Z7-12:OH present (Linn et al., 1984). The synthetic chemicals for the six-component mix were the same as in Linn et al. (1984). The proportions of each compound were as follows: 12:OAc (5.6), Z5-12:OAc (7.7), Z7-12:OAc (100), 11-12:OAc (1.9), Z7-14:OAc (0.8), and Z9-14:OAc (0.6). A solution of this blend was prepared in Skelly B and checked on capillary GLC.

Chemical Sources. For RBLR and OFM, the single components Z11-14:OAc and Z8-12:OAc, the respective Z/E mixes, and the seven- and three-component blends were prepared in Skelly B (predominantly *n*-hexanes) and applied in 100-μl amounts to rubber septa (red, 5 × 9 mm, A.H. Thomas Co., Philadelphia, Pennsylvania) to achieve dosages of 3, 10, 30, 100, and 300 μg/septum for RBLR, and 0.001, 0.01, 0.1, 1, and 10 μg/septum for OFM.

For the CL, Z7-12:OAc and the six-component solution in Skelly B were applied to polyethylene caps (OS-6 closures, American Scientific Products, McGaw Park, Illinois) from a 1, 10, or 100 μg/μl solution to achieve dosages of 0.1, 0.3, 1, 3, and 10 mg/cap.

Test Procedures. Moth behavior was observed in the flight tunnel of Miller and Roelofs (1978). Each species was tested independently, in the order CL, OFM, RBLR. For RBLR and OFM, males were placed in the room housing the tunnel 1 h prior to testing (2 h prior to the initiation of scotophase), to acclimate to photophase temperature and light intensity: 21–22°C, 350 lux. Male CL were placed in the tunnel room at the initiation of scotophase, 4 h prior to testing (the fifth and sixth hours of the 8-h scotophase). Flight tunnel temperature and light intensity were 25°C, 0.3 lux. Relative humidity was 50–70% and wind speed was 50 cm/sec for all three species.

The procedures and apparatus for handling and testing males were as previously described (Linn and Roelofs, 1983; Linn et al., 1984). Males were scored for three key behaviors in the flight sequence: taking flight (TF), initiation of upwind flight (UP), and source contact (SC). During each 2-h test period, three treatments were tested, with ten males tested with each treatment. Treatments were always tested in the order of increasing blend complexity. Analysis was made of the number of males exhibiting each behavior in the

sequence, based on the total tested to each treatment ($N = 70$ for CL, 50 for OFM, and 50 for RBLR). Statistical comparison of treatments was based on χ^2 2×2 test of independence with Yates' correction (Sokal and Rohlf, 1969), or the method of adjusted significance levels for proportions (Ryan, 1960, $P < 0.05$).

RESULTS

For all three species, at all dosages, males took flight (TF, Figure 1) in significantly higher percentages to the complete blend of components when compared to single components or the *Z/E* mix (with the exception of the highest dosage tested for RBLR and CL, Figure 1). However, the effect of the blend on male behavior was even more dramatic at the initiation of upwind flight (UP, Figure 1) phase of the response, with significantly higher percentages of males responding to the complete blends at all dosages tested. Male sensitivity, evidenced by the lowest dosage at which complete flights to the source occurred (SC, Figure 1), was also greater, by at least an order of magnitude, to the complete blends. Thus, addition of minor components at all dosages, and particularly at the lower dosages tested, significantly enhanced male sensitivity and recognition of the pheromone signal.

The enhancement of male response brought about by the addition of minor components, while in evidence for each species, varied considerably among species. For RBLR, males exhibited very little behavior with the Z11–14 : OAc isomer alone. The lower levels of activity to 3, 10, 30, and 100 μg were not significantly different from spontaneous levels of activation, and so it is questionable whether or not the observed activations were pheromone induced. Response levels to the *Z/E* mix were significantly enhanced over that with Z11–14 : OAc alone, with some males completing the flight at two dosages (30 and 100 μg) at which males did not initiate upwind flight to Z11–14 : OAc alone. With the full seven-component blend, male response was not only increased significantly with the 30-, 100-, and 300-μg dosages, but males also initiated upwind flight and reached the source with the 3- and 10-μg dosages.

With OFM, the taking flight response to Z8–12 : OAc alone was greater at the higher dosages when compared with RBLR, but addition of the *E* isomer did not significantly enhance this initial behavior. A low percentage of males initiated upwind flight to the *Z/E* mix, but the three-component blend was essential for complete flights at all dosages tested. Similar to the RBLR results, the full blend at the 0.001- and 0.01-μg dosages resulted in complete flights to the source, whereas these dosages did not elicit any upwind flight behavior with the *Z/E* mix.

For the CL, males took flight in higher percentages to all dosages tested, compared to OFM and RBLR. For male CL, blend enhancement of activity

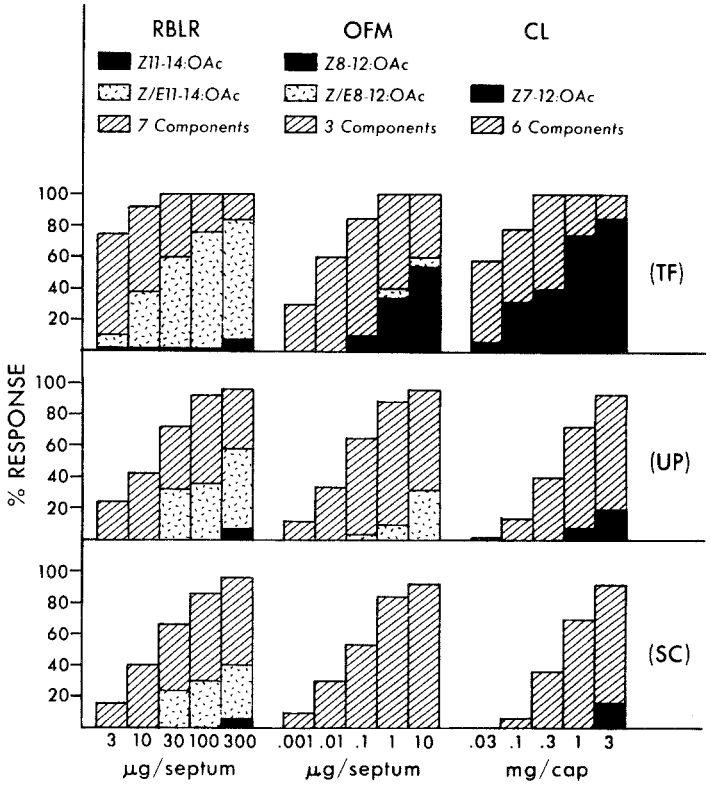

FIG. 1. Percentage of male RBLR, OFM, and CL exhibiting three key behaviors in the sustained flight tunnel (taking flight, TF; upwind flight over a 1.5-m distance, UP; and source contact, SC). Responses for each species are to the major component alone (solid area), the *Z/E* mixture (stippled area), and the complete blends (hatched area). Dosages represent the amount of the major component applied to the source, with the other components added to achieve the correct proportions (see Methods and Materials). $N = 70$ for CL, 50 for RBLR, and 50 for OFM to each blend–dosage combination.

was most evident in the upwind flight phase of the sequence. The lowest dosage of the main component to elicit upwind flight activity was 1 mg, whereas the lowest full blend dosage for this activity was 0.03 mg.

DISCUSSION

The results of the present study support the hypothesis that male moths are more sensitive to the female-released blend of components over a dynamic range

of release rates compared to the major component alone. In each case, the addition of the full complement of minor components not only enhanced male response over that observed to the single major component, but also resulted in completed flights to dosages of the major component that, when presented alone, did not elicit upwind flight activity. We conclude from this that the observations made with OFM by Baker and Cardé (1979) concerning the role of the blend do not constitute a specialized case, but rather that blend enhancement of male response represents an important general principle.

Pheromone Components and Behavioral Functions. The success of the present study and the previous reinvestigations was critically dependent on the fact that observations were made using the female-released blend of components (Baker et al., 1980; Bjostad et al., 1984b), rather than a partial blend (for CL, Linn and Gaston 1981a,b), or exaggerated ratios of components derived from field-screening trials (for RBLR, Baker et al., 1976; for OFM, Cardé et al., 1975a,b). It is clear from earlier results obtained with RBLR, OFM, and CL that certain minor components, when presented in exaggerated ratios, or when added singly to the major component, can significantly enhance trap catch and also give the appearance of controlling the expression of a specific aspect of the flight response. With RBLR, for example, field trials showed that addition of 12:OAc to the previously identified mixture of *Z*- and *E*11–14:OAc (8% *E*) (Roelofs and Arn, 1968; Klun et al., 1973) in a ratio of 1–1.5 times the level of *Z* isomer significantly increased trap catch (Roelofs and Comeau, 1968). Chemical analysis confirmed that 12:OAc was present in female glands, but at a ratio of only 3–5% of the *Z* isomer (Roelofs et al., 1975). At this ratio, however, 12:OAc did not enhance male activity in the field, and it was concluded on the basis of field trapping studies and crude airborne collections that females must be rapidly synthesizing and releasing larger amounts of 12:OAc.

Further observations of male RBLR flight behavior in the lab and the field (using only three of the recently identified seven components), showed that the *Z/E* isomer mix was responsible for upwind anemotactic flight and that 12:OAc significantly enhanced close-range approach, landing, and attempted copulations (Baker et al., 1976). Our most recent evidence indicates, however, that this is incorrect and that when 12:OAc is presented at the appropriate female-released ratio (3–5% of the *Z*11–14:OAc isomer), it does not enhance the response to the *Z/E* mix (Bjostad et al., 1984b). Rather, 12:OAc is one of seven pheromone components (12:OAc, *Z*9–12:OAc, *E*9–12:OAc, 11–12:OAc, 14:OAc, *Z*11–14:OAc, and *E*11–14:OAc) that act as a unit to enhance male sensitivity and flight response.

Similarly with OFM, 12:OH significantly enhanced trap catch when in a 3:1 ratio with the major component *Z*8–12:OAc (6% *E*) (Roelofs et al., 1969, 1973). As with RBLR, field and laboratory studies suggested that the *Z/E* mix was responsible for upwind anemotactic flight and that the relatively high ratio of 12:OH enhanced close-range behavior, including the dramatic hairpencil

courtship display (Cardé et al., 1975a,b). At this time the important blend constituent, Z8–12:OH, was not included in the tests. Subsequent studies showed, however, that Z8–12:OH is an important pheromone component, and that 12:OH, when presented at the appropriate ratio (<10% of the Z isomer and an equal or lower amount compared to Z8–12:OH), exhibited no discernable effect on male behavior. Further studies were then undertaken to show how variations in the ratio of components might affect male behavior (Linn and Roelofs, 1983). The results showed that off ratios did not enhance male response over that observed to the natural blend of components and that, over a wide range of *Z/E* mixtures, males were not able to compensate for the lack of the Z8–12:OH component and exhibit a complete flight to the source.

The CL provides a third, and somewhat different, example from that for RBLR and OFM. Characterization of the functional role of the minor component in this species was not the result of observations using an exaggerated ratio of components, rather they were the result of using a partially identified blend (Bjostad et al., 1980). The major component, Z7–12:OAc, was identified by Berger (1966). Subsequently Bjostad et al., (1980) identified 12:OAc from female gland and airborne collections, and it was shown that females released a 97:3 ratio of Z7–12:OAc to 12:OAc. The initial hypothesis was that 12:OAc was a short-range component, a hypothesis proposed directly from the results reported with RBLR (Baker et al., 1976), and OFM (Cardé et al., 1975a,b). The results of flight tunnel tests confirmed that 12:OAc did not appear to affect upwind flight, rather it enhanced close-range approach and contact with the source, when combined with Z7–12:OAc. It was concluded that the two-component system fit the existing paradigm concerning pheromone components and their functions (Linn and Gaston, 1981a,b).

As with RBLR and OFM, however, our most recent studies indicate that the previously observed effect with 12:OAc represents a response that can be exhibited by a low percentage of the male population to a partial pheromone blend (Linn et al., 1984). The male response to the six-component blend (Z7–12:OAc, 12:OAc, Z5–12:OAc, 11–12:OAc, Z7–14:OAc, and Z9–14:OAc) was in all respects superior to that observed with the two-component mix. These studies also involved subtraction tests with five-, four-, three-, and two-component blends containing Z7–12:OAc. The major component was necessary for any behavior to occur, but it was the only compound that fit this criterion. The subtraction tests showed that all five-component and several four-component blends elicited peak levels of response similar to those with the six-component mix. This suggested that the individual minor components were not acting to initiate specific behaviors, as several substitutions were possible. Rather, the minor components acted as an ensemble to enhance male response to the Z7–12:OAc component and thus effect optimal flight behavior.

Our present view is that individual minor components do not function to trigger specific behaviors in the response sequence, but rather that the full blend

acts as a unit in the male flight response and courtship sequence. It is evident from the above examples that these types of observations may be indicative of a partial, incorrectly characterized, or inappropriate blend of the pheromone and should not be proposed as evidence for the functional importance of individual compounds (Bradshaw et al., 1983), without comparative data for male response to female or gland effluvium/extracts (Linn et al., 1984).

Blend Perception and Active Space of the Pheromone. Data presented in this paper support the hypothesis that blends of components, rather than one predominating component, are acting at long distances from the source and are responsible for initiating and maintaining anemotactic flight (Baker and Roelofs, 1981). This conclusion is based on one of the major results of the present study that the blend of components markedly enhanced male sensitivity (or lowered the threshold for response) to the pheromone. We would conclude, with Baker and Roelofs (1981), that the active space of the pheromone is determined by the appropriate blend of components, not just the major component(s) (Nakamura and Kawasaki, 1977; Nakamura, 1979), and that the dimensions of the active space will be determined by the upper and lower concentration thresholds for the blend (Roelofs, 1978, Elkinton and Cardé, 1984).

The importance of sex pheromones as specific mate recognition signals is one of the formative concepts in research on chemical communication (Cardé and Baker, 1984; Roelofs and Brown, 1982). With the widespread awareness that moth species utilize multicomponent blends (Roelofs, 1980), it has become clear that signal specificity is a function of the composition and ratio of components, and the release rate of the blend (Roelofs and Cardé, 1977; Roelofs, 1978; Baker et al., 1981; Linn and Roelofs, 1983). The importance of a unique blend and ratio of components for the male is that it reduces the time spent in locating a mate. If it is the case, as is often stated, that females are a limiting resource for males, then rapid detection of the chemical signal is of critical importance for the male. A single component or isomer mix could certainly serve this purpose, if it were not for the fact that closely related, cohabitating, species often utilize the same compounds (Roelofs and Brown, 1982; Cardé and Baker, 1984). With a unique blend and ratio of compounds, however, specificity is added to the signal, enhancing the ability of the males to recognize the pheromone of conspecific females, and thus locate a female before conspecific males do, and also to aid the male in discriminating among closely related signals. Rapid detection and recognition of the signal aid the male in locating a female, and also in not wasting time and energy in false trail following (Cardé and Baker, 1984). We would argue that this strongly supports the concept that the blend is the active element in controlling male behavior at all distances from the female.

We recognize that our conclusions concerning the active space of the pheromone are based in large part on flight tunnel observations, but we would propose that they can be tested in the field. Baker and Roelofs (1981) determined

the upper and lower thresholds for the active space of OFM males to the three component blend over a dosage series. We propose to test males in the field, using the procedure developed by Baker and Roelofs, to the single Z8–12 : OAc isomer, the *Z/E* mix, and the three-component blend, over the same dosage series. Our hypothesis would be that the active space for the blend, at any dosage, would be significantly greater than to the single component or partial blend.

Acknowledgments—We thank K. Poole for aid in rearing the insects, and G. Rule for preparing the synthetic chemicals and blends. This study was motivated, in part, by discussions at the NSF-NATO seminar on mechanisms of perception and orientation in insects to olfactory stimuli, held at Oxford University in August 1984. We wish to thank all participants for their input and stimulus to undertake the present study. We also wish to thank R. McMillen-Sticht, B. Aldwinkle, and J. Ogrodnick for preparation of the figure.

(Received March 1, 1985; accepted July 12, 1985)

Abstract—The Dufour glands of worker ants of *Tetramorium caespitum*, and the morphologically similar *T. impurum* are filled with similar, but species-specific mixtures of linear hydrocarbons and three homologous sesquiterpene compounds. Glands of workers of *T. caespitum* contain, on average, 70 ng of oil containing C_{13} to C_{17} linear hydrocarbons with *n*-pentadecane (64%) and a mixture of pentadecenes (14%) as major components. *T. impurum* glands are smaller and contain an average of 40 ng of the same mixture but with *n*-pentadecane (49%) and a sesquiterpenoid compound (19%) the major components. Two isomeric pentadecenes, (*Z*)-6-pentadecene and (*Z*)-7-pentadecene are present in both species. *T. semilaeve* workers contain on average only 30 ng of a simple mixture of hydrocarbons with pentadecane contributing more than 90% of the total.

Key Words—Dufour gland, ant, *Tetramorium*, pentadecane, isomeric pentadecenes, sesquiterpene homologues, Hymenoptera, Formicidae.

INTRODUCTION

The Dufour gland is a saclike structure, which, together with the poison gland, is attached to the sting in females and workers of all the Hymenoptera. Its primary function is unknown. Its contents have been examined in a number of ant species and in every case been shown to be a mixture of hydrocarbons, or

0098-0331/86/0300-0669$05.00/0

hydrocarbon derivatives, such as long-chain acetates and ketones (Blum and Hermann, 1978; Attygalle and Morgan, 1984a).

We have investigated the contents of a number of myrmicine Dufour glands (cf. Attygalle et al., 1983, and references therein) and in each species we have found a moderately simple, species-specific mixture of hydrocarbons. We describe here the first investigations from the tribe Tetramoriini.

Tetramorium caespitum L. and *T. impurum* Foerster have attracted attention recently because morphologically, they are very similar, in fact almost indistinguishable, except by reference to the male genitalia (Dr. B. Poldi, private communication, quoted in Pasteels et al., 1981). Some work has been carried out on their mandibular gland contents. In addition to the 3-alkanols and 3-alkanones commonly found in myrmicine mandibular glands, 2-undecanone, 2-undecanol, and perillen have been claimed to be identified in the mandibular glands of *T. caespitum* (Longhurst et al., 1980). Pasteels et al., (1980, 1981) have identified very small quantities of chiral 4-methyl-3-hexanol and 4-methyl-3-hexanone in the heads of *T. impurum*.

Whereas *T. caespitum* and the hitherto little known *T. impurum* are found (one or the other) all over Belgium, *T. semilaeve* André comes from the quite different environment of the Mediterranean area. Several points emerged from our studies of these *Tetramorium* species. The two morphologically similar species, *T. caespitum* and *T. impurum* have very similar patterns of hydrocarbons. We have discovered here three new compounds of sesquiterpene type which differ by one or two CH_2 groups which differentiate the species. However, we find this pair of species are easily separated by another chemical test using trail pheromones. For the first time, a mixture of two isomeric alkenes, i.e., pentadecenes which differ only in the position of the double bond, have been found in mymircine Dufour glands. We have compared two techniques by which double-bond positions in such mixtures can be studied, namely methoxymercuration–demercuration and formation of dimethylthioethers. The di(methylthio)ether method is preferred in this work.

METHODS AND MATERIALS

Sources of Insect Materials. Colonies of *T. caespitum* were collected from heathland in Dorset and Surrey in England and various sites in Belgium; *T. impurum* from Belgium and northern France, and *T. semilaeve* from the island of Corsica.

The live colonies were maintained in the laboratory as described previously (Attygalle et al., 1983) in artificial nests formed from conical flasks (250 cm^3) partially filled with plaster of Paris (Wadhams, 1972). Nourishment was supplied in the form of larvae of *Tenebria molitor* and *Musca* and sugar solution.

Identification was made by A. Abbott and J.A. Pontin for the English

samples, by Prof. J.K.A. van Boven for *T. semilaeve*, and R. Cammaerts for *T. impurum*.

Gas Chromatography (GC). The ants were killed by momentary immersion in liquid nitrogen. The Dufour glands were then removed by dissecting the ants in water, under a binocular microscope (magnification ×15). After gently blotting dry, the individual glands were mounted on a small piece of glass and sealed in a section of soft glass capillary tubing (25 × 1.8 mm). This sample was then introduced into the modified injection port of a Pye 104 chromatograph incorporating the solid injector described by Morgan and Wadhams (1972a). Gas chromatography was carried out on a Pye 104 using: (A) 1.5 m × 4 mm ID packed column of 5% OV-101 on Diatomite M (AW-HMDS), with a GC oven temperature of 150°C; and (B) 2.75 m × 4 mm ID packed column of 10% PEGA on Chromosorb W, 100–120 mesh, at 130°C isothermal or at 155°C for 5 min, then programmed at 10°/min to 190°C and then isothermal, in order to look at the higher hydrocarbons.

A Carlo Erba 4160 gas chromatograph with split–splitless injection was employed to analyze hexane extracts of whole gasters on 50 m × 0.24 mm ID WCOT capillary (column C) coated with a mixture of diethylene glycol succinate and polyethylene glycol succinate (DEGS–PEGS). Hydrogen was the carrier at an inlet pressure of 1.2 kg/cm.

For a study of the sesquiterpenoid compounds, a polar capillary column (SP-2340, 30 m × 0.22 mm; column D) was used with helium at 1 ml/min.

Gas Chromatography–Mass Spectrometry (GC-MS). The identification of the major glandular components was confirmed by linked GC-MS, employing a Pye 104 gas chromatograph linked through a glass jet separator to an AEI MS12 mass spectrometer, with a 70-eV electron energy, 5-kV accelerating voltage and 15-kV multiplier voltage. Helium was used in all GC-MS analyses at a flow rate of 20 ml/min. The OV-101 column (A) was employed for its low bleed properties.

Mass spectra of the sesquiterpene compounds were obtained with a fused silica capillary column (CP-19, 38 m × 0.22 mm) linked directly to a Finnigan 3200 E quadrupole mass spectrometer with a 6000 Data System. The carrier gas was helium at 1 ml/min. Ten Dufour glands sealed in a glass capillary were injected by the same solid sampling method (Morgan and Wadhams, 1972a; Morgan et al. 1979a). The column was held at room temperature for 3.5 min and them programmed at 6°C/min to 260°C.

Hydrogenation. For microscale hydrogenation of glandular components, 1% palladium catalyst (Beroza and Sarmiento, 1966) was prepared by evaporating an aqueous solution (150 ml) of palladium chloride (25 mg) and sodium hydroxide (11.2 mg) in contact with 100–120 mesh Chromosorb W (1.5 g) in a rotary evaporator, followed by drying overnight at 150°C. This catalyst was then packed into a glass tube between two silanized glass wool plugs and activated by purging with hydrogen (40 ml/min) for 60 min at 200°C (Attygalle

and Morgan, 1982). The active catalyst was used to prepare a precolumn in the form of a plug of packing (6 cm) between two silanized glass wool plugs on column B. The individual Dufour glands were injected onto the column at 146°C as described previously but using hydrogen as the carrier gas at a flow rate of 40 ml/min.

Ozonolysis of Pentadecenes. The pentadecane and pentadecenes were trapped in a glass capillary (45 × 0.5 mm ID) cooled in liquid nitrogen, from the solid injection and GC separation of the Dufour gland volatiles of three *T. caespitum* workers, employing an all-glass splitter (Baker et al., 1976) attached to the end of column A. The trapping capillary was broken into three pieces and transfered to a solid sample vial (35 × 1.8 mm ID) cooled in ice. Ozonolysis of the trapped alkenes was performed by passing ozone (10 ml/min) from a microozone generator (Beroza and Bierl, 1967) over the capillary fragments using a finely drawn capillary (0.5 mm ID) which extended to the bottom of the vial; after 20 sec, the ozone purge was withdrawn and the vial immediately sealed. The ozonides were cleaved pyrolytically by placing the sealed vial in a solid sampler (Morgan and Wadhams, 1972a) and heating at 200°C for 5 min (Attygalle and Morgan, 1983a). Crushing the vial released the carbonyl products into the carrier gas for analysis on column B.

Methoxymercuration–Demercuration. Fifty workers' gasters were homogenized with *n*-hexane (4 × 50 μl) in a small tissue grinder (prepared from a 5-ml Pyrex test tube and a glass rod; abrasive surfaces on the tip of the rod and base of the test tube were produced by grinding the two together with a slurry of carborundum and water). Following decantation, drying by filtration through anhydrous sodium sulfate (0.1 g, held in a Pasteur pipet plugged with glass wool), evaporation (25 μl), and GC analysis, the extract was treated with methanol (100 μl) and mercuric acetate (1.0 mg, room temperature, 15 hr, dark). After this, sodium borohydride (1 mg) was added to reduce the mercuric complexes to the methyl ethers (RT, 1 hr). Isolation of the latter compounds and unreacted hydrocarbons was performed by partitioning the reaction mixtures between distilled water (1 ml) and *n*-hexane (0.5 ml). Decantation of the hexane followed by evaporation (25 μl) yielded a concentrate which was analyzed by GC and GC-MS on a column of OV-101 silicone.

Formation of Di(methylthio)ethers. The gasters of 25 workers were sealed in a glass tube and chromatographed using our solid injection technique (Morgan and Wadhams, 1972a) and the all-glass splitter (Baker et al., 1976). The pentadecene fraction was collected in a metal U-tube, then transferred to a Reacti-vial (Pierce and Warriner, Chester, U.K.) with hexane (2 × 10 μl). This material was combined with that from a further 25 workers.

Dimethyl disulfide (10 μl) was added to the hexane solution of pentadecenes, followed by a solution of iodine in ether (2 μl, 60 mg/ml). The mixture was left overnight, and aqueous sodium thiosulfate (5% w/w) was added with agitation until the mixture became colorless. The hexane layer was separated

and used for gas chromatography and GC-MS. For this work a 25-m silica capillary column, wall coated with OV-1, was used, temperature programmed from 50 to 280°C at 6°/min. The mass spectrometer was operated in the multiple ion detection mode, monitoring only *m/z* 117, 131, 145, 159, 173, 187, and 304.

RESULTS

T. caespitum. Analysis of single Dufour glands of *T. caespitum* workers revealed detectable amounts of up to 11 components (Figure 1). Components 1, 2, 3, 5, and 7 had retention times on polar (PEGA) and nonpolar (OV-101) chromatography phases corresponding to *n*-tridecane, *n*-tetradecane, *n*-pentadecane, *n*-hexadecane and *n*-heptadecane. Components 4, 6, 8, and 9 were found to correspond in retention times to pentadecene, hexadecene, heptadecene, and heptadecadiene, respectively. Peaks 10 and 11 were recognized as polar substances which did not fit into the hydrocarbon series. On-column mi-

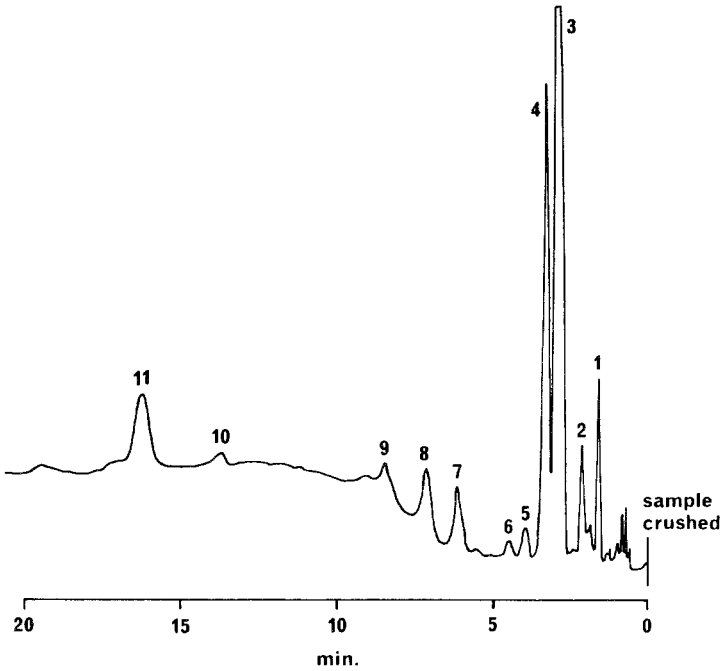

FIG. 1. Typical gas chromatogram from a Dufour gland of a single worker of *T. caespitum* on a 10% PEGA column at 155°C, isothermal for 5 min, then programmed at 10°C min to 190°C and then isothermally. The numbering of the peaks corresponds to the numbers in Table 1.

croscale hydrogenations altered the retention times of components 4, 6, 8, 9, 10, and 11, but did not affect components 1, 2, 3, and 5. Peak 4 disappeared and peak 3 increased in area correspondingly. Peaks 6–11 all were replaced by ones of shorter retention.

Satisfactory mass spectra were obtained for all components. Peaks 10 and 11 gave spectra recognized as belonging to open-chain sesquiterpenoid homologs. Peak 10 (M^+ 236) and Peak 11 (M^+ 250) had very similar spectra but from their behavior on a variety of stationary phases, it was evident they differed by one carbon atom.

To determine the position of unsaturation in the major alkene component, peak 4, material was trapped from several glands, ozonized, and rechromatographed, which revealed four ozonolysis products (hexanal, heptanal, octanal and nonanal), from which it can be deduced that the alkene consisted of 6-pentadecene and 7-pentadecene.

As confirmation of this identification, another sample of pentadecene collected from workers was converted to a mixture of methoxy derivatives via methoxy mercuration–demercuration (Abley et al., 1970; Blomquist et al., 1980), and these products were submitted to combined gas chromatography–mass spectrometry (GC-MS). The methoxy derivatives were not separated by GC, but the mass spectrum showed ions at the following *m/z* values (intensities in parentheses) 171(4), 157(22), 143(35), 129(38), 115(19), 111(8), 97(37), 83(45), 69(100), 55(65). No molecular ion (M^+, 242) was observed. The ions from *m/z* 171 to *m/z* 115 arise from the methoxy derivatives, those at *m/z* 115, 129, 157, and 171 from 6-pentadecene as indicated in Figure 2, while 7-pentadecene gives derivative ions at *m/z* 129, 143, and 157. The absence of other

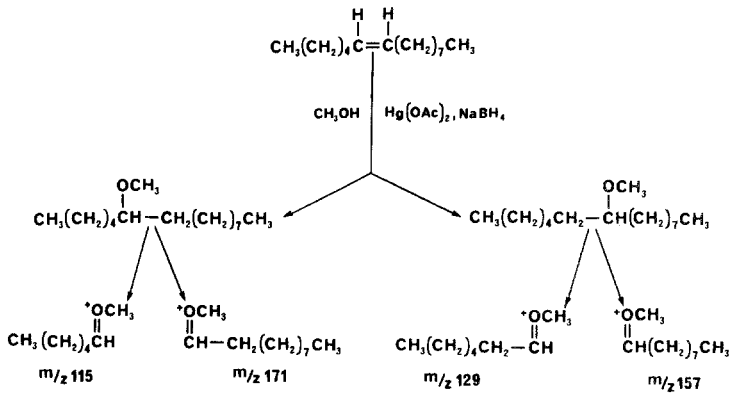

FIG. 2. Scheme showing the formation of two methoxyalkanes from 6-pentadecene by methoxymercuration–demercuration and the production of four intense and characteristic ions by cleavage of the ethers in the mass spectrometer.

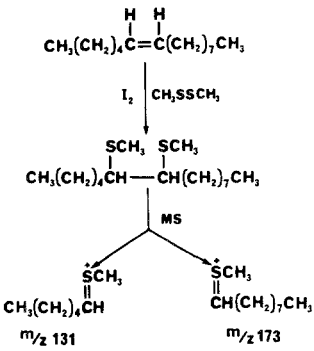

FIG. 3. Scheme showing the formation of the dithioether derivatives of 6-pentadecene and the characteristic ions found in its mass spectrum.

ions means that only these two pentadecenes were present in the original mixture.

Further confirmation was made using the technique of converting the alkenes into their di(methylthio)ethers (Francis and Veland, 1981) and submitting these to GC-MS (Figure 3). The mass spectrometer was operated in the multiple-ion detection mode for greater sensitivity and in order to be able to quantify the proportion of derivatives from the two alkenes. The spectrometer was set to scan ions of *m/z* 117, 131, 145, 159, 173, 187, and 304 (see Figure 4 for an example using *T. impurum*). Only those ions at *m/z* 131, 145, 159, and 173 were detected, so only 6- and 7-pentadecene were found and, from the peak intensities, in the ratio of 1.2 : 1 or approximately equal amounts.

Chromatography on a capillary column, wall-coated with a mixture of DEGS and PEGS, gave baseline resolution of the two pentadecene isomers collected from *T. caespitum* (Figure 5). Coinjection of a synthetic mixture of (*Z*)- and (*E*)-pentadecenes showed clearly that the natural compounds were entirely (*Z*)-pentadecenes; the (*E*)-isomers had retention times almost 2 min shorter. The ratio of (*Z*)-6-pentadecene to (*Z*)-7-pentadecene of 1 : 1.2 found here was different from that obtained from the dithioether experiment; the latter is considered to be more reliable. The quantifications and identifications are summarized in Table 1. Because the amount of material in the Dufour gland varies considerably from one individual worker to another, the percentage composition is calculated for each individual, and then the mean and standard derivation for the set are calculated for each component. It can be seen from Table 1 that the proportions of the major components do not vary much.

T. impurum. Chromatography of the Dufour glands of workers of *T. impurum* showed the same major components in approximately the same proportions as was found for *T. caespitum*. The major difference was that the second sesquiterpenoid with M^+ 250 was now more abundant than the mixture of pen-

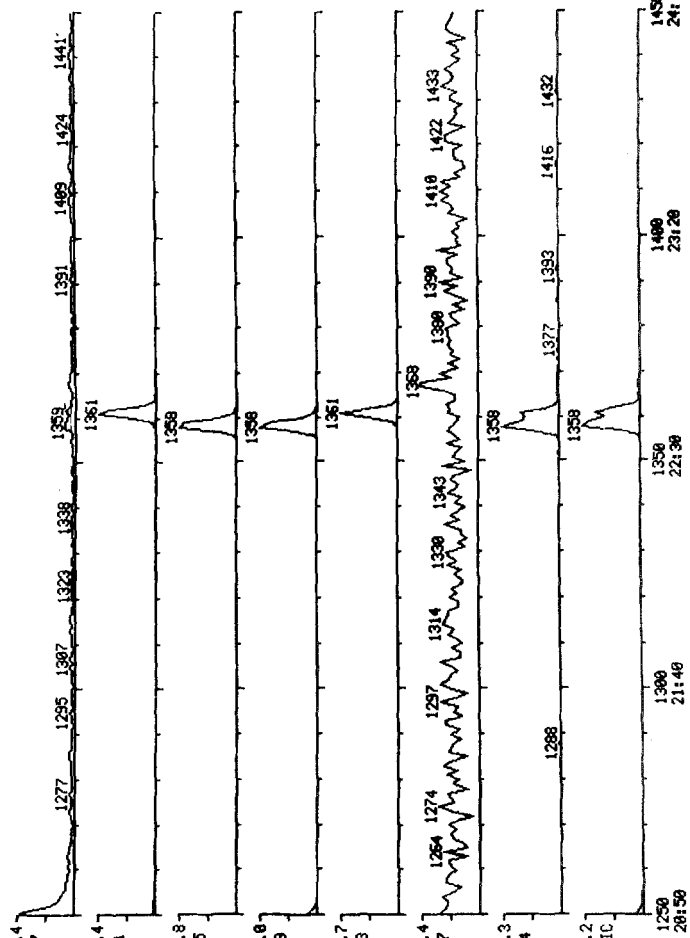

FIG. 4. Results of computerized GC-MS analysis employing multiple ion detection of the dimethyl-thioether derivatives of 6- and 7-pentadecenes from *T. impurum*. The result was similar with *T. caespitium*. The ions at *m/z* 117, 131, 145, 159, 173, 187, and 304 were monitored, their appearances in the mass chromatograms are shown from the top down. Essentially only background noise is seen for *m/z* 117 and 187 (which would arise from 5-pentadecene). The *m/z* 304 mass chromatogram corresponds to the molecular ion. The total ion chromatogram (bottom trace) and that for *m/z* 304 show that the thioether derivatives from 6- and 7-pentadecenes were partially resolved by the capillary column.

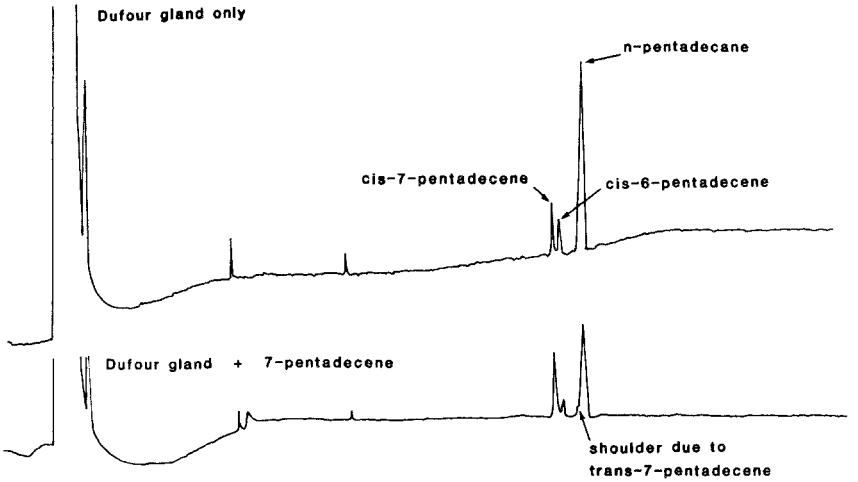

FIG. 5. Capillary gas chromatogram, on column C, of the Dufour gland contents of *T. caespitum* and the same cochromatographed with a mixture of synthetic *cis* or (Z)- and *trans* or (*E*)-7-pentadecenes showing the resolution of the geometric isomers and the absence of *trans* or *E* isomer in the gland.

TABLE 1. QUANTIFICATION OF SUBSTANCES IN DUFOUR GLAND OF *T. caespitum* WORKERS[a]

Peak	Identification[b]	Amount (ng)		Percent	
		M	SD	M	SD
1	tridecane	1.7	0.84	2.4	0.66
2	tetradecane	1.5	0.63	2.2	0.31
3	pentadecane	43.9	13.2	64.0	3.7
4	{(Z)-6-pentadecene, (Z)-7-pentadecene}[c]	9.5	3.2	13.7	1.3
5	hexadecane	t	—	t	—
6	hexadecene	t	—	t	—
7	heptadecane	2.7	1.7	3.7	1.6
8	heptadecene	1.5	1.5	1.9	1.6
9	heptadecadiene	1.0	0.79	1.3	1.1
10	sesquiterpenoid (M^+ 236)	1.2	0.48	1.8	0.93
11	sesquiterpenoid (M^+ 250)	5.8	1.5	8.9	2.6
Mean total			70.4 ± 20.9 ng		

[a] Expressed as the mean (M) with the standard deviation from the mean (SD) for 11 determinations, for both the absolute amount and the percentage of the total; *t* means an unquantifiable trace detected in some samples.

[b] Identification in each case by mass spectrometry, and retention time of authentic compounds for all except the unidentified sesquiterpenoids.

[c] 6-Pentadecene and 7-pentadecene present in a ratio of 1.2:1.

tadecenes, and a third sesquiterpenoid homolog (M^+ 264) was also present in variable amounts (Figure 6). As with *T. caespitum*, the pentadecenes were collected from a GC column and ozonized. The same mixture of *n*-aldehydes was obtained, indicating a mixture of 6- and 7-pentadecenes was present here. Another sample was converted to the dithioethers and submitted to GC-MS with multiple ion detection (Figure 4) at the same time as the sample from *T. caespitum*. The positions of the double bonds were confirmed and the ratio of 6-pentadecene to 7-pentadecene found to be close to 1 : 1 with slightly more 7-pentadecene. Capillary GC showed that both were exclusively the *Z* isomers. There is rather less material in the Dufour glands of *T. impurum*; the quantifications and identifications are summarized in Table 2.

T. semilaeve. The Dufour glands of workers of this species contained still

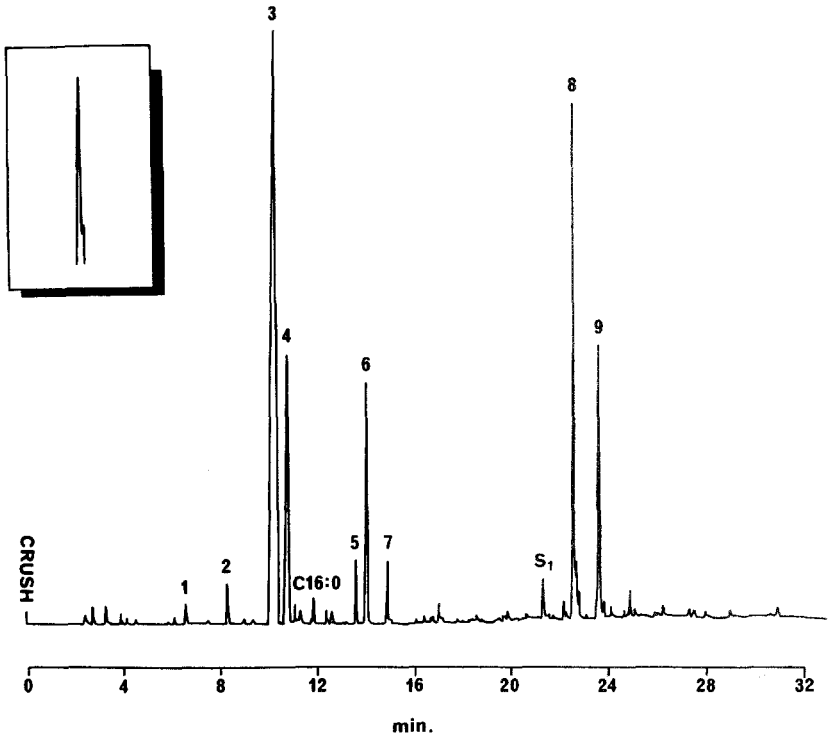

FIG. 6. Capillary gas chromatogram of a single Dufour gland from a worker of *T. impurum* on column D, 3.5 min at room temperature then programmed at 8°C/min to 200°C. Numbers on peaks correspond to those in Table 2. S_1 marks a small amount of the first sesquiterpenoid compound. The hexadecane peak on this sample is also visible. On this phase, the mixed pentadecenes are partially resolved, as shown in the inset using a much faster chart speed.

9	sesquiterpenoid (M^+ 264)	2.8	1.5	9.1	2.7
Mean total		40.7 ± 16.0 ng			

[a] Expressed as the mean (M) with the standard deviation from the mean (SD) for 10 determinations; *t* indicates an unquantifiable amount sometimes detected.
[b] Identification in each case by mass spectrometry, and retention time of authentic compounds for all except the unidentified sesquiterpenoids.
[c] 6-Pentadecene and 7-pentadecene present in a ratio of 1:1.4.

less material, and that almost entirely one component, identified by retention time and cochromatography on different phases as *n*-pentadecane (component 3, Figure 7). Small amounts of three other components were identified by retention times as *n*-tridecane, *n*-tetradecane, and pentadecene. There was insufficient material to investigate whether the pentadecene consisted of positional isomers. The quantifications are shown in Table 3.

DISCUSSION

The Dufour glands of the three species of *Tetramorium* examined here, like those of other myrmicine species, contain characteristic mixtures of hydrocarbons (Attygalle et al., 1983, and references therein), but in addition, two of the species contain three homologs based on a polar sesquiterpene of unknown structure. *T. caespitum* has the largest gland, and *T. semilaeve* the smallest, but all are much smaller than those of *Myrmica rubra* and the seven other *Myrmica* species studied earlier (Attygalle et al., 1983).

The glands of workers of *T. caespitum* contain 70 ± 20 ng of oily hydrocarbons within the range C_{13} to C_{17}. *T. impurum* contains 40 ± 16 ng of a very similar mixture, and *T. semilaeve* is unique in that it has the simplest mixture we have yet encountered. Over 90% of the material in the gland is *n*-penta-

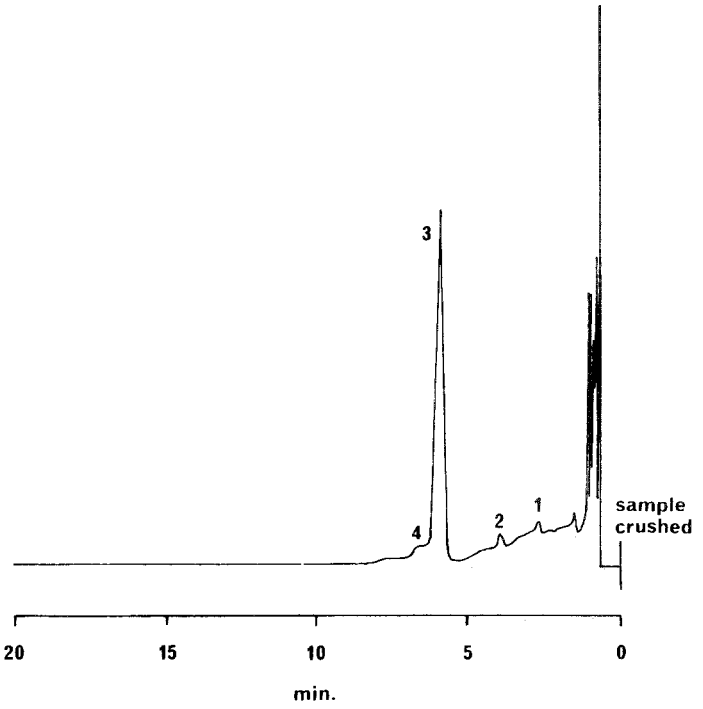

FIG. 7. Gas chromatogram of a single Dufour gland from a *T. semilaeve* worker on a 10% PEG column, isothermally at 142°C. Numbers on the peaks correspond to those in Table 3.

TABLE 3. Quantification of Substances in Dufour Gland of *T. semilaeve* Workers[a]

Peak	Identification[b]	Amount (ng) M		SD
1	*n*-tridecane	1.3		1.6
2	*n*-tetradecane	0.9		0.2
3	*n*-pentadecane	24.5		9.0
4	pentadecene	1.0		0.4
Mean total		27.7	±	11.2

[a]Expressed as mean (M) with standard deviation (SD) for 11 replicates. Percent composition has not been calculated since the amounts of the minor components are so small and variable.
[b]Identification is by retention times only on two columns of different polarity.

decane. The very small amounts of tridecane, tetradecane, and pentadecene observable in some samples are difficult to quantify in relation to the much larger pentadecane peak, making percentage composition rather inaccurate.

The absolute amounts of the different substances vary quite widely from one individual ant to another, as indicated by the large standard deviations (Tables 1–3), but the proportions, as expressed by percentage composition, are remarkably constant. We have examined samples of *T. caespitum* from Dorset, Surrey, and Belgium and *T. impurum* from various sites in Belgium. Although we have not quantified the mean from these various sites, the immediate appearance of the pattern of peaks on the gas chromatograph recorder was the same for the given species regardless of origin.

T. caespitum and *T. impurum* are morphologically very similar, and the first impression of their Dufour gland contents was that they were so alike as to be indistinguishable, but further examination by chromatography at higher temperatures showed they differed clearly in their content of components eluting later. Three peaks were recognized with retentions that behaved anomalously on different phases and did not correspond to hydrocarbons. Satisfactory mass spectra were obtained by capillary GC-MS, which showed that they formed a homologous series of three sesquiterpenoid compounds of molecular mass 236, 250, and 264. All three showed base peaks at *m/z* 69 and with very similar spectra, with the high-mass ions shifted by one CH_2 unit. They have not yet been identified and further work on them is in progress. The substance of mass 250 does not have a mass spectrum close to faranal (Ritter et al., 1977). The series is reminiscent of the three homologous farnesenes (C_{15} to C_{17}) first identified in *Myrmica rubra* (Morgan and Wadhams, 1972b) and later found in other *Myrmica* species (Attygalle et al., 1983) sometimes accompanied by a fourth (C_{18}) (Morgan et al., 1979b). The middle homolog of this new series (M^+ 250) was present in both *T. caespitum* and *T. impurum*. In the latter it was the second largest peak. The lowest homolog was present in quantity only in *T. caespitum*, although it could sometimes be detected in *T. impurum*. The highest homolog was found only in *T. impurum* (Figure 6). The amount and proportions of these sesquiterpenoid homologs vary much more from one sample to another than do the hydrocarbons.

Although pentadecane is the major component in the Dufour gland of all three species, each species has its specific composition, as was found in the eight species of *Myrmica* studied earlier. However, there is a still simpler chemical means of distinguishing these three: through their trail pheromone, present in the poison gland. The trail pheromone of *T. caespitum* consists of a mixture of alkylpyrazines (Attygalle and Morgan, 1983b, 1984b, and unpublished results); that of *T. impurum* is a substance of much higher molecular mass (Attygalle and Morgan, 1984b, and unpublished) and no species follows well the trails of the other two (R. Cammaerts, private communication). Neither do *T. caespitum* and *T. guineense* follow each other's trails (Blum and Ross, 1965).

Determination of Double-Bond Position. 7-Pentadecene has been found in the Dufour gland of a number of ant species, including *Myrmica rubra*, *Anoplolepis custodiens*, *Iridomyrmex humilis*, four species of *Formica*, and four of *Camponotus* (Blum and Hermann, 1978). However, we were surprised to find, on ozonolysis of the *Tetramorium* pentadecene, that it consisted of at least two isomers. We had not encountered alkene isomeric mixtures in our studies of myrmicine and attine ants, although Cavill and Houghton (1973) had reported a mixture of 7- and 8-heptadecenes as minor constituents of the Dufour gland of *Iridomyrmex humilis*, a dolichoderine ant, and the same group found a mixture of 6- and 7-pentadecenes and 7- and 8-heptadecenes in a formicine *Polyrhachis* species (Brophy et al., 1982). We therefore examined the pentadecene from *T. caespitum* and *T. impurum* carefully by ozonolysis, capillary gas chromatography (which separated the pentadecenes as well as separating *E* and *Z* isomers on a high-efficiency column), and by mass spectrometry of two types of derivatives. These two methods have not been compared before, so they are discussed here. The methoxymercuration–demercuration method (Abley et al., 1970) has been used many times for this purpose. The reaction mixture is a heterogeneous system and is difficult to handle once mercury has been displaced. It is not quantitative, yields being typically between 55 and 70%. In contrast, methylthiolation is a homogeneous reaction. All the components are miscible, much smaller quantities of alkene can be used, and the reaction is near quantitative.

By the methoxymercuration–demercuration method, each alkene produces two derivatives (Figure 2), and these are not usually separated by GC; hence a mixed mass spectrum is obtained, and each alkene gives four characteristic peaks. Methylthiolation gives only one product with two intense ions (Figure 3); the spectrum is therefore simpler to interpret. Further, the methoxy derivatives rarely show a molecular ion, so the identification of the derivative is less certain. The dimethyldisulfide derivatives of all the alkenes examined clearly showed a prominent molecular ion (Figure 4). Those of alkenyl acetates showed an M − 60 peak as highest mass.

Finally, the methoxy-derivative method does not distinguish between *E* and *Z* isomers of alkenes whereas the methylthioether method gives stereospecific *trans* addition; the *E* and *Z* isomers yield erythro and threo isomers, respectively, which may give almost identical mass spectra, but they are easily resolved on capillary GC, with the threo isomer eluting first.

The only disadvantage of the methylthiolation method that has emerged is that it does not work well for dienes, and the mass spectra of the derivatives obtained were difficult to interpret. Methoxy derivatives have been used for dienes successfully.

Working with nanogram quantities of Dufour gland alkenes, it was found that dimethylthioethers have several advantages over the mixed methyl ethers produced by the methoxymercuration–demercuration procedure. The absence of 5-pentadecene as more than 0.2% of the total pentadecenes could be dem-

onstrated (Figure 4). The ratio of the two isomers in the two samples showed a difference, with more 6-pentadecene in *T. caespitum* and more 7-pentadecene in *T. impurum*, but it is not known if this is constant for the species. The double bond has the *Z* geometry found for all such examples where it has been investigated.

The Dufour gland contents of eight species of *Myrmica* fall into one of two classes, either dominated by linear hydrocarbons or sesquiterpenes (Attygalle et al., 1983), with C_{17} the major linear hydrocarbons. Among the Attini, *Acromyrmex octospinosus* has homofarnesene (20–100 ng) as almost the only constituent (Evershed and Morgan, 1980), while *Atta cephalotes* and *A. sexdens* belong to the linear hydrocarbon group with C_{17} and C_{19} dominant in *A. cephalotes* and C_{19} and C_{23} [(Z)-9-tricosene] in *A. sexdens* (Evershed and Morgan, 1981). Now *Tetramorium* forms a new group within the myrmicines, with C_{15}-dominated linear hydrocarbons, and a new group of sesquiterpenoids.

On present chemical evidence, supported by behavioral experiments (Attygalle et al., 1983, and earlier references therein), each ant species produces its specific mixture of oily substances in the Dufour gland, which in the *Myrmica* genus, at least, is used as a home-range-marking pheromone (Cammaerts et al., 1977; Attygalle et al., 1983; Morgan, 1984).

It is interesting to note that pure linear hydrocarbons up to *n*-pentadecane (mp 10°C) are liquids at ambient temperature; *n*-hexadecane (mp 18°C) and higher saturated hydrocarbons are solids. Introducing a double bond into the longer carbon chains lowers the melting point considerably (octadecane, mp 28°C; 1-octadecene, mp 17.5°C); a double bond in the middle of the chain is much more efficient at lowering melting point (9-octadecene, mp −30°C), and *Z* double bonds lower melting point more than *E* double bonds. Ants use saturated hydrocarbons up to C_{15} and thereafter use unsaturated hydrocarbons with *Z* double bonds somewhere near the middle of the carbon chain. Some ants use methyl-branched hydrocarbons which have the same effect. Nature thereby ensures that the Dufour gland contents remain liquid.

Acknowledgments—We thank Miss Vivien Lancaster for technical help, Dr. A.M. Abott for gifts of *T. caespitum*, Dr. A.J. Pontin for a nest of *T. caespitum*, Prof. J.K.A. van Boven for guidance, the Belgian National Fund for Scientific Research for the award of a Research Assistantship to J.P.J.B., the SERC and Rothamsted Experimental Station for support to R.P.E. through a CASE award, R. Cammaerts for his efforts in collecting samples of *Tetramorium* from many sites in Belgium and northern France, and Miss Maria Bohan for the synthesis of 6- and 7-pentadecenes. Some of the mass spectra were obtained with the help of Prof. G. Eglinton and NERC grants GR3/2951 and GR3/2758, and the capillary GC-MS was performed in the laboratory of Prof. H.J. Bestmann, whose help is gratefully acknowledged.

IDENTIFICATION OF A VOLATILE ATTRACTANT FOR *Diabrotica*[1] AND *Acalymma*[1] SPP. FROM BLOSSOMS OF *Cucurbita maxima* DUCHESNE

J.F. ANDERSEN[2] and R.L. METCALF

Department of Entomology
University of Illinois
Urbana, Illinois 61801

(Received March 25, 1985; accepted July 12, 1985)

Abstract—Fractionation of headspace volatiles from *Cucurbita maxima* blossoms by high-performance liquid chromatography resulted in the isolation of a single component which was highly active in an electroantennogram bioassay on *Diabrotica undecimpunctata howardi* antennae. This compound was identified as indole by gas chromatography–mass spectrometry. Field-trapping bioassays were conducted which indicated that indole is a potent attractant of the western corn rootworm, *D. virgifera virgifera*, and the striped cucumber beetle, *Acalymma vittatum*. The southern corn rootworm, *D. u. howardi*, did not respond, despite its strong EAG response. The sex ratio of *D. v. virgifera* found in indole-baited traps varied seasonally. Males were trapped in abundance in late July and later September, 1983, while females were more abundant August and early September. The effectiveness of indole as a *D. v. virgifera* attractant also varied seasonally. A prolonged period of depressed trap catches occurred in early August 1983, during the silking and tasseling period of the corn in the field where trapping was carried out.

Key Words—Attractant, *Diabrotica virgifera virgifera*, *Diabrotica undecimpunctata howardi*, *Acalymma vittatum*, indole, *Cucurbita maxima*, electroantennogram, floral volatile, Chrysomelidae, Cucurbitaceae, Coleoptera.

INTRODUCTION

The chrysomelid genera *Diabrotica* and *Acalymma* contain numerous pest species, including the western corn rootworm, *Diabrotica virgifera virgifera*

[1] Coleoptera: Chrysomelidae.
[2] Present address: USDA-ARS Northern Regional Research Center, 1815 N. University St., Peoria, Illinois 61604.

LeConte; the southern corn rootworm, *D. undecimpunctata howardi* Barber; and the striped cucumber beetle, *Acalymma vittatum* (Fabr.). This group is known to show a close association with host plants of the family Cucurbitaceae, particularly with the genus *Cucurbita* (Metcalf, 1979). The adults are most commonly found in the blossoms of *Cucurbita* spp. where they feed on pollen (in staminate flowers) and nectar. Studies have indicated that these beetles show a definite preference for certain species of cultivated *Cucurbita* (Fronk and Slater, 1964; Bach, 1977; Andersen, 1964). In most instances, adults prefer the blossoms of *C. maxima* Duchesne cultivars over those of *C. pepo* L. and *C. moschata* Poir.

No investigations have been made concerning a chemical basis for beetle orientation to the blossoms or foliage of *Cucurbita* spp. However, the effect of plant chemistry of feeding behavior has been intensively studied. A group of tetracyclic triterpenes, the cucurbitacins, are characteristic of the family and serve as potent feeding stimulants for *Diabrotica* and *Acalymma* adults (Chambliss and Jones, 1966; Metcalf et al., 1980, 1982). These relatively large (mol wt $\simeq 500$) and heavily oxygenated compounds are essentially nonvolatile and serve no apparent function in orientation to plants (Branson and Guss, 1983). The purpose of this study was to investigate the role of plant volatiles in the orientation of *Diabrotica* and *Acalymma* adults to the blossoms of *Cucurbita maxima* cultivars.

METHODS AND MATERIALS

Collection of Volatile Material. Plants of two *C. maxima* cultivars, "Blue Hubbard" and "Pink Banana Jumbo" were grown in a field plot at the University of Illinois. Male blossoms were harvested between the hours of 8:00 AM and 10:00 AM and returned to the laboratory on ice. Volatiles were trapped on Porapak-Q (80–100 mesh) by enclosing 20–40 blossoms in a tubular glass chamber (84 × 11 cm diameter) which was closed at both ends with jointed glass adaptors. At one end of the chamber, a short column (2 cm ID) containing approximately 5.0 g Porapak-Q was attached, while at the other, a 35 × 2-cm column containing activated carbon was attached. A vacuum pump coupled to the Porapak-Q column pulled an airflow of 2.0 liters/min through the chamber. Groups of blossoms were aerated for approximately 4 hr. After collection, the Porapak-Q was removed from the column and extracted with anhydrous diethyl ether in a Soxhlet apparatus. The extracts were dried over anhydrous sodium sulfate and concentrated to a volume of 15 ml by vacuum rotary evaporation. Final concentration to 0.5–1.0 ml was performed under a gentle stream of nitrogen.

Analysis of Volatile Mixture. Gas–liquid chromatography (GLC) was carried out using a Varian 2700 series instrument equipped with a hydrogen flame

ionization detector. Columns were packed with 3% OV-17 on Gas Chrom-Q (80–100; 3.7 m × 2 mm ID glass) or 3% SE-30 on Chromosorb-W (100–120; 1.8 m × 2.0 mm ID glass). The carrier gas was nitrogen at 60 ml/min.

For gas chromatography–mass spectrometry (GC-MS), a Hewlett Packard model 5985 GC-MS system was employed. The gas chromatograph was equipped with a 30-m × 0.32-mm ID fused silica capillary column coated with DB-1 (J&W Scientific, Rancho Cordova, Ca.). Helium was used as the carrier gas and electron impact spectra were recorded at a source voltage of 70 eV.

Normal-phase high-pressure liquid chromatography (HPLC) was performed using a single Waters Associates (Milford, Ma.) M-45 pump coupled with a radial-compression-type silica gel column. For preparative separations, a mobile phase of 10% tetrahydrofuran (glass distilled) in hexane (spectrograde) was used. At a flow rate of 2.0 ml/min, 1.0-ml fractions were collected for 6.5 min (13 fractions). The fractions were concentrated for bioassay and analysis under a gentle stream of nitrogen.

Thin-layer chromatography (TLC) was carried out using 0.1-mm silica gel plates on polyethylene terephthalate backing (Eastman Chromatogram, Rochester, N.Y.). The plates contained fluorescent indicator (F254) and were developed in a solvent system of chloroform–benzene–ethanol (83:8.5:1).

Electroantennogram Bioassay. Electroantennogram (EAG) measurements were obtained using a system similar to that described by Visser (1979) with the exception that stimuli were delivered to the antenna in a discrete puff of air. Antennae of *D. u. howardi* females were excised with small scissors after removal of the distal segment. They were then placed between two 0.9% NaCl-filled capillary tubes which covered silver–silver chloride wires. Signals were amplified and recorded by conventional apparatus. Stimuli were delivered to the antenna in 1.0-sec pulses of air (16 ml) traveling through a 1.0-cm ID glass tube. The test stimuli were applied to the inner surfaces of aluminum foil cylinders which fit in the glass delivery tube. A continuous air stream was shunted through the tube for 1.0 sec as a result of opening a solenoid valve by means of a physiological stimulator.

Field Trapping Tests. Traps consisted of white 0.95 liter paper cylindrical containers which were inverted and stapled to the tops of wooden stakes. The external surfaces, except the tops of the traps, were coated with Tack Trap. Test compound was normally applied in 1.0 ml diethyl ether to one surface of a 4.0 × 28.0-cm strip of xerographic transparency. The strip was then wrapped around the center of the sticky surface and securely fastened. Control traps contained an untreated plastic strip. In late season experiments, 1-dr glass vials were used as release sources and were attached to the top of the trap. *D. v. virgifera* sex pheromone, 8-methyl-2-decanol propanoate (5 μg racemic; Guss et al., 1982), was applied in methylene chloride solution to red rubber septa. These were pierced by wires which were attached to the top of the trap. All

traps in comparisons of test volatiles and pheromone contained both a strip and a septum, and each was treated as described above or not treated as appropriate.

The traps were positioned just below canopy level in the center row of a 98 × 18-m plot of hybrid dent corn. In some experiments, each baited trap was paired with an unbaited control. The traps within a control–treatment pair were separated by 10 m and the pairs by 20 m. In other experiments, traps were treated individually. In these cases, all traps were separated by 10 m.

Trapping was also conducted in a small plot containing various *Cucurbita* spp. The traps were placed slightly above canopy level (1.0 m) next to plants of the zucchini cultivar of *C. pepo* or the hybrid *C. pepo* × *C. texana.*

In all field-trapping experiments, traps were baited between 5:30 and 7:00 PM and the insects were removed the following morning between 10:00 and 11:00 AM. Males were distinguished from females by the presence of the supraanal plate (Mendoza and Peters, 1968).

Release Rates of Trap Sources. Indole was applied to the plastic strips used as trap baits by evenly pipetting the desired dosage onto the strip in 1.0 ml of diethyl ether. Strips containing each dosage level were aerated seperately, immediately after preparation in a small glass chamber similar to that described above. The chamber was coupled to columns of activated carbon and Porapak-Q as described above, and each strip was aerated for a period of 2 hr. The Porapak-Q was then extracted with diethyl ether, and the extract was concentrated as described above. Quantifications were made by measurement of GLC peak areas using the 3.7-m OV-17 column run at an isothermal temperature of 160°C.

RESULTS AND DISCUSSION

Analysis and Bioassay of Floral Volatile Mixture. Initial GLC analysis indicated that the volatile mixture released by *C. maxima* "Blue Hubbard" male blossoms is quite complex. Over 40 components were resolved on 3% OV-17 (Figure 1). A fractionation scheme was devised using HPLC and employing the EAG technique for bioassay. Analysis of the fractions by GLC revealed that the entire mixture seen in Figure 1 was eluted within 6.5 min.

Figure 2 displays the EAG responses to the fractions expressed as the ratio of the microvolt response value for each treatment fraction divided by the response to a control air puff. Two peaks of activity are apparent. The first, and most active, was eluted between 2.0 and 2.5 min (fraction 5) and the second peak between 4.5 and 5.0 min (fraction 10).

GLC analysis (OV-17) of the large early peak of activity (fraction 5) indicated that only one sample component was present. A larger quantity of this component was obtained by preparative HPLC of a head space volatile sample collected from the male blossoms of the "Pink Banana Jumbo" cultivar of *C.*

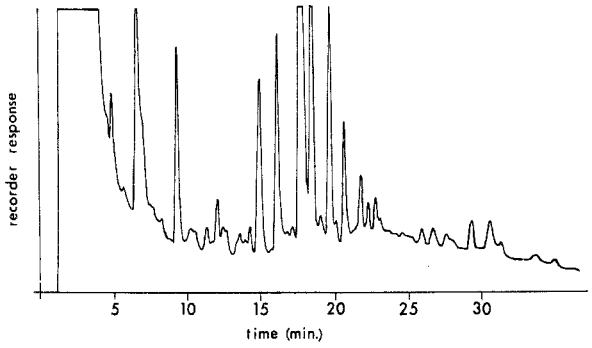

FIG. 1. Gas chromatogram of *C. maxima* cv. "Blue Hubbard" floral volatiles. Column: 3% OV-17 on Gas Chrom Q. Temperature program: 110°C for 5 min, then 4°C/min to 180°C, with a 15-min hold at 180°C.

maxima. Gas chromatography on a capillary column (DB-1) leading to the MS source verified that only a single compound was present. A mass spectrum was obtained which was consistent with the structure of indole, showing a strong molecular ion at *m/e* 117 and major fragment ions at *m/e* 90 and *m/e* 89.

The isolated compound was found to cochromatograph with authentic indole (Aldrich 99% pure) on both the 3% OV-17 (160°C isothermal) and 3% SE-30 (70°C isothermal) columns. Comparison by silica gel thin-layer chromatography resulted in identical R_f values (0.51) for both the active compound and indole as determined by quenching of fluorescence under shortwave UV light. Also, both reacted with Ehrlich's reagent (*p*-dimethylaminobenzaldehyde) to form a pink spot on the developed plate. Ehrlich's reagent is commonly used for the detection of indoles (Durkee and Sirois, 1964) and was found in this case to have a limit of detection of 0.1 μg. The presence of indole in the "Blue Hubbard" floral volatile mixture used for fractionation and bioassay was confirmed by GC-MS and TLC of the unfractionated mixture.

Components responsible for the second peak of activity were not detected by GLC. This activity is most likely due to a single or group of low-boiling polar compounds whose presence was masked by the large solvent peak.

Field Bioassay of Indole. Indole was tested using sticky traps in a corn field containing populations of both *D. v. virgifera* and *D. u. howardi*. *D. v. virgifera* were attracted to baited traps in a dosage-dependent manner (Table 1), while *D. u. howardi* were not attracted to any dosage, despite the strong responses seen in the EAG assay. When traps were observed during the morning hours, *D. v. virgifera* could be seen approaching the source from the downward direction at trap height. Individuals apparently orienting to the bait were seen as far as 10 m downwind from the trap. After reaching the immediate vicinity of the trap, individuals would land directly on the downwind surface or, in some cases, circle the trap and land on the upwind side.

FIG. 2. Electroantennogram responses of female *D. undecimpunctata howardi* to HPLC fractions of *C. maxima* cv. "Blue Hubbard" headspace volatiles. The t/c ratio indicates the response to a treatment fraction (in microvolts) divided by the response to a control air puff.

[a]Means followed by a different letter indicate that the total trap catches (male + female) are significantly different at the 5% level as indicated by ANOVA and Student-Newman-Keuls (SNK) multiple-comparison test.

The measured release rates of the plastic sources were quite high during the first 2 hr after application of indole (Figure 3). Andersen (1984) has reported indole release rates of ca. 367 ng/hr for cut blossoms of the "Pink Banana Jumbo" cultivar and ca. 117 ng/hr for "Blue Hubbard." This low release rate (relative to that of the traps) suggests that either floral indole is effective only at short range, or that behavioral cues other than indole contribute to the large numbers of insects found in these blossoms. This is especially true of *D. u. howardi* which shows the same strong preference for *C. maxima* blossoms that *D. v. virgifera* and *A. vittatum* demonstrate, but does not respond to indole as a trap bait. It is noteworthy, however, that the behavioral observations discussed above were made on the morning following baiting. At this time, the release rate of the 1.0 mg trap would be greatly reduced, since approximately 30% of the applied indole is volatilized in the first 2 hr after application (Figure 3). It is possible though, that the complete volatile mixture emitted by *C. maxima* blossoms would be more effective than any single component, including indole. Work is currently in progress to determine the importance of additional floral volatile components in beetle flower selection behavior.

As indicated in Table 1, *D. v. virgifera* catches during this period (August 29–September 2, 1983) consisted almost exclusively of females. In reality, the trap sex ratios were found to vary seasonally. Early in the *D. v. virgifera* emergence season (July 18–20) males and females were caught in nearly equal numbers (Table 2). This may possibly be explained by the phenology of the species and by beetle movement patterns. Males of *D. v. virgifera* are protandrous (Cates, 1969), and the early trapping dates correspond roughly to the period of male predominance in the field (Cates, 1969). The period of female predomi-

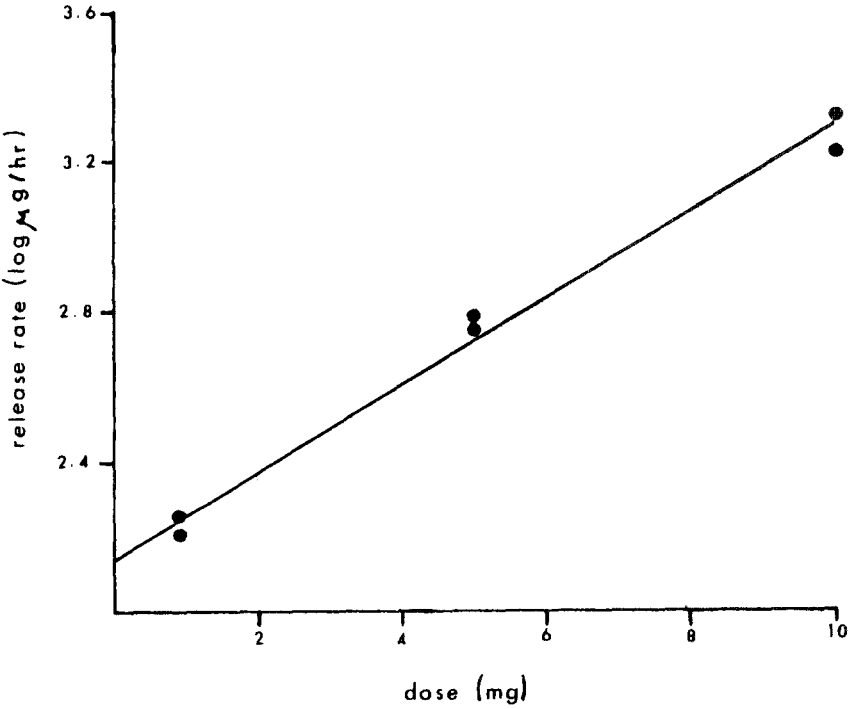

FIG. 3. Indole release rates of plastic strip substrates the first 2 hr after preparation.

[c] 100 mg indole released from a glass vial.

nance in sticky traps likewise corresponded roughly to the peak of female abundance in the field (Cates, 1969). Also, it has been recently reported that catches in unbaited sticky traps at ground level are biased toward males (Hein and Tollefson, 1984), suggesting a stratification of male and female flight patterns in

the field. If females do fly at higher levels in the field than males, the expected trap sex ratios at canopy level would be skewed in the direction of females. The high numbers of males on July trapping dates would, as mentioned above, be due to male predominance during this period.

The presence of males in the test field during the period of low female response was determined by sex pheromone trapping. In September 1983 (directly following the experiments described in Table 1), *D. v. virgifera* field responses to indole and 8-methyl-2-decanol propanoate, the sex pheromone of the species (Guss et al., 1982), were compared. As expected, almost exclusively males responded to pheromone, while nearly all females were found in indole-baited traps (Table 3). This suggests that the lack of male response is not due to an absence of males in the test field.

In late September 1983, the numbers of males caught in baited traps increased, resulting in trap sex ratios near unity (Table 2). These data were obtained using large dosages of indole (100 mg) released from glass vials instead of the plastic strips normally baited with 1–10 mg. The high release rates of these sources may have been the cause for the increase in male response. However, these experiments were performed after the first seasonal frost, and the corn plants had dried almost completely. The paucity of available food during this period may have resulted in enhanced male response to indole-baited traps. To positively determine the extent of sexual differences in response, comparisons of trap sex ratios will have to be made with those obtained by an independent field sampling method.

In addition to variations in trap sex ratio, the effectiveness of indole as a *D. v. virgifera* lure varied seasonally. Trapping experiments pairing a 5-mg indole-baited trap with an unbaited control trap were performed from July 18 to August 15, 1983. On the first two days of trapping, the mean catches were high, but also quite variable (Figure 4). Between July 20 and August 10, how-

TABLE 3. MEAN TRAP CATCHES OF *Diabrotica virgifera virgifera* WITH 10 mg INDOLE, 5 μg SEX PHEROMONE (8-methyl-2-decyl propanoate) OR THE TWO IN COMBINATION (EIGHT REPLICATES OF EACH TREATMENT)

[a] Means within a column followed by different letters are significantly different at the 5% level as indicated by ANOVA and SNK comparisons of means.

ever, indole trap catches were consistently low and were not significantly different than control catches (Figure 4). On August 1 and 2, the traps were moved to a second corn field which contained an extremely high *D. v. virgifera* population. Over 50 individuals were counted on some corn plants. In this field on August 2, the indole dosage was increased to 20 mg/trap. Despite these manipulations, the trap catches remained low. After August 10, the catches again increased and continued at high levels for the remainder of the trapping study (Figure 4).

The period of minimum *D. v. virgifera* trap catch corresponded to the time of both the normal maximum emergence in Illinois (Musick et al., 1980) and the silking-tasseling period of the corn. Adults were observed to be feeding on pollen in the vicinity of the tassel and in lesser numbers on the silks. It is possible that during this period of food abundance, *D. v. virgifera* adults show a reduced sensitivity to indole, a food-derived attractant. The response to indole may be related to the degree of satiation of the insect. Replete individuals may perceive the lure but be less apt to make oriented movements toward its source.

Trapping was carried out in a cucurbit field which contained large numbers of *D. v. virgifera* and *D. u. howardi* adults. Also present was a third beetle species, *Acalymma vittatum.* Although related to members of the *Diabrotica*, *A. vittatum* is a cucurbit specialist in the larval stage, and is not normally found in corn fields (Houser and Balduf, 1925). This species was significantly attracted to indole-baited traps (Table 4, paired *t*-test, $P < 0.01$), and the sex ratios (male/female) over the final four days of trapping (August 5–8) were 1.52 for baited traps, and 1.60 for unbaited. These data indicate that male and female *A. vittatum* are attracted equally well to baited and unbaited traps.

The abundance of *D. v. virgifera* and *D. u. howardi* resulted in high control trap catches in cucurbit fields (Table 4). However, numbers of *D. v. virgifera* caught in indole-baited traps (5 mg) were nearly always larger than those found in controls ($P < 0.10$, paired *t*-test). Again, *D. u. howardi* showed no significant response to indole baited traps, with statistically equal numbers of individuals being caught in treatment and control traps (Table 4).

CONCLUSIONS

In past studies, cucurbitacins have been shown to be classic examples of "sign stimuli," as designated by Fraenkel (1959), for *Diabrotica* and *Acalymma* adults. Their narrow taxonomic distribution and their potent feeding stimulant activity make them important factors in the selection of cucurbit hosts by beetles (Metcalf et al., 1982). However, this study indicates that host volatiles are also of importance. A single compound which occurs in the floral essence of the beetle host plant *C. maxima* is strongly attractive to adult *D. v. virgifera* and *A. vittatum.* The relatively broad distribution of indole in floral

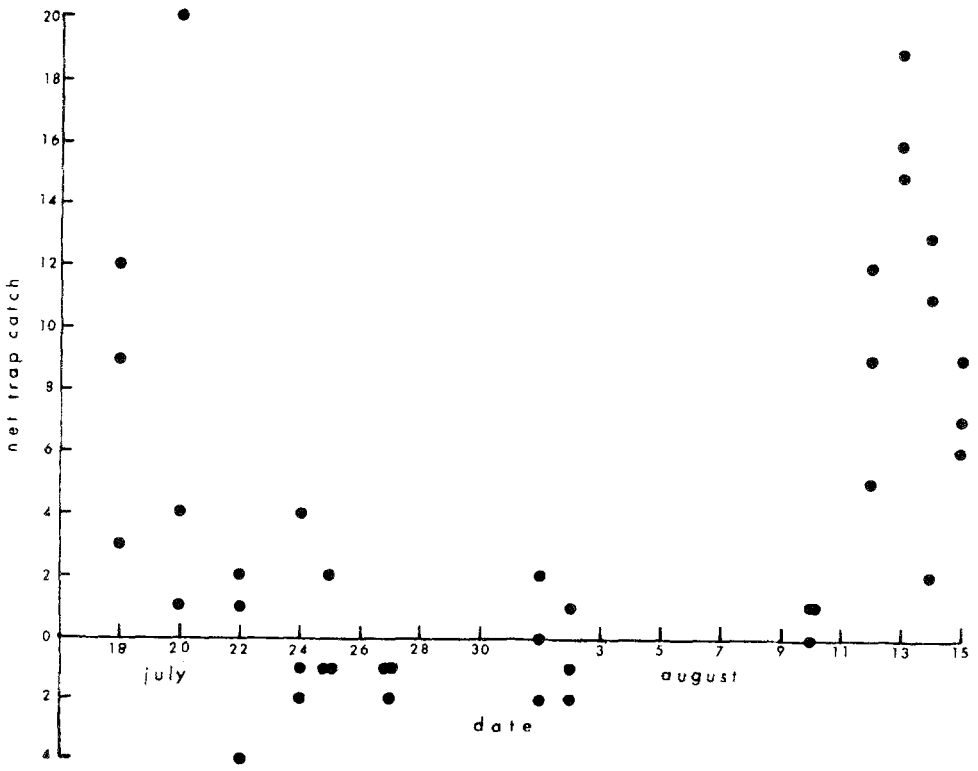

FIG. 4. Catches of *D. virgifera virgifera* in traps baited with 5 mg indole in July and August 1983. Net trap catch indicates the number of *D. v. virgifera* found in baited traps minus the number found in the corresponding unbaited trap. Each spot represents the net catch of one control-treatment pair.

odors (Stowe, 1959) suggests that it does not function as a "sign stimulus" in the *Diabrotica/Acalymma–Cucurbita* association. It may, however, act in concert with other components of the floral volatile mixture to form a unique attractive blend (Visser, 1979).

The cucurbitacins and indole appear to play roles in host selection which are consistent with models described by Kogan (1977). Indole would serve in the "host-finding" phase of host selection by eliciting orientation to the host plant from a distance. Cucurbitacins are minimally volatile and would only act in the "host acceptance" stage by stimulating feeding and arresting locomotion (Metcalf, 1979). Variability in both of these factors could influence the overall preference for a particular *Cucurbita* species or cultivar. The influence of these factors on beetle field distribution will be addressed in a separate report.

Acknowledgments—This research was supported in part by grants from the SEA, USDA Competitive Research Grants Office, 81-CRCR-1-0659 "Kairomones in corn and cucurbits in monitoring and controlling corn rootworms," and from the Illinois Institute of Natural Resources. Division of Environmental Management. Any opinions, findings, conclusions, or recommendations are those of the authors and do not necessarily reflect the view of the USDA. Special thanks go to J.E. Ferguson for helpful comments and assistance in the preparation of this manuscript and to R. Larson for performing the gas chromatography–mass spectrometry.

(Received April 15, 1985; accepted July 15, 1985)

Abstract—Soldier defense secretions of the genus *Hospitalitermes* (Isoptera, Termitidae, Nasutitermitinae) were chemically analyzed by GC-MS and were found to contain volatile monoterpenes and polyoxygenated diterpenes. Interspecific and intraspecific chemical variations for *H. umbrinus*, *H. hospitalis*, *H. flaviventris*, and *H. bicolor* are described. Interspecific variations in monoterpene and diterpene structures and compositions were evident. A remarkable example of large intraspecific variation from a single species was observed in *H. umbrinus*, indicating that colonies of this species can be separable into two chemically distinct groups. The diterpenes found in one of these groups have unusually high molecular weights.

Key Words—Termites, Isoptera, Termitidae, defense secretions, interspecific variations, *Hospitalitermes* species, diterpenes.

INTRODUCTION

The genus *Hospitalitermes* belongs to the subfamily Nasutitermitinae, in which the soldier castes are characterized by having conical, nozzle-shaped projections on the head from which they eject defensive secretions produced by the enlarged frontal glands located within the head capsules. The genus is restricted to the Old World Tropics with over 22 species having been recorded (Tho, 1982). The soldiers are all monomorphic and are characterized by having long antennal segments, long legs with the hind leg much longer than the body length, and highly pigmented body colors.

Behaviorally, all species recorded have free-ranging habits, in that they march out in long columns without any covered trails. These columns often

0098-0331/86/0300-0701$05.00/0

extend more than 50 m from the nest site, and the termites are often observed climbing up to the top of the forest canopy. Food comprises scrapings off the surfaces of leaves, twigs, and the bark of trees (a mixture of dead plant material and lichen). The food material is collected by the worker caste and is rolled into a small ball that is then carried all the way back along the trail to the nest. The soldiers protect their foraging columns by positioning themselves along the fringes of the columns. Defense is effected by shooting chemical secretions at their enemies. Our observations so far have indicated that these termites, while on the march, are seldom attacked by predators or enemies, which would therefore attest to the effectiveness of the soldiers and hence the defense secretions.

The biochemistry and chemistry of the soldier defense secretions of *Hospitalitermes* are therefore of great interest and have been reported for two species, *Hospitalitermes monoceros* (Maschwitz et al., 1972; Prestwich, 1984) from Ceylon and *Hospitalitermes umbrinus* (Chuah et al., 1983) from peninsular Malaysia. In peninsular Malaysia, there are six species of *Hospitalitermes* (Tho, 1982), and in this paper we report our studies of the chemistry of the defense secretions of four species, which includes *H. umbrinus*.

METHODS AND MATERIALS

Termite Material. Soldier termite materials used for the present studies were all collected from within closed canopy dipterocarp forests from the following localities in Peninsular Malaysia: (1) Pasoh forest reserve [2°58′N, 101°55′E; 100 m above sea level (ASL)]—a lowland dipterocarp forest which was the site for intensive ecological studies under the auspices of the International Biological Programme; (2) Fraser's Hill forest reserve (3°43′N, 101°44′E; 1200 m ASL)—an upper hill dipterocarp forest bordering to the oak montane forest; (3) Taman Negara (4°20′N, 102°25′E; 1000 m ASL)—the national park of peninsular Malaysia in the state of Pahang; (4A) Gombak forest reserve (3°20′N, 101°46′E; 300 m ASL); (4B) Klang Gate (3°15′N, 101°46′N; 300 m ASL); (4C) Genting Sempah (3°14′N, 101°46′E; 500 m ASL); (4D) Templer Park (3°22′N, 101°40′E; 200 m ASL)—4A–4D are hill dipterocarp forests in the state of Selangor; (5) Pulau Langkawi (6°22′N, 99°50′E; 200 m ASL)—an island in the state of Kedah; (6) Bukit Buak forest reserve (4°40′N, 103°20′E; 500 m ASL)—a hill dipterocarp forest in the state of Trengganu, and (7) Penang Hill (5°25′N, 100°12′E; 1200 m ASL)—an upper hill dipterocarp forest, most of which has been disturbed.

Analytical Methods. Gas chromatography (GC) was performed on a Pye 104 instrument fitted with a Gow-Mac flame ionization detector. Gas chromatography–mass spectrometry (GC-MS) was performed on a Pye 104 gas chromatograph interfaced to a double-beam Kratos MS30 mass spectrometer by a membrane separator. Mass spectra were obtained at 70 eV with the source and

interface temperatures at 150°C and 230°C, respectively, and data were accumulated by a Kratos DS55 data system. Three glass columns (5-ft × 3-mm 3% OV-17, 5-ft × 3-mm 3% OV-1, and 3-ft × 3-mm 1% SE-30 on 100–120 Gas Chrom Q) were used to analyze the diterpenes. A 10-ft × $\frac{1}{8}$-in. stainless-steel column packed with 10% Carbowax 20 M on 120–140 Gas Chrom Q was also used to analyze monoterpenes.

The monoterpenes (I–IX) have been characterized by GC-MS and coinjection with standards and the results are summarized in Table 1. Similarly, diterpenes (X–XX, Figure 1) were characterized by the NMR and MS data (Vrkoc et al., 1978a,b; Prestwich, 1979; Dupont et al., 1981) and by coinjection with compounds identified (Chuah et al., 1983; Goh et al., 1982, 1984). The results are summarized in Table 2.

The whole gas chromatographic profile of the total secretion was usually obtained by on-column injection at 90°C and then programmed at 8°C/min to 270°C on the 5-ft glass column, or the column was kept isothermal at 90°C for 5 min before temperature programming. The analysis for the diterpenes of *H. umbrinus* chemoform A was done on the 3-ft column. The gas chromatographic profiles are shown in Figures 2 and 3. *H. umbrinus* chemoform A provides two major new diterpenes which have molecular weights of 650 and 664 as shown by MS probe samples. The R_f values of these two compounds on silica gel TLC in EtOAc–Hexane (1 : 20) are 0.37 and 0.38, respectively. These are quite complex molecules and are tentatively assigned as epoxytrinervitenepentaol pentapropionate and epoxytrinervitenepentaol acetate tetrapropionate esters, respectively, based on the mass spectra and [^{1}H]NMR spectra which showed strong propionate CH_2 resonances at δ2.27 and 2.35. A pair of AB doublets (5.8 Hz) centered at δ2.75 and 3.14 were assigned as due to the presence of an epoxy group. Retention indices of all diterpenes were made relative to *n*-alkane standards and R_f values on silica gel TLC plates are summarized in Table 3.

The chemical identities of the major diterpenes were confirmed after liquid chromatographic isolation. Preparative scale separations of the individual terpenoid compounds from the defense secretions (ca. 100 mg or more) of the various species of soldier termites were performed by flash chromatography. Column lengths of 0.5–0.8 m and 1–2 cm diameter were slurry packed with 40–63 μm silica gel (Merck 9385) in dichloromethane, and to separate most of the terpenoids, a gradient elution of 2–10% ethyl acetate in dichloromethane was used. Further purification, if necessary, of the isolated terpenoids was aided by a Waters 440 HPLC instrument fitted with a 25-cm × $\frac{1}{4}$-in. Ultrasphere silica gel column. Elution of the diterpenoids was by a gradient of 2–10% ethyl acetate in hexane. Isolated samples were checked by GC and TLC on 5 × 10-cm 0.25-mm silica gel 60 plates. Proton and carbon-13 NMR spectra were recorded on a Jeol JMN-FX100 spectrometer.

The isolated diterpenoids were identified by their [^{1}H]NMR and mass spectral data as well as by comparison of their retention times with those previously

identified (Chuah et al., 1983; Vrkoc et al., 1978a,b; Prestwich, 1979; Dupont et al., 1981).

RESULTS AND DISCUSSION

Defensive secretions of the soldiers of *Hospitalitermes* comprise mainly mono- and diterpenoids. The results obtained are summarized in Tables 1 and 2 and Figures 2 and 3. The monoterpenes (I–IX) were all hydrocarbons and were usually dominated by α-pinene as was found for *H. umbrinus*, *H. hospitalis*, and *H. bicolor*. However, a dominant amount of myrcene was found in the secretion of *H. flaviventris*. In general, monoterpenes alone may not be useful for chemotaxonomic diagnosis (Goh et al., 1982). However, when coupled with the diterpene components, which exhibit greater diverse structural

The diterpenes of *Hospitalitermes* are mainly dominated by trinervitenes (X–XX) with trinervitenediol (XV) being the most commonly encountered. The only other skeletal type detected in minor quantities is the methyl-shifted rippertenol (X). Interspecific variation is exhibited mainly by the degree of oxygenation of the diterpenes. Thus *H. bicolor* showed a distinct diterpene composition that had a preponderance of the 13-keto triacetate (XIX).

The chemistry of *H. umbrinus* has already been reported previously (Chuah et al., 1983). However, we have now found consistent intraspecific variation for individual colonies. Based on the diterpene components, colonies can be separable into two distinct groups. These are referred to as chemotype A and B for purposes of discussion here. Thus chemotype B colonies are characterized by having large amounts and varieties of the common trinervitenediols (XV), while chemotype A soldier secretions were found to be dominated by two high-molecular-weight diterpenes (UI and UII) as illustrated by the gas chromatograms in Figure 2 and effectively demonstrated in Table 2. Our preliminary studies on the structures of these new diterpenes have shown that they possess unusually high molecular weights. One of these was determined to have a molecular weight of 664 while the other was recorded as 650. These are tentatively assigned as epoxytrinervitenepentaol pentapropionate and epoxytrinervitenepentaol acetate tetrapropionate esters, respectively.

Although the defense secretions are chemically distinct, our examination of the morphological characteristics of the termites from colonies of these two chemotypes has not revealed that they could be taxonomically separated. However, some preliminary ethological observations seem to indicate that soldiers of chemotype B are relatively more aggressive in response to disturbances. Our chemical data are based on collections from various localities in peninsular Malaysia which includes allopatric and sympatric colonies. We therefore infer, from the differences observed, that there are two chemotypes within the species.

On the assumption that such differences could be the result of temporal variation, we have checked and screened soldier termite secretions of several colonies over a period of four years during which we found no major variations. This does imply that the chemical compositions are specific for each colony. In this respect, we are faced with the question of the existence of two "chemically distingishable" species. Current termite taxonomy is based largely on the morphological features of the termite castes. It would be rather difficult to justify the existence of two species based on observed differences in the chemistry of soldier defense secretions. However, speciation in nature need not necessarily be manifested morphologically. Behavioral and physiological changes could precede morphological change. Yet, short of an in-depth study, it can only be concluded here that our present studies have revealed that within the species *H. umbrinus* there are two chemically distiguishable groups of termite colonies.

Phylogenetically, *Hospitalitermes* together with *Trinervitermes* (Prestwich and Collins, 1981) are considered the more advanced genera in the family Na-

sutitermitinae. In these genera, intraspecific variation of the chemical defense secretions has generally been observed to be not common, unlike the case of the primitive *Longipeditermes longipes* (Goh et al., 1984), which demonstrated extreme intraspecific chemical variability in their soldier defense secretions in both allopatric and sympatric colonies. Should the two chemotypes currently observed for *H. umbrinus* prove to be two distinct species, then the present studies for the genus *Hospitalitermes* would provide additional evidence that the more advanced genera exhibit little intravariability. Interspecific differences are discernible, even more so when based on a matrix of the qualitative and quantitative composition of the various monoterpenes and diterpenes.

(Received April 3, 1985; accepted July 16, 1985)

Abstract—*Lespedeza cuneata* contains high levels of phenolics and is a common food plant of the meadow vole (*Microtus pennsylvanicus*); *Penstemon digitalis* contains substantial quantities of alkaloids and is a common food plant of meadow voles and prairie voles (*M. ochrogaster*). We investigated the palatability of these plants and the effects of their secondary compounds on the digestion efficiencies and growth of both species of voles. Voles ate very little of either plant when alternative food was present. Phenolics and alkaloids were extracted from the plants, incorporated into separate artificial diets, and fed to weanling voles for three weeks. *Lespedeza* phenolics reduced the growth of meadow voles but not prairie voles throughout the feeding trial. These compounds disrupted digestion, reducing protein digestibility by more than half. *Penstemon* alkaloids lowered only the initial growth rates of prairie voles and had no significant effect on meadow voles. Prairie voles tended to increase food consumption rates on both *Lespedeza* and *Penstemon* diets. This response offset some of the decrease in digested protein intake in the first case, and offset the increased metabolic cost of processing the diet in the latter case. Our results indicate that although *Lespedeza* phenolics and *Penstemon* alkaloids do influence consumption and digestibility of artificial diets, they do not greatly reduce the performance (i.e., growth or survival) of voles when consumed at levels generally observed for wild voles. However, these compounds probably do place an upper limit on the amount of fresh *Lespedeza* and *Penstemon* that can be consumed and contribute to the generalist feeding strategy of voles.

Key Words—Alkaloids, phenolics, feeding trials, digestibility, growth, *Lespedeza cuneata*, *Penstemon digitalis*, *Microtus pennsylvanicus*, *Microtus ochrogaster*.

INTRODUCTION

Diet selection by herbivores is largely determined by the phytochemical composition of the available forage and the nutrient requirements/detoxication capacities of the animals. Both plant nutrients and secondary compounds influence the foraging ecology of mammalian herbivores (e.g., Swift, 1948; Swank, 1956; Cooper-Driver et al., 1977; Belovsky, 1978, 1981; Milton, 1979; Bryant and Kuropat, 1980; McKey et al., 1981; Radwan et al., 1982; Fraser et al., 1984; Calvert, 1985), but most studies have simply reported correlations between food habits or palatability and types and amounts of these plant constituents. Only recently have researchers begun to address a more pertinent question regarding plant defenses, viz., do the specific secondary compounds encountered by mammalian herbivores actually inhibit their growth, survival, or reproduction? Also, do differing food habits of closely related species reflect different abilities to detoxify or otherwise circumvent plant chemical defenses (e.g., Jung and Batzli, 1981)?

The meadow vole (*Microtus pennsylvanicus*) and prairie vole (*M. ochrogaster*) are primarily herbivorous, and commonly occur in herbaceous habitats in east-central Illinois. Our previous work (Lindroth and Batzli, 1984a) showed that in a tallgrass prairie habitat, meadow voles consumed substantial quantities of the forbs *Lespedeza cuneata* and *Penstemon digitalis*. In summer, these species comprised 28 and 16% of meadow vole diets, respectively, but preference indices showed that they were neither significantly preferred nor avoided. Cole and Batzli (1979) listed *Penstemon*, but not *Lespedeza*, among the forbs commonly eaten by prairie voles in a similar tallgrass prairie habitat.

Although they are common food plants in our study sites, *Lespedeza* and *Penstemon* contain relatively high levels of secondary plant compounds. As a forage crop, *Lespedeza* is known for its high concentrations of tannins (Donnelly and Anthony, 1969, 1970), and *Lespedeza* plants in our prairie site contain much higher (2–4×) levels of protein-binding phenolics than other common food items (Lindroth and Batzli, 1984a). *Penstemon* contains appreciable amounts of alkaloids, which are not detectable in other food plants (Lindroth and Batzli, 1986). Moreover, in laboratory feeding trials in which prairie voles and meadow voles are provided with a mixture of fresh *Lespedeza* and *Penstemon*, animals lose weight and die within several days (Lindroth, personal observation).

This paper reports results from experiments conducted to evaluate the effects of *Lespedeza* phenolics and *Penstemon* alkaloids on prairie voles and meadow voles. We were interested first in ascertaining whether secondary compounds from major food plants reduce the performance of voles. Second, to help explain the difference in utilization of *Lespedeza* by the two vole species, we tested the hypothesis that prairie voles are more susceptible (i.e., exhibit slower growth or lower digestion efficiencies) to *Lespedeza* phenolics than are meadow voles.

METHODS AND MATERIALS

Palatability Trials. We conducted palatability trials to assess the relative preferences of each vole species for *Lespedeza* and *Penstemon*. *Lespedeza* and *Penstemon* leaves were collected in mid-summer, divided into subsamples, weighed, and fed fresh to six adults of each species. We used the same individuals to test both plant species; the *Penstemon* trial was conducted 24 hr after the *Lespedeza* trial. Trials lasted 15 hr, during which time the voles were housed individually and had access to the test plant ($\simeq$ 5 g), water, and a standard palatable diet (Purina Rabbit Chow, No. 5321). Thus the voles were not forced to eat any of the test plant. To account for evaporative water loss, we also weighed out five additional subsamples of fresh leaves at the onset of each trial. At the conclusion of each trial plant material was collected and all samples were oven-dried (100°C, 24 hr) and weighed. Palatability of each plant species to each vole was calculated as leaf dry weight ingested (dry weight offered minus dry weight not eaten).

Artificial Diets. When using whole plant tissues in bioassays, investigation of the effects of any one plant compound is complicated by the impossibility of controlling the concentrations of a plethora of other plant compounds. Thus we conducted our experiments with an adaptation of an artificial diet developed earlier for use with microtine rodents (Lindroth et al., 1984). Although they do not mimic many of the physical and chemical characteristics of fresh plants, artificial diets are particularly useful for investigations of the action of particular plant compounds or interactions among compounds. All diets described in this study contained 10% protein, consisting of casein supplemented with methionine.

Lespedeza was collected in September 1983 and air-dried leaves were separated, ground, and stored (−20°C) until extracted. The level of protein-binding phenolics in this plant material was similar to that observed in *Lespedeza* in several preceding autumns (Lindroth, 1984; Lindroth et al., 1986). The concentration of condensed tannins was 34% dry weight in quebracho equivalents [vanillin HCl assay, Broadhurst and Jones (1978)], although we doubt that the true level of condensed tannins was quite so high. Ground *Lespedeza* leaves (125-g lots) were extracted sequentially in 2, 1, and 1 liter volumes of 80% ethanol over a period of two days. We then combined the filtrates, concentrated the extract (rotary evaporator, 38°C), mixed it with the dry artificial diet, and dried the diet (28°C) in a forced-air oven for two days. To make the corresponding control diet, a quantity of 80% ethanol equivalent to the final extract volume was added to another batch of artificial diet and dried.

When fed the artificial diet with phenolics equivalent to an 80% *Lespedeza* diet, weanling prairie voles ate only small amounts, lost weight, and died within several days. Because we were more interested in the toxic or digestibility-reducing effects rather than feeding-deterrent effects of *Lespedeza* phenolics, we lowered the phenolic levels to a point where palatability of the diet was not

strongly affected. The artificial diet used for the experiments presented here was approximately equivalent to a natural summer diet consisting of 50% *Lespedeza*.

Leaves of *Penstemon* rosettes were collected in May 1984, freeze-dried, ground, and stored (−20°C) until extracted. The level of alkaloids in *Penstemon* leaves was similar to that observed in preceding spring seasons (Lindroth, 1984; Lindroth et al., 1986), comprising about 0.01% of plant dry weight (Lindroth et al., 1986). We extracted ground *Penstemon* leaves (80-g lots for 30 min) twice in 800 ml of 0.1 N H_2SO_4. We combined the filtrates and basified the extract to pH 10 with a concentrated NaOH–water solution. We washed the basified extract four times with 200 ml $CHCl_3$, then concentrated the combined organic phases to about 300 ml (rotary evaporator, 38°C). This solution was washed three times with 30, 30, and 20 ml of 0.1 N H_2SO_4; the washes were combined and briefly evaporated (rotary evaporator, 38°C) to remove residual chloroform. The resulting solution and corresponding control (equal volume of 0.1 N H_2SO_4) were mixed with dry artificial diet and freeze-dried because alkaloids decomposed when dried in a forced-air oven at 28°C. The alkaloid diet had a concentration of alkaloids equivalent to a natural diet consisting of about 50% *Penstemon* in spring or 100% *Penstemon* in summer (alkaloid concentrations decrease by about half from spring to summer).

Feeding Trials. We conducted the *Lespedeza* diet experiment in autumn 1983, and the *Penstemon* feeding experiment the following spring. For each study, prairie voles were obtained from a colony maintained at the University of Illinois; colony founders came from nearby oldfields. Because we have been unable to breed meadow voles under laboratory conditions, we live-trapped pregnant females in a nearby tallgrass prairie, brought them into the laboratory, and used the ensuing young for the feeding trials. We used the growth of weanling voles as a bioassay of diet quality. Young were weaned at 18 days old and fed a transition diet of rabbit pellets mixed with a control or experimental artificial diet. We divided litters between control and experimental diets to eliminate confounding genotypic or maternal effects. When 20 days old, young were paired with nonsiblings and weighed. We maintained the voles in plastic shoebox cages with hardwood chip bedding and cotton nesting material, at room temperature (22–25°C) on a 15:9 light–dark cycle. Artificial diets and demineralized water were provided ad libitum. We weighed the animals at three- to four-day intervals for three weeks.

Many plant phenolics and alkaloids assimilated by mammals are metabolized by conjugation with glucuronic acid and are then excreted in the urine. We found previously that uronic acid excretion may be used as an index of phenolic detoxication metabolism (Lindroth and Batzli, 1983). To check for evidence of biochemical detoxification of *Lespedeza* phenolics or *Penstemon* alkaloids, we collected 24-hr urine samples from our animals when 42 days old and analyzed these as described in Lindroth and Batzli (1983).

Digestibility Trials. We conducted digestibility trials in order to determine the general mode of action of the plant compounds. Voles were maintained in the same metabolic cages as used for urine collections and fed an artificial diet and water ad libitum for four days. At the end of the trials we dried and weighed feces and excess food and calculated digestibilities as the difference between intake and output. We analyzed samples of food and feces for total organic nitrogen by acid digestion and determination of ammonia by the Nessler method (Association of Official Analytical Chemists, 1975). We did not conduct digestibility trials for all of the voles in the *Penstemon* feeding trial because some of those animals were required for other purposes.

At the conclusion of the digestibility trials, voles were sacrificed, necropsied, and the gastrointestinal tract removed. The carcasses were freeze-dried and extracted with petroleum ether (30–60°C bp) to determine fat content.

RESULTS

Palatability. Fresh *Lespedeza* and *Penstemon* leaves were poorly palatable to both species of voles; ≤ 0.15 g dry weight were consumed (Table 1). Calculations from data in Batzli and Cole (1979) indicate that prairie voles would consume about 3.5 g dry weight of alfalfa in a similar trial. In each trial, the variability in consumption was quite high, with one to several animals showing no consumption. A two-way analysis of variance revealed no significant effects due to vole species ($F_{1,20} = 1.43$, $P = 0.25$), plant species ($F_{1,20} = 2.43$, $P = 0.13$), or interaction ($F_{1,20} = 0.50$, $P = 0.49$).

Growth. The initial (5 day) growth rate of prairie voles on the *Lespedeza* diet was 0.22 ± 0.11 g/day, significantly less than the 0.81 ± 0.05 g/day of control animals ($t_{18} = 4.90$, $P < 0.001$). However, by the end of the trial, voles on the two diets had attained similar body weights (Figure 1). Initial growth rates of meadow voles were also different, 0.30 ± 0.06 and 0.64 ± 0.08 g/day, respectively, for voles fed the *Lespedeza* or control diets ($t_{18} =$

TABLE 1. MEAN CONSUMPTION OF FRESH *Lespedeza* AND *Penstemon* LEAVES BY ADULT VOLES IN PALATABILITY TRIALS[a]

	Consumption (g dry wt ± SE)	
	Lespedeza	*Penstemon*
Prairie voles	0.13 ± 0.05	0.02 ± 0.02
Meadow voles	0.15 ± 0.06	0.11 ± 0.05

[a] (ANOVA showed no significant differences among means at $P < 0.10$). Sample sizes were six for each treatment.

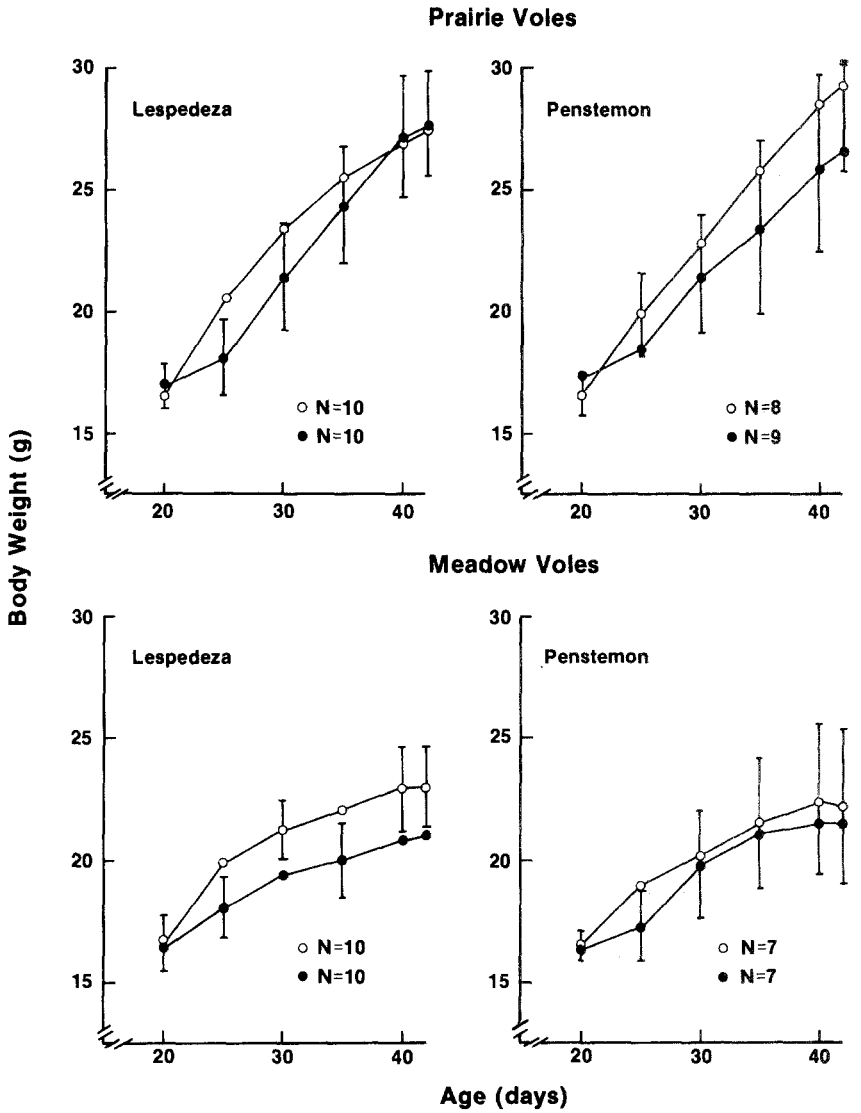

FIG. 1. Growth of weanling prairie voles and meadow voles fed control (○) or experimental (●) diets. Vertical lines indicate the largest 95% confidence intervals.

3.39, $P < 0.001$). At the conclusion of the trial, meadow voles fed *Lespedeza* weighed significantly less than control animals. Moreover, meadow voles as a group grew less than did prairie voles. A two-way analysis of variance of final weights showed that the main effect of vole species was significant, but the effects of diet and species–diet interaction were not (Table 2).

TABLE 2. *P* VALUES FROM TWO-WAY ANOVAS FOR RESULTS OF EXPERIMENTS ON PRAIRIE VOLES AND MEADOW VOLES FED DIETS WITH *Lespedeza* OR *Penstemon* EXTRACTS

Analysis	Source of variation		
	Species	Diet	Interaction
Lespedeza trials			
Final body weight	<0.001	0.636	0.408
Body fat content	0.537	0.181	0.514
Ingested dry matter	0.327	0.012	0.862
Dry matter digestibility	0.860	<0.001	0.838
Digested dry matter	0.347	0.581	0.770
Apparent protein digestibility	0.031	<0.001	0.131
Protein digested	0.969	<0.001	0.835
Uronic acid excretion	0.088	<0.001	0.197
Penstemon trials			
Final body weight	<0.001	0.206	0.539
Body fat content	0.001	0.051	0.231
Ingested dry matter	<0.001	0.227	0.075
Dry matter digestibility	0.782	0.849	0.293
Digested dry matter	<0.001	0.216	0.041
Apparent protein digestibility	0.015	0.377	0.191
Protein digested	0.213	0.204	0.750
Uronic acid excretion	0.003	0.542	0.231

For prairie voles in the *Penstemon* feeding trial, initial growth rates were again significantly different, 0.22 ± 0.15 and 0.68 ± 0.15 g/day, respectively, for experimental and control animals ($t_{15} = 2.15$, $P < 0.05$). Body weights of voles fed the *Penstemon* diet exhibited considerable variability, so we observed no significant differences in weights of animals in the two treatments (Figure 1). Initial growth rates for meadow voles fed the *Penstemon* or control diet showed a similar trend, 0.17 ± 0.13 and 0.49 ± 0.10 g/day, respectively, but were not significantly different ($t_{12} = 1.87$, $P > 0.05$). Voles on the two diets showed similar body weights for most of the feeding trial (Figure 1). Two-way analysis of variance of final weights again showed that only the effect of vole species was significant (Table 2).

In the *Lespedeza* feeding trial, body fat content did not differ significantly between vole species or between treatment and control animals (Figure 2, Table 2). In the *Penstemon* trial, we also found no significant differences between treatment and control animals within each vole species. However, in a two-way analysis of variance, we found that the main effect of species explained a significant amount of the variation and the main effect of diet explained a marginally significant amount of the variation (Table 2). Thus prairie voles contained

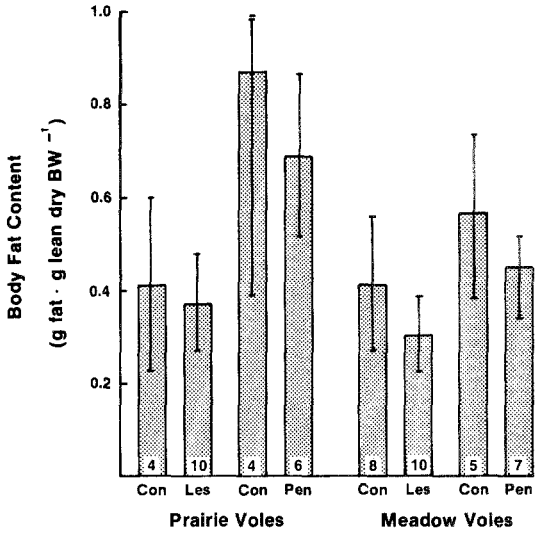

FIG. 2. Body fat content of prairie voles and meadow voles. Vertical lines show 95% confidence intervals; numbers represent sample sizes.

more body fat than meadow voles, and control animals tended to have more body fat than animals fed the *Penstemon* diet. Finally, fat content of all animals in the *Penstemon* trial tended to be greater than that of animals in the *Lespedeza* trial. Reasons for the differences between control animals in the two trials remain unclear, but could be due to differences in the control diets (ethanol vs. sulfuric acid added) or due to differences among animals used in the two trials. The latter possibility emphasizes the need to run control and experimental animals simultaneously in all feeding trials.

Consumption and Digestion of Diets. Voles fed diets containing *Lespedeza* phenolics tended to have higher consumption rates than did voles fed the corresponding control diet (Table 3). Overall digestibility of the *Lespedeza* diet was about 7% less than that of the control diet for both species of voles, but because intake rates were slightly higher in the former case, amounts of digested dry matter were similar for the two diets. Voles fed the *Lespedeza* diet digested only about 44% of the protein digested by voles fed the control diet. Increased consumption offset this difference only slightly; total protein digested by voles on the *Lespedeza* diet was about 51% of that digested by voles on the control diet. Two-way analyses of variance (Table 2) indicated that in general, prairie voles digested protein better than did meadow voles, and that for both species together, *Lespedeza* phenolics significantly increased food consumption and decreased total digestibility, protein digestibility, and amount of digested protein.

Prairie voles fed the *Penstemon* diet consumed more of the diet than did voles fed the control diet, but meadow voles did not show such a response

TABLE 3. MEAN (±1 SE) CONSUMPTION AND DIGESTIBILITY OF *Lespedeza, Penstemon,* AND CONTROL DIETS BY SUBADULT VOLES*

Species and diet	Ingested dry matter (mg/g $BW^{0.5}$/day)	Dry matter digestibility (%)	Digested dry matter (mg/g $BW^{0.5}$/day)	Apparent protein digestibility (%)	Protein digested (mg/g $BW^{0.5}$/day)
Lespedeza digestibility trials					
Prairie vole					
Control (10)	$905 \pm 43^{a**}$	58.3 ± 0.9^{g}	528 ± 26^{i}	77.5 ± 1.2^{o}	67.2 ± 3.2^{s}
Lespedeza (10)	$1076 \pm 44^{a,b**}$	51.3 ± 0.9^{f}	555 ± 29^{i}	33.3 ± 2.1^{m}	34.0 ± 3.0^{r}
Meadow vole					
Control (10)	$974 \pm 47^{a,b}$	58.3 ± 1.2^{g}	567 ± 28^{i}	71.3 ± 1.3^{n}	66.6 ± 3.5^{s}
Lespedeza (10)	1124 ± 92^{b}	51.7 ± 0.8^{f}	576 ± 42^{i}	32.2 ± 1.8^{m}	34.8 ± 2.5^{r}
Penstemon digestibility trials					
Prairie vole					
Control (4)	851 ± 27^{c}	57.6 ± 0.5^{h}	490 ± 13^{j}	77.2 ± 1.9^{q}	62.9 ± 3.1^{t}
Penstemon (6)	982 ± 32^{d}	58.5 ± 0.9^{h}	573 ± 18^{k}	75.8 ± 1.4^{q}	71.2 ± 2.0^{t}
Meadow vole					
Control (6)	1125 ± 44^{e}	58.1 ± 0.5^{h}	654 ± 24^{l}	65.4 ± 3.8^{p}	71.0 ± 6.6^{t}
Penstemon (7)	$1099 \pm 45^{d,e}$	57.5 ± 0.5^{h}	632 ± 27^{l}	71.9 ± 2.9^{p}	76.0 ± 5.1^{t}

[a] Values within each digestibility trial–performance category that bear different superscripts are significantly different (LSD test, $P < 0.05$). Sample sizes are shown in parentheses.

[b] Ingestion rates for prairie voles in the *Lespedeza* trial are significantly different at $P < 0.055$.

(Table 3). Both species of voles digested similar amounts of the two foods. Prairie voles on the *Penstemon* diet digested more dry matter than did control animals, reflecting their increased consumption rate; meadow voles showed similar rates for this parameter. Neither apparent protein digestibility nor amount of protein digested differed between voles fed the *Penstemon* or control diets. Two-way analyses of variance (Table 2) verified that meadow voles ate and digested more of both the control and *Penstemon* diets than did prairie voles. Meadow voles digested protein less well than did prairie voles, but because of their higher intake rates, the two species digested similar amounts of protein. The main effect of diet was not significant for any of the consumption/digestibility parameters for both species together. However, the interactive effect was significant or nearly so for ingested and digested dry matter and suggests that those two vole species respond differently to the presence of *Penstemon* alkaloids in their food.

Uronic Acid Excretion. Prairie voles and meadow voles on the *Lespedeza* diet excreted 2.0 and 2.3 times, respectively, the amount of uronic acid excreted by control animals (Figure 3). Uronic acid excretion did not differ, however, between voles fed *Penstemon* or control diets. In this trial, meadow voles excreted less uronic acid than did prairie voles (Table 2).

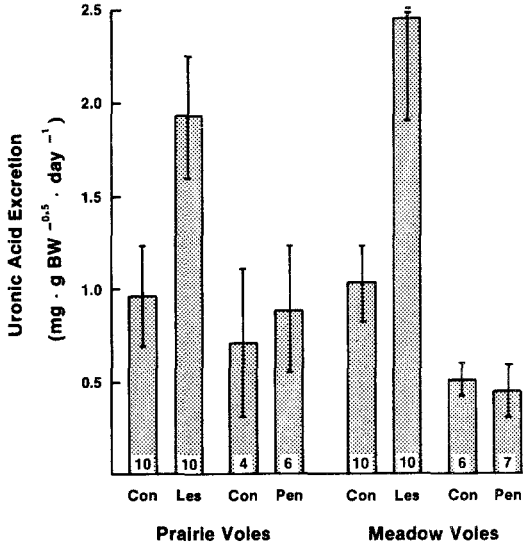

FIG. 3. Uronic acid excretion by prairie voles and meadow voles. Excretion rates are adjusted for weight-dependent average daily metabolic rates [$BW^{-0.5}$, Grodzinski and Wunder (1975)]. Vertical lines indicate 95% confidence intervals; numbers represent sample sizes.

DISCUSSION

That phenolics and alkaloids influence the palatability of plants to mammalian herbivores is well known (e.g., Kendall and Sherwood, 1975; Oates et al., 1977; Bryant and Kuropat, 1980; Lindroth and Batzli, 1984b). Thus it is likely that the phenolics in *Lespedeza* and the alkaloids in *Penstemon* made fresh leaves of these plants unpalatable to voles compared with a highly palatable alternative (rabbit pellets). Results from a previous study (Batzli and Cole, 1979) indicate that in an experiment like ours, prairie voles would consume 20–30 times more alfalfa than they did *Lespedeza* or *Penstemon* in our palatability trials. The reason that voles consume *Lespedeza* and *Penstemon* in the field but not in the laboratory is probably because more palatable, alternative foods are less available in the prairie.

Lespedeza cuneata contains condensed tannins (Bell et al., 1965), compounds that are too large for animals to assimilate and that are purported to reduce the digestibility of dietary protein by binding to the protein itself and/or to proteolytic digestive enzymes (Swain, 1979). Studies with cattle have shown that the dry matter digestibility of *Lespedeza* is inversely correlated with its tannin content (Donnelly and Anthony, 1969, 1970). Booth and Bell (1968), however, found that *Lespedeza* tannins (2% of diet) had no effect on growth or reproductive performance of rats.

Results from our study show that voles required about five days to develop at least partial acclimation to a *Lespedeza* diet. During this time growth rates were slow, most likely because of the physiological and/or deterrent effects of the tannins. After this initial phase, the growth rates of experimental animals more closely matched those of control animals. Cecal and ruminal microbes metabolize a variety of plant secondary compounds, and a change in the diet of an herbivore often induces a shift in the activity and composition of its microbial community (Allison, 1978). Voles have enlarged ceca, and although little is known about the microbial metabolism of tannins, it is possible that the shift in growth rates of voles fed *Lespedeza* diets occurred concomitantly with a change in their cecal microbial community.

Clearly, the most pronounced effect of *Lespedeza* tannins on voles was to greatly reduce the digestibility of protein. Voles fed *Lespedeza* diets digested only about half the amount of protein digested by control animals. Our previous research (Lindroth and Batzli, 1984b) showed that prairie voles require between 5 and 8% dietary protein for normal growth, and this may explain why the growth of voles in this study was not substantially affected. The protein level of our artificial diet was 10% (similar to that of *Lespedeza* in summer), so a 50% reduction in digested protein is near the lower limit of protein that will provide normal growth for voles. Meadow voles may have slightly higher requirements (as suggested by the work of Shenk et al., 1970), and this may

explain why the relative performance of meadow voles fed *Lespedeza* was poorer than that of prairie voles. These results may also explain the low palatability of fresh *Lespedeza* and the poor survival of voles in the preliminary experiment with a higher concentration of *Lespedeza* phenolics. Given that digested protein decreased by more than 50% on a diet with 50% of the normal concentration of *Lespedeza* phenolics, a pure *Lespedeza* diet would probably provide very little, if any, protein to voles.

This study indicates that *Lespedeza* tannins function primarily by disrupting digestive processes rather than by producing a toxic effect (to be toxic, a chemical must first be assimilated). Although uronic acid excretion doubled in animals fed *Lespedeza*, our previous work with assimilable phenolics showed uronic acid excretion to increase by one to several orders of magnitude (Lindroth and Batzli, 1983). Moreover, Booth and Bell (1968) were unable to detect the presence of phenolic degradation products in the urine of rats fed lower levels of *Lespedeza* tannins. Thus, most of the tannins we fed to voles were probably excreted bound to protein in the feces. The relatively small increase in uronic acid excretion probably reflects the presence of smaller, assimilable phenolics that were extracted and incorporated into the artificial diet along with the tannins.

These results lend support to digestibility reduction as the mode of action of tannins as proposed by Feeny (1976) and Rhoades and Cates (1976). This study is one of only a few that have actually demonstrated such a mode of action by tannins in wild animals. Effects of tannins are not limited to the disruption of digestive processes, however. As our earlier work (Lindroth and Batzli, 1984b) showed, tannins also may function as toxins (tannic acid) or feeding deterrents (quebracho) to voles. If tannin structure determines function (Zucker, 1983) it may be that at least for mammalian herbivores, condensed tannins (if consumed at all) operate as digestibility reducers, whereas hydrolyzable tannins do not. This possibility is consistent with the fact that condensed tannins are more refractory to chemical degradation than are hydrolyzable tannins (Roux et al., 1980).

Our data do not support the hypothesis that *Lespedeza* phenolics are more deleterious to prairie voles than to meadow voles. In fact, we found the opposite to be true. Thus some factor(s) other than differential response to phenolics must explain the difference in utilization of *Lespedeza* by prairie voles and meadow voles in tallgrass prairie.

Lindroth et al. (1986) recently identified the alkaloid in *Penstemon digitalis* as boschniakine, a pyridine monoterpene alkaloid. This alkaloid is similar to those that occur in related genera and species of the Scrophulariaceae (McCoy and Stermitz, 1983; Roby and Stermitz, 1984). Except that it appears to act as an attractant to cats [similar to neonepetalactone (Sakan et al., 1967)], little is known about the physiological effects of boschniakine. Pyridine monoterpene alkaloids in general exhibit a variety of physiological effects, including hypotensive, antiinflammatory, and muscular relaxant actions (Cordell, 1981).

Prairie voles and meadow voles differed in their initial response to the *Penstemon* diets; growth rates of prairie voles were significantly lowered (due to toxicity and/or feeding deterrence) whereas those of meadow voles were not. Following this initial phase, the growth rates of prairie voles increased, suggesting induction of enzymatic detoxication systems such as the mixed function oxidases, hydrolases, or glucuronyltransferases, all of which are involved in the metabolism of various alkaloids (Robinson, 1979). Although the final body weights of prairie voles fed control or *Penstemon* diets did not differ significantly (Figure 1), the fact that voles fed the latter diet had elevated intake rates (15%) indicates an increased metabolic cost in the processing of this diet, i.e., a "toxic" response. Growth rates of meadow voles fed the *Penstemon* diet also increased after the first five days (Figure 1), suggesting adaptation to the diet. However, meadow voles on the two diets did not differ for any of the intake/digestibility parameters (Table 3) and, unlike prairie voles, did not exhibit a metabolic cost in utilization of the *Penstemon* diet. Finally, we observed no evidence that *Penstemon* alkaloids were metabolized by conjugation with glucuronic acid. Levels of ingested alkaloids (0.005%) may simply have been too low for us to detect or the compounds may have been detoxified by an alternative biochemical pathway. Our results agree with those of Kendall and Sherwood (1975), who found that reed canarygrass containing various indole alkaloids was unpalatable to voles. Unlike our results, Kendall and Sherwood (1975) also showed that isolated alkaloids decreased consumption of a test diet. However, in a later study Kendall and Goelz (1981) found that intake of an artificial diet by meadow voles increased with nonlethal levels of gramine.

In general the performance of meadow voles on the various diets was inferior to that of prairie voles. Meadow voles tended to consume more food (Table 3) but grew less (Fig. 1) than prairie voles. Thus their efficiencies of conversion of ingested food were lower than those of prairie voles. The two species showed similar capacities to digest diet dry matter, but meadow voles generally digested a smaller proportion of dietary protein (Table 3). One possible explanation for the poor performance of meadow voles is that the artificial diet used in this study may not have been adequate for them. However, another set of meadow voles were fed rabbit pellets during the course of our experiments, and although their initial growth rates were faster, their final body weights and rates of intake for food and digested dry matter did not differ significantly from voles fed the artificial diet (Lindroth, unpublished data). Another explanation, which agrees with our previous experience with meadow voles, is that meadow voles simply perform (grow and reproduce) poorly under laboratory conditions.

That *Lespedeza* phenolics and *Penstemon* alkaloids tended to increase consumption rates by prairie voles is a surprising outcome for compounds that supposedly protect plants from grazing. In an earlier study (Lindroth and Batzli, 1984b), we observed a similar response for prairie voles fed quercetin or tannic acid. This anomaly can be explained in part by the fact that voles in our studies

had no alternative foods from which to choose, whereas in a field situation a variety of alternative foods (some perhaps less noxious) are available. Second, as has been suggested for insect herbivores (Price et al., 1980), longer periods of foraging will lead to longer exposure to predators, and this could indirectly reduce the impact of voles upon plants.

In conclusion, our results show that some of the secondary compounds abundant in the dominant forbs of a local prairie habitat influence consumption and digestibility of diets, but probably do not greatly reduce the performance (growth or survival) of voles when consumed at the levels we have observed. Although *Lespedeza* and *Penstemon* are not excellent foods in an absolute sense, they probably contain more nutrients or fewer chemical defenses than many alternative food plants. We do not yet know how *Lespedeza* phenolics or *Penstemon* alkaloids may influence vole performance when ingested with other secondary compounds within the same plant (e.g., phenolics in *Penstemon*) or in a mixture of plants (e.g., *Lespedeza* tannins may disrupt digestion of other forage plants as well, all of which have lower levels of protein than *Lespedeza*). These compounds probably place an upper limit on the amount of any one species that can be consumed, thereby enforcing a generalist feeding strategy by voles. Finally, we see once again that mammalian herbivores have nutritional needs and adaptations that differ among closely related species. These differences should be recognized and considered in studies assessing the role of forage quality in the dynamics of herbivore communities.

FEEDING RESPONSES OF SNOWSHOE HARES (*Lepus americanus*) TO VOLATILE CONSTITUENTS OF RED FOX (*Vulpes vulpes*) URINE

THOMAS P. SULLIVAN[1] and DOUGLAS R. CRUMP[2]

(Received February 20, 1985; accepted July 16, 1985)

Abstract—This study investigated the influence of the volatile constituents of red fox (*Vulpes vulpes*) urine in suppressing feeding by snowshoe hares (*Lepus americanus*) on coniferous tree seedlings. Pen and field bioassays indicated that the odor of fox urine and its principal component, 3-methyl-3-butenyl methyl sulfide, had a negative effect on feeding behavior of hares. The other sulfur-containing compounds, 2-phenylethyl methyl sulfide and 3-methylbutyl methyl sulfide, as well as six other constituents, were not effective. Synthetic urine mixtures composed of eight and nine volatile constituents, respectively, did not suppress feeding in pen bioassays. However, the mixture of eight compounds in a field bioassay did result in significantly fewer seedlings being eaten by hares than in the control. 3-Methyl-3-butenyl methyl sulfide may act as an interspecific chemical signal which induces a fear or avoidance response in hares. Additional work is required to determine the optimum concentration and release system for 3-methyl-3-butenyl methyl sulfide to be used as a mammalian semiochemical in crop protection.

Key Words—Red fox urine, snowshoe hare, crop protection, sulfur-containing compounds, kairomones, forestry, volatile constituents, feeding suppression, bioassays, synthetic urine mixture, interspecific communication, *Vulpes vulpes*, *Lepus americanus*, 3-methyl-3-butenyl methyl sulfide.

INTRODUCTION

Chemical communication among mammals may involve the use of scent gland secretions, feces, and urine. A major mode of olfactory communication in the

0098-0331/86/0300-0729$05.00/0

Canidae is urination. Volatile chemical constituents have been identified in the urine of the red fox (*Vulpes vulpes*) (Jorgenson et al., 1978; Wilson et al., 1978; Bailey et al., 1980) and the wolf (*Canis lupus*) (Raymer et al., 1984). The red fox has also been reported to communicate chemically via the supracaudal gland (Albone and Flood, 1976) and anal sac (Albone and Perry, 1976).

On a behavioral basis, synthetic urinary constituents have induced marking behavior in wild red foxes (Whitten et al., 1980). The major sulfur compound, 3-methyl-3-butenyl methyl sulfide, along with 2-phenylethyl methyl sulfide, are responsible for the characteristic odor of fox urine (Wilson et al., 1978). The former compound, in addition to other sulfides, has also been reported in wolf urine (Raymer et al., 1984). Bailey et al. (1980) reported the presence of 3-methylbutyl methyl sulfide in red fox urine. Thus, these odorous compounds presumably play an important role in social communication, particularly for a solitary species such as the red fox. However, are these compounds meaningful to other species such as mammalian prey?

Certain mustelid scent compounds have suppressed feeding by snowshoe hares (*Lepus americanus*) (Sullivan and Crump, 1984), presumably because of a predator-induced "fear response" in the prey species. Sullivan et al. (1985a) reported that several predator odor preparations reduced feeding on coniferous tree seedlings by hares. Of the urines tested, red fox produced the most effective short-term suppression of feeding (Sullivan et al., 1985a). Reduction or elimination of seedling destruction by hares is a necessary prerequisite to successful forest renewal in many parts of the boreal forest of North America. Thus, this study reports on the influence of the volatile constituents of red fox urine in suppressing snowshoe hare feeding on coniferous tree seedlings.

METHODS AND MATERIALS

Pen Bioassays. Bioassays were conducted at the Applied Mammal Research Institute, Langley, B.C., Canada. The bioassay enclosure (9.15 × 18.3 m) was composed of three sections or pens set in a natural environment (see Sullivan and Crump, 1984). The entire enclosure was covered by a fiberglass roof to eliminate effects of adverse weather. The control and experimental pens (A and B) were enclosed by polyethylene on the walls to keep odors within the respective treatment sections. These pens had all natural vegetation cleared prior to start of trials. Douglas fir (*Pseudotsuga menziesii*) bark mulch covered the ground of each pen to a depth of 20 cm. Each pen had three experimental units, each composed of 10 styrofoam blocks to anchor coniferous seedlings. One-year-old (nursery stock) lodgepole pine (*Pinus contorta*) seedlings were used in all trials with one seedling per block. Thus, there was a maximum of 30 seedlings in each of the control and treatment pens (A or B) at the start of a

given trial. Lodgepole pine is preferred by snowshoe hares over all other coniferous species (see Sullivan et al., 1985a).

The natural habitat (pen C) was not cleared of native vegetation and provided cover and some grasses and forbs for hares. Thus, this pen served as a potential refuge area for hares. Access of hares to pens A or B from pen C was through 30 × 30-cm openings in each adjoining wall. Hares moved freely among all three pens and new animals were always allowed at least five to seven days to acclimate to this experimental configuration. To exert adequate feeding pressure on the experimental material and keep social interactions at a minimum, two hares were used in each trial. All hares used were from our northern study areas at Prince George, B.C. Hares were replaced at regular intervals to overcome potential variability and habituation among animals. Rabbit pellets, grass hay, and water were available ad libitum throughout these trials.

One pen bioassay (screening trial) was conducted for each fox urine compound or test mixture. Real fox urine was tested in an earlier pen bioassay as reported by Sullivan et al. (1985a).

Field Bioassays. Spring field trials (A and B) of red fox urine odors were conducted at Tabor Mountain, 25 km southeast of Prince George, B.C., during April to June 1984. This study area was located in the subboreal spruce biogeoclimatic zone (Krajina, 1969). It was overgrown with deciduous brush species, mainly willow (*Salix* spp.) and Sitka alder (*Alnus sinuata*), with some aspen (*Populus tremuloides*), black cottonwood (*P. trichocarpa*), and paper birch (*Betula papyrifera*); and had experienced coniferous plantation failure because of feeding damage by snowshoe hares. The hare population cycle peaked in this area in 1980–1981 but the peak was much more of a plateau (Sullivan and Sullivan, in preparation) than that described elsewhere (Keith and Windberg, 1978). Thus, the population of hares on Tabor Mountain continued to inflict severe damage to planted coniferous seedlings during the spring of 1984, thereby providing a suitable study area for testing our fox urine compounds.

Additional trials at Prince George may not have subjected seedlings to heavy feeding pressure as the low point in the 10-year hare cycle approaches, with increased numbers not expected before 1987–1988. Thus, fall field tests were conducted in a 4.5-hectare enclosure at the Pineridge Forest Nursery, 130 km northeast of Edmonton, Alberta. The enclosure was composed of 2-m-high steel mesh and was buried in the ground to a depth of 30 cm. This study area was located in the boreal mixed wood zone (Strong and Leggat, 1981) with jack pine (*P. banksiana*) and aspen being the main tree species. Wild rose (*Rosa* spp.) and Saskatoon berry (*Amelanchier alnifolia*) were the dominant shrub species. Within this area, four (30 × 30 m) blocks were established and separated by at least 100 m. In July 1984, each block was cleared of trees and scarified in a manner similar to a typical logging and site preparation prescription. After planting, these blocks acted as plantations of coniferous tree seedlings in our

field trial. The enclosure was stocked with snowshoe hares captured locally and from Prince George. This stocking allowed us to simulate a peak population (5–8 hares/hectare; Keith and Windberg, 1978) of hares, thereby providing a rigorous test of various predator odor compounds in a "field" situation. Both spring and fall represent periods when coniferous seedlings are particularly vulnerable to snowshoe hare feeding attacks. Snow cover is not adequate to protect seedlings, and alternative summer herbaceous foods are not available.

Fox Urine Compounds. Volatile constituents from red fox urine were prepared: 3-methyl-3-butenyl methyl sulfide according to Wilson et al. (1978); 2-phenylethyl methyl sulfide by alkylation of the corresponding thiol (von Braun et al., 1929), which was obtained from 2-phenylethanol via the Bunte salt method of El-Hewehi and Taeger (1958); and 3-methylbutyl methyl sulfide from 3-methylbutyl bromide using lithium thiomethoxide according to Wilson et al. (1978). These and 4-heptanone, 6-methyl-5-hepten-2-one, benzaldehyde, acetophenone, 2-methylquinoline, and geranylacetone (available commercially) were tested in pen bioassays. A synthetic mixture was prepared according to the composition of compounds (8) reported by Wilson et al. (1978) and Whitten et al. (1980). A second mixture, containing 9 compounds and incorporating 3-methylbutyl methyl sulfide in equal proportion with 3-methyl-3-butenyl methyl sulfide (i.e., 50 mg/liter solution), was also prepared and tested in pen bioassays. No odor fixative was added to either of these test mixtures. Real fox urine, collected and frozen prior to use (Triple D Game Farm, Kalispell, Montana), 3-methyl-3-butenyl methyl sulfide, and two test mixtures were also tested in field bioassays. Purity of synthesized compounds ranged from 45% to 98%.

Except for the real fox urine dispensed in 5-ml plastic vials in spring trial A, all compounds were dispensed in 140-μl capillary tubes (75 mm in length), one tube (or vial) attached by a plastic twist-tie to each seedling. The capillary tubes protected the compounds from adverse weather conditions (in field bioassays) and maintained the respective odor around the seedlings for optimum evaluation purposes. Approximately 30 mg of each compound (neat) or test solution was placed in a given capillary tube using a 1-ml microsyringe with 20-gauge needle. A capillary tube was attached to each control seedling to complete the design of a given experiment.

Spring Field Trial A. Each of two blocks (each 400 m^2 in area and separated by 100 m) was planted with 50 (5 $\times$ 10) two-year-old (nursery stock) lodgepole pine seedlings on April 22, 1984, at Tabor Mountain. One block served as a control and the other had real fox urine dispensed in vials. These vials were not protected from prevailing weather conditions, and so fresh urine was added each time the seedlings were checked for feeding damage by hares (days 5, 8, 12, 19, and 25). This trial was terminated on day 25 (May 17), at which time no control seedlings remained. In all trials, feeding (clipping) on

the terminal shoot was considered as mortality to a given seedling. Coniferous seedlings rarely recover from terminal feeding damage, and even if they do, growth and form of the young tree are usually severely impaired.

Spring Field Trial B. Because of the late spring at Tabor Mountain, another trial was initiated on May 17 when four blocks were established and planted in an identical manner to those described above. Blocks were assigned treatments as follows: control, real urine, synthetic urine mixture (8), and 3-methyl-3-butenyl methyl sulfide. Hare browsing of seedlings was checked on days 5, 12, 17, and finally on day 23 (June 9) when the experiment was terminated. Hares had switched to summer herbaceous foods, and hence were no longer feeding on coniferous material.

Fall Field Trial. Each of the four blocks (each 900 m^2 in area) at the Pineridge Forest Nursery was planted with 100 (10 × 10) one-year-old (nursery stock) lodgepole pine seedlings on October 3, 1984. Blocks were assigned treatments as follows (in accordance with available amounts of compounds): control, real fox urine, split block of 50 (5 × 10) seedlings with synthetic mixture (8) and 50 seedlings with synthetic mixture (9), and the fourth block had 30 (3 × 10) seedlings with 3-methyl-3-butenyl methyl sulfide. Browsing of seedlings was checked initially on day 9 and finally on day 20 (October 23) when the experiment was terminated. Snow had covered the majority of seedlings at this time, and the treatments were not designed to be tested through the winter. Monitoring (live-trapping) of snowshoe hares introduced into the enclosure indicated that at least 13 hares were present at the start of the trial. An additional 13 hares were added on day 9 for a total of 26 hares (5.8/ha) which represented a peak density of this herbivore.

Statistical Analysis. Comparison of the number of seedlings surviving in control and treatment blocks was analyzed by chi-square with significance levels $P < 0.05$ and $P < 0.01$.

RESULTS

Pen Bioassays. Of the sulfur compounds tested, 3-methyl-3-butenyl methyl sulfide was very effective in suppressing feeding by snowshoe hares (Figure 1). Control seedlings were completely eaten at the third day after survival rates of 20% and 16.7% at days 1 and 2, respectively. No treatment seedlings were eaten in the first two days. Upon removal of 3-methyl-3-butenyl methyl sulfide after the fourth day, hares readily consumed the unprotected seedlings. 2-Phenylethyl methyl sulfide suppressed feeding (80% survival) after one day but survival of seedlings declined sharply thereafter. This latter response was typical of a novel odor whereby hares react negatively to a new odor for one or two days before realizing that the volatile substance is apparently not biologically meaningful. 3-Methylbutyl methyl sulfide and the synthetic urine mixtures

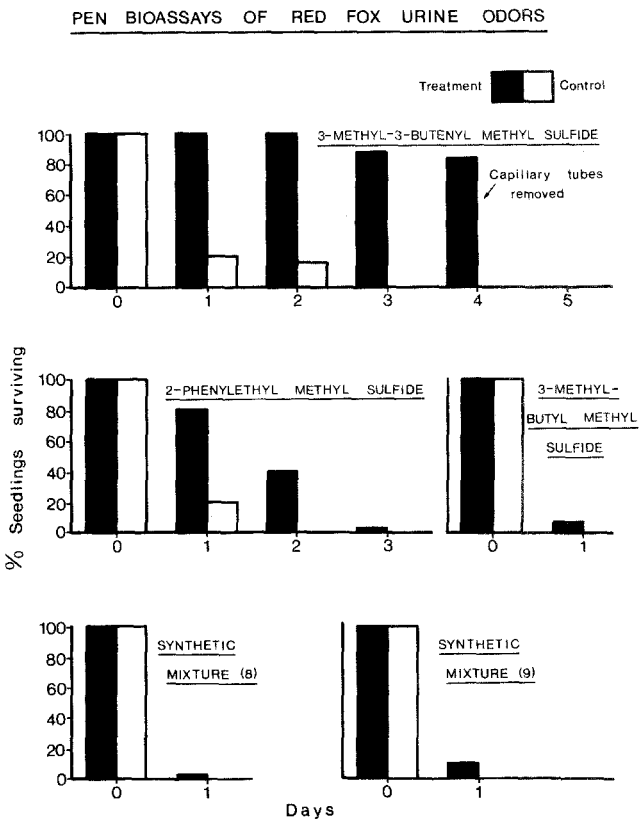

Fig. 1. Effectiveness of volatile constituents of red fox urine in suppressing snowshoe hare feeding on lodgepole pine seedlings in pen bioassays: 3-methyl-3-butenyl methyl sulfide, 2-phenylethyl methyl sulfide, 3-methylbutyl methyl sulfide, and the synthetic urine mixtures (8) and (9).

did not suppress feeding by hares in a pen situation. Individual bioassays of 4-heptanone, 6-methyl-5-hepten-2-one, benzaldehyde, acetophenone, 2-methylquinoline, and geranylacetone indicated that these compounds did not suppress feeding by hares.

Field Bioassays. In the spring trial A, real fox urine (in vials) suppressed feeding by hares compared with the control (Figure 2). This difference was significant ($P < 0.01$) and was maintained throughout the 25-day trial. As indicated in Figure 2, substantial rainfall occurred on days 10, 16, 21, and 22, and this may have contributed to the declining efficacy of the urine odor by dilution in the vials. This was particularly noticeable after day 12, since prior to this check, seedling survival had apparently stabilized at 82%.

To further test real urine and some of its constituents as repellents to feed-

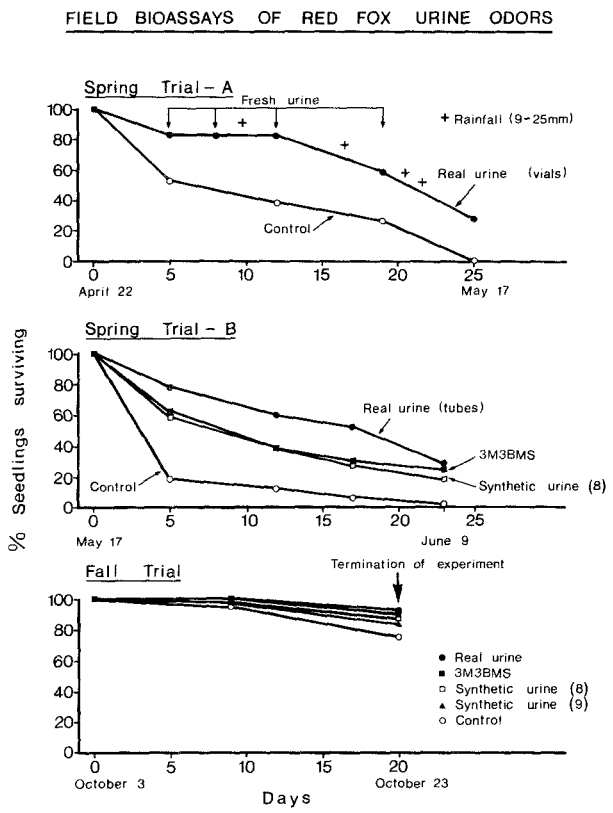

Fig. 2. Field efficacy of volatile constituents of red fox urine in suppressing snowshoe hare feeding on lodgepole pine seedlings: spring trial A, real urine (vials); spring trial B, real urine (capillary tubes), 3M3BMS (3-methyl-3-butenyl methyl sulfide), and synthetic urine mixture (8); fall trial, real urine (capillary tubes), 3M3BMS, and synthetic urine mixtures (8) and (9).

ing by hares, the spring trial B was initiated. Results of this trial are also illustrated in Figure 2. Again, real urine (in capillary tubes) was the most effective odor with significantly ($P < 0.01$) higher survival of seedlings than in the control block throughout the trial. Survival of control seedlings was reduced to 18% at day 5. In addition, real urine was significantly ($P < 0.05$) more effective than 3-methyl-3-butenyl methyl sulfide or the synthetic mixture (8) up to day 17. The difference between real urine and 3-methyl-3-butenyl methyl sulfide at day 5 approached significance ($P = 0.08$). There was little difference between these three odors at day 23. Both 3-methyl-3-butenyl methyl sulfide and the synthetic mixture (8) also significantly ($P < 0.01$) suppressed feeding by hares compared with the control block.

To further assess the negative effect of urine odors on snowshoe hare feeding, and to provide some degree of replication, the fall trial was conducted in habitat typical of coniferous plantations in the boreal forest. As a result, intensity of feeding was reduced compared with the spring trials (see Figure 2). There was little feeding up to day 9 in this trial but, following an introduction of more hares, significant differences among treatments appeared at day 20. Hares consumed more control seedlings (25%) than those in the real fox urine (8%) block ($P < 0.01$). In addition, the differences between the control block and 3-methyl-3-butenyl methyl sulfide ($P = 0.08$) and synthetic mixture (8) ($P = 0.07$) approached statistical significance and may certainly be biologically meaningful results. There were no significant differences among the various treatments.

DISCUSSION

This study has demonstrated that the odor of red fox urine and its principal volatile constituent, 3-methyl-3-butenyl methyl sulfide, will suppress feeding on lodgepole pine seedlings by snowshoe hares. This conclusion corroborates that obtained by Sullivan et al. (1985a) for red fox urine tested on hares in a short-term pen bioassay. Although field results were not as outstanding as those obtained with certain mustelid scent-gland compounds (Sullivan and Crump, 1984), suppression of feeding in the presence of real urine and 3-methyl-3-butenyl methyl sulfide was still highly significant when compared with a control. Pen bioassays clearly demonstrated that 3-methyl-3-butenyl methyl sulfide was the functional compound responsible for altering hare feeding behavior, of the eight volatile constituents identified by Jorgenson et al. (1978) and the additional 3-methylbutyl methyl sulfide reported by Bailey et al. (1980).

3-Methyl-3-butenyl methyl sulfide may be potentially regarded as a kairomone (Brown et al., 1970), since it presumably acts as a scent-marker signal to hares that a fox is, or was recently, in the area. As discussed for snowshoe hares and certain mustelids (Sullivan and Crump, 1984), this interspecific communication is of adaptive advantage to the hare if it avoids the marked area, and hence is less likely to be preyed upon. The red fox is an opportunistic predator whose diet is influenced by food availability. Several dietary studies of the red fox in North America indicate that their major prey is small rodents and lagomorphs (Errington, 1935; Scott, 1943; Scott and Klimstra, 1955; Pils and Martin, 1978). In boreal forest habitats during years of hare abundance, the diet of this canid is dominated by snowshoe hare (Jones and Theberge, 1983). Thus, 3-methyl-3-butenyl methyl sulfide may act as an interspecific signal between predator (fox) and prey (hare).

Vernet-Maury et al. (1984) reported that several volatile compounds, isolated from red fox feces (and urine) induced stress in laboratory rats. Of the

compounds tested, 3-methyl-3-butenyl methyl sulfide and 2-phenylethyl methyl sulfide did not cause stress. The result with the former compound is in marked contrast with our results for the hare–fox interaction. The presence of 3-methyl-3-butenyl methyl sulfide in wolf urine (Raymer et al., 1984) may explain the significant suppression of feeding by hares (Sullivan et al., 1985a) and black-tailed deer (*Odocoileus hemionus columbianus*) (Sullivan et al., 1985b) when tested with the urine odor of this other canid species. In addition, deer avoided food associated with red fox urine (Sullivan et al., 1985b).

It is not clear at this stage why real fox urine was more effective than 3-methyl-3-butenyl methyl sulfide and the synthetic mixture (8) in the second spring trial. If one or more components of real urine were missing from the synthetic mixture, then the conclusive results obtained by Whitten et al. (1980) for induction of marking by wild red foxes would not be expected. The eight compounds identified were mixed together in a test solution very similar to that used by Whitten et al. (1980). We did not include an odor fixative so as to eliminate any artificial smell associated with the urine. However, it may have been useful to include an inert binding compound such as squalene to retard volatility of the compounds, particularly the highly volatile 3-methyl-3-butenyl methyl sulfide and 2-phenylethyl methyl sulfide. The inclusion of 3-methylbutyl methyl sulfide was an attempt to improve the efficacy of synthetic urine by adding another compound. The latter compound had little effect compared with the original synthetic mixture (8). It should be noted that 3-methylbutyl methyl sulfide was tested as a novel odor and had no effect on hare feeding reported by Sullivan et al. (1985a). There was little difference between real urine and the synthetic mixtures as well as 3-methyl-3-butenyl methyl sulfide in the fall field trial.

The original hypothesis of Sullivan et al. (1985a) that the negative but transient response of hares to predator odors was due to evaporative loss of the active repellent compound(s) rather than habituation should be discussed in light of our results. Clearly, the survival of seedlings in both control and treatment blocks in the field declined over time. In the first spring trial (Figure 2), much of this decline might be explained by dilution of the urine by rainfall. However, in the subsequent trials, all treatments were dispensed in capillary tubes and were essentially weatherproof. If the decline in efficacy was due to habituation, then the differences between treatment and control should not have been maintained for periods of 25 days (spring trial A) and 23 days (spring trial B). Hares which habituate to an olfactory stimulus in a treatment area would presumably consume seedlings at a level comparable to the control situation. A sudden increase in consumption of treatment seedlings did not occur in these trials. Therefore, perhaps the concentration and release rates of compounds, particularly 3-methyl-3-butenyl methyl sulfide, is the critical factor in maintaining a predator-induced "fear response" in snowshoe hares. Additional work is required to determine the optimum concentration and release system for 3-methyl-

3-butenyl methyl sulfide to produce a functional avoidance response in snowshoe hares. Such investigation might help explain the poor efficacy of synthetic urine mixtures in pen compared with field bioassays.

The reduced intensity of feeding in the "open" plantation habitat (fall trial) compared with the overgrown habitat at Tabor Mountain was not surprising. In a habitat manipulation study, Sullivan and Moses (1986) reported a dramatically reduced abundance of hares in a scarified habitat, but the amount of feeding damage to planted coniferous trees was still unacceptable. This was the case in our study as well, where 25% of seedlings were destroyed after only 20 days. A scheme of integrated management is urgently required combining habitat alteration and predator odor repellents to reduce or eliminate feeding damage by hares and related herbivores. This study and those of Sullivan and Crump (1984) and Vernet-Maury et al. (1984) have clearly demonstrated the potential of mammalian–predator semiochemicals for use as area repellents to protect forest and agricultural crops.

Acknowledgments—We thank the Forest Research Branch of the Alberta Forest Service for financial support and provision of seedlings; and W. Kaiser, C. Robinson, and F. Keitsch for field assistance. We are grateful to Pineridge Forest Nursery, Alberta Forest Service, for the enclosure facility and assistance of P. Au and B. Court.

IDENTIFICATION OF CANTHARIDIN IN FALSE BLISTER BEETLES (COLEOPTERA, OEDEMERIDAE) FROM FLORIDA

JAMES E. CARREL,[1] JAMES P. DOOM,[2] and JOHN P. McCORMICK[2]

(Received April 9, 1985; accepted July 23, 1985)

Abstract—Cantharidin, a potent vesicant and antifeedant, is identified for the first time in two oedemerid beetles from the western hemisphere. Amounts of the substance per beetle were found to range from 2 to 7 μg in *Heliocis repanda* and from 15 to 35 μg in *Oxycopis thoracica*. Females had two to three times more cantharidin than males of the same species. Cantharidin loads of these beetles are sufficient to irritate human skin.

Key Words—Cantharidin, defense, chemical, vesicant, antifeedant, *Heliocis repanda*, *Oxycopis thoracica*, Coleoptera, Oedemeridae, sexual dimorphism.

INTRODUCTION

Beetles of the family Oedemeridae in Florida, Puerto Rico, Japan, and elsewhere occasionally cause severe skin blisters in humans (Herms, 1925; Vaurie, 1951; Fleisher and Fox, 1970; Kurosa, 1977; Arnett, 1984). Gentle manipulation can cause the insects to discharge vesicating droplets from the elytra and pronotum, but most cases of dermatitis arise after these "false blister beetles" are crushed on the body (Fleisher and Fox, 1970; Arnett, 1984). Patch tests using squashed beetles suggest that most oedemerid species can irritate human skin (Kurosa, 1958).

The vesicant in adult oedemerids is thought to be cantharidin (Arnett, 1984), the potent antifeedant widespread in "true blister beetles" (family Meloidae) (Carrel and Eisner, 1974), but evidence for this idea is scant. To our knowledge only one false blister beetle has been rigorously tested. Kurosa and

0098-0331/86/0300-0741$05.00/0

Watanabe (1958) identified pure cantharidin in extracts of *Xanthocroa waterhousei* Harold, a Japanese species, by mixture melting point as well as elemental and infrared spectral analyses. Based on gas chromatographic and mass spectral evidence, we here report that cantharidin also is present both in *Oxycopis thoracica* (Fabricius) and in *Heliocis repanda* (Horn) from central Florida.

METHODS AND MATERIALS

Insects. Nine *O. thoracica* adults were collected April 27, 1984, at UV lights at the Archbold Biological Station in Highlands County, Florida. Transported alive to our laboratory, they were placed by sex into two groups (N = 4 males, 5 females), weighed, and frozen.

Sixty-seven *H. repanda* adults caught from April 20 to May 10, 1984, while feeding on the flowers of dwarf chestnut, *Castanea pumila* (L.), outside the Doyle Conner Building in Gainesville, Alachua County, Florida, were preserved together in a vial of alcohol. Beetles were removed from the vial, air-dried for 0.5 hr, sexed (N = 31 males, 36 females), and then a subset (N = 40 beetles total) was placed by sex into eight groups of five individuals each. Each group was weighed and then frozen. To ascertain the amount of cantharidin leached from beetles, two aliquots (1 ml each) of the alcohol (13.2 ml total) used to preserve all 67 beetles were placed separately in the freezer.

Chemical Analysis. After thawing, beetles in each group were cut into several pieces and submitted as a group to acid hydrolysis and extraction (Carrel and Eisner, 1974; Carrel et al., 1985). Samples of alcohol were treated as extracts.

Cantharidin in each extract was determined by capillary gas chromatography with flame ionization detection (Carrel et al., 1985). A fused silica column (27 m × 0.329 mm ID) coated with 0.25-μm DB-5 (J&W Scientific, Rancho Cordova, California) was used in a Varian 3700 gas chromatograph with the injector and detector temperatures maintained at 190° and 320°C, respectively. The column was programmed from 100°C upon injection to 270°C at 20°C/min. Air, hydrogen, and helium flow rates were 300, 30, and 30 ml/min, respectively. A Hewlett-Packard 3390 integrator was used to quantify the chromatograms. Benzophenone (Aldrich Chemical, Milwaukee, Wisconsin) was used as an internal standard to verify the retention time of cantharidin and to permit accurate quantification of the amounts of cantharidin in unknown extracts. Authentic cantharidin from Inland Alkaloid, St. Louis, Missouri, served as a reference standard.

The identification of cantharidin as a component in oedemerid extracts was verified by gas chromatographic–mass spectrometric (GC-MS) analyses using a Carlo Erba 4160 capillary gas chromatograph coupled to a Kratos 25 mass spectrometer. The GC-MS data for extracts and the cantharidin standard were

obtained using a 0.25-μm methylsilicone capillary column (30 m $\times$ 0.25 mm ID) run at 60°C for 2 min, then programmed to 250°C at 15°/min with helium (2.5 ml/min) as the carrier gas. Electron impact (EI) mass spectra were collected at 70-eV ionizing voltage with the separator at 230°C and the source at 200°C. The EI spectra were acquired and processed by a Kratos 55 data system.

RESULTS

Cantharidin was detected in both oedemerid species we examined. Representative chromatograms of the extracts for each species are shown in Figures 1 and 2. GC-MS comparisons with the reference compound confirmed the authenticity of cantharidin in the extracts.

Quantitative measurements, presented in Table 1, reveal two major differences in the cantharidin content of individual oedemerids. First, *O. thoracica* adults each contained much more cantharidin (15–35 μg/beetle) than *H. repanda* adults (2–7 μg/beetle). Second, intraspecific comparisons show that females had two to three times more cantharidin in their bodies than did males. Because both species showed the same modest size dimorphism (males and females each weighed approximately 7 and 10 mg, respectively), the species and sexual differences are maintained when cantharidin amounts are expressed on a body weight basis (see Table 1). Cantharidin (72 μg total) in the alcohol used to preserve 67 *H. repanda* was omitted from our calculations; its inclusion would only slightly change our data for individuals of this species.

DISCUSSION

The results in this paper represent the first definitive demonstration of cantharidin in oedemerids from the western hemisphere. The amounts of cantharidin we detected in oedemerids (0.03–0.3% of beetle weight) are low in comparison to those in meloids (1% of beetle weight on average) (Dixon et al., 1963; Walter and Cole, 1967), but they are sufficient to irritate human skin (Sollman, 1948; J. Carrel, unpublished observations). If cantharidin is widespread in oedemerids, then at least in a biochemical sense there is nothing "false" about these blister beetles, as their common name suggests.

That cantharidin serves as a defensive function in oedemerids, much as it does in meloids (Carrel and Eisner, 1974), seems reasonable to propose. Our data in Table 1 suggest three specific topics for future research on the defensive chemistry of oedemerids. First, is the cantharidin content of individual beetles correlated with an aspect of their behavioral ecology? Our findings show that a nocturnal species, *O. thoracica*, contains more cantharidin than a strictly diurnal species, *H. repanda*. We suspect that beetles moving about freely in the

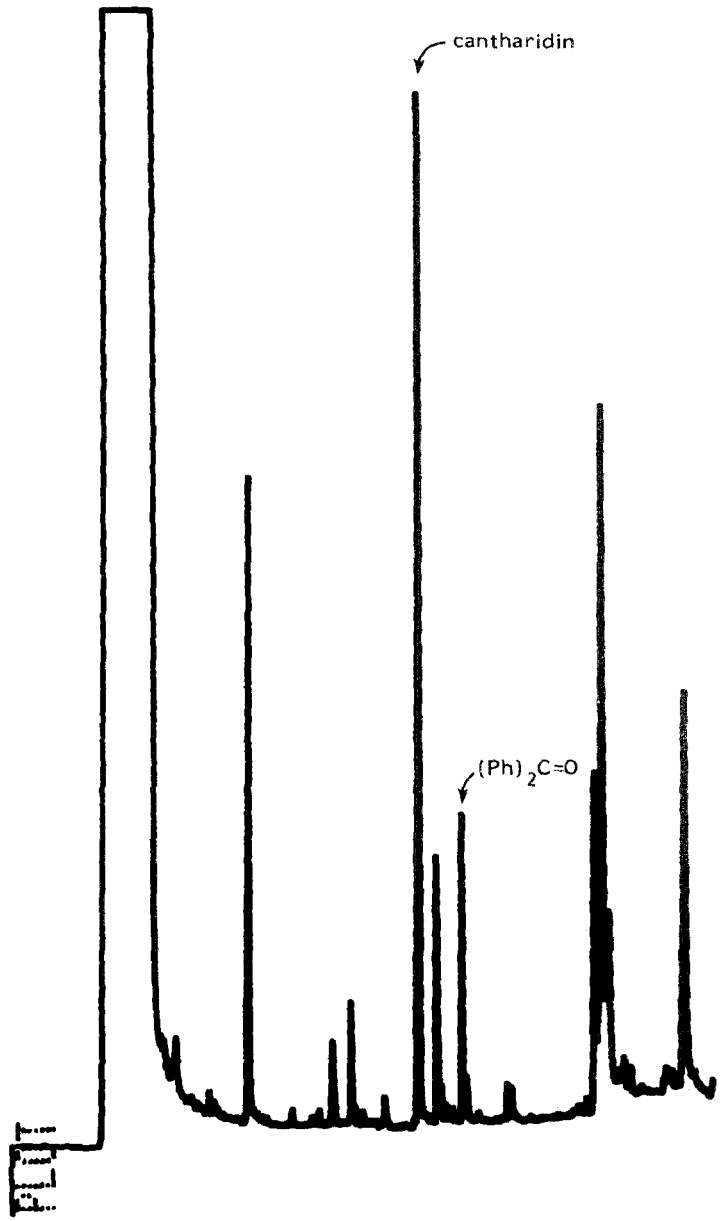

FIG. 1. Gas chromatogram showing the quantitation of cantharidin in an extract of five adult female *Oxycopis thoracica*. Labeled peaks of interest indicate an injection that was found to contain 211 ng cantharidin using 24.4 ng of added benzophenone as the internal standard. Retention times are 5.16 and 5.71 min, respectively.

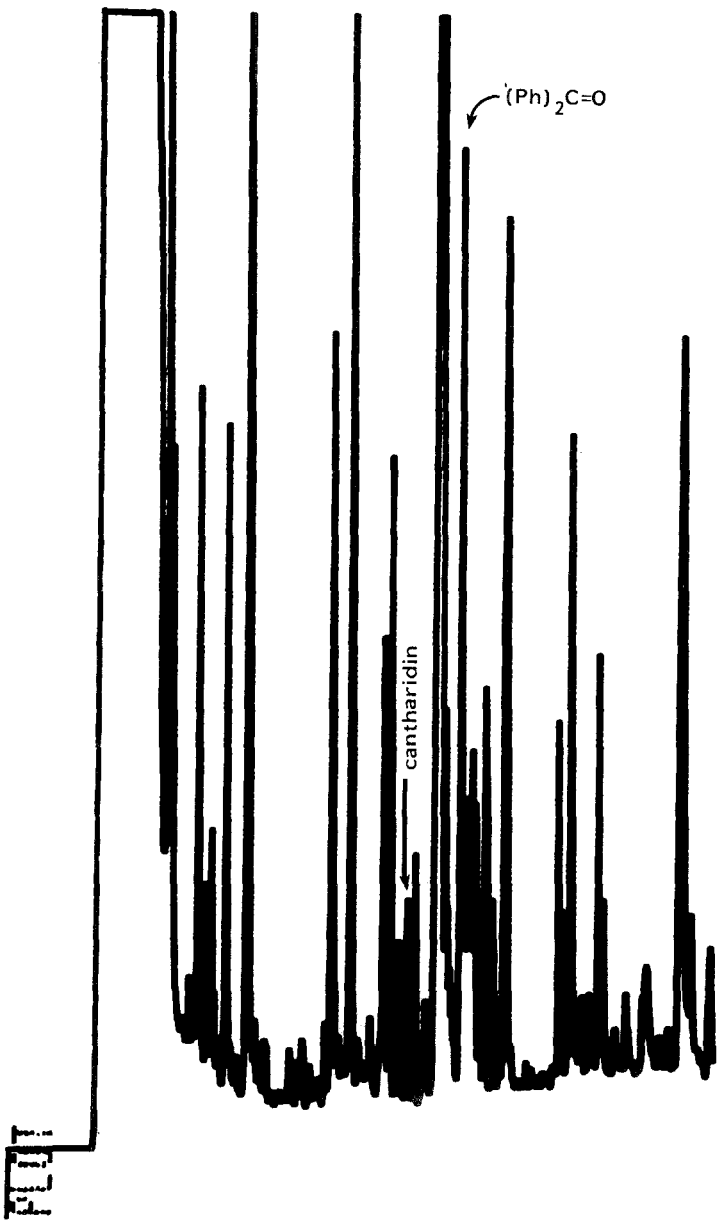

FIG. 2. Gas chromatogram showing the quantitation of cantharidin in an extract of five adult male *Heliocis repanda*. Labeled peaks of interest indicate an injection that was found to contain 34.3 ng cantharidin using 61.1 ng of added benzophenone as the internal standard. Retention times are identical to those in Figure 1.

TABLE 1. CANTHARIDIN IN OEDEMERID BEETLES FROM FLORIDA

Species	Sex	Number of samples analyzed	Beetle body mass (mg)[a]	Cantharidin[a]	
				μg/beetle	μg/mg of beetle
Oxycopis thoracica (Fabricius)	Male	1	6.7	15.5	2.3
	Female	1	10.4	35.2	3.4
Heliocis repanda (Horn)	Male	4	7.3 ± 0.4 [b]	2.1 ± 0.1 [b]	0.29 ± 0.03 [b]
	Female	4	10.3 ± 0.4	7.4 ± 0.8	0.72 ± 0.08

[a] Values are means ($\bar{X} \pm$ SEM) for samples containing four or five beetles.
[b] Adjacent values in a column are significantly different at $P < 0.01$ using Student's t-test.

dark might depend primarily on chemical mechanisms to deter predators, whereas their day-active counterparts might rely on a combination of visual and chemical defenses.

Second, what is the adaptive explanation for sexual differences in the cantharidin content of oedemerids? Perhaps female beetles have more of the substance in order to achieve a greater degree of protection for themselves and for the gametes they harbor than that enjoyed by males. A similar situtation exists in the meloid *Epicauta pennsylvanica* (Carrel, 1971), but the opposite is true for several other meloid species (Sierra et al., 1976).

Third, what is the source of cantharidin in oedemerids? Is it the case, as in meloids (Sierra et al., 1976), that male beetles biosynthesize the substance de novo from farnesyl pyrophosphate and then transfer it during mating to females? Or do they obtain cantharidin through dietary means? We are conducting predation and biosynthetic studies with oedemerids and meloids to answer these questions.

Acknowledgments—We thank R.M. Brattain, M.A. Deyrup, R.E. Woodruff, and H.R. Arnett, Jr., for collecting and/or identifying beetles; R.H. Rice for performing GC-MS analyses; G.R. Buckingham for suggesting the problem to us; and the Archbold Biological Station for providing research facilities. Abstract—The defensive secretion of the lubber grasshopper, *Romalea microptera*, shows extreme chemical variation among individual adults of the same sex within a single wild population. Certain phenolic compounds were absent in some individuals and present in others. Concentrations of compounds, when present, varied over two to three orders of magnitude. Chemical variation attributable to individuals accounted for 60–88% of the total quantitative variation and was evenly contributed by all individuals in both sexes. Cluster and regression analyses showed no discernible predictable patterns in the defensive secretion variation. The specificity of chemical cues used by predators may explain why these defenses are so idiosyncratic.

Key Words—Lubber grasshopper, *Romalea microptera* (= *guttata*), Orthoptera, Romaleidae, phenolic secretion, inter-individual quantitative and qualitative variation, idiosyncratic patterns.

INTRODUCTION

Arthropod defenses often involve chemical secretions whose taste, odor, or irritancy command rapid predator attention (Blum, 1981). Successful defense is

assumed to require predator recognition of relatively predictable chemical cues, and subsequent avoidance of prey. These allelochemicals are often viewed as characteristic, species-specific signals of limited variability (Brower and Brower, 1964; Whittaker and Feeny, 1971; Rothschild, 1973). Consequently, studies on chemical variation in defensive secretions have primarily focused on species differences and secondarily on population differences (Tschinkel, 1975; Pasteels et al., 1983; Prestwich, 1983; Pasteels and Gregoire, 1984). Variation between individuals within a population is rarely examined, and the amount of this variation is generally unknown (Blum, 1981). The extent to which chemical variation occurs and the ecological scale at which it takes place have considerable bearing on how such defenses may operate. For example, it will affect how predators may perceive and respond to chemically defended prey and how selection for and adaptation against such predators may operate.

The lubber grasshopper, *Romalea microptera* Beavois (Orthoptera; Romaleidae) (= *R. guttata* Houttyun; Kevan, 1980) is an aposematic, generalist herbivore that is unpalatable to a number of different predators (Whitman et al., 1986). This insect produces a principally phenolic secretion from metathoracic glands. The secretion is produced as a froth generated by respiratory air from the metathoracic spiracles. The pooled, frothy, metathoracic spiracular secretion has been previously examined chemically and has also been shown to be repellent to certain ants (Eisner et al., 1971). In contrast to pooled samples, we analyzed metathoracic secretions from individuals. We wished to know whether or not individuals within a defined population showed any significant quantitative or qualitative variation in these chemical defenses. We also wanted to know whether or not such variation, if any, showed predictable patterns.

METHODS AND MATERIALS

Secretion Collection. Metathoracic glandular secretions were collected from sexually mature males and females in a single wild population occurring within a 10-m-diameter area of early successional habitat in Athens, Georgia. All individuals were sampled within a 15-min period. Secretions were collected from individuals in the field by gently squeezing the thorax while applying a microcapillary (10 μl) to the metathoracic spiracular orifices. Capillaries were sealed in the field and then stored cold ($-10°C$). Quantity and quality of secretion stored in this manner did not change over six months. Fresh live weight (± 0.01 g) of the insect and the volume of secretion collected (± 0.25 μl) were also recorded.

Qualitative Secretion Analysis. Compounds were identified by gas chromatography–mass spectroscopy. Splitless injection (10 psi) capillary GC-MS of undiluted secretion and ether extracts (2 μl) from pooled secretions of male or female insects were carried out on a Finnigan 4021 using a 30-m $\times$ 0.3-mm-

ID DB-5 fused silica bonded phase column (J&W), programmed at 50 °C for 1.5 min, then 100°C to 250°C at 15°C/min. The mass spectrometer was operated in EI mode at 70 eV, 1400 V and 10^{-7} amp/V. Scanning was done at 45–350 amu with 1.5 sec/scan. Spectra were identified using libraries and confirmed with authentic samples. Identified compounds were reconfirmed in samples by retention time and co-chromatography using GC (Varian 6000) with on-column injection, flame ionization detection, and the same conditions as GC-MS, and using HPLC.

Quantitative Secretion Analysis. Secretions diluted to 1% in 18 mohm deionized water were analyzed by gradient reverse-phase HPLC (Varian 5500) using a 15-cm × 4-mm-ID C_{18} tri-methyl end-capped bonded silica column (5 μm) (Varian Micropak HCN-N-Cap 5) with a 4-cm × 4-mm-ID guard column (Varian Universal) packed with the same type of phase (Vydac SC reverse phase), and kept at 35°C. A convex solvent elution gradient of water, methanol, and 1% H_3PO_4 was used. Gradient commenced at 80:15:5 and finished at 20:75:5 composition, respectively. Peaks were detected at 275 nm. Stop-flow spectral scanning was used to confirm absorption maxima of peaks with some samples. Samples (three replicates of 10 μl of a 1 or 2% dilution of the secretion of each individual) were spiked with a fixed amount (56.7, 157, or 201 ng) of 4-hydroxybenzoic acid as an internal standard. Repetitive analyses of pooled secretions (N = 30 females or 20 males), collected at the same time and place as secretions from individuals, showed that retention times were accurate to ±1% (P = 0.95) and peak heights were accurate to ±10% (P = 0.95). Minimum detectable quantities per injection were: hydroquinone, 3.4 ng; *p*-benzoquinone, 23.7 ng; phenol, 3.8 ng; catechol, 4.1 ng; guaiacol, 2.5 ng; 4-methoxybenzaldehyde, 0.5 ng; unknown, 1.2 ng as 4-hydroxybenzoic acid equivalents. Peak heights were measured by an integrator (Varian 402). Data analysis was carried out on an IBM 4371 using CMS-SAS statistical packages.

RESULTS

Components of Pooled Secretions. GC-MS analysis of pooled secretions showed that they were exceedingly complex. Consequently our subsequent analyses focused on the 'phenolic' compounds and an unknown that comprised the major components detected by HPLC/$UV_{275\,nm}$ and GC-FID. Some of the identified compounds were similar, or identical, to those reported previously from pooled secretions (Meinwald et al., 1968; Meinwald and Hendry, 1969; Eisner et al., 1971). For example, we found phenol, hydroquinone, *p*-benzoquinone, guaiacol, and romallenone—although we did not quantify the last component. However, there were some notable qualitative differences in our pooled samples as compared to previous studies. We did not detect *p*-cresol, 2,5-dichlorophenol, or the ketones isophorone and verbenone found by Eisner

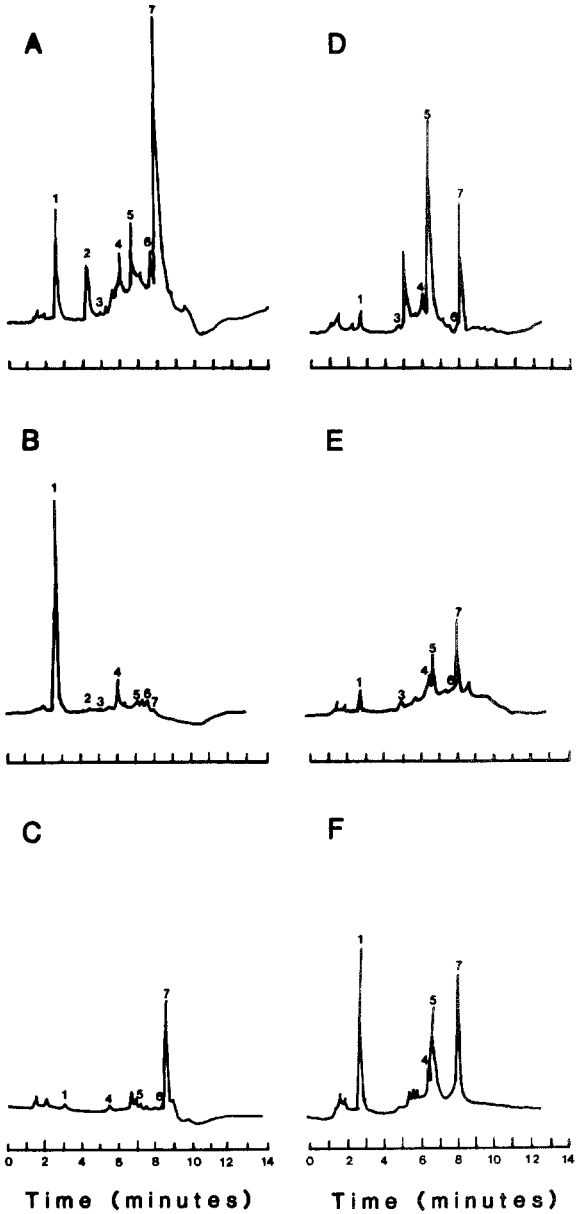

FIG. 1. HPLC traces (0.2 μl) of secretions of *Romalea microptera*: A, pooled females (N = 30); B, C, individual females; D, pooled males (N = 20); E, F, individual males. 1, hydroquinone; 2, catechol; 3, *p*-benzoquinone; 4, phenol; 5, guaiacol; 6, 4-methoxybenzaldehyde; 7, unknown. The internal standard peak has been deleted for clarity. Missing peak numbers denote concentrations below detectable limits.

et al. (1971). Since the halogenated phenol was purported to be a sequestered herbicide degradation product (Eisner et al., 1971; Berger, 1976), its absence in our samples, collected in an unsprayed area, is not surprising. We detected catechol and 4-methoxy benzaldehyde as major components not previously reported, and an unknown major component detected by HPLC/$UV_{275\,nm}$ that we are presently unable to analyze by GC or GC-MS.

Qualitative Variation among Individuals. The compounds identified in pooled secretions were quantified in secretions from 10 female and 11 male individual insects from the same population, using HPLC. Secretions from individuals differed substantially from pooled secretions for both males and females (Figure 1). Secretions from certain individuals lacked detectable amounts of some compounds that were found in other individuals (Table 1). In particular, males were qualitatively more variable than expected (χ^2, $P < 0.05$) due to the sporadic occurrence of catechol (Table 1), so much so that this component is not detectable in pooled male secretions because of its low frequency of occurrence and consequent dilution. Therefore, pooled secretions were not qualitatively representative of the secretion of individuals.

Quantitative Variation among Individuals. Concentrations of compounds showed extreme variation among individuals within a sex (Table 2). A minimum of fivefold (males, guaiacol) and a maximum of nearly 70-fold (males, hydroquinone) variation in concentration occurred within sexes. This variation in concentration increased to 90-fold and 100-fold (phenol and unknown, respectively) across sexes. While absolute variation (s^2) was greater in females, relative variation (i.e., coefficient of variation, $s/\bar{X}$) was as high or higher in males and was not constant among compounds, ranging from 66 to 183%. Analysis of variance showed that all compounds significantly differed in con-

	♀	♂	♀	♂
Number of Compounds	6.4(11)	5.7(14)	5-7	4-7
Fresh weight (±0.01 g)	5.56[b] (17[c])	2.37(11)	2.70-7.49	1.92-3.15
Secretion volume (±0.25 μl)	2.73[b] (26[c])	1.14(28)	1.75-4.00	1.00-2.00

[a] Means and other statistics are based only on individuals containing these compounds (see Table 1). Similar statistics are also shown for some other insect variables.
[b] Mean significantly different between sexes (*t* test, $P \leq 0.05$).
[c] Variance significantly different between sexes (*F* test, $P \leq 0.05$).

centration among individuals within a sex and between sexes (F test, $P < 0.0001$). Variance from partial sum of squares was apportioned 60–88% to individuals, 9–39% to sex, and 1–4% to analytical error between replicates, depending on the compound (Table 3).

The analysis of variance showed that variation among individuals was the major source of variation. However, the ANOVA could not distinguish between variation contributed by one or a few individuals at extreme values of concentrations versus equal contributions to variation by all individuals. Maximum-likelihood estimation was used to determine the best fit of data to, and distribution along, a normal distribution generated by probit analysis from the range of compound concentrations found. The resultant χ^2 values for testing deviation from a normal distribution were not significant ($P = 0.65$–0.99, depending on sex and compound), and all data points were evenly placed along the probit distribution. These results indicate a good fit of data to normality, even contribution to variance by each individual, and the classification of all individuals as members of a single population.

In contrast to the extreme variation in secretion component concentrations among individuals, the variables fresh weight, secretion volume, and the number of components present in the secretion all had small coefficients of variation that were similar among variables and sexes (Table 2). This showed that only the secretion components were showing the extensive quantitative variation.

Although individual variation predominated, sexual differences were apparent and significant. Defensive secretions of females contained more of all components except catechol and *p*-benzoquinone. The lack of significant differences between sexes for these compounds is almost certainly a reflection of the extreme variation and does not imply equality of the means. Relative composition of the secretion was different between sexes; males had higher propor-

TABLE 3. PARTITIONING OF VARIANCE, FROM PARTIAL SUM OF SQUARES, IN CONCENTRATION OF PHENOLICS AND AN UNKNOWN (AS 4-HYDROXYBENZOIC ACID EQUIVALENTS) FOR *R. microptera*

Compound	r^2 (% variance) partitioned to		
	Sex	Individuals	Analytical error

4-Methoxybenzaldehyde	26	72	2
Unknown	39	60	1

tions of *p*-benzoquinone and guaiacol, while females had higher proportions of phenol and the unknown (Table 2). Males and females differed significantly in weight and secretion volume but not in the total number of components in the secretion (Table 2).

Patterns of Variation. Patterns of variation were described using regression and ordination. Relatively few significant correlations existed between concentrations of different compounds. Only nine of 42 possible pairwise regression analyses had $P \leq 0.1$, with only phenol vs. *p*-benzoquinone and guaiacol vs. unknown being both significant and common to both sexes (Table 4). The independent variables insect fresh weight, volume of defensive secretion, and number of components in the secretion (i.e., secretion "quality") accounted for little variation in compound concentration, and not with any consistent pattern. Only six of 42 of the possible pairwise regression analyses had $P \leq 0.1$. The strongest relationship was between *p*-benzoquinone and secretion volume in females only (Table 4). Cluster analysis was used to investigate patterns among individuals. When insect fresh weight and secretion volume were used as ordinating variables, two clusters clearly separating the sexes were produced (Figure 2A). However, when compound concentrations were used, the analysis produced diffuse clusters that were not sexually differentiated and were very different from those produced by insect fresh weight and secretion volume (Figure 2B). Thus, patterns in the chemical variation were not very predictable.

TABLE 4. LISTING OF CORRELATION COEFFICIENTS (r) AND PROBABILITIES (P), BY SEX (♀ = FEMALE, ♂ = MALE), FOR PAIRWISE REGRESSIONS BETWEEN CONCENTRATIONS OF DIFFERENT COMPOUNDS AND BETWEEN COMPOUND CONCENTRATIONS AND OTHER VARIABLES FOR *R. microptera* WHEN $P \leq 0.1$

Variable 1	Variable 2	Sex	r	P
Hydroquinone	Catechol	♀	0.68	0.09
p-Benzoquinone	Phenol	♀	0.80	0.03
p-Benzoquinone	Phenol	♂	0.92	0.001
p-Benzoquinone	Secretion volume	♀	0.99	0.001

Guaiacol	Unknown	♀	0.87	0.001
Guaiacol	Unknown	♂	0.65	0.03
4-Methoxybenzaldehyde	Unknown	♀	0.89	0.0005
4-Methoxybenzaldehyde	Number of compounds	♀	0.60	0.06
4-Methoxybenzaldehyde	Fresh weight	♀	0.72	0.02
4-Methoxybenzaldehyde	Secretion volume	♀	0.62	0.06

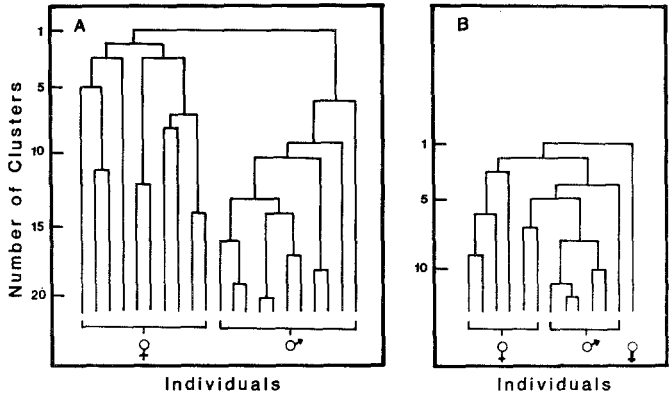

FIG. 2. Cluster analysis dendrograms for relatedness between individual female (♀) and male (♂) *Romalea microptera*: (A) using fresh weight and secretion volume as ordinating variables; (B) using concentrations of hydroquinone, *p*-benzoquinone, phenol, guaiacol, and 4-methoxybenzaldehyde as ordinating variables. Only 13 individuals had all five of these compounds in common.

Concentrations of compounds were not strongly correlated with each other or with obvious attributes such as insect sex, size, and volume of defensive secretion produced.

DISCUSSION

Our data show that lubber grasshoppers show extensive inter-individual qualitative and quantitative chemical variation in glandular defensive secretions. Furthermore, the patterns of chemical variation appear to be unpredictable. What sources or causes of chemical variation might be responsible? Chemical changes in the quantity and quality of arthropod defensive secretions are known to occur and to be influenced by a number of factors (Blum, 1981). Stage, age, sex, season, instar, social caste, physiological condition, population, genotype or colony, defensive history and regeneration, and dietary sequestration have all been previously reported as sources or causes of variation (Wallbank and Waterhouse, 1970; Tschinkel, 1975; Owen, 1978; Blum, 1981; Brower et al., 1982; 1984; Prestwich, 1983; Goh et al., 1984).

We do not believe that these factors explain the bulk of the variation we found for the following reasons. We sampled insects of the same developmental stage. These adults were very likely of similar age because of the relatively synchronous development of this insect (Jones, Whitman and Blum, unpublished data). We took sexual variation into account and found it always to be considerably less than that due to inter-individual variation. We can eliminate season and instar because we looked at one point in time at a single stage. Since

R. microptera is not a social insect, neither social caste nor colony are applicable. The generally poor correlations between insect fresh weight and secretion component quantity imply little direct influence of physiological condition. The maximum-likelihood probit analysis clearly showed that we were sampling a single population. Studies on the distribution of *R. microptera* in the sampled habitat indicate that individuals have a high probability of having a common genotype because egg pods hatch synchronously and larvae form sibling aggregates that do not disperse widely (Jones, Whitman and Blum, unpublished data).

Furthermore, we had no knowledge of the defensive history of the individuals we sampled, and it is conceivable that discharge of secretion prior to sampling could have affected variation. However, there was very little variation in the expected indicators of secretion use, i.e., secretion volume and the number of components in the secretion, and they were generally poorly correlated with secretion component quantity. Although *R. microptera* can sequester compounds from the diet (Eisner et al., 1971; Jones et al., 1986a), the compounds we quantified are produced on all diets and are almost certainly not sequestered (Jones et al., 1986b). While the distribution and abundance of precursors of defensive compounds in the diet accounts for some variation between individuals, it is similar in magnitude to the degree of variation due to sex that we found here (Jones et al., 1986b). We therefore feel justified in eliminating the above factors as significant contributions to inter-individual variation. We consider that the majority of the two to three orders of magnitude of variation in compound concentration, as well as qualitative variation in compound distribution that we found, is attributable to the individual insects themselves. Thus lubber grasshopper defensive secretions are truly idiosyncratic, and a typical species or population defensive secretion composition does not really exist.

Because most analyses of chemical variation in arthropods have been based on pooled samples, the extent to which inter-individual variation occurs is generally unknown (Blum, 1981). We know of a few studies where inter-individual variation was examined. With one exception, these studies report no detectable or obvious variation, or they report variation among individuals that is less than that found between castes, sexes, colonies, populations, or geographic areas. In all these cases, quantitative variation was less than one order of magnitude (Tricot et al., 1972; Doyen, 1973; Tschinkel, 1975; Daloze and Pasteels, 1979; Goh et al., 1984). The exception is a report of variation in cyanide yield from individual millipedes that is of a similar magnitude to the variation we found (Eisner et al., 1967). In their study, however, individuals were collected from an undefined population in a woodland, over a six-month period, and the quantitative contribution of these factors to variation was not determined. The occurrence of such extensive inter-individual chemical variation in *R. microptera* strongly suggests that future studies with other arthropods should avoid the pooling of defensive secretion samples unless there is a priori knowledge that inter-individual variability is not significant. It also shows that, at least for *R.*

microptera, comparison of defenses among populations is not necessarily the most meaningful within-species comparison.

How might such extensive variation arise and be maintained within a population? We suggest two alternative explanations that are based on the signal specificity used by predators to select or reject chemically defended prey within a prey population. Suppose that most of the predator species interacting with *R. microptera* respond to threshold concentrations of a gestalt odor or taste that can be produced from a large number of combinations of compounds and concentrations in a manner analogous to that suggested by Blum (1974) and Tschinkel (1975). In this situation, selection for a specific composition of secretion would not occur, provided the composition is above this threshold. Secretion quality and component quantity might not be tightly regulated and any inherent variation, or variation subsequently arising by other means, would not necessarily be selected against.

Alternatively, suppose that different species within the guild of predators interacting with *R. microptera* respond to different sets of specific chemical cues, in a manner analogous to that proposed by Pasteels et al. (1983); or are subsequently conditioned to different prey cues, as has been shown for a sawfly predator (Pasteels and Gregoire, 1984). In these situations, divergent predator selection pressure would favor divergent composition within prey populations. We know that different predator species vary in their responses to *R. microptera* (Whitman et al., 1986). We also know that the same predator species varies its responses to different *R. microptera* secretions (Jones et al., 1986a). However, the specificity of the chemical cues used by these predators is unknown, and so choosing between these alternate explanations as reasons for the maintenance of idiosyncratic variation must await further study.

The occurrence of such notable inter-individual variation in an insect chemical defense, and its fundamentally idiosyncratic and unpredictable nature, is directly analogous to the recent discovery of extensive chemical variation within and among individual plants (Denno and McClure, 1983; Jones, 1983). These discoveries illustrate the potentially important contribution of heterogeneity to the operation of chemical signals and defense in both animals and plants.

(Received May 20, 1985; accepted July 25, 1985)

Abstract—Twelve products related to the sex pheromone main components (Z)-9- and (Z)-11-tetradecenyl acetate (Z9–14 : Ac and Z11–14 : Ac, respectively), were identified in female pheromone gland extracts of the laboratory-reared summerfruit tortrix moth, *Adoxophyes orana* F.v R. These are the geometric isomers and the alcohols of the main components, (Z)-9-dodecenyl acetate, (Z)-11-hexadecenyl acetate, and saturated acetates of 12–22 carbons. The ratio of Z9–14 : Ac to Z11–14 : Ac in individuals varied from 3.5 : 1 to 11 : 1 with an average of 6.2; their total added up to 462 ng/female with an average of 182 ng for 2- to 7-day-old individuals. No qualitative or quantitative differences were observed between laboratory and field insects. Z9–14 : Ac, Z11–14 : Ac and the corresponding alcohols were also found in female effluvia. Addition of either of the two alcohols to a blend of the two acetates augmented trap catch in the field. The same was true for (Z)-9,(E)-12-tetradecadienyl acetate which was not detected in gland extracts.

Key Words—Summerfruit tortrix, *Adoxophyes orana*, Lepidoptera, Tortricidae, sex pheromone, (Z)-9-tetradecenyl acetate, (Z)-11-tetradecenyl acetate, (Z)-9-tetradecen-1-ol, (Z)-11-tetradecen-1-ol, individual variation.

INTRODUCTION

Adoxophyes orana (Fischer von Röslerstamm) was one of the first species known to use a sex pheromone of more than one compound (Meijer et al., 1972). The two components, (Z)-9-tetradecenyl acetate (Z9–14 : Ac; for other short forms, see Table 1) and Z11–14 : Ac, were also found in two related species, the smaller

0098-0331/86/0300-0763$05.00/0

tea tortrix, *Adoxophyes* sp. (Tamaki et al., 1971a), and the summerfruit tortrix, *A. orana fasciata* (Tamaki et al., 1971b), in Japan.

Meanwhile, reports on multicomponent pheromones have become numerous. Tamaki et al. (1979) later described the *Adoxophyes* sp. pheromone as a four-component blend with another seven related compounds present. From behavioral observations, Den Otter and Klijnstra (1980) suggested that *A. orana* also used additional pheromone components in courtship. In connection with a study on mating disruption, Charmillot (1981) observed that males responded to a broader range of Z9–14:Ac/Z11–14:Ac blends than reported originally. For these reasons, a reinvestigation of the *A. orana* sex pheromone appeared appropriate. A preliminary account of this work has been presented (Guerin et al., 1982).

METHODS AND MATERIALS

Insects. Wild populations of *A. orana* were sampled at opposite ends of Switzerland, at Vich near Lake Geneva and Güttingen near Lake Constance. A laboratory colony derived from a 10-year-old culture (ca. 100 generations) at Changins was reared on the diet used for *Eupoecilia ambiguella* (Rauscher et al., 1984). Sexed pupae and adults (provided with sucrose solution) were kept in a 16:8-hr photoperiod at 24°C, 56% relative humidity with 3000–6000 lux in the photophase, and 18°C, 85% relative humidity, and 1 lux in the scotophase. Sex glands extracts were made from 3- to 7-day-old females during calling which, under this regime, occurred at the end of the scotophase.

Pheromone Gland Extraction. Employing a method similar to that described by Klun et al. (1979), batch extracts of some 5–25 excised female glands were obtained using ca. 1 μl/gland of hexane (Merck "for residue analysis") and 5 μl in the case of single glands. The terminal abdominal segments were forcefully everted with blunt forceps, and the tip incorporating the gland was sliced off with a scalpel blade. Extraction was made in a V-bottomed vial for 10 min; for direct gas chromatographic (GC) analysis, the gland wash was transferred to another vial, concentrated at room temperature, and injected. Extracts were stored at −80°C in microampoules.

Collection of Female Effluvia. Fifty females were placed in a 1-liter glass bottle containing nylon gauze as a resting site 24 hr before collection. Synthetic air (50 ml/min) passed over the insects during calling (3 hr) onto 1 ml of 1-mm glass beads held in a Pasteur pipet. The beads were washed with 0.5 ml hexane and the eluate concentrated at room temperature.

Gas Chromatography (GC). For GC analysis, we employed 15- to 50-m glass capillary columns (0.3–0.4 mm ID) coated with the polar phases Silar 10c or SP-1000 in a Carlo Erba gas chromatograph equipped with a Grob '76-type splitless injector. Typical programs were 60°C for 3 min, 20°/min to 100°C

and 3–5°/min to 240°. The elution sequence is given in Table 1. Silar 10c gave a better separation of *E*9–14 : Ac and *Z*9–14 : Ac; SP-1000 was superior for the pair *Z*9–14 : Ac/*E*11–14 : Ac and eluted the alcohols with less tailing.

Electroantennographic detection (GC-EAD) (Arn et al., 1975) was carried out using male antennae from various moth species of known sensitivity (Guerin et al., 1985).

Gas Chromatography–Mass Spectrometry. GC-MS was carried out on a Finnigan 4000 quadrupole instrument equipped with a 6115 data system operating in the EI mode. Complete mass spectra were obtained from injections of 5–15 female equivalents (FE). A systematic search was made for compounds structurally related to the previously identified pheromone components, using, among others, the key ions *m/z* 61 ($CH_3COOH_2^+$) for acetates and *m/z* 166, 194, and 222 for monoenic acetates and alcohols of 12, 14, and 16 carbons ($M^+ - CH_3COOH$ and $M^+ - H_2O$, respectively). Mass fragmentograms (MF) to confirm retention times were recorded by injecting 10 FE and synthetic standards at levels similar to the gland constituents (1–100 ng).

To determine the location of double bonds of monoenes, dimethyl disulfide (DMDS) derivatives (Buser et al., 1983) were prepared by keeping an extract of some 140 FE in 20 μl hexane plus 60 μl DMDS and 10 μl 6% ethereal iodine solution overnight at 40°C in a flame-sealed ampoule. Approximately 30 μl 5% $Na_2S_2O_3$ solution was added and, after rigorous mixing, the organic phase removed and concentrated. Mass spectra (*m/z* 35–535) of the adducts were obtained from injections of 25 FE.

Field Tests. These were done in 6–10 replicates in apple orchards using rubber caps for dispensing the chemicals and tetra traps with flaps (Arn et al., 1979). Treatment positions within replicates were systematically varied; catch differences were assessed by two-way analysis of variance and Duncan's multiple-range test after log $(x + 1)$ transformation ($P = 0.05$).

Chemicals. Acetates were purified by argentation chromatography (Heath et al., 1977); alcohols were derived from acetates. Isomeric purity was better than 99.97% for monoenes and 98% for dienes.

RESULTS

Chemical Analysis

Identification of Pheromone Gland Components. A listing of the compounds found in gland extracts of laboratory-reared females, along with identification criteria, is given in Table 1. *Z*9–14 : Ac and *Z*11–14 : Ac were main components at the ratio of 85 : 15, as previously established. The corresponding *E* isomers were present in the range of a few percent. Two additional monoenic acetates were identified as *Z*9–12 : Ac and *Z*11–16 : Ac. The alcohols *Z*9–14 : OH

TABLE 1. COMPONENTS IDENTIFIED IN *A. orana* FEMALE SEX PHEROMONE GLANDS[a]

Compound	Short form	Identified by	Amount (ng/FE)
Dodecyl acetate	12:Ac	GC-MS	0.04
(*Z*)-9-Dodecenyl acetate	*Z*9–12:Ac	GC-MS, MF, GC-EAD	0.2
Tetradecyl acetate	14:Ac	GC-MS	0.1
(*E*)-9-Tetradecenyl acetate	*E*9-14:Ac	GC-MS, MF	2
(*Z*)-9-Tetradecenyl acetate	*Z*9-14:Ac	GC-MS, DMDS	155
(*E*)-11-Tetradecenyl acetate	*E*11-14:Ac	GC-MS, DMDS, GC-EAD	4
(*Z*)-11-Tetradecenyl acetate	Z11-14:Ac	GC-MS, DMDS	27
(*Z*)-9-Tetradecen-1-ol	*Z*9-14:OH	GC-MS, DMDS, GC-EAD	4
(*Z*)-11-Tetradecen-1-ol	Z11-14:OH	GC-MS	0.4
Hexadecyl acetate	16:Ac	GC-MS	0.005
(*Z*)-11-Hexadecenyl acetate	Z11-16:Ac	GC-MS, MF, DMDS, GC-EAD	3
Octadecyl acetate	18:Ac	GC-MS	0.005
Eicosyl acetate	20:Ac	GC-MS	0.005
Docosyl acetate	22:Ac	GC-MS	0.005

[a]In order of elution on Silar 10c and SP-1000.

and Z11–14:OH were present in the percent range at the ratio of the corresponding acetates. Smaller amounts of saturated acetates from 12 to 22 carbons were also found. Analysis of extracts from insects collected near Lake Geneva and Lake Constance revealed no qualitative or quantitative difference to the laboratory material.

The DMDS procedure confirmed the structures of the monoenic acetates except for *Z*9–12:Ac and *E*9–14:Ac (concentration too low). A DMDS adduct (M^+, 306; A^+, 117; B^+, 189) also confirmed the presence of *Z*9–14:OH. No evidence for monounsaturated acetates of 10, 13, 15, 17, or 18 carbons or for monounsaturated alcohols of 12 or 16 carbons was found with this method.

The presence of *Z*9–12:Ac, *E*11–14:Ac, *Z*9–14:OH, and Z11–16:Ac in the extract was confirmed with GC-EAD using *E. ambiguella*, *Zeiraphera diniana*, *Maliarpha separatella*, and *Mythimna unipuncta* as detector species, respectively (Figure 1). In each case, the intensity of the EAD versus the FID signal matched that obtained with authentic standards.

As reported by Priesner (1983), *A. orana* male antennae carry receptor cells specialized for the dienes (*Z*)-9,(*E*)-11-tetradecenyl acetate (*Z*9,*E*11–14:Ac) and (*Z*)-9,(*E*)-12-tetradecenyl acetate (*Z*9,*E*12–14:Ac). However, our analyses revealed no trace of these compounds in female extracts. Detection limit was 1 pg/FE in GC-EAD using *Spodoptera littoralis* for *Z*9,*E*11–14:Ac and *Ephestia kuehniella* for *Z*9,*E*12–14:Ac, and 1 ng for both in GC-MS (m/z = 192 for $M^+ - CH_3COOH$). A search for 10-methyldodecyl acetate, a pheromone component of the smaller tea tortrix, *Adoxophyes* sp. (Tamaki et al., 1979), by GC-MS was equally negative at a detection limit of 1 ng/female.

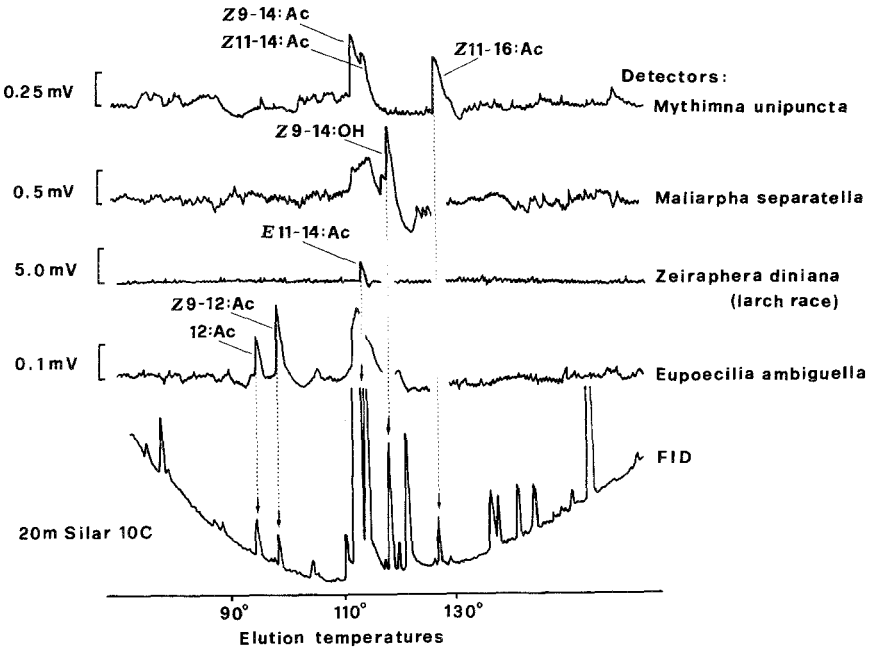

FIG. 1. Combined GC-EAD traces of *Adoxophyes orana* sex gland extracts with detector species selective to Z11-16:Ac, Z9-14:OH, *E*11-14:Ac, and Z9-12:Ac. Silar 10c, 20 m × 0.3 mm glass column, 40°C for 2 min, 10°/min to 60°C, 5°/min to 180°C.

Analysis of Effluvia. GC-MS of a glass-bead wash indicated the presence of Z9-14:Ac, Z11-14:Ac, and the corresponding alcohols in the female effluvia. The overall amount (1.5 ng from 50 females during 3 hr) was very low, probably due to low trapping efficiency. The isomer ratio of 11.5:1 for both alcohols and acetates and the proportion of alcohols (30% of the total blend) in the effluvia differed markedly from the analysis of the female glands but are more in line with the field results.

Analysis of Individuals. Due to the relatively high pheromone content, quantitation of the main components in individual glands was possible by GC with flame ionization detection. Forty laboratory-reared females of less than 2 hr up to 8 days old were analyzed (Figure 2).

The Z9-14:Ac + Z11-14:Ac content was lowest in newly emerged females (9 ± 3.4 ng), increased through day one (103 ± 16 ng), remained high from days 2 to 7 (182 ± 15), and dropped off on day 8 (80 ± 15). The highest amount (460 ng) was found in a 4-day-old. The ratio of Z9-14:Ac to Z11-14:Ac showed considerable variation, with values ranging from 3.5:1 to 11:1 in the 1- to 8-day-old individuals. The mean value for the laboratory stock was 6.2:1, similar to those of the pooled samples of wild material (5.3:1 for Lake Geneva and 5.8:1 for Lake Constance).

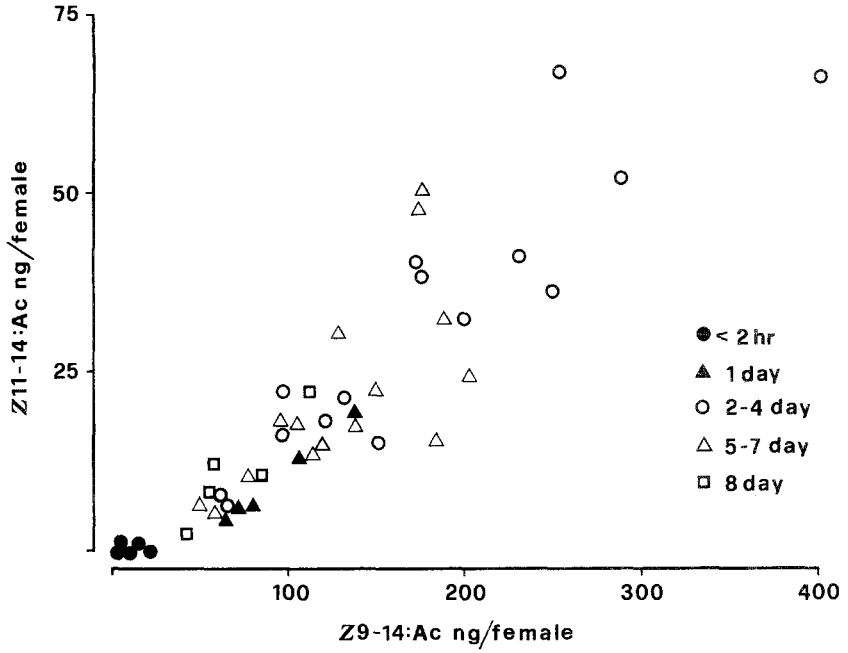

FIG. 2. Content of the main pheromone components in individual *Adoxophyes orana* female sex glands with age.

Field Responses

Attraction to Z9-14:Ac/Z11-14:Ac Blends. While Z9-14:Ac alone was ineffective, blends with Z11-14:Ac at a total cap load of 100 μg were attractive to males over a wide range (Figure 3). At locations where overall catch was high, the maximum was at 5-10% Z11-14:Ac, closer to the ratio found in the female effluvia than in the gland extract. At other locations no distinct attraction maximum was observed; the response curve was equally broad when the total dose was lowered to 10 μg. Increasing the dose of a 85:15 blend by factors of 10 up to 10 mg/cap (the highest dose tested) augmented the catch significantly.

Effects of E *Isomers.* *E*9-14:Ac and *E*11-14:Ac were each tested at various doses added to a blend of 90 μg Z9-14:Ac and 10 μg Z11-14:Ac. At levels of 0.5% and above, *E*9-14:Ac strongly inhibited trap catch, as observed by Minks and Voerman (1973) (Figure 4). Isomeric purity of Z11-14:Ac was less critical: inhibition was only found at levels of 5% *E*11-14:Ac of the binary blend or higher. On the other hand, the positive effect of high doses (10%) of *E*11-14:Ac reported earlier (Guerin et al., 1982) could not be substantiated.

Effects of Corresponding Alcohols. In tests similar to the above, Z9-14:OH and Z11-14:OH both augmented trap catch at levels of 10-50 μg (Figure 4).

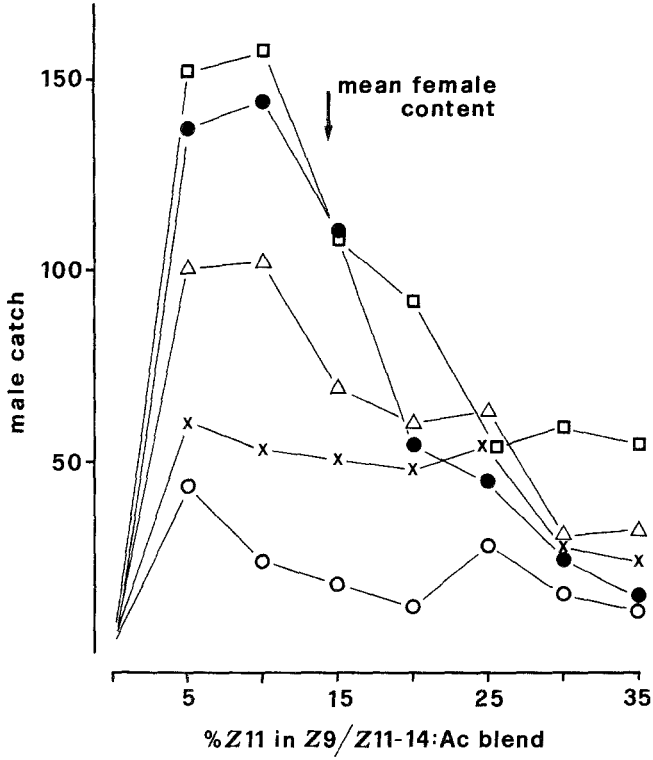

FIG. 3. Field captures of *Adoxophyes orana* males with different blends of Z9–14 : Ac and Z11–14 : Ac at Vich •—•, Güttingen ×—×, Geneva △—△, and Châteauneuf ○—○ (first) and □—□ (second) flight (the latter at half scale).

These effects were obtained in two consecutive years, although not in all experiments. *E*9–14 : OH could be present at up to 10% of Z9–14 : OH without affecting trap catch.

Effects of Other Pheromone Gland Components. No effects on catch were obtained when 12 : Ac, Z9–12 : Ac, 14 : Ac, or Z11–16 : Ac were added at levels between 0.1 and 50 μg to the blend of 85 μg Z9–14 : Ac and 15 μg Z11–14 : Ac. Addition of the full complement of acetates at the proportions found in the gland was also without effect. Traps containing 100 μg Z11–16 : Ac in addition to the binary blend caught an average of ca. 10 males per trap of the noctuid *Oligia latruncula* in June 1981.

Effects of Dienic Acetates. Two compounds for which Priesner (1983) found receptor cells on *A. orana* male antennae were combined with the 90 : 10 blend of Z9–14 : Ac and Z11–14 : Ac at levels ranging from 0.1 to 50 μg. Addition of 2 μg of Z9,*E*12–14 : Ac resulted in a twofold increase in trap catch but

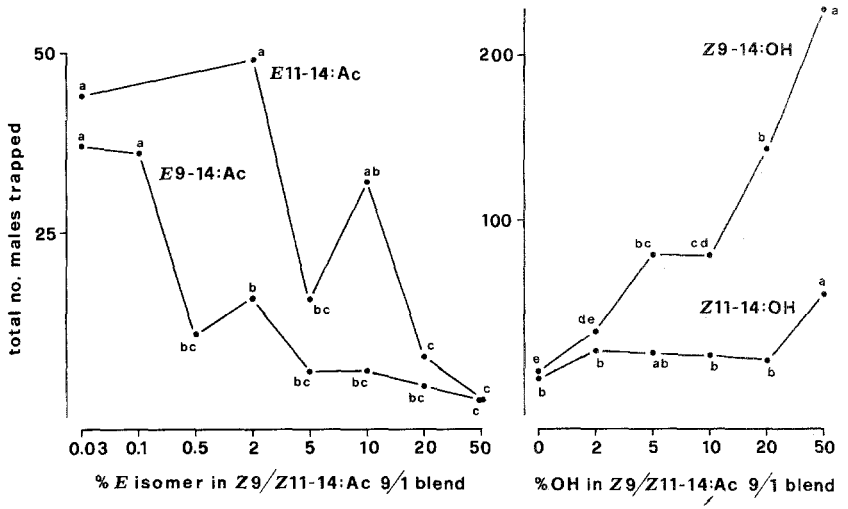

FIG. 4. Field captures of *Adoxophyes orana* males with a blend of 90 μg Z9–14 : Ac and 10 μg Z11–14 : Ac and different proportions of *E* isomers and corresponding alcohols added. Points marked with the same letters within a curve are not significantly different at $P = 0.05$.

was inhibitory at 50 μg. This confirms the results obtained by Voerman (1982). Z9,*E*11–14 : Ac, on the other hand, reduced trap catch to one half at 2 and totally at 50 μg. Neither of the binary mixtures of Z9,*E*12–14 : Ac with Z9–14 : Ac or Z11–14 : Ac was attractive.

DISCUSSION

In addition to confirming the presence of Z9–14 : Ac and Z11–14 : Ac, this study revealed 12 related components in the female pheromone glands of *A. orana*. Three of these, 12 : Ac, 14 : Ac, and *E*11–14 : Ac also occur in *Adoxophyes* sp. (Tamaki et al., 1979). The dodecenyl and hexadecenyl acetates common to both may be the Z-9 and Z-11 isomers identified here, present as possible byproducts of biosynthesis. Several components found by Tamaki et al. (1979) could not be detected in *A. orana*, notably 10-methyldodecyl acetate which is biologically active for *Adoxophyes* sp. At our detection limit, we would have found the compound if present at a similar proportion to the main components as in the smaller tea tortrix. We also identified the alcohols corresponding to the main components, *E*9–14 : Ac, and even-numbered saturated acetates up to 22 carbons.

The ratio of Z9–14 : Ac to Z11–14 : Ac showed considerable variation between individuals. This is in contrast with the strict control of the Z11–14 : Ac/

*E*11–14:Ac ratio in *Argyrotaenia velutinana* (Miller and Roelofs, 1980), possibly because of less closely linked biosynthetic pathways for the positional than the geometric isomers (see Roelofs and Bjostad, 1984).

Similar to the observations by Minks and Voerman (1973), male captures were made over a wide window of isomer ratios, ranging from 5 to 25% of *Z*11–14:Ac in the blend. This compares favorably to the 7–20% found in the female glands. According to Den Otter (1977), the male receptor cells are not tuned to the perception of a particular isomer ratio.

The effect of the additional pheromone gland components on male behavior has not been fully elucidated. *Z*9–14:OH and *Z*11–14:OH added to the main components strongly enhanced trap catch in more than one experiment. An explanation for some lack of consistency might be that these compounds exert an effect not amenable to measurement by trap catch under all conditions. *A. orana* males bear receptor cells sensitive to *Z*9–14:OH (Priesner, 1983).

As reported by Minks and Voerman (1973), attraction is strongly inhibited by a fraction of a percent of *E*9–14:Ac in the blend. Contrary to observations by the same authors, *E*11–14:Ac can be present at up to 20% of *Z*11–14:Ac without loss of activity. This situation is similar to that observed in *Adoxophyes* sp. where *E*11–14:Ac is a synergist (Tamaki et al., 1979).

Based on this study we currently use a *Z*9–14:Ac of high isomeric purity in a 90:10:10:2 blend of *Z*9–14:Ac, *Z*11–14:Ac, *Z*9–14:OH and *Z*11–14:OH.

CHEMICAL MATE RECOGNITION AND RELEASE OF MALE SEXUAL BEHAVIOR IN POLYBIINE WASP, *Belonogaster petiolata* (DEGEER) (HYMENOPTERA: VESPIDAE)

M.G. KEEPING, D. LIPSCHITZ, and R.M. CREWE

Department of Zoology
University of the Witwatersrand
Johannesburg 2001, South Africa

(Received May 7, 1985; accepted July 25, 1985)

Abstract—The results of bioassays using freshly killed gynes of *Belonogaster petiolata* (Degeer) and hexane extracts of their tagmata and abdominal glands provide evidence for the existence of chemical signals in the venom, thorax, and head of gynes that serve as mate recognition cues and releasers of copulatory behavior in conspecific males. Attraction of males to the source of the chemicals occurs over short distances (a few centimeters).

Key Words—Polybiine wasp, *Belonogaster petiolata*, Hymenoptera, Vespidae, chemical signals, mate recognition, copulatory behavior, venom.

INTRODUCTION

Chemical communication and the production of pheromones in social wasps is probably the least explored aspect of the communicative and social biology of this group of insects. The majority of studies have been directed at determining and describing the source and functions of pheromones, rather than their chemical nature and composition. Only three pheromones, a queen substance (Ikan et al., 1969), a thermoregulatory pheromone (Veith and Koeniger, 1978) and an alarm pheromone (Veith et al., 1984) have been chemically characterized from the Vespinae, and one of the active components of the ant-repellent allomone of the sixth sternal gland of *Polistes fuscatus* has been identified (Post et al., 1984b). In addition, two compounds have been identified from the seventh sternal gland of *Vespa crabro* (Wheeler et al., 1982), although the function of this gland is still unknown.

0098-0331/86/0300-0773$05.00/0

There are indications that the queens of certain vespine species produce substances that attract males and release copulatory behavior. Sandeman (1938) reported that freshly killed queens of *Dolichovespula sylvestris* were attractive to males and produced attempted copulation. Thomas (1960) noted that males of *Vespula germanica* which had recently mated queens, became attractive to other males, indicating that some of the queen's sex attractant may have been transferred to the former males. This behavior has also been observed among males of *V. maculifrons* under laboratory conditions (Ross, 1983). Initial detection of queens by vespine males appears to be visually achieved (Batra, 1980; Post, 1980; MacDonald et al., 1974; Akre et al., 1982; Ross, 1983) and, with the possible exception of *V. atropilosa* (MacDonald et al., 1974), males contact and mount females on a substrate. It has been suggested that mate recognition and release of copulatory behavior at this stage is mediated by short-range olfactory or contact pheromones in *Vespa crabro germana* (Batra, 1980), *Vespula atropilosa* (MacDonald et al., 1974), *V. consobrina* (Akre et al., 1982), and *V. maculifrons* (Ross, 1983). In particular, conspecific males were attracted to the queen's thorax in *V. crabro* and to her gaster in *V. maculifrons* (Batra, 1980; Ross, 1983, respectively).

Post and Jeanne (1983a, 1984a) reported the presence of a sex pheromone in the venom of *Polistes fuscatus* and *P. exclamans* that attracts males over short distances and releases copulatory behavior, although they were not able to establish how the sex pheromone is released by the females. The same authors found that this attractant is not species specific and that its action in these species is supplemented by a chemical cue on the cuticle (of at least the thorax and gaster) of females that is species specific (Post and Jeanne, 1984a). Long-range attraction of male *P. fuscatus* to conspecifics in their territories is visually mediated (Post and Jeanne, 1984b).

Observations (M.G. Keeping, unpublished data) on the mating behavior of *B. petiolata* in the field and laboratory have produced indications that the females of this species secrete a pheromone which attracts males, facilitates mate recognition, and releases copulatory behavior. Males and gynes emerge during late summer (February and March), when adult population size reaches its peak. During March and April, males fly to different nests, where they land and attempt to mate with resident gynes; there is no territoriality between males such as that observed in various species of *Polistes* (Kasuya, 1981; Lin, 1972; Post and Jeanne, 1983b; Turillazzi and Cervo, 1982).

Copulation in the field and laboratory is initiated when a male approaches a female and the pair undergoes either mutual antennation (male and female antennate each other's heads and antennae) or unilateral antennation (male antennates female's thorax and abdomen). The male then mounts the female and immediately begins vibrating his antennae against hers, with the latter generally becoming hooked in the curled section at the end of the male's antennae. The male's head is tucked back and down so that his mouthparts contact the female's

thorax; at this stage he curves his abdomen down to one side of the females's abdomen and attempts to establish genital contact. Genital extrusion only occurrs once contact has been established—this seldom lasts longer than about 5 sec—but is achieved several times during copulation. The male generally vibrates his wings while chasing or attempting to mount a female.

Since large numbers of adults are present on the nests during the mating period and since there is no specialized visual signaling by females (the sexes are also similar in their gross morphology and coloration), it appeared unlikely that visual cues provide the only means whereby males ultimately distinguish between the sexes. Agitated females also produce a strong, acrid odor which persists for some time in containers in which females have been kept; the same odor is evident from crushed venom glands and sacs, and it seems reasonable to expect that this odor may function in alarm or allomonal contexts or in mate attraction. An alarm response to venom has been demonstrated for three vespine species (Maschwitz, 1964, 1984), three species of *Polistes* (Jeanne, 1982; Post et al., 1984a), and *Polybia occidentalis* (Jeanne, 1981); it remains to be fully investigated in *Belonogaster*.

The present study was carried out to investigate whether males of *B. petiolata* are attracted to and recognize conspecific females on the basis of chemical cues, and if so, what body parts or glands in the female may be responsible for producing the odors involved.

METHODS AND MATERIALS

Colonies of *B. petiolata* were collected from Sterkfontein, Transvaal, during late March 1985, when males were still actively mating. Males and females were placed into separate cages soon after capture, and the males were used in the bioassays after a week of isolation. Trials were performed by placing 15 males in a Perspex box (14 × 10 × 10 cm) together with a test object for 10 min; interactions were recorded in terms of antennation of the test object and homosexual copulatory attempts. Our justification for using the latter interaction in quantifying the response of males to the test object is the same as that of Post and Jeanne (1983a), namely that homosexual copulatory attempts involved an identical sequence of behaviors to heterosexual ones (see Introduction) and they allowed us to eliminate the visual cue of the female in determining the efficacy of various female body parts in the chemical release of copulatory behavior. Antennation was interpreted in terms of the attractiveness of the test object to males.

Bioassays Combined with Visual Cue. Initially males were tested against gynes which were freshly killed, by freezing at −20°C for 15 min, and mounted on a wall of the test box. Females were handled gently before freezing to prevent agitation and release of venom. Controls consisted of presenting a dead female (dried at 60°C for 36 hr) to the males in an identical manner. In these

trials, the number of mountings (with the usual sequence of behaviors) of test and control females by males and how many of these resulted in genital linkage were scored in addition to the interactions mentioned above.

Bioassays in Absence of Visual Cue. Hexane extracts of body parts and glands of females were prepared by placing them in solvent at −4°C for 36 hr in the following quantities: 10 heads in 500 μl; 10 thoraxes in 1000 μl; 10 venom sacs and glands in 100 μl; 10 Dufour's glands in 100 μl; 10 sternal glands (sixth abdominal sternite) in 100 μl; and abdominal sternites 2–5 in 1000 μl. For each bioassay, an extract of one of the above was syringed onto a 2.7-cm-diameter disk of filter paper in appropriate quantities to obtain one body part or gland equivalent to test against the males. The solvent was allowed to evaporate, and the disk was pinned in position against the side of the test box. Controls consisted of presenting filter paper disks onto which pure hexane was syringed in a quantity equal to that of the extract used in the corresponding test; again the solvent was allowed to evaporate before presentation.

Controls and tests were paired, because male activity varied with the time of day. The same males were always used for the test and control of a particular trial, so that individual differences in male behavior were constant between the two. The experiments were carried out between 10 AM and 4 PM, since this coincided with the period of greatest male activity. Lighting was provided in the form of overhead neon tubes, together with a 60-W incandescent lamp which also maintained temperatures between 24.5 and 26°C. Consecutive trials were separated by at least 10 min, during which time the males were transferred back to a general holding cage and the test box was thoroughly cleaned. For each trial, males were taken at random from the holding cage and allowed to settle down in the test box at the correct temperature, before commencing with the bioassay.

RESULTS

Bioassays Combined with Visual Cue. Male activity in the presence of the dried (control) female was low; no homosexual copulatory attempts were observed and antennations of the dried female were infrequent (Table 1). When a freshly killed gyne was placed into the test box, there was a noticeable rise in male activity and aggression; there was also a significant increase in the number of homosexual copulatory attempts and antennations of the freshly killed female (Table 1). A significantly higher number of mountings was observed for freshly killed females than for dried females (freshly killed female = 119; dried female = 4; $P = 0{,}005$; $T = 0$; $N = 10$; Wilcoxon matched-pairs signed-ranks test); 41 of these mountings resulted in genital linkage with freshly killed females, but no genital linkage was attempted with dried females; thus the lack of genital contact with the latter was not due to the inability of males to grasp the hardened, inflexible genitalia of a dried female.

TABLE 1. RESULTS OF BIOASSAYS USING FRESHLY KILLED *B. petiolata* GYNES AND HEXANE EXTRACTS OF TAGMATA, ABDOMINAL GLANDS, AND VENOM.[a]

Test object	Antennation of test object		Homosexual copulatory attempts		Number of trials
	Control	Test	Control	Test	
Whole female	88	425[b]	0	27[c]	10
Hexane extract of:					
Head	28	140[b]	5	45[b]	10
Thorax	46	180[b]	9	41[b]	10
Venom gland and sac	32	211[b]	25	111[b]	10
Dufour's gland	43	57	72	74	10
Sixth sternal gland	35	35	41	33	10
Sternites 2–5	40	57[b]	12	28	10

[a] Male response is measured in terms of antennation of the test object and homosexual copulatory attempts by 15 males in the test box during a 10-min trial period. Comparison of tests and controls carried out using Wilcoxon's matched-pairs signed-ranks test.
[b] Significant at $P = 0.005$.
[c] Significant at $P = 0.01$.

Bioassays in Absence of Visual Cue. Hexane extracts of head, thorax, and venom elicited significantly higher numbers of antennations of the filter paper disk and homosexual copulatory attempts than the controls (Table 1). Venom extract proved to be particularly efficacious in releasing copulatory behavior (Table 1); the number of male responses was highest at the start of a trial and declined as time progressed. Extract of sternites 2–5 was attractive to males but was not capable of releasing a significant amount of copulatory behavior (Table 1).

In both sets of bioassays (with and without a visual cue), males responded with attempted copulation when in close proximity to the test object (a few centimeters), indicating that the chemical signals produced by females are close-range attractants.

DISCUSSION

The significantly higher number of antennations and mountings (together with genital linkage), directed at freshly killed gynes compared to dried females, provides evidence for the production by gynes of *B. petiolata* of a pheromone which attracts conspecific males and releases copulatory behavior. In this instance the visual cue was identical for both control and test females, and any significant increase in the release of copulatory behavior in the presence of the freshly killed female can only be accounted for in terms of chemical cues

present on one or more body parts of the latter. The odor produced by freshly killed gynes was also capable of releasing homosexual copulatory behavior, which further diminishes the role of close-range visual cues in mate recognition by males. Males which had recently mounted a freshly killed gyne were generally the subject of subsequent homosexual copulatory attempts, indicating that the substances involved are transferable from females to males. This same phenomenon has been observed during normal mating in *Vespula germanica* (Thomas, 1960) and *V. maculifrons* (Ross, 1983).

The odor contained in venom is clearly involved in the release of male sexual behavior in *B. petiolata*, but its action is probably augmented by the substances produced or harbored in or on the head and thorax (Table 1). Post and Jeanne (1984a) found that males of *P. fuscatus*, in addition to responding strongly to the venom of their species and to a smaller degree to that of *P. exclamans* and *Vespula maculifrons*, also responded to whole thorax and gaster or extracts derived from these; in the latter case, the responses of the males were species specific, which suggested that a chemical cue was present at least on the cuticle of the thorax and gaster and this allowed males to recognize and copulate with conspecific females. The transferability of odors from females to males of *B. petiolata* indicates that the pheromone in this species may also have a cuticular component, and as suggested for *Polistes* by Post and Jeanne (1984a, b), venom may be spread over the surface of other body parts (e.g., the head and thorax) during grooming, thereby increasing the attractiveness of the latter to males. This is supported by the finding that extract of sternites 2–5, which do not have cuticular glands (M.G. Keeping, personal observation), was attractive to *B. petiolata* males and probably contained traces of venom.

Since the pheromone produced by gynes of *B. petiolata* is only effective over short distances, it is likely that long-range attraction of males occurs on the basis of visual cues and may entail a response chain such as that described for *P. fuscatus* by Post and Jeanne (1984b). However, the absence of territoriality in *B. petiolata*, and consequently the lack of a need for males to differentiate between conspecifics and other wasp-sized objects and ultimately between free-flying male and female conspecifics (as occurs in *P. fuscatus*), suggests that the visual response chain would be relatively simple, with its major component being the sight of a populated nest. These possibilities remain to be tested. Recognition of females by males on the nest would subsequently be achieved using chemical cues.

SELECTIVE OLFACTORY CHOICES OF THE HONEYBEE AMONG SUNFLOWER AROMAS: A Study by Combined Olfactory Conditioning and Chemical Analysis

(Received March 4, 1985; accepted July 30, 1985)

Abstract—A bioassay based on an olfactory conditioning method simulating the foraging situation in laboratory conditions was coupled with chemical analysis of volatile sunflower blends. Behavioural data obtained from foragers' responses to volatile fraction point out that honeybees need to use only a limited fraction acting as a "simplified aromatic pattern" of the plant, among hundreds of compounds constituting the whole aroma. This active fraction included 27 polar compounds among which 14 were identified. Extension of such data to crop pollination and plant improvement is discussed.

Key Words—Honeybee, sunflower aroma, foraging behavior, olfactory conditioning, active volatile fraction.

INTRODUCTION

The sunflower crop has become very important in these last years, and the sunflower is now the second oil plant in the world (Bonjean, 1983). This fact is linked to a better knowledge in the field of plant improvement, and, more particularly, to the discovery of cytoplasmic male sterility (Leclercq, 1969), which allowed the creation of hybrid varieties.

At the beginning, *Helianthus* genus was allogamous and submitted to entomophilous fecundation (Putt, 1940; Free and Simpson, 1964); foraging insects, particularly honeybees, are needed for hybrid seed production (Radford

and Rhodes, 1978; Parker, 1981a, b) and lead to a benefit in oil seed production: increase in seed yield, oil rate, and seed germination ability (Benedek and Manninger, 1972; Furgala et al., 1979; Radford et al., 1979; Parker, 1981c).

Sunflower hybrid seed production is strictly dependent on pollen transport from a male fertile line to a male sterile line. However, sometimes low seed production was due to a selective foraging behavior of honeybees; field observations thus pointed out a constancy of foragers to some sunflower lines, which led to a lack of entomophilous cross-pollination (Shein et al., 1978; Parker, 1981a, b); Freund and Furgala, 1982). Such a behavior, defined in honeybees, as a "floral constancy" (Grant, 1950; Free, 1963), is based on a learning process in which chemical cues are mostly implied (Masson, 1982): bees, by landing on a plant, memorize plant aroma during food uptake (nectar, pollen) and then are likely to use olfactory parameters as cues for selective orientation.

The aim of this work was thus to determine how far foragers are able to use volatiles as cues for discriminating different sunflower lines. Chemical analysis carried by Etievant et al. (1984) and based on both gas chromotography and mass spectrometry applied to extracts coming from solvent or headspace extractions, showed qualitative and quantitative variations in aroma composition of different sunflower genotypes. A recent study based on a compared analysis of chromatographic profiles of volatile constituents emitted by living heads of different sunflower hybrid parent lines (Marianne, Mirasol, and Primasol varieties), confirmed previous data and identified the specific constituents of each genotype (Pham-Delegue et al., in preparation).

The existence of such genotypic differences among sunflower aroma compositions being proved, the ability of bees to use these differences as cues for selective orientation towards one given genotype has to be studied. A plant aroma is a highly complex chemical blend, and one can ask if all constituents of the blend are equally identified, or if only a few of them are particularly significant and sufficient to lead to a food-oriented behavior. In order to answer these questions, the role and nature of the chemical implied in pollinator attractiveness were studied by a combined chemical and behavioral analysis.

The chemical data have been described elsewhere (Etievant et al., 1984); we will refer to that work while developping, in this paper, the behavioral aspects of the study. Behavioral data were carried out from a bioassay previously set up and based on an olfactory conditioning method (Pham-Delegue, 1983; Pham-Delegue and Masson, 1985).

METHODS AND MATERIALS

Plant Material. In order to provide general information on sunflower aroma constituents, a bulk sample was composed of flower heads from the cultivars H_9P_2, US 894, Marianne, and Mirasol and their inbred lines; flower heads were

frozen at −25°C immediately after their collection and analyzed during the following six months.

Choosing the Extraction Method. Methods for extraction and concentration of sunflower volatile constituents, as well as for analyzing the composition of resulting extracts, were described in detail by Etievant et al. (1984).

The kind of extract used for this behavioral study first had to be chosen, because the analysis of the former authors clearly pointed out that dichloromethane and headspace extraction methods were both valid. In a first step we tried to condition honeybees in a same way to both kinds of extracts. This conditioning was obtained in both cases but six times more material was needed for the headspace extract (three flower heads compared to half a head for the dichloromethane extract); these data confirm the conclusions drawn by Etievant et al. (1984) relative to the different concentration of each kind of extract. Therefore, taking account of bioassay duration, we chose the extract obtained by dichloromethane extraction of sunflower heads.

Splitting of Bulk Sample Obtained by Dichloromethane. The solvent extract was separated into polar and apolar fractions by adsorption chromatography (Etievant et al., 1984). The dilution factor of these two fractions had been carefully adjusted to that of the global extract before their use in behavioral tests. The results of our tests allowed us to divide the polar fraction into three subfractions (A, B, C) using a gas chromatograph set up with a $\frac{1}{8}$-in. glass capillary column packed with chromosorb W (80–100 mesh, acid-washed, DMCS-treated) soaked with a 10% SE 52 phase. Operating conditions were as follows: N_2 was used as the carrier gas (2.5 ml/min); the oven was programmed from 60 to 180°C at 2°C/min; the amount injected was about 40 μl.

The chromatogram was arbitrarily separated in three parts and substances eluted from each of these parts were successively trapped into three glass capillary tubes filled with 10 mg of previously conditioned Porapak Q.

The content of each trap was then eluted by 5 ml of Freon 11 and the resulting fractions A, B, and C were concentrated to the same volume before their use in bioassays. The constituents of the different extracts were separated using a Girdel 300 gas chromatograph fitted with a split/splitless glass injector and a flame ionization detector. Column characteristics were: length 37 m; inside diameter 0.4 mm; SE 52 phase; film thickness 0.6 mm. Temperature was programmed from 40 to 180°C at 3°C/min. Helium was used as a carrier gas (17.1 ml/min). Peak areas were calculated by using a Spectra-Physics Minigrator.

Identification of polar and apolar fraction constituents was detailed by Etievant et al., (1984). The B fraction included compounds eluted from acetic acid ethyl ester to 2-hexanal (*trans*). The B fraction included compounds eluted from eucalyptol to myrtenal, and C fraction, compounds eluted after verbenone, on to the end of the chromatogram of the polar fraction.

The scheme of the different events needed for global extract preparation

from flower heads and for separation of different fractions is reported in Figure 1.

Bioassay. Foraging behavior of honeybees was observed in a flight room (12 m^3) with laboratory controlled conditions (temperature: 25 ± 1°C; humidity: 55%; photoperiod: 12 hr/12 hr) (Figure 2). Foragers come from a honeybee colony of 3000 workers clustered around a fertile 1-year-old queen and its brood. They are presented to a conditioning device set up by Pham-Delegue (1983) and based on the principle of the artificial flower feeder described by Waller (1972) (Figure 2). Honey bees visiting the device undergo an associative conditioning, in which a sugary solution (50% sucrose) is the unconditioned stim-

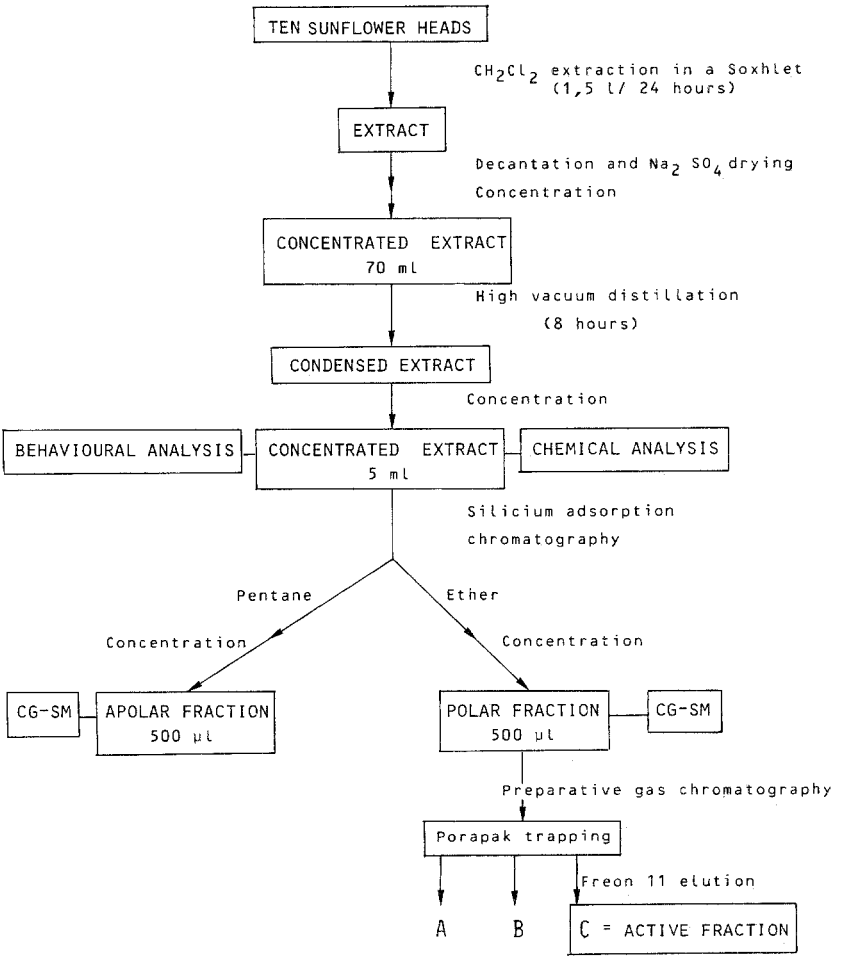

FIG. 1. Chemical processes leading to the isolation of an active fraction.

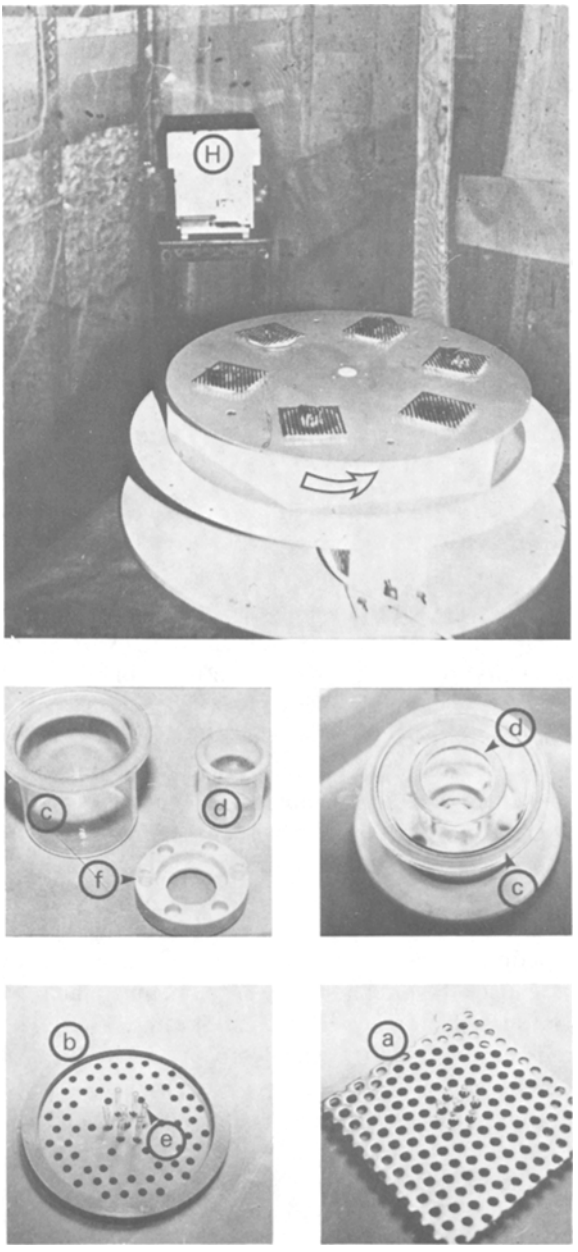

FIG. 2. Artificial flower feeder device used for the test: foragers flying freely from the hive (H) in a flight room are presented to the device set up on a rotating table ($\frac{1}{3}$ rpm). Conditioning period: association of the conditioning scent with sucrose solution in six artificial flower feeders (cf. Figure 6); a, perforated metal screen; b, plastic perforated lid; c, 80-ml glass beaker; d, 15-ml glass beaker filled with the sucrose solution; e, glass pipet, ID: = 1 mm; f, scent diffusor.
Testing period: three unscented sites (paraffin oil) alternating with three scented sites. No sugary reinforcement.

ulus, and a scent diffusing close to the food source is the conditioned stimulus. The conditioning period lasted 2 hr; conditioning efficiency was then tested, without any food reward.

The choice was given between the conditioning scent and an unscented control, or between the conditioning scent and different scents. The testing period was divided into four phases of 5 min, each phase corresponding to 20 successive responses (or visits) at least. Each testing phase followed by a 10 min reward period where the conditioning stimulus was associated with the sugary solution again. Such a protocol allowed a high visit frequency during tests and a high reproducibility of bee responses.

A statistical analysis of the distribution of visits among the different stimulus allowed to define how far foragers are able to discriminate (pooled χ^2 applied to percent visit distribution).

RESULTS

Volatile extracts obtained from splitting were diluted in Freon 11 and kept in sealed glass tubes in a deep freezer. Thus, before any experiment with such extracts, it is necessary to check if Freon 11, a very volatile substance (boiling temperature = 23°C), would induce any disturbance in bee choice.

Control of Solvent Effects. Foragers were trained to visit an unscented food source (paraffin oil as unscented control). Then bees were given a choice between paraffin oil added with a large amount of Freon 11 (1 ml Freon 11 in 1 ml paraffin oil) and pure paraffin oil. In such experimental conditions, visit distribution was perfectly random (61 visits to paraffin oil and 63 visits to paraffin oil added with Freon 11).

In order to control possible interaction between Freon 11 and scents, another control experiment was set up with a pure odorant, geraniol. This compound, which is part of the aroma spectra of numerous plants, was the major constituent of Nasonov pheromone (Boch and Shearer, 1962) which acted as a recruiting pheromone on slightly scented food sources (Frisch, 1923; Free, 1962). In this control experiment honeybees were trained to a 1% geraniol solution (paraffin oil as solvent) and were then given a choice between the conditioning solution and the same solution with added Freon 11 (volume per volume). No significant discriminatory effect linked to Freon 11 was apparent (56 visits to geraniol scented sites and 64 visits to sites diffusing geraniol added with Freon 11). Thus, one could conclude that Freon 11, which was not significantly identified, will not disturb aroma recognition.

Existence of Active Fractions. The global extract kept in Freon 11 was diluted in paraffin oil to limit evaporation speed. In order to determine the dilution ratio sufficient for an efficient conditioning (i.e., a significant recognition of the extract), several dilutions were made. A dilution of the initial extract (5

ml) at a ratio of 100 μl/ml of paraffin oil corresponding to half a flower head extraction, allowed a highly significant conditioning (66 visits to scented sites vs. 29 visits to unscented controls, during the testing period) (Table 1).

The polar and apolar fractions obtained from the global extract were then respectively tested against the global extract being considered as the conditioning stimulus. It appears that the apolar fraction is significantly discriminated from the global aroma, while the polar fraction is confused with the conditioning aroma (Table 1; Figure 3-A). Thus the polar fraction (Figure 5) may be considered by honeybees as very similar to the global aroma (Figure 4).

Because of the low quantities of global extract being kept, from this phase of experimentation experiments were carried out with the polar fraction as a conditioning stimulus. Conditioning efficiency of this polar fraction was first checked (80 visits to sites diffusing the polar extract vs. 31 visits to unscented controls, during the testing period) (Table 1). Then the three fractions (A, B, C) obtained from preparation chromatography (Figure 5) were successively presented versus the conditioning polar fraction. Behavioral responses indicated that only fraction C is statistically confused with the polar fraction (Table 1,

TABLE 1. TOTAL NUMBER OF VISITS[a] TO SUNFLOWER EXTRACTS AND ITS FRACTIONS DURING CHOICE EXPERIMENTS AFTER CONDITIONING

	Global extract			Polar fraction of the global extract

Fraction C of the polar fraction		—		54	41	8

[a] Number of visits recorded along four successive tests, each test including at least 20 landings ($N_1 + N_2 > 80$).
[b] Mean number of different foragers performing the tests.

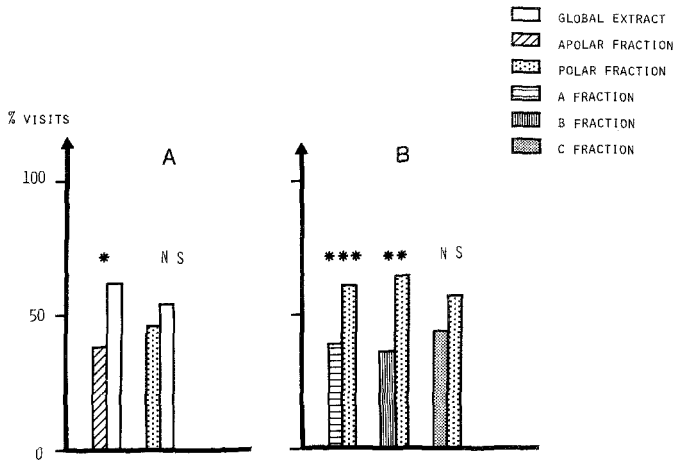

FIG. 3. Foragers behavioral responses (as a percent of visits) tested after a conditioning to: (A) the global sunflower extract; (B) the polar fraction previously defined as active. Values were calculated from four test experiments of at least 20 visits each.

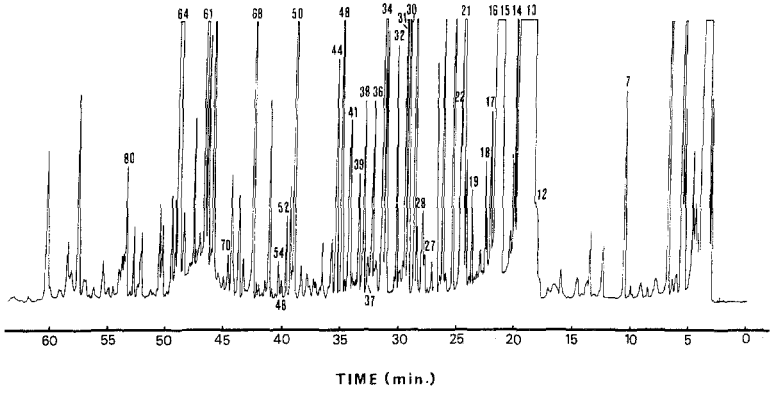

FIG. 4. Capillary GC analysis of sunflower-head volatile components from dichloromethane extraction (conditions are described by Etievant et al., 1984, and are reported in the text; peaks are numbered according to the notation of these authors).

Figure 3-B). Thus fraction C represented the new active fraction for bees, more limited as regards the number of chemicals than the previous one (i.e., the polar fraction of the global extract). Compounds identified from this fraction are presented in Table 2.

The mean number of individuals performing the tests (Table 1) was rather low compared to the number of recorded visits. These data show the high frequency of landings performed by each conditioned forager.

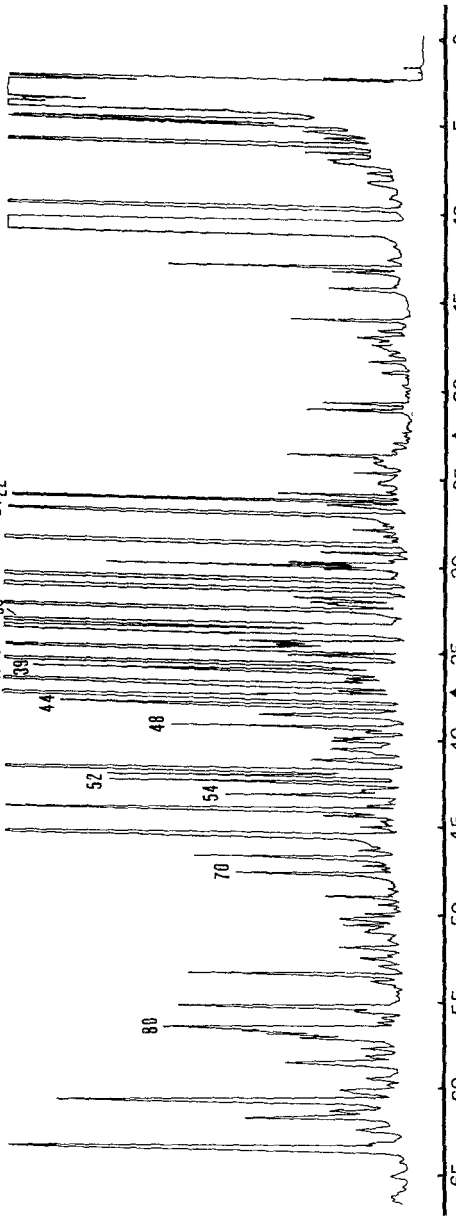

FIG. 5. Polar fraction of the global sunflower extract obtained from adsorption chromatography and then separated into three subfractions (A, B, C) according to conditions described in the text.

[a]See Etievant et al. (1984); numbers underlined are reported in the chromatogram of Figure 5 (C fraction).

Thus, this succession of experiments showed that a limited pool of molecules of the C fraction is sufficient for bees to identify a wider blend, including the active fraction. Successive steps leading to these results are summarized in Figure 6.

DISCUSSION

Data obtained from responses by foragers to different volatile extracts in an olfactory conditioning situation give a better understanding of the method used by bees to analyze complex olfactory information. In a complex aromatic

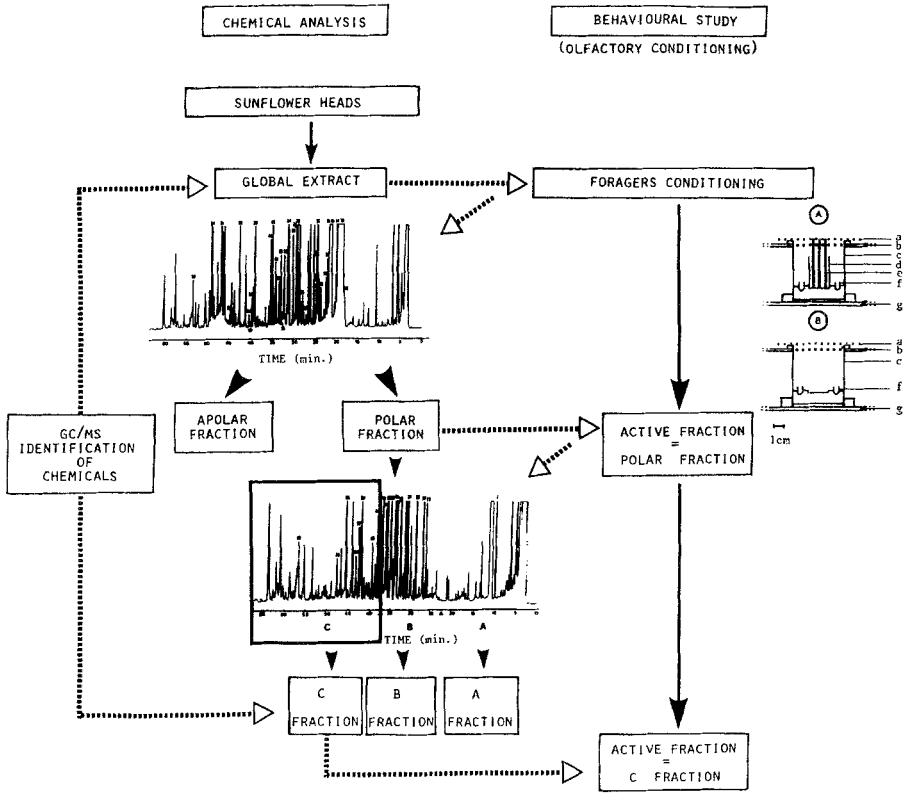

FIG. 6. Scheme summarizing the successive steps of combined chemical analysis and behavioral study leading to the identification of a limited fraction (fraction C) acting on bees foraging behavior. Artificial flower feeder: see Figure 2; A: conditioning device; B: testing device.

blend including hundreds of compounds, a limited fraction is extracted in a sufficient quantity to allow global olfactory information recognition. This fraction is acting as a "simplified aromatic pattern" of the plant.

While behavioral bioassays described in this work were carried out, 47 compounds were listed in the "mean aroma" obtained from the different sunflower genotypes collected. Through subsequent chemical analysis, Etievant et al. (1984) obtained 84 compounds among which 58 were identified.

The C fraction, identified as an active fraction in sunflower head aroma recognition, was quantitatively limited since it represented only about 2.5% of the global extract. Qualitatively, this fraction included monoterpenic alcohols and ketones as well as esters of these alcohols, a diunsaturated aldehyde, three phenols, one product of carotenoid degradation, and several sesquiterpenic al-

cohols, among which five are still to be identified and can be compared to the sesquiterpenic compounds identified in *Helianthus* genus by Gershenzon et al. (1981).

However, it must be noted that the main problem in the study of the bioactivity of complex chemical blends was to realize assays with microquantities of material for which composition was likely to alter with time. Thus, for further studies, stimulus control requires a theorical study of volatile release and the use of dynamic release processes in order to maintain a known and constant composition of the volatile fraction. Currently, in our laboratory, a multigate olfactory stimulating device is at our disposal; this device, set up by Masson et al. (in preparation), allows the automated stimulation of a biological material to be performed with a series of pure odorants in various dilutions of more or less complex blends in controlled quantities.

Through this device, a more analytical approach to the study of olfactory stimulus and resulting responses should be obtained. Biological activity resulting from this kind of stimulation should be quantified as peripheral nervous system responses, in the case of classical electrophysiological methods, and as behavioral responses, as registered in an adapted bioassay.

Improvement of such studies should allow us to complete our knowledge of the sunflower "aromatic pattern" composition, taking into account that the active fraction previously described was defined from a blend of different sunflower genotypes; aromatic pattern specificity as a function of plant genotypes should thus be determined, since qualitative and quantitative differences in volatile composition among sunflower cultivars have already been pointed out (Etievant et al., 1984).

In conclusion, such attractive fractions and plant-specific aromatic patterns should be useful cues for plant breeding. A joint genetic and chemical analysis could allow the determination of the genetic bases responsible for plant aromatic constituents biosynthesis (e.g., in *Mentha* genus according to Hefendehl and Murray, 1976). One should thus be able to create plant varieties with aromatic patterns attractive towards pollinating insects or, on the contrary, to improve chemical resistance to pests, linked to some terpenes, as suggested by Gershenzon et al. (1981) for sunflower. Such a genetic control could also allow the control of olfactory cues of discrimination between different cultivars and improve hybrid seed production linked to cross pollination.

Acknowledgments—We gratefully acknowledge Ph. Douault and J. Chauffaille for helpful technical assistance and the Club de Selection du Tournesol for valuable material support in this study.

ROLE OF SECONDARY METABOLITES IN FEEDING ASSOCIATIONS BETWEEN A PREDATORY NUDIBRANCH, TWO GRAZING NUDIBRANCHS, AND A BRYOZOAN

BRAD CARTÉ and D. JOHN FAULKNER

Scripps Institution of Oceanography
University of California, San Diego
La Jolla, California 92093

(Received April 22, 1985; accepted August 2, 1985)

Abstract—The carnivorous nudibranch *Roboastra tigris* preys preferentially upon two nudibranchs, *Tambja abdere* and *T. eliora*, that in turn feed upon the bryozoan *Sessibugula translucens*. All four organisms contain tambjamines A–D (I–IV) that were shown to be fish feeding inhibitors. When attacked by *Roboastra, T. abdere* secretes a distasteful mucus containing a total of 3 mg of the tambjamines that sometimes causes the *Roboastra* to break off the attack. Under similar circumstances *T. eliora* attempts to swim away; it presumably contains insufficient of the tambjamines to deter *Roboastra. Roboastra* follows the slime trail of nudibranchs using contact chemoreception and reverses direction when the trail is broken. The slime trail of *T. abdere* contains low concentrations of the tambjamines. In Y-maze experiments, *T. eliora* was attracted towards seawater containing *S. translucens* and seawater containing 10^{-10} M tambjamines A and B (1 : 1) but was repelled by seawater containing $>10^{-8}$ M tambjamines A and B. At higher concentrations the mixture of tambjamines may be recognized as an alarm pheromone.

Key Words—*Roboastra tigris*, *Tambja abdere*, *Tambja eliora*, *Sessibugula translucens*, tambjamines A–D, chemical defense, alarm pheromones, trail-following behavior.

INTRODUCTION

Gastropod mollusks of the subclass Opisthobranchia do not seem to derive any physical protection from a shell which, if present, is often reduced or covered by soft tissue. In the Nudibranchia, a shell is completely lacking. The lack of a shell is correlated with alternative defense mechanisms (Faulkner and Ghi-

0098-0331/86/0300-0795$05.00/0

selin, 1983). Sea hares and dorid nudibranchs employ defense mechanisms based on dietary chemicals (Thompson *et al.*, 1982; Schulte and Scheuer, 1982) that are effective in deterring most potential predators. However, these chemical defense mechanisms can be penetrated by specialist predators such as the cephalaspidean *Navanax inermis* (Paine, 1963) and the nudibranch *Roboastra tigris* (Farmer, 1978). The added level of complexity in the association between a carnivorous nudibranch and the nudibranchs it eats led us to investigate the role of secondary metabolites in this relationship.

Roboastra tigris is a large carnivorous nembrothid nudibranch that is known to prey upon two smaller nembrothid nudibranchs, *Tambja abdere* and *Tambja eliora*. In their attempts to avoid predation by *R. tigris*, the two species of *Tambja* employ very different escape responses: *T. eliora* swims away by undulating the body from side to side while *T. abdere* secretes copious amounts of a yellow mucus from numerous goblet cells found in the skin (Farmer, 1978).

Chemical studies of *R. tigris*, *T. abdere*, and *T. eliora* revealed that all three nudibranchs contained a similar array of pharmacologically active metabolites that exhibited antimicrobial properties and inhibited cell division in the fertilized sea urchin egg assay (Carté and Faulkner, 1983). The metabolites were identified as the tambjamines A–D (I–IV) and the aldehydes V–VII (Figure 1). The aldehydes V–VII were subsequently shown to be artifacts produced by hydrolysis during the extraction procedure. By comparing the antimicrobial spectra of crude extracts, it became apparent that both species of *Tambja* obtained the tambjamines (I–IV) from a single dietary source, the bryozoan *Sessibugula translucens*. Field observations confirmed these associations. The quantitative distribution of the tambjamines (I–IV) and aldehydes V–VII in the four organisms is recorded in Table 1 (from Carté and Faulkner, 1983). These data establish that the bryozoan *S. translucens* is a principal component of the diets of both species of *Tambja* that are in turn preyed upon by *R. tigris*.

These observations raised several questions. What is the role of the tambjamines in the close association among the bryozoan and the three nudibranchs? How do the *Tambja* species locate their preferred food source? Why does *T. abdere* use an apparent chemical defense against predation by *R. tigris* while *T. eliora* attempts to swim away? Can *R. tigris* detect its prey by chemorecep-

Percent dry wt	0.39%	3.42%	2.15%	0.45%

tion? In this paper we report both field observations and laboratory experiments that establish the chemical relationships between the four organisms.

METHODS AND MATERIALS

Major collections of specimens were made in several locations in the Gulf of California: Puerto Escondido, Baja California (May 1980)—*T. abdere* and *T. eliora*; Bahia de los Angeles, Baja California (May 1980 and April 1982)—*R. tigris*, *T. abdere*, *T. eliora* and *S. translucens* (1982 only); and Isla Partida (April 1982)—*T. eliora* and *S. translucens*. The animals were observed and collected at 2–6 m depth. Live specimens of all four organisms were collected at Bahia de los Angeles and transported to La Jolla in aerated seawater. All organisms were maintained in flowing seawater aquaria. *R. tigris* was maintained on a diet of *T. eliora*, the two *Tambja* species on a diet of *S. translucens*, and the bryozoan was fed daily with unicellular algae (*Isochrysis galbana*, *Anacystis marina*, *Rhodomonas lens*, and *Monochrysis lutheri*, all of which were cultured in GPM media under standard conditions).

Samples of tambjamines A–D (I–IV) were isolated and purified using the procedures described previously (Carté and Faulkner, 1983). In some experiments, mixtures of compounds were employed. The mixtures were obtained by omitting the final LC separation.

Feeding Inhibition Assays. Feeding inhibition was assayed by observing the feeding response of the spotted kelpfish *Gibbonsia elegans* toward food pellets ("San Francisco Bay Brand" freeze-dried euphausids) treated with pure compounds at concentrations ranging from 1 to 50 μg/mg. The kelpfish, collected intertidally at La Jolla, were kept in aquaria and were trained to accept

food from a glass tube. The test compounds were applied to the pellets (N = 10) in redistilled dichloromethane solutions, and the solvent was removed at 25°C under vacuum. Control pellets were treated with solvent only. Fish were fed the pellets in a random order and the response (eaten vs. rejected) recorded. The probability of obtaining the observed results was calculated using a chi-square distribution to determine the level at which a significant feeding avoidance was observed ($P < 0.5$ level). The following results were obtained: 3:2 mixture of tambjamine A (I) and tambjamine B (II); 10 μg/mg—7 of 10 pellets rejected, control—9 of 10 pellets eaten ($\chi^2 = 7.50$, $P < 0.01$); 5 μg/mg—3 of 10 pellets rejected, control—9 of 10 pellets eaten ($\chi^2 = 1.25$, $P < 0.5$). In a 3:7 mixture of tambjamine C (III) and tambjamine D (IV); 5 μg/mg—7 of 10 pellets rejected, control—9 of 10 pellets eaten ($\chi^2 = 7.50$, $P < 0.01$); 1 μg/mg—2 of 10 pellets rejected, control—9 of 10 pellets eaten ($\chi^2 = 0.39$, $P < 0.95$).

Analysis of Tambjamines A–D (I–IV) in Exudate and Slime Trail of T. abdere. A specimen of *R. tigris* was allowed to attack an average-sized specimen of *T. abdere* in a dish containing "Instant Ocean" synthetic seawater (100 ml). After the specimen had exuded copious quantities of a yellow mucus from glands on the dorsal surface, the animals were separated and removed. The dish and its contents were extracted with dichloromethane (3 × 75 ml), the combined extracts dried over anhydrous sodium sulfate and the solvent removed to obtain a green oil (4.8 mg).

Two specimens of *T. abdere* were allowed to crawl over a bed of aquarium dolomite that had previously been washed sequentially with water, dichloromethane, water, and synthetic seawater. The trails were marked with colored dolomite, the animals were carefully removed, and the dolomite on which the trails were laid was removed with a "lab scoop" spatula. The dolomite was washed with dichloromethane (3 × 200 ml), the combined extracts dried over anhydrous sodium sulfate, and the solvent evaporated to obtain an organic residue (3.1 mg).

The concentrations of the tambjamines A–D (I–IV) were determined by analytical LC. Separation of the tambjamines (I–IV) was accomplished by LC on an Alltech spherisorb 5-μm C18-ODS analytical column using a linear solvent gradient from 20% to 75% acetonitrile in 0.05 M pyridinium acetate buffer (pH 5.0) (see Figure 2). The tambjamines were detected by UV absorption at 400 nm. Standard response curves of concentrations vs. peak area (height × width at half height) for each pure compound were used to calculate concentrations of the tambjamines in the exudate and the slime trail (see Table 2).

Y-Tube Experiments. A Y-tube apparatus was constructed from clear Plexiglas tubing (3.75 cm ID) and "aged" in seawater. Prior to each experiment, the Y tube was thoroughly washed in natural seawater using a bottle brush to remove any attached materials. A coin flip was used to determine which arm of the Y tube would be the control arm. The control arm contained a stream of

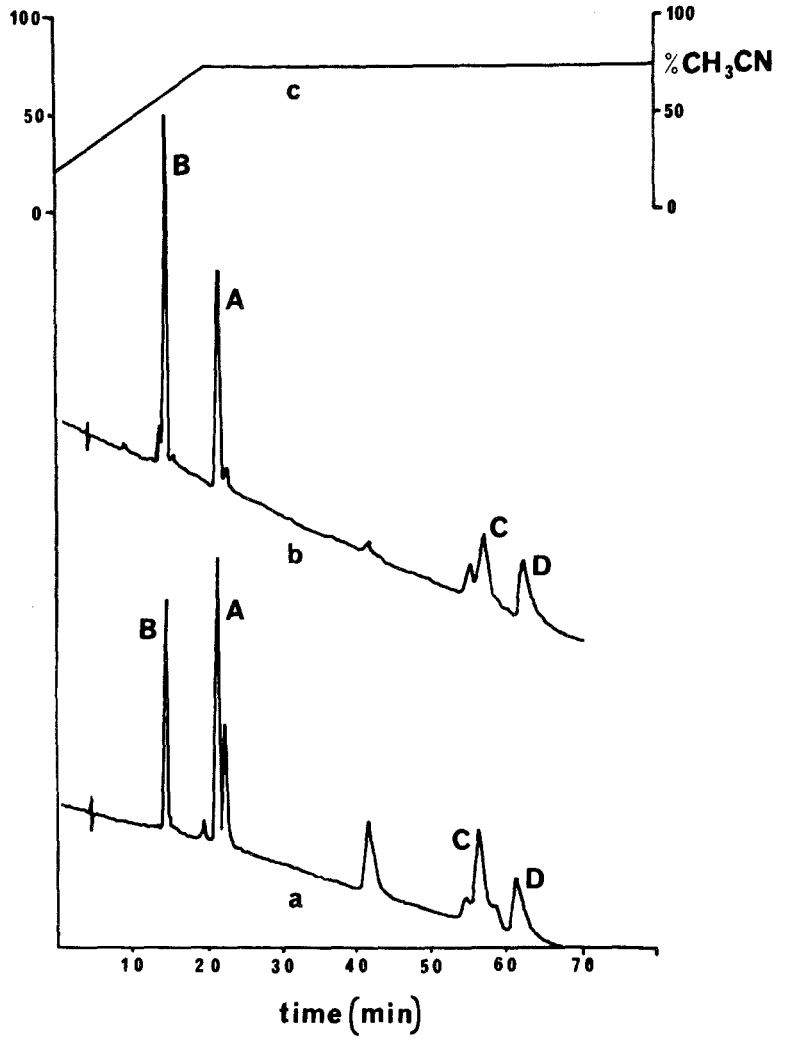

FIG. 2. HPLC analysis of (a) the defensive secretion of *Tambja abdere* compared with (b) a partially purified mixture of the tambjamines A–D isolated by extraction of whole animals. Compounds were identified by coinjection with pure samples. The samples were chromatographed on an analytical column of Alltech spherisorb 5 μm C18-ODS packing using a solvent gradient (c) from 20% to 75% acetonitrile in 0.05 M aqueous pyridinium acetate (pH = 5.0) at a flow rate of 1 ml/min.

either natural seawater or seawater containing ethanol (25 μl/liter of seawater). The test arm contained either seawater emanating from an aquarium containing the test organism or a solution of a 1 : 1 mixture of tambjamines A (I) and B (II) in ethanol (25 μl) in seawater (1 l) adjusted to produce final concentrations

TABLE 2. DISTRIBUTION OF TAMBJAMINES A–D (I–IV) IN *T. abdere* DEFENSIVE EXUDATION AND SLIME TRAIL

	Exudate (mg)	Trail
Crude	4.8	3.1 mg/50 cm
Tambjamine A (I)	0.85	0.06 μg/cm
Tambjamine B (II)	0.80	0.02 μg/cm
Tambjamine C (III)	0.79	0.13 μg/cm
Tambjamine D (IV)	0.56	0.15 μg/cm
Total	3.0	17.7 μg/50 cm

TABLE 3. RESULTS OF Y-TUBE EXPERIMENTS WITH *T. eliora*

Test sample	No. of Runs	Positive[a]	Negative[b]	Remarks
S. translucens	36	34 (94%)	2 (6%)	Attraction[d]
S. translucens (Δ 12 hr)[c]	20	9 (45%)	11 (55%)	Random[e]

[e] $P > 0.05$; binomial probability, $p = q = 0.5$.

ranging from 10^{-7} to 10^{-11} M tambjamines in seawater. Flow rates were adjusted to give equal flow rates (100–150 ml/min) in each arm of the Y tube. A specimen of *T. eliora* was introduced into the apparatus and the result recorded as positive if the animal crawled up the test arm of the Y tube. The results are recorded in Table 3.

RESULTS

Field and Aquarium Observations. There is a very close association between the three nembrothid nudibranchs and the bryozoan *S. translucens*. In particular, the nudibranchs *T. abdere* and *T. eliora* occurred only in locations where *S. translucens* was common, and individuals were generally found on or

near the bryozoan. Although *Roboastra tigris* was known to feed on a variety of smaller nudibranchs (J.R. Lance, personal communication), it prefers to prey on *T. abdere* and *T. eliora* and was most commonly found in areas where the *Tambja* nudibranchs, and therefore the bryozoan *S. translucens*, also occurred. However, a few specimens of *R. tigris* were encountered in habitats seemingly devoid of either *Tambja* species.

Field observations of the feeding habits of *R. tigris* suggested that the nudibranch could easily detect and follow fresh slime trails of *T. abdere*, *T. eliora*, and several other nudibranchs. The trail-following behavior is similar to that described by Paine (1963) for the Cephalaspidean opisthobranch *Navanax inermis*. To follow a slime trail, *R. tigris* "feels" for the trail with external, anterior located cephalic tentacles while sweeping its head from side to side. If the trail is broken, *R. tigris* will usually turn around and follow the trail in the reverse direction. It appears that *R. tigris* relies on direct contact between the cephalic tentacles and the slime trail and is not capable of detecting the resumption of the trail by distant chemoreception.

Once the prey has been located, *R. tigris* rapidly everts a blue buccal hood that engulfs the prey. In attempting to avoid predation by *R. tigris*, the two *Tambja* species use different escape strategies. *Tambja eliora* attempts to escape by writhing vigorously, while *T. abdere* excretes an apparently distasteful yellow mucus (Farmer, 1978). In aquarium situations, *T. abdere* was more successful in repelling attacks of *R. tigris*, but in field situations, where currents and wave motion were present, the swimming motion of *T. eliora* seemed equally effective because the slime trail is thereby broken.

Chemical Studies. We had previously found that specimens of *T. abdere* contained an average of approximately 10 mg of a mixture of tambjamines while specimens of *T. eliora* contained less than 2 mg of the same mixture of tambjamines (Carté and Faulkner, 1983). In order to demonstrate their deterrent value, mixtures of the tambjamines were assayed for feeding inhibition against the spotted kelpfish *Gibbonsia elegans* and were found to be effective at concentrations of 5–10 μg/mg pellet for a 3:2 mixture of tambjamines A and B and at 1–5 μg/mg pellet for a 3:7 mixture of tambjamines C and D. The aldehydes V–VII, which are formed by hydrolysis of the tambjamines, are not effective feeding inhibitors at concentrations less than 20 μg/mg. These data indicate that the tambjamines are relatively effective fish feeding inhibitors (cf., Thompson et al., 1982) and might be considered to provide protection against predators other than *Roboastra*. Since the differences in the escape responses of *T. eliora* and *T. abdere* might be an outcome of the different quantities of the tambjamines in the two animals, it was important to determine the quantity of tambjamines in the defensive secretion of *T. abdere*. LC analysis of the exudate from an average-sized specimen of *T. abdere* revealed that the defensive secretion contained a total of 3 mg of a mixture of tambjamines A–D (I–IV) (Table 2).

Since *R. tigris* had been observed to hunt *Tambja* species in preference to other nudibranchs, we suspected that the slime trails of *Tambja* might contain distinctive chemicals. A 50-cm length of the dolomite on which the trail of *T. abdere* had been secreted was extracted with dichloromethane to obtain a total of 18 μg of the tambjamines A–D (I–IV) (Table 2).

Although our field observations suggested that *R. tigris* could not detect the tambjamines by distant chemoreception, there was a good reason to believe that the *Tambja* species could find their food source, *Sessibugula translucens*, by using chemical detection. To test this hypothesis, a number of Y-maze experiments, modeled on those of Davenport and Hickock (1951), were performed using *T. eliora* as the test animal. *T. eliora* were clearly attracted by water that had been passed over *S. translucens*, but they were unaffected by water passing over *Bugula neritina*, a species of bryozoan that is common in areas populated by *Tambja* and that appears to be eaten only when *S. translucens* is unavailable. Water removed from an aquarium containing *S. translucens* and allowed to stand for 12 hr no longer elicited a positive response, indicating that the chemical responsible for attraction was not stable in seawater. These results suggested that the tambjamines (I–IV), which are easily hydrolyzed to the aldehydes V–VII, might be responsible for the observed chemotactic response of *T. eliora*. A 1 : 1 mixture of tambjamines A (I) and B (II) was tested at several concentrations from 10^{-7} M to 10^{-11} M. At very low concentrations, the tambjamines elicited no response, but the nudibranchs were attracted to a 10^{-10} M solution of tambjamines A and B in seawater. At concentrations greater than 10^{-9} M, *T. eliora* was repelled by the test solution (see Table 3).

DISCUSSION

Our previous chemical studies had established the presence of the tambjamines in the bryozoan *Sessibugula translucens* and the three nembrothid nudibranchs *Tambja abdere*, *Tambja eliora*, and *Roboastra tigris* (Carté and Faulkner, 1983). These results, together with our random field observations and those of Farmer (1978) and Lance (personal communication), clearly established that *T. abdere* and *T. eliora* favored the bryozoan *S. translucens* as a food source and were, in turn, eaten by *R. tigris*. The Y-maze experiments demonstrate that the *Tambja* species can locate their preferred food source by detection of low concentrations of the tambjamines that are produced by the bryozoan *S. translucens*. While it is not firmly established that *R. tigris* can distinguish the slime trails of *Tambja* species from those of other species by detecting tambjamines, their presence in low concentrations in the slime trail of *T. abdere* certainly suggests that this is the case. It would be difficult to test this hypothesis because we would require a synthetic slime trail sufficiently similar to the natural material that it would be followed by *Roboastra*.

The exudate of *T. abdere* contains a very large quantity of the mixture of tambjamines, representing approximately 30% of the metabolites stored by a typical animal. The exudate is clearly distasteful enough to deter most potential predators and can sometimes repel the specialist predator *R. tigris* (Farmer, 1978). However, the use of such a great proportion of the stored tambjamines to repel a single attack must render the animal susceptible to repeated attacks if it cannot rapidly replace the active ingredients of its defensive secretion. Since the entire tambjamine content of an average specimen of *T. eliora* is less than that used by *T. abdere* during a single, sometimes unsuccessful encounter with *R. tigris*, it is not surprising that *T. eliora* has adopted an escape strategy that is not dependent on a chemical feeding inhibitor.

The Y-maze experiments demonstrated that *T. eliora* avoided a 10^{-8} M solution of a 1 : 1 mixture of tambjamines A and B in seawater but were attracted by a 10^{-10} M solution of the same compounds. The ability to detect a two order of magnitude difference in the concentration of tambjamines in seawater may assist *T. eliora* in avoiding predation. While it is unlikely that *R. tigris* exudes a sufficient quantity of the tambjamines to be detected at a distance, an encounter between *Roboastra* and a *Tambja* species might result in the localized release of tambjamines, thus warning other potential prey of the presence of a predator, similar to a situation found among some fishes (von Frisch, 1941) and for the marine mud snail *Nassarius obsoletus* (Atema and Stenzler, 1977). Concentration-dependent properties have also been observed for ant trail pheromones (Tumlinson et al., 1971).

The ease with which the tambjamines (I–IV) are hydrolyzed to obtain the less active aldehydes V–VII provides a natural mechanism to remove old trails and exudations that might otherwise provide false information. This is considered an important factor in maintaining the efficacy of a chemical messenger.

Acknowledgments—We thank James R. Lance for providing information on the distribution and behavior of the nudibranchs. The feeding inhibition assay was devised by Joseph R. Pawlik who has also critically reviewed this manuscript. The research was supported by a grant from the National Science Foundation (CHE81-21471).

Book Review

Semiochemistry: Flavors and Pheromones. Proceedings of an American Chemical Society Symposium, Washington, D.C., U.S.A., August 1983. Terry E. Acree and David M. Soderlund (eds.). Berlin, Walter de Gruyter, 1985. DM 160, 289 pp. (ISBN 3 11 010120 3; 0 89925 008 4)

The pheromone chemist becomes curious about how insects or mammals perceive odor and turn it into a nervous signal and that leads his curiosity on to theories of odor. This brings pheromone and flavor chemists onto common ground, and I find the increasing signs of the mingling of these disciplines exciting and informative. Cross-fertilization of this kind will help us to understand the mechanism of odor. Here lies the value of such mingling rather than the exchange of technical methods of chromatography or bioassay.

This is a very readable book, an account of one of these exchanges of information, a splicing of knowledge at an ACS symposium. The first chapter, by Miller and Harris described how the onion fly uses chemical and visual (shape and color) clues to find the onion plant for laying its eggs. They describe a number of neatly designed experiments which illustrate the case. The subsequent theoretical treatment with the cumbersome (and is it really necessary?) term "across-modality stimulus summation" puts the case that taste, smell, visual, and tactile signals all interlock to release a particular behavior such as movement or oviposition. They rightly point to the danger of trying to narrow down a behavioral pattern to a single stimulus such as a chemical odor. The next contribution, by Acree and Nishida, illustrates the effect of chirality on odor with respect to the methyl jasmonate isomers. One isomer (the one normally found in nature) has a much lower detection threshold (1000×) than any other. Another paper describes the interaction of various female- and male-derived pheromones, described as a chemical dialog, which produces copulation in the Oriental fruit moth.

The pheromone emphasis is on insects, but there is one interesting contribution by R.W. Bullard on the quite different problem of devising attractants and repellents for birds and wild animals. A point which emerges here and elsewhere is that in many cases (not all) the same compounds are odorous for us, mammals and insects. It is unfortunate there were no data anywhere in the book about comparative detection thresholds for different animals. (+)-α-Terpineol, which may be a pheromone for a pentatomid bug is shown to be an

0098-0331/86/0300-0805$05.00/0

attractant for its predators and parasites. Silverstein gives a general account of chirality and its effect on pheromones and odor, which makes very pleasant reading. Most researchers are now thoroughly alert to the importance of chirality in this respect, but this chapter will be a very useful guide for beginners in the subject.

There is a discussion of bitter compounds in citrus fruit, on the attractiveness of sunflowers to insects, and the volatile flavor substances of the cherimoya fruit. T.H. Parliment describes an interesting experiment where he mixed 18 synthetic flavor chemicals and then fractionated them on various HPLC phases and obtained fractions with distinctly different flavors. Inevitably, at a symposium, not all contributions will be equally addressed to the topic, and some are more technical and limited in their view than others, but overall, the 16 contributions make interesting and easy reading. Papers with emphasis on technical detail, such as the bioassay of lepidopteran sex pheromones, were less interesting to me than those with a more wide-ranging discussion.

It is true, as the editors point out, that researchers into flavors, fragrances, and pheromones often find themselves confronted by identical problems of separation and characterization. I have the impression we are usually quick to adopt or adapt techniques, once we have heard of them, but the theoretical understanding is where we have most to gain by contact. It is therefore important that we speak the same language, as far as possible, and avoid the use of too much specialized jargon.

This book is for browsing, rather than for reference. Its 289 pages are double-space typewritten, with justified margins. There are not many words to the page, and the style is often cursive; it does not take long to read. Unfortunately the price means that many will read the library copy, but it is certainly worth seeking out. Like a flavor, this book is intended to stimulate. It does.

Editors' Note

This special issue is devoted to a symposium on interactions between insects and photoactive chemicals. It includes invited papers presented at the December 1984 national meeting of the Entomological Society of America in San Antonio, Texas, and several subsequent related contributions. Dr. May Berenbaum, who has written an introduction to the issue, served as coordinator of the symposium and as a reviewer of the manuscripts. Others serving as reviewers were: A. Eisenstark, C.S. Foote, J.R. Heitz, G.W. Ivie, T.W. Mize, D. Sharp, G.H.N. Towers, R.W. Tuveson, and S.J. Yu.

We acknowledge the cooperation of Plenum Publishing Corporation in producing extra copies of this issue to accommodate registrants of the symposium and others interested.

Introduction

Many plants, including several economically important weeds and crop plants, are able to produce blistering, swelling, and erythema (reddening) upon contact or ingestion in a variety of organisms (Galitzer and Oehme 1978). These effects were, of course, of most concern in humans and the pharmacological applications of these plants are legion in human history, dating back at least to 1400 BC, when the Atharva Veda, a Hindu sacred book, refers to the use of certain black seeds, thought to be *Psoralea corylifolia*, in the treatment of certain skin diseases (Fitzpatrick and Pathak, 1959). Early herbalists such as Mattioli and Gerard cautioned readers against the hazards of collecting rutaceous plants such as *Ruta*, which "causes blisters and pimples on the hands and reddens them" (Knowlton and Ockert, 1950). In 1905, Busck first suggested that sunlight may be a critical component in this and similar reactions, known collectively as phytodermatitis; it was not, however, until 1939 that Jensen and Hansen established that only those solar wavelengths between 320 and 400 nm were capable of effecting pigmentation and erythema (Clare 1952). This range comprises the near-UV (NUV; 300–400 nm) or UV-A region of the solar spectrum.

Ultraviolet light can have dramatic effects when absorbed by a biomolecule. Absorption of photon energy can change the reactivity of a chemical by altering its electron configuration. Under standard conditions, molecules tend to stay in their least reactive electron state, called the ground state. Higher states result from absorption of a photon and subsequent movement of an electron from a low-energy orbital to a higher energy orbital. Each electron has a spin of + or $-\frac{1}{2}$; when the spins are parallel, the configuration is referred to as a triplet and if the spins are opposite, the state is referred to as a singlet. Excited states are generally reactive and short-lived. Molecules in excited states can dispose of their surplus energy in several ways; they can relax and return to ground state by emitting a photon, resulting in fluorescence; they can return to ground state and emit heat; or they can undergo intersystem crossing—that is, an excited singlet can form an excited lower-energy triplet state, which can then go on to transfer energy to another molecule in ground triplet state.

In the case of the furanocoumarins, photosensitizing substances in the Umbelliferae and Rutaceae, excited triplets interact with DNA, particularly pyrimidine DNA bases, to form irreversible cycloadducts which then interfere with transcription and template formation (Scott et al., 1976). In the case of many other photosensitizers, the excited triplet state interacts with molecular oxygen. In its ground state, oxygen is a triplet, which can take the energy of an absorbed

0098-0331/86/0400-0809$05.00/0

photon to form a singlet state. Singlet oxygen is highly reactive and can proceed to react with other biomolecules, including proteins, lipids, and DNA, to cause oxidative damage. As a diradical, ground-state oxygen can also form superoxide free radicals in the presence of a photosensitizer. Superoxide can peroxidize lipids, denature enzymes, cleave DNA, depolymerize polysaccharides, and otherwise interfere with basic biological processes (Larson, 1978).

The presence of photoexcitable compounds in plants remained something of a scientific curiosity (and nuisance to cattle, horse, and sheep ranchers whose stock was prone to periodic phytodermatitis as a result of ingesting photoactive species; Ivie, 1977) long after the actual mechanism of photosensitization was described. In 1959, however, Fraenkel introduced the idea that plant secondary substances, compounds—such as photoactive biomolecules—with no known physiological function in the plants producing them, actually serve plants as in situ insecticides; as a result of the intensive selection pressure exerted over time by herbivorous insects, these chemicals evolved to reduce losses to insect herbivores. Almost 20 years later, the importance of ultraviolet light as an ecological factor mediating the toxicity of plant secondary substances to insects was first demonstrated (Berenbaum, 1978); since that time, considerably more evidence has been amassed to suggest that, over evolutionary time, many plants have exploited two ubiquitous components of their physical environment—sunlight and oxygen—to enhance the efficacy of their defensive armamentarium against insects.

In December 1984, the Entomological Society of America sponsored the first symposium focusing on interactions between insects and photoactive plant chemicals. Seven papers were presented at the meeting in San Antonio, Texas; since that time, several other investigators in the field have consented to contribute to the published proceedings of the symposium. The contributors address the interactions among insects, allelochemicals, and light at levels ranging from the cell to the ecosystem. Towers provides an overview of the distribution of photoactivity among angiosperm plants; Downum and Rodriguez expand upon known mechanisms of phototoxicity and the ecological correlates of photoactivity in plants. Champagne et al. provide a thorough study of the toxic properties of photoactive chemicals in the Asteraceae, documenting the efficacy of these chemicals as deterrents and toxicants toward ecologically appropriate insect herbivores. As Ehrlich and Raven (1964) suggest, insects can and do, by the process of coevolution, develop resistance to secondary substances; photoactive compounds are no exception. Larson, in his article, describes the distribution of insect chemicals whose structures suggest a defensive function against toxic oxygen species such as would be generated by photoactive plant compounds; Ivie et al. and Bull et al. describe in detail the elaborate biochemical defense of one insect—the black swallowtail caterpillar (*Papilio polyxenes*)—that feeds almost exclusively on photoactive plants.

Since the phenomenon of photosensitization was first documented, its potential applications in insect control have been clearly recognized. Barbieri (1928) demonstrated that several photosensitizing dyes, including rose bengal, eosin, and erythrosin, were effective against mosquito larvae. Contributors to this symposium, however, graphically demonstrate the practical potential of natural photoactive plant compounds for insect control. Philogène et al. report that α-terthienyl, a natural product widespread among members of the Asteraceae, is not only equal or superior to commercial synthetic organic insecticides for control of *Aedes intrudens*, it is considerably less toxic to nontarget organisms than are many synthetic alternatives. Kagan et al. describe details of the phototoxicity of secondary substances to mosquitoes from species of Asteraceae and Apiaceae; effects range from immediate death to delayed mortality and impaired development depending upon dosage.

Since phototoxins do not discriminate on the basis of phylogenetic status, affecting living organisms ranging from one-celled protists to humans and other mammals, rapid and sensitive bioassays with relatively simple organisms, such as bacteria, can be used to identify and purify photoactive substances. These compounds, once isolated and purified, can be used both for ecological investigations designed to elucidate the evolutionary aspects of phototoxin production in plants and for screening programs designed to identify potential control chemicals for pest insects. Ashwood-Smith et al. describe a bacterial bioassay based on a DNA-repair-deficient mutant *Escherichia coli* that is particularly sensitive to photodamage to DNA; this assay, as they demonstrate, can be used not only to detect phototoxic plant constituents but also to detect metabolism of photoactive compounds in resistant insects. Tuveson et al. have developed a series of mutant *E. coli* strains that are differentially sensitive to DNA damage and to oxidative damage associated with photoactivity; these strains can therefore be used to elucidate the mechanism of phototoxicity and estimate the mutagenicity of potential control chemicals.

That over 25 people contributed to the papers in this issue is evidence of increasing interest in insects and photoactive plants. Light quality is rarely controlled in routine assays of plant constituents for insecticidal properties—it might well be that phototoxicity is far more widespread as a defensive strategy than is indicated here. Aside from merely documenting its occurrence, plant phototoxicity to insects offers outstanding opportunities for research in the areas of toxicology, ecology, and evolutionary biology. It is our hope that this issue will stimulate research in this area; we could learn from plants about the tremendous potential of solar energy when it comes to insect control.

SIGNIFICANCE OF PHOTOTOXIC PHYTOCHEMICALS IN INSECT HERBIVORY

G.H.N. TOWERS

Department of Botany
University of British Columbia
Vancouver, B.C., Canada V6T 2B1

(Received May 28, 1985; accepted August 13, 1985)

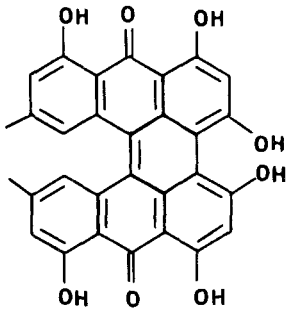
Abstract—The significance of the wide range of phototoxins, occurring in many plant species, with respect to their role in insect herbivory and on insects, is not fully understood. The types of compounds include polyacetylenes, quinones, furanocoumarins, tryptophan- and tyrosine-derived alkaloids and are distributed throughout some of the major families of flowering plants. Efforts are being made to determine the mechanisms of cellular toxicity of these compounds at the cellular and the organismal levels.

Key Words—Furanocoumarins, furanoquinolines, polyacetylenes, alkaloids, quinones, photosensitizers, photodynamic action, phototoxicity.

The effects on insects of phytochemicals which require light for the full expression of their toxicities was briefly reviewed recently with an emphasis of the role of photoactive polyacetylenes (Arnason et al., 1983). With our increasing understanding of the ecological importance of secondary plant chemicals, it is interesting now to examine more carefully the possible significance of these compounds, especially in relation to insect herbivory. This symposium is therefore most timely.

In addition to photodynamic synthetic xanthene dyes (Carpenter et al., 1984), an increasing variety of photochemicals, including quinones, acetylenes, and alkaloids have been shown in recent years to be phototoxic to virus, bacteria, fungi, nematodes, and insects (Towers, 1984). The accumulation, in conspicuous quantities in plants, of these phytochemicals, in resin canals or glandular trichomes, suggests that they may play a role in deterring or destroying other organisms, including insects. These photoactive chemicals otherwise have no known metabolic or physiological functions in plants. For example, hyper-

0098-0331/86/0400-0813$05.00/0

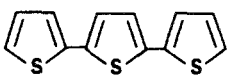


I

icin (I), a quinone photosensitizer which accumulates in specialized glands in leaves of species of St. John's wort [*Hypericum* spp. (Clusiaceae)] and which is responsible for photodermatitis in grazing animals is not toxic to some species of beetles in the genus *Chrysolina* (Daloze and Pasteels, 1979). In fact, one species, *C. brunsvicensis*, stores hypericin (Rees, 1969). What role, if any, does this phototoxic chemical have in relation to other insects? We simply do not know.

Phototoxic compounds or photosensitizers are chemicals which, when excited to a new electronic or electric state by absorption of a photon, react with other molecules in a given system. The resulting chemical changes in cells are often sufficiently severe to result in cell death. In many photoreactions of this type the excited photosensitizer transfers the excitation energy to oxygen which subsequently brings about an oxidation of another molecule. In this so-called photodynamic reaction, singlet oxygen, which may be the reactive species formed, may react with phospholipids, proteins, and sterols of plant membranes. For example, α-terthienyl (II), a not uncommon thiophene product of acetylene metabolism in members of the Compositae or Asteraceae, is a very efficient singlet oxygen producer (Reyftmann et al., 1985). Photosensitizers like α-terthienyl damage cell membranes (Yamamoto et al., 1984). Other photosensitizers, with equal potential for cellular destruction, penetrate cells to react with organelles including nuclei. Compounds of this type do not require oxygen. They form covalent adducts with bases in nucleic acids and may be termed photogenotoxic (Towers and Abramowski, 1983). There exist additional photosensitizers for which cellular targets have not yet been defined.

Many polyacetylenes, or polyines as they are more correctly called, and their thiophene derivatives have recently been found to display phototoxicities.



II

This large class of phytochemicals, characteristic of the Compositae (Asteraceae), Campanulaceae, Umbelliferae, and a number of other families of flowering plants (Bohlmann et al., 1973) include photosensitizers which have been shown to be phototoxic to many types of cells as well as to mosquito larvae (Arnason et al., 1981). On the other hand, none of the polyacetylenes of the Campanulaceae nor the characteristic acetylenes of the Umbelliferae and Araliaceae, namely falcarinone, falcarindione, falcarinol, or falcarindiol (III), appears to be phototoxic. Falcarindiol, however, in the leaf cuticle of the cultivated carrot, apparently stimulates oviposition in the female carrot fly, *Psila rosae* (Stadler and Buser, 1982). Concentrations of polyacetylenes in species of Compositae may be as high as 1% of the fresh weight, especially in young rhizomes at certain times of the year. The range of compounds usually differs between flowers, seeds, leaves, stems, and roots. Often the roots contain high levels. Is it possible that insect larvae, feeding on acetylene-rich roots or rhizomes, in the soil, may, on subsequent exposure to sunlight, either as larvae or as adults, suffer from phototoxicity? This has not been examined. Alpha-terthienyl, which has been studied most intensively, is so phototoxic to insect larvae that its potential as a commercial larvicide has been evaluated in stimulated pond trials. The cellular target of α-terthienyl and of polyacetylenes appears to be membranes but not all of them require oxygen for their activity (McLachlan et al., 1984). Serious field studies remain to be done with respect to this large class of chemicals, many of which are demonstrably phototoxic to insects under laboratory conditions. Especially significant would be comparable analyses of their possible effects on phytophagous insects along the lines of the research on phototoxic furanocoumarins.

The furanocoumarins, derivatives of phenylalanine, are characteristic of the Rutaceae and the Umbelliferae (Apiaceae). They also occur in members of the Leguminosae, Moraceae, Solanaceae, Pittosporaceae, Thymeleaceae, and Orchidaceae (Murray et al., 1982). Many of these tricyclic, planar compounds are phototoxic but perhaps the majority are not. Two nontoxic examples are 8-hydroxypsoralen and isopimpinellin. Common plant species in which phototoxic linear furanocoumarins occur are given in Table 1.

Many, but not all, of the biological effects of these much-studied compounds can be explained by photoinduced modification of DNA. The furanocoumarin intercalates in DNA and, on subsequent irradiation, reacts with pyrimidine bases to form covalently bound adducts. The photochemical reaction(s) is dependent on the presence of double bonds in the pyrone and in the furan rings. Some simple coumarins, however, e.g., 5,7-dimethyoxycoumarin are also

photosensitizers. The formation of bi-adducts by furanocoumarins occurs only with certain linear types and depends on nucleotide sequences, poly(dA–dT) · poly(dA–dT) sequence regions being the most favorable sites for intercalation and photocyclization. In the photoconjugation of furanocoumarins with pyrimidine bases there is no involvement of oxygen. It has been suggested, however, that with certain furanocoumarins such as angelicin (IV), reactive species of oxygen may play a major role in their carcinogenic effects (Joshi and Pathak, 1983).

Plants usually store furanocoumarins as the photochemically active aglycones, the major sites of accumulation being oil channels or ducts present in leaves, stems, roots, and flower parts. They may also be found in the cuticle (Stadler and Buser, 1982). Many of them accumulate in roots, as with acetylene reservoirs in roots of Compositae, but their ecological importance as phototoxic defense compounds in not obvious as ultraviolet light does not penetrate more than a few millimeters below the soil surface. Why do they accumulate in roots? Insect predation of the leaves of umbellifers has been studied in some detail, and at least one species of butterfly, *Papilio polyxene*, elaborates furanocoumarin detoxifying enzymes (Ivie et al., 1983). Some species of *Papilio* actually appear to select species of umbellifers or members of the Rutaceae which con-

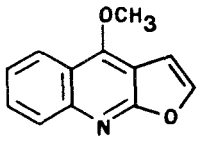
$R=OCH_3;\ R_1=OCH_3$

VI

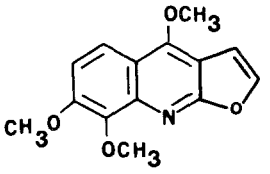
tain linear furanocoumarins as food sources (Berenbaum, 1981). The possible ecological importance of the furanocoumarins will be presented in later papers.

The furanochromones khellin (V), and visnagin (VI), which are of polyketide origin, cooccur with furanocoumarins in species of *Ammi* (Umbelliferae) (Schonberg and Sinha, 1950; Spath and Gruber, 1941) and, like them, are phototoxic to bacteria and to fungi. They cause chromosomal damage to CHO cells in UV-A (Abeysekera et al., 1983). By analogy with the furanocoumarins (Kanne et al., 1982), khellin could be expected to react with a base such as thymine in a 2 + 2 photoaddition involving either the 2–3 or the 6–7 double bond of khellin and the 5′–6′ double bond of thymine. UV-A irradiation of a frozen aqueous solution of khellin and thymine in fact yields photoadducts including one between the 2–3 double bond of khellin and the 5′–6′ double bond of thymine (Abeysekera et al., 1983). The effects of these compounds on phytophagous insects has not been studied so far, nor have the polyketide benzofurans, 6-methoxyeuparin as well as encecalin and 7-hydroxyencecalin from species of *Encelia*, although these compounds have been shown to be phototoxic to bacteria and to fungi (Proksch et al., 1983).

Some species in the Rutaceae, such as *Skimmia japonica*, *Dictamnus alba*, and even species of *Citrus*, contain, in addition to appreciable concentrations of furanocoumarins such as 5- and 8-methoxypsoralens, photosensitizing furanoquinoline alkaloids, derivatives of anthranilic acid. These tricyclic planar compounds, such as dictamnine (VII) and skimmianine (VIII), intercalate in



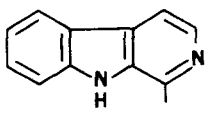
VII



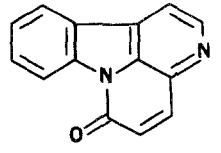
VIII

DNA in the dark and subsequently undergo photobinding in UV-A. Dictamnine binds preferentially to the same sites as 8-methoxypsoralen (Pfyffer et al., 1982). Dictamnine, as well as a number of other furanoquinolines and certain other alkaloids, is mutagenic and causes gross chromosomal abnormalities in CHO cells in UV-A (Towers and Abramowski, 1983). Their importance in relation to insect predation is unknown as is the significance of the cooccurrence of two biogenetically unrelated phototoxic compounds in one species.

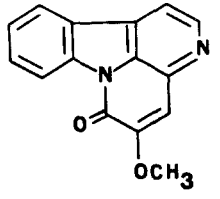
A second group of alkaloids which has been found to be photogenotoxic to CHO cells (Towers and Abramowski, 1983) and phototoxic to larvae of *Aedes atropalpus* is the β-carbolines or harman compounds, e.g., harman (IX) (Arnason et al., 1983). These are very widely distributed, occurring in about 26 families of plants (Allen and Holmstedt, 1980). Additional tryptophan-derived alkaloids, such as 6-canthinone (X) and 5-methoxy-6-canthinone (XI) of *Zanthoxylum* (Rutaceae) and brevicolline (XII), an *N*-methylpyrolidine-substituted harman alkaloid which occurs in the sedge, *Carex brevicollis*, have also been shown to be phototoxic to bacteria, fungi, and CHO cells (Towers and Abramowski, 1983) but their effects on insects remain unstudied. Berberine, a well-known phenylalanine-derived alkaloid is also phototoxic to mosquito larvae but



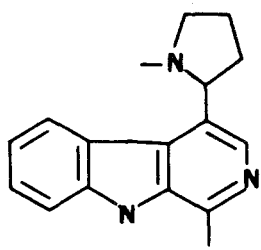
IX



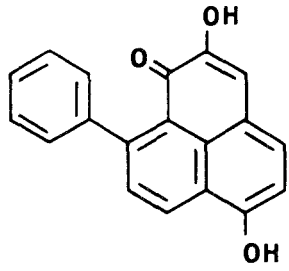
X



XI



XII



XIII

its mechanism of action is not known (Philogene et al., 1984). There are undoubtedly very many other alkaloids with this type of bioactivity awaiting research by chemical ecologists with an understanding of photobiology.

The excreta of the silkworm (*Bombyx mori*), used in traditional Chinese medicine, contains cytostatic/cytotoxic porphyrins, including the phototoxic methyl esters of pheophorbides (Nakatani et al., 1981). The generation of singlet oxygen in light by excited states of certain porphyrins is responsible for their phototoxicity. How many kinds of phytophageous insects produce phototoxic frass? The ecological significance of phototoxic frass may be of interest in relation to microbial colonization of this material but is this phototoxicity fortuitous and is it really important ecologically?

One can extend these questions to include the many other miscellaneous compounds of plant origin such as lachnanthocarpone (XIII), in species of *Lachnanthes* of the Hemodoraceae which are phototoxic to bacteria and even to vertebrates (Kornfeld and Edwards, 1972). How important are they to phytophagous insects?

Some of these problems have been addressed in work reported in this symposium but much remains to be done; it seems to be clear from research so far that interesting and important new ecological concepts concerning the relations between insects, phytochemicals, and light remain to be discovered.

TOXICOLOGICAL ACTION AND ECOLOGICAL IMPORTANCE OF PLANT PHOTOSENSITIZERS

K.R. DOWNUM[1] and E. RODRIGUEZ

Phytochemical Laboratory
Department of Ecology and Evolutionary Biology
University of California, Irvine, California 92717

(Received May 28, 1985; accepted October 15, 1985)

Abstract—This review discusses the biochemical action and ecological significance of phototoxic phytochemicals. Mechanistic details of photosensitization as well as cellular and molecular targets of plant-derived phototoxins in model biological systems (microbial and in vitro) and in herbivorous insects are described. Findings from these studies suggest the potential importance of phototoxic plant metabolites in plant–insect interactions. Aspects of phototoxin distribution and significance in diverse ecosystems are considered, and areas for future research are suggested.

Key Words—Phototoxic phytochemicals, insect photosensitization, mechanisms of photosensitization, plant–insect interactions.

INTRODUCTION

Many phytochemicals capable of photosensitizing action have been isolated from plants (Towers, 1984; Knox and Dodge, 1985; Downum, 1986). Most are potent biocidal agents that effect an array of organisms in the presence of sunlight or UV-A irradiation (320–400 nm). In addition to killing or inactivating viruses, bacteria, fungi, nematodes, and assorted other organisms (see review by Towers, 1984), the susceptibility of herbivorous insects to some of these chemicals has also been demonstrated (Berenbaum, 1978; Kagan et al., 1983; Downum et al., 1984; Champagne et al., this issue). This review discusses aspects of the toxicology of plant photosensitizers (or phototoxins) toward herbivorous insects that might encounter such chemicals in their diets. In addition, we also address

[1] Present address: Department of Biological Sciences, Florida International University, Miami, Florida 33199.

0098-0331/86/0400-0823$05.00/0

questions concerning the ecological importance of photosensitizing chemicals in nature.

MECHANISMS OF PHOTOSENSITIZATION

Two general types of photosensitizers or phototoxins are recognized: those that participate in radical or electron transfer reactions (type I mechanisms) and those that catalyze the formation of singlet oxygen ($^1O_2$) via a type II mechanism (Spikes, 1977; Krinsky, 1985). The contrasting mechanisms and the molecular targets of important classes of phototoxic phytochemicals are reviewed in detail elsewhere (Towers, 1984; Knox and Dodge, 1985) and will be mentioned only briefly here to aid the reader in subsequent discussions.

Both type I and type II reactions result from the excitation of a ground-state sensitizer (S) to its singlet-excited state (^1S) following absorption of a photon ($h\nu$) (equation 1). ^1S is highly unstable and readily undergoes electron rearrangement (intersystem crossing) to form a triplet-excited sensitizer (^3S) (2), a longer-lived species that is responsible for catalyzing most biological photosensitizations.

$$S \xrightarrow{h\nu} {}^1S \tag{1}$$

$$^1S \longrightarrow {}^3S \tag{2}$$

In type I mechanisms, the triplet-excited sensitizer ^3S generally bonds covalently to some biomolecule. DNA is one of the most important targets of type I photosensitizers (Dall'Acqua et al., 1971; Song and Tapley, 1979; Towers, 1984), although tRNA and cellular proteins also represent potentially significant targets (Ou and Song, 1978; Averbeck et al., 1978; Veronese et al., 1982; Granger and Helene, 1983). Type II mechanisms, in contrast, involve transfer of excitation energy between ^3S and ground-state or molecular oxygen (which exists in the triplet state, $^3O_2$) (3). Bimolecular reactions such as these result in the formation of singlet oxygen ($^1O_2$), a highly reactive oxygen species, and S which is free to catalyze additional reactions if reexcited by other photons. Membranes are important targets of $^1O_2$. Damage to these cellular structures results from photooxidation of unsaturated fatty acids (Rawls and Van Santen, 1970; Rahimtula et al., 1978), sterols (especially cholesterol) (Teng and Smith, 1973; Suwa et al., 1978; Smith and Stroud, 1978), free amino acids (Fisch et al., 1971), and amino acid residues in proteins (Lamola and Doleiden, 1980; Dubbelman et al., 1980).

$$^3S + {}^3O_2 \longrightarrow S + {}^1O_2 \tag{3}$$

The mechanisms of photosensitization for the major classes of phototoxic phytochemicals are listed in Table 1.

INSECT PHOTOSENSITIZATION

Phototoxic constituents occur in a wide variety of plant families (Downum, 1986). Many of these natural products are toxic to insects as well as to numerous other organisms following excitation by light (Towers, 1984). Although the mechanisms and the molecular targets of quite a few phototoxic phytochemicals have been established using model cell and in vitro systems, parallel investigations with herbivorous insects that might encounter photosensitizers in their food plants are just beginning. Furocoumarins, polyines, quinones, β-carboline and isoquinoline alkaloids (Figure 1) are the major classes of plant-derived photosensitizers which have been shown to interfere with insect growth and development.

Berenbaum (1978) was the first to demonstrate the light-activated toxicity of a plant chemical to an herbivorous insect. She reported that southern armyworm larvae (*Spodoptera eridania*) reared on diets containing the furocoumarin xanthotoxin (also known as 8-methoxypsoralen or 8-MOP) did not mature past the second instar under simulated daylight conditions but that 40% of the larvae survived through pupation to adult emergence when UV-A wavelengths were excluded. Enhanced larval survival in the absence of UV-A is consistent with

FIG. 1. Chemical structures of important phototoxic phytochemicals. I, 8-methoxypsoralen (a linear furocoumarin); II, angelicin (an angular furocoumarin); III and IV, khellin and visnagin, respectively (furochromones); V and VI, dictamnine and skimmianine, respectively (furoquinoline alkaloids); VII, phenylheptatriyne (an acetylenic polyine); and VIII and IX, 2,2′:5′,2″-terthiophene (alpha-terthienyl) and 5-(3-buten-1-ynyl)-2, 2′-bithiophene, respectively (thiophenic polyines).

the type I photomechanism previously demonstrated for 8-MOP (Song and Tapley, 1979). Although formation of 8-MOP/DNA photoadducts could be responsible for much of the larvicidal activity of this common furocoumarin, the susceptibility of *S. eridania* in the absence of UV-A suggests that at least part of its toxic action is not light dependent. Frameshift mutations resulting from noncovalent DNA interactions occur in bacteria exposed to 8-MOP in the dark (Ashwood-Smith, 1978). Similar interactions might explain some of the non-UV-A-induced toxicity of 8-MOP reported by Berenbaum (1978), but this remains to be demonstrated. Light-independent mechanisms have been demonstrated with other phototoxic chemicals from plants (McLachlan et al., 1982; Champagne et al., this issue) as well as with synthetic xanthene dyes (Heitz, 1982).

Discovery of 8-MOP phototoxicity to southern armyworm larvae stimulated research into the photoactivity of other plant compounds toward herbivorous and nonherbivorous insects. The larvicidal activity of 27 polyines (acetylenes and thiophenes) to first and fourth instar mosquito (*Aedes aegypti*) and blackfly (*Simulium vitattum*) larvae in sunlight and UV-A was the subject of two complementary studies (Wat et al., 1981; Arnason et al., 1981b). Exposure of *A. aegypti* larvae to 16 of the compounds and light resulted in substantial mortality. Four of the 14 phytochemicals tested against *S. vitattum* were lethal in light, but three killed larvae in the dark. Alpha-terthienyl (alpha-T) and phenylheptatriyne (PHT) were among the most powerful of the plant-derived photosensitizers tested in these studies.

Alpha-T and PHT, as well as several biosynthetically related derivatives of each, are also potent feeding inhibitors of herbivorous larvae including: the tobacco hornworm (*Manduca sexta*); the dark-sided cutworm (*Euxoa messoria*); and the European cornborer (*Ostrinia nubilalis*) (McLachlan et al., 1982; Champagne, this issue). Feeding inhibition in *M. sexta* and *E. messoria* is UV-A-mediated, but substantial deterrence in the absence of UV-A wavelengths also occurs (Champagne, this issue). *O. nubilalis*, an herbivore that specializes on polyine-containing members of the Asteraceae (sunflower family), is least affected by polyine-containing diets. This may indicate that *O. nubilalis* larvae have an evolved tolerance to these potent light-activated phytotoxins which allows them to feed on plants containing such phototoxins.

Alpha-T, in addition to the above effects, elicits severe toxic responses from tobacco hornworm larvae (*M. sexta*) (Downum et al., 1984). Larval growth and development are drastically altered following ingestion of the thiophene in artificial diets and subsequent exposure to UV–A irradiation. The pupal abnormalities that result from larval treatment with this allelochemical are quite similar to the deformities caused by the action of L-dopa on *S. eridania* (Rehr et al., 1973). Rehr and coworkers suggested that failure of their pupae to sclerotize completely may have resulted from interference of tyrosinase (i.e., phenoloxi-

dase), an enzyme essential for hardening and darkening of the insect cuticle, by the nonprotein amino acid. Singlet oxygen produced by UV-A-activated alpha-T cross-links membrane proteins in *E. coli* (Downum et al., 1982) and inactivates human erythrocyte enzymes (Yamamoto et al., 1979; Wat et al., 1980). Similar effects caused by $^1O_2$ in the integument of *M. sexta* might be responsible for impaired sclerotization and melanization. Preliminary studies of *M. sexta* integument proteins, however, show no pronounced protein cross-linking or enzyme inactivation immediately following treatment with alpha-T/UV-A (Downum et al., 1984).

The extended quinone hypericin, assorted β-carboline alkaloids, and the isoquinoline alkaloid berberine are phototoxic to mosquito larvae (Arnason et al., 1983; Philogene et al., 1984). In addition to killing nonherbivorous insect larvae, hypericin is also phototoxic to the tobacco hornworm *M. sexta* (Knox and Dodge, 1985). Numerous other classes of phytochemicals (e.g., furochromones, furoquinoline alkaloids, lignans, etc.) mediate photosensitized reactions in microbial and in vitro systems (Towers, 1984; Knox and Dodge, 1985; Downum, 1986); however, their phototoxic mechanisms and cellular targets in insects have yet to be established.

ECOLOGICAL IMPORTANCE OF PHOTOSENSITIZING PHYTOCHEMICALS

Considerable information is available on the types of plant secondary metabolites capable of photosensitization and the nonspecific nature of their biocidal action, but little is known about the distribution, frequency, and variation of photosensitizers evolved by plants in different environments. A recent review by Downum (1986) reveals that phototoxic constituents occur in at least 30 plant families. The potential importance of these naturally derived phototoxins in ecological interactions can be appreciated when one realizes that the major plant families synthesizing these light-activated compounds (e.g., Apiaceae, Asteraceae, Fabaceae, Liliaceae, Moraceae, Rutaceae, Solanaceae, and Zygophyllaceae among others) are widely distributed in nature (Heywood, 1978).

In a recent survey of more than 100 plants from North American deserts, we found that species which contained photosensitizers belonged to 13 genera from two of the most successful families of arid/semiarid plants: the Asteraceae and the Zygophyllaceae (Downum et al., 1986). Table 2 lists several of the dominant desert genera which were found to produce phototoxins. All of the Asteraceae genera examined belonged to the tribe Heliantheae (as revised by Robinson, 1981), while the creosote bush *Larrea tridentata* was the only genus in the Zygophyllaceae to give a positive phototoxic response.

Acetylenic and thiophenic polyines which are common phytochemical constituents (Bohlmann et al., 1973) and potent photosensitizers in the Asteraceae (Camm et al., 1975; Towers et al., 1977) are probably responsible for the ma-

TABLE 2. IMPORTANT PHOTOTOXIN-CONTAINING GENERA FROM ARID AND SEMIARID REGIONS OF SOUTHWESTERN UNITED STATES AND MEXICO FOUND IN A RECENT SURVEY (Downum et al., 1986)[a]

Asteraceae	Zygophyllaceae
Adenophyllum (Pectidinae)	*Larrea*
Ambrosia (Ambrosiinae)	
Chrysactinia (Pectidinae)	
Dyssodia (Pectidinae)	
Encelia (Ecliptinae)	
Helianthus (Helianthinae)	
Hymenantherum (Pectidinae)	
Nicolletia (Pectidinae)	
Pectis (Pectidinae)	
Porophyllum (Pectidinae)	
Thelesperma (Coreopsidinae)	
Viguiera (Helianthinae)	

[a] All genera in the Asteraceae belong to the tribe Heliantheae and are followed by their subtribal affiliations in parentheses (after Robinson, 1981).

jority of positive bioassay responses elicited by species in the Heliantheae. Thiophenic polyines are characteristic of most genera in the subtribe Pectidinae (Asteraceae; Heliantheae), although such allelochemicals do not occur in *Pectis*, the largest genus in the Pectidinae (Downum and Towers, 1983; Downum et al., 1985). Despite the lack of thiophenic metabolities in *Pectis*, crude extracts from 12 species are phototoxic to *E. coli* and the yeast *S. cerevisiae* (Downum et al., 1986). The chemical(s) responsible for this activity have yet to be identified, but it is clear from our preliminary work that they do not belong to currently recognized photosensitizer classes from the Asteraceae.

Benzofurans and benzopyrans are another group of phototoxic compounds produced by various genera in the Asteraceae (Proksch and Rodriguez, 1983; Proksch et al., 1983). These acetophenone-derived compounds are effective insect antifeedents (Wisdom et al., 1983; Proksch and Rodriguez, 1983), elicit antijuvenile responses in insects (Bowers, 1982), and recent studies by Aregullin (1985) establish that many naturally occurring derivatives are also phototoxic to insects and to fungi. Several common desert genera in the Heliantheae (e.g., *Encelia*, *Enceliopsis*, *Flourensia*, *Helianthella*, and *Gereae*) produce substantial quantities of these secondary metabolites. Although their exact mode of action has not been determined, they may form quinone methide intermediates which might alkylate important metabolic enzymes and/or DNA in susceptible organisms (Proksch and Rodriguez, 1983; Aregullin, 1985).

The creosote bush *L. tridentata* (Zygophyllaceae) is perhaps the most im-

portant phototoxin-containing plant found in our survey of North American arid-land plants (Downum et al., 1986). The photosensitizer, identified as nordihydroguiaretic acid (NDGA) (Downum et al., in preparation), occurs primarily on external leaf surfaces where it comprises 20–30% of the total leaf resin and up to 5–10% of the leaf dry weight (Mabry et al., 1977). Although the leaf resin of the creosote bush has been shown to deter leaf-chewing insects (Rhoades, 1976, 1977), the involvement of photoactivated NDGA in this herbivore deterrence was not studied and remains unknown. The potential importance of NDGA is apparent when one considers that *L. tridentata* is the dominant woody shrub throughout the Chihuahuan, Mojave and Sonoran deserts of North America (Hunziker et al., 1977). Closely related species *L. ameghinoi*, *L. cuneifolia*, *L. divaricata*, and *L. nitida* (which also synthesize NDGA) are dominant components of South American deserts. Other genera of the Zygophyllaceae such as *Guaiacum*, *Kallstroemia*, and *Viscainoa* from Chihuahua and Baja California either do not contain NDGA or lack sufficient quantities to elicit phototoxic activity (Downum et al., 1986).

Tropical plants, unlike arid and semiarid plants from warm deserts, have not yet been systematically investigated for naturally occurring photosensitizers. This is rather surprising, since one might predict that tropical plants which can be exposed to high levels of solar irradiation throughout the year might elaborate a plethora of light-activated chemicals for defensive purposes (assuming that photosensitizers do in fact have a defensive role). Survey studies are currently underway to establish the significance of plant-derived photosensitizers in tropical ecosystems.

CONCLUSION

It is clear that a considerable amount of toxicological information is available concerning the mechanisms and the targets of plant photosensitizers; however, most of the data result from studies of their action in model cell systems. Efforts to elucidate the toxicology of phototoxic phytochemicals in herbivorous insects have only recently begun. Detailed information in this area is essential to clarify the influence such chemicals might have on the interactions between plants and their insect herbivores.

It is also clear that much remains to be learned about the ecology of phototoxin-containing plants. Studies involving the distribution and quantitative significance of these allelochemicals in a range of diverse habitats as well as their effect on herbivory patterns are areas that remain to be explored. Until such investigations are in progress, the ecological importance and the evolutionary implications of phototoxic phytochemicals must remain highly speculative.

Acknowledgments—We would like to express our gratitude to Drs. Suzanne Koptur (FIU) and G.H.N. Towers (UBC, Canada) for critical reading of this manuscript and acknowledge the support of NSF grant PCM 8209100 and NIH grant AI 18398.

(Received May 28, 1985; accepted October 23, 1985)

Abstract—Polyacetylenes and their thiophene derivatives, characteristic secondary metabolites of the Asteraceae, were examined for their effects on herbivorous insects. Three thiophenes (a monothiophene, a bithiophene, and α-terthienyl) and four polyacetylenes (phenylheptatriyne, phenylheptadiynene, phenylheptadiyene acetate, and matricaria lactone) were studied for their phototoxicity and light-independent toxicity to (1) a polyphagous lepidopteran, *Ostrinia nubilalis*, whose host range includes a number of phototoxic Asteraceae, (2) a polyphagous lepidoteran, *Euxoa messoria*, whose host range includes very few species of Asteraceae, and (3) an oligophagous lepidopteran, *Manduca sexta*, which is a specialist on Solanaceae. Several compounds were phototoxic to *M. sexta* and *E. messoria* even at very low irradiance levels, but behavioral adaptations, including spinning silk and boring into diet, allowed *O. nubilalis* to avoid photosensitization. Light-independent activity of the compounds to all three species involved feeding deterrence increasing in the order *O. nubilalis*, *E. messoria*, and *M. sexta*, and long-term metabolic toxicity in the form of impaired nutrient utilization. The biosynthetically derived thiophenes were more toxic than their acetylenic precursors, and toxicity increased with increasing number of thiophene rings. The results are discussed in terms of plant–insect coevolution.

INTRODUCTION

Studies of the allelochemical effects of plant secondary metabolites on herbivorous insects have usually examined the activity of these compounds in the ground state. Recently, it has been realized (Towers, 1980) that many natural products of plant origin interact with light, yielding excited state molecules with the capacity to undergo a variety of toxic high-energy processes. Most of these naturally occurring photosensitizers have been examined for their effects on microorganisms, with insects only recently receiving attention. Furanocoumarins of the Apiaceae (Berenbaum, 1978, 1981, 1983; Berenbaum and Feeny, 1981) are the only photosensitizers that have been thoroughly investigated for their role in plant–insect relations.

Among the more active natural photosensitizers are the polyacetylenes and their thiophene derivatives (Towers, 1980, Arnason et al., 1983a). These are characteristic secondary metabolites of the Asteraceae, where they are diverse and abundant, but they also occur in several other plant families (Bohlmann et al., 1973). Simple aliphatic polyacetylenes have an oxygen-independent (nonphotodynamic) mechanism of action which may involve the formation of free radicals upon photoexcitation, whereas the biosynthetically advanced thiophenes are type II photodynamic photosensitizers which damage biological targets via the catalytic production of singlet oxygen (McLachlan et al., 1984; Downum et al., 1982; Arnason et al., 1981a). Partly cyclized polyacetylenes, intermediate in structure between the aliphatic acetylenes and the thiophenes, apparently have access to both photodynamic and nonphotodynamic mechanisms of action (McLachlan et al., 1984). Target sites appear to involve membranes (Downum et al., 1982; Wat et al., 1980; Yamamoto et al., 1979).

Some polyacetylenes and thiophenes are highly phototoxic to insects in bioassays using mosquito (*Aedes aegypti*) and blackfly larvae (Arnason et al., 1981b; Wat et al., 1981). The thiophene α-terthienyl (α-T) is not only phototoxic to blood-feeding insect larvae (Philogène et al., 1985) but also to larvae of the phytophagous lepidopterans *Euxoa messoria* (Champagne et al., 1984) and *Manduca sexta* (Downum et al., 1984). Polyacetylenes and thiophenes may photosensitize a variety of other organisms, including pathogenic fungi (Bourque et al., 1985), vascular plants (Campbell et al., 1982), nematodes (Wat et al., 1981; Gommers and Geerligs, 1973; Bakker et al., 1979), trematodes (Graham et al., 1980), and numerous prokaryotic and eukaryotic microorganisms (Chan et al., 1975; Wat et al., 1979; Towers, 1980; Arnason et al., 1981b).

The toxic action of these natural products is not confined to light-mediated reactions, as a number of polyacetylenes and thiophenes are antibiotic. Gener-

ally phytoalexin polyacetylenes are toxic to fungi without photosensitization (e.g., DeWitt and Keddie, 1981), although their activity may possibly be enhanced in the presence of near-UV light. Light-independent toxicity of acetylenes to phytophagous insects has also been described. Binder et al. (1979) found that matricaria ester, a widespread aliphatic polyacetylene in the Asteraceae, was toxic to three species of herbivorous lepidopterans, and McLachlan et al. (1982) reported that phenylheptatriyne (PHT), a partially cyclized polyacetylene, reduced the growth of the cutworm *Euxoa messoria*. In both cases, feeding deterrence was suggested to be a major component of the mechanism of action. Some matricaria ester derivatives are antifeedants to the Colorado potato beetle (Jermy et al., 1981). A polyacetylene from an insect, *Chauliognathus pennsylvanicus*, is also a powerful antifeedant, conferring protection from carnivores (Eisner et al., 1981)

The effects of polyacetylenes and thiophenes on herbivorous insects and the role of photosensitization in this activity, are as yet poorly understood. In this study, we examine the effects of seven polyacetylenes and thiophenes, administered orally, on the survivorship, growth, and feeding behavior of three phytophagous insects: the darksided cutworm, *Euxoa messoria* (Lepidoptera: Noctuidae), the European corn borer, *Ostrinia nubilalis* (Lepidoptera: Pyralidae), and the tobacco hornworm, *Manduca sexta* (Lepidoptera: Sphingidae). These insects cover a range of feeding habits from specialization on nonphototoxic Solanaceae (*M. sexta*), through polyphagy excluding phototoxic Asteraceae (*E. messoria*), to polyphagy including phototoxic Asteraceae (*O. nubilalis*). The compounds selected for the study (Figure 1) are representative of the Asteraceae generally and are found in many species in the tribes Heliantheae, Cynareae, Helenicae, and Asteraceae.

METHODS AND MATERIALS

Source of Compounds. PHT was extracted as described by Wat et al., (1979) from leaves of *Bidens pilosa* L. from Tampa, Florida. Alpha-terthienyl was prepared synthetically (Philogène et al., 1985). All other compounds were obtained by one of us (J. Lam) as described in McLachlan et al. (1984) from *Dahlia* spp., *Echinops* spp., and *Solidago vigaurea*.

Insect Cultures. Insects were reared on meridic diets as described by Stewart and Philogène (1983) for *M. sexta*, Guthrie (1971) for *O. nubilalis*, and Devitt et al. (1980) for *E. messoria*. Growth conditions were 27°C, 80% relative humidity and a photoperiod of 18:6 light–dark under fluorescent Vitalites® (100 W/m^2).

Test Diets. Appropriate amounts of the test compounds in 95% EtOH were placed in 50- or 100-ml beakers, to which was added warm liquid diet. The temperature of the diet was not more than 35°C at this time in order to prevent

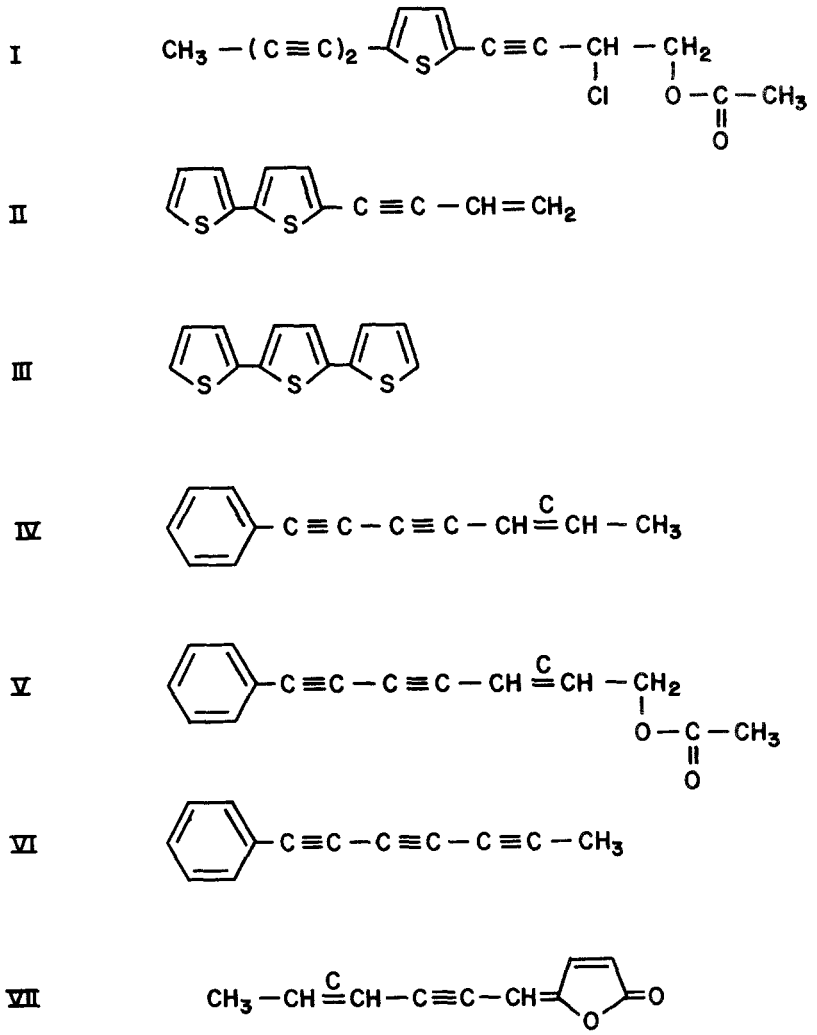

FIG. 1. Polyacetylenes and thiophenes used in the study. Compound III is known by the trivial name α-terthienyl and compound VI, phenylheptatriyne.

degradation of the acetylenes. The diet and acetylenes in EtOH (or EtOH alone in the case of controls) were mixed vigorously by hand for about 2 min; the diet was then poured into 1 × 1 × 0.6-cm molds to cool. The amount of 95% EtOH carrier in the diets did not exceed 2.5% (0.5 ml 95% EtOH in 25 g diet). Fresh diet for all insect species was prepared weekly and refrigerated at about 5°C until used.

Growth Studies with Manduca sexta. Thirty or forty mature eggs of *M. sexta* were placed into each Petri dish with an appropriate diet cube containing

100 μg/g PHT or α-T. The dishes were examined 24 h later, and unhatched eggs and larvae in excess of 25 were removed. Irradiation was begun on day 5 of the test, to allow larvae to accumulate the test compounds and to facilitate distinction of light-independent effects from phototoxicity. Larvae were weighed on days 5, 7, 10, 14, and 15 post-hatch, at which time the experiment was terminated. Diets were changed every 2–3 days. The experiments were repeated twice, and each experiment included two replicates of the α-T and PHT treatments and three of the control.

The light system used for these experiments included a bank of eight Vitalites augmented by four black light blue (BLB) lamps, 54 cm above the insects. The near-UV contributed by the Vitalites was negligible as these lamps were located above a UV-opaque Plexiglas partition in the growth cabinet. The near-UV was contributed by the BLB lamps and was measured at 2.0 W/m^2.

Growth Studies with Euxoa messoria. Three thiophenes (compounds I–III) and four polyacetylenes (compounds IV–VII) were screened for allelochemical effects against *Euxoa messoria*.

Diet cubes (two to four, depending on the age and size of the insects containing 100 μg/g test compound), were cut in two and placed in a Petri dish; the perimeter of the dish was lined with Whatman No. 1 glass fiber filter paper. Twenty-five larvae of *E. messoria* were placed in each dish, which was sealed with polyethylene film. One dish was prepared for each combination of test compound and light treatment (2 W/m^2 near-UV) because of limitations in the available amount of test compounds. The experiment was subsequently repeated but followed for two, instead of three weeks. Diets were changed, dead larvae counted and removed every second day, and larvae were weighed every fourth day. The larvae were reared individually from day 18 to day 21, at which time the experiment was terminated.

The same light system as described for *M. sexta* was used in these experiments (2 W/m^2 near-UV).

For experiments at low-light intensity, groups of 30 larvae were treated with combinations of 0.5 W/m^2 near-UV and diet containing 10 or 100 μg/g α-T. Larvae were reared individually in ventilated polystyrene vials. Fresh diet was provided, larvae weighed, and exuvia checked every two days until all individuals in each treatment group had entered the prepupal stage. Prepupae were transferred to vials containing moist peat moss and checked every two to three days until pupation occurred, at which time pupae were weighed. Darkened pupae were transferred to 62 × 60 × 30-cm oviposition cages for adult emergence.

Light was provided by a bank of 12 Vitalite fluorescent tubes 50 cm above the insects. The near-UV intensity to which the larvae were exposed was measured at 0.5 W/m^2.

Growth Studies with Ostrinia nubilalis. The toxicity of three polyacetylenes (IV, V, and VI) and three thiophenes (I, II, and III) to *Ostrinia nubilalis* at 100 μg/g in diets was examined.

TABLE 1. EFFECT OF POLYACETYLENES AND THIOPHENES ON FEEDING BEHAVIOR OF NEONATE *Manduca sexta, Euxoa messoria,* and *Ostrinia nubilalis* IN NO-CHOICE TEST[a]

Compound	*Manduca sexta*	*Euxoa messoria*	*Ostrinia nubilalis*
Control	100 a	100 a	100 a
I		80.8 a	91.2 a
II		38.0 b	72.8 b
III	0 b	38.0 b	64.8 b
IV	5.0 b	32.8 b	103.2 a
V		25.1 b	108.0 a
VI		16.3 b	85.6 b
VII		80.1 a	94.4 a

[a] Feeding rate is given as percent of control; all compounds were tested at 100 μg/g and without near-UV irradiation. Values in a column followed by the same letter are not significantly different (Duncan's multiple-range test, $P \leq 0.05$).

To screen compounds I–VI (Table 1), egg masses at the blackhead (hatching) stage, containing 10–30 eggs each, were pinned to appropriately treated diet cubes in glass scintillation vials and stoppered with a cotton plug. Hatching neonates moved onto the diet cubes and began feeding. The following morning (15 hr later), larvae were distributed to six vials with appropriate diet for each treatment group, five larvae to a vial. Thus, all of the 30 larvae in each treatment group were of the same age, within 15 hr. Diets were changed and larvae weighed every four to five days over a 20-day period.

Feeding Deterrency Tests. To test the effect of thiophenes and polyacetylenes on neonate feeding behavior, test compounds were applied in acetone to both surfaces of a leaf disk. Control disks were treated with acetone alone. Lettuce (*Lactuca sativa*) leaves were used for *E. messoria*, corn leaves (*Zea mays* cultivar Silver Queen) for *O. nubilalis*, and tobacco (*Nicotiana tabacum* cultivar Delhi 77) leaves for *M. sexta*. Leaf disks were weighed and placed in glass scintillation vials; five *E. messoria* and *O. nubilalis* or two *M. sexta* neonates were placed on each leaf disk and the vials were loosely capped to allow ventilation. Experiments were conducted in a Conviron ET growth cabinet at 26°C, 80% relative humidity, and a photoperiod of 18:6 hr light–dark. After 48 h, the surviving larvae in each vial were counted and the leaf disks were dried for 24–48 h at 80°C in a drying oven and weighed. Consumption was calculated as the difference in leaf dry weight; initial dry weights were calculated from regression equations based on not less than 10 dry weight/fresh weight determinations for each plant species. All compounds were tested at 100 μg/g (and in some cases 10 μg/g) concentrations. At least five replicates of each treatment were obtained. The design of these experiments was "no-choice."

More mature *E. messoria* and *M. sexta* larvae were tested in no-choice and choice experiments. For no-choice tests, preweighed fourth and fifth instar unstarved larvae were presented with an appropriately treated weighed cube of artificial diet. Consumption and frass production were measured after 24 and 48 hr, and larvae were reweighed. Diet weight loss due to evaporation was corrected for on the basis of diet cubes not exposed to insect feeding; evaporation accounted for a daily weight decline of about 16%. At least ten replicates of each concentration were obtained. For *E. messoria* fed 100 μg/g α-T, trials with and without near-UV (4 W/m^2) were conducted. For choice tests, eight diet cubes were pinned around the perimeter of a 14-cm-diameter desiccator. Each experiment included three control and five dosed diet cubes; the dosed cubes included two at each of two concentrations plus one at a third concentration. Four *E. messoria* larvae were released in the center of the desiccator. Experiments were conducted with both starved (18 hr) and unstarved larvae, but no difference in the behavior of the two groups was apparent. Both α-T and PHT were tested at 0.1, 1.0, 10.0, and 100 μg/g, each concentration at least seven times. Feeding larvae were exposed to a regime of visible light without UV of 18:6 hr light–dark.

Nutritional Indices. Nutritional indices determined (Reese, 1979; Waldbauer, 1968) included the consumption index (CI), the approximate digestibility (AD), the efficiency of conversion of ingested food (ECI), and efficiency of conversion of digested food (ECD).

Larvae of *E. messoria*, from the test in which three thiopenes and four polyacetylenes were examined, were weighed on day 18 of that test, then transferred to individual 3.5 × 6.0-cm clear polystyrene vials with a fresh, weighed diet cube dosed with the same compound (100 μg/g) to which the insects had been exposed. Larval weights, frass, and unconsumed diet were determined daily for the next three days. The same procedure was followed with fourth instar larvae from the stock culture: such larvae were "naïve" in that they had not previously been exposed to the test compounds. Remaining diet was dried at 80°C in a drying oven. Frass was dried for 48 hr under vacuum in a desiccator. The initial dry weight of the diet was calculated from the dry weight/fresh weight ratio (=0.2624), as were both the initial and final dry weights of the larvae (for unstarved larvae, dry weighted = 0.1415 fresh weight).

Data Analysis. Data sets from all treatment groups were log transformed and tested for homogeneity of variance with the Bartlett box F test before proceeding to Duncan's multiple-range test.

RESULTS

Growth Studies with M. sexta. When a model thiophene, α-T (III) and a model acetylene PHT (IV) were added to insect diets, both had a light-independent and phototoxic effect on growth and survival of *M. sexta* larvae (Figure 2).

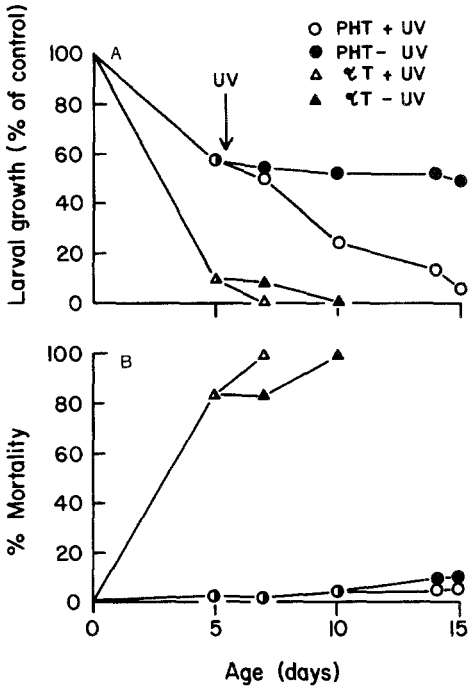

FIG. 2. *Manduca sexta* growth (A) and mortality (B) in response to combinations of 2 W/m^2 near-UV and diet containing 100 $\mu g/g$ α-T or PHT. The arrow indicates the initiation of radiation on day 5. Standard errors were less than 5% and are omitted.

Neonates fed 100 $\mu g/g$ α-T or 100 $\mu g/g$ PHT without photosensitizing radiation had significantly ($P \leq 0.05$) lower growth (Figure 2A) than controls at five days. α-T had greater growth reducing effects than PHT. During the first five days of growth, mortality occurred only in the α-T-treated insects (Figure 2B). Larvae in these groups consumed little diet and produced few fecal pellets, suggested that starvation contributed to mortality.

Subjecting half the insects at day 5 to photosensitizing near-UV led to a separation of the growth and survival curves. With PHT, irradiated larvae had significantly ($P \leq 0.05$) less growth than nonirradiated larvae from day 10 on. With α-T, the same trends were observed in mean growth, although the photosensitized and nonphotosensitized groups were not significantly different. Increase mortality trends were also observed in the irradiated group with α-T as compared to nonirradiated larvae.

Irradiated larvae developed black necrotic lesions on the dorsal surface, particularly along the mid-dorsal vein, which were never seen in unirradiated larvae treated with α-T or PHT or in larvae given control diets and irradiated. Lesions were more evident in PHT-treated than α-T-treated insects. Larvae

from one replicate of each experiment were exposed to direct sunlight for 50 min, and the number of lesions was seen to increase substantially during this period. Small lesions caused the larvae no immediate observable distress. However, at moulting they were often unable to ecdyse past the lesion. The partially moulted cuticle constricted the larvae, preventing passage of the gut contents and restricting circulation of the hemolymph. Eventually, the anterior part of the larvae became turgid, and the larvae stopped feeding and died.

Growth Studies with E. messoria. With this insect, the full range of seven compounds available was tested at 100 μg/g in insect diets with and with near-UV treatments (Figure 3). Near-UV irradiation alone, without the compounds, clearly had no effect on growth as compared to controls. Three compounds: α-T (III), PHD (IV), and PHT (VI) were clearly phototoxic and caused more growth reduction under irradiated than nonirradiated conditions. Little difference between irradiated and nonirradiated groups was seen with control diets or with compound II, while compounds I, V, and VII showed reduced activity over part of the growth curve in irradiated groups. These latter compounds are highly unstable in the presence of near-UV (McLachlan et al., 1984), and their loss of activity can be explained by photodegradation to inactive polymers.

The sublethal effects of α-T on *E. messoria* were further investigated when larvae were reared on diet containing 100 and 10 μg/g α-T and exposed to a low intensity (0.5 W/m^2) of near-UV (as compared to 2 W/m^2 in the previous experiment or 4 W/m^2 as described in Champagne et al., 1984). These low levels of near-UV actually stimulated growth of insects given control diets, a phenomenon not observed at higher intensities.

Larvae fed 100 μg/g α-T showed significantly depressed growth relative to the irradiated and nonirradiated controls (Figure 4) and development time to the prepupal stage (indicated by the leveling off of growth curves in Figure 4) was increased from 34 to 50 days ($P \leq 0.01$). Maximum larval weight decreased from 478 mg to 385 mg ($P \leq 0.05$) (without irradiation) or 338 mg (irradiated) ($P \leq 0.01$). No increase in the number of individuals entering supernumerary instars was noted. Pupal weights were similarly reduced. The mean weight of larvae treated with α-T and near-UV was consistently lower than that of larvae exposed to α-T alone, and the observed weights were lower than would be expected, if α-T and near-UV light did not interact, from day 28 on.

Similar results were found when larvae were fed diet containing 10 μg/g α-T (data not shown). The growth of these larvae was depressed to a rate intermediate between the control groups and the larvae fed 100 μg/g α-T. These larvae reached the prepupal stage four days earlier than larvae treated with α-T at 100 μg/g but significantly later than control larvae ($P \leq 0.05$). Maximum larval weights were similar to those observed for larvae treated at the higher α-T concentration. Pupal weights were significantly ($P \leq 0.05$) lower than the controls. There were no significant differences in mortality rates between any of the treatment groups.

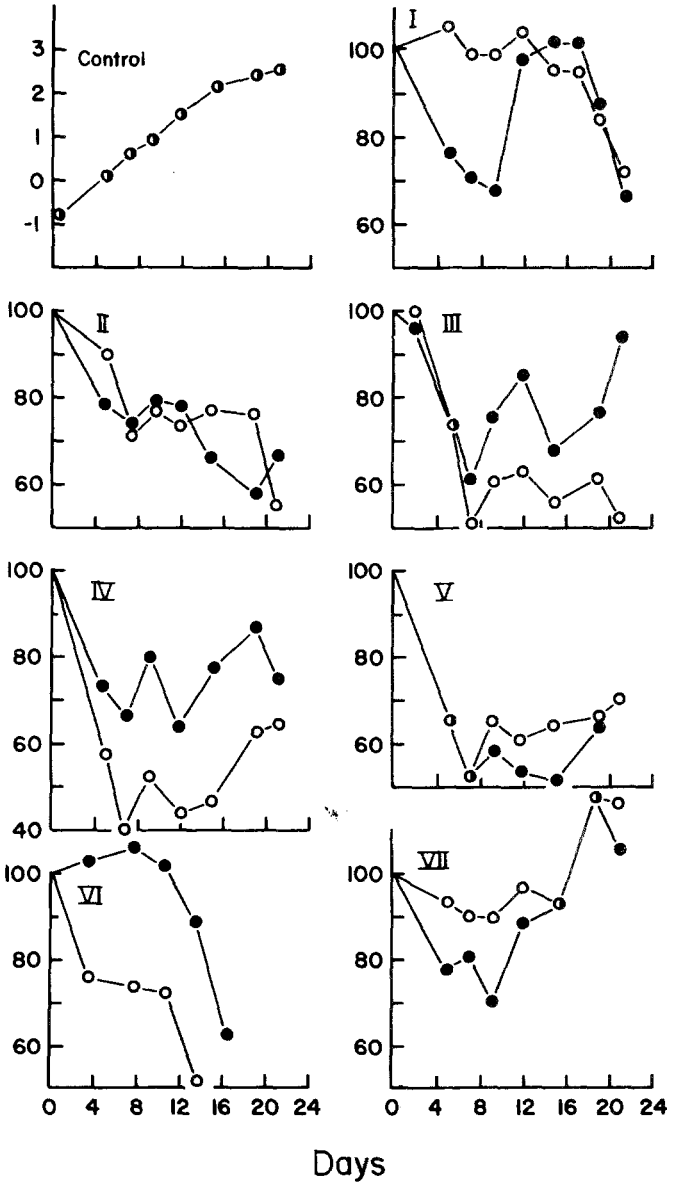

FIG. 3. *Euxoa messoria* growth as percent of control with exposure to 2 W/m^2 near-UV and diet containing 100 μg/g compounds I–VII. The growth of control larvae, as log wt (mg), is given in the top left figure. Standard errors were generally less than 10% and are omitted. ○, irradiated; •, unirradiated.

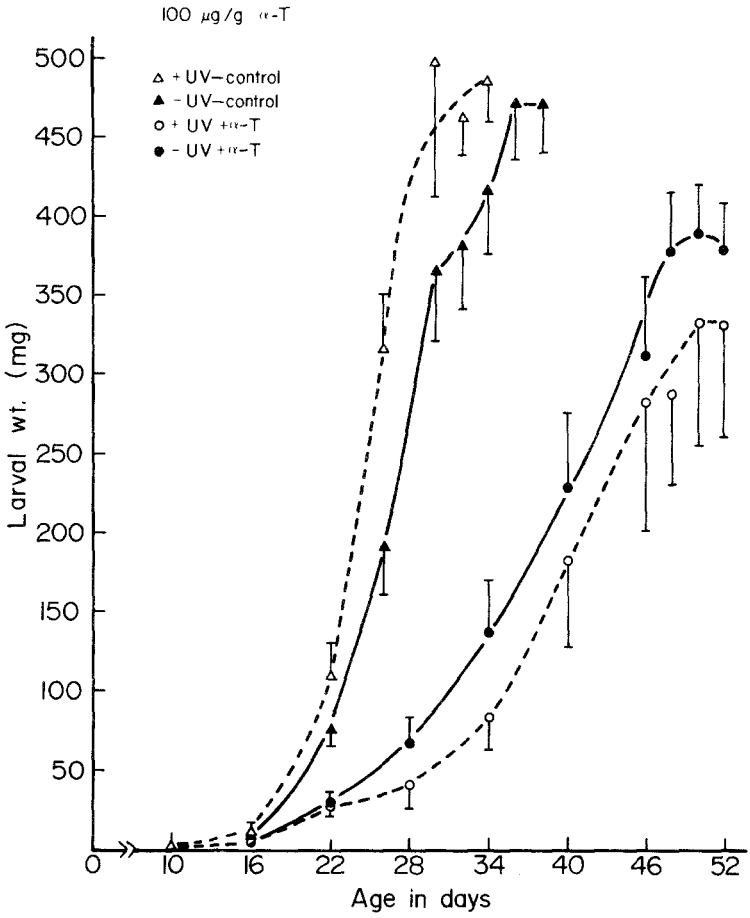

FIG. 4. *Euxoa messoria* growth with exposure to combinations of 100 μg/g α-T and very low UV irradiation (0.5 W/m^2 near-UV). Bars represent one standard deviation.

Growth Studies with O. nubilalis. All larvae lined the rearing vials with UV-opaque silk or bored into diets, thus preventing an investigation of the effects of near-UV irradiation. Nonphotosensitizing effects resulting in growth reduction (Figure 5) were found with all seven compounds tested at 100 μg/g in diet. The thiophenes I–III were more inhibitory than the nonthiophenic acetylenes (IV–VII), with inhibition increasing with the number of thiophene rings. High mortality was seen with compounds II (67%) and III (90%) at the end of the trial as compared to controls (20%), but with compounds I, IV, V, VI, and VII mortality was not different from controls.

Antifeedant Activity. The rapid initial decline in relative weight of neonate *E. messoria*, *O. nubilalis*, and *M. sexta* seen with most of the acetylenes and

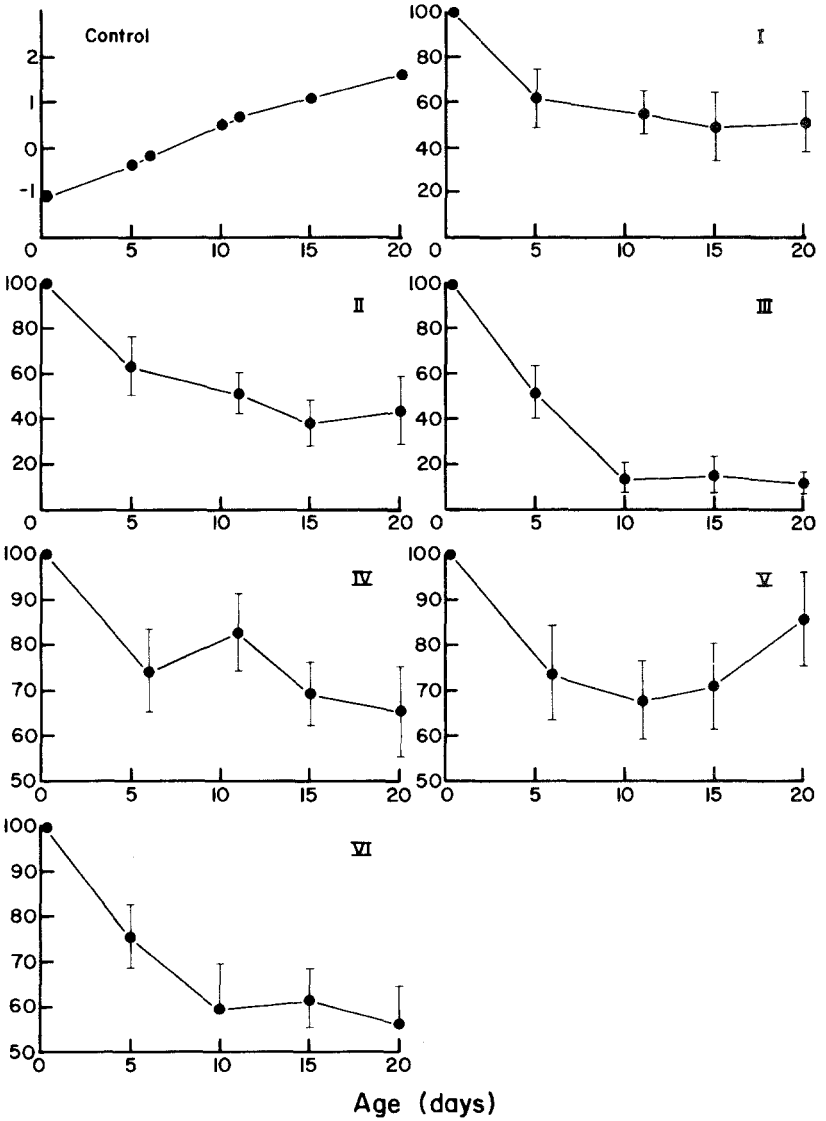

FIG. 5. *Ostrinia nubilalis* growth as percent of control with exposure to diet containing 100 μg/g compounds I–VI. The growth of control larvae, as log wt (mg), is given in the top left figure. Bars represent one standard deviation.

thiophenes suggested that these compounds reduced the feeding activity of these insects. Experiments in which leaf disks of appropriate plants were treated with 100 μg/g of the test compounds without irradiation showed that neonates of *M. sexta* were strongly deterred by α-T (III) and PHT (IV) (Table 1). Supression of feeding was much less in neonates of *E. messoria* and even less in neonate

O. nubilalis with these two compounds. A test of all compounds with *E. messoria* showed that neonates were deterred by all compounds except VII. *O. nubilalis* neonates were only deterred significantly by II, III, and VI.

A choice test with fifth-instar larvae of *E. messoria* (Figure 6) yielded a PC_{50} (a 50% protective concentration) of 6.2 μg/g for α-T ($r = 0.99$) and 119 μg/g for PHT ($t = 0.81$). In this same figure we can see feeding rates that are 80% of control feeding with 100 μg/g α-T in a no-choice situation as compared to 25% in the choice test. Irradiation reduced feeding of *E. messoria* to 60% of controls compared to 80% for nonirradiated insects.

Nutritional Indices. Both thiophenes and polyacetylenes were found to de-

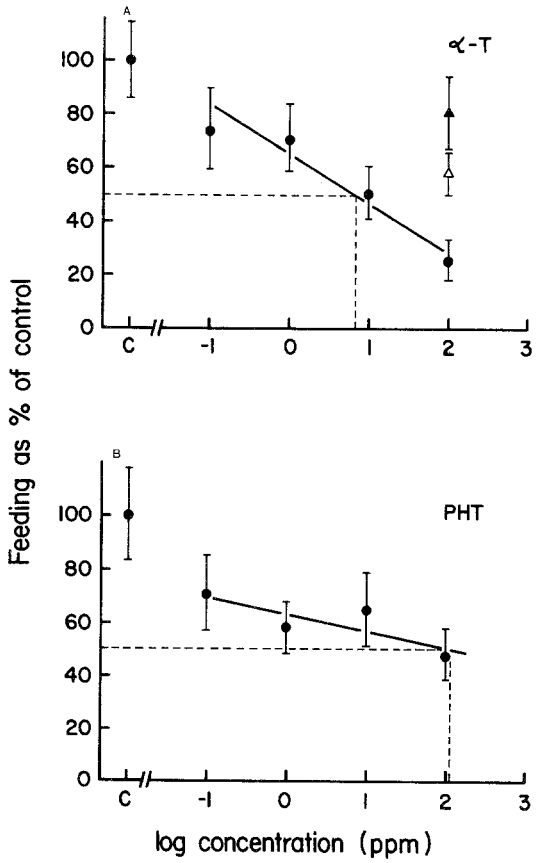

FIG. 6. *Euxoa messoria* feeding rate as percent of control in response to α-T and PHT. (A) Feeding activity with 0-100 μg/g α-T in a choice test. ▲ indicates feeding on diet containing 100 μg/g α-T in a no-choice test without near-UV irradiation, and Δ indicates feeding, in a no-choice test, to a combination of 100 μg/g α-T and 4 W/m^2 near-UV. (B) Feeding activity in a choice test in response to diet containing 0-100 μg/g PHT. In both cases, the dashed line indicates the concentration required to produce a 50% decrease in feeding. Bars represent one standard deviation.

TABLE 2. NUTRITIONAL INDICES FOR HABITUATED *Euxoa messoria* EXPOSED TO DIET CONTAINING 100 μg/g COMPOUNDS II–V WITH AND WITHOUT NEAR-UV IRRADIATION[a]

Compound	Near-UV	ECI	AD	ECD	CI
Control	+	100 a	100 a	100 a	100 a
	−	98.2 a	103.3 a	95.8 a	108.4 a
II	+	49.8 b	89.4 a	51.7 b	92.4 a
	−	39.0 b	86.6 a	37.2 b	87.7 a
III	+	33.7 b	84.4 a	37.2 b	88.9 a
	−	40.3 b	93.5 a	39.0 b	91.5 a
IV	+	23.7 b	103.4 a	21.4 b	102.3 a
	−	38.8 b	96.4 a	37.3 b	98.7 a
V	+	38.8 b	96.4 a	29.9 b	110.3 a
	−	31.8 b	95.9 a	29.9 b	94.1 a

[a] All larvae were exposed to the test compounds for the 18-day period preceding the initiation of the three-day test. Values are given as percent of control; values in a column followed by the same letter are not significantly different (Duncan's multiple-range test, $P \leq 0.05$).

crease the efficiency with which *E. messoria* larvae converted ingested diet into insect biomass. The simplest measure of the ability of an animal to utilize dietary items is the "efficiency of conversion of ingested food" or ECI. Compounds II, III, IV, and V all reduced the ECI to 32–50% of the control in "habituated" larvae that had been exposed to the compounds for 15 days (Table 2). Reduction in the ECI was generally proportional to the decrease in growth rate. Thiophenes (II and III) and polyacetylenes were about equally efficient at reducing the ECI. Among the phototoxic compounds (III and IV), the irradiated larvae had a lower ECI than nonirradiated larvae. The ECI has two components, the "approximate digestibility" (AD) and the "efficiency of conversion of digested food" (ECD). In all cases, the AD was close to control values, demonstrating that the acetylenes and thiophenes did not interfere with the digestibility of the diet. However, the ECD was lowered to 20–60% of control.

Table 3 compares values of ECI for naive fourth-instar larvae and larvae habituated to compounds in their diet for 18 days. Only α-T (III) reduced the ECI in naive larvae significantly ($P \leq 0.05$), while all compounds had a significant effect on habituated larvae.

DISCUSSION

Photosensitizing Activity of Acetylenes and Thiophenes. The present study demonstrates that the interaction of electromagnetic radiation and some acetylenic allelochemicals can lengthen larval development time, increase mortality, reduce growth, decrease ECI and ECD, or decrease feeding of some but not all

TABLE 3. MEAN ECI VALUES FOR NAIVE AND HABITUATED *Euxoa messoria* LARVAE AFTER 24-HR FEEDING ON DIET CONTAINING 100 μg/g COMPOUNDS III, IV, OR V[a]

Compound	Near-UV	Mean ECI at 24 hr	
		Naive larvae	Habituated larvae
Control	+	50.8 a	48.2 a
	−	43.6 a	47.4 a
III	+	23.6 b	16.2 b
	−	23.1 b	19.1 b
IV	+	[b]	11.4 b
	−	46.6 a	16.6 b
V	+	[b]	18.7 b
	−	42.2 a	15.1 b

[a] Naive larvae were not exposed to the test compounds prior to the experiment, whereas habituated larvae had 20 days exposure to treated diets. Values in a column, followed by the same letter, were not significantly different (Duncan's multiple-range test, $P \leq 0.05$).
[b] Not measured.

herbivorous insect species. In previous studies from this and other laboratories (Champagne et al., 1984; Downum et al., 1984), high mortality was observed with insects photosensitized by α-T at relatively high irradiance. The low near-UV levels (0.5–2 W/m^2) used in this study are more representative of levels occurring under leaf canopies. Thus, unadapted insects like *E. messoria* or *M. sexta* feeding on plants containing α-T or PHT at concentrations similar to those used in this study are likely to be photosensitized even in relatively shady microhabitats. Given that *Bidens pilosa* leaves contain 600 μg/g PHT (Bourque, 1984), that above ground parts of *Flaveria trinervis* contain at least 60 μg/g of α-T (Arnason et al., 1983b), and that sunlight may exceed 50 W/m^2 near-UV in temperate regions, it is probable that photosensitization has real ecological significance in plant–pest interactions under natural conditions. Obviously, one insect in the study, *O. nubilalis*, was able to avoid photosensitization by its behavioral adaptations of silk spinning or boring into diet, a behavior that parallels its stem-boring habit in the field. Avoidance of light may be of importance in allowing *O. nubilalis* to feed on host plants rich in phototoxins.

The development of photosensitized lesions in *M. sexta* fed PHT (or to a less extent fed α-T) suggests that the allelochemicals were transported from the gut, through the hemolymph, to tissues adjacent to the hemocoel. The absence of necrotic lesions in *E. messoria* suggests photosensitized targets at the subcuticular level, as has been observed with other cases of photosensitization, i.e., involving furanocoumarins (Berenbaum, 1978; Berenbaum and Feeny, 1981) and various synthetic dye compounds (Lavialle, 1983; Clement et al., 1980; Broome et al., 1975; Yoho et al., 1971, 1973). Polyacetylene photosensitization may be associated with the inhibition of enzymatic processes, as PHT in-

activates membrane-bound enzymes in human erythrocytes (Yamamoto et al., 1979). Synthetic dye sensitizers also inactivated acetylcholinesterase and lactic dehydrogenase in vitro, but in vivo effects were ambigous (Callaham et al., 1975, 1977a,b). Of course, the effect of photosensitizers in insects may be modified by various factors, including the optical density of the cuticle and the ability of the insect to metabolize and excrete compounds, which will affect the amount of phototoxin reaching susceptible target sites. The cuticle of *E. messoria* is more pigmented than that of *M. sexta*, and only transmits about 2% of the incident light at the λ_{max} of α-T, 350 nm.

It is difficult to compare the photoactivity of α-T and PHT to other insecticidal photosensitizers because of differences in experimental designs and test organisms. Xanthotoxin is highly phototoxic to *Spodoptera eridania* larvae at 0.1 and 1.0% concentrations (Berenbaum, 1978). Tests with synthetic dyes have usually involved feeding or injecting test insects with relatively large amounts of compound, then irradiating the insects briefly (1–12 hr) with high levels of visible light. However, it would appear that α-T and PHT, at least, are comparable to the furanocoumarins and dyes in their ability to photosensitize insects.

As many thiophenes, polyacetylenes, and other photosensitizers are highly phototoxic to mosquito and blackfly larvae at low concentrations, these insects have provided a convenient bioassay for photoinsecticidal activity. Arnason et al. (1981c) and Wat et al. (1981) have identified a number of polyacetylenes and thiophenes with marked phototoxic activity to *Aedes aegypti* larvae. Kagan et al. (1983) have produced a number of synthetic 1,3-butadiynes, also toxic to mosquito larvae. α-T has been investigated as a possible commercial mosquito and blackfly larvicide (Philogène et al., 1985) and has been patented for this application (Towers et al., 1984). Three of the compounds utilized in the present study have been tested for mosquito larvicidal activity. Matricaria lactone, compound VII, is inactive against both mosquito larvae and herbivorous insects, whereas α-T and PHT are phototoxic to both. That mosquito larvae are more sensitive to these compounds is likely the result of their route of entry into the insect: in mosquito tests, phototoxins added to the water containing the larvae penetrate the cuticle to reach target tissues, whereas phototoxins ingested by phytophagous insects may be excreted or metabolized before they can translocate through the insect and reach susceptible sites.

Light-Independent Effects on Growth. Without photosensitizing radiation, acetylenes and thiophenes can still act as highly toxic allelochemicals to herbivorous insect species. At 100 μg/g, all of the thiophenes and polyacetylenes examined, except compound VII, reduced the growth of *E. messoria* and *O. nubilalis* larvae in the absence of photosensitizing light. *M. sexta* growth was similarly inhibited by 10 μg/g α-T and 100 μg/g PHT; α-T at 100 μg/g was lethal. In the absence of photosensitization, thiophenes were about ten times as toxic (in terms of both mortality and growth reduction) as polyacetylenes to *M.*

sexta, about twice as effective at reducing the growth of *O. nubilalis*, and the two reduced the growth of *E. messoria* to a similar extent. The increase in thiophene toxicity with increasing number of thiophene rings is a relationship which was also found by McLachlan et al. (1984) in tests with microorganisms.

The ability of thiophenes and polyacetylenes to reduce the growth of phytophagous insect larvae, even in the absence of photosensitizing light, is comparable to well-established allelochemicals. Thiophenes and polyacetylenes effectively impair growth at concentrations below the levels required to reduce growth by 50% with sesquiterpene lactones, methylated flavonoids (Isman and Rodriguez, 1983) and various phenolic compounds (Isman and Duffy, 1982). Effects produced by exposure to polyacetylenes and thiophenes resemble those produced by some alkaloids (Devitt et al., 1980) at concentrations an order of magnitude greater. These compounds would seem to constitute a potentially powerful component of the plant's defense even without access to photochemical reactions.

Allelochemicals may interfere with the growth and survivorship of an insect by disrupting metabolic processes, by interferring with nutrient assimilation, or by deterring feeding. Two components of the light-independent activity of polyacetylenes and thiophenes were discerned in the present study: feeding deterrence and inhibition of nutrient utilization.

Feeding Deterrence. Feeding deterrence is an important compact of the toxicity of many allelochemicals and may, in some cases, largely account for their activity (Isman and Rodriguez, 1983). This activity may explain much of the initial growth response of the three test insects to polyacetylenes and thiophenes.

The high mortality exhibited by neonate *M. sexta* larvae fed α-T may be accounted for by the antifeedant activity of this thiophene as α-T at 100 μg/g abolished feeding and neonates given no diet at all had a similar rate of mortality. PHT also produced a marked initial retardation of growth, due initially to a 95% reduction in feeding. Normal feeding rates were gradually assumed after the initial period of starvation, but growth rates remained below controls, again suggesting another toxic mechanism.

Neonate larvae of *E. messoria* were strongly deterred from feeding on diet containing 100 μg/g of compounds II–VI (Table 1). These compounds all produced an initial decrease in relative weight gain (Figure 3). The two least deterrent compounds, I and VII, produced only a small and transient decline in relative weight, and that only in the absence of near-UV light. In these cases, and possibly with II and V as well, photodegradation of these light-unstable compounds (McLachlan et al., 1984) may have led to a small decrease in the effective concentration of the allelochemical at the surface of the diet cube. This would primarily affect neonate larvae feeding on the surface of the diet, rather than mature larvae which typically ate into the cube to a greater depth than light could be expected to penetrate. In all cases, feeding inhibition was abolished

by 24–72 hr of starvation of neonates. Growth inhibition continued, however, and subsequently became evident in larvae fed compound I as well. This was again consistant with another light-independent toxic activity for polyacetylenes and thiophenes.

The growth of *O. nubilalis* was inhibited by 100 μg/g of compounds I–VI. However, only II, III, and VI inhibited feeding to any extent (Table 1), and this activity was insufficient to account for the observed growth reduction.

α-T was also more deterrent if insects were given a choice between treated and untreated diet (choice test). Choice tests more accurately reflect the situation facing a mobile, polyphagous insect, such as *E. messoria*. If an insect is immobile, monophagous, or occurs in an agricultural monocrop situation, no-choice tests are more likely to indicate its behavior in the field (Schoonhoven, 1982).

Near-UV enhanced the feeding deterrent effect of α-T in a no-choice test with sixth- and seventh-instar *E. messoria*. This may indicate photosensitization of insect chemoreceptors or other sensillae or, alternatively (or perhaps in addition), light-dependent toxicosis may be occurring quickly enough to affect feeding in a 24-hr trial. As an insect feeding in daylight will certainly be exposed to some near-UV, this result suggests that α-T (and perhaps other phototoxins) will be more effective as an antifeedant against diurnally active insect herbivores.

The feeding deterrent activity of polyacetylenes and thiophenes occurred at concentrations well below those found in many Asteraceae, which are likely to deter feeding by all but the highly adapted insects.

Nutrient Utilization. Decreased growth persisted even after larvae assumed normal feeding rates. This led to an examination of the effect of thiophenes and polyacetylenes on some standard measures of the efficiency with which insects (*E. messoria* in this case) assimilate and utilize their diet. All of the compounds tested reduced the gross efficiency with which diet was converted to insect biomass (ECI) (Table 3). This effect did not involve changes in the assimilation (AD) of diet, indicating that the availabilty of diet components was not affected by the test compounds. These compounds do not, then, behave as digestibility reducers. Rather, the conversion of assimilated diet to biomass (ECD) was strongly reduced over 15 days by all of the compounds tested. This is evidence of damage to metabolic processes: nutrients are diverted to the repair of such damage and do not contribute to new growth (Waldbauer, 1968).

Differences in the rate at which thiophenes and polyacetylenes affect the ECI were noted. α-T reduced this index in naive larvae by 48% within 24 hr, whereas polyacetylenes were less effective. Only after long exposure (habituated larvae) were polyacetylenes as effective as thiophenes in reducing ECI. One possible explanation is that thiophenes may attack sites in the midgut and/or hindgut leading to rapid interference in nutrient processing and utilization,

while acetylenes may lower ECI as a response to progressive damage during long-term exposure at the same or another site. An observation consistent with this hypothesis is that fourth- and fifth-instar *M. sexta* fed diet containing α-T frequently produced liquid frass, an indication that the hindgut is failing to readsorb water. This effect was not noted when larvae were fed diet containing PHT. Sublethal doses of some synthetic insecticides (e.g., fenitrothion and aminocarb) increase liquid loss from the digestive tract of insects by disrupting the epithelial membrane of the midgut and by interfering in the function of the rectal glands (Tauton and Khan, 1978).

The effect of thiophenes and polyacetylenes (over the longer term) on the ECI and ECD was similar to that found by Beck and Reese (1976) for a variety of different allelochemicals. For example, thiophene effects were similar to those of highly toxic alkaloids such as L-dopa. The gradual reduction of nutrient utilization by polyacetylenes is similar to the effect of the nonprotein amino acid canavanine on *M. sexta* (Dahlman, 1977). The toxicity of nonprotein amino acids is expressed gradually, as insects accumulate defective proteins.

Insect Host Range and Tolerance to Acetylenes and Thiophenes. A correlation can be made between the response of the neonate larvae to polyacetylenes and thiophenes, and their host plant range. *M. sexta* larvae were the most strongly deterred, as the feeding inhibition due to α-T at 100 μg/g could not be overcome by starvation. As solanaceous host plants of this insect do not usually contain these compounds, the ability to detect and avoid them probably allows *M. sexta* larvae to avoid ingesting potentially toxic nonhost plants. At low concentrations, α-T and PHT had little deterrent effect or were phagostimulatory, even though α-T reduces growth at that level. *E. messoria* larvae were also deterred by all of the test compounds except VII, the only one that did not reduce growth. The host plant range of this polyphagous insect is extensive but apparently includes only those Asteraceae that lack polyacetylenes and thiophenes. Again, avoidance of these compounds may lead the insect to avoid toxic nonhost plants. *O. nubilalis* larvae were only slightly deterred by the thiophenes and PHT and did not respond to the other acetylenes. This insect utilizes at least 25 species of Asteraceae (Caffrey and Worthley, 1927) most of which are phototoxic in screening tests (Towers et al., 1979).

The severely and frequently attacked plants include the highly phototoxic *Bidens* spp. and *Dahlia* spp., which were the source plants for some of the compounds used in this study. First-instar larvae feed on leaves but may be able to avoid resin canals, glands, and other sites with high levels of phototoxins. Such a behavior allows neonate *Heliothis zea* to avoid ingesting gossypol from cotton leaves (Reese et al., 1981). Later instar *O. nubilalis* avoid photosensitization by spinning silk and by boring into stems or, less frequently, fruits. Furthermore, the concentration of polyacetylenes and thiophenes is frequently lower in the stems than in other plant tissues (Bohlmann et al., 1973; Towers

and Wat, 1978). This may be one reason why *O. nubilalis* is able to exploit plants not accessible to *M. sexta* or *E. messoria* or, presumably, many other insects.

The activity of polyacetylenes and thiophenes may be compared to other known feeding deterrents. These compounds are not as active as azadirachtin and warburganal, which are antifeedants of potential commercial significance (Schoonhoven, 1982; Jermy, 1983). However, polyacetylenes and thiophenes are as efficient as several other limonoid and isoflavonoid antifeedants and are considerably more effective than tannins, gossypol, or tomatine. In particular, several of the compounds tested in this study are effective antifeedants at much lower concentrations than are the sesquiterpene lactones, widely considered to constitute a major part of the biochemical defenses of many plants, especially in the Asteraceae (Burnett et al., 1974; Mabry and Gill, 1979).

Evolutionary Considerations. Chemotaxonomic and biosynthetic evidence indicates strongly that the series fatty acid to polyacetylene to thiophene represents an evolutionary elaboration (Bohlmann et al., 1973). The toxicity of the substances appears to be correlated with their position in this evolutionary sequence. Fatty acids, particularly oleic acid, are ubiquitous among vascular plants (Robinson, 1980). Some of these compounds are toxic to herbivorous and nonherbivorous insects; this led to their early use in insecticidal soaps (Puritch, 1975). The C_{10}–C_{12} fatty acids and oleic acid are the most toxic. Binder et al. (1979) and Binder and Chan (1982) examined the toxicity of a series of C_{10}–C_{12} fatty acids to three phytophagous lepidopterans, *Pectinophora gossypiella*, *Heliothis zea*, and *Heliothis virescens*. Concentrations required to reduce larval growth by 50% (ED_{50}) ranged from 0.1 to 0.6%, with some variation between species. Toxicity increased with increasing unsaturation.

Polyacetylenes are derived from the fatty acids (oleic acid) via β-oxidations, and occur in a more limited range of plant families, particularly the Asteraceae and the Apiaceae (Bohlmann et al., 1973). We have determined that several of these compounds markedly reduce the growth of lepidopteran herbivores at a concentration of 0.01%. In addition, matricaria ester, a widely distributed polyacetylene in the Asteraceae, was the most toxic of the compounds examined by Binder et al. (1979), with an EC_{50} of 0.0046–0.017%. Polyacetylenes appear to be an order of magnitude more toxic to insects than their fatty acid precursors.

Thiophenes represent a further evolutionary step: they are derived from polyacetylenes by cyclization with sulfur. These compounds are restricted to advanced tribes of the Asteraceae, including the Veronieae, Eupatorieae, Inuleae, Heliantheae, Helenieae, Anthemideae, Senecioneae, Cynareae, and particularly the Tageteae (Hohlmann et al., 1973). The more toxic bithiophene and terthiophene compounds are restricted to the last three tribes listed. In our study, these compounds were one order of magnitude more toxic than the polyacetylenes to *M. sexta*, about twice as toxic to *O. nubilalis*, and equally toxic to *E. messoria*.

The increasing toxicity of this evolutionary sequence of secondary metabolites suggests that they have been selected for on the basis of their activity against herbivores and other plant enemies. This supports the hypothesis that polyacetylenes and thiophenes function in the defense against herbivores and pathogens.

INSECT DEFENSES AGAINST PHOTOTOXIC PLANT CHEMICALS

RICHARD A. LARSON

Institute for Environmental Studies

(Received May 28, 1985; accepted October 15, 1985)

Abstract—In addition to avoidance strategies, insects may use one or more biochemical defenses against phototoxic plant constituents or the reactive forms of oxygen they generate. These biochemical defenses may include metabolism; excited state quenching; deactivation of singlet oxygen, superoxide, or free radicals; and destruction of reaction products. This article is a survey of the antioxidative enzymes and simpler molecules produced by insects and their possible roles in combating phototoxic chemicals.

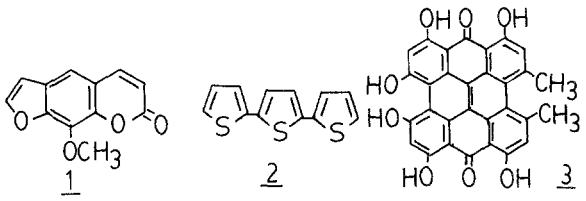
Key Words—Phototoxicity, enzymatic, detoxification, Insecta, insect herbivory, furanocoumarins, polyacetylenes, thiophenes, hypericin, oxygen quenching, defense.

INTRODUCTION

Photochemically activated toxicants from higher plants, such as 8-methoxypsoralen (8-MOP) (*1*) and related furanocoumarins, alpha-terthienyl (*2*), and hypericin (*3*), are known to have several biochemical interactions with target organisms. The formation of 2 + 2 cycloadducts between furanocoumarins and DNA bases is well known; however, there are many other possible biologically significant pathways for the generation of cytotoxic species. In addition to direct adduct formation, a phototoxin may also transfer an electron from its excited state to a target biomolecule (or accept one from a biomolecule) or produce an intermediate reactive species by interacting with oxygen.

An insect may deactivate an ingested phototoxin by several routes; it may metabolize the toxin fast enough so that phototoxicity is never manifested; quench, by physical or chemical means, the excited state of the phototoxin;

0098-0331/86/0400-0859$05.00/0



quench or destroy reactive forms of oxygen produced by phototoxin–O_2 interactions; or destroy toxic intracellular reaction products. Very few of these alternatives have been examined in the case of insects. In this paper, I will discuss the existing literature and also speculate on possible routes of detoxification used by insects.

EXCITED OXYGEN SPECIES AND PHOTOTOXICITY

Many of the biological effects of phototoxic agents are due to the formation of reactive oxygen species—either free radicals or other modified forms of oxygen itself, or oxygenated organic compounds produced by the interactions between oxygen and photoexcited organic substrates. Ground-state oxygen, a triplet (diradical) species, is negligibly reactive with nearly all singlet organic molecules having paired spins, but does react very rapidly with many organic free radicals, including those formed photochemically. The product of such reactions, a peroxy radical (ROO·) is usually quite unstable; its fate depends on its surroundings. In the case of lipid peroxidation, peroxy radicals abstract hydrogen atoms from neighboring molecules, often other lipids, leading to lipid hydroperoxides (ROOH) and new radicals which can again react with oxygen by a chain reaction. Some hydroperoxides are acutely toxic, and others may also have mutagenic activity (Yamaguchi and Yamashita, 1980).

Ground-state oxygen can be converted to a more reactive species, singlet oxygen ($^1O_2$), by reaction with certain photochemically excited states of dyes known as photosensitizers. Many synthetic and natural pigments have been shown to have photosensitizing activity (Foote, 1981). Singlet oxygen, as its name suggests, is a spin-paired species and exhibits a different range of reactivity (relative to ground-state O_2) toward organic molecules. It has little tendency to react rapidly with most free radicals but is much more reactive than ground-state oxygen to a few selected organic compounds which include electron-rich phenols, highly substituted olefins, small unsaturated heterocyclic rings, and organic sulfur compounds (Foote, 1981).

Under certain conditions, ground-state oxygen can also be reduced by one-electron transfer to a monoradical form, superoxide radical anion (O_2^-). Among the species which can promote this reaction are photochemically excited organic molecules such as flavins and ketones (via intermediate organic free

radical intermediates). Superoxide, in nonpolar environments, is a very powerful nucleophile, displacing leaving groups such as halogens and cleaving ester linkages at fast rates. In polar environments, its conjugate acid, HOO· is formed; it reacts very rapidly with itself (with a half life about 1 sec at 10^{-5} M) in a spontaneous redox ("dismutation") reaction to afford two nonradical species, oxygen and hydrogen peroxide. Hydrogen peroxide, in turn, may be homolytically cleaved either by transition metal-catalyzed processes or by UV light to an extremely reactive, unselective, and potentially toxic intermediate, the hydroxyl radical (HO·).

Thus, by a number of light-induced pathways, oxygen can be converted to many reactive and potentially damaging species (Figure 1).

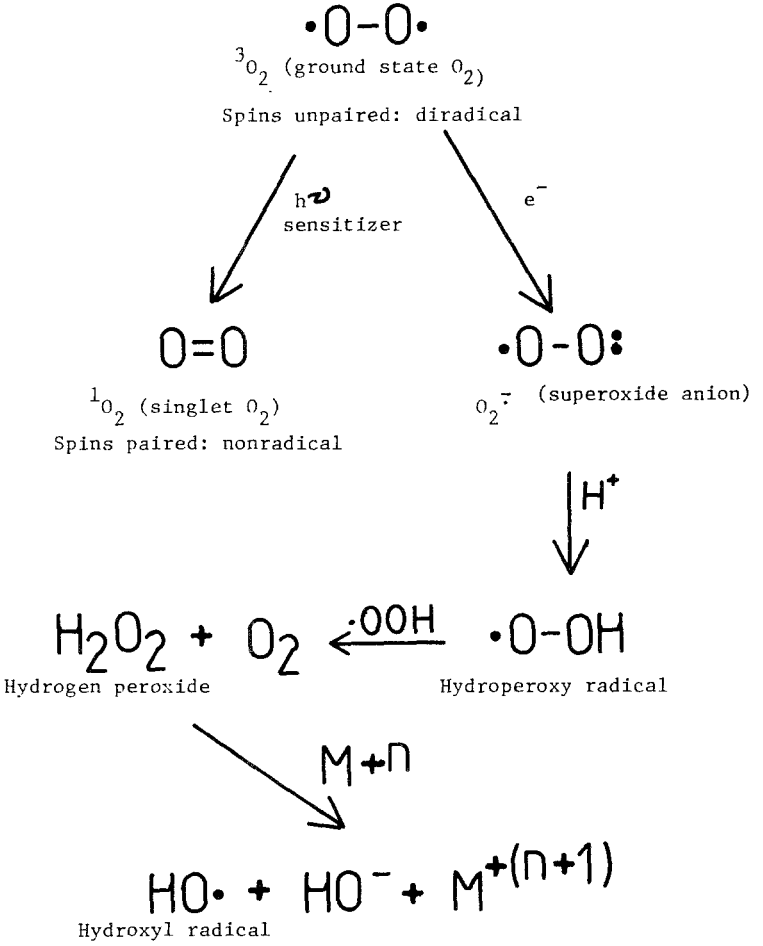


FIG. 1. Reactive oxygen species.

PHOTOBIOCHEMISTRY OF PHOTOTOXIC SUBSTANCES

Furanocoumarins. For many years, furanocoumarins, a group of oxygenated tricyclic aromatic compounds found primarily in the plant families Umbelliferae and Rutaceae, have been known to be phototoxic. The broad phototoxicity of these molecules has stimulated much fundamental research on their photochemical and photophysical properties as well as on their photobiological effects. The lowest excited singlet state of 8-MOP (and perhaps other furanocoumarins) is reached by excitation with UV light around 330 nm. It is a pi-pi* state (Mantulin and Song, 1973), strongly localized in the pyrone ring, which fluoresces more or less efficiently depending on the solvent. The best known photoreactions of furanocoumarins are their cycloadditions with DNA constituents (for a review, see Song and Tapley, 1979). However, there are other photoreactions of furanocoumarins with biologically important molecules. 8-MOP strongly inactivates the *E. coli* enzyme, DNA polymerase I, in the presence of UV light (Granger and Helene, 1983). It binds physically to the protein in an oxygen-independent step and then becomes covalently bound in the presence of light. Continued irradiation of the bound 8-MOP-modified enzyme led to progressive loss of enzymatic activity, which was not significantly retarded by the addition of a $^1O_2$ quencher, 1,8-diazabicyclooctane (DABCO) (see Table 1). In view of this evidence, the authors proposed that 8-MOP sensitized the destruction of amino acids in the neighborhood of its binding sites by a mechanism not involving $^1O_2$.

Earlier work had shown that 8-MOP forms photoadducts with tryptophan (Megaw et al., 1980) and that tyrosine, as well as tryptophan, efficiently quenched furanocoumarin triplets (Land and Truscott, 1979).

8-MOP also sensitizes the photooxidation of the naturally occurring phenolic antioxidant, alpha-tocopherol (vitamin E) to unspecified products, apparently without participation of $^1O_2$ (Potapenko et al., 1983).

The photoionization mechanism for furanocoumarin phototoxicity has not received much attention. In this mechanism, an excited state ejects an electron into the surrounding medium and an acceptor takes it up (becomes photoreduced). Joshi and Pathak (1983) showed that many furanocoumarins, when irradiated in aerated aqueous ethanol solution, produce O_2^-; apparently, electron transfer to dissolved O_2 is quite efficient for furanocoumarins having a variety of structural elements.

The universal occurrence of unsaturated cell and membrane lipids among living organisms could also account for some of the broadly biocidal effects of furanocoumarins. Insects, for example, are susceptible to UV-mediated furanocoumarin phototoxicity. Free fatty acids constitute almost 50% of surface components of some insects, and previous evidence suggests epidermal involvement in furanocoumarin toxicity; the epidermal layer appears discolored and damaged after ingestion (Berenbaum, 1978). There are at least two possible mech-

TABLE 1. POTENTIAL $^1O_2$ QUENCHERS IN INSECTS

Insect chemical	Source	Analogue
 perillen	*Lasius fuliginosus* (field ant): Bernardi *et al.*, 1967	 $k_q\ ^1O_2 = 9 \times 10^{7a}$
Beta-carotene and other carotenoids	Widespread in hemolymph, integument, and wings: Needham, 1974	$\beta - C\ k_q = 1.6 \times 10^{10}$
Histamine	*Zygaena lonicerae* and other photopohagous moths (Bisset *et al.*, 1960)	$k_q = 2.8 \times 10^7$
Serotonin	*Automeris illustris* (silkworm moth): Welsh and Batty, 1963	Tryptophan $k_q = 2.5 \times 10^8$
 Propyleine	*Chauliognathus pulchellus* (soldier beetle): Moore and Brown, 1978	 DABCO $k_q = 1.5 \times 10^7$
Benzoquinone	Many families	$k_q = 3.4 \times 10^7$
 Chrysomelidial	*Gastrophysa cyanea* (leaf beetle): Blum *et al.*, 1978	 $k_q = 3.3 \times 10^7$

[a] K_q = quenching rate constant for $^1O_2$ in M^{-1} sec^{-1}.

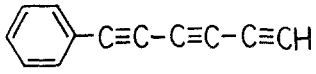
anisms for the interaction of furanocoumarins with unsaturated lipids. In the first, furanocoumarins may generate $^1O_2$ by the interaction of their triplet states with ground-state oxygen (Poppe and Grossweiner, 1975). Singlet oxygen is very reactive toward unsaturated fatty acids; the reactivity increases with the number of double bonds (Doleiden et al., 1974), and the initial products are hydroperoxides. A second possibility is the direct light-induced cycloaddition of one of the double bonds of the furanocoumarin with the double bonds of the lipids. Although no reports of such a reaction have appeared, a similar cycloaddition occurs efficiently between 8-MOP and tetramethylethylene (Shim and Kim, 1983).

Some attempts have been made to correlate the biological activity of furanocoumarins with their relative photoreactivity toward pyrimidine nucleotides (see, for example, Song et al., 1971). For genotoxic damage, the correlation appears good. There are many other factors to consider, however. Salet et al. (1982) pointed out that the relatively hydrophobic furanocoumarin, 4,5,8-tri-

methylpsoralen, was much more active in inducing oxidative damage in rat liver mitochondrial membranes than was the less hydrophobic compound, psoralen. The quantum yield of triplet formation for the two compounds was comparable. The authors suggested that the partition coefficients of the two molecules drove the furanocoumarins to different regions of the cell and that the higher concentration of 4,5,8-trimethylpsoralen within the hydrophobic membranes permitted it to react more rapidly with some membrane constituents or to generate $^1O_2$ which reacted with them.

Polyacetylenes and Thiophenes. Thiophenes such as alpha-terthienyl which are biosynthetically derived from long-chain polyacetylenes, are common constitutents of the Compositae. They display a broad range of phototoxic effects toward a variety of organisms including insect eggs (Kagan et al., 1983) and larvae (Wat et al., 1981; Arnason et al., 1981) and humans (contact dermatitis; Chan et al., 1975). Aromatic polyacetylenes are similarly broadly biocidal; phenylheptatriyne (*4*), for example, is toxic to bacteria, fungi, protozoa, nematodes, insects, fish, and human fibroblast cells (Arnason et al., 1981; Wat et al., 1979).

Light and oxygen appear to play important roles in the toxicity of many polythiophenes and aromatic polyacetylenes. In some cases, $^1O_2$ is apparently involved in the cytotoxic events. In particular, there is good evidence that photoexcited alpha-terthienyl is a photosensitizer (Wat et al., 1980). Downum et al. (1982) suggested that $^1O_2$-mediated attack on membrane proteins was responsible for the membrane photodestruction observed in *E. coli* treated with alpha-terthienyl. The membrane was also the site of damage for several viruses treated with phenylheptatriyne in the presence of light. In this case, however, O_2 was not required for activity (Hudson et al., 1982).



4

Many aliphatic polyacetylenes, which occur principally in the Umbelliferae, are also quite toxic but may have a different mode of action. Although some of them absorb solar UV light, the importance of light or even of O_2 for their toxicity has not been conclusively established.

Hypericin. Many plants, especially in the families Polygonaceae and Guttiferae, contain complex phototoxic quinones. Livestock poisoning caused by ingestion of *Hypericum* (St. John's-wort or Klamath weed) material has long been known. The active priniciple, hypericin a dark red, fluorescent pigment, occurs in glands on the leaves, petals, sepals, and stems. It is phototoxic only when irradiated with visible light; near-UV wavelengths are virtually ineffective. Oxygen is required for the toxic effects, which include erythrocyte hemo-

lysis. Light-colored mammals are particularly susceptible (Towers, 1982). Little is known concerning possible toxic effects of hypericin and similar quinones on insects. *Hypericum* has a specifically associated insect, the Klamath beetle (*Chrysolina quadrigemina*) that is not only not affected by hypericin but has a specific receptor for it, apparently using it as a feeding stimulant (Rees, 1969). The Klamath beetle is highly reflective; it may be using this property as a physical method to reduce light intensity inside its body cavity (see next section). There have been few studies of the fundamental photochemical properties of hypericin or related compounds; however, a somewhat similar quinone, cercosporin (a fungal product), has been shown to produce $^1O_2$ (Youngman et al., 1983; Dobrowolski and Foote 1983). Hypericin itself sensitizes the photooxidation of tyramine, by what is apparently a $^1O_2$ process (Seely, 1977).

INSECT DEFENSE MECHANISMS

Physical Defenses. Light-avoidance defenses appear to be used by some phytophagous insects. For example, leaf rollers shield themselves for light by wrapping themselves in leaves as they feed. Dark pigmentation or highly reflective surfaces may also be ways of preventing damaging light wavelengths from reaching critical cellular machinery (Pathak and Fitzpatrick, 1974).

Metabolism. Very few data are available on the metabolism of furanocoumarins or other phototoxic molecules by any organisms. Work on their metabolic products in insects is limited to the findings of Ivie's group, which are discussed in detail elsewhere in this issue. In brief, a susceptible species (*Spodoptera frugiperda*) lacked the ability to metabolize 8-MOP, whereas a resistant species (*Papilio polyxenes*) was able to oxidatively cleave the furan ring.

Excited-State Quenching. In order to prevent photochemically excited states from reacting with biomolecules or oxygen, a possible strategy of defense would be to intercept the excited state with another molecule; this interaction would keep the toxin in the presumably harmless ground state. In classical photochemistry, several types of excited state quenching mechanisms have been described (Calvert and Pitts, 1966). In physical or collisional quenching, the electronic energy of the excited state ("donor" molecule) is removed by the "acceptor" (quencher) as some combination of electronic, vibrational, rotational, and kinetic energy. The excited quencher is not chemically changed, that is, no covalent bonds break. Either singlet or triplet excited states of donor molecules may be quenched, but because of the very short lifetime of most singlet states, the concentration of a singlet quencher, even a very efficient one, must be rather high (typically 10^{-3} M or greater). Such molecules as beta-carotene, amines, furans, and a few anions such as I^- and N_3^- have been repeatedly shown to be efficient physical excited state quenchers (Calvert and Pitts, 1966). Carot-

TABLE 2. POTENTIAL FREE RADICAL QUENCHERS IN INSECTS

Insect chemical	Source	Synthetic analogue
Vitamin C	Synthesized by many but required by some phytophagous types (Chippendale, 1978)	
Vitamin E	Essential dietary requirement for some (Needham, 1978)	 "BHA"
Nicotine	Tobacco-feeding insects and *Musca domestica*, *P. americana*, and *B. germanica* (Self *et al.*, 1964)	Nicotine is a patented (US Pat. 1916437, 1933) petroleum antioxidant
	*Solenopsis* (fire ant) spp: Brand *et al.*, 1972	
enoids, as well as some amines and furans, are constitutents of many phytophagous insects (see Tables 1-2).

Physical quenching may involve radiative or nonradiative phenomena. In radiative processes, the acceptor absorbs some of the electromagnetic energy emitted by the donor as it fluoresces. For this process to occur efficiently, the absorption spectrum of the acceptor must be similar to the emission spectrum of the donor. For the special case of furanocoumarins, with maximal fluorescence in the region around 450–550 nm, it would seem reasonable that insect pigments such as carotenoids would be effective quenchers, since their absorption maxima occur in that region. There has been no work reported on this possibility, however. At short ranges (ca. 10 angstroms), one of the most important mechanisms of quenching is exchange energy transfer, a nonradiative process in which the electron clouds of the donor and acceptor molecules overlap and there is electrostatic transfer of energy between two of the overlapping orbitals.

Chemical quenching is the rapid photochemical reaction of an excited state with another molecule to form one or more products. The normal consequence of this process is that both the donor and acceptor molecules are destroyed. A good example of chemical quenching is the 2 + 2 cycloaddition of the singlet state of *trans*-stilbene with electron-rich unsaturated esters (Lewis and DeVoe, 1980).

Oxygen Quenching. Reactive oxygen species, either $^1O_2$ or O_2^- (and related free-radical species whose ultimate source is oxygen) are well-known inter-

mediates in phototoxicity. Deactivation of these substances by enzymes or lower-molecular-weight constitutents would be a possible defense pathway for phytophagous insects.

The quenching of $^1O_2$ has been rather well studied (for a review, see Wilkinson and Brummer, 1981) for synthetic molecules and a few naturally occurring chemicals. Only a few classes of compounds destroy $^1O_2$ rapidly; these include amines, highly substituted olefins (particularly carotenoids), furans, polycyclic aromatic hydrocarbons, and some electron-rich sulfur and oxygen derivatives. The rate constants for these quenchers with $^1O_2$ range from near diffusion control (k_q around 10^{10}/M/sec) to about three orders of magnitude lower. Some of these materials react with $^1O_2$ to form oxygenated derivatives such as peroxides, and others quench it physically.

Certain insect constituents are known fast quenchers of $^1O_2$, and others appear to be close relatives of such quenchers (Table 1). It was recently discovered that several plant alkaloids, closely related to some nitrogen heterocycles found in insects, are efficient $^1O_2$ quenchers (Larson and Marley, 1984; Gorman et al., 1984). Admittedly, some of these chemicals may have other physiological functions for insects, and some appear to be restricted to special glands where contact with ingested phototoxins would seem unlikely. Nevertheless, it is possible that these or related compounds may occur at sufficiently high concentrations in tissue to act as $^1O_2$ quenchers and inhibit photosensitized toxicity to a significant degree. This possibility requires further research.

Free radical inhibitors are widely used in industry to prevent oxidative deterioration of many products such as foods, fuels, plastics, rubber, etc. Phenolic derivatives are very widely used. Mechanistically, synthetic inhibitors act by deactivating peroxy radicals. The well-known antioxidant BHA, for example, converts two moles of peroxy radicals to inactive, nonradical products. Some naturally occurring phenols have the same mechanism of action. Vitamin E, for example, exhibits one of the fastest rates of attack toward peroxy radicals, and has the same 2:1 stoichiometry as BHA (Burton and Ingold, 1981). Vitamin E is an essential dietary requirement for some insects; it and other insect chemicals with possible free radical quenching activity, are listed in Table 2 along with some related industrial antioxidants.

Sohal et al. (1983) demonstrated that adult houseflies (*Musca domestica*) contain chloroform-soluble free-radical antioxidants and that the antioxidant concentration declines with the age of the insect. No individual antioxidants were identified.

Some commercial antioxidants are reducing agents; they act by destroying peroxides that can act as chain carriers in free-radical chain reactions. Their structures incorporate easily oxidized groups like disulfides, P=S linkages, etc. One low-molecular-weight insect chemical that may have similar activity is dimethyl disulfide (Table 3). Its high volatility, however, probably limits its utility.

TABLE 3. POTENTIAL PEROXIDE DESTROYERS IN INSECTS

Insect chemical	Source	Synthetic Analogue
$CH_3-SS-CH_3$	*Paltothyreus tarsatus* (ponerine ant) (Casnati *et al.*, 1967)	Ph-SS-Ph
Glutathione	*Musca domestica* (Sohal *et al.*, 1983) *Aedes aegypti* (Hazelton & Lang, 1982)	—
SOD (superoxide dismutase)	*Apis mellifera* *Drosophila* spp. *Musca domestica*	—
Catalase	*Apis mellifera* *Drosophila* spp. *Brachinus* spp. *Musca domestica*	—

Glutathione, a tripeptide with an easily oxidizable —SH group, can act as an antioxidant either nonenzymatically or in a catalyzed reaction involving glutathione peroxidase. The enzymatic reaction is important in mammals; however, insects appear to lack glutathione peroxidase (Smith and Shrift, 1979). Adult houseflies, however, do contain glutathione; its concentration is maximal at about 10 days of age and declines sharply thereafter (Sohal et al., 1983). A similar decline in glutathione concentration with senescence was reported for the mosquito, *Aedes aegypti* (Hazelton and Lang, 1982).

Other likely peroxide-destroying agents are enzymes; nearly all aerobic organisms that have been tested contain highly active catalysts for the destruction of reactive oxygen species such as O_2^- and H_2O_2. Few insect species have been examined for their content of these enzymes. Sohal et al. (1983) demonstrated that both catalase and superoxide dismutase activity were present in houseflies.

SUMMARY AND CONCLUSIONS

Higher plants have evolved a wide variety of molecules phototoxic to some phytophagous insects. Their photobiological mechanisms of action are diverse; many forms of transfer of photochemical excitation energy are possible and a number of biochemical targets are available. Insects, however, appear to have coevolved several efficient defense mechanisms. A number of other insect chemicals also appear on structural grounds to be possible defensive agents. Very little work has been done in the whole area, and it appears that many

fruitful avenues of interdisciplinary research will be available to groups of entomologists, chemists, and botanists who are willing to work together.

Acknowledgments—I thank May Berenbaum and Karen Marley for valuable discussions and assistance.

(Received May 28, 1985; accepted August 5, 1985)

Abstract—The comparative fate of tritiated preparations of a linear furanocoumarin (psoralen) and an angular furanocoumarin (isopsoralen) was determined in last-instar caterpillars of the black swallowtail butterfly (*Papilio polyxenes* Fabr.). Oral administration of either furanocoumarin at 5 μg/g is followed by rapid metabolism, primarily through oxidative cleavage of the furan ring, and the metabolites are rapidly excreted. Isopsoralen is, however, metabolized at a somewhat slower rate than is psoralen, and levels of unmetabolized isopsoralen in body tissues of the treated caterpillars are about three-fold higher. These data are compatible with the hypothesis that a reduced detoxification rate accounts at least in part for the susceptibility of *P. polyxenes* caterpillars to the deleterious effect of isopsoralens.

Key Words—Psoralen, isopsoralen, furanocoumarin, *Papilio polyxenes*, Lepidoptera, Papilionidae, metabolism, detoxification.

INTRODUCTION

Furanocoumarins occur in nature as components of hundreds of higher plant species. These compounds are of interest from a coevolutionary perspective because many furanocoumarins act as potent photosensitizers and apparently function in the plants that contain them as protective agents against parasites and predators. Furanocoumarins act as phytoalexins against microbial and other stresses in some plants (Beier and Oertli, 1983), as allelopathic agents (Friedman et al., 1982; Shimomura et al., 1982), and as allomones against herbivorous mammals (Ivie, 1978). It is now well known that furanocoumarins are

important factors in the resistance of some plant species to the predatory actions of herbivorous insects (Berenbaum, 1978, 1981; Muckensturm et al., 1981).

There are two major groups of natural furanocoumarins (Figure 1). The potent biological activity of these compounds is thought to arise primarily as a result of light-induced alkylation of DNA (Scott et al., 1976). Psoralens may form both mono- and di-adducts with pyrimidine bases of DNA, but the angular configuration of the isopsoralens permits only mono-adducts to be formed. Some researchers believe that among the naturally occurring furanocoumarins, the psoralens possess greater photosensitizing potential than the isopsoralens (Pathak et al., 1960, 1962; Musajo and Rodighiero, 1962; Scott et al., 1976), although others suggest that such differences may not be significant under natural, multiwavelength light activation circumstances (Potapenko et al., 1984).

Irrespective of the high photosensitizing potential of furanocoumarins, certain insect species, particularly among butterflies of the family Papilionidae, have adapted to feed successfully and preferentially on plants that contain relatively high levels of linear furanocoumarins (Berenbaum and Feeny, 1981). Recent studies in our laboratories have shown that tolerance to these compounds by caterpillars of the black swallowtail butterfly (*Papilio polyxenes* Fabr.) results from rapid and almost quantitative detoxification of psoralens in the midgut and body tissues to nonphotosensitizing metabolites that are rapidly excreted (Ivie et al., 1983; Bull et al., 1984). These reactions are mediated by microsomal mixed-function oxidases present in high titer in both midgut and body tissues (Bull et al., 1986). However, *P. polyxenes* avoids plants that contain appreciable quantities of angular furanocoumarins (isopsoralens) and, in fact, isopsoralens are known to reduce growth and fecundity of this insect species (Berenbaum and Feeny, 1981).

The studies reported here were undertaken to evaluate the possibility that differences in metabolism of psoralens and isopsoralens by caterpillars of *P. polyxenes* might account for the observed differences in toxicity of these compounds.

FIG. 1. Structures of the linear furanocoumarin, psoralen, and of the angular furanocoumarin, isopsoralen (angelicin). The asterisks (*) indicate sites of tritium incorporation in the labeled compounds used in these studies.

METHODS AND MATERIALS

Insects. Caterpillars of wild *P. polyxenes* were collected on *Thamnosma texana* (Gray) (Rutaceae) in Medina County, Texas. They were reared in the laboratory on sprigs of fresh parsley obtained from a local supermarket. Emerging adults were fed a mixture of honey and water, and 2- to 3-day-old females were mated with 1- to 2-day-old males. Parsley was provided for oviposition and successive generations were reared as above.

Chemicals. Samples of tritiated psoralen (4.5 Ci/mM) and isopsoralen (1.2 Ci/mM) were obtained from HRI Associates, Emeryville, California. In each labeled preparation, the label was incorporated into the double bond of both the furan and lactone rings (Figure 1). Unlabeled samples of psoralen and isopsoralen were also obtained from HRI. The radiochemical purity of each labeled sample, as determined by thin-layer chromatography and subsequent liquid scintillation counting (LSC), was approximately 98%. Prior to use, the labeled samples were diluted with unlabeled psoralen or isopsoralen as appropriate to a specific activity of 0.14 μCi/μg.

In Vivo Metabolism Studies. Last-instar caterpillars were weighed, held individually in covered Petri dishes, and starved 2 hr prior to treatment. [^{3}H]Psoralen and [^{3}H]isopsoralen dosages were individually tailored to the prestarvation weights of each caterpillar. To a small sprig of parsley was pipetted (using a microsyringe) an appropriate volume of radiochemical (as a 0.25 μg/μl solution in acetone) so that subsequent consumption by the insect would result in a dosage equivalent to 5 μg of psoralen or isopsoralen/g of body weight. The appropriate solution was spread evenly over the dorsal leaf surface and allowed to air dry for a few minutes, then the caterpillar was placed on the twig. Essentially total consumption of the dosage was usually complete within 1–5 min, and the caterpillar was then transferred to a clean covered Petri dish (with fresh, untreated parsley added), and the residual treated parsley twig (stem) subjected to LSC to determine that small portion of the dosage, if any, not consumed. All subsequent calculations of dosage accountability, etc., were based on actual dpm consumed by each insect. Four replicates were run for each chemical and analysis interval.

Treated caterpillars were held under low-intensity fluorescent lighting and analyzed at 0.75, 1.5, 3, 6, and 12 hr after treatment. For analysis, the caterpillars were pinned in wax, slit open along the dorsal midline, and the entire gut and content removed. This procedure resulted in three fractions: gut and contents, body, and excreta. Each fraction was transferred to a 50-ml-capacity screw-cap glass tube containing 10 ml of distilled water, and the samples were then immediately frozen for later analysis.

Sample Extraction and Analysis. Sample fractions in the glass tubes were thawed, acidified to pH < 2.0 with concentrated aqueous hydrochloric acid, and extracted three times with 20-ml volumes of ethyl acetate. Polytron ho-

mogenization was utilized to facilitate tissue disruption and enhance extraction efficiency, and homogenized samples were centrifuged to separate the organic and aqueous phases. Aliquots of the combined organic, and aqueous–tissue slurry phases were quantitated by LSC. The organic phases were then dried over anhydrous sodium sulfate and concentrated by vacuum distillation and finally by a gentle stream of nitrogen to a final volume of 0.2–0.3 ml for subsequent TLC analysis.

Resolution and Quantification of Metabolites. TLC studies utilized precoated silica gel chromatoplates (Silplate F-22, 20 × 20 cm, 0.25-mm gel thickness, with fluorescent indicator, Merck, Darmstadt, Germany). The concentrated sample extracts were spotted as short bands along one edge of the plates, then the plates were developed in a solvent system consisting of ethyl acetate–acetic acid (99 : 1). Appropriate gel areas containing the radioactive components were subsequently scraped from the plates and quantitative measurements were made by LSC.

Isolation of Psoralen and Isopsoralen Metabolites on a Submilligram Scale. To facilitate metabolite characterization, several last-instar *P. polyxenes* caterpillars were fed parsley twigs that had been dipped in 1.0 mg/ml solutions of unlabeled psoralen or isopsoralen. Excreta collected from these caterpillars was extracted as described above and the extracts subsequently analyzed by TLC. Metabolite isolation was facilitated by the fact that with both psoralen and isopsoralen, two major metabolites were generated (see below) that were readily visualized by viewing the developed plates under long-wavelength ultraviolet light. These products were extracted from the gel with either ethyl acetate or methanol, were subjected to methylation with diazomethane, and were subjected to further TLC cleanup (ethyl acetate–acetic acid, 99 : 1; chloroform–ethyl acetate, 2 : 1; or ethyl acetate–methanol–acetic acid, 150 : 50 : 2). The metabolites were then subjected to mass spectral analysis.

Mass Spectroscopy. Direct insertion probe mass spectral studies were performed as previously described (Bull et al., 1984).

RESULTS

Absorption and Elimination of Psoralen and Isopsoralen. Exposure of last-instar *P. polyxenes* caterpillars to either [^{3}H]psoralen or [^{3}H]isopsoralen as 5.0 μg/g oral doses was followed by rapid disappearance of radiolabel from the gut (Figure 2). Within 1.5 hr after dosing, less than half of the administered [^{3}H]psoralen or [^{3}H]isopsoralen remained within the gut, and by 12 hr post-treatment, $<5\%$ of the dose of either compound remained inside the gut.

Tritium-labeled residues in body tissues (Figure 3) reached levels that were consistently about two-fold higher in caterpillars treated with [^{3}H]isopsoralen than in caterpillars treated with [^{3}H]psoralen. Residues in body tissues appeared to reach their maximum levels 0.75–1.5 hr after treatment, then steadily declined to $\leq 5\%$ of the dose after 12 hr.

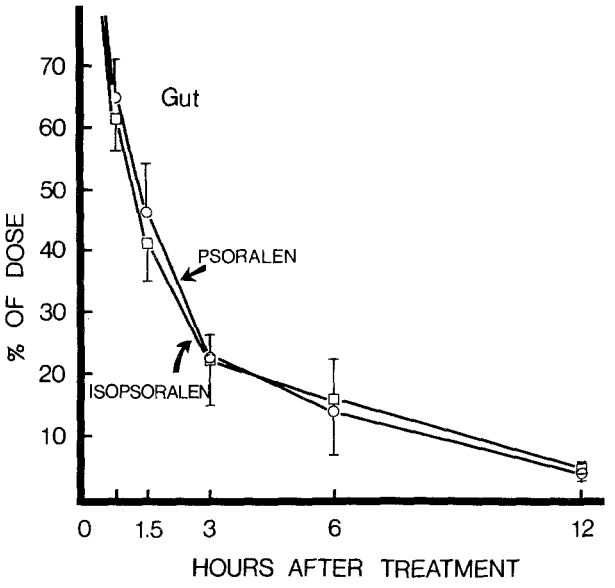

FIG. 2. Disappearance of tritium residues from the gut of last-instar *Papilio polyxenes* caterpillars after oral treatment with either [^{3}H]psoralen or [^{3}H]isopsoralen at dosages equivalent to 5 μg/g. Data points are means $\pm$SD.

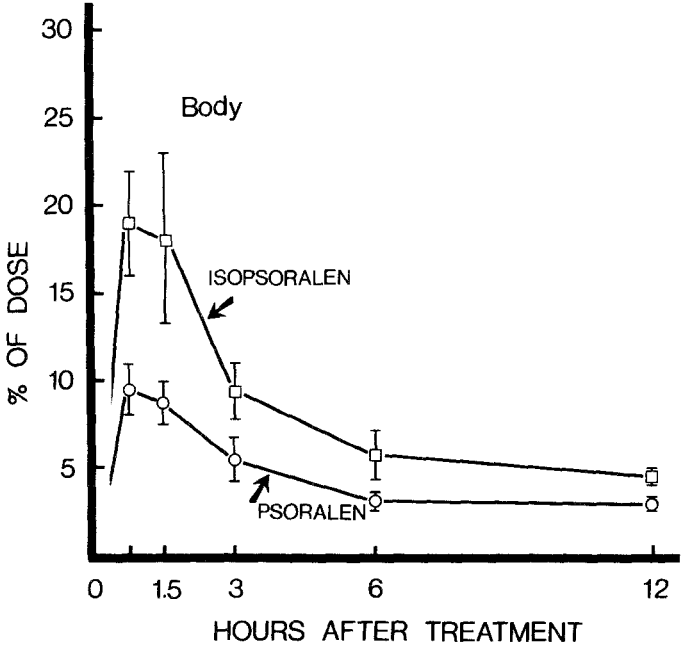

FIG. 3. Tritium residues in body tissues (exclusive of the gut and its contents) of last-instar *Papilio polyxenes* caterpillars after oral treatment with either [^{3}H]psoralen or [^{3}H]isopsoralen at dosages equivalent to 5 μg/g. Data points are means $\pm$SD.

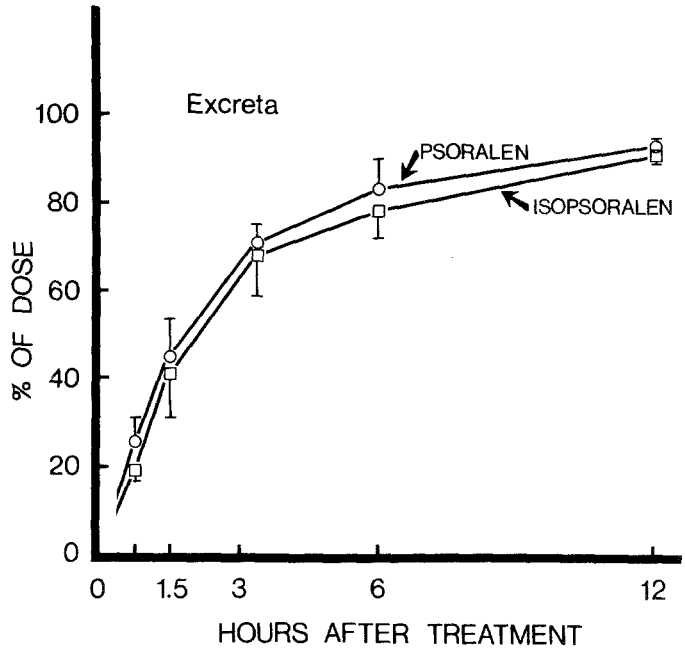

FIG. 4. Elimination of tritium residues in the excreta of last-instar *Papilio polyxenes* caterpillars after oral treatment with either [^{3}H]psoralen or [^{3}H]isopsoralen at dosages equivalent to 5 μg/g. Data points are means $\pm$SD.

Tritium residues from both psoralen and isopsoralen treatments were rapidly eliminated in the excreta (Figure 4). Within 0.75 hr after dosing, 20–25% of the administered dosages were recovered in fecal pellets, and by 3 hr, >70% of the doses had been eliminated. Caterpillars treated with [^{3}H]psoralen exhibited slightly higher excretion levels of tritium than those treated with isopsoralen at all analysis intervals (Figure 4), but these differences are not statistically significant.

Metabolite Distribution. Ethyl acetate extraction of the gut and its contents, body tissues, and excreta resulted in most cases in >90% partitioning of the tritium present into the organic phase (Tables 1–3). Almost all samples, irrespective of the compound, fraction, or analysis interval, contained two major metabolites (designated P1 and P2 for psoralen and IP1 and IP2 for isopsoralen). In the 0.75-hr gut samples from the psoralen-treated caterpillars, metabolites P1 and P2 comprised about 66% of the total ^{3}H residues present, whereas only about 30% of the tritium seen in the 0.75 hr gut samples of isopsoralen-treated caterpillars was as metabolites IP1 and IP2 (Table 1). Similar relative distributions of tritium was observed in body tissues (Table 2). In body tissue extracts from isopsoralen-treated caterpillars, the unmetabolized
