5 mm away resulting in 50% inhibition of root length. Lettuce (*Lactuca sativa* L. "Ithaca") was particularly sensitive as rye residues caused the apical root meristem to become discolored and root growth was subsequently inhibited. Phytotoxicity from shoot tissue or extracts persisted in the absence of soil microorganisms, suggesting they were more toxic than decomposition products.

The second step in proof of allelopathy is chemical isolation, identification, and assay (Fuerst and Putnam, 1983). Aqueous extracts of greenhouse-grown rye shoot tissue were separated via solvent partitioning, and all fractions were bioassayed for relative activity on cress (*Lepidium sativum* L. "Curly") germination and seedling growth. The greatest toxicity occurred from the diethyl ether fraction, and two compounds inhibitory to cress seedling growth were identified from this fraction: 2,4-dihydroxy-1,4(2*H*)-benzoxazin-3-one (DIBOA) and its breakdown product, 3(3*H*)-benzoxazolinone (BOA) (Barnes et al., 1986).

The purpose of this research was to further characterize the activity and assess the role of DIBOA and BOA in allelopathy by rye. This is directed toward final steps in proof where it is necessary to simulate the interference by supplying the toxin as it might be supplied in nature and to quantify the release, movement, and uptake of the toxins produced (Fuerst and Putnam, 1983).

METHODS AND MATERIALS

Comparison of Organic Extracts from Field- and Greenhouse-Grown Rye. Field grown "Wheeler" rye shoots for extraction were obtained from a planting made on October 2, 1983. On May 11, 1984, rye (preboot stage) was mowed down. Four days later, shoot tissue was collected, dried at 50°C, ground through a 40-mesh screen in a Wiley mill, and stored at −20°C until extracted.

Thirty-five-day-old greenhouse-grown rye shoots were cut, dried, ground, and stored similarly. Root tissue of 35-day-old greenhouse-grown rye was rinsed free of most soil and processed as shoot material. From this point all tissues were treated similarly.

For qualitative comparisons, equivalent weights of tissues were extracted for 24 hr with equal volumes of H_2O. Aqueous fractions were precipitated with Me_2CO and sequentially partitioned against a series of solvents of increasing polarity (hexane, Et_2O, CH_2Cl_2, EtOAc). All organic fractions were dried over $MgSO_4$ (anhydrous), concentrated, and weighed for percent recovery. Organic fractions were also qualitatively compared via thin-layer chromatography (TLC) on silica plates (Merck SF-254, 250 μm) in two solvent systems (EtOAc and CH_2Cl_2–MeOH (95:5)]. Each extract (100 μg) was spotted, developed, and detected by UV-visible, vanillin–H_2SO_4, $CeSO_4$–H_2SO_4, and $FeCl_3$–HCl.

Preparation of Extracts for Quantification. Dried rye tissue (1.0 g) and

H_2O (12 ml) were added to test tubes, vortexed for 1 min, and sonicated for 3 hr (32°C). The residue was transferred from test tubes by rinsing nine times sequentially with H_2O (2 ml) and suction filtered through Whatman No. 2 filter paper until dry. The residue was discarded, and the pH of the filtrate was adjusted to 2.0 with concentrated HCl. The filtrate was then heated for 1 min at 65°C, cooled in an ice bath, and filtered (Millipore, 0.45 μm). A 5-ml aliquot of this sample was extracted with two (4 ml) volumes of EtOAc. EtOAc was removed with a syringe, transferred to a second set of tubes, and dried by blowing a stream of nitrogen gas over the sample maintained at 50°C. Samples were redissolved in 3 ml of MeOH and filtered (Millipore, 0.45 μm).

Quantification of Hydroxamic Acids. DIBOA was quantified by the $FeCl_3$ method (Corcuera et al., 1978; Hamilton, 1964; Long et al., 1974; Sullivan et al., 1974; Argandona et al., 1980; Zuniga et al., 1983). Hydroxamic acids form with $FeCl_3$ reagent (50 g of $FeCl_3 \cdot 6H_2O$; 500 ml 95% EtOH; 5 ml of 1.5 M HCl) a blue complex whose absorbance is measured at 590 nm. Fifty microliters of $FeCl_3$ solution was added to each extract and concentrations were determined by comparing absorbance of the extract with a standard curve made with DIBOA. The purest DIBOA crystals from previous separations were used. All samples were replicated three times. The validity of the method has been discussed (Woodward et al., 1979).

Purification of DIBOA for Bioassays. DIBOA used for all assays was purified via preparative TLC. Any organic extracts containing DIBOA from previous solvent extractions were applied to prewashed silica plates (Whatman PLK5F 1000 μm) and ascendingly developed in $CHCl_3$–MeOH (9 : 1). Portions of the plates were sprayed with $FeCl_3$–HCl which specifically reacts blue with DIBOA. The corresponding zone on the unsprayed portion of the plate was scraped, ground with a mortar and pestle, and eluted with Me_2CO. The Me_2CO–silica slurry was suction filtered through fritted glass funnels, concentrated, and checked for purity by TLC (Whatman SF-254). The resultant pink-colored solution contained DIBOA and crystallized, but it still had a few contaminants. Therefore, the preparative TLC procedure was repeated on the resultant sample an additional three times (until pure by TLC). The purified DIBOA was then filtered (0.45 μm) to ensure removal of silica which would influence rate of application in bioassays.

Seed Germination and Seedling Growth Bioassays. DIBOA and BOA were bioassayed for activity on seed germination and seedling growth. Initially, BOA extracted from rye was compared with BOA obtained from Aldrich Chemical Company, for activity on cress. Equivalent weights of chemicals were applied in MeOH to Whatman No. 1 filter paper in Petri dishes (60 × 15 mm). Pure MeOH, similarly applied to filter paper, was used as a control. After solvent evaporation, 1.5 ml H_2O and 10 cress seeds were added to each dish. Root and shoot lengths were measured after 72 hr dark incubation in a high-humidity growth chamber (27°C).

Shilling et al. (1985) have previously identified and implicated β-phenyllactic acid (PLA) and β-hydroxybutyric acid (HBA) in rye residue toxicity. These chemicals are commercially available (Sigma Chemical Company) and were compared to DIBOA and BOA for their relative activity and selectivity on seed germination and seedling growth of several weeds [large crabgrass (*Digitaria sanguinalis* L. Scop.), barnyardgrass (*Echinochloa crusgalli* L. Beauv.), proso millet (*Panicum milaceum* L.) and redroot pigweed (*Amaranthus retroflexus* L.) with 20 seeds tested per replication] and crops [lettuce (*Lactuca sativa* L. "Ithaca") and tomato (*Lycopersicon esculentum* Mill. "Lafayette") with 10 seeds tested per replication]. The experimental design was a randomized complete block with four replications. Germination and average root and shoot length data were obtained after 72 hr.

For bioassay on seed germination and seedling growth, pure chemicals were applied in MeOH or H_2O (depending on solubility) to filter paper in Petri dishes. The final volume of H_2O in all dishes was 1.5 ml. Seeds were added and Petri dishes were dark incubated prior to evaluation. The experimental design was a randomized complete block with four replications.

Algae Growth Bioassay. DIBOA and BOA were also tested for activity on the alga, *Chlamydomonas rheinhardtii* Dangeard. The bioassay was developed by Hess (1980) and modified by Ries and Wert (personal communication). The stock culture was grown for one week in aerated nutrient solution in a growth chamber (30°C/18°C; 103 $\mu E/m^2/sec$; 16 hr day length). Prior to bioassay, the culture was subjected to 1 min of CO_2 gas (0.57 hl/min/2 l algal solution). Aliquots (10 ml) of algal solution were pipetted into test tubes (16 $\times$ 100 mm), and chemicals were added in 200 μl of Me_2CO. The control tubes received 200 μl of pure Me_2CO. All tubes were placed in the growth chamber for the bioassay.

After 28 hr incubation, samples were centrifuged for 15 min to pellet all cellular material, after which the supernatant was removed by aspiration. The pellet was resuspended in 5 ml of 80% Me_2CO in H_2O to solubilize the chlorophyll. After a second centrifugation (5 min), the supernatant was decanted and absorbance at 652 nm was determined. Zero-time, or initial, growth was determined on four (10-ml) aliquots of algae taken prior to addition of chemicals.

The experimental design was a randomized complete block with four replications. The effect of DIBOA and BOA on growth of algae over a 28-hr period was determined by subtracting the zero-time absorbance from the absorbance of the treated sample and expressed relative to the Me_2CO control.

Soil Activity of Hydroxamic Acids. Uptake of rye allelochemicals by susceptible plant species may be from direct contact with tissue or through the soil. To test the potential for uptake from soil, DIBOA from rye and BOA (Aldrich Co.) were applied to the soil immediately after planting indicator species [cress, barnyardgrass, and lettuce (10 seeds each)]. Pots (43 $\times$ 43 mm) were filled

with soil [Spinks loamy sand (Psammentric hapludalf, sandy, mixed, mesic)], and indicators were planted 3 mm deep. To reduce disturbance to the seed and soil interface, pots were subirrigated prior to spraying. Chemicals were dissolved in 4 ml of 50% Me_2CO in H_2O and uniformly applied to soil with an air-forced TLC spray reagent applicator at rates of 25, 50, and 100 kg/hectare. Controls received 4 ml of 50% Me_2CO in H_2O. Pots were placed in the greenhouse (28°C/18°C; 15-hr day length) under fluorescent lights (168 μE/m^2/sec) and subirrigated during bioassay. Emergence was recorded at 4 and 14 days. The experimental design was a randomized complete block with four replications.

RESULTS AND DISCUSSION

Comparison of Organic Extracts from Field- and Greenhouse-Grown Rye. Since DIBOA and BOA were implicated as the most active allelochemicals in 35-day-old greenhouse-grown rye (Barnes et al., 1986), it was necessary to confirm their presence in field-grown tissue harvested at similar stages of growth. DIBOA was found in the Et_2O, CH_2Cl_2, and EtOAc fractions, while BOA was only detected in the Et_2O fraction (Table 1). In both greenhouse- and field-grown herbage, the greatest quantity of DIBOA partitioned into the Et_2O fraction, and all fractions were generally very similar in appearance. DIBOA and

TABLE 2. RECOVERY OF ORGANIC FRACTIONS OBTAINED FROM SEQUENTIAL PARTITIONING OF ROOT AND SHOOT EXTRACTS[a]

	Initial aqueous extract (%, w/w)		
Fraction	Field rye shoots	Greenhouse rye shoots	Greenhouse rye roots
Hexane	0.37	0.13	0.11
Et_2O	0.55	0.96	0.56
CH_2Cl_2	0.17	0.22	0.04
EtOAc	0.18	0.59	0.19
Total	1.27	1.90	0.90

[a] Dried tissue, (50 g), was extracted with 1 liter H_2O (24 hr; 4°C). Aqueous extracts were sequentially partitioned against solvents (250-ml volumes; 6–8 times), and concentrated on a rotary evaporator. Entire sample was transferred to preweighed glass tubes for recovery.

BOA were also detected in the same extracts of root tissue, although the EtOAc fraction contained the greatest quantity of DIBOA, and the entire range of compounds differed considerably.

Recovery of fractions by solvent partitioning also varied among tissues extracted (Table 2). Although Et_2O extracted more compounds from all tissues relative to other solvents, greenhouse-grown shoot tissue contained the greatest quantity of Et_2O-extractable compounds. Field-grown shoot tissue contained more hexane-soluble compounds than greenhouse-grown rye roots or shoots. Taking all fractions together, greenhouse-grown shoot tissue contained the greatest percentage of solvent extractable compounds.

Quantification of Hydroxamic acids. The content of hydroxamic acids has been shown to vary with the species (Zuniga et al., 1983), age of the plant, and organ assayed (Argandona et al., 1981). Most of the previous work on quantification of hydroxamic acids in rye has involved fresh tissue from young seedlings grown in the greenhouse (Argandona et al., 1980; Zuniga et al., 1983), which may differ from the content in residues of older, field-grown plants. As DIBOA is the predominant hydroxamic acid detected in rye (Hofman and Hofmanova, 1969; Zuniga et al., 1983) and the only compound which reacted with $FeCl_3$ in TLC separations, its concentration in dried tissues was determined colorimetrically.

Thirty-five-day-old greenhouse shoots contained up to 28-fold more hydroxamic acids than the other tissues (Table 3). These data represent only one harvest each of greenhouse and field plants and do not allow for assessment of variability due to age, environment, etc. The apparent difference in hydroxamic acid content between the two shoot tissues may account for the differential re-

TABLE 3. CONCENTRATION OF HYDROXAMIC ACIDS IN GREENHOUSE-GROWN RYE ROOTS AND SHOOTS AND FIELD GROWN RYE SHOOTS[a]

Tissue	Source	Concentration (μg hydroxamic acids/g dry wt)[b]	SD

[b]Concentration was determined from mean of three samples.

covery of solvent-extractable compounds. Argandona et al. (1980) found the content of hydroxamic acids in rye to decrease with increasing age, which may further explain the large concentration difference between field- and greenhouse-grown shoots. The difference in concentration between roots and shoots of greenhouse rye is probably responsible for the differential activity demonstrated by the tissues in greenhouse and Petri dish bioassays of residues (Barnes and Putnam, 1985).

Activity on Seed Germination and Seedling Growth. The commercial availability of BOA provided an opportunity for further evaluation of the biological activity. The Aldrich product and BOA extracted from rye were initially compared for activity on cress root and shoot growth (Figure 1). BOA isolated from rye and Aldrich BOA similarily reduced cress seedling growth. Aldrich BOA is of higher purity and readily available and was therefore substituted for rye BOA in all remaining bioassays.

As results of toxicity by allelochemicals can vary with the bioassay and indicator species tested, chemicals must be tested in similar bioassays for comparison of activity. Shilling et al. (1985) have previously implicated PLA and HBA in allelopathic activity of field-grown rye residues. The relative activity of these compounds was compared with DIBOA and BOA in our seed germination and seedling growth bioassays (Figures 2 and 3). Overall, DIBOA and BOA were consistently more inhibitory than PLA and HBA to germination and seedling growth of all weeds and crops tested. Monocotyledenous and dicotyledenous plants varied in their response and sensitivity to the four compounds tested.

Of the four chemicals, DIBOA was most active against the monocot species (Figure 2A–C). While no chemical inhibited barnyardgrass germination, DIBOA significantly reduced germination of large crabgrass and proso millet. Root growth of grass species was more sensitive than shoot growth, with greatest activity by DIBOA. BOA reduced growth of large crabgrass and proso millet

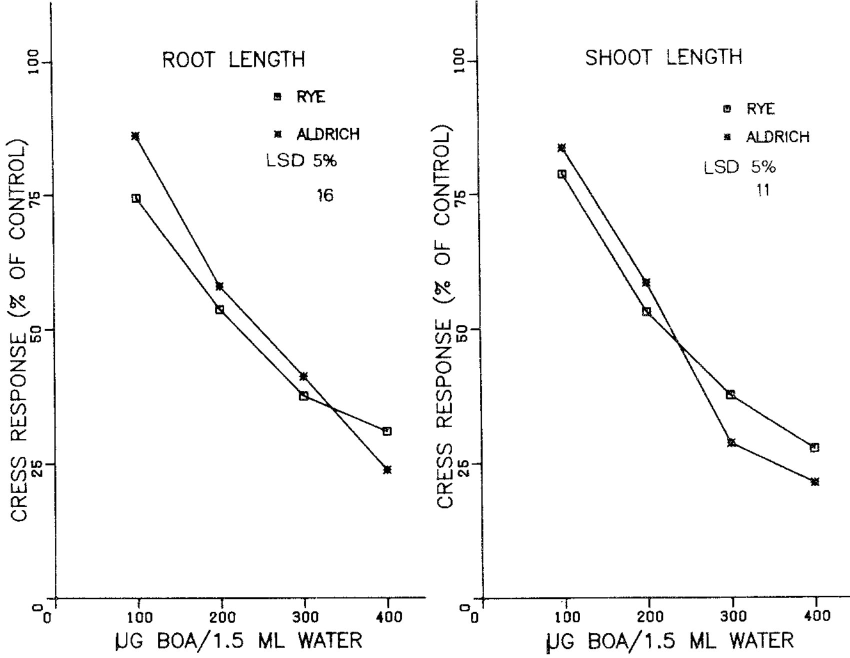

FIG. 1. Comparison of activity of BOA from Aldrich Co. and BOA extracted from rye on cress seedling growth.

at high concentrations but had little effect on barnyardgrass. The only significant activity by PLA was a reduction of large crabgrass root and shoot length at the highest concentration. Response of smooth crabgrass [*Digitaria ischaemum* (Schreb.) Muhl.] was similar to large crabgrass (data not presented). HBA had no effect at any concentration on any growth parameter tested. In general, germination was less sensitive than seedling growth to chemicals tested.

In contrast, both germination and seedling growth of dicot species tested were significantly inhibited by the benzoxazinone compounds tested (Figure 3A–C). BOA was inhibitory to germination of all three dicot species, while DIBOA showed significant reductions only at the higher concentrations. Both PLA and HBA had little effect on germination of the test species. Root and shoot growth of dicots were similarily affected by the chemicals tested. DIBOA and BOA were most toxic to seedling growth. BOA, in particular, caused lettuce root meristems to turn black. The necrosis of the apical root meristem closely resembled symptoms evident on lettuce germinating in the soil/residue Petri dish bioassays. PLA resulted in some significant reduction of dicot seedling growth, but it was still less active than DIBOA and BOA. Once again, HBA had no effect on any growth parameter of dicots tested.

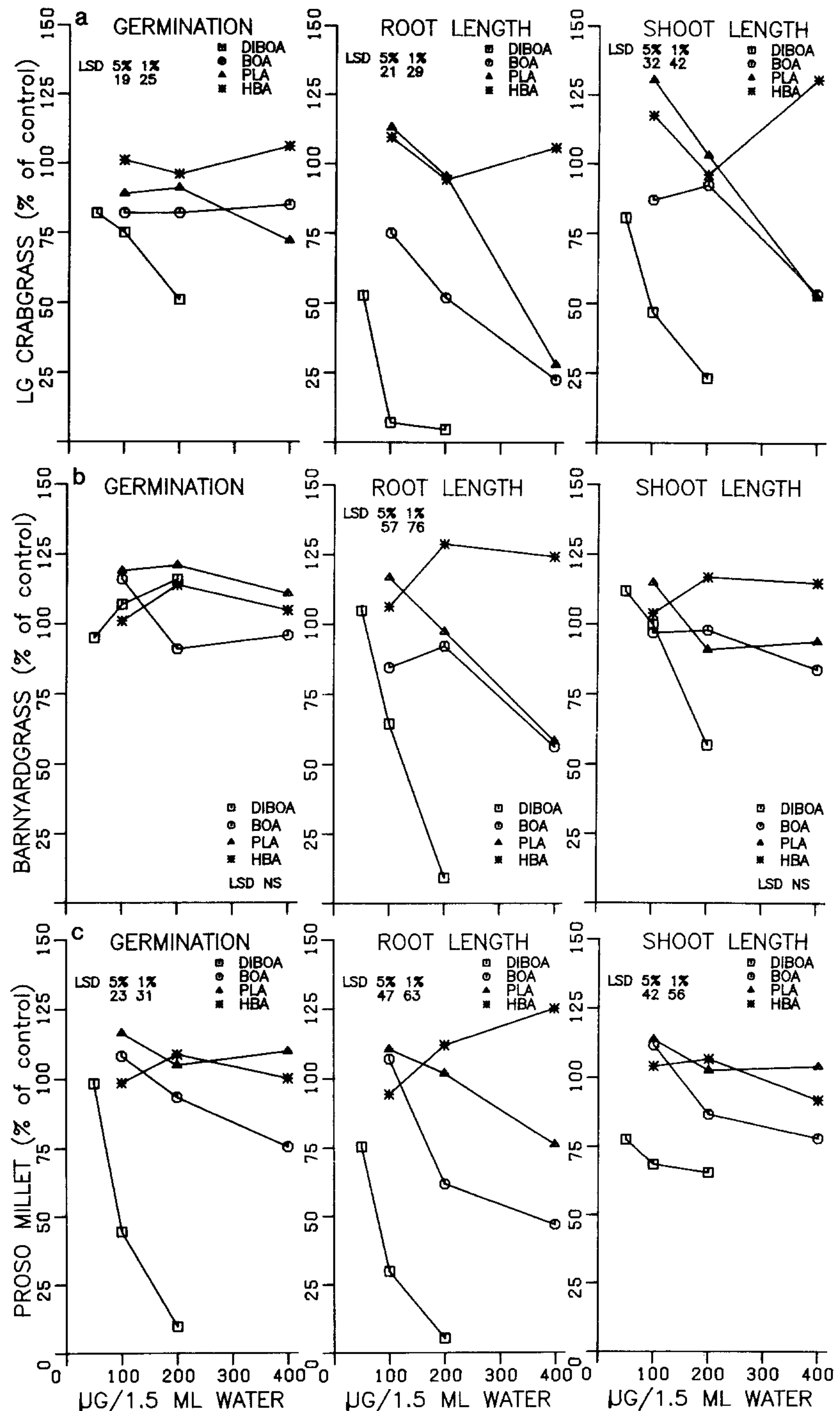

FIG. 2. Response of (A) large crabgrass, (B) barnyardgrass, and (C) proso millet to various concentrations of DIBOA, BOA, PLA, and HBA in Petri dishes.

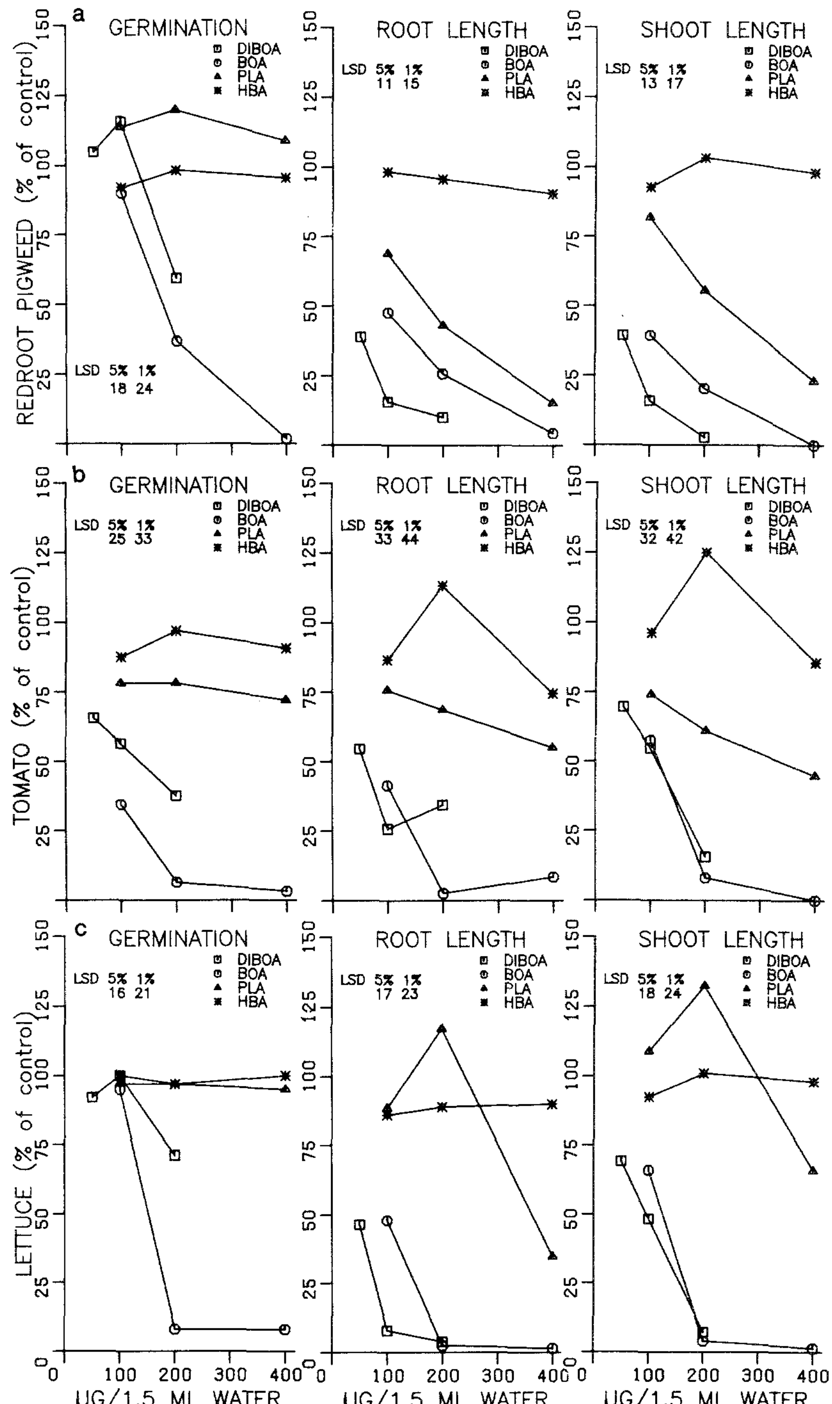

FIG. 3. Response of (A) redroot pigweed, (B) tomato, and (C) lettuce to various concentrations of DIBOA, BOA, PLA, and HBA in Petri dishes.

On average, the dicots were 30% more sensitive than the monocots to all rates of all chemicals tested. DIBOA and BOA were anywhere from 2 to 30 times more active than PLA and HBA. Of the two benzoxazinone compounds, BOA was more toxic to dicot germination, while DIBOA had greater activity on germination of monocots. Both chemicals similarily reduced dicot seedling growth, while only DIBOA had any significant effect on seedling growth of monocots.

Activity on Growth of Algae. Symptoms of DIBOA and BOA injury on cress when bioassayed in the light included a characteristic chlorosis starting at the leaf margin and progressing toward the midvein. As the concentration of DIBOA increased, the color of the cotyledons changed from a dark green to pale yellow and white. The injury resembled that of several commercial photosynthetic-inhibitor herbicides. Therefore, DIBOA and BOA were bioassayed on *Chlamydomonas*. At the highest concentrations tested, both compounds killed the algae (Figure 4). Although all cells appeared dead, the results from BOA

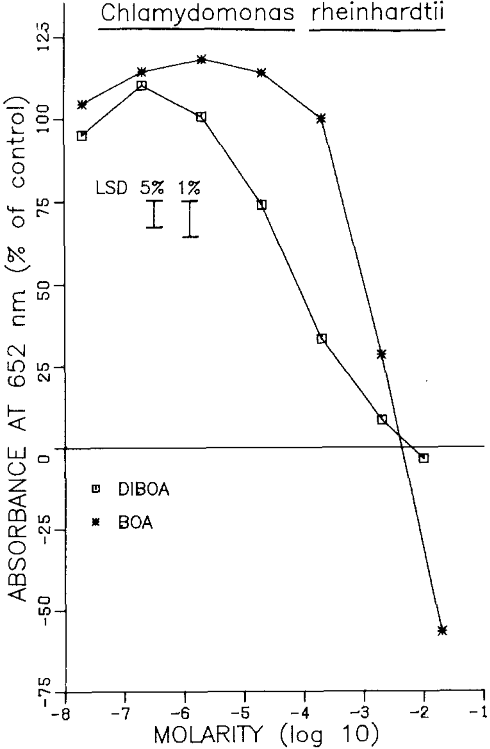

FIG. 4. Response of *Clamydomonas rheinhardtii* Dangeard to various concentrations of DIBOA and BOA based on absorbance at 652 nm.

at the highest concentrations may be somewhat misleading as it interfered with absorbance at 652 nm. Fifty-percent inhibition of growth occurred at ca 7.5×10^{-5} M and 1.0×10^{-3} M for DIBOA and BOA, respectively. At low concentrations, both DIBOA and BOA stimulated algae growth relative to control over a 28-hr period.

Queirolo et al. (1981) found both 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) and its glucoside, extracted from maize, inhibited both cyclic and noncyclic photophosphorylation in spinach (*Spinacea oleracea* L.) chloroplasts. Inhibition of coupled electron transport was attained at concentrations of 1 and 4 mM, respectively. Several years ago, BASF Co. manufactured and evaluated a benzoxazinone related herbicide, Benzazin (BASF 1700H), with photosynthetic activity. Moreland and Hill (1963) proposed that the H—N—C=O fragment found in many polycyclic urea herbicides was related to activity. This fragment is present in BOA and reduced forms of DIBOA. Chlorosis was a symptom of injury by rye residues on several indicators (Barnes and Putnam, 1983) and may be related to the effects of DIBOA and BOA on photophosphorylation and electron transport.

Activity of DIBOA and BOA in Soil. Uptake of allelochemicals from rye residue may be by direct contact with tissue fragments or through the soil (Barnes and Putnam, 1985). Therefore, the pure compounds DIBOA and BOA were applied to soil for evaluation of activity on emergence of three indicator species. All rates of DIBOA and the higher rates of BOA completely inhibited emergence of both cress and lettuce four days after application (Table 4). Barnyardgrass emergence was less sensitive to the chemicals, although high rates of both compounds significantly reduced emergence relative to controls. Barnyardgrass seedlings which did emerge appeared to be stunted and chlorotic.

Two weeks after chemical application, emergence of lettuce and cress was

TABLE 4. EMERGENCE OF BARNYARDGRASS (BYGR), CRESS, AND LETTUCE 4 DAYS AFTER SPRAY APPLICATION OF DIBOA AND BOA TO SOIL

Chemical	Rate (kg/hectare)	% of control		
		BYGR	Cress	Lettuce
DIBOA	25	88	0	0
	50	20	0	0
	100	5	0	0
BOA	25	112	21	72
	50	63	0	0
	100	15	0	0
LSD 5%		31	19	20

TABLE 5. EMERGENCE OF BARNYARDGRASS (BYGR), CRESS, AND LETTUCE 14 DAYS AFTER SPRAY APPLICATION OF DIBOA AND BOA TO SOIL

Chemical	Rate (kg/hectare)	% of control		
		BYGR	Cress	Lettuce
DIBOA	25	65	11	10
	50	19	0	0
	100	7	0	0
BOA	25	81	51	72
	50	61	9	16
	100	32	0	0
LSD 5%		29	19	24

still inhibited completely by the highest rates of DIBOA and BOA (Table 5). Although still reduced relative to control, some cress and lettuce germinated and emerged in the lower rates of DIBOA after 14 days. In general, emergence of barnyardgrass at 14 days was similar to that at four days.

The concentrations of benzoxazinones applied to soil in this study are considerably higher than the potential calculated for production in field situations if the data from fall-planted, spring-harvested rye (Table 3) are representative. In field studies where shoot residue biomass was 4.9 Metric Tons (MT)/hectare (rye killed at pre boot stage), the potential hydroxamic acid concentration was ca 0.5 kg/hectare. This figure does not take into account the relative contribution from root tissue. Calculations of hydroxamic acids in residues of 35-day-old rye were based on 4.7 MT/hectare [biomass of 40-day-old spring planted rye (Barnes, 1981)] and indicate a potential for ca. 13.5 kg/hectare from shoots and ca. 0.8 kg/hectare from roots. None of the field calculations accurately assess the possible contribution of BOA to the total activity. When the pure compounds were bioassayed in separate studies at rates lower than 10 kg/hectare, there was no inhibition and occasional stimulation by the chemicals (data not included).

The stimulatory effects of hydroxamic acids at lower concentrations may result from their ability to chelate iron (Waid, 1975; Lewin, 1984). Tipton and Buell (1970) have determined the stability constants for ferric iron complexes with two hydroxamic acids in maize [DIMBOA ($\log K = 21.3$); DIBOA ($\log K = 19.4$)] and found them to be much greater than that of citric acid ($\log K = 11.9$) which is reported to function in microbial iron metabolism (Lewin, 1984) and absorption and transport in higher plants (Sillen and Martell, 1964). Tipton and Buell concluded that at the concentrations (10^{-5} M to 10^{-3} M) present in young maize plants, a higher proportion of ferric iron must be bound as complexes of the hydroxamic acids.

Argandona et al. (1980) have similarily determined the concentration of hydroxamic acids in leaf extracts of different aged greenhouse-grown rye. In order to transform their concentrations for 34-day-old rye to kilograms hydroxamic acid per hectare, the following assumptions have been made: (1) 10 kg fresh weight is equivalent to 1 kg dry weight; (2) the predominant hydroxamic acid in rye is DIBOA with a weight of 181 g/mol; and (3) a similarily aged spring-grown rye produces ca. 4.7 MT dry tissue/hectare in the field. According to the concentrations presented by Argandona et al. (1980), 34-day-old rye contains 1.9 mmol hydroxamic acids/kg fresh weight or a potential of 16.2 kg hydroxamic acids/hectare. This calculation is somewhat greater than our data, but it further supports the potential for high levels in rye.

Although no data are available on the concentration of benzoxazinones in field-grown, spring-planted, rye, it is logical to assume that the trend of decreasing hydroxamic concentrations with increasing age, determined by Argandona et al. (1980), holds true. Two major differences between spring- and fall-planted rye are age and the exposure to cold. Both of these factors may influence the quantity and quality of chemicals produced by rye, as distinct developmental changes including emergence, shooting, heading, and flowering occur in winter rye as it matures. Temperature has the greatest influence on the duration of each stage in a given locality—light, moisture, and nutrients being other important factors (Nuttonson, 1958). As both spring-planted and greenhouse-grown ryes lack the significant exposure to cold, concentrations in similarily aged greenhouse tissue may provide a rough approximation of the field tissue. The potential levels of 13.5 and 16.2 kg hydroxamic acids/hectare calculated from concentrations determined by the authors and Argandona et al. (1980), respectively, could be considered at least 10 times greater than most rates of commercial herbicides used today. They are, however, about 10–100 times less active than most synthetic herbicides.

While our major field obsevations for proof of allelopathy have been based on phytotoxicity by residues of fall-planted, spring-killed rye, there is evidence for toxicity by spring-planted rye (Barnes, 1981). Residues of 40-day-old spring-planted rye reduced total weed density by 69% and total weed biomass by 32% when compared to a PE control mulch. As age may be an important variable and could be managed by timing the kill, the potential exists for maximizing benzoxazinone concentrations in the field. Additional studies which quantify and compare concentrations in both fall- and spring-planted rye killed at different ages would provide data useful in this regard. Ideally, the actual release of benzoxazinones into soil, and uptake by plants, perhaps using radiolabeled material, should also be documented for conclusive proof of their role in allelopathy.

While phytotoxicity by residues in nonsterile soil was significant after incubation for 72 hr (Barnes and Putnam, 1985), benzoxazinones may be easily degraded by microorganisms. Undoubtedly, several compounds, in addition to

the solvent extractable benzoxazinones, contribute toward toxicity by rye residues. This is evidenced by the fact that almost 50% of the initial aqueous extract activity was associated with the protein precipitate and final aqueous fractions (Barnes et al., 1986). The identification of benzoxazinones, and their subsequent implication in allelopathy by rye, has been based on steps directed toward isolation of the most active chemicals. Although the ether extract accounted for only 12% of the potential toxicity, it was 11–25 times more active than the protein and final aqueous fractions.

Some allelochemicals may leach from green rye or in the early stages after it is killed. Additional toxicity by residues may also result from phytoactive degradation products. Chou and Patrick (1976) found significant toxicity with residues of rye which had decomposed for up to 30 days. BOA is the major chemical breakdown product of DIBOA and, in our studies, shows greater activity against germination of all dicot species tested. Although the $FeCl_3$ method precludes quantitation of BOA and subsequent determination of its significance in rye residue toxicity, levels should presumably increase as DIBOA is broken down. Monitoring the breakdown and resultant toxicity in the soil over time should provide evidence for the persistance of both chemicals.

The importance of allelochemicals produced in response to injury or infection is indicated by the benzoxazolinone series of compounds which occur naturally in many grain plants (Beck and Reese, 1976). Previously, their role and significance in resistance to insects and disease organisms have been investigated more thoroughly than their role in allelopathy.

With regard to their plant activity, the greenhouse bioassays provided evidence for the toxicity of the benzoxazolinone series of compounds on whole plants in simulated no-till systems. The similar injury symptoms noted where residues had previously been applied and, further, where pure compounds are applied, strongly support the premise of allelopathic interference by rye with benzoxazinones playing a prominent role.

IDENTIFICATION OF SEX PHEROMONE OF CALENDULA PLUME MOTH, *Platyptilia williamsii*

K.F. HAYNES[1]

Division of Toxicology and Physiology
Department of Entomology
University of California
Riverside, California 92521

(Received April 7, 1986; accepted May 27, 1986)

Abstract—The sex pheromone of the calendula plume moth, *Platyptilia williamsii* was identified as (Z)-11-hexadecenal (Z11-16:Ald). Extracts of female sex pheromone glands contained several compounds when analyzed by capillary and packed-column GLC. However, airborne collections of volatiles from glands contained only one of these compounds, having the same retention time as Z11-16:Ald. GC-MS and microozonolysis analyses of the natural product were consistent with those of synthetic Z11-16:Ald. In a flight tunnel, males oriented upwind and touched sources of Z11-16:Ald and gland extract with equal frequency. Field tests of synthetic Z11-16:Ald already have shown it to be a potent sex attractant for males of this species. This study further supports the hypothesis that *P. williamsii* and a sympatric species, *Platyptilia carduidactyla*, are not reproductively isolated by chemical differences in the composition of the sex pheromone, but rather by temporal differences in sexual activities.

Key Words—*Platyptilia williamsii*, Lepidoptera, Pterophoridae, calendula plume moth, insect pheromones, (Z)-11-hexadecenal, reproductive isolation, insect behavior.

INTRODUCTION

The calendula plume moth, *Platyptilia williamsii* Grinnell, is part of a composite-feeding subgroup of the genus *Platyptilia* (Lange, 1950). It can be an occasional pest of greenhouse flowers (Lange, 1942), has been reported to feed (rarely) on artichokes (Lange, 1950), and is most common in composite wildflowers of coastal California. This species is very closely related to, and sym-

[1] Present address: Department of Entomology, University of Kentucky, Lexington, KY 40546.

patric with, the artichoke plume moth, *Platyptilia carduidactyla* (Riley) (Lange, 1942). Under natural conditions there is little cross-attraction between the two species, but manipulation of the photoperiodic regimes that synchronizes sexual activities leads to cross-attraction and even interspecific mating (Haynes and Birch, 1986). Furthermore, (Z)-11-hexadecenal (Z11-16:Ald), the identified sex pheromone of *P. carduidactyla* (Klun et al., 1981) was effective in attracting males of both species to traps (Haynes and Birch, 1986). However, the sex pheromone of *P. williamsii* has remained unknown. The present study provides evidence that Z11-16:Ald is the sex pheromone of *Platyptilia williamsii*, and there is no behavioral or chemical evidence of additional components. These findings support the important role of temporally based rather than chemically based reproductive isolation between *P. williamsii* and *P. carduidactyla*.

METHODS AND MATERIALS

Infested seaside daisies, *Erigeron glaucus*, were collected near Bodega Bay, California. Larvae and pupae were dissected out of the plant, and larvae were transferred to potted *Calendula officinalis*, on which they were allowed to complete development. Pupae were kept individually in 3.9 × 2.2-cm-diam. plastic vials with nylon screen tops. On emergence, adult males and females were separated and housed in separate environmental chambers (16:8 hr light-dark, 21°C-15.5°C). Adults had access to 8% sugar water on a cotton wick.

Calling behavior of 3- to 5-day-old females was observed every half hour [following the procedures of Haynes and Birch (1984a)] for the duration of the scotophase and until calling had ceased for 3 hr in the photophase in order to determine the optimal time to extract pheromone from the females.

Extracts of pheromone glands were made between the sixth hour of the scotophase and the beginning of the photophase. The ovipositor and the associated bilobed sex pheromone gland were forcibly extruded and removed with a pair of fine-tipped forceps. Several types of gland extracts were prepared, including (1) individual glands dipped for 2 sec in 5 μl of glass-distilled CS_2, (2) pooled extracts of ca. 20 female-equivalents in which the glands were dipped for 2 sec in 200 μl CS_2, and (3) pooled extracts of ca. 20 female equivalents each in which the glands were left in 200 μl of CS_2 or hexane overnight.

Airborne collections of volatiles from forcibly extruded pheromone glands were carried out following the procedure outlined by Baker et al. (1981). A single female was inserted abdomen first into the large-diameter end of a glass tube that tapered to an internal diameter of 1.5 mm. At the small distal end of the tube, a 0.5-mm hole allowed the ovipositor and sex pheromone gland to emerge when pressure was applied to the head of the moth with a pipe cleaner. When the bilobed sex pheromone gland was fully extruded, the glass tube was inserted through a Teflon-coated rubber septum into the all-glass collector de-

scribed by Haynes et al. (1983). After the 10-min collection period, an internal standard (either 1 ng of (*Z*)-11-octadecenyl acetate or 1 ng of (*Z*)-5-undecenyl acetate) was added to the glass wool at the distal end of the collector before it was rinsed out with ca. 100 μl of CS_2. The volume of CS_2 was reduced to ca. 1 μl for GLC analysis.

Gland extracts were analyzed by GLC using a Varian model 3700 GLC equipped with a flame ionization detector and a capillary and packed column. A 30-m DB-5 capillary column was run using the following conditions: temperature program 100°C for 2 min, 30°C/min to 190°C; He flow rate through column, 4 ml/min; N_2 flow, 26 ml/min; H_2 flow, 23 ml/min; and air flow, 300 ml/min. A 4-m column packed with 3.6g 10% Silar 10C on 100–120 mesh Chromosorb W was used under the following conditions: isothermal at 170°C; N_2 flow, 45 ml/min; H_2 flow, 22 ml/min; air flow, 330 ml/min.

To determine the functional group of the pheromone, 18 female equivalents extracted in 200 μl CS_2 (dipped for 2 sec) were blown down to apparent dryness under N_2 in a 1-ml reaction vial. Red-Al® (50 μl, Aldrich Chemical Co.) was added to the vial, and immediately 2 N NaOH (100 μl) was added. The resulting solution was extracted two times with 0.25 ml hexane, and the hexane fraction was then washed twice with 0.5 ml water. The hexane fraction was blown down to apparent dryness, and CS_2 (10 μl) was added. Five microliters were injected onto the Silar 10C column for analysis; the remainder was blown down to apparent dryness, and acetyl chloride (50 μl, Aldrich) was added to the vial. After 30 min at 24°C, this solution was blown to apparent dryness, CS_2 (5 μl) was added, and then injected onto the Silar 10C column.

GC-MS analysis was conducted using a 12-m DB-1 capillary column, a Hewlett-Packard 5880A GC, and a Hewlett-Packard 5970 Mass Selective Detector using a temperature program with initial temperature 65°C for 6 min, 8°C/min to 200°C. An extract containing 15 female equivalents extracted in hexane overnight was blown down to apparent dryness under a stream of N_2, CS_2 (10 μl) was added, and the resulting solution reduced to ca. 2 μl before injection into the GC-MS.

For determination of the double-bond position, microozonolysis (Beroza and Bierl, 1967) was carried out on only the GC fraction that contained the one compound detected in airborne collections. Twenty female equivalents of glands extracted in CS_2 overnight were cleaned up first by collecting this GC fraction as it eluted from the Silar 10C and then from the DB-5 column, using a glass capillary tube (12.7 cm × 1.3 mm ID) packed with ca. 2 mg of glass wool. This resulted in ca. 20 ng of the compound previously detected in airborne collections with no detectable contaminants. For 1 sec, ozone was bubbled into 50 μl of pure CS_2 in a 4 cm × 3-mm-ID test tube in an acetone bath of Dry Ice. The cleaned-up natural product was then injected into the CS_2–O_3 solution, and immediately 30 ng of triphenylphoshine was added, cleaving the ozonide

at the position of the original double bond. The volume of CS_2 immediately was reduced to ca. 1 μl under a N_2 stream and analyzed by capillary GLC. Ozonolysis reactions also were run on the following synthetic standards: (Z)-7-, (Z)-9-, (Z)-11-hexadecenal, (Z)-13-octadecenal, and (Z, E)-2,13-octadecadienol.

Behavioral tests were carried out in the wind tunnel described by Vetter and Baker (1983), which was modified from that of Miller and Roelofs (1978). Males were transferred from their original individual holding cages to individual screen cages (3.5 × 3.3 cm diam.), during the photophase preceding the flight tunnel test. During the peak hour of calling activity 7–9 h after the scotophase began, males were released individually. Their response was tested to 10 ng of Z11–16:Ald, 10 ng of the peak of interest from CS_2 extracts of female glands, and CS_2 alone. The light level during the test was 0.3 lux, which allowed observation of the following behavioral categories: wing fanning, flight, upwind flight in the pheromone plume, and contact with the pheromone source. The wind speed in the tunnel was 0.5 m/sec and the temperature was 20°C.

RESULTS AND DISCUSSION

Observations of female *P. williamsii* indicated that under the specified photoperiod and temperature regime, the moths everted their sex pheromone glands during the last $1\frac{1}{2}$ hr of the scotophase and for up to 2 hr into the photophase. Airborne collections and extracts of pheromone glands were only conducted during this $3\frac{1}{2}$-hr period. Because there is a well-defined periodicity in responsiveness of male *P. williamsii* that is synchronous with calling behavior of females (Haynes and Birch, 1986), flight tunnel tests were conducted over the same time period as pheromone extractions, but always under scotophase conditions.

Analysis of individual gland extracts dipped for 2 sec in CS_2 on the DB-5 capillary column revealed a compound with the same retention time as Z11–16:Ald with several additional peaks having longer retention times (Figure 1A). Airborne collections of volatiles from extruded glands were free of these later peaks (Figure 1B). Similarly, individual gland extracts and pooled extracts analyzed on the Silar 10C packed column contained up to four detectable peaks (Figure 2A). The largest of these agreed in retention time with Z11–16:Ald. In airborne collections, the only detectable peak had a retention time identical to that of synthetic Z11–16:Ald. The Silar 10C column effectively separates *cis* and *trans* isomers of monounsaturated 16-carbon aldehydes, and many of the positional isomers.

Reduction of a pooled gland extract with Red-Al yielded a peak with the same retention time as synthetic (Z)-11-hexadecenol on the Silar 10C column. In addition, the peak corresponding to Z11–16:Ald was no longer detected.

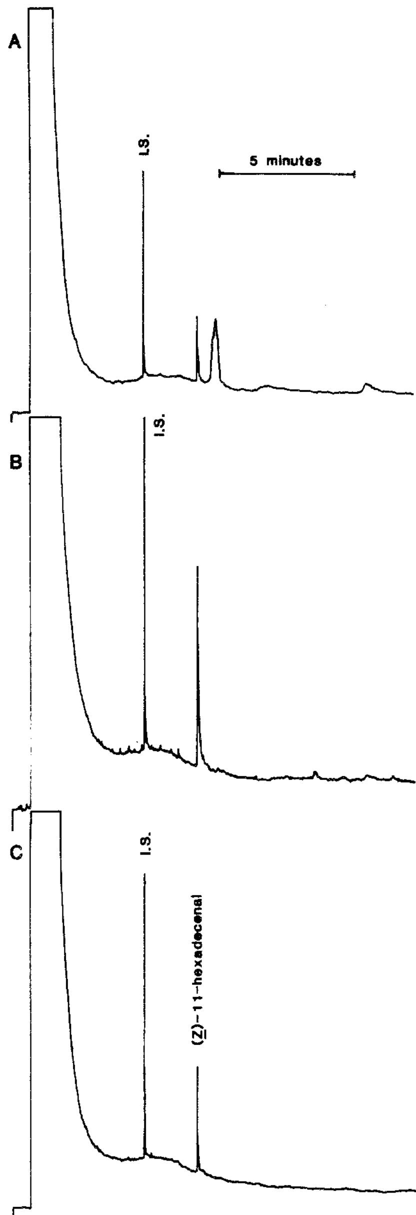

FIG. 1. (A) GLC analysis on DB-5 capillary column of sex pheromone gland extracted for 2 sec in CS_2 with internal standard, (Z)-5-undecenyl acetate. (B) Airborne collection of volatiles emitted from sex pheromone gland with internal standard. (C) Synthetic standards: 1 ng (Z)-5-undecenyl acetate and 0.5 ng Z11-16:Ald.

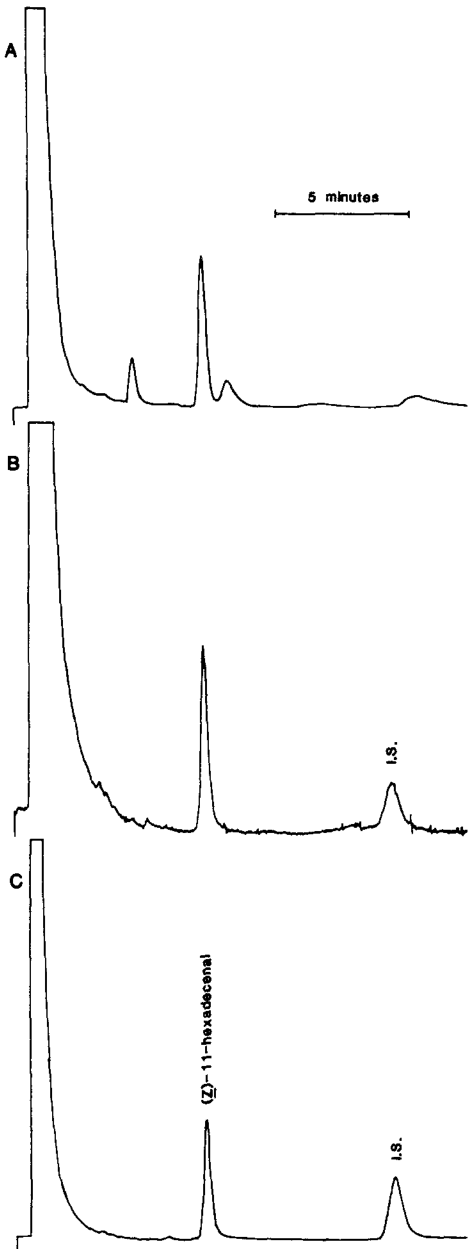

FIG. 2. (A) GLC analysis on Silar 10C packed column of four female equivalents from glands extracted for 2 sec in CS_2 with no internal standard. (B) Airborne collections of volatiles emitted from sex pheromone gland with internal standard, (Z)-11-octadecenyl acetate. (C) Synthetic standards: 10 ng Z11–16: Ald and 10 ng (Z)-11-octadecenyl acetate.

Acetylation of the reduced product yielded a compound with the retention time of (Z)-11-hexadecenyl acetate and loss of the putative alcohol product. These data provided additional evidence that the peak of interest was an aldehyde. Identical derivitization of synthetic Z11–16:Ald yielded the products with the same retention times as those from natural extract.

GC-MS analysis of 15 female equivalents containing ca. 40 ng of the putative pheromone (retention time 21.07 min) gave a good match to the spectrum obtained from 20 ng of synthetic Z11–16:Ald (base peak at *m/e* 55 and $M^+ - 18$ at *m/e* 220). The M^+ peak expected at *m/e* 238 was not detected in synthetic standards of 20 ng or less but was detected in standards of 100 ng (ca. 1% of base peak), and in the 40-ng sample of natural extract (ca. 1% of base peak).

The GC-purified natural extract sample was analyzed on DB-5 and found to contain no detectable peaks other than the putative pheromone. This purified sample was then ozonized and examined on the DB-5 column for reaction products. A peak that agreed in retention time with an ozonolysis product (undecanedial, retention time 5.1 min) of synthetic Z11–16:Ald was detected. A compound with the same retention time was detected in the ozonolysis products of (Z, *E*)-2,13-octadecadienol, but not the dial products of (Z)-7-hexadecenal (R_t 2.41 min), (Z)-9-hexadecenal (R_t 3.96), and (Z)-13-octadecenal (R_t 6.35 min). The separation of the ozonolysis products was sufficient to allow the position of the double bond to be determined unambiguously to be between the 11 and 12 carbons in the 16-carbon aldehyde.

Behavioral data from the flight tunnel clearly supported the role of Z11–16:Ald as the sex pheromone of *P. williamsii*. There was no significant difference between the behavior elicited by 10 ng of synthetic Z11–16:Ald (>98% free of other sex pheromone-like volatile impurities) and a gland extract containing 10 ng of the putative pheromone plus other potential minor components obtained by the method of extraction (glands in CS_2 overnight) (Table 1). In tests of solvent controls, there was some background level of wing fanning and flight (although significantly less than that stimulated by natural extract or the synthetic compound, but upwind flight and source contact were observed only in response to extract or synthetic Z11–16:Ald.

Field tests also supported the identification of Z11–16:Ald as the sex pheromone of this species (Haynes and Birch, 1986). Traps baited with 10 8-mil black hollow fibers loaded with Z11–16:Ald (provided courtesy of the Controlled Release Division of Albany International) captured more, although not significantly more, males than traps baited with two virgin females [20.4 ± 31.8 and 17.3 ± 28.6 (SD) males per trap per week], while blank traps caught no males. Higher release rates of Z11–16:Ald resulted in the capture of significantly fewer males (Haynes and Birch, 1986), suggesting an upper limit for upwind flight to the sex attractant.

Based on these chemical, behavioral, and trapping data, there is sufficient evidence to classify Z11–16:Ald as the sex pheromone of *P. williamsii*. No

TABLE 1. CONDITIONAL PROBABILITIES OF BEHAVIORAL TRANSITIONS OF MALE *Platyptilia williamsii*'S RESPONSE TO EXTRACTS OF SEX PHEROMONE GLANDS, SYNTHETIC (Z)-11-HEXADECENAL, AND SOLVENT CONTROL IN FLIGHT TUNNEL ASSAY[a]

[a] Proportions in the same column are significantly different if they do not share a letter in common according to Ryan's (1960) multiple comparison test for proportions.
[b] Gland extract contains 10 ng of the putative pheromone component in 10 μl CS_2.
[c] Ten nanograms of synthetic (Z)-11-hexadecenal in 10 μl CS_2.
[d] Ten microliters of CS_2.

other pheromone components are implicated in any of these studies. Haynes and Birch (1986) demonstrated that calling behavior by females of *P. williamsii* and *P. carduidactyla* is temporally separate, with female *P. carduidactyla* emitting pheromone during the first half of the night and *P. williamsii* calling during the second half of the night. In addition, males only seek conspecific females during these times. Male *P. williamsii* are attracted to sex pheromone from calling female *P. carduidactyla* when the females' photoperiod is manipulated in a way that synchronizes the sexual activities of the two species (Haynes and Birch, 1986). This is strong evidence that the composition of the sex pheromone cannot be responsible for reproductive isolation between the two species. No minor pheromonal components of *P. carduidactyla* other than Z11-16 : Ald have been detected by gas chromatography (Klun et al., 1981; Haynes et al., 1983) nor are they suspected from field tests (Klun et al., 1981) or flight tunnel observations of behavior (Haynes and Birch, 1984b). Temporal differences between the sexual activities of the two species, rather than chemical differences in the pheromone blend, are sufficient to ensure that cross-attraction does not normally occur. Apparently this type of reproductive isolation is rare, since most sympatric species use blend differences with or without temporal differences (Cardé and Baker, 1984).

Acknowledgments—I am indebted to Dr. T.C. Baker for encouraging me to pursue this line of research, as well as for reviewing the manuscript. I appreciate Dr. C. Wilkins and J. Cooper for allowing us access to the GC-MS. Dr. L. Bjostad and Dr. P.L. Phelan were helpful in suggesting certain microchemical techniques. I thank R.S. Vetter for drawing the figures.

LACK OF CHEMICAL FACTORS IN HOST-PLANT RESISTANCE OF ALFALFA TOWARDS ALFALFA WEEVIL:
Ovicidal Activity of Some Coumarin Derivatives

DAVID L. DREYER, KENNETH C. JONES, and LEONARD JURD

U.S. Department of Agriculture
800 Buchanan St.
Albany, California

(Received April 14, 1986; accepted June 3, 1986)

Abstract—A resistant line of alfalfa was studied in an attempt to identify possible chemical factors responsible for alfalfa weevil (*Hypera brunneipennis*) resistance. Bioassays were developed to measure ovicidal, larval development, pupation, and adult development rates. Serial alfalfa extracts of a weevil-resistant line showed no effect in the bioassays when compared to those of a weevil-susceptible line. It was concluded that resistance substances are not present but that resistant lines are simply more tolerant to weevil attack. Alfalfa constitutents and synthetic analogs were also screened in the egg hatch bioassay. Among these were a series of 3-acyl-4-hydroxycoumarins. 3-Acyl-4-hydroxycoumarins with short-chain acyl groups showed good ovicidal rates, but activity decreased with increasing length of the acyl group.

Key Words—*Medicago sativa*, alfalfa, *Hypera brunneipennis*, *H. postica*, Coleoptera, Curculionidae, alfalfa weevil, host-plant resistance, bioassay, feeding deterrency, ovicide, antigrowth, coumarins.

INTRODUCTION

The Egyptian alfalfa weevil, *Hypera brunneipennis* (Boheman), was initially introduced into the American southwest in 1939 and is a destructive pest on commercial alfalfa in California (App and Manglitz, 1972). Morphologically it is indistinguishable from and differs from the closely related species, *H. postica* (Gyllenhal), largely in its overwintering behavior and its degree of parasitization, respectively. Much effort has been expended in a search for weevil-resistant alfalfa lines and the enhancement of weevil-resistant traits has been a

0098-0331/87/0400-0917$05.00/0 © 1987 Plenum Publishing Corporation

central theme in a number of alfalfa breeding programs (Sorensen et al., 1972). To date, however, pronounced resistance to the weevil in commercial alfalfa lines has been elusive.

The life cycle of the alfalfa weevil has a number of different stages which may be sensitive to potential resistant substances in the plant. After about three weeks as an adult, the female weevil begins laying clusters of eggs in the hollow alfalfa stems. The choice of stems for egg laying by the female is highly dependent on their diameter (Norwood et al., 1967a; VanDenburgh et al., 1966). The females lay about two egg clusters per week with 1–30 eggs per cluster for the remainder of their reproductive life. The eggs hatch after an incubation period of one to two weeks. The resulting newly hatched larvae feed on the growing plant tip and are fully grown in three to four weeks. Pupation lasts one to two weeks. The duration of these different development phases is, of course, highly dependent on humidity, temperature, and photoperiod.

It is not known which stage(s) of the insect's life cycle is effected by possible plant substances in resistant alfalfa lines. Among the possible modes of alfalfa resistance having a chemical basis is the presence of: (1) ovicidal materials causing a decrease of the egg hatch rate; (2) feeding deterrent or antigrowth materials causing a decrease in larval development rate; (3) substances which would extend the duration of pupation; (4) materials causing a decrease in pupation rates, and (5) substances causing a decrease in the adult development rate.

This paper describes efforts to develop bioassay procedures designed to measure inhibition of various phases of weevil development. The bioassays were used to search for possible antibiotic activity in alfalfa extracts and constituents during experiments attempting to identify chemical factors contributing to weevil resistance in alfalfa. A number of synthetic materials related to alfalfa constituents have also been screened in the ovicidal bioassay for activity against weevil eggs.

METHOD AND MATERIALS

Maintenance of Weevil Colony. Weevils, biotype Colusa, were maintained on caged alfalfa bouquets of Caliverdi under an 8-hr light and 16-hr dark photoperiod. This light regimen was necessary to prevent the insects from going into diapause (Schroder and Steinhauer, 1976). The stems were immersed in water and replaced every few days as needed. Eggs were collected from excised stems of the discarded alfalfa when needed. Plant material for all operations was raised in a greenhouse. The commercial cultivar Weevlchek (Buker et al., 1983) was used consistently as the resistant line and Caliverdi as the weevil-susceptible line.

Extracts and Test Compounds. The aerial portion of 30-day-old alfalfa plants was cut and air dried, ground, and exhaustively extracted serially in a Soxhlet extractor using hexane, acetone, methanol, and water in sequence. Solvent was removed from the extracts using a rotary evaporator. The thick tarry residue was used directly in the bioassays described below.

The 3-acyl-4-hydroxycoumarins were prepared according to published procedures from 4-hydroxycoumarin and alkanoic acid (Klosa, 1956).

Bioassay of Larval Development. The Berger diet containing 0.5 g alfalfa/cup was made up as previously described (Chan et al., 1978). Extracts to be tested were added until they constituted 5% of the final diet. The diet slices were placed in 10 polystyrene cups and each cup inoculated with two 48-hr-old larvae. The cups had mesh lids to prevent buildup of condensed moisture. Diets and cups were changed every three to four days to prevent accumulation of fungal contamination. After 11 days on the diet, the surviving larvae were counted and weighed.

Egg Hatch Bioassay. Filter paper was impregnated with an aliquot of solution containing 0.05 g of test material in acetone. The concentration of the solution and area of spot were arranged so that the final concentration of test substance was 0.01 mg/cm^2 of filter paper. The acetone was allowed to evaporate, and the filter paper was dampened with 3 ml of sterile water, placed in a Petri dish with 20 weevil eggs on the paper, and incubated in an environmental cabinet at 25°C and 80% relative humidity. The number of eggs hatched was counted after seven days and compared with the appropriate controls under the same conditions. All test compounds which were ovicidal at 0.01 mg/cm^2 were retested at 0.001 mg/cm^2. The data for active substances in the tables is at this concentration.

Plant Damage Ratings. The ratings for plant resistance were carried out on caged alfalfa bouquets. In each of these cages were placed two bouquets of alfalfa in water: one resistant, Weevlchek; and one susceptible, Caliverdi. Each bouquet contained 30 alfalfa stems. Fifty adult weevils were placed in each cage and the cages maintained at ambient temperature with an 8-hr light and 16-hr dark photoperiod. After five days, the bouquets were removed and evaluated for damage using an arbitrary 1–10 rating scale and judged by six independent observers. There was no significant difference in damage between the two different lines.

Determination of Ovipositional Rates. Two separate caged bouquets of Caliverdi alfalfa and two similar bouquets of Weevlchek alfalfa were inoculated with 50 adult weevils to a cage. Each bouquet consisted of 10 stems in water, and the cages were maintained under the conditions described for the damage rating experiment. After four days, the stems were sliced open and the number of egg clusters and eggs per cluster counted.

DISCUSSION

Bioassays were developed to measure the effect of plant extracts and chemical constituents on larval development, pupation rates, fecundity, and ovicidal activity.

Several artificial diets for the alfalfa weevil have been previously proposed (Hsiao and Hsiao, 1974; Hsiao, 1969; Nash and Tombes, 1966). In our experience these diets proved to be only marginally acceptable, especially with neonate larvae. As a result the standard Berger diet frequently used on *Heliothis* was employed (Chan et al., 1978). As Nash and Tombes (1966) reported, the diet still leaves much to be desired since survival rate and weight gain on the synthetic diet is so poor relative to insects raised on alfalfa. The addition of various alfalfa extracts to the standard Berger diet did not improve it. To be successful with the Berger diet, it was necessary to start with second-instar larvae to achieve an acceptable weight gain. The use of larvae which had spent their first 48 hr on alfalfa greatly increased the survival rates on the diet. The weights of the 48-hr-old introduced larvae ranged from 1.15 to 1.3 mg. After 20 days on the diet their weights ranged from 10.6 to 14.2 mg. Insects living on susceptible alfalfa plants over the same period ranged in weight from 15.9 to 18.9 mg. Pupation rates after 14 days on the diet were 60–75%. There was no difference in insect weights on the controls and those diets containing acetone extracts of susceptible or resistant alfalfa, the marc remaining from the extracts or whole alfalfa leaf powder.

By far the most convenient bioassay was the measurement ovicidal activity. Excised alfalfa weevil eggs gave a 95–100% hatch rate in seven days when incubated on damp filter papers pretreated with alfalfa extracts or other test materials. There was no difference in hatch rate between the controls and those treated with extracts of susceptible or resistant alfalfa lines.

To determine if plant resistance involved the egg-laying phase of weevil reproduction (Norwood et al., 1967b), the average number of eggs per cluster and average number of egg clusters per stem were measured in resistant and susceptible lines. Again there was no difference between the susceptible and resistant lines. The susceptible Caliverdi line averaged 1.7 clusters/stem and 7 eggs/cluster while the resistant line, Weevlchek, averaged 1.9 clusters/stem and 6 eggs/cluster.

Since no antibiotic difference could be detected between resistant and susceptible alfalfa lines when surveyed by the bioassay procedures described above, whole, intact plant material was studied in an attempt to demonstrate the presence of resistance in Weevlchek. This was done in a choice test using neonate larvae on intact, but detached alfalfa stems. There was no preference in plant material consumed, no difference in the amounts eaten, and no difference in the weights of emergent larvae from the two alfalfa lines. The mean weight of 10 newly emerged larvae from either line was 0.25 mg.

As a result, it is concluded that weevil resistance in the resistant line, Weevlchek, and probably all commercial resistant alfalfa lines, is not based on antibiosis but is due to greater plant tolerance to insect damage. Some degree of tolerance in Weevlchek has been previously suggested (Sorensen et al., 1972).

The ovicidal bioassay was also extended to screen a number of alfalfa constituents and related substances for activity. The ovicidal activity of coumarin, particularly on *Drosophila* species, has been well documented (Nakajima and Kawazu, 1980; Kagan et al., 1983). The intense activity of coumarin verified on alfalfa weevil eggs in the ovicidal bioassay prompted the examination of a number of related coumarin derivatives (Table 1). Coumarin and 7-methoxycoumarin showed good inhibition of egg hatch. Replacement of the methyl ether group by other alkyl or ester groups resulted in loss of activity. The addition of further substituents to the 7-methoxycoumarin system also resulted in loss of activity. Transfer of the methoxy group to other positions resulted in decreased activity (6-methoxy) or total loss of activity (4- or 8-methoxy). The dimethylpyranocoumarin, seselin, previously reported (Tanaka et al., 1985) as ovicidal against spider mite eggs, was inactive in the weevil bioassay.

Among the coumarin derivatives tested for their effect on egg hatch rates were a series of 3-acyl-4-hydroxycoumarins which show a wide range of biological activity against bacteria and insects. The results are displayed in Table 2. In common with aphid feeding deterrency (Dreyer et al., 1987) and bactericidal sporostatic activity (Lewis and Jurd, 1972) the egg hatch rate was totally suppressed by those 3-acyl-4-hydroxycoumarins with short alkyl groups. The presence of all the structural features found in 3-acyl-4-hydroxycoumarins apparently is required for ovicidal activity since separation of the structural features in 4-hydroxycoumarin and 3-acetylcoumarin resulted in loss of activity in each case (Table 1).

The inhibition of egg hatch of the 3-acyl-4-hydroxycoumarins declined with increasing length of the 3-acyl group. Under the conditions of the experiment, those members of the series with eight or more carbons in the acyl group were inactive. This order of activity parallels bacterial sporostatic action (Lewis and Jurd, 1972) for these same compounds. Again members with small acyl groups showed the highest sporostatic activity which decreased as the size of the acyl group increased. A similar order of activity was found for pea aphid feeding deterrents except that the change in activity occurred with the C_4 butyryl analog (Dreyer et al., 1987). To what degree this falloff in activity is due to decreasing water solubility is not clear. Antibacterial activity of the 3-acyl-4-hydroxycoumarins increased with increasing size of the 3-acyl group and reached a maximum with the decanyl derivative (Toda et al., 1958; Ukita et al., 1951). Insecticidal activity of 3-acyl-4-hydroxycoumarins has also been previously noted (Laeuger et al., 1944). Of two related tricarbonylmethanes, one, dehydroacetic acid, was ovicidal, while the second, the lichen constituent, usnic acid, was inactive. Coumestrol, saponin, and dicoumarol, constituents associ-

(Received April 14, 1986; accepted June 3, 1986)

Abstract—A series of 3-acyl-4-hydroxycoumarins, structurally related to dicoumarol, as well as several alfalfa constituents including coumestrol were tested for their feeding deterrency towards the pea aphid. Feeding deterrency of the 3-acyl-4-hydroxycoumarins decreased as the size of the 3-acyl group increased.

Key Words—*Medicago sativa*, alfalfa, *Acyrthosiphon pisum*, pea aphid, Homoptera, Aphididae, host-plant resistance, phytoalexin, 4-hydroxycoumarins, coumestrol, symbiotes, feeding deterrency.

INTRODUCTION

Aphids are a major, worldwide pest on crop plants. In many cases, plant breeders have been fairly successful in developing aphid-resistant varieties. However, because of the adaptability of aphids to form new, virulent biotypes, resistance in cultivars is frequently overcome in relatively short time periods.

The mechanism of resistance in many crop plants towards aphids is frequently ascribed to the presence of secondary plant constituents which have toxic or feeding-deterrent effects (Dreyer and Jones, 1981). The evidence supporting this view comes mostly from bioassays which employ artificial diets to which plant extracts or purified compounds have been added. From the bioassay data, a dose–response curve can be constructed from which an ED_{50} value can be obtained. This ED_{50} is the concentration of material that deters 50% of the

0098-0331/87/0400-0925$05.00/0 © 1987 Plenum Publishing Corporation

aphids from feeding and serves as a convenient comparative value to describe feeding deterrency between a variety of plant compounds.

A disadvantage to testing plant extracts or compounds in the above manner is that most aphids probe either intercellularly or bypass vacuoles containing toxic substances. Since aphids feed in the phloem, if such bioactive plant substances are not located either intercellularly or in the phloem, they play a minimal role in host-plant resistance.

Role of Pectin in Host-Plant Resistance. More recently, compelling evidence has been advanced which extends and supports an earlier idea (Adams and McAllan, 1958) that host-plant resistance towards phloem-feeding aphids, which probe intercellularly, is related to the ease with which the aphid's salivary pectinase catalyzes the depolymerization of intercellular pectin (Dreyer and Campbell, 1984; Campbell and Dreyer, 1985). Pectin is a polysaccharide chiefly found in the middle lamella and primary cell wall which cements plant cells together (Ishii, 1984). Pectinase-catalyzed depolymerization of intercellular matrix pectin mediates probing by the aphid stylets in attaining the phloem.

In the case of sorghum, it has been shown by electronically monitoring probing behavior that stylets of an aphid pest, the greenbug [*Schizaphis graminum* (Rondani)], reach the phloem in a susceptible line more than twice as fast as in an aphid-resistant line (Campbell et al., 1982). This rate of access to the phloem is associated with the rate of depolymerization of the isolated plant pectin catalyzed by the aphid's pectinase system (Dreyer and Campbell, 1984; Campbell and Dreyer, 1985). It is further argued that aphids evolved an intercellular mode of probing to avoid many potentially deleterious secondary plant constituents which are normally compartmentalized inside specialized storage cells or vacuoles (Matile, 1984).

Host-plant-resistance studies on sorghum have been extended to the pea aphid on alfalfa and the results support the idea that pectin, again, plays a major role in mediating aphid probing and controlling access to the phloem (Dreyer et al., 1986). The salient points are: (1) The pea aphid is a phloem feeder and probes intercellularly. (2) It takes more than twice as long for the pea aphid to reach the phloem of an aphid-resistant line as on a susceptible alfalfa line. (3) Once in the phloem, the pea aphid feeds equally well on resistant as on susceptible alfalfa lines. (4) Pectin fills the intercellular spaces in plants and acts as an intercellular cement that binds cells together. (5) The rate of enzymatic catalyzed depolymerization of the pectin isolated from different alfalfa lines correlates with plant resistance to aphids. (6) Aphid resistance in alfalfa can be enhanced in susceptible lines by the application of plant growth bioregulators, for example CCC, which have been shown to influence pectin composition.

These results argue for a major role of intercellular pectin in host-plant resistance to aphids and that pectin functions by mediating aphid stylet penetration towards the phloem. The structural features of pectin, a complex poly-

saccharide (Jarvis, 1984), which govern the depolymerization rate by enzymes are, to date, only partially understood.

The aphid pectinase relationship with plant pectin has many parallels with the mechanism of bacterial or fungal pathogen attack on plants (Bateman, 1976). Indeed, the aphid's salivary pectinase is very likely a product of the extensive bacterial endosymbiotes (Campbell and Dreyer, 1985) that are ubiquitously found in sap-sucking insects (Homoptera) (Koch, 1960). It appears likely that the differences in aphid biotypes (Diehl and Bush, 1984) are due to differences in the bacterial endosymbiotes (Houk and Griffiths, 1980) rather than inherent biochemical differences in the insect (Campbell and Dreyer, 1985). Circumstantial evidence supporting this view includes the induction of the aphid's ability to feed on otherwise unacceptable hosts as well as the frequent appearance of new, more virulent biotypes.

Natural Products and Host-Plant Resistance to Aphids. In spite of a central role proposed for pectin in governing host-plant resistance to aphids, there are some plants where a persuasive argument can be made for a role of secondary plant constituents in aphid resistance, especially if such constituents are transportable in the phloem. In certain lupins aphid resistance correlates with the concentration of quinolizidine alkaloids in the plant (Wink et al., 1982; Wegorek and Krzymanska, 1970). It has been shown that these alkaloids are transported in the phloem (Wink and Witte, 1984). These results argue that the role of certain secondary plant constituents in host-plant resistance to aphids cannot be dismissed out of hand.

METHODS AND MATERIALS

The 3-acyl-4-hydroxycoumarins were prepared according to published procedures (Klosa, 1956) from 4-hydroxycoumarin and the *n*-alkanoic acid. The bioassay, using biotype Chualar of the pea aphid, was carried out using the Akey diet (Akey and Beck 1971). The bioassay procedure has been described in detail (Dreyer et al., 1981).

RESULTS AND DISCUSSION

This paper describes the feeding deterrency of a series of related 3-acyl-4-hydroxycoumarins towards the pea aphid. These compounds are structurally related to dicoumarol, a known alfalfa constituent, and other anticoagulants which, in general, retard the growth of gram-positive bacteria (Dadak and Hodak, 1966). The pea aphid, *Acyrthosiphon pisum* (Harris), is a significant pest on alfalfa and was selected as the test system because alfalfa is a known phytoalexin producer with relatively well-studied chemistry.

Coumestrol	no effect at 1000 ppm

Although none of the hydroxycoumarins were strongly active, compounds of this series with a small alkyl residue in the 3-acyl group showed the greatest feeding deterrency towards the pea aphid (Table 1). The activity declined so that there was little or no effect when the acyl residue was three carbons or larger. This order of activity for these compounds paralleled bacterial sporostatic action (Lewis and Jurd, 1972). In this case, members with small acyl groups showed the highest sporostatic activity with decreasing activity as the size of the acyl group increased. This series of 3-acyl-4-hydroxycoumarins are known to be active antibacterial agents against gram-positive but not against gram-negative bacteria (Toda et al., 1958; Ukita et al., 1951). The order of compounds showing feeding-deterrent activity against the pea aphid was the reverse of bactericidal activity previously described against gram-positive bacteria. Structure–activity studies (Toda et al., 1958; Ukita et al., 1951) showed increasing antibacterial activity towards gram-positive bacteria with increasing size of the acyl group. Activity reached a maximum with the 3-decanoyl derivative. Insecticidal activity of 3-acyl-4-hydroxycoumarins has also been previously noted (Laeuger et al., 1944).

Two different modes of action of secondary plant constituents on aphids might be distinguished. One is a mechanism by which compounds act as bactericides on the endosymbiotes and the other when these substances act directly as feeding deterrents or toxicants on the aphid itself. Compounds having a deleterious effect on the symbiotes might have a profound effect on the aphid's

probing ability if the pectinase arose from the symbiotes. In the present case, it has not been determined if the activity of the hydroxycoumarins has a direct effect on the aphid or the endosymbiotes.

Degradation of plant pectin catalyzed by the aphid pectinase system could give rise to oligosaccharides which can act as elicitors in initiating phytoalexin biosynthesis (Darvill and Albersheim, 1984). Such oligosaccharides have been identified in the honeydew of aphids, indicating their potential for translocation (Campbell, 1985).

It has been reported that pea aphid or spotted alfalfa aphid infestations on alfalfa results in very high increases in coumestrol levels (Loper, 1960). Similar coumestrol increases result from fungal infestations on alfalfa (Loper et al., 1967). Coumestrol, dicoumarol and saponin, all alfalfa constituents, were bioassayed for their feeding deterrency and showed no effect up to 1000 ppm. Coumestrol has been reported to have poor antifungal activity (Perrin and Cruickshank, 1969; Van Etten, 1967) and modest antibacterial properties (Lyon and Ward, 1975) so that, even though its formation may be triggered by aphid probing, it apparently has little effect on the insect. It should be recognized that phytoalexins are not always effective in protecting plants from pathogens. The selective inhibition or modification of aphid symbiotes may not only be a possible insect control method but may also yield information about the nature and role of symbiotes in insect host-plant relationships.

(Received February 14, 1986; accepted June 3, 1986)

Abstract—A field survey of 10,12-hexadecadienyl alcohols, acetates, and aldehydes showed attraction to a wide range of sphingid moths. Data are presented showing the attraction of *Smerinthus jamaicensis*, *Smerinthus cerisyi*, *Pachysphinx modesta*, *Hemaris diffinis*, and *Proserpinus flavofasciata* to these compounds. Mass spectral, EAG, and EAD data show evidence for the presence of these dienes in female extracts of *S. cerisyi*, *Hyles gallii*, and *Sphinx drupiferarum*.

Key Words—Attractant, pheromone, 10,12-hexadecadienal, 10,12-hexadecadienyl acetate, *Smerinthus jamaicensis*, *Smerinthus cerisyi*, *Paonias excaecatus*, *Paonias myops*, *Pachysphinx modesta*, *Hemaris diffinis*, *Proserpinus flavofasciata*, *Hyles gallii*, *Hyles euphorbiae*, *Sphinx vashti*, *Sphinx drupiferarum*, Lepidoptera, Sphingidae.

INTRODUCTION

Bombykol, *E*10,*Z*12-16:OH[2], was the first pheromone component ever isolated and identified (Butenandt et al., 1959) from the extraction of 500,000 female scent glands of *Bombyx mori* L. Improved isolation and identification techniques have led to the discovery of hundreds of additional pheromones and

[1]NRCC No. 25857.
[2]In this paper the chemical nomenclature is abbreviated as follows: *Z* and *E* indicate the *cis* and *trans* configurations of the double bond, the number following *Z* or *E* indicates the position of that double bond, the last number indicates the carbon chain length, the terminal functional groups are :Ac = acetate; :OH = alcohol; :Ald = aldehyde.

0098-0331/87/0400-0931$05.00/0 © 1987 Plenum Publishing Corporation

attractants but relatively few involved 10,12-hexadecadienyl alcohols, aldehydes, or acetates (hexadecadienyls). Bombykol was also identified in the female gland extracts of *Bombyx mandarina* by Kuwahara and Yen (1979).

Kasang et al. (1978a) have shown bombykal (*E*10,*Z*12–16:Ald) is a second component of the *B. mori* pheromone and *E*10,*E*12–16:OH is present in its female scent gland (Kasang et al., 1978b). Starratt et al. (1979) identified bombykal as a pheromone component of a sphingid *Manduca sexta* (L.), and Hall et al. (1980) identified *E*10,*E*12–16:Ald as a pheromone component of the noctuid, *Earis insulana* (Boisduval).

Hyles euphorbiae (L.), an Old World sphingid, has been introduced into North America, and most recently to Saskatchewan, as a biological control of leafy spurge (*Euphorbia esula* L.) (Harris, 1984). We are presently investigating the pheromone of *H. euphorbiae* as a potential population monitor, and initial studies have indicated that hexadecadienyl aldehydes are present in female abdominal tip extracts, (Underhill, unpublished). This evidence, as well as the proven pheromone activity of 10,12-hexadecadienyl compounds in several lepidopteran families and previous success in using conjugated dienyl compounds as attractants for a wide range of Lepidoptera (Reed and Chisholm, 1985), led us to synthesize and field test the 10,12-hexadecadienyls. We report here field trapping, electroantennograph (EAG), and coupled gas chromatograph–electroantennographic detector (GC-EAD) data that suggest several members of Sphingidae family use 10,12-hexadecadienyl compounds as pheromone components. We also present mass spectral data that show the presence of one of these compounds in female abdominal tip extracts.

METHODS AND MATERIALS

The chemicals used in this study were synthesized and purified in this laboratory. The *EE*, *EZ*, and *ZE* alcohols were synthesized using methods described by Chisholm et al. (1981). The *E*10,*E*12–16:OH and *E*10,*Z*12–16:OH were recovered from a Wittig condensation reaction of the ylide of butyltriphenylphosphonium bromide with (*E*)-12-tetrahydropyranyloxy-2-dodecenal. *E*10,*E*12–16:OH and *Z*10,*E*12–16:OH were recovered from the Wittig condensation reaction of the ylide of 10-acetoxydecyltriphenylphosphonium bromide with (*E*)-2-hexenal.

Synthesis of the *ZZ* isomer, and purification and conversion of all alcohols to aldehydes and acetates was similar to that described by Chisholm et al. (1985). *Z*10,*Z*12–16:OH was synthesized by the catalytic coupling of 10-undecynol with 1-bromopentyne and the subsequent dicyclohexylborane reduction of the diyne to the diene.

Structures were verified by 90-MHz NMR, IR, and mass spectrometry. Isomeric purity was greater than 99% and was checked on a Hewlett Packard

5890A gas chromatograph with flame ionization detector (FID) using a 0.32-mm-ID × 30-m DB-5 fused silica capillary column (J. & W. Scientific, Rancho Cardova, California).

Chemical ionization mass spectral analyses of female tip extracts were done with a Finnigan 3300 GC-MS using a 0.32-mm × 60-m DB-5 fused silica column with hydrogen as carrier gas and methane as reagent gas.

Injections were made at an oven temperature of 40°C, heated to 120°C and temperature programmed 4°/min to 280°C. A multiple-ion detection (MID) method was used to scan for characteristic ions of the 10,12-hexadecadienyls which included ions with m/z 169, 219, 221, 235, 237, 239, 253, 265, 279, and 321.

From May 2 to September 10, 1985, field trapping was carried out 100 km northeast of Saskatoon, Saskatchewan, Canada, in a forest area containing spruce, pine, birch, aspen, and poplar trees and a number of herbaceous shrub species. The sticky wing traps (Phero Tech Inc., Vancouver, B.C.) contained chemical lures impregnated into rubber septa (Arthur H. Thomas Co. Philadelphia, Pennsylvania, No. 1780 J07) and protected from oxidation with 100 μl of a solution of 10% buylated hydroxytoluene in acetone. The traps were hung on tree branches 1–2 m from the ground and spaced at least 10 m apart. Inspections of traps and recording of captures were done weekly, and lures were replaced on June 4 and July 12.

The survey consisted of 96 nonreplicated traps containing each of the 10,12-hexadecadienyls as a single component at 500 μg dose and two component lures formulated by adding an additional 50 μg of a compound which differed from the primary component by a single change in functional group or isomeric geometry; also, 500-μg doses of single-component 10-hexadecenyl and 12-hexadecenyl compounds were surveyed.

Light trapping of moths was done using 8-W portable UV light traps (Bioquip Products, Santa Monica, California) in the area of the survey and in an area 10 km south of Saskatoon.

EAG responses of moths to synthetic chemicals were recorded following the method of Chisholm et al. (1975) using light-trapped males of unknown age which were maintained in the laboratory at 5°C and used within 36 hr of capture. EAG data presented are from single male moths which gave reproducible responses. Although the intensity of the absolute responses may have differed from those of other males of the same species, the relative responses were very consistent. EAD responses (Arn et al., 1975) of male antennae to synthetic standards and female extracts were done with light-trapped or hand-caught males and females. The majority of light-trapped females had mated, and extracts showed no EAD activity. Female abdominal tips were excised and extracted with methylene chloride for 0.5 hr. Extracts were concentrated and separated chromatographically using a modified gas chromatograph (Hewlett Packard

5710A) with a 0.32-mm × 30-m DB-5 fused silica capillary column. The effluent was split in a 7:3 ratio to an FID and EAD. Injections of ~1 female equivalent (FE) of extracts or 2- to 5-ng quantities of standards were injected splitless at 40°C for 30 sec and the oven heated to 90°C and temperature programmed 4°/min to 230°C. Good separations of the geometrical isomers of the 10,12-hexadecadienyls were achieved with typical separations being greater than 10 sec and resolutions of better than 1.0.

Replicated experiments were set out when possible to verify captures in the unreplicated survey.

Summed trap captures from randomized, three-times replicated, field tests were transformed $\sqrt{X + 0.5}$, where X is the number of male moths captured in the trap, and then submitted to an analysis of variance, and significantly different means separated by Duncan's multiple-range test.

RESULTS AND DISCUSSION

The 1985 survey attracted five sphingid species: *Smerinthus jamaicensis* (Drury), *Smerinthus cerisyi* Kirby, *Pachysphinx modesta* (Harris), *Hemaris diffinis* (Boisduval), and *Proserpinus flavofasciata* (Walker) (Tables 1 and 2) as well as at least eight other lepidopteran species (unpublished data). Although the survey traps were not replicated, male captures were replicated over time, and attractive lure components were clearly evident for a number of sphingids. The best example is that of *S. cerisyi*, where all baits containing Z10,*E*12-16:Ald at the 500-μg dose (Table 2) except where Z10,*E*12-16:Ac or *E*10,*E*12-Z10,*E*12-16:Ac (500 μg) + Z10,*E*12-16:Ald (50 μg) caught more than six times as many moths as any other trap. In a replicated test (Table 3), this two-component mixture at 550 μg was a significantly better attractant than the mixture at 110 μg or the acetate alone at 500 μg. Z10,*E*12-16:Ald alone or in combination with any other hexadecadienyl compound as well as the corresponding hexadecenyl compounds failed to attract *S. cerisyi*. EAGs done on male *S. cerisyi* (Figure 1) showed strong responses to its attractant components.

Smerinthus jamaicensis males were caught in traps containing Z10,*E*12-16:Ald at the 500-μg dose (Table 2) except where Z10,*E*12-16:Ac or *E*10,*E*12-16:Ald was a second component. EAG data (Figure 1) for *S. jamaicensis* showed a strong response to its attractant, Z10,*E*12-16:Ald, as well as relatively large responses to *E*10,*E*12-16:Ald, and to Z10,*E*12-16:Ac, which suggests they may have inhibited trap capture in the survey. Corresponding hexadecenyl compounds were not attractive in the field, and EAG analysis showed only weak responses.

Pachysphinx modesta males were captured along with *S. cerisyi* in traps containing Z10,*E*12-16:Ac at 500 μg except in traps where Z10,*E*12-16:Ald was a second component (Tables 2 and 3). EAG data for *P. modesta* (Figure

1) shows strong responses for its attractant *Z*10,*E*12–16:Ac and also *E*10,*Z*12–16:Ac and *Z*10,*E*12–16:Ald. The presence of this aldehyde in *S. cerisyi* female extracts (see below) may indicate that, as well as being an attractant component of *S. cerisyi*, it serves to inhibit the attraction of *P. modesta* and thereby aids in species isolation.

From field observations it was noticed that the day flyer *Hemaris diffinis* was readily attracted to lures containing *Z*10,*E*12–16:Ald but few of these agile flyers landed in traps. Specimens for EAG analysis were literally "hand caught" when males were attracted to contaminated hands after handling lures containing 10,12-hexadecadienals. The EAG profile shows strong responses to all the hexadecadienals (Figure 2). Again, the corresponding hexadecenyl aldehydes were not attractive in the field nor were they EAG active.

Proserpinus flavofasciata was similar to *H. diffinis* in that very few of this agile, bee mimic were captured (five males) but all were taken in traps containing *Z*10,*E*12–16:Ald as a major component. No suitable specimens were obtained for EAG or EAD analysis.

A few specimens of each of the two *Paonias* species were light trapped, and EAG profiles showed strong responses for only the 10,12-hexadecadienyl acetates (Figure 2). One *Paonias exceactus* was captured in a trap containing *E*10,*Z*12–16:Ac (500 μg) + *E*10,*Z*12–16:Ald (50 μg).

Data were obtained supporting the occurrence of 10,12-hexadecadienyl acetates and aldehydes in female abdominal tip extracts of *S. cerisyi*, *Sphinx drupiferarum* (J.E. Smith), and *Hyles gallii* (Rottenburg).

Female abdominal tip extracts were obtained from light-trapped *S. cerisyi*, and GC-EAD analysis with conspecific male antennae to 1 FE showed responses corresponding to retention times of *Z*10,*E*12–16:Ac (140 μV signal) and *Z*10,*E*12–16:Ald (50 μV signal) (Figure 3). This evidence, along with trapping and EAG data, suggests strongly that these are actual pheromone components.

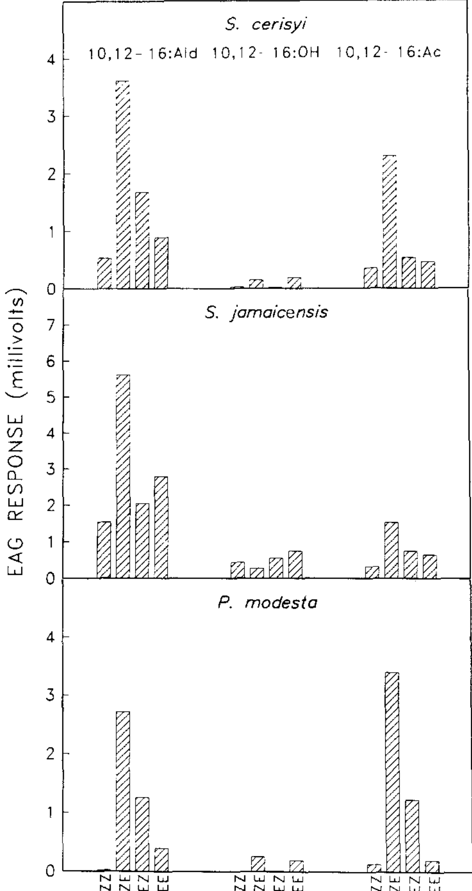

FIG. 1. EAG responses of males to synthetic 10,12-hexadecadienyls at 1-μg doses for *S. cerisyi* and *S. jamaicensis* and 10-μg doses for *P. modesta*.

Light-trapped *S. drupiferarum* females were collected and abdominal tip extracts were prepared and analyzed by GC-EAD using the antennae from light-trapped *S. vashti*. Analysis showed responses corresponding to the retention times of *Z*10,*E*12-16:Ald (80 μV signal), *E*10,*Z*12-16:Ald (430 μV signal), and *E*10,*E*12-16:Ald (80 μV signal) (Figure 3). GC-MS analysis using the MID method for *S. drupiferarum* tip extracts showed a peak at the same retention time of synthetic *E*10,*Z*12-16:Ald with characteristic ions: $(M + 29)^+$, *m/z* 265; $(M + 1)^+$, *m/z* 237; $(M - 1)^+$, *m/z* 235; and $[(M + 1) - 18]^+$, *m/z* 219 in the same relative ratios as synthetic *E*10,*Z*12-16:Ald.

Both MS and GC data showed the *E*10,*Z*12-16:Ald present in amounts greater than 30 ng/female. The *ZE* and *EE* may be present in picogram quan-

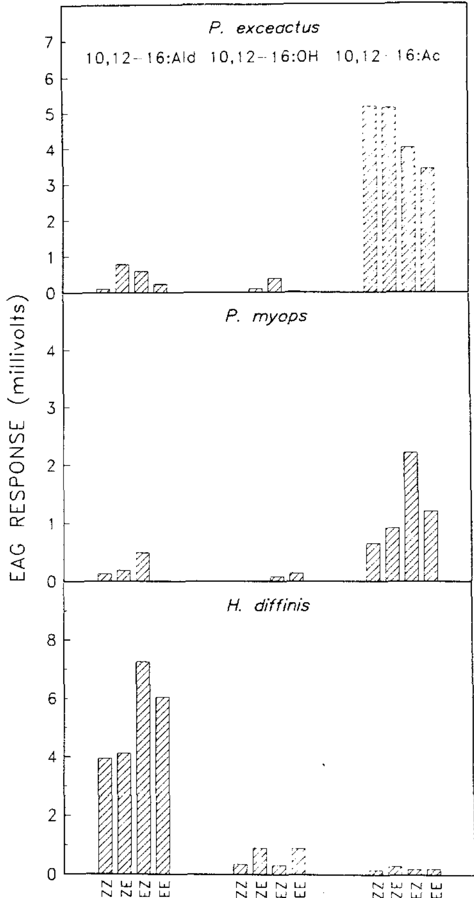

FIG. 2. EAG responses of males to synthetic 10,12-hexadecadienyls at 10-μg doses.

tities, but they were not verified by MS analysis. No *S. drupiferarum* were captured in baited traps, but the EAD shows the presence of at least one and possibly three 10,12-hexadecadienals in the extract and a multicomponent mixture may be necessary for attraction. *Hyles gallii* was not found in the trapping survey area (light trap or survey traps), but males and females were obtained from the light trap south of Saskatoon (no survey traps). Female abdominal tip extracts showed EAD responses corresponding to the retention time and presence of *E*10,*E*12–16 : Ald (130 μV signal) when using a male *H. gallii* antenna. *Hyles euphorbiae* male antennae (obtained from a lab culture) responded to female *H. gallii* extracts, indicating the presence of *E*10,*Z*12–16 : Ald (50 μV signal). GC-EAD analysis of *H. gallii* to standard solutions of hexadecadienyls showed strong responses to the *EE* and *EZ* aldehydes, with *EE* being the strongest.

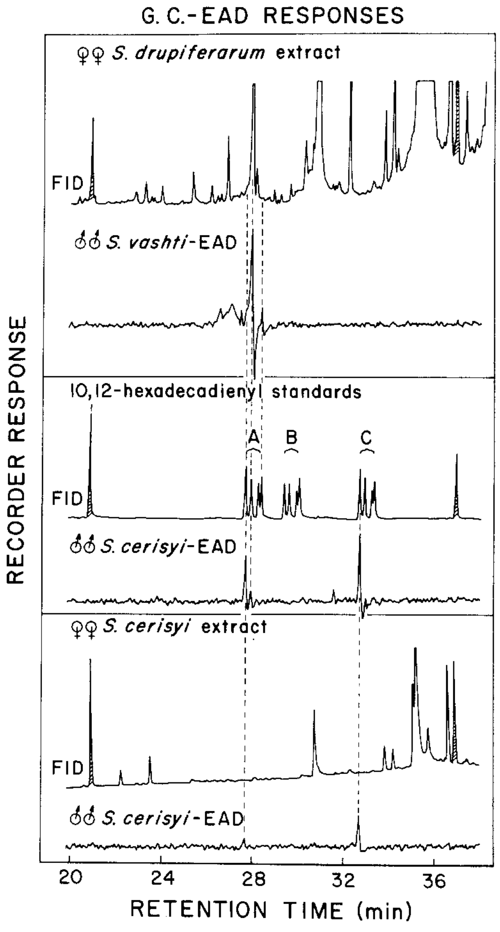

FIG. 3. Representative EAD and associated FID responses of male sphingids to female extracts (FID 0.7 FE : EAD 0.3 FE) and synthetic standards (FID 2.8 ng : EAD 1.2 ng). The elution order of the 10,12-hexadecadienyl isomers was *ZE*, *EZ*, *ZZ*, and *EE* for the aldehydes (A), alcohols (B), and acetates (C).

On several occasions the presence of only scales in the sticky traps indicated a lack of moth retention, particularly for the larger moth species. When the large *P. modesta* was captured in the sticky traps, the traps became saturated when they contained only three or four moths, and results may have been more conclusive if a retentive, nonsaturating trap had been used.

A comparison was made of captures of *S. cerisyi* and *S. jamaicensis* in sticky wing traps and large (9-liter) double inverted cone-orifice traps with varying orifice diameters (Steck and Bailey, 1978). An opening of 2 cm was necessary to allow the *Smerinthus* species to enter but these were found to be no

better than the sticky wing traps. None of the other sphingids attracted to wing traps could be trapped using the inverted cone-orifice trap.

A different problem arose with the more agile flyers such as *Hemaris diffinis*, *Proserpinus flavofasciata*, and possibly the *Sphinx* and *Hyles* species. These hovering, nectar feeders very rarely landed in the sticky traps even though some were obviously attracted to the lures.

In North America there are two subfamilies of Sphingidae, containing five tribes. Our data show attraction to and/or the presence of 10,12-hexadecadienyl acetates or aldehydes in species representing four tribes. A chemotaxonomic approach using hexadecadienyl compounds could be used for any other sphingid species whose pheromones need to be identified.

TECHNIQUE FOR VISUALIZATION OF EPIDERMAL GLANDULAR STRUCTURES IN PLANTS

THOMAS EISNER,[1] MARIA EISNER,[1] and JERROLD MEINWALD[2]

[1]*Section of Neurobiology and Behavior*

(Received April 25, 1986; accepted June 3, 1986)

Abstract—The distribution of microscopic glandular structures (hairs, capsules, nodules) on a leaf or other plant part can be recorded visually by pressing the plant part against an indicator surface (filter paper, thin-layer chromatography plate) soaked in Tollens' reagent. The glandular sites are revealed instantly on the test surface as dark spots.

Key Words—Chemical ecology, plant defenses, glandular trichomes, Tollens' reagent.

Leaves and stalks of plants are commonly beset with microscopic glandular structures, such as secretory hairs, capsules, or nodules, widely believed to be defensive (Levin, 1973; Stipanovic, 1983). Because of their intrinsic botanical interest, and because they are often the source of unusual chemicals, such glands have been the subject of considerable research (Levin, 1973; Stipanovic, 1983; Rodriguez et al., 1984). Visualization of the glands may prove problematic, particularly in the field, since it may be possible only by use of magnifying devices. Some structures, particularly nodular glands, which may be embedded in the leaf tissue itself, may not be apparent. We here describe a simple technique whereby the epidermal glandular specializations of a plant can be quickly demonstrated and recorded. The technique involves obtaining a printout of the glands by pressing leaves or other vegetative portions of the plant against a chemically pretreated indicator surface.

Filter paper or, better, commercial thin-layer silica-gel chromatography plates, can serve as indicator surfaces. Pieces of these materials, cut to appropriate size, are soaked just prior to use in freshly prepared Tollens' reagent (Tollens, 1882a,b; Feigl, 1966). This is made by adding droplets of aqueous

0098-0331/87/0400-0943$05.00/0 © 1987 Plenum Publishing Corporation

potassium hydroxide (10%) to aqueous silver nitrate (10%), and dissolving the resulting silver oxide precipitate by addition of aqueous ammonia (10%). The soaked pieces are blotted off, and then pressed tightly (to ensure rupture of glandular capsules and nodules) for some seconds against the plant surface to be tested. Glandular sites are immediately revealed as a pattern of dark spots (metallic silver) on the indicator surface. Tollens' reagent deteriorates with time (caution: explosive potential!), but fresh preparation from the stable precursors poses no problem, even under field conditions, for which purpose the technique is particularly useful, since it can afford a rapid means for screening plant surfaces for incidence, as well as varying density, of glandular defenses. Microscopic closeups of representative leaf glands, as well as typical printouts of glandular patterns, are shown in Figure 1. Note how the technique reveals even nodular glands (Figure 1A–A″), which may not be apparent with a hand lens (Figure 1A was taken with a microscope and dark-field transmitted light).

Our initial choice of Tollens' reagent was prompted by an interest in cat thyme (Figure 1 B–B″), whose glandular capsules contain the terpenoid aldehyde dolichodial (Pagnoni et al., 1976). We soon realized, however, that this traditional aldehyde reagent gave distinct glandular printouts with a diverse group of plants, including some not known to produce aldehydic exocrine secretions. At least two factors could account for this unexpectedly broad reactivity. First, it is likely that some aldehydes are present, if only at low levels, in almost every epidermal plant secretion. And second, many other functionalities can reduce ammonia-complexed silver ion, as implied by Tollens himself, and documented extensively by subsequent workers (Tollens, 1882a,b; Feigl, 1966).

FIG. 1. Glandular leaf structures: morphology and chemical printout patterns. (A–A″) *Ruta graveolens* (family Rutaceae); (A) portion of leaf (dark-field, transmitted light) showing pinpoint pattern of translucent glandular nodules; (A′) scanning electronmicrograph (SEM) of single nodule; (A″) printout pattern of leaf. (B–B″) *Teucrium marum* (cat thyme, family Labiatae); (B) leaf portion (horizontal incident light) showing stalkless glandular capsules; (B′) SEM of capsule; (B″) printout pattern of leaf. (C–C″) *Heterotheca psammophila* (camphorweed, family Compositae); (C) leaf portion (horizontal incident light) showing glandular hairs; (C′) SEM of glandular hair with apical secretory globule; (C″) printout pattern of leaf. (D, E, F) Leaf printout patterns of (D) marjoram (*Origanum majorana*, family Labiatae), (E) tomato (*Lycopersicum esculentum*, family Solanaceae), and (F) absinthe (*Artemisia absinthium*, family Compositae). The chemicals produced by these glandular structures include a diversity of terpenoids, acetogenins, and phenylpropanes, among others (Karrer, 1958; Pagnoni et al., 1976; Rodriguez et al., 1984; Stipanovic, 1983); *Heterotheca* produces a mixture of terpenoids, including camphor and borneol (Silverstein, West, Webster, Hummel, and Eisner, unpublished results). INTERACTION OF NUCLEAR POLYHEDROSIS VIRUS WITH CATECHOLS:
Potential Incompatibility for Host-Plant Resistance against Noctuid Larvae

G.W. FELTON, S.S. DUFFEY, P.V. VAIL,[1] H.K. KAYA,[2] and J. MANNING,[3]

Abstract—Two major orthodihydroxy phenolics of *Lycopersicon esculentum*, rutin and chlorogenic acid, have previously been identified as potential sources of host-plant resistance against the tomato fruitworm *Heliothis zea*. We report here the possible incompatibility of these chemically based resistance factors with viral control of *H. zea*. We have found that both rutin and chlorogenic acid significantly inhibited the infectivity of nuclear polyhedrosis viruses. Chlorogenic acid, when added to tissue culture medium containing TN-368 ovarian cells, inhibited the infectivity of a multiply embedded virus (AcMNPV) by over 86%. Rutin or chlorogenic acid, when fed to *H. zea*, inhibited the infectivity of a singly embedded nuclear polyhedrosis virus (HzSNPV), with the greatest degree of inhibition occurring at low doses of viral inoculum. Additionally, the ingestion of these phytochemicals significantly prolonged the survival time of virally infected *H. zea* larvae. These results suggest that the effectiveness of nuclear polyhedrosis viruses in controlling *H. zea* populations may be adversely affected by varieties of *L. esculentum* with significant levels (eg. 3.5 μmol/g wet weight) of rutin or chlorogenic acid.

Key Words—*Heliothis zea, Spodoptera exigua, Noctuidae, Lycoperiscon esculentum*, nuclear polyhedrosis virus, chlorogenic acid, rutin, orthodihydroxy phenolics, flavonoids, host-plant resistance, microbial control agents, biological control, antibiosis, tomato, pathogenesis.

INTRODUCTION

It is normally assumed that the use of host-plant resistance (HPR) against insect pests is compatible with the concurrent use of biological control (BC) agents (Adkisson and Dyck, 1980; Bergman and Tingey, 1979; Kogan, 1975), presumably because of the lesser degree of evidence to the contrary (Pimentel and Wheeler, 1973; Starks et al., 1972). This assumption may not be valid in certain instances where HPR is based upon chemical antibiosis. For example, it was suggested that the unwitting use of tomatine in HPR programs against noctuid larvae may be incompatible with the survival of endoparasitoids, as evidenced by the poisoning of the endoparasitic ichneumonid *Hyposoter exiguae* by tomatine (Campbell and Duffey, 1979; Campbell and Duffey, 1981). This potential incompatibility may apply as well to other types of BC agents such as bacteria, fungi, and viruses.

The literature on the compatibility of HPR with microbial control agents is exceptionally meager (Jones, 1983). It has been theorized that the nutritional state of the insect, as well as the type of plant products ingested, can predispose the insect to disease (Price et al., 1980; Schultz, 1983; Vago, 1963; Steinhaus, 1956). The factual evidence to support this contention is usually correlational; however, in several instances the potential of specific natural products to modify the course of disease has been documented. In one case, the leaf resin of a leguminous plant, *Hymenaea courbaril*, was shown to induce mortality in virally infected *Spodoptera exigua* (Stubblebine and Langenheim, 1977). In another instance, the nonprotein amino acid, *L*-canavanine, which occurs in many leguminous plants, was shown to enhance the pathogenicity of *Bacillus thuringiensis* in the hornworm *Manduca sexta* (Felton and Dahlman, 1984). Also, plant-derived caffeic acid and other simple phenolics when ingested by the silkworm, *Bombyx mori*, were shown to have antibacterial activity against the pathogenic *Streptococcus faecalis* (Koike et al., 1979; Iizuka et al., 1974). Additionally, in the gut of *B. mori*, enzymatic degradation of chlorophyll-a leads to a chlorophyll–protein complex which confers antiviral activity against a nuclear polyhedrosis virus (Hayashiya, 1978). In contrast to this, a number of studies have implicated the presence of unidentified antimicrobial substances in the foliage as being responsible for or having the potential to reduce the efficacy of the pathogens (Hare and Andreadis, 1983; Ramoska and Todd, 1985; Kushner and Harvey, 1962; Maksymiuk, 1970; Merdan et al., 1975; Morris, 1972; Smirnoff, 1967).

The tomato plant, *Lycopersicon esculentum*, has a number of natural products that have been implicated in resistance to insects, such as tomatine (Campbell and Duffey, 1981; Juvik and Stevens, 1982; Sinden et al., 1978), proteinase inhibitors (Ryan and Green, 1974; Broadway, *et al.* 1986), and orthodihydroxy phenolics including rutin and chlorogenic acid (Isman and Duffey, 1982a,b). Some of these natural products from *Lycopersicon* are also thought

to contribute to the plant's ability to resist pathogens (Carrasco et al., 1978; Chadha and Brown, 1974; Cleveland and Black, 1983; Matta et al., 1969; Mendez and Brown, 1971; Roddick, 1974; Schlosser, 1977). The ability of natural products to serve as bases of resistance against both insects and pathogens suggest that their use might be highly compatible with integrated pest management. However, since it is possible for plant natural products to inhibit the activity of pathogens against insects, as discussed above, it is also possible that these natural products may be incompatible with the concurrent use of microbial control agents.

In light of the ability of caffeic acid to act antibacterially against the pathogenic bacterium *Streptococcus faecalis* in the gut of *B. mori* (Koike et al., 1979; Iizuka et al., 1974), the possibility of the incompatibility of orthodihydroxy phenolics (rutin and chlorogenic acid) with microbial control agents exists in the tomato systems where these phenolics might be used as a basis of resitance (Isman and Duffey, 1982a,b) against the tomato fruitworm. The ability of some phenolics (rutin and quercetin, as examples) to inhibit infectivity and/or inhibit replication of certain RNA and DNA viruses has been documented (Verma, 1973; Harborne et al., 1975; Beladi et al., 1977). These phenolics have the ability to oxidatively couple with viral protein coats and viral nucleic acids (Pierpoint et al., 1977; Davies et al., 1978; Mink et al., 1966) and modify their properties; therefore, it is reasonable to assume that such oxidative coupling to insect nuclear polyhedrosis viruses (NPVS) may influence the degree of infectivity.

In this present study, we wished to determine the effect of rutin and chlorogenic acid on the infectivity of nuclear polyhedrosis viruses. The antiviral effects of these phytochemicals were assayed under both in vitro and in vivo conditions to assess the potential compatibility of host-plant resistance based on these phenolics with viral control of the tomato fruitworm.

METHODS AND MATERIALS

Cell Line and Culture Media. For the in vitro virus assay, the *Trichoplusia ni* (TN-368) cell line was used and grown under conditions similar to those described by Hink (1970). The tissue culture medium (TCM) contained 90 ml Grace's insect tissue culture medium, 8 ml of fetal bovine serum, 8 ml whole egg ultrafiltrate, 0.5 g bovine albumin, 0.3 g yeastolate, 0.3 g lactalbumin hydrolysate, and 100 μg/ml each of the antibiotics streptomycin sulfate and penicillin.

Virus. The virus used in the in vitro assay was a multiply embedded nuclear polyhedrosis virus (MNPV) originally isolated from *Autographa californica* (Speyer) by Vail et al. (1971) and designated as AcMNPV-13. The AcMNPV-13 polyhedral inclusion bodies (PIB) were produced in *Spodoptera*

exigua (Hübner) larvae. The virus used in the in vivo assay was a singly embedded virus (SNPV) originally isolated from *H. zea* larvae and designated as HzSNPV. The virus was obtained as the commercial formulation Elcar from Sandoz-Wander (Wasco, California).

Insects. Eggs of *Heliothis zea* were obtained from a laboratory colony of Shell Development Company, Modesto, California. Larval *H. zea* were reared in an environmental chamber at 27°C with a 16:8 light–dark photoperiod in 25-well plastic rearing trays obtained from Bio-Serv Inc. (Frenchtown, New Jersey). Larvae were fed semidefined artificial diet (No. 976L3) purchased from Bio-Serv Inc. with streptomycin sulfate (100 ppm) and 5.5% aureomycin (1000 ppm) added as antibiotics. Chlorogenic acid and rutin were purchased from Sigma Chemical Co. (St. Louis, Missouri) and were mixed in the diet at a concentration of 3.5 μmol/g diet on a wet weight basis. This concentration has been found to reduce larval weight gain by approximately 50% compared to larvae fed control diet in a standardized bioassay (Isman and Duffey, 1982b).

In Vitro Assay of Viral Infectivity with MNPV. The in vitro virus assay used was an endpoint titration in Falcon 96-well microtiter plates. The TN-368 cells were used 24 hr after transfer while in the log phase of growth and were diluted to give a concentration of 4.5×10^4 cells/ml TCM. Each well was seeded with 0.2 ml of cell suspension. Nonoccluded virus was diluted by 10-fold or twofold with TCM and was added to the wells at 0.1 ml inoculum/well. Control wells containing TN-368 cells received 0.1 ml of TCM in lieu of the viral inoculum. For each dilution of inoculum, 24 wells or replicates were treated with the virus.

To test the effect of orthodihydroxy phenolics on viral infectivity, rutin or chlorogenic acid was added to the TCM (without cells added) immediately prior to seeding the plates with the TN-368 cells. The control treatment did not contain added phenolics. Then the rutin or chlorogenic acid–TCM mixture was heated to 36°C for 1 hr with stirring, after which the solution was immediately filtered through a sterile 0.22-μm Falcon 150-ml filtration unit. The final concentrations of the two phenolics used in the endpoint titrations were 0.11 and 2.2 μmol/ml TCM for rutin and chlorogenic acid, respectively (as determined by spectroscopy; Pesez and Bartos, 1974). The resulting concentration of rutin was less than that of chlorogenic acid because of the limited solubility of rutin in aqueous medium. The addition of these phytochemicals did not significantly alter the pH of the TCM. Approximately 50% of the cells became melanized by the 5th day in treatments using chlorogenic acid. Additionally, chlorogenic acid when added to the TCM at much higher concentrations than were used in these assays (10×) did inhibit cell growth by approximately 30%. The effect of these phenolics on viral infectivity was determined by endpoint titration as described above for untreated TCM.

The seeded plates were incubated at 27°C for five days, and then each well was checked for the presence of infected cells under an inverted light micro-

scope. The presence of a single infected cell in a well, as determined by the presence of polyhedra, was considered to be a positive response to infection. The median tissue infective dose ($TCID_{50}$) and 95% confidence limits were calculated by the method of Reed and Muench (1938).

In Vivo Assay of Viral Infectivity with SNPV. Larval *H. zea* were reared from neonates in 25-well plastic trays on control diet or diet supplemented with rutin or chlorogenic acid. Approximately 75 μl of the respective artificial diet was added to each well of a Falcon 96-well microtiter plate and a specified dose of HzSNPV in 1 μl of H_2O was added to the diet surface. Controls in each treatment received 1 μl of H_2O in lieu of virus. Newly molted third-instar *H. zea* (ca. 6 hr postecdysis) were then individually placed in the wells of the microtiter plates and parafilm was used to cover the wells to prevent larvae from escape. After 36 hr, larvae that had consumed all of the diet were transferred to 18-ml clear plastic cups containing a surfeit of the respective diet. At least four doses of virus and a control were used in each diet treatment with a minimum of 50 larvae per dose. Mortality was monitored on a daily basis and LD_{50} values for each diet treatment were computed from 10-day mortality figures using a probit analysis procedure developed by the Statistical Analysis System (SAS).

RESULTS

Results from the in vitro assay indicated that chlorogenic acid significantly reduced AcMNPV infectivity in both replicates (Table 1). In the first replicate, the infectivity of the virus was reduced by 70.7% compared to the control, while in the second replicate, an 86.4% reduction in infectivity was observed. In both replicates, the effect of rutin on infectivity (7.1% and 25.0% reduction)

was not significant as determined by an overlap of the 95% confidence limits of the $TCID_{50}$ between rutin and control treatments. The observed differences in antiviral activity between rutin and chlorogenic acid may be due to the differences in their concentrations used in this assay.

Results from the in vivo assay indicate that at viral concentrations below the LD_{50}, larvae fed either rutin or chlorogenic acid were much less sensitive to the virus than larvae fed control diet (Table 2). For example, at a dose of 12 polyhedral inclusion bodies (PIB)/insect, 34% mortality was observed in larvae fed control diet while larvae on rutin or chlorogenic acid diets showed significantly lower ($P < 0.05$ by chi-square analysis) mortalities of 8% and 15.5%, respectively. The LD_{10}s for larvae on rutin- or chlorogenic acid-supplemented diets were respectively 4.21× and 3.66× greater than the control (Table 2). At concentrations above the LD_{50}, the response to rutin was not as significant. For example at the LD_{50}, rutin significantly inhibited HzSNPV infectivity by over 51%, but at the LD_{90} the effect of the virus was statistically similar to the control infected larvae. Although larvae ingesting chlorogenic acid showed decreased sensitivity to HzSNPV at the LD_{50}, the response was not considered significant because of overlapping confidence limits for the LD_{50}s. The LD_{90} for chlorogenic acid-treated larvae was also not significantly different from the controls.

In addition to affecting the relative susceptibility of larval *H. zea* to HzSNPV, ingestion of rutin and chlorogenic acid significantly prolonged the survival time of virally infected larvae (Table 3). For instance, at a dose of 200

Control	6.50
Chlorogenic acid (3.5 μmol/g)	7.14[b]
Rutin (3.5 μmol/g)	7.84[b]

[a] Survival time until death following ingestion of virus.
[b] Significantly different from the control at $P < 0.01$ by Tukey's studentized range test.

PIB/insect, the survival time of infected larvae fed control diet was 6.50 days but was extended to 7.14 and 7.84 days, respectively, in larvae that fed on chlorogenic acid- or rutin-supplemented diet. A significant prolongation of the survival time of infected larvae was observed for each concentration of virus which produced a lethal infection. The survival time of infected larvae was defined as the survival time until death following ingestion of virus in lethally infected larvae. Significant differences between mean survival times were determined by Tukey's studentized range test.

DISCUSSION

We show that both rutin and chlorogenic acid in vivo inhibit the infectivity of a nuclear polyhedrosis virus in larval *H. zea* (Table 2). The effect of both phytochemicals was greatest at low concentrations of viral inoculum. Under field conditions, the occlusion bodies of NPV are inactivated rapidly in ultraviolet light on tomato foliage (Young and Yearian, 1974) and, therefore, larvae would be expected to consume small amounts of inoculum. We predict the effect of ingestion of rutin or chlorogenic acid on viral infectivity would be greatest under natural conditions. Because both phenolics may be involved in host-plant resistance to *H. zea* (Isman and Duffey, 1982a,b), these data suggest a potential incompatibility of host-plant resistance with viral control of *H. zea* in tomatoes under normal field conditions. The concentrations of rutin and chlorogenic acid used in the bioassays (3.5 μmol/g wet weight) are representative of the concentrations that occur in the foliage of many *L. esculentum* varieties (Isman and Duffey, 1982b). For example, the foliar concentration of rutin and chlorogenic acid in the commercial fresh market variety, Castlemart, averaged approximately 3.7 and 3.6 μmol/g wet weight, respectively, during the course of a growing season in 1984 (unpublished data). As a result, the efficacy of HzSNPV as a mortality factor in *Heliothis* populations in tomato ecosystems

may be reduced by the use of varieties of *Lycopersicon* with high rutin and/or chlorogenic acid content.

Additionally, we have preliminary evidence suggesting that these phenolics may adversely affect other parameters of the disease process which may be important in modifying the occurrence and progression of viral epizootics. A short survival time of infected insects and a high rate of production of infective stages are considered important factors in determining the epizootic potential of a pathogen (Anderson and May, 1981). For instance, the survival time of infected larvae was significantly prolonged in larvae feeding upon diets containing either chlorogenic acid or rutin. Also, fewer occlusion bodies containing the infectious virions would be liberated in the environment in larvae consuming orthodihydroxy phenolic-containing diets because of the reduction in the relative numbers and size of infected larvae. This present study points to the necessity of developing a mechanistic understanding of the multitrophic effects of plant natural products before attempting to manipulate their concentrations in planta.

The mechanism(s) by which these phenolics modify the infectivity of nuclear polyhedrosis viruses has not been determined. Chlorogenic acid and rutin are able to bind to the protein coat of certain viruses which may render the virus incapable of initiating infection (Mink, 1965; Pierpoint et al., 1977). Thus, the observed mitigation of infectivity may be due to a reduction in the ability of the virus to attach to host receptor sites and/or due to changes in the solubility of the viral matrix protein in the midgut of the host. Moreover, these phenolics may directly inactivate the virions. Following uncoating of the virus within the midgut epithelial cells and the subsequent release of viral DNA, the viral nucleic acid may be susceptible to modification by these phenolics (Mink, 1965).

Because both chlorogenic acid and rutin are ubiquitous in occurrence among plant species (Harborne et al., 1975; Harborne, 1973) and are thus an adventitious dietary component of many herbivorous insects, the results from this study may have broad implications to the study of insect–plant interactions. It is reasonable to assume that the ingestion of these phytochemicals by lepidopterous insects may offer some protection from viral infections and may even affect the occurrence of viral epizootics in larval populations. This study emphasizes the necessity of considering pathogenicity and host-plant resistance not as two component systems, but instead as a three-component system, namely the interactions of plant–insect–pathogen. The role of the host-plant, particularly phytochemicals, in the epizootiology of insect disease is in need of further investigation.

(Received April 22, 1986; accepted June 9, 1986)

Abstract—During the summers of 1984 and 1985, a variety of structurally related benzenoid compounds was evaluated in sweet corn plots as attractants for adult southern corn rootworms (SCR), western corn rootworms (WCR), and northern corn rootworms (NCR). Field response to the volatiles was measured by beetle counts on baited cylindrical sticky traps placed inside the corn plots at a height of 1 m above ground level. SCR adults were attracted late in the season (last week of August through September, 1984 and 1985) to numerous aromatic compounds, including phenylacetaldehyde, benzyl acetone, phenethyl alcohol, phenyl acetate, indole, veratrole, methyl eugenol, methyl isoeugenol, eugenol, and isoeugenol. Although many compounds attracted SCR adults late in the season, only veratrole, phenylacetaldehyde, and chavicol were significantly active in early and middle August 1985. WCR adults were attracted to a different group of compounds, namely estragole, *trans*-anethole, and indole. Estragole (4-methoxy-l-allylbenzene) was an effective WCR attractant from corn tasseling in early August 1985, until the end of the trapping period in late September and early October 1985. Indole and *trans*-anethole (4-methoxy-l-propenylbenzene) were less effective attractants than estragole and were most active at the beginning and/or end of the corn season. Traps baited with 100 mg of estragole caught an average of 20 times more WCR adults than unbaited control traps, and the females outnumbered the males in the baited traps. Estragole dosage tests were conducted in three sweet corn plots on different dates in 1985 and the minimum effective dose ranged between 5 and 30 mg/trap. Field tests with structural analogs revealed the importance of the site of unsaturation in the allylic side chain of

0098-0331/87/0400-0959$05.00/0 © 1987 Plenum Publishing Corporation

estragole and the effect of different ring substituents on WCR response. The phenylpropanoids, eugenol and isoeugenol, significantly attracted NCR adults, even though these beetles were in low abundance in the test corn plots. Field tests indicate there is no cross-species response by WCR and NCR adults to their related phenylpropanoid attractants. However, in late August, SCR adults do respond to some WCR and NCR attractants (indole and several eugenol analogs). Electroantennographic analysis of SCR males revealed they can perceive peripherally a wide range of benzenoid compounds.

Key Words—*Diabrotica*, Coleoptera, Chrysomelidae, western corn rootworm, southern corn rootworm, northern corn rootworm, attractants, semiochemicals, veratrole, estragole, *trans*-anethole, indole, eugenol, phenylacetaldehyde.

INTRODUCTION

Larvae and adults of the northern corn rootworm (NCR), *Diabrotica barberi* Smith and Lawrence, and the western corn rootworm (WCR), *D. virgifera virgifera* LeConte, are serious root and silk pests of field and sweet corn in the corn belt. The univoltine NCR and WCR overwinter as diapausing eggs in North America and the oligophagous larvae develop only on the roots of grasses (Poaceae), primarily corn (Branson and Krysan, 1981; Branson and Ortman, 1967, 1971; Smith, 1966). In contrast to these two *Diabrotica* species, the multivoltine southern corn rootworm (SCR) = spotted cucumber beetle, *D. undecimpunctata howardi* Barber, overwinters in southern areas as an adult, annually reinvades the Midwest, and both larvae and adults are polyphagous (Smith, 1966; Branson et al., 1978). SCR bettles are pests of cucurbits, peanuts, corn, and a variety of vegetable and field crops (Campbell and Emery, 1967).

Although the New World diabroticites (Chrysomelidae: Galerucinae: Luperini: Diabroticina) have greatly expanded their host distribution and range from their origins, they apparently retain an ancestral compulsive feeding response to the bitter-tasting cucurbitacins found in the cotyledons, foliage, fruit, and flowers of many species of the Cucurbitaceae (Chambliss and Jones, 1966; Sharma and Hall, 1973; Howe and Rhodes, 1976; Metcalf et al., 1982; Ferguson et al., 1983; Andersen, 1984). Cucurbitacins are undoubtedly potent kairomones for the diabroticites, as well as potent allomones for many other herbivores and for some diabroticite predators (Metcalf, 1979; Tallamy, 1985; Ferguson and Metcalf, 1985), yet their high molecular weights and low vapor pressures make them ineffective as volatile semiochemicals (Branson and Guss, 1983).

Considerable progress has been made recently in understanding *Diabrotica* response to volatile attractants. The sex pheromone of WCR virgin females, 8-methyl-2-decyl propanoate, attracts both WCR and NCR males; however, the

two species demonstrate temporal differences in response and high doses of the racemic synthetic mixture inhibits NCR response (Guss et al., 1982, 1985). SCR females release 10-methyl-2-tridecanone and the *R* enantiomer is the most active attractant for male SCR and *D. u. undecimpunctata*, the western spotted cucumber beetle (Guss et al., 1983). Furthermore, the nonpheromonal phenylpropanoids eugenol, isoeugenol, and 2-methoxy-4-propylphenol strongly attract NCR adults, whereas WCR adults do not respond to these compounds (Ladd et al., 1983; Ladd, 1984). Andersen and Metcalf (1986) isolated the shikimic acid derivative indole from the male blossoms of *Cucurbita maxima* cultivars, where *Diabrotica* and *Acalymma* adults often congregate in large numbers, and found adult WCR and striped cucumber beetles, *Acalymma vittatum* (Fabr.), are attracted early and late in the season to as little as 5 mg of indole. Although indole is clearly a kairomonal attractant of WCR adults, a host-plant relationship has not been established in the literature for the attractants of NCR adults (Ladd, 1984).

During the summers of 1984 and 1985, we investigated the response of WCR, SCR, and NCR adults to a wide variety of benzenoid compounds using baited, one-quart (0.95-liter) white cylindrical sticky traps in sweet corn plots. Chemical analogs of attractive compounds were used to determine the specificity of response by the corn rootworm species. This report summarizes the data obtained with more than 20 aromatic compounds, many of which have been detected in corn or cucurbits (Buttery et al., 1978, 1980, 1982; Andersen, 1984). A preliminary electroantennographic (EAG) study with SCR males evaluates their response to several benzenoid compounds.

METHODS AND MATERIALS

Field Tests. During the summers of 1984 and 1985, various volatile compounds were evaluated for corn rootworm attraction on the South Farms of the University of Illinois in Urbana, Illinois. In 1984, tests were conducted in a single sweet corn plot which measured 52 × 22 m with eight rows each of cultivars, "Florida Stay Sweet" and "Gold Cup." The corn plot was bordered on one side by a grass lane and on the other side by a cucurbit plot. The adjacent cucurbit plot included several common squash varieties (predominantly *Cucurbita maxima* cv. "Blue Hubbard"), as well as high cucurbitacin-containing species and hybrids (*Cucurbita andreana, C. texana,* and *C. andereana* × *C. maxima* hybrids) (Rhodes et al., 1980). Large numbers of SCR adults (>20,000 beetles) aggregated on the leaves, blossoms, and fruits of the bitter cucurbits and "Blue Hubbard" cultivar in 1984 and 1985. In both years, SCR adults were ca. 10–20 times more abundant than WCR and *A. vittatum* adults during the test period. The experimental design for the main plot used in 1985 was essentially the same as in 1984, except the corn was a monoculture of 20 rows

of cultivar "Illini Xtra Sweet." Tests were also conducted in 1985 in two non-adjacent sweet corn plots located approximately 150 m and 250 m from the main plot. These auxilliary plots were not adjacent to any cucurbits and WCR adults were the predominant rootworm species present.

The 1984 test plot was planted on June 12 and initial tests were conducted in late August after tasseling. After the first frost (last week of September 1984), field tests were discontinued. In 1985, trapping began in mid-July, before tasseling, and continued until the corn foliage was totally dry in late September. The two auxiliary sweet corn plots were used to test WCR attractants and were planted approximately two and four weeks, respectively, after the main plot (June 6, 1985) and were used until the first week of October. Pretest whole-plant counts were taken every other week in the main plot and once in the two auxiliary plots by counting beetles in the rows used for testing treatments.

All compounds tested, except two, were from commercial sources and verified as being ≥95% pure by gas chromatographic analysis. Chavicol (4-hydroxy-l-allylbenzene) was prepared (R.L.M.) by the method of Buu-Hoi et al. (1954) and 4-methoxy-l-propylbenzene by reacting the sodium salt of 4-propylphenol with dimethyl sulfate. The products were glass distilled and purity and identity confirmed by boiling points, infrared analysis, and gas chromatography–mass spectrometry. Compounds were field tested for attraction of rootworms by treating dental cotton wicks with 200 mg or less of each compound (see Tables). In order to prolong volatilization of the treatment compound, the wicks (ca. 15 mm long × 6 mm diameter) were soaked in polyethylene glycol and the excess squeezed out prior to treatment with each test compound. The treated wicks were attached to the tops of one-quart (0.95-liter) white paper cartons, similar to those described by Hein and Tollefson (1984). The paper cartons were 15.2 cm high and had a circumference of 27.9 cm and were evenly coated with clear Tangletrap® in the field. The baited sticky traps were placed in the corn plots in the early afternoon (1–4 PM) and beetle counts were taken periodically for one to three days.

In 1984, the traps were placed ca. 1 m high by breaking off the corn stalk at ear level and placing the hollow carton trap on top of the stalk. In 1985, the traps were placed in corn rows on 1 m-high wood stakes. In both years, the baited traps were arranged in a randomized complete block design with treatments 3 to 5 m apart and blocks 2 to 3 m apart, depending on the number of compounds and replicates in a test. Results were analyzed by an ANOVA program and, in the case of multiple comparisons, means were separated by Duncan's multiple-range test with significance levels set at $P = 0.05$ (Nie et al., 1975).

Electroantennographic Analysis. Several SCR attractants with variable field activity were selected for EAG analysis (see Table 4 for a list of compounds). Antennae of male SCR adults were excised at the head following removal of the distal segment. The antennae were placed between two glass capillaries

filled with 0.9% NaCl solution. Silver–silver chloride wires were used as electrodes and connected by shielded leads to a Grass P-18 preamplifier. Sample compounds were dissolved in paraffin oil (Fisher) at 100- and 1000-fold dilutions, and filter paper triangles were impregnated with 5 μl of each solution. The treated triangles were then inserted into Pasteur pipets and a glass syringe used to pass 0.4 ml of air through the pipet into a charcoal-filtered airstream (100 ml of air per minute) which flowed over the beetle antennae. Since EAG response diminishes through time, the response of the antenna to each treatment is expressed as a percent relative response in comparison to a standard compound (*cis*-3-hexen-l-ol) at a 1 : 100 dilution in paraffin oil (similar to that used by Visser, 1979). Six replicates were conducted for each compound at both dilutions, and the laboratory-reared beetles ranged in age from 2 to 4 weeks postemergence. Each treatment was compared to the control by a single-classification ANOVA (Sokal and Rohlf, 1969).

RESULTS

SCR Attractants. In the first field test, August 28, 1984, the mean 24-hr trap catches (± standard error) for phenylacetaldehyde (PAA), indole, eugenol, and control traps were 238.0 ± 14.5, 95.8 ± 3.3, 55.5 ± 5.9, and 16.0 ± 2.6 SCR adults per trap, respectively (N = 6; dosage = 200 mg/trap). All three treatments were significant attractants; however, PAA traps significantly attracted 2.5 and 4.3 times more SCR adults than indole- and eugenol-baited traps. The downwind surface of all baited traps had the greatest concentration of beetles, suggesting an anemotactic response by the insects. Since a pretest whole-plant count in the corn plot yielded a mean (± standard error) of 3.0 ± 0.4 SCR adults per corn stalk (N = 50), the ca. 1500 beetles captured on the six PAA traps were more than could have been present on the surrounding corn stalks. In fact, SCR adults were often observed, in both years, flying from the adjacent cucurbit plot into the corn plot and orienting to the treated traps from several meters downwind.

Since PAA was such an active semiochemical for SCR adults, structurally related compounds were evaluated in the same corn plot over a 4-hr period for potential activity (September 9, 1984) (Table 1). Although PAA-baited traps had the highest mean trap catch, ca. 8 times greater than the control traps, they were not significantly more attractive to SCR adults than benzyl acetone-baited traps. Phenethyl alcohol and benzyl acetate were significantly less active than PAA-baited traps; however, both compounds were still 5.6 and 3.9 times more attractive, respectively, than controls. The structural similarity of these active compounds suggests that they may interact with the same sensory receptors. A substantial decrease in SCR attraction was observed between compounds which differed only by one carbon and two hydrogens. For example, PAA traps were

6.6 times more attractive than benzaldehyde traps; phenethyl alcohol traps, 1.7 times more than benzyl alcohol traps; and phenyl acetate traps, 1.6 times more than benzyl acetate-baited traps.

Eugenol-related compounds were also investigated (Table 2) in 1984. This evaluation was conducted in mid-September and SCR activity was reduced due to lower day and night temperatures (compare controls in Tables 1 and 2). The 24-hr mean beetle catches of veratrole-, isoeugenol-, methyl isoeugenol-, and methyl eugenol-baited traps were significantly greater than the control beetle catch. Veratrole (orthodimethoxybenzene) consistently attracted more beetles than the other compounds in this series; however, the metadimethoxybenzene and paradimethoxybenzene isomers of veratrole were not significantly different from the control trap catch. This indicates the ortho ring position of the methoxy groups is important for activity. Eugenol and indole had higher mean trap catches than controls in this test but were not significantly different from controls. Apparently, the propenylbenzenoid compounds are slightly more attractive than the allylbenzenoid compounds (Table 2).

Field tests with SCR adults were discontinued in late September 1984 after the first frost. In 1985, veratrole- and PAA-baited traps were reevaluated in the main corn plot from July 18 to September 13. Veratrole-baited traps attracted

[c] Means followed by the same letter are not significantly different at the 5% level by Duncan's multiple-range test.

an average of two times more SCR adults than PAA traps and eight times more than control traps (Table 3). Initial baited trap catches of beetles in 1985 were much lower than the late season beetle catches in 1984; however, trap catches dramatically increased at the end of August and early September for both treatments and controls (in Table 3 compare mean trap catches from July 18 to August 13 to those from August 25 to September 13).

Analysis of the 1985 data by two-way ANOVA (blocks versus treatments) yielded significantly different block mean squares for SCR trap catches in all late-August and September tests; therefore, there was a substantial field effect. The beetle trap catches in the main plot were 3–10 times greater in the block closest to the cucurbit plot than the trap catches in the other blocks. The whole-plant count in the corn plot on August 20 revealed there were 4.9 ± 0.54 SCR adults per stalk (mean ± standard error, $N = 20$) on the cucurbit side of the plot and 1.5 ± 0.36 SCR per stalk ($N = 20$) on the opposite, open field side of the plot. Within a four-day period from August 16 to August 20, the whole-plant count doubled. Mean (± standard error) whole-plant counts in 1985 were 0.1 ± 0.05 (July 23, $N = 79$), 0.7 ± 0.12 (August 7, $N = 70$), 1.5 ± 0.16

TABLE 3. MEAN TRAP CATCH OF SOUTHERN CORN ROOTWORM ADULTS ON STICKY TRAPS BAITED WITH VERATROLE AND PHENYLACETALDEHYDE (PAA)

		Treatment		
Date (1985)	Dose (mg)/trap	Veratrole	PAA	Control
July 18	100	5.00 ± 0.71a[a]	1.00 ± 0.41b	0 ± 0 c
August 2	100	6.75 ± 3.28a	2.50 ± 0.96b	0.75 ± 0.25c

[b]Compound not tested on that date.

(August 16, $N = 54$), and 3.2 ± 0.28 (August 20, $N = 40$) SCR adults per stalk. The field effect and late season increase in SCR trap catches was apparently the result of an increase in SCR dispersal from the cucurbit plot into the corn test plot.

Other field tests conducted in August 1985 showed chavicol (4-hydroxy-l-allylbenzene) also significantly attracted SCR adults (Table 5). Related compounds like estragole (4-methoxy-l-allylbenzene), *trans*-anethole (4-methoxy-l-propenylbenzene), and 4-methoxy-l-propylbenzene, as well as several eugenol-related compounds, were not significant attractants of SCR adults in early and mid-August, 1985. However, the late August and September results in the main plot were similar to those obtained in 1984, with eugenol, isoeugenol, PAA, veratrole, and indole having significantly greater trap catches than controls. SCR trap catch increases late in the season and previously unattractive compounds become significant attractants. This suggests SCR adults in central Illinois exhibit an enhanced response to volatiles in late August and early September.

Electroantennograms of SCR Males. The relative EAG response (compared to *cis*-3-hexen-l-ol) for male SCR was determined for several aromatic compounds (Table 4). Males were used for the EAG analysis since they often outnumber females in high cucurbitacin-containing cucurbit plots (Andersen, 1981), and our plot was adjacent to such a cucurbit plot. The EAG response to indole, phenethyl alcohol, PAA, benzyl acetate, benzyl acetone, eugenol, and veratrole, at 100- and 1000-fold dilutions in mineral oil, was seven or more times greater than that of control air puffs. Indole, phenethyl alcohol, and PAA had EAG responses 20–40 times greater than that of the control. This indicates

[b]Mean response ± SD; $N = 6$.

SCR males are able to perceive peripherally a wide variety of aromatic compounds. Although all the compounds evaluated yielded significant responses, veratrole, one of the most active field attractants, had the lowest EAG response, and indole, a moderately active field attractant, had the highest EAG response.

WCR Attractants. In a late season experiment, October 7, 1984, *trans*-anethole- and indole-baited traps significantly attracted WCR adults; therefore, these and related compounds were intensively evaluated in 1985. Estragole (4-methoxy-l-allylbenzene), a structural analog of *trans*-anethole (4-methoxy-l-propenylbenzene), was the most active WCR attractant throughout the 1985 field evaluation of volatiles. Estragole was initially tested in the main plot on August 9, 1985, approximately one week after the sweet corn tassels had started to shed pollen. The treated (100 mg) mean trap catch (± standard error) was 34.25 ± 6.86 and the control, 1.5 ± 0.65 WCR adults per trap per 24 hr ($N = 4$). The test was replicated on August 11, and estragole traps had ca. 40 times more WCR adults than control traps (estragole, 32.5 ± 6.60 WCR per trap and control, 0.8 ± 0.96 WCR per trap per 24 hr; $N = 4$). Fifty WCR adults per trap were removed 48 hr later (August 13) and sexed in the laboratory. The estragole traps had sex ratios (female–male) of 4.3 : 1, 1.4 : 1, 2.1 : 1, and 4.1 : 1; a mean sex ratio of 2.98 females to 1.0 male per trap. Whether the predominance of females reflected field, chemical, or trap bias was not determined.

Estragole (100 mg/trap) and control traps were also tested in the main plot on August 16 and 28 and September 3, 1985, with mean trap catches (± standard error) of 23.4 ± 2.93, 31.0 ± 6.94, and 7.25 ± 2.53 WCR per trap per

24 hr for estragole-baited traps and 3.5 ± 0.65, 2.25 ± 0.75, and 1.5 ± 0.50 WCR per trap per 24 hr for control traps ($N = 4$ for each trap date). On all dates, estragole was significantly different from controls ($P < 0.05$) by single classification ANOVA. Whole-plant counts in the main corn plot yielded means (± standard errors) of 2.1 ± 0.22 (August 7, $N = 54$), 0.8 ± 0.15 (August 16, $N = 37$), and 0.5 ± 0.07 (August 28, $N = 45$) WCR per stalk. Although the WCR population decreased throughout August (unlike the SCR population), estragole traps consistently attracted WCR adults.

The attraction of WCR adults to estragole and several phenylpropanoid compounds was investigated in the main plot on August 9 and August 16, 1985 (Table 5). Estragole trap catches were 3.64 ± 0.90 (mean ± standard error) times greater than that of the propenyl isomer *trans*-anethole and 4.6 ± 1.50 times greater than the propyl analog, 4-methoxy-l-propyl-benzene (MPB) ($N =$ 28 for the estragole–anethole comparison). Furthermore, estragole with a para-methoxy ring substituent was eight times more attractive to WCR adults than chavicol, an estragole analog with a parahydroxy ring substiutent (see Table 5). Other allyl and propenyl compounds, such as eugenol, methyl eugenol, isoeugenol, and methyl isoeugenol, as well as veratrole and PAA, were not significantly different from control WCR trap catches. WCR attraction to estragole is characterized by a highly specific structure–activity relationship; the position of the double bond and the methoxy ring substituent are critical for activity.

A nitrogen containing phenylpropanoid derivative, indole, was attractive to WCR adults early and late in the test period. On July 18, 1985, in the main plot prior to corn tasseling, indole (100 mg/trap) attracted a mean (± standard error) of 10.8 ± 5.57 WCR per trap per 48 hr compared to a control trap catch of 4.0 ± 0.82 WCR per trap per 48 hr, ($N = 4$). After this test (August 2, 13, and 16, 1985), indole was not significantly different from controls until August 23, 1985 (indole traps, 8.8 ± 2.87 WCR per trap per 24 hr and control traps, 1.5 ± 1.00 WCR per trap per 24 hours; $N = 4$). When indole (20 mg/trap) was tested on September 28, 1985 in the auxiliary plot 250 m from the main plot, 22.0 ± 8.29 WCR were caught per trap per 24 hr versus a control of 2.8 ± 2.36 WCR per trap per 24 hr. The early and late season attraction of WCR adults by indole agrees with the results of Andersen and Metcalf (1986).

Dosage–activity tests with estragole were conducted in all three experimental plots on different dates (Table 6). In the auxiliary field 150 m from the main plot, the minimum dose per trap which significantly attracted WCR adults was 5 mg, and the highest dose, 100 mg/trap, attracted ca. 31 times more beetles than the control (tested from August 20 to 22, 1985). In the main plot the minimum effective dose was 30 mg and the highest dose, 100 mg/trap, attracted 18 times more beetles than the control (tested from August 28 to 30, 1985). In the plot 250 m from the main experimental plot, the minimum effective dose was 10 mg and the highest dose, 30 mg/trap, attracted four times more WCR adults than the control (tested from September 19 to 20, 1985). In the last dos-

age test, the 24-hr control trap catch was ca. 10 times greater than the 48-hr control trap catches in the two previous tests. Since this field was planted one month after the main plot, it had the only fresh host available in the test area on that date. The high pretest whole-plant count (Table 6) suggests beetles were attracted to this field.

NCR Attractants. Northern corn rootworms were significantly attracted to eugenol- and isoeugenol-baited traps in mid-August (Table 5), with eugenol-baited traps having a higher mean trap catch than the isoeugenol baited traps. A pretest whole-plant count found only one NCR per 45 stalks, and the control traps caught no NCR adults; therefore, both compounds must be very active attractants. In the auxiliary plot 250 m from the main plot, 10 mg eugenol-baited traps had a mean (± standard error) of 3.8 ± 2.06 NCR per trap per 24 hr and 30 mg eugenol-baited traps, 8.0 ± 0.82 NCR per trap per 24 hr, with control trap catch of 0.8 ± 0.96 NCR per trap per 24 hr ($N = 4$, tested on September 19, 1985). None of the related compounds, such as estragole, anethole, chavicol, 4-methoxy-l-propylbenzene, methyl eugenol, methyl isoeugenol, or safrole significantly attracted NCR adults. Veratrole and PAA, the two major SCR attractants, also did not attract NCR adults. The results of this study in-

dicate both the methoxy and hydroxy ring substituents and the propanoid side chain in eugenol and isoeugenol are critical for NCR attraction, which agrees with the results of Ladd (1984).

DISCUSSION

Southern, western, and northern corn rootworm adults exhibited a species-specific pattern of response to sticky traps baited with various benzenoid compounds. Southern corn rootworm (SCR) adults were attracted in early and mid-August to traps baited with veratrole (1,2-dimethoxybenzene), phenylacetaldehyde, and chavicol (4-hydroxy-1-allylbenzene). In late August and September, 1984 and 1985, SCR trap catches dramatically increased for veratrole and phenylacetaldehyde, as well as for some previously unattractive compounds, such as indole, several eugenol-related compounds, benzyl acetone, and phenethyl alcohol. The rapid change in trap catch was at least partially due to an increase in SCR beetles dispersing from an adjacent cucurbit plot into the sweet corn test plot. Environmental conditions and/or host quality in mid- to late August apparently enhanced SCR response to volatiles. Regardless of the seasonal variability in beetle response, SCR adults demonstrated a relatively specific structure–activity relationship for veratrole and phenylacetaldehyde, since closely related compounds were always less attractive to beetles. An electroantennographic analysis (EAG) of SCR males revealed the beetles can perceive peripherally a variety of benzenoid compounds; however, the level of EAG response did not reflect the magnitude of field response. Subsequent field tests indicate that indole, which yielded a high EAG response but low field response, interacts synergistically with veratrole which had a low EAG response, but a high field attraction of beetles (unpublished data). A more detailed EAG analysis of all three *Diabrotica* species with single compounds and mixtures is in progress to determine whether species differences in field attraction to volatiles can be related to different characteristics of the EAG response.

Western corn rootworm (WCR) adults were significantly attracted to the phenylpropanoid estragole in three nonadjacent corn plots from early August to the end of the trapping period in late September 1985. In the main experimental plot WCR trap catches with 100 mg of estragole per trap were ca. 20 times greater than that of blank controls, and the minimum amount of estragole resulting in a significant trap catch was 5 mg/trap. Furthermore, estragole attracted more females than males, comparable to the results recorded by Ladd et al. (1985) for eugenol and NCR adults. The paramethoxy ring substituent and the position of the double bond in the propanoid side chain are critical for maximum WCR response; compounds differing in either aspect were less attractive. For example, estragole caught an average of 3.6 times more beetles than its structural analog *trans*-anethole. Despite the specificity of estragole for

WCR attraction, another shikimic acid derivitive, indole, was active early and late in the season. Andersen and Metcalf (1986) had previously noted that indole showed a decrease in activity during corn tasseling and silking, which may reflect multiple sensory cues from the corn plants outcompeting the attraction to single-component traps or it may indicate a seasonal change in beetle response to volatiles. A greatly enhanced response to volatiles, comparable to that of the SCR adults under the late season conditions, was not recorded for WCR adults.

Northern corn rootworm (NCR) adults were relatively rare in this test; control trap catches never exceeded one to two beetles per trap, and the mean number of NCR per plant was typically less than 0.1 adult throughout the season in all plots. Despite the low bettle population, eugenol and isoeugenol were significant attractants and 10 mg of eugenol per trap caught a significant number of beetles. None of the other test compounds, such as estragole, *trans*-anethole, chavicol, and 4-methoxy-1-propylbenzene, attracted NCR adults. Ladd (1984) found NCR response is optimal for phenylpropanoids with a metamethoxy and parahydroxy substituent. In our study conducted in mid-August using 100 mg/trap, more NCR adults were attracted to eugenol, an allylbenzenoid, then isoeugenol, a propenylbenzenoid, analogous to the greater attraction of estragole to WCR adults than *trans*-anethole. Ladd (1984), using 1500 mg/trap, found NCR attraction to isoeugenol was 1.6 times greater than eugenol in early August, roughly equivalent in mid-August, and the results reversed in late August. NCR adults apparently display a seasonal change in response to attractants similar to that previously discussed for SCR and WCR adults in this study. Whether this seasonal variability in beetle response to volatiles is due to changes in the environment, host plant, and/or beetle biology is undetermined.

A comparison between the rootworm species indicates the ecologically similar NCR and WCR adults are attracted to structurally related phenylpropanoids and both species respond to changes in the ring substituents of the major attractants. However, WCR and NCR adults are not attracted to the same phenylpropanoids, although SCR adults are occasionally attracted to indole, a WCR attractant, and eugenol and isoeugenol, NCR attractants. An increase in SCR trap catch has also been recorded for either eugenol or veratrole added to insecticide-impregnated cucurbitacin baits (unpublished data). Apparently, SCR adults cross-respond (especially late in the season) to some WCR and NCR attractants, although the main attractants for each species is highly specific.

Perhaps one of the most intriguing aspects about the newly described *Diabrotica* semiochemicals is the establishment of an allelochemical basis for their activity. Indole has been isolated from natural aggregation sites, cucurbit blossoms, as well as corn whorls (Andersen and Metcalf, 1986; Thompson et al., 1974). The major SCR attractants, veratrole and phenylacetaldehyde, are present in corn husk and silk volatiles (Cantelo and Jacobson, 1979b; Buttery et al., 1978), and phenylacetaldehyde and several di- and trimethoxybenzenes have

been detected in *Cucurbita maxima* blossoms (Andersen, 1984). The presence of veratrole, phenylacetaldehyde, and indole in larval or adult host plants suggests they act as kairomonal attractants. Other NCR, WCR, and SCR attractants (such as eugenol, isoeugenol, estragole, and *trans*-anethole) have not been described from the essential oils of the primary larval host, *Zea mays*, or cucurbits (Thompson et al., 1974; Flath et al., 1978; Buttery et al., 1980; Buttery and Ling, 1984; Andersen, 1984). However, vinyl guiacol, which is structurally similar to eugenol and isoeugenol, has been isolated from corn husks (Buttery et al., 1978).

Ladd et al. (1983) originally described eugenol as a "food-type" attractant present in a number of alternative NCR adult hosts. SCR and NCR adults are often found on composites, grasses, legumes, and cucurbits not adjacent to corn, especially late in the season, whereas WCR adults are considered to have a closer association with corn and weeds in the immediate area (Cinerski and Chang, 1968; Ludwig and Hill, 1975; Branson and Krysan, 1981; Rhodes et al., 1980; Messina and Root, 1980; Sholes, 1984). In Illinois, NCR, SCR, and *D. cristata* are often found feeding on the pollen in flower heads of Canada thistle (*Carduus arversis*), white heath aster (*Aster pilosis*), goldenrod (*Solidago* spp.), and sunflowers (*Helianthus* spp.) in late August and September (personal observation). Since eugenol and phenylacetaldehyde are volatile constitutents of sunflowers (Etievant et al., 1984), these phenylpropanoids may be the cues SCR and NCR adults utilize to locate pollen sources. This would suggest that eugenol and/or phenylacetaldehyde may also attract *D. cristata*, as it is occasionally found on the same plant species. It also suggests the other pollen hosts previously mentioned may release volatile compounds that attract Diabroticites. Phenylacetaldehyde, which attracts numerous Lepidoptera, Diptera, Coleoptera, and Hymenoptera and which is widely distributed among the plant families, may act as a general insect attractant to numerous pollen or nectar sources (Cantelo and Jacobson, 1979a,b, references therein, and unpublished data). The major WCR attractant, estragole, has not been detected in cucurbits, corn, or any of the aforementioned wildflowers; therefore, a host-plant relationship remains to be established.

Acknowledgments—This research was supported in part by a grant from the SEA, USDA Competitive Research Grant Office, 81-CRCR-01-0659; "Kairomones in corn and cucurbits in monitoring and controlling corn rootworms." Any opinions, findings, conclusions, or recommendations are those of the authors and do not necessarily reflect the view of the USDA. We would like to thank Phil Lewis for his valuable field assistance and Drs. Berenbaum and Ferguson for their criticisms of this manuscript. We would like to thank Lavella Whited for typing numerous drafts of this manuscript.

SEX PHEROMONE OF ORIENTAL ARMYWORM *Mythimna separata* WALKER

ZHU PINGCHOU, KONG FANLEI, and YU YONGQING

Jiangsu Institute of Pheromones
Jintan, Jiangsu, China

(Received November 5, 1985; accepted April 4, 1986)

Abstract—In the mainland of China, the male Oriental armyworm was not attracted to the sex pheromone components (Z)-11-hexadecenyl acetate and (Z)-11-hexadecenol identified by Takahashi et al. in 1979. By means of EAG, GC, and GC-MS techniques, (Z)-11-hexadecenal, hexadecenal, and (Z)-11-hexadecenol were found in female gland washings, and encouraging captures were obtained in preliminary field trapping.

Key Words—Sex pheromone, *Mythimna separata,* Lepidoptera, Noctuidae, 11-hexadecenal, hexadecenal, 11-hexadecenol.

INTRODUCTION

The sex pheromone of the female Oriental armyworm (*Mythimna separata* Walker) was identified as a blend of (Z)-11-hexadecenyl acetate (Z11–16:Ac) and (Z)-11-hexadecenol (Z11–16:OH) with a ratio of 8:1 by Takahashi et al. (1979). The activity of this pheromone composition had been reexamined in the island of Taiwan (Lin et al., 1983), but few males were caught on the mainland of China with pheromone component ratios ranging from 9:1 to 1:9. Field screening tests using compounds of "one structure change" (Steck et al., 1982) from Z11-16:Ac indicated that (Z)-11-hexadecenal (Z11–16:Ald) is an attractant. Occurrence of pheromone polymorphism or different species was assumed, and the chemical constituents of the sex pheromone of the Oriental armyworm in mainland China was investigated.

METHODS AND MATERIALS

Extraction of Pheromone. Laboratory-reared and emerged females were fed on 10% honey solution for seven days, and then the abdominal tips were

0098-0331/87/0500-0977$05.00/0 © 1987 Plenum Publishing Corporation

excised at 2 or 3 AM. The glands were soaked twice in methylene chloride, 20 min for the first portion and 4 hr for the second. The extracts were combined for structure identification.

TLC Separation. The extract of 50 FE was concentrated and dropped onto silica gel plates of 0.2 mm thick. After developing with *n*-hexane–ethyl ether (4:1), the adsorbate was cut into seven fractions, followed by washing with ethyl ether. Twenty FE of the washing concentrates were used for EAG assay, and two active fractions were selected for structure identification.

Structure Identification. Electroantennograms were obtained by Ag–AgCl electrodes with antennae plucked from laboratory-reared males three days after emerging. Preliminary GC analysis was conducted on a Shimadzu GC-RIA chromatograph with polar or nonpolar glass columns and a hydrogen flame detector. GC-MS analysis was conducted on a Finnigan-MAT 4510 quadrupole mass spectrometer with EI source or methane CI source at 0.86 torr. Ozonolysis procedures described by Beroza and Bierl (1967) were used to locate double bonds. Geometrical configuration of active component was examined on a GC capillary column by comparison with synthetic isomers. Chromatographic conditions are shown in Table 1.

Field Trapping. Preliminary field trappings were carried out in Jintan (first flight, March 29–April 23, 1984) and Beijing (second flight, June 2–15, 1984). Water basin traps were used, and chemicals synthesized at the institute were applied to rubber septa as dispensers with a dosage of 100 μg, which were not renewed throughout the test period. Three replicates were arranged for each treatment.

RESULTS AND DISCUSSION

Fractions of R_f 0.52–0.71 corresponding to long-chain aldehydes with an EAG response of 1.8 mV, and of R_f 0.10–0.23 corresponding to long-chain alcohols with an EAG response of 0.7 mV were selected by TLC separation.

Identification of Aldehyde Fraction. The retention time of the aldehyde fraction was coincident with that of Z11–16:Ald on columns A, B, and C (see Table 1) in a preliminary GC test. In GC-MS with EI source, a major peak (peak 1) of 16 min 16 sec and a less remarkable one (peak 2) of 17 min 4 sec were eluted. The fragment ions and their abundances in the mass spectrum of peak 1 were identical with those of synthetic Z11–16:Ald, but the molecular ion *m/e* 238 and the characteristic ion 220 were not detected. For further confirmation, a concentrated sample with a larger amount was introduced, and methane CI source at 0.86 torr was used. The ions *m/e* 239 (MH^+), 238 (M^+), 237 (M−1), 221 (MH−18), and 267 (M+29), which occurred in the mass spectrum of peak 1 indicated that a straight-chain hexadecenal is the active component. The ions *m/e* 241 (MH^+), 239 (M−1), 223 (MH−18), and 269

TABLE 1. CHROMATOGRAPHIC CONDITIONS

Sample	Column	Temperature	Carrier gas
Preliminary test A	2.3 m × 2 mm, 2% CHDMS, 101 White support	150° 3 min, 2°/min to 170°	26 ml/min N_2

TABLE 2. FIELD TRAPPING OF FIRST FLIGHT ARMYWORM[a]

Compound	Ratio	Total captures per trap
Z11-16:Ald		471
Z11-16:Ald + 16:Ald	3:1	392
	10:1	284
Z11-16:Ald + Z11-16:OH	3:1	118
	10:1	149

[a] March 29–April 23, 1984, Jintan; 100 μg/lure.

(M+29) of peak 2 indicated that saturated hexadecanal (16:Ald) may occur in the gland extract. The ozonolysis product was eluted at 19 min 33 sec and ions *m/e* 185 (MH^+), 183 (M−1), 167 (MH−18), 149 (MH−36), and 213 (M+29) occurred in the mass spectrum. They are identical with those of 1,11-undecadial, thus supporting the assumption that 11-hexadecenal is the major component of the pheromone. The capillary gas chromatogram of the aldehyde fraction, in comparison with those of synthetic *Z*- and *E*11–16:Ald, is shown in Figure 1. Synthetic *Z*- and *E*11–16:Ald were eluted at 12 min 12 sec and 11 min 40 sec respectively, while a peak at 12 min 10 sec was displayed by the aldehyde fraction, and no signal occurred at 11 min 40 sec. Z11–16:Ald was then identified as major component of the sex pheromone of the Oriental armyworm.

Identification of Alcohol Component. In GC-MS analysis, the alcohol fraction displayed a peak at 21 min 32 sec and characteristic ions *m/e* 241 (MH^+), 239 (M−1), 269 (M+29), and 223 (MH−18). These results indicated that hexadecenol is the active component. Owing to its extremely small amount, we could not get more information about the location and geometrical configuration

TABLE 3. FIELD TRAPPING OF SECOND FLIGHT ARMYWORM[a]

Compound	Ratio	No. captures per trap: Total	No. captures per trap: Daily max.
Z11-16:Ald		76	20
Z11-16:Ald	100:10:1	59	15
+ 16:Ald	100:10:0.1	108	21
+ Z11-16:OH	100:10:0.5	102	14
Z11-16:Ald	100:10	42	11
+ 16:Ald	100:1	47	8

[a] June 3–15, 1984, Beijing, 100 μg/lure.

of the double bond other than EAG tests of known isomers of Δ7 to Δ11 hexadecenols. An EAG response of 1.6 mV was obtained from Z11-16:OH, while no response greater than 0.8 mV was obtained from the other isomers.

Field Trapping. The captures by various component ratios are shown in Tables 2 and 3. Although the data are rather insufficient and scattered, we believe that Z11-16:Ald + 16:Ald + Z11-16:OH (100:10:0.1) is the preferred blend.

Acknowledgments—For technical assistance, we thank Prof. Qian Yumin of Changchun Institute of Applied Chemistry, Academia Sinica, and for field area, the Scientific-Technical Station of Shibalidian Town, Shaoyang District, Beijing. SEX PHEROMONE COMPONENTS OF PURPLE STEM BORER *Sesamia inferens* (WALKER)

ZHU PINGCHOU, KONG FANLEI, and WANG ZEHUA

Jiangsu Institute of Pheromones
Jintan, Jiangsu, China

(Received November 7, 1985; accepted April 4, 1986)

Abstract—The pheromone of the female purple stem borer, *Z*-11-hexadecenyl acetate, identified by Nesbitt, was not active in field trapping in China. From EAG, TLC, GC, and GC-MS tests, we found that *Z*-11-hexadecenyl acetate, *Z*-11-hexadecenol, and *Z*-11-hexadecenal were the pheromone components, and the preferred blend ratio in field tests was 4 : 1 : 0.1. The number of captures of the later generations was substantially lower than that of the overwintered generation.

Key Words—*Sesamia inferens*, Lepidoptera, Noctuidae, purple stem borer, sex pheromone, *Z*-11-hexadecenyl acetate, *Z*-11-hexadecenol, *Z*-11-hexadecenal.

INTRODUCTION

Recently, various crops, particularly in the paddies of southern China, were heavily damaged by the purple stem borer *Sesamia inferens* (Walker) (Li and Wen, 1983). The pest insect develops three or four generations, occasionally five generations a year, and the generations overlap. The sex pheromone of the female purple stem borer was identified by Nesbitt et al. in 1976 as *Z*-11-hexadecenyl acetate (Z11–16 : Ac); however, few males were lured with this compound in field trapping in China (1977). Several enols, acetates, and their mixtures were tested as lures in field trapping, and Z11–16 : Ac blended with *Z*-11-hexadecenol (Z11–16 : OH) elicited a high activity to the overwintered generation (Jiangsu Institute, 1981). Lately, Takahashi et al (1983) reported that male *S. inferens* had been captured in their traps baited with 9 : 1 or 4 : 1 mixtures of Z11–16 : Ac and Z11–16 : OH for the armyworm. Z11–16 : Ac and Z11–16 : OH were identified as the main components of *S. inferens*, and a trace amount of *Z*-11-hexadecenal (Z11–16 : Ald) was also detected.

0098-0331/87/0500-0983$05.00/0 © 1987 Plenum Publishing Corporation

METHODS AND MATERIALS

Extract from Female Glands. Full-grown larvae were collected from the field. After pupation and sexual separation, the females were put into screen cages. Up to 90% of the moths raised their abdominal tips for calling during the period from midnight to 1:00 AM of the third day after emerging, and this is the time to excise. The excised glands were soaked twice in *n*-heptane, 1 hr for the first portion and 7 hr for the second. The extracts were combined, sealed, and stored in a refrigerator for structure identification.

TLC Separation. Sixty FE of the above extract were concentrated and dropped onto a silica gel plate 0.2 mm thick. After developing with a 4:1 mixture of *n*-hexane and ethyl ether, the plate was cut into five fractions and washed with treated acetone.

Instrumentation. Electroantennograms were obtained by Ag-AgCl electrodes with antennae cut from males of the same field source as described above during the 24–48 hr after emergence. Preliminary GC analysis was conducted on a Shimadzu GC-RIA with a hydrogen flame detector. GC-MS was done with a Finnigan-MAT 4510 quadruple mass spectrometer using an EI source of 0.25 mA and 70 eV. The chromatographic conditions are shown in Table 1.

Ozonolysis and Acetylation. Ozonolysis was done as described by Beroza and Bierl (1967) and acetylation by the procedure of Nesbitt et al. (1980).

Preliminary Field Trapping. Preliminary field trapping was carried out at monitoring stations of several counties in Jiangsu Province from 1981 to 1985 under the direction of the Cooperative Group for Application of the Sex At-

TABLE 1. CHROMATOGRAPHIC CONDITIONS

[a]Dosage: 150 μg. Blending ratio: A, Z11-16:Ac, Z11-16:OH, 4:1; B, Z11-16:Ac, Z11-16:OH, 8:1, C, Z11-16:Ac, Z11-16:OH, Z11-16:Ald, 4:1:0.1. Average captures followed by the same letter are not statistically different at the 5% level.

tractant of Purple Stem Borer. Water basin traps were placed 30 m apart in a grid system and 1 m above wheat stems. Pheromone compounds were synthesized in this institute and dispersed from rubber septa at a dosage of 150 μg/lure and blending ratios as shown in Table 2. The lures were used throughout a generation without renewing them.

RESULTS AND DISCUSSIONS

Preliminary Tests. Two active fractions were elicited by TLC separation. The more active fraction evoked an EAG response of 1.8 mV and occurred at R_f 0.54–0.75, which corresponds to long-chain acetates and aldehydes, while the less active one evoked 1.0 mV at R_f 0.15–0.35, corresponding to long-chain alcohols.

The chromatogram of the preliminary GC analysis in comparison with synthetic chemicals is shown in Figure 1. The retention time, 11.35 min of peak 3, was close to that of Z11-16:Ac; peak 5 (13.38 min) was close to that of Z11-16:OH; peak 4 (12.28 min) was close to that of 16:OH, and peak 2 (9.26 min) might be hexadecenal.

Identification of Acetate Fraction. The acetate fraction from TLC separation was eluted at 23 min 52 sec in GC-MS analysis, and the major fragment ions *m/e* 222 ($M^+ - CH_3COOH$), 194 ($C_{14}H_{26}^+$), 166 ($C_{12}H_{22}^+$), 152 ($C_{11}H_{20}^+$), 138 ($C_{10}H_{18}^+$), 124 ($C_9H_{16}^+$), 110 ($C_8H_{14}^+$), 96 ($C_7H_{12}^+$), 82 ($C_6H_{10}^+$), 61, and 43 were identical with the characteristic fragment ions of synthetic Z11-16:Ac reported by Ando et al. (1980). The ozonolysis product of the acetate was eluted

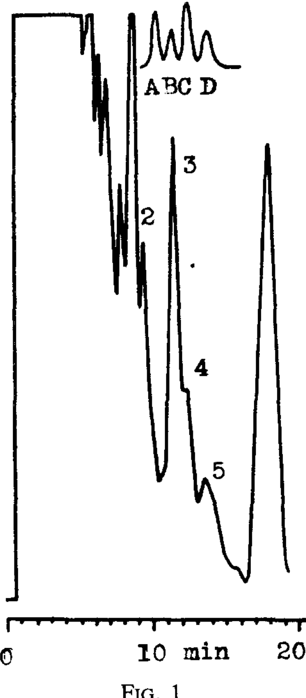

FIG. 1.

at 35 min 52 sec; the major fragment ion *m/e* 185 (M^+-43), 150 (M^+-78), 140 (M^+-88), 125 (M^+-103), 111 ($C_8H_{15}^+$), 97 ($C_7H_{13}^+$), 83 ($C_6H_{11}^+$), 61, and 43, as well as their relative abundances were in agreement with those of synthetic 11-acetoxyundecanal (Bierl-Leonhardt et al, 1980). Thus, the double bond location of 11 was further confirmed. The retention time of the acetate on the capillary column was 15 min 54 sec, while those of the synthetic *Z*- and *E*11-16:Ac were 15 min 54 sec and 15 min 16 sec, respectively. Thus, the configuration of the pheromone acetate double bond was *Z*.

Identification of Alcohol Fraction. The alcohol fraction was acetylized and purified before GC-MS analysis. Three peaks were eluted at 26 min 13 sec, 63 min 27 sec and 72 min 49 sec, respectively. The characteristic fragment ions of peak 1, *m/e* 196 (M^+-CH_3COOH), 168 ($C_{12}H_{24}^+$), 154 ($C_{11}H_{22}^+$), 140 ($C_{10}H_{20}^+$), 125 ($C_9H_{17}^+$), 111 ($C_8H_{15}^+$), 97 ($C_7H_{13}^+$), 83 ($C_6H_{11}^+$), 61, and 43 were in agreement with those of *n*-tetradecyl acetate; those of peak 2, *m/e* 224 (M^+-CH_3COOH), 154 ($C_{11}H_{22}^+$), 61, and 43 were in agreement with those of *n*-hexadecyle acetate; and those of peak 3, *m/e* 222 (M^+-CH_3COOH), 194 ($C_{14}H_{26}^+$), 180 ($C_{13}H_{24}^+$), 166 ($C_{12}H_{22}^+$), 152 ($C_{11}H_{20}^+$), 138 ($C_{10}H_{18}^+$), 124 ($C_9H_{16}^+$), 110 ($C_8H_{14}^+$), 96 ($C_7H_{12}^+$), 82 ($C_6H_{10}^+$), 61, and 43 were in agreement with those of *n*-hexadecenyl acetate.

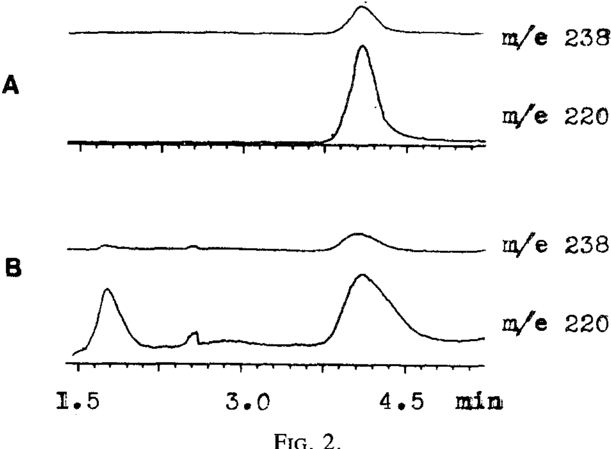

FIG. 2.

Three peaks were eluted in GC-MS of the ozonolysis product of acetylized alcohol, two of which were 14:Ac and 16:Ac. The third peak at 74 min 55 sec showed characteristic fragment ions *m/e* 185 (M^+-43), 150 (M^+-78), 140 (M^+-88), 125 (M^+-103), 111 ($C_8H_{15}^+$), 97 ($C_7H_{13}^+$), 83 ($C_6H_{11}^+$), 61, and 43, which were in agreement with those of 11-acetoxy-undecanal. This confirms the C-11 location of the double bond of pheromone hexadecenol. The retention times of synthetic *E*- and *Z*11-16:OH and the pheromone alcohol on the capillary column were 19 min 29 sec, 20 min 20 sec, and 20 min 20 sec, respectively. Thus, *Z*11-16:OH, 16:OH, and 14:OH may occur in the alcohol fraction from TLC separation of the purple stem borer abdominal tip extract.

Identification of Aldehyde Component. Owing to the trace content of aldehyde occurring in the pheromone, no peak could be detected in the total ion chromatogram. A multiple ion detection technique was adopted, and the molecular ion *m/e* 238 and the characteristic ion 220 (M^+-18) of hexadecenal were chosen as detecting ions. The chromatograms of the acetate-aldehyde fraction from TLC separation and of the synthetic hexadecenal are compared in Figure 2. Occurrence of hexadecenal in the pheromone may be demonstrated by the coincidence between the peaks. Capillary column MID chromatograms of the pheromone fraction and of the synthetic hexadecenal isomers are shown in Figure 3; the *Z* configuration of pheromone aldehyde may thus be presumed.

CONCLUSIONS

Although the field trapping was preliminary, and no statistical data are available, a preferred blend ratio of 4:1:0.1 of *Z*11-16:Ac + *Z*11-16:OH + *Z*11-16:Ald may be assumed. No evident synergic or inhibitory effect was

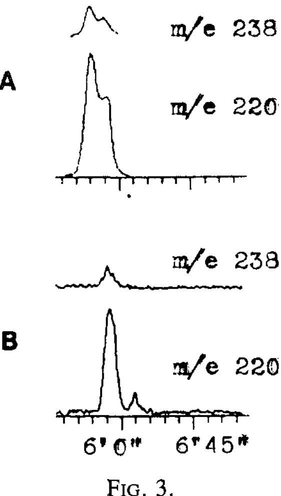

FIG. 3.

shown in field trapping by adding 16 : OH or 14 : OH to this blend. The captures during later generations were lowered substantially as shown in Table 2, and this phenomenon needs further study.

Acknowledgments—For technical assistance in MS analysis, we thank analyst Xu Xinrong, analyst Zhang Huiling, Mr. Wu Dechun, and Mr. Huang Guanlu of the Second Medical College of Shanghai. Field trapping data were furnished by the Cooperative Group for Application of Sex Attractant of Purple Stem Borer. Also thanks are due Messrs. Zhao Kouzhong, Wei Zhihong, Hu Xinhua, Yin Chenglin, Pan Famin, Xu Jianwei, Zhang Xinhua, and Zhu Jianhua of this institute for their experimental assistance. The manuscript was improved by Prof. Wu Tongjia of Nanjing Institute of Geology and Palaeontology, Academia Sinica.

Abstract—The sex pheromone glands of *Plusia chalcites* release, dodecyl acetate, (Z)-7-dodecenyl acetate, (Z)-9-dodecenyl acetate, 11-dodecenyl acetate, (Z)-8-tridecenyl acetate, and (Z)-9-tetradecenyl acetate. A combination of capillary GC, GC-MS, and dimethyl disulfide derivatization enabled a rigorous identification of all these compounds, some of which were previously found in gland extracts. Bioassays in a flight tunnel showed that a ternary blend of (Z)-7-dodecenyl acetate, (Z)-9-dodecenyl acetate, and (Z)-9-tetradecenyl acetate elicited directed flights from 85 to 100% of the males tested and elicited copulation attempts, at the end of the flights, from 44 to 74% of the males tested. This blend was equal in activity to the natural gland extract. Addition of the other acetates had only a slight influence on the activity of this mixture. Substitution of either (Z)-9-dodecenyl acetate or (Z)-9-tetradecenyl acetate in this blend by 11-dodecenyl acetate gave two ternary mixtures which also elicited high levels of courtship activity, almost as high as that of the original blend. Addition of (Z)-7-dodecenyl alcohol inhibited almost totally the flight activity of males.

INTRODUCTION

A common sex pheromone component of several moths of the Plusiinae subfamily has been identified as (Z)-7-dodecenyl acetate (Z7-12:Ac) (Berger, 1966; Tumlinson et al., 1972a; Kaae et al., 1973a). At that time, it seemed as if different species of Plusiinae utilize the same compound for their sexual communication. Different concentrations of Z7-12:Ac and temporal factors (Kaae et al., 1973a, b), were proposed as means for reproductive isolation among species utilizing the same pheromone.

With the advance of sensitive analytical instrumentation, in particular, efficient capillary GC columns, additional compounds to Z7-12:Ac were identified in the sex pheromone blends of various species of Plusiinae. At the present time, partial or complete blends are known for *Plusia chalcites* (Dunkelblum et al., 1981), *Chrysodeixis eriosoma* (Benn et al., 1982), *Autographa gamma* (Dunkelblum and Gothilf, 1983; Toth et al., 1983), and for *Trichoplusia ni*, which has been studied thoroughly for many years (Berger, 1966; Bjostad et al., 1980, 1984). Extensive use of the wind tunnel, as a reliable tool for bioassays, was of crucial significance in evaluating the biological importance of various components (Linn et al., 1984).

Two components of the sex pheromone of the tomato looper, *Plusia chalcites*, were previously identified as Z7-12:Ac and (Z)-9-tetradecenyl acetate (Z9-14:Ac). These compounds were found in gland extracts, and their activity was assessed in field tests (Dunkelblum et al., 1981). Several additional potential pheromone components were identified later (Dunkelblum et al., 1985).

The present study reports the chemical identification of sex pheromone components collected as gland volatiles and gland extracts of *P. chalcites*. Tests in a wind tunnel were conducted for the behavioral evaluation of these compounds.

METHODS AND MATERIALS

Insects and Extracts. The insects were reared on an artificial medium (Shorey and Hale, 1965), and females were separated from males as pupae. Adults were kept in separate rooms on a light cycle of 14:10 hr light-dark. Pheromone glands were dissected from the ovipositors of 4- to 5-day-old females during their calling period, i.e., 1-3 hr into scotophase (Snir et al., 1986) and immersed in hexane. After 15 min, the supernatant solution was transferred into small conical vials sealed with a Teflon-lined screw cap and concentrated to the desired volume by letting the samples stand in a fume hood.

Gland volatiles were obtained from ligated glands in a modified four-port, glass-wool collector similar to that described by Baker et al. (1981) and Gaston (1984). The trapped volatiles, collected for approximately 20 min, were rinsed

from the glass wool with 500 μl hexane, and samples from 10–20 glands were pooled in a conical vial sealed with a Teflon-lined screw cap and concentrated as described for gland extracts.

Chemical Identification. Capillary GC was conducted on a Varian 3700 model equipped with a FID detector and a splitless injector system. A 30 m × 0.25 mm bonded cyanosilicone column (DB 225, J&W) was kept at 60°C for 2 min and then was programmed from 60° to 130°C at 10°/min for the routine analyses of the C_{12}–C_{14} compounds.

For the analysis of only the C_{12} complex a program of 60°C to 120°C at 10°/min and for the complete range (C_{12}–C_{18}) a program of 60° to 180°C at 5°/min was used. For all programs, the purge valve was opened 1 min after injection, and the helium pressure was 15 psi. Quantification of peak areas was performed by a Varian 4270 electronic integrator.

Capillary GC-MS analysis was conducted on a Finnigan 5100 EI system, at 70 eV, coupled with a Superincos data system. A 30-m × 0.25-mm SE 54 fused silica column (J&W) was programmed from 60° to 250°C at 15°/min, after a 3-min delay, for pheromone components and from 60° to 250°C at 20°/min, after a 2-min delay, for dimethyl disulfide adducts. The column was operated in the splitless mode, with a purge 30 sec after injection and helium pressure of 10 psi.

Dimethyl disulfide (DMDS) adducts were prepared from several standards (Z7–12:Ac, Z9–12:Ac, 11–12:Ac, and Z7–12:OH), gland extracts, and gland volatiles. Samples in hexane (20–50 μl) were treated with DMDS (70–100 μl) and one drop of iodine solution (60 mg iodine in 1 ml diethyl ether). Reaction mixtures were kept at 40°C for 20 hr, cooled, and worked up as described by Buser et al. (1983) and Dunkelblum et al. (1985).

Behavioral Tests. The design of the wind tunnel has been described recently (Snir et al., 1986). Males 6- to 8-day-old, 1–4 hr into scotophase, were used for flight tests. They were kept in cages (30 × 30 × 30 cm) in the tunnel room. Individual moths were transferred carefully into small cages (7 × 7 × 7 cm) and placed on a tripod in the center of the tunnel, 20 cm from the downwind side. After 2–4 min when the males had settled down, the cage was opened and baits were introduced into the tunnel. The tests were performed at a light intensity below 0.5 lux, with a wind speed of 50 cm/sec, at 26° ± 3°C.

Baits were prepared by impregnating 1-cm^2 filter paper squares (Whatman No. 1) with 20 μl of a hexane solution containing the synthetic compounds. They were kept in Teflon-lined 20-ml screw cap vials on pins and fixed on the inside of the caps above an empty rubber septum under the Teflon lining. The baits were placed on a mesh tray, hanging from the roof of the tunnel, 20 cm from the upwind side with the vial cap down and the paper square up. Each bait was used for only one to three tests, within 60 min after preparation. All compounds used in the behavioral tests were from our collection and had an isomeric purity of 98–99% (verified by capillary GC).

RESULTS

Chemical Identification. Analysis of gland extracts by GC indicated the presence of several compounds in small amounts in addition to the major components Z7–12:Ac, Z9–14:Ac, and hexadecyl acetate (16:Ac) which were previously identified (Dunkelblum et al., 1981). The GC profile of the gland volatiles was similar to that of the gland extracts in the C_{12}–C_{14} range only;

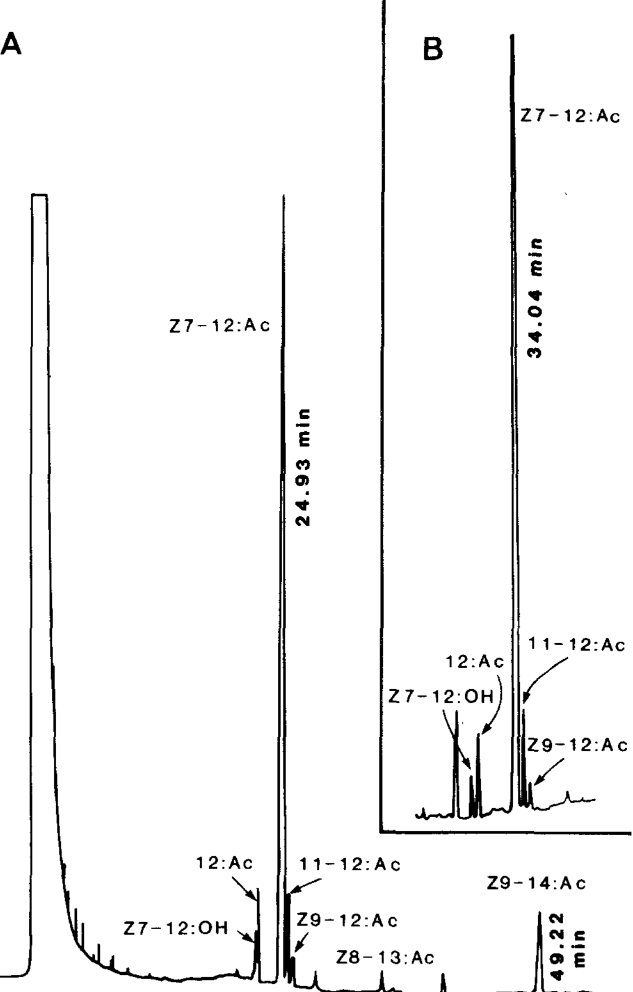

FIG. 1. Capillary GC traces of extracts of *Plusia chalcites*: (A) gland volatile, column programmed from 60° to 130°C; (B) C_{12} complex in gland extract, column programmed from 60° to 120°C. Representative retention times are indicated on some peaks.

higher acetates were almost nonexistent. Analysis at 60° to 130°C gave a satisfactory, but lengthy, separation of all C_{12}, C_{13}, and C_{14} compounds, and the analysis at 60° to 120°C gave an excellent separation of the C_{12} complex (Figure 1). The DB 225 column was able to resolve efficiently all *E/Z* pairs and most positional isomers, including the separation of (Z)-9-dodecenyl acetate (Z9–12:Ac) and 11-dodecenyl acetate (11–12:Ac), which were not resolved before on various capillary columns (Bjostad et al., 1984; Dunkelblum et al., 1981, 1985). A comparison of the relative amounts of the identified compounds in gland extracts and volatiles is presented in Table 1.

The GC-MS analysis (SE 54 column) confirmed the presence of most components in the gland volatiles, although difficulties were encountered with the separation of the C_{12} acetates. Derivatization of both the gland extracts and gland volatiles with DMDS and subsequent GC-MS analysis confirmed the presence and established the position of the double bond in all unsaturated compounds which were detected on the DB 225 column. The separation of the DMDS adducts was much better than that of the parent compounds. Although the amount of some of the minor compounds was extremely low and the peaks of their DMDS adducts on the reconstructed GC profile were barely visible, monitoring of the intensive A^+ or B^+ fragments enabled a reliable identification. The separation of the six DMDS adducts of (Z)-7-dodecenol (Z7–12:OH) and the unsaturated acetates, in the gland volatiles, is presented in Figure 2.

TABLE 1. RELATIVE PROPORTIONS OF COMPOUNDS IDENTIFIED FROM SEX PHEROMONE GLAND EXTRACTS AND GLAND VOLATILES OF *Plusia chalcites*[a]

	Gland extracts[b]		Gland volatiles	
Compound	$\bar{X}$	SE	$\bar{X}$	SE
Z7–12:OH	1.1	0.31	1.4	0.05
12:Ac	3.0	0.21	3.7	0.32
Z7–12:Ac	100.0		100.0	
Z9–12:Ac	1.3	0.05	1.6	0.13
11–12:Ac	3.6	0.27	3.3	0.20
Z8–13:Ac	1.4	0.19	1.2	0.13
Z9–14:Ac	15.8	1.03	7.3	0.66
Z11–14:Ac	0.2[c]	0.08		
16:Ac	23.2	2.01	0.7	0.09
Z9–16:Ac	1.2	0.31		
Z11–16:Ac	1.0	0.08		

[a]Relative proportions were calculated with respect to the main component Z7–12:Ac; each proportion is the mean value $\bar{X} \pm$ SE from four samples, each of 10–20 glands.
[b]The gland extracts contained also small amounts of higher acetates and trace amounts of 14:Ac.
[c]Detected only in three samples; its presence was confirmed by DMDS derivatization.

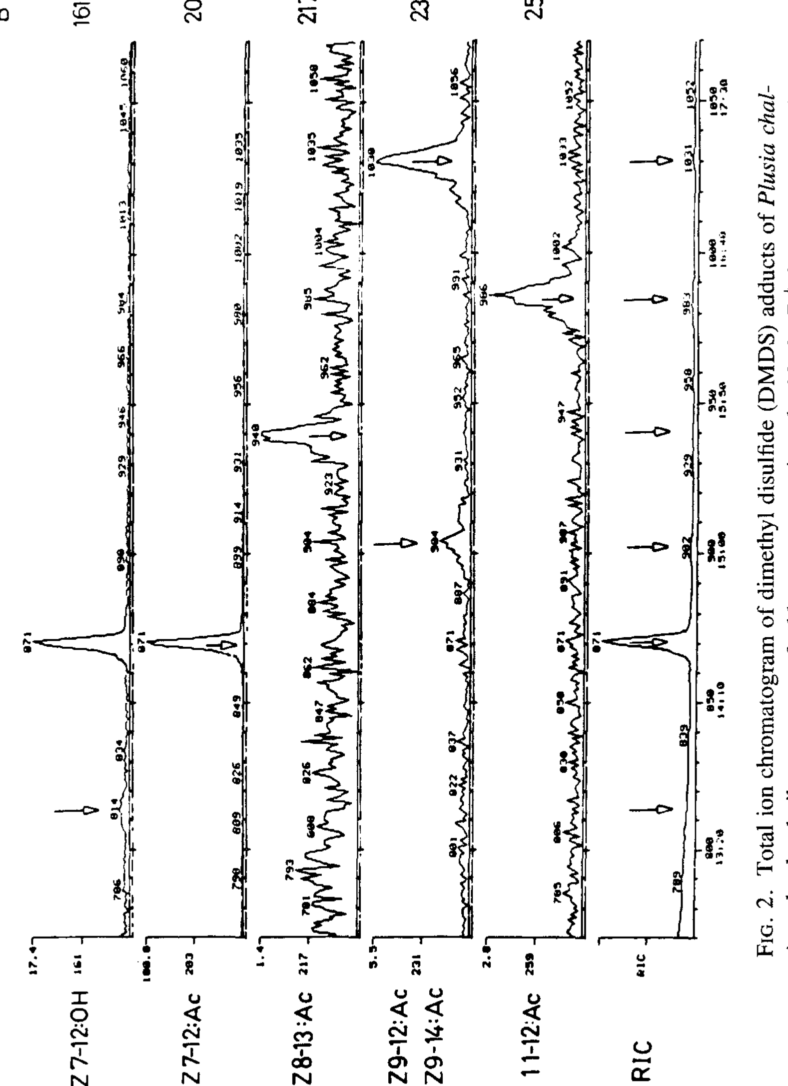

FIG. 2. Total ion chromatogram of dimethyl disulfide (DMDS) adducts of *Plusia chalcites* gland volatile; presence of adducts was monitored with the B^+ fragment (Table 2).

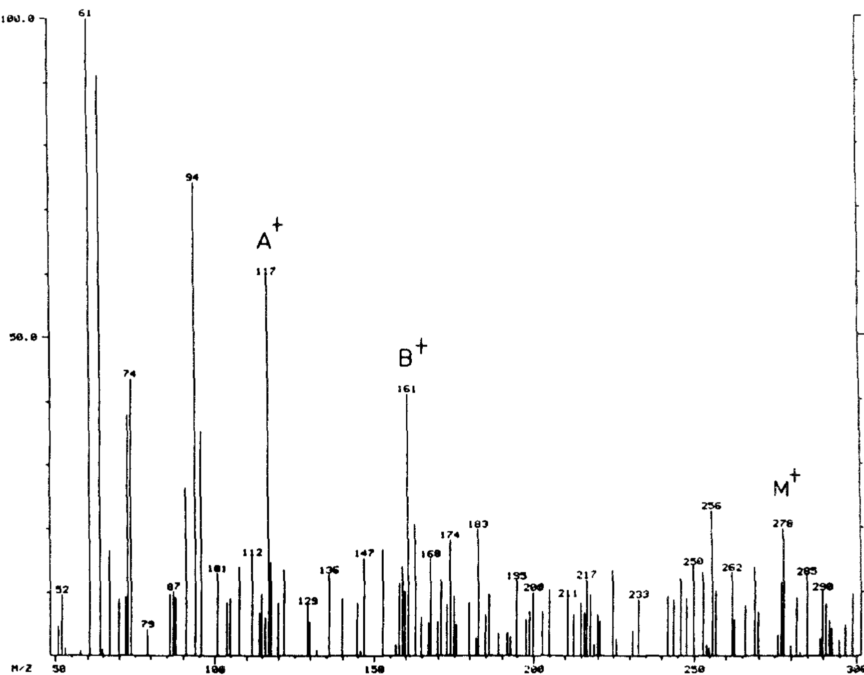

FIG. 3. Mass spectrum of dimethyl disulfide (DMDS) adduct of *Z*7–12:OH from the analysis presented in Figure 2.

Good mass spectra were obtained for all adducts including *Z*7–12:OH · DMDS, which was present in trace amounts only (Figure 3). The mass spectrometric data from all DMDS derivatives are summarized in Table 2.

Behavioral Tests. From field experiments (Dunkelblum et al., 1981; Dunkelblum et al., in preparation) and from preliminary wind tunnel work, we knew that the most active components in the extracts were *Z*7–12:Ac, *Z*9–12:Ac, and *Z*9–14:Ac. These compounds were tested individually in the wind tunnel, and it was found that only *Z*7–12:Ac initiated flights of males. Four concentrations were tested, and the results indicated that 200 ng/bait gave the highest flight response of the males, but with a few exceptions they did not reach the bait (Table 3). In view of these findings, we decided to test mixtures containing 200 ng of *Z*7–12:Ac and 20 ng each of 12:Ac, *Z*9–12:Ac, 11–12:Ac, and *Z*9–14:Ac. Complete gland extracts, calibrated by GC to contain 200 ng *Z*7–12:Ac, were also tested in order to compare the natural blend with the synthetic mixtures. Four behavioral stages were recorded—directed flight, landing, hairpencilling, and copulation. The copulation attempts were readily recognized by the bending of the abdomen; some males repeated this action several times consecutively.

TABLE 2. MASS SPECTROMETRIC DATA OF DMDS DERIVATIVES OF UNSATURATED COMPOUNDS FROM PHEROMONE GLANDS OF *Plusia chalcites*

$$\underbrace{CH_3(CH_2)_mCH(SCH_3)-}_{A^+} \vdots \underbrace{-CH(SCH_3)(CH_2)_nOR}_{B^+} \quad M^+ \quad R = H \text{ (alcohol)}, \; R = COCH_3 \text{ (acetate)}$$

DMDS adduct	Diagnostic ions[a]			
	M^+	A^+	B^+	B^+-60
Z7-12:OH	278(21)	117(60)	161(42)	
Z7-12:Ac	320(7)	117(66)	203(25)	143(30)
Z9-12:Ac	320(18)	89(38)	231(41)	171(18)
11-12:Ac	320(11)	61(100)	259(42)	199(38)
Z8-13:Ac	334(5)	117(83)	217(47)	157(29)
Z9-14:Ac	348(10)	117(75)	231(53)	171(25)
Z11-14:Ac	348(25)	89(50)	259(64)	199(30)
Z9-16:Ac	376(11)	145(100)	231(80)	171(21)
Z11-16:Ac	376(5)	117(68)	259(43)	199(15)

[a] Numbers in parentheses are relative intensities of ions. There are variations in these values, but fragments A^+ and B^+ are very intense in all DMDS adduct spectra.

TABLE 3. RESPONSES OF MALE *Plusia chalcites* IN WIND TUNNEL TO DIFFERENT CONCENTRATIONS OF Z7-12:Ac[a] ($N = 20$)[b]

Z7-12:Ac concentration (ng)	Taking flight	Directed flight	Source contact	Distance source (cm)[c]
2	8b	0c	0a	
20	15a	6b	3a	20
200	17a	13a	1a	40
2000	18a	8ab	1a	120

[a] Baits were used only once.
[b] Percentages followed by the same letter are not significantly different according to χ^2 test of independence ($P \leq 0.05$).
[c] The length of the flight track from the release cage to the source was 150 cm. The numbers represent the approximate distance from the source at which the males lost the plume and stopped the directed flight. This distance was measured with the help of the black and white stripes (10 cm wide) on the stationary floor of the tunnel.

TABLE 4. RESPONSE (%) OF MALE *Plusia chalcites* IN WIND TUNNEL TO MIXTURES OF COMPOUNDS IDENTIFIED FROM FEMALE SEX PHEROMONE GLAND VOLATILES[a]

[a]Sources contained 200 ng of Z7-12:Ac and 20 ng of each of the other compounds. The gland extract was calibrated to contain 200 ng Z7-12:Ac. Percentages followed by the same letter are not significantly different according to χ^2 test of independence ($P < 0.05$).

The tests in the wind tunnel were conducted over several months, and there was considerable variation in male response during these experiments. To overcome this difficulty, the ternary mixture of Z7-12:Ac + Z9-12:Ac + Z9-14:Ac was included in each test as a behavioral internal standard. This ternary blend gave a high response: in one test about 70% of the males completed the courtship sequence. Addition of the other components to this mixture had only a moderate influence on its activity (Table 4). The alcohol Z7-12:OH was tested separately only at a high dosage of 200 ng in a mixture of Z7-12:Ac + Z9-14:Ac. Significant inhibition of the directed flight was observed; out of 20 males tested, only three reached the bait as compared with 18 in the absence of the alcohol.

DISCUSSION

The sex pheromone of *P. chalcites* was investigated by our group several years ago (Dunkelblum et al., 1981), and a number of saturated and unsaturated

acetates were identified in gland extracts. Field tests confirmed the essential role of at least two components: Z7–12 : Ac and Z9–14 : Ac (Dunkelblum et al. 1981, 1982). Recently, when studying the fatty acids in pheromone glands of four lepidopterous species, additional unsaturated acetates were discovered in *P. chalcites* (Dunkelblum et al., 1985). The presence of a relatively large number of saturated and unsaturated acetates in the gland extracts made it clear that females of *P. chalcites* utilize a multicomponent sex pheromone. Therefore, it was of importance to identify the compounds actually emitted by the female and to assess their role in wind-tunnel tests.

A combination of a very efficient capillary column, DMDS derivatization and mass spectrometry made it possible to identify the components of the gland volatiles to a level of 0.2% relative to the main component Z7–12 : Ac. The gland extracts contained additional components, in particular, large amounts of 16 : Ac (Table 1). It is plausible that some of the compounds, present only in the gland extracts, are biosynthetic intermediates or side products (Bjostad and Roelofs, 1983; Bjostad et al., 1984). The trace amounts of (Z)-11-tetradecenyl acetate (Z11–14 : Ac) could be an indication of the presence of an intermediate compound in the biosynthesis of Z9–12 : Ac (Bjostad et al., 1985).

The gland volatiles contained 12 : Ac, Z7–12 : Ac, Z9–12 : Ac, 11–12 : Ac, Z8–13 : Ac, Z9–14 : Ac, and Z7–12 : OH (Table 1). The very small amount of 16 : Ac present in the volatiles is probably a residue from the large pool of this compound in the interior of the pheromone gland (Table 1). For this reason 16 : Ac was excluded from the flight tests. The exceptional compound in this mixture is Z8–13 : Ac, which is very rare as a pheromone component. Recently it has been detected in the sex pheromone glands of *Chilo auricilius* (David et al., 1985), and it is also known to be a sex attractant for some species of the genus *Chrysochrista* (Ando et al., 1977). A few other Δ13 : Acs are known to be pheromone components in Lepidoptera (Inscoe, 1982). This compound (Z8–13 : Ac) might arise via a shortening by one carbon or a lengthening by one carbon of either a Z9–14 or Z7–12 precursor, respectively. Trapping experiments using Z8–13 : Ac, as a substitute for either Z7–12 : Ac or Z9–14 : Ac, in lures gave negative results. Traps baited with these lures did not catch *P. chalcites* males, indicating that this compound is inactive (Dunkelblum et al., in preparation).

It was also surprising that both the gland extracts and the gland volatiles consistently contained small amounts of Z7–12 : OH. This alcohol, at higher concentrations, is a potent inhibitor for the trapping of *P. chalcites* (Dunkelblum et al., 1982). This is also true for *T. ni* (Bjostad et al., 1984; Tumlinson et al., 1972b), in which it was found in small amounts in the gland volatiles (Bjostad et al., 1984). The alcohol was tested only briefly in the wind tunnel. Addition of 200 ng of Z7–12 : OH to a lure of Z7–12 : Ac + Z9–14 : Ac inhibited almost totally the flight activity of males. The possibility of Z7–12 : OH

being an artifact in pheromone glands of *T. ni* was raised by Bjostad et al. (1984); the same might be true for *P. chalcites*. A plausible source of the small amounts of Z7–12 : OH in both insects could be some hydrolysis of Z7–12 : Ac catalyzed by tissue from the female. Such a process was reported recently for the hydrolysis of (*E*)-11-tetradecenyl acetate to the corresponding alcohol (Silk et al., 1985).

The behavioral tests concentrated on the C_{12} and C_{14} acetates, in particular, Z7–12 : Ac, Z9–12 : Ac, and Z9–14 : Ac, which were used previously as trap baits in field experiments. Only Z7–12 : Ac elicited directed flights of males when used alone, although none of these males reached the source. Most of the moths lost the plume after a short distance and flew to the ceiling of the tunnel (Table 3). The strongest response was observed to sources containing 200 ng Z7–12 : Ac, and this concentration was therefore used in the mixture. Since field tests (Dunkelblum et al., 1981) indicated that *P. chalcites* males were not sensitive to the ratio of the components in baits, we decided at this stage to test only one ratio (10 : 1) between Z7–12 : Ac and the other acetates. Addition of one compound, either Z9–12 : Ac or Z9–14 : Ac to Z7–12 : Ac, had a significant effect on the response of the males. A considerable percentage of the insects (15–44%) completed the courtship sequence and attempted to copulate with the sources. On the other hand, addition of either 12 : Ac or 11–12 : Ac to Z7–12 : Ac enhanced only the percentage of males performing flights, although without landing on the sources. The ternary mixture of Z7–12 : Ac + Z9–12 : Ac + Z9–14 : Ac elicited a very high response, with 44–74% of the males performing a complete courtship sequence. The activity of this blend equaled that of the natural gland extract. Substitution of Z9–12 : Ac or Z9–14 : Ac in this blend, by 11–12 : Ac yielded two additional ternary blends which were almost as active as the mixture of Z7–12 : Ac + Z9–12 : Ac + Z9–14 : Ac (Table 4). Addition of either 12 : Ac or 11–12 : Ac to this mixture had no effect, whereas the addition of both slightly enhanced the activity of the five-component blend (Table 4).

Although a relatively large number of components were identified in the gland volatiles, it may be that only a few of them are essential for the complete male response. The purpose of the present behavioral tests was to assess the activity of the major components released by *P. chalcites* females. The results indicate that Z7–12 : Ac is responsible for initiating flight activity in males, but addition of Z9–12 : Ac + Z9–14 : Ac or Z9–12 : Ac + 11–12 : Ac or 11–12 : Ac + Z9–14 : Ac is essential for the performance of the entire courtship sequence, including a high percentage of copulatory attempts. Since male responses to ternary mixtures were already high, a comprehensive set of behavioral tests such as response to different ratios of components and measurement of time of flight is necessary in order to determine whether all the released compounds are indeed essential as sex pheromone components.

(Received April 18, 1986; accepted June 12, 1986)

Abstract—In laboratory flight tunnel bioassays, response rates of male cabbage looper, *Trichoplusia ni* (Hübner), to female soybean looper, *Pseudoplusia includens* (Walker), were similar to response rates of male *T. ni* to conspecific females for plume tracking and source contact. Male soybean loopers, however, exhibited a greatly reduced response to female cabbage loopers compared to conspecific females. Similar differences were observed in male responses to extracts of female abdominal tips. Studies of flight tunnel responses of male soybean loopers to the different chemicals known to be components of the female cabbage looper sex pheromone indicated that the reduction in response was due to inhibitory effects of (Z)-5-dodecen-1-ol acetate and (Z)-9-tetradecen-1-ol acetate, when added singly to (Z)-7-dodecen-1-ol acetate (major component of both species) at release rates and at ratios close to those observed in female cabbage loopers.

Key Words—*Trichoplusia ni*, *Pseudoplusia includens*, Lepidoptera, Noctuidae, (Z)-5-dodecen-1-ol acetate, (Z)-9-tetradecen-1-ol acetate, (Z)-7-dodecen-1-ol acetate, pheromone, pheromone blends, cross-attraction, inhibition, reproductive isolation.

INTRODUCTION

Many moth species in the noctuid subfamily Plusiinae have chemically overlapping female sex pheromones, characterized by the presence of (Z)-7-dodecen-1-ol acetate (Z7–12:Ac) as a major component. This compound has been found to be a sex pheromone of the cabbage looper (CL), *Trichoplusia ni* (Hüb-

0098-0331/87/0500-1005$05.00/0 © 1987 Plenum Publishing Corporation

ner) (Berger, 1966), the soybean looper (SBL), *Pseudoplusia includens* (Walker) (Berger and Canerday, 1968; Tumlinson et al., 1972), *Autographa biloba* (Stephens), *Rachiplusia ou* (Guenee) (Berger and Canerday, 1968), and *Plusia chalcites* (Espinosa) (Dunkelblum et al., 1981), and a sex attractant for *Trichoplusia oxygramma* (Geyer) (Mitchell, 1972), *Autographa californica* (Speyer), and *Syngrapha falcifera* (Kirby) (Butler et al., 1977), among others.

While many closely related moth species are known to maintain premating and behavioral reproductive isolation through chemical differences in their female sex pheromones, if not through other means such as geographic, seasonal, or temporal isolation (Roelofs and Cardé, 1974; Greenfield and Karandinos, 1979), such mechanisms are unknown or undocumented within the Plusiinae, despite the similarities of known pheromones within the subfamily. The CL and SBL are sympatric over much of eastern North America (Eichlin and Cunningham, 1978) and can occur at the same time within the same field, as indicated by trap catches in pheromone-baited traps (Mitchell, 1972; Kaae et al., 1973). Both species have very broad and widely overlapping diel periods of sexual activity, insufficient to achieve sexual isolation (Mitchell, 1973). Leppla (1983) reported attraction of both SBL and CL males to heterospecific females in a laboratory flight chamber bioassay, and Mitchell (1972) and Kaae et al. (1973) observed attraction of CL males to traps baited with SBL females, although SBL males were not appreciably attracted to CL females. Although mating between these two species should be impossible due to genitalic differences (Callahan, 1961), the degree of behavioral reproductive isolation between these two species and any preventive role played by sex pheromone chemistry have not been elucidated.

Behavioral reproductive isolation through differences in the sex pheromone chemistry may be accomplished by differences in the component makeup of the sex pheromones, in the ratios of shared components, or in the pheromone release rates. The sex pheromones of the female CL and SBL apparently are qualitatively different. A six-component blend has been reported as the sex pheromone of the CL (Bjöstad et al., 1980a, 1984), comprised of the saturated dodecen-1-ol acetate (Sat-12:Ac), (Z)-5-dodecen-1-ol acetate (Z5–12:Ac), (Z)-7-dodecen-1-ol acetate (Z7–12:Ac), 11-dodecen-1-ol acetate (Δ11–12:Ac), (Z)-7-tetradecen-1-ol acetate (Z7–14:Ac), and (Z)-9-tetradecen-1-ol acetate (Z9–14:Ac). Only Z7–12:Ac has been reported as a SBL female sex pheromone (Tumlinson et al., 1972). Estimates of the release rate of the major component of the CL pheromone, Z7–12:Ac, were reported by Sower et al. (1972), Bjöstad et al. (1980b), and Baker et al. (1981). Comparable information is not available for female SBL.

We report here the results of studies of the interspecific sex pheromone responses between SBL and CL moths. The investigations were designed to determine if any differences in the release rates or chemical composition of the

female sex pheromones contribute to the maintenance of premating reproductive isolation between the two species. Quantitative determinations were made of pheromone emitted from calling female CL and SBL moths to ascertain the release rates of known components of the natural pheromone blends. Male responses to heterospecific females, female abdominal tip extracts, and two-component synthetic sex pheromone blends were evaluated in laboratory flight-tunnel bioassays and in a field-trapping experiment.

METHODS AND MATERIALS

Insect Rearing and Handling. All moths used were obtained as pupae from colonies maintained at the USDA Insect Attractants, Behavior, and Basic Biology Research Laboratory, Gainesville, Florida, using methods described by Guy et al. (1985) for the CL. The SBL colony was established in November 1984 from pupae collected in a soybean field near Alachua, Alachua County, Florida.

Pupae were sorted by sex, with males and females kept in separate environmental chambers on a 14:10 light–dark reversed-light cycle, at 24°C and 60% relative humidity. Pupae and emerging moths were held in 25 × 25 × 25-cm aluminum frame and plastic screen cages with a 40-ml cup of honey-sucrose solution on cotton. Pupae were moved periodically to new cages to provide moths of discrete ages.

Volatile Collections. Pheromone release rates and the ratios of sex pheromone components emitted by female CL and SBL moths were determined by gas chromatographic (GC) analysis of moth volatiles collected on charcoal filters described by Tumlinson et al. (1982). The glass chamber used to contain the moth(s) was 5 cm OD × 30 cm in length. Air was purified prior to its introduction into the chamber of the volatile collection system by passage through charcoal filters and was humidified using a split air-flow system. The split flow system allowed a variable portion of the air flow to be humidified to near saturation (95%) by its passage through a gas diffusion chamber that contained distilled water. By altering the ratio of humidified to dry air, system humidity could be adjusted from 10 to 95%. A glass frit near the upwind end of the volatile collection chamber provided laminar air flow over the insect which typically perched on the frit. A stainless-steel mesh cone confined the insect to the chamber area near frit. Air flow through the system was maintained at 0.5 liters/min with a slight positive pressure established in the volatile collection chamber (incoming air to vacuum). This was monitored with a vent flowmeter measuring air flow (0–20 ml/min) from a vent in the chamber. During these experiments, vent flow was ca. 2% of air flow through the filters. Pressure drop across the charcoal collection filters was reduced to near zero by

the use of an air-flow regulator on the vacuum line downwind of the collection filters. After collection, the charcoal filters were extracted for analysis using 3 × 20-μl portions of CH_2Cl_2 as described by Tumlinson et al. (1982).

Moths were placed in the chambers of the volatile collection system 0.5 hr before observations and collections were begun during the fifth and sixth hours of the scotophase. A dim, red light was used to illuminate the holding chambers for observations. Room temperature was 24 ± 1°C. Moths were 4–6 days old. Twelve separate 15-min volatile collections were obtained from individual female SBL moths. Ten separate 10-min volatile collections were obtained from individual female CL moths.

Chemical Analyses. Gas chromatographic (GC) analyses were conducted on a Varian model 3700 GC and a Hewlett-Packard model 5890 GC equipped with splitless capillary injectors and flame ionization detectors. A Nelson 4000 data system was used for chromatogram storage and analysis. Helium was used as the carrier gas at a linear flow of 18 cm/sec. Columns used for analysis were a 50 m × 0.25 mm ID CPS-1 (high-polarity cyano column equivalent obtained from Quandex), operated at 60°C for 2 min, then temperature programmed at 30°/min to 180° or a 20 m × 0.25 mm ID Supelco wax (bonded Carbowax), operated at 60°C for 2 min, then temperature programmed at 30/min to 160°C. Both of these columns afforded complete resolution of the four dodecenol and the two tetradecenol acetates reported previously as the pheromone components of the CL (Bjöstad et al., 1980a, 1984).

Samples were analyzed by GC–mass spectrometry with a Nermag model R1010 mass spectrometer in the chemical ionization mode. The CPS-1 capillary column used in previous analyses was used in the GC–mass spectrometric analyses using helium carrier gas. Either methane or isobutane was used as the reagent gas in the mass spectrometer. Spectra of the natural products were compared with those of candidate synthetic compounds.

All synthetic standards used in this study were obtained from commercial sources and were purified by high-performance liquid chromatography on a 25 × 2.5-cm (OD) $AgNO_3$-coated silica column eluted with toluene (Heath and Sonnet, 1980). These compounds were analyzed on the capillary GC columns described previously and determined to be greater than 99% pure.

Formulation. Synthetic blends and individual synthetic compounds were formulated on 5 × 9-mm rubber septa (A.H. Thomas Co.) for all biological tests. Septa were Soxhlet extracted with CH_2Cl_2 for 24 hr and air dried prior to loading. Desired release ratios of the components of blends were obtained by loading the septa with mixtures containing calculated percentages by weight of each component of the blend. The percentage of a component in the loading mixture was calculated on the basis of its relative volatility determined from retention indices on liquid crystal capillary GC columns (Heath and Tumlinson, 1986) and a method developed to predict release ratios of components of a blend

from rubber septa (Heath et al., 1986). Each septum was loaded with 100 μl of a hexane solution of the blend pipetted into the well on the large end of the septum. Septa were aired for two days at room temperature before use.

Determination of the ratio and rate of release of the pheromone from a septum consisted of placing the septum in a stainless-steel chamber in which purified air was introduced at a wind velocity of 0.225 m/sec over the septum. The volatilized pheromone was collected on a charcoal trap (3–5 mg of charcoal), extracted with ca. 60 μl CH_2Cl_2 and 20 μl hexane, concentrated, and analyzed by capillary gas chromatography using the 50-m CPS-1 column. Collection time varied from 0.5 to 1 hr, depending on the amount of material emitted from the septum for a given load.

Flight-Tunnel Bioassays. A comparison was made in a flight-tunnel bioassay of the responses of male CL and SBL moths to a range of release rates of Z7–12:Ac encompassing those determined from volatile collections from females of both species. Desired release rates were obtained by altering the flow of air over a rubber septum containing Z7–12:Ac. A pheromone-loaded septum was placed inside a small stainless-steel chamber (positioned near the center of the upwind end of the tunnel) through which regulated air from a compressed air cylinder was forced. Determinations of the pheromone loads and air-flow rates required to provide the desired range of release rates from the septum were made as described above (Figure 1). Air flow within the tunnel (1 × 1 × 4-m Plexiglas box) was calibrated at 0.22 m/sec. Air was drawn into the tunnel from

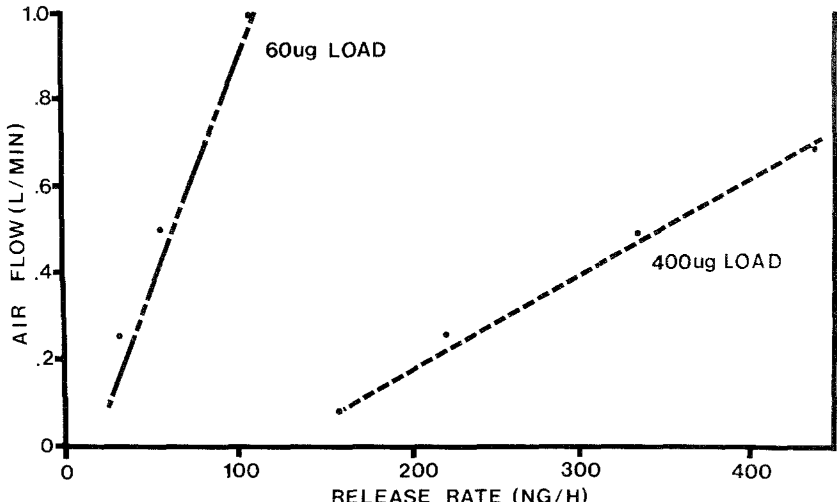

Fig. 1. Measured release rates of Z7–12:Ac from septa at different flow rates of air over septa, for a 60-μg load and a 400-μg load per septum.

within the environmental chamber housing the tunnel by a blower motor and fan. The environmental chamber was kept at 24 ± 1°C and 65 ± 10% relative humidity.

Moths tested were released singly from a 60-ml plastic vial hung on a metal stand 20 cm from the downwind end of the tunnel and near the center of the long axis of the tunnel. Test moths were then observed for a 2-min period following release, or until the maximum response occurred, and were scored for flight from the release vial, for upwind-oriented flight within the pheromone plume (plume tracking), and for contacting the pheromone emitter (source contact). When a male contacted the source, the time from release to source contact was also recorded. Responses of male CL and SBL to Z7-12:Ac were evaluated at 0, 10, 20, 40, 100, 200, and 500 ng/hr, as determined by measurements of release rates (Figure 1). On each of five days, each release rate was tested with two moths of each species in an ascending release rate order to avoid contamination problems. All bioassays were conducted in the fourth and fifth hour of the scotophase.

Differences between CL and SBL plume tracking response data were determined by regression analysis of percent response on log release rate.

The responses of male CL and SBL moths to calling heterospecific females were evaluated in a similar flight-tunnel bioassay. For each species, three 3- to 6-day-old females were confined in a 5 × 7-cm screen cylinder placed on a wire hook near the center of the upwind end of the tunnel 1 hr prior to the bioassays. Male response bioasays were conducted during the fourth hour of the scotophase for CL females and fifth hour of the scotophase for SBL females. Males were released singly from 50-ml vials near the downwind end of the tunnel and observed for 2 min following release or until they contacted the cage of females. Males were scored for flight from the vial, for upwind-oriented flight, for contacting the cage of females, for hairpenciling (CL), and for copulatory attempts (SBL). Twenty-five conspecific and 25 heterospecific males were tested with females of each species, conducted as five sets of 10 bioassays (five conspecifics followed by five heterospecifics). All other bioassay conditions were as described previously.

Male response to extracts of abdominal tips of conspecific and heterospecific females was also evaluated in a flight tunnel bioassay. Abdominal tips (segments 8-10) were cut and placed in a vial containing 300 μl hexane for 30-60 min, and the amount of Z7-12:Ac was determined by quantitative capillary gas chromatography. Dosages of abdominal tip extracts containing 100 ng Z7-12:Ac in 100 μl hexane were compared to 100 ng synthetic Z7-12:Ac in 100 ml hexane as a control. These were applied to 6-cm-diam. filter papers and air dried for 2 min prior to bioassay. Papers were suspended from a wire hook near the center of the upwind end of the flight tunnel. Males were released singly near the downwind end and their behavior observed for 2 min following release. Males were scored for flight from the vial, upwind-oriented flight, con-

tacting the filter paper, and the time from release to source contact. Bioassays were conducted as sets of five males exposed consecutively to the abdominal tip extracts followed by five males exposed consecutively to synthetic Z7–12:Ac. Each data set (10 males) was replicated five times, each on a different day. Bioassays were conducted during the fourth and fifth hours of the scotophase.

Male SBL responses to synthetic female CL sex pheromone components were evaluated in a flight tunnel bioassay. Each of the five minor components of the female CL sex pheromone reported by Bjöstad et al. (1984) (Sat-12:Ac, Δ11–12:Ac, Z5–12:Ac, Z7–14:Ac, and Z9–14:Ac) was tested with the major component of the CL female pheromone (Z7–12:Ac) in load ratios determined to produce release ratios similar to those reported by Bjöstad et al. (1984) from female CL. These five two-component blends: Z7–12:Ac/Sat-12:Ac (100:9 load ratio), Z7–12:Ac/Z5–12:Ac (100:9), Z7–12:Ac/Δ11–12:Ac (100:4), Z7–12:Ac/Z7–14:Ac (100:6), Z7–12:Ac/Z9–14:Ac (100:3), and Z7–12:Ac alone were tested at dosages of 100, 500, and 1000 μg on rubber septa. Bioassays were conducted in sets of 30, with five male SBL tested for each of the six blends at a given dosage. Each set was replicated five times per dosage (on 15 days) for a total of 450 males. Males were released singly as described, were observed for 2 min following release, and were scored for upwind-oriented flight, contacting the septum, and reorienting to the septum (after first contacting it and then leaving the plume entirely). The time from release to first contact with a septum was also recorded. Moths were 3–6 days old and were tested for the fourth and fifth hours of the scotophase. For each behavioral response, treatment means were separated using Duncan's new multiple-range test at $P \leq 0.05$.

Field Test. The sex pheromone blends tested in the flight-tunnel bioassay (Z7–12:Ac plus synthetic female CL pheromone minor components) were also evaluated (along with a six-component synthetic blend) for attractancy in a six-day field-trapping test. The blends were formulated as before in rubber septa at 1 mg/septum and were tested in International Pheromones Moth Traps (bucket trap), with 5 × 4 × 1-cm pieces of Vapona to kill captured moths. Traps were mounted on wooden stakes ca. 1 m above ground and were placed 45 m apart in two north–south rows 320 m apart. Each row consisted of seven traps, each with one of the seven blends tested. Traps were checked and treatments were randomized daily within each row and septa were replaced after three days.

Treatment means for trap catch data were compared by Duncan's new multiple-range test at $P \leq 0.05$ for treatment differences.

RESULTS

Amounts of Z7–12:Ac collected from air passed over female SBL moths in the volatile collection apparatus averaged 1.6 ± 0.48 ng ($\bar{X}$ ± SD) per min

of collection (range 0.32–1.66 ng/min). Amounts of Z7–12 : Ac collected from female CL moths averaged 4.26 ± 2.18 ng/min of collection (range 2.42–9.08 ng/min). Ratios of CL pheromone components observed were similar to those reported by Bjöstad et al. (1984).

Responses rates of CL and SBL males to different release rates of Z7–12 : Ac were similar throughout the ranges tested (0–500 ng/hr). Mean release rates of Z7–12 : Ac from calling female CL and SBL moths (256 vs. 96.0 ng/hr averages) were both well within the ranges tested for male response. The observed regressions for plume tracking were both significant but were not significantly different from each other in slope (Figure 2). Response rates by both CL and SBL males for source contact were nearly identical to those for plume tracking.

In the flight-tunnel bioassay, CL males responded to SBL females by orienting within and flying up the pheromone plume to the cage of females. The percentages of CL males responding to SBL females were significantly greater than those of CL males responding to conspecific females (Table 1). Soybean looper males, however, exhibited much lower response rates to CL females than to conspecific females, with significantly fewer males tracking the plume and

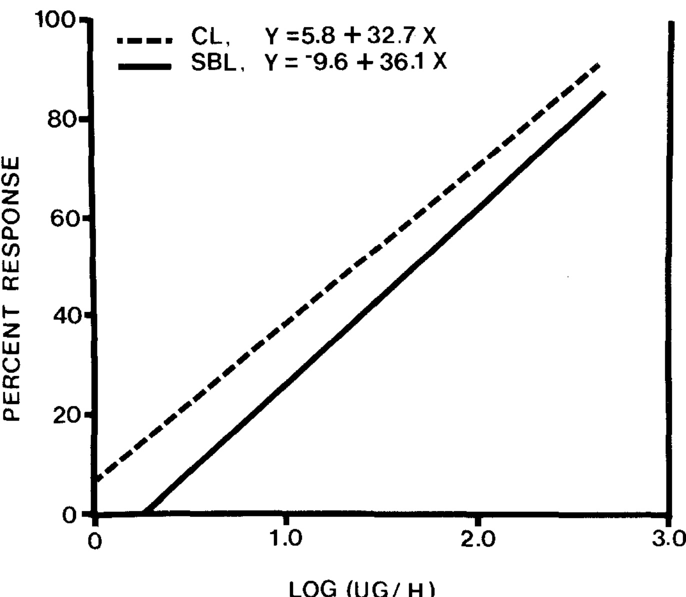

FIG. 2. Percentages of male soybean loopers and male cabbage loopers exhibiting upwind oriented flight to contact the emitter (septum) in a flight tunnel bioassay, for different release rates of Z7–12 : Ac. For cabbage looper, R^2 = 0.81, for soybean looper, R^2 = 0.76.

TABLE 1. MEAN PERCENTAGE RESPONSES ($\bar{X} \pm$ SD) OF SBL AND CL MALES TO THREE CALLING SBL OR CL FEMALES AND MEAN TIMES (SEC) TO CONTACT FEMALE CAGE[a]

	Three CL females		Three SBL females	
Response	CL male	SBL male	CL Male	SBL Male
Plume tracking	80.0 ± 17.9b	20.0 ± 0.0a	100.0 ± 0.0c	83.3 ± 15.1b
Source contact	76.7 ± 19.7b	13.3 ± 10.0a	96.7 ± 8.2c	76.7 ± 15.1b
Time to contact	24.2 ± 5.5a	64.3 ± 28.2b	27.8 ± 5.3a	34.8 ± 10.6a

[a] Means within a row followed by the same letter are not different significantly by Duncan's new multiple-range test at $P \leq 0.05$.

contacting the cage of CL females. Soybean looper males also took significantly longer to contact the cage of females when they did respond.

There were no differences in CL male flight-tunnel responses to 100-ng dosages of *Z*7–12 : Ac and comparable amounts of extracts of female SBL abdominal tips on filter paper. Male SBL response rates, however, were significantly reduced to extracts of female CL abdominal tip extracts, compared to *Z*7–12 : Ac alone (Table 2). Fewer males oriented with the plume, contacted the filter paper, and hairpenciled.

At 100-μg loads on rubber septa, SBL males exhibited a reduced response to *Z*7–12 : Ac with the CL minor components *Z*5–12 : Ac or *Z*9–14 : Ac added vs. *Z*7–12 : Ac alone (Figure 3A). The addition of *Z*7–14 : Ac had no significant

TABLE 2. MEAN PERCENTAGE RESPONSES ($\bar{X} \pm$ SD) OF SOYBEAN LOOPER (SBL) AND CABBAGE LOOPER (CL) MALES TO 100-NG SAMPLES OF (Z)-7-DODECEN-1-ol ACETATE ON FILTER PAPER VS. EQUIVALENT SAMPLES OF FEMALE ABDOMINAL TIP EXTRACTS ON FILTER PAPER[a]

Behavior	*Z*7–12 : Ac	Heterospecific female abdominal tip extracts
SBL male response		
Plume tracking	75.0 ± 10.0a	20.0 ± 23.1b
Source contact	70.0 ± 11.5a	10.0 ± 20.0b
Copulatory attempts	70.0 ± 11.5a	5.0 ± 10.0b
CL male response		
Plume tracking	68.0 ± 17.9a	76.0 ± 16.7a
Source contact	64.0 ± 16.7a	72.0 ± 22.8a
Hairpenciling	36.0 ± 26.1a	48.0 ± 22.8a

[a] Means within a row followed by the same letter are not different significantly by Student's *t* test, $P \leq 0.05$.

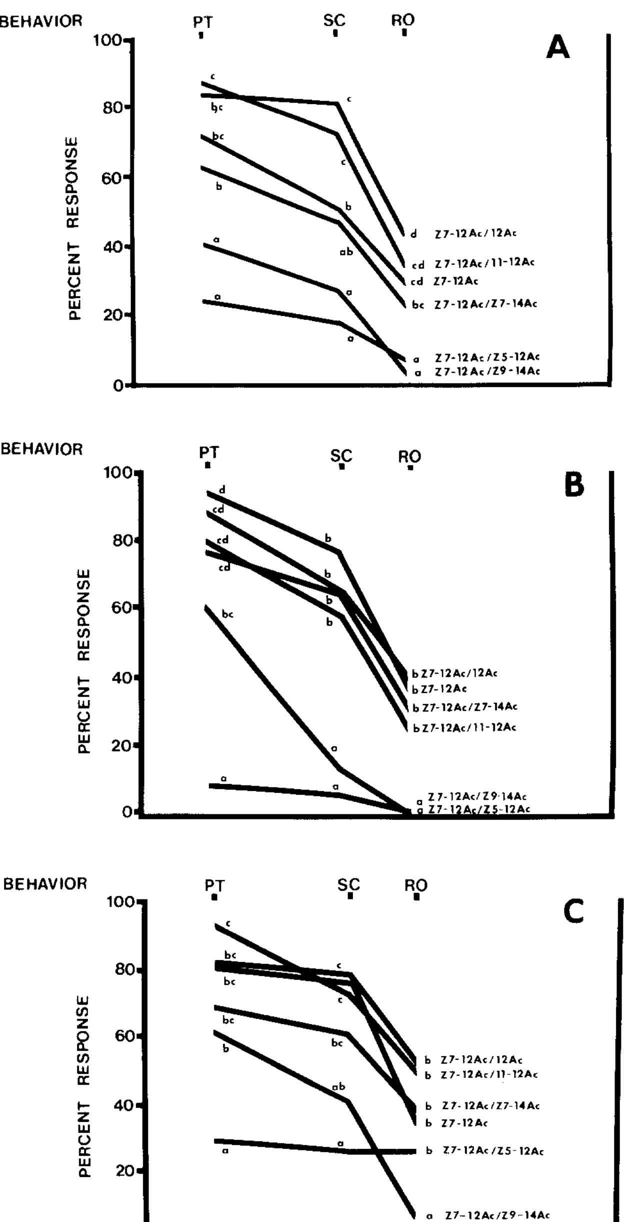

FIG. 3. Percentages of male soybean looper moths responding to pheromone blends formulated at loads of 100 μg (A), 500 μg (B), or 1 mg (C). PT = plume tracking, SC = source contact, and RO = reorientation to the source. Percentages within a behavioral response category followed by the same letters are not significantly different at $P \leq 0.05$, Duncan's new multiple-range test.

effect on numbers of male SBL tracking the plume, contacting the releaser, or reorienting to the releaser. However, with the addition of Sat-12:Ac or Δ11-12:Ac, significantly more males contacted the releaser. Similar results were observed at 500 μg (Figure 3B). At this dosage, SBL male responses to blends containing *Z*5-12:Ac and *Z*9-14:Ac were reduced, while the addition of *Z*7-14:Ac, and in this case Sat-12:Ac and Δ11-12:Ac, had no significant effect on the response. At 1-mg loads (Figure 3C), the presence of *Z*5-12:Ac and *Z*9-14:Ac both reduced numbers reaching the releaser. However, *Z*9-14:Ac did not significantly reduce the number of males tracking the plume but did reduce reorientation to the releaser, while *Z*5-12:Ac reduced the number of males tracking the plume.

Similar results were obtained in the field trapping test. Significantly fewer male SBL were caught in traps baited with either the six-component CL blend ($\bar{X} = 0.0$), with *Z*5-12:Ac/*Z*7-12:Ac (0.0) or with *Z*9-14:Ac/*Z*7-12:Ac (0.8 ± 0.9), than with *Z*7-12:Ac alone (8.6 ± 9.7). Catches in traps baited with Sat-12:Ac/*Z*7-12:Ac (3.7 ± 5.6), Δ11-12:Ac/*Z*7-12:Ac (6.7 ± 8.9), or *Z*7-14:Ac/*Z*7-12:Ac (7.1 ± 11.1) were not different significantly from those baited with *Z*7-12:Ac alone.

DISCUSSION

Since spermatophore transfer between the cabbage looper and soybean looper should be impossible because of genitalic incompatibility (Callahan, 1961), and the production of viable hybrid offspring extremely unlikely, interspecific attraction and courtship interactions would appear to be maladaptive, reducing the fitness of those involved. In the very least, males flying upwind in response to the pheromone of a heterospecific female are wasting time and energy that could be expended searching for potential conspecific mates. Also, close-range heterospecific interactions may interfere with the attractiveness of a calling female to conspecific males. Copulation attempts may cause physical damage or eventual death without reproduction, as reported for male *Heliothis zea* (Boddie) copulating with female *Heliothis virescens* (Fab.) (Stadelbacher et al., 1983).

Our experimental results and observations of male CL and SBL flight-tunnel behavior in response to calling females, extracts of abdominal tips of females, and combinations of synthetic sex pheromone components indicate that inhibition of male SBL sex pheromone response by the female CL sex pheromone, although not absolute, is a principle factor contributing to the maintenance of behavioral reproductive isolation between SBL and CL moths by greatly reducing male SBL attraction to calling female CL. However, no such role is served by the female SBL pheromone in species isolation; male CL are attracted strongly to female SBL. These results are similar to the trap catches reported by Mitchell (1972) with very few male SBL caught in female CL-

baited traps and as many male CL in female SBL-baited traps as in traps baited with synthetic Z7–12:Ac.

Results of our dose–response test (Figure 2) and those of Kaae et al. (1973) indicate no difference between the responses of male CL and SBL to a range of release rates of Z7–12:Ac covering those of females of both species. It is then unlikely that pheromone concentration is a factor in reproductive isolation here, as was reported by Kaae et al. (1973) for the CL and *A. californica*. Our experimental results also demonstrate that the inhibition of the male SBL sex pheromone response by the female CL pheromone is due to the presence of the two minor components, Z5–12:Ac and Z9–14:Ac in the released pheromone blend.

Differences in the observed effects of the addition of Z5–12:Ac vs. Z9–14:Ac to the major component Z7–12:Ac suggest a longer range effect by Z5–12:Ac. At the 500-μg and 1-mg dosages tested, the percentages of male SBL tracking the plume from the septum were significantly higher with Z9–14:Ac added to Z7–12:Ac, compared to Z5–12:Ac and Z7–12:Ac (Figure 3). Since the release rate of Z5–12:Ac was considerably higher than that of Z9–14:Ac (because of the different load ratios and higher volatility of Z5–12:Ac compared to Z9–14:Ac, the Z5–12:Ac may have been more readily detected at the release site in the flight tunnel.

The increased response rates of male SBL to the synthetic blends containing Sat-12:Ac and Δ11–12:Ac at the 100-μg dosage were unexpected. These compounds may be as yet undetermined minor components of female SBL sex pheromone. Despite the presence of these two compounds in the six-component blend tested in the field, it was still unattractive to male SBL, compared to Z7–12:Ac alone, presumably because of the inhibitory effects of Z5–12:Ac and Z9–14:Ac in the blend.

Interactions between female CL and male SBL are minimized by inhibition of the male SBL sex pheromone response by Z5–12:Ac and Z9–14:Ac in the female CL pheromone and by ecological factors (Leppla, 1983). Male SBL that do respond and fly to calling CL females reportedly are aggressively rejected (Leppla, 1983), precluding any further interactions. However, since male CL are attracted strongly to calling female SBL, close-range interactions are in this case likely, and it is not known how reproductive isolation is maintained. Although Leppla (1983) reported attempts by male CL to copulate with female SBL, nothing is known of the likelihood of such coupling occurring in nature or of any effects on the ability of a conspecific male to locate and subsequently copulate with such a female. Male CL may be better able to discriminate conspecific females from SBL females in a choice situation, which may minimize these heterospecific sexual interactions in the field.

REINVESTIGATION CONFIRMS ACTION OF Δ11-DESATURASES IN SPRUCE BUDWORM MOTH SEX PHEROMONE BIOSYNTHESIS

WALTER A. WOLF and WENDELL L. ROELOFS

Department of Entomology
New York State Agricultural Experiment Station
Geneva, New York 14456

(Received March 27, 1986; accepted June 13, 1986)

Abstract—The biosynthesis of a large number of sex pheromone components of various moth species has been shown to start with common fatty acids and involve chain shortening by two carbons and introduction of a double bond at the 11–12 position. A recent report indicates that one of these common components, (*E*)-11-tetradecenyl acetate, is present in the eastern spruce budworm, *Choristoneura fumiferana*, but is not made by this pathway. Reinvestigation of this insect using in vivo and in vitro techniques indicates that the acetate indeed is made by a sequence of reactions similar to that used in other leafroller moths. In fact, evidence was found for the presence of several Δ11-desaturase systems in spruce budworm. One produced a large quantity of (Z)-11-hexadecanoic acid, and another produced (*E*)-11-tetradecanoic acid. It is not known if the small amount of (*Z*)-11-tetradecanoic acid is produced by either of those two systems or by a third system. A comparison with other species showed that cabbage looper moths have only the first system, red-banded leafroller moths use the last two systems, and European corn borer moths have all three.

Key Words—Spruce budworm, *Choristoneura fumiferana*, sex pheromone biosynthesis, Δ11-desaturase, *Trichoplusia ni*, *Argyrotaenia velutinana*, *Ostrinia nubilalis*, Lepidoptera, Tortricidae, Noctuidae, Pyralidae.

INTRODUCTION

The biosynthesis of many lepidopterous sex pheromone components has been shown to involve the reaction of common fatty acids with two key enzyme systems (Roelofs and Bjostad, 1984). These include microsomal β-oxidation to give limited chain shortening by two carbons, and a Δ11-desaturase to yield

0098-0331/87/0500-1019$05.00/0 © 1987 Plenum Publishing Corporation

acids with unsaturation at the 11–12 position. A variety of compounds is produced by varying (1) the length of the starting fatty acids (normally between 12 and 18 carbons), (2) the order in which the chain shortening and desaturation steps occur, (3) the number of times chain shortening occurs, (4) the stereochemistry of the unsaturated products, and (5) the functionality (alcohol, acetate, aldehyde) of the pheromone components, which are finally produced by reducing the acid precursors.

A good example of these key steps is given by the biosynthetic routes for the cabbage looper moth (CL), *Trichoplusia ni*, pheromone components. In this species the Δ11-desaturase system produces large quantities of Z11–16 : Acid[1] and Z11–18 : Acid from palmitic and stearic acid, respectively. These are chain shortened to give pheromone precursor acids Z9–14 : Acid and Z7–12 : Acid from the former, and Z7–14 : Acid and Z5–12 : Acid from the latter (Bjostad and Roelofs, 1983). The Δ11-desaturase enzyme from CL was partially purified from the microsomal fraction and found to have a substrate specificity for 16- and 18-carbon acids (Wolf and Roelofs, 1986). However, in the redbanded leafroller moth (RBLR), *Argyrotaenia velutinana*, the Δ11-desaturase enzyme produces unsaturated 14-carbon acids from myristic acid in an *E*/*Z* ratio of ca. 3/2 (Bjostad and Roelofs, 1981). These are reduced to give a specific 8 : 92 ratio of the pheromone components, *E*11– and *Z*11–14 : OAcs.

Recently, Morse and Meighen (1984, 1986) indicated that the eastern spruce budworm (SBW), *Choristoneura fumiferana*, does not utilize the Δ11-desaturase enzyme system for production of the *E*11– and Z11–14 : OAcs found in their pheromone glands as precursors to the corresponding aldehyde pheromone components. Their data did not support a specific desaturation of myristic acid to give Δ11–14 : Acid, and so they suggested that the pheromone was produced by some unspecified pathway, perhaps starting directly from acetate.

We found it surprising that there were two different biosynthetic pathways for *E*11– and Z11–14 : OAcs in two leafroller moth species. It was difficult to accept an alternate route in the case of SBW also because Dunkleblum et al. (1985) had shown that the SBW pheromone glands contain both 14- and 16-carbon Δ11-unsaturated fatty acyl moieties, indicating the presence of a Δ11-desaturase in their pheromone gland. Thus we decided to reinvestigate the biosynthesis of the *E*11– and Z11–14 : OAcs in SBW by both in vivo and in vitro techniques.

Since the SBW apparently desaturated both 14- and 16-carbon acids, we also conducted a comparative study with the Δ11-desaturase system of other species, such as the CL moth (specific to 16- and 18-carbon acids), the RBLR moth (specific to 14-carbon acids), and two strains of the European corn borer

[1] Specific compounds will be referred to by an abbreviated naming system, where a letter (*Z* or *E*) indicates the stereochemistry, the first number gives the site of unsaturation, the second number the chain length, and symbols indicate the oxygen function. Thus Z9–18 : Acid is the abbreviation for oleic acid.

moth (ECB), *Ostrinia nubilalis*, that use *E*11- and *Z*11-14:OAc pheromone components (Roelofs et al., 1985) but produce Δ11 products of both 16- and 14-carbon acids. We tested the ability of pheromone gland extracts of each of these species to desaturate 14- and 16-carbon fatty acyl coenzyme A derivatives.

METHODS AND MATERIALS

Female SBW pupae were obtained from Dale Grisdale, Forest Pest Management Institute, Sault Ste. Marie, Canada, and maintained in our laboratory on a 16:8 light-dark regime. Experiments (gland removal or compound topical application) were conducted on 2-day-old (24–48 hr) insects approximately 1 hr before the onset of scotophase. CL, RBLR, and ECB pupae were obtained from cultures raised in our laboratory and were treated in the same manner.

[1-^{14}C]Palmitoyl-coenzyme A (59 mCi/mmol), [1-^{14}C]myristoyl-coenzyme A (31 mCi/mmol), [U-^{14}C]palmitic acid (403 mCi/mmol), [1-^{14}C]lauric acid (36 mCi/mmol), [1-^{14}C]myristic acid (38 mCi/mmol), and [1-^{14}C]-palmitic acid (57 mCi/mmol) were obtained from Amersham Corporation, Arlington Heights, Illinois. Solutions of the acids in dimethyl sulfoxide were prepared, with each containing aproximately 100,000 dpm/μl.

Extracts were prepared by adding the whole glands or the cell-free reaction mixture to 3 ml of 2:1 chloroform-methanol. After 15 min, 1 ml water was added, the organic layer was removed, and the water extracted with chloroform. The organic layers were combined and concentrated (Folch et al., 1957).

Fatty acids were analyzed as their methyl esters. The extracts were concentrated and placed in a solution containing 2 ml methanol, 1 ml benzene, and 0.1 ml sulfuric acid. The mixture was heated for 1 hr at 85°, cooled, and 1 ml water added. The organic layer was removed, washed three times with water and dried. The transmethylated extract was concentrated and 0.2 ml of acetyl chloride added to regenerate the acetates from the pheromone alcohols. After 10 min, the residual acetyl chloride was removed with N_2.

Gas-liquid chromatography (GLC) separation of the mixtures into fractions of differing chain length (C_{12}, C_{14}, and C_{16}) was performed on a column containing 3% OV-1 (methyl silicone) on 100–120 mesh Gas Chrom Q, with fractions being collected in 30-cm capillary tubes when appropriate. Further separation of *E* and *Z* isomers was accomplished on a column containing 10% XF-1150 (50% cyanoethyl, methyl silicone) on 100- to 120-mesh Chromosorb W-AW-DMCS. Capillary GLC was carried out using a 30-m Supelcowax column, 0.25 mm ID, on a Hewlett-Packard 5890 gas chromatograph.

Thin-layer chromatography (TLC) was performed on Whatman K5 plates that had been sprayed with a solution of 10 g silver nitrate in 65 ml 80% ethanol until damp. The plates were activated for 1 hr at 110° before use. The plates

were developed with a 9:1 mixture of Skelly B and ether, and the areas of radioactivity located by autoradiography. Areas of the plate were scraped into vials, scintillation fluid added, and radioactivity determined in a Packard Tri-Carb scintillation counter.

Ozonolysis was accomplished by adding a solution of the compound in CS_2 to a solution of ozone in CS_2 at $-70°C$. The reaction was allowed to slowly warm to room temperature and was concentrated and directly subjected to GLC analysis.

Topical application was performed in a manner similar to that previously reported (Bjostad and Roelofs, 1983). Female insects were anesthetized with carbon dioxide and their pheromone glands held everted by means of smooth-jawed alligator clips. A droplet of radiolabeled material dissolved in DMSO was applied to the glands. After 1 hr, the insects were removed from the clips and maintained in the dark for 3 hr. At this time they were cooled to 0° for 10 min and the glands removed and extracted as above.

Cell-free reactions were conducted similarly to that reported in Wolf and Roelofs (1986). Pheromone glands were removed and placed in a cold buffer containing 0.10 M phosphate, 0.35 M sucrose, and 5 mM dithiothreitol, pH 7.6. The glands were homogenized in a Potter Elvehjem tissue grinder and centrifuged at 12,000*g* for 15 min at 4°C. The supernatent was combined with 0.1 μCi of labeled fatty acid CoA ester and cofactors in a total volume of 0.20 ml. Cofactor concentrations were: NADH, 5 mM; 5 mM; NADPH, 1 mM; BSA, 1 mg/ml. After 1 hr at 25°C, the assays were extracted as above.

For capillary GLC, five glands were excised, extracted, and transmethylated. An aliquot was subjected to capillary GLC and compared to standards. The rest of the material was subjected to GLC on OV-1, and the relevant peaks subjected to ozonolysis to confirm the position of the double bond.

For in vivo experiments, 3.0 μl of radiolabeled fatty acid in DMSO was topically applied to the glands of 10 insects. After extraction and transmethylation, the products were subjected to GLC on OV-1. Trapped fractions were counted or subjected to further GLC on XF-1150 or ozonized.

In vitro experiments were conducted by preparing the cell-free extract, adding 0.1 μCi of labeled fatty acid, and subsequent extraction and transmethylation. The resultant mixture was analyzed by TLC, GLC, and ozonolysis.

RESULTS

Five SBW glands were extracted, transmethylated, and analyzed by capillary GLC as well as by ozonolysis of the compounds collected from nonpolar and polar GLC columns. This confirmed the presence of $\Delta 11$-unsaturated acids in SBW extracts (Table 1). Both the *E* and *Z* isomers of the 14-carbon acid were found, but only the *Z* isomer of the 16-carbon acid was detected.

TABLE 1. FATTY ACIDS IN SBW EXTRACTS[a]

Chain length (carbons)	Saturated	Δ-9	*E*11	*Z*11

16	26.17	1.19	[b]	0.90

[a] As percent of total fatty acids.
[b] Not found.

In Vivo Experiments. The results of topical application of radiolabeled saturated fatty acids are presented in Table 2. Using uniformly labeled palmitic acid as the starting material, significant radioactivity was obtained in both the 14-carbon acid and 14-carbon acetate fractions. When palmitic acid labeled in only the 1-carbon was used, the amount of label found in the 14-carbon acid fraction decreased more than 60%, and very little radioactivity was detected in the unsaturated 14-carbon acetates. Similarly, lauric acid labeled in the 1-position gave rise to some labeled 14-carbon acids, but no radioactivity was detected in the acetate fraction.

When myristic acid labeled in the 1-carbon was topically applied, the greatest amount of incorporated radioactivity was detected in the 14-carbon acetates. The 14-carbon acid fraction in this reaction was not counted directly, but was collected from the XF-1150 GLC column to separate the saturated acid (starting material) and the isomers of the Δ11-unsaturated acids. Typical results, presented as percent of initial radioactivity incorporated into the fraction, were: saturated, 0.52%; *E* isomer, 0.54%; *Z* isomer, 0.07%. The ratio of *E*/*Z*

[1-^{14}C]16:CoA	0.35	1.82

[a] As percent of starting material.

incorporation is very close to that found for the total amounts of the acids present (Table 1).

In Vitro Experiments. Pheromone glands from SBW were excised, homogenized in buffer, centrifuged, and the resulting extracts reacted with radiolabeled CoA esters. After transmethylation and TLC separation, the isomers of the desaturated acids were located by autoradiography and quantified. The results are given in Table 3. Both 14- and 16-carbon acids were desaturated. The 14-carbon acids showed a high reactivity (over 7% of the starting saturated acid was isolated in the products), and the *E/Z* ratio was similar to that observed in the topical application experiments. The 16-carbon acids, however, were much less reactive in this system (just over 2% total) and gave predominantly the *Z* isomer.

These same experiments were repeated using extracts prepared from other species. As shown in Table 4, the results show a pattern similar to the acid

TABLE 4. INCORPORATION OF RADIOLABELED COMPOUNDS USING CELL-FREE EXTRACTS PREPARED FROM SEVERAL INSECTS

	Product (pmol)[a]			
	11–14:Acid		11–16:Acid	
Species	*E*	*Z*	*E*	*Z*
CL	[b]	4	[b]	67
RBLR	17	25	[b]	[b]
SBW	200	24	6	31
ECB (*Z* strain)	114	45	1	189
ECB (*E* strain)	41	18	<1	142

[a] Products were *E*- and *Z*11 isomers of the 14- and 16-carbon acids. Starting materials were 14:CoA and 16:CoA, respectively.
[b] Not found.

precursors in each species. For CL only the *Z* isomer of the 11-desaturated product was observed, predominantly from the 16-carbon acid. In RBLR, only the 14-carbon acid underwent desaturation, but both the *E* and *Z* isomers of the product were labeled. In two strains of ECB, one having a predominantly *E*11 pheromone and the other having mostly *Z*11, the pattern of unsaturated products was similar. In both strains, the 14-carbon starting material gave about 70% *E* product, whereas the 16-carbon acid produced less than 1% *E* product. Also in both, the 16-carbon substrate was preferred (11.2% incorporation total compared to 5.0% for the 14-carbon acid in the *Z* strain).

DISCUSSION

Investigations of the biosynthesis of sex pheromones in moths have involved techniques such as analysis of the fatty acid content of the pheromone gland and in vivo and in vitro incorporation of radiolabeled precursors to gain insight into possible pheromone intermediates or precursors (Lofstedt and Roelofs, 1985; Roelofs and Bjostad, 1984). When we applied these techniques to the SBW, we obtained strong evidence that this insect uses the previously proposed (Roelofs and Bjostad, 1984) biosynthetic pathway involving chain-shortening of palmitic to myristic acid, followed by Δ11-desaturation and then reduction to *E*11- and *Z*11-14 : OAcs.

First, we confirmed the presence of 11–12 unsaturated 14- and 16-carbon acids in the gland (Dunkelblum et al., 1985). Since previous studies with moth sex pheromone glands demonstrated that acids unsaturated in this position are made directly by a Δ11-desaturase (Wolf and Roelofs, 1986), our findings indicate the presence of such an enzyme in SBW.

We then topically applied several radiolabeled fatty acids to SBW sex pheromone glands. If the *E*/*Z*11-14 : OAcs were being made directly from acetate, we would expect similar results from all of the starting materials, as they each would be degraded to this common intermediate. As can be seen in Table 2, this was not the case. Both lauric and palmitic acids labeled in the 1-carbon gave rise to little or no labeled *E*/*Z*11-14 : OAcs. This is the expected result if the first step in the biosynthetic pathway involves chain shortening of palmitic acid, resulting in the loss of the first two carbons, including the labeled one. Lauric acid cannot participate in this reaction. Note that in both cases some activity is incorporated in the myristic acid fraction, perhaps by degradation and recycling through the fatty acid cycle.

Radiolabel from uniformly labeled palmitic acid and from myristic acid labeled in the 1-carbon is incorporated into the *E*/*Z*11-14 : OAcs. In addition, the myristate gives rise to labeled *E* and *Z*11-14 : Acids in a ratio close to that of the total Δ11-14 : Acid found in the gland. Again, this supports the pathway involving chain shortening to myristic acid followed by 11-desaturation.

More direct evidence for the existence of a Δ11-desaturase was provided by in vitro experiments. Cell-free preparations from SBW sex pheromone glands were capable of introducing an 11–12 double bond into CoA esters of myristic and palmitic acids. No radioactivity was found in any compound other than the starting material and this product, indicating that degradation–resynthesis was not occurring under these conditions.

These data demonstrate that the biosynthesis of the *E*/*Z*11–14:OAcs in SBW follows a pathway similar to that in other moths, involving chain shortening and Δ11-desaturation. It differs only in that in SBW these acetates, which are found as major components in the pheromone gland, are converted to the corresponding aldehydes when emitted as a pheromone components.

While collecting the data to prove the pheromone biosynthetic pathway for SBW, we were surprised at the results found in Table 3 showing the stereoselective production of Z11–16:Acid. This had not been found in RBLR, which also produces an *E*/*Z* mixture of Δ11–14:Acids. We conducted studies similar to those of Table 3 with other species and found evidence for the presence of several Δ11-desaturase enzyme systems. The results in Table 4 show that there is a system that produces the *Z* isomer and is specific to 16-carbon chain acids. This system is found in all the insects studied except RBLR. Another system is specified to 14-carbon chain acids and produces the *E* isomer. This is found in all the species except CL. There also may be a third enzyme system that is specific to 14-carbon chain acids and produces the *Z* isomer. Although some of the Z11–14:Acid could be produced by the enzyme specific to 16:Acid, such as in CL, this does not appear to be the case with RBLR or SBW. The presence of an isomerase to yield the *E*/*Z* mixtures of 14:Acids has been ruled out by previous studies using radiolabeled Δ11–14:Acids (Bjostad and Roelofs, 1981). Further purification and characterization of these Δ11-desaturase systems will be needed to clarify the number of variations involved.

Acknowledgments—We gratefully acknowledge Kathy Poole and Marlene Campbell for rearing the insects used in these studies. This research was supported by National Science Foundation grant DCB-8406348.

AN INTERACTIVE VIDEO-COMPUTER TRACKING SYSTEM FOR QUANTIFICATION OF LOCOMOTOR BEHAVIOR

CARL H. ROYCE-MALMGREN and WINSOR H. WATSON, III

Zoology Department
University of New Hampshire
Durham, NH 03824

(Received April 14, 1986; accepted June 18, 1986)

Abstract—We have developed a flexible, moderately priced, behavioral analysis system which has been used to determine the response of salmonids to certain olfactory stimulants. The system, which we call ITS for interactive computer-video tracking system, consists of a 128K Apple IIe computer with software, a video camera and videocassette recorder, and a special-effects generator. Experiments are video taped and then, during playback, the special effects generator is used to simultaneously display the video image and the graphics output of the computer on a monitor. The user tracks the animal of interest using an electronic pen, and the position of that animal in the test chamber, in the form of x–y coordinates, is determined by the computer at user-defined time intervals. When tracking is complete, a plot of the track of the animal is printed within the outline of the test chamber. The following data can also be calculated: swimming velocity, distance from a predetermined point in the chamber (for example, olfactory stimulant source), and time spent in a given area. These variables can be calculated over any chosen time periods and/or for the entire experiment. ITS has numerous advantages over commercially available devices that perform similar tasks. First, it is relatively inexpensive, especially if one already owns video equipment and a computer. Second, it can analyze many types of experiments that can be stored on video tape, including field observations or manipulations. Third, because it is not automated, it is easy to track multiple objects, even if their tracks cross or are not easily located against a low-contrast background. Finally, because whole images do not have to be digitized, and data collection intervals can be adjusted by the user, it is possible to analyze very long experiments with a microcomputer. In this paper we describe ITS and then we demonstrate how we have used it to demonstrate that changes in ambient pH alter the behavioral response of juvenile Atlantic salmon to olfactory stimuli.

Key Words—computers, video, tracking, locomotion, fish behavior, acid precipitation, olfaction.

INTRODUCTION

One of the most difficult challenges encountered when investigating animal behavior is developing a way to express data quantitatively. In recent years, behavioral analysis of an animal's reaction to environmental or toxicological manipulation has become much more quantitative, due in large part to technological advances in remote monitoring and manipulation of data by computers. Several commercially available systems now enable researchers to track both aquatic and terrestrial animals and to determine behavioral parameters such as distance traveled, time spent in particular areas, and even the number of social interactions (Crawley et al., 1982; Miller et al., 1982; Kaufman, 1983). These modern laboratory tools have enabled investigators to analyze and manipulate behavioral data in increasingly more effective and efficient ways and thus perform experiments that previously would have been too tedious or complex to undertake.

While these systems have proven to be quite useful, they have three major disadvantages for the average investigator. First, they are expensive, costing on the order of $10,000–80,000. Second, the investigator is often separated from the raw data. Many subtle, but important, behavioral responses might not be noticed by the computer. Finally, sophisticated systems are often not flexible enought to allow for widespread applications, such as field work. In the field the areas in which behaviors are being monitored are often not standarized and have varied backgrounds, which would confound most automated tracking systems. What is needed is an inexpensive and flexible, yet sophisticated, technique that allows for close investigator interaction with the data from the initial stage to plotting of the final results.

We have developed a system that uses a standard video camera and video cassette recorder (VCR) to record the movements of an animal, and an Apple IIe computer, with peripherals, to digitize these tracks. We have written software to perform data analysis and statistical calculations, store data in appropriate files, and, if desired, plot the final values. The only unique piece of hardware in the system is a special-effects generator that allows the user to display a video image along with the computer's graphics output on a single monitor. The user can then use the computer-generated targeting crosshairs to track an animal and, thereby, create a digitized record of the animal's movements.

The experimental techniques and methodology described herein have been applied to an investigation of the effect of pH on the olfactory-related behavior of fish. However, this system can be, and has been, used for a wide variety of experiments. A number of different types of quantitative analyses can be performed with it if one simply modifies the controlling software.

METHODS AND MATERIALS

The interactive tracking system (ITS) consists of three parts: (1) recording components; (2) a video–computer interface and digitizer; and (3) integrated data analysis software.

The recording module consists of the behavioral chamber, video recording components, and video integration hardware. The behavioral chamber we used was the Y-maze shown in Figure 1 (Greer and Kasolsoski, 1978; Royce-Malmgren, 1985). The video recording equipment included a color video camera and video recorder (Figure 1). The video integrating hardware enabled us to overlay, on the recording of the fishes' behavior, data pertinent to the experiment, which in this case included pH, temperature, date, and time (Figure 1). The video recording components of the ITS are all portable, enabling data collection in the field and analysis in the lab.

The computer components of the ITS consist of an Apple IIe 128K computer equipped with an Apple digitizer tablet, dual disc drives, internal clock, x/y plotter, and dot matrix printer (Figure 2A). Coupled to these is the video integration hardware that allows for simultaneous projection of the output of the video recorder and computer graphics onto the display monitor (Figure 2B,C). The user tracks one animal at a time using the targeting crosshairs controlled by the electronic pen of the graphics tablet. The computer samples the x–y coordinates at user-determined time intervals and writes these to data files on disc for later analysis.

The software consists of 25 interactive programs, all under the control of a master menu program. The master menu program leads the user through the tracking, data analysis, and plotting programs using a question and answer format. A complete analysis of a 2-hr experiment involving 720 x–y coordinate locations (one every 10 sec) takes approximately 30 min.

Components

Video Equipment. The color camera we used was a moderately low light model with high sensitivity and resolution (Hitachi model 8A). It has a 12:1, 50- to 200-mm telephoto zoom lens with macro capabilities and a minimum focal range of 8.4 mm. The video recorder was a Cannon VR-20. It uses a four-head system with separate recording and playback circuits for low-distortion recording and playback of high-resolution images at variable speeds. A high-resolution Sanyo monitor was used during the experimental recording phase. During the playback and subsequent data digitization phase, we used either an Amdek model I, 13-inch color monitor or a 25-inch high-resolution RCA RGB monitor (model 2526). Recording speed was super long play (SLP) for 6 hr of data collection per video tape (Scotch Color Plus T-120).

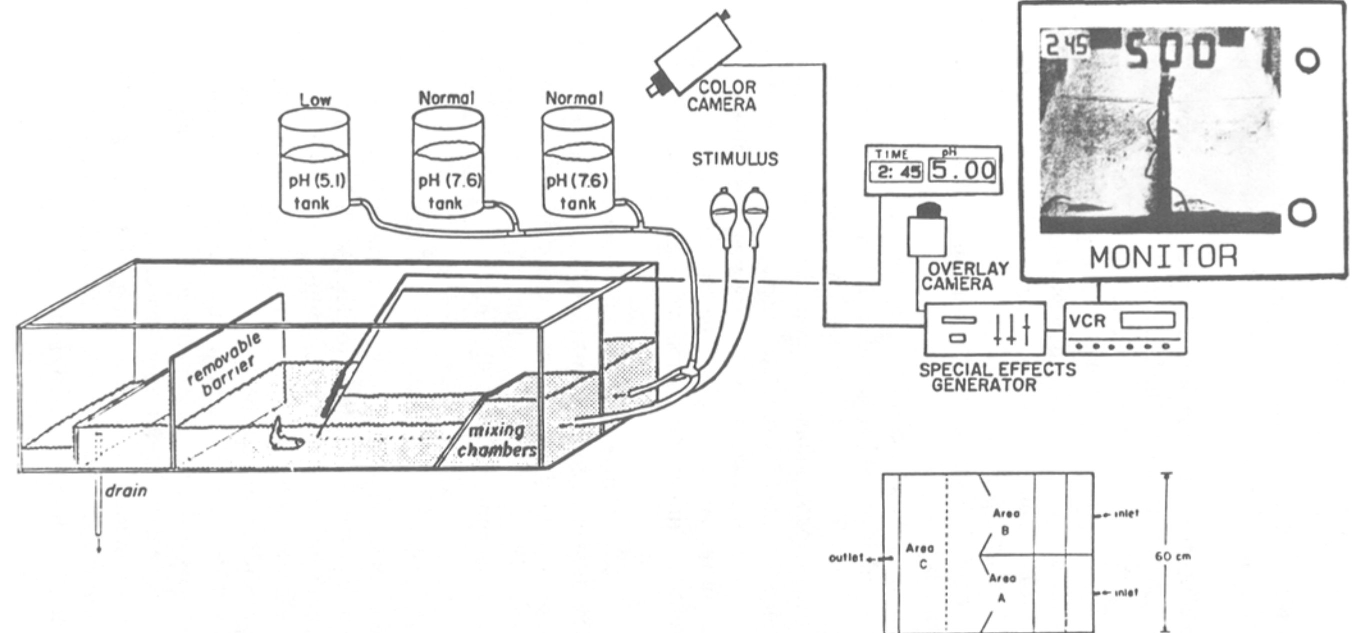

FIG. 1. Test chamber. Fish are introduced into area C behind the removable barrier. Dechlorinated, aerated tap water from overhead storage tanks flows by gravity through the chamber at a rate of 3 liters/min. Following an acclimation period, the removable screen is lifted to start the experiment. During control experiments, no olfactory stimulus is added. During the test experiments, stimulus is added to area A or B from the stimulus reservoirs. The concentration of stimulus falls off as the water from area A and B mix in area C. This creates a concentration gradient from the stimulus input to the opposite side of the tank. This gradient has been confirmed with dyes with fish present. A color video camera mounted above the chamber is used to record the experiment. The video image of the test chamber and a video display of the pH, temperature, and time throughout the experiment is combined using the special-effects generator, recorded by the VCR, and displayed on the monitor. The photograph on the monitor is a view of the experimental chamber from an actual experiment, showing the digitized display of pH and time overlayed on the video image. Two fish are visible in the lower left corner of the test chamber in area A and another in the lower left corner of the right channel in area B. The wire in the middle of the chamber comes from the pH electrode.

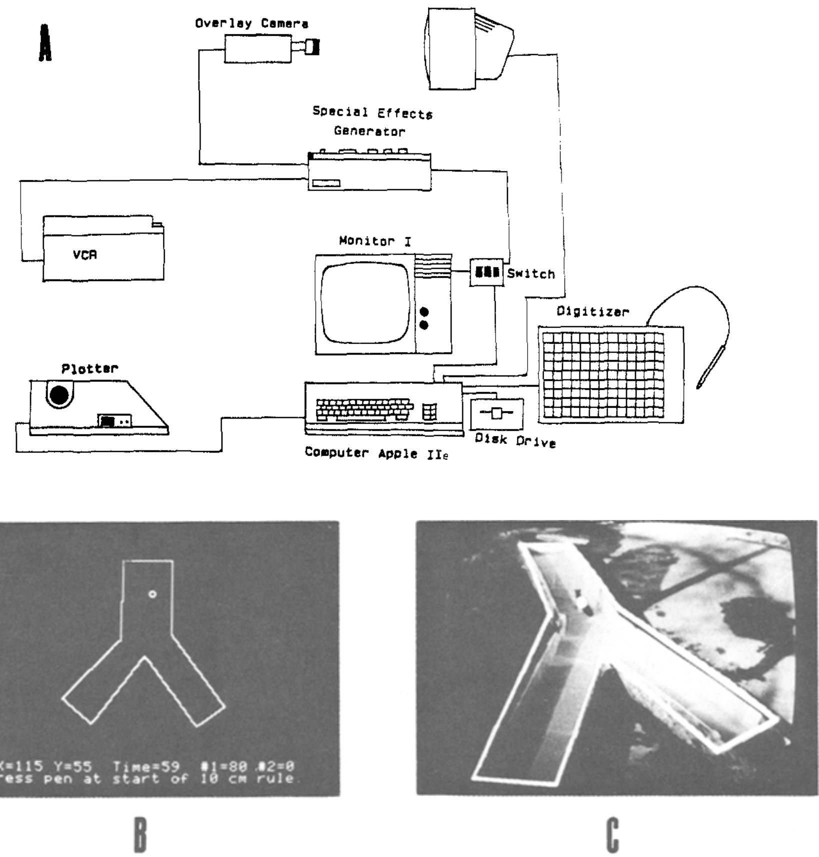

FIG. 2. Interactive computer–video tracking system (ITS). (A) Schematic showing equipment for data analysis. Experiments are video taped, and this record along with the graphics output of the computer is combined for analysis using a special-effects generator to create a composite video of the two signals. (B) Computer generated graphics output consisting of flashing cursor and a test chamber outline. The text at the bottom includes *x–y* coordinates, time in seconds, and additional key system levels. The user is being told to place the pen at the start of the 10-cm calibration rule and press the button on the tablet. (C) Photo of an actual screen during analysis. Computer generated flashing cursor (presently over a fish near the top of the chamber) is used to track individual fish, and *x–y* coordinates from the digitizer table are sampled at user determined time intervals, and then transferred to the data files on the disc.

Our video equipment is more sophisticated than necessary for most purposes. A simple black and white camera, VCR, and monitor can be purchased for as little as $700. It is likely, however, that most investigators will have suitable video components available to them, which can be adapted for use with this ITS. This eliminates the need to purchase any new video equipment, other than the special-effects generator.

The most unique piece of hardware in the ITS is the Ambico special effects generator that comes equipped with a special monochrome camera sensitive to the red/orange range of the visual spectrum. This unit costs approximately $700. It allows us to perform two important procedures: (1) overlay output of instruments such as a pH meter, clock, and thermometer on the original video signal, and (2) combine the graphics output of the computer (Figure 2B) with the prerecorded video images of the experiment to yield a composite image for data analysis (Figure 2C).

Computer and Associated Equipment. An Apple IIe with 128K memory was utilized for track digitization, data analysis, and presentation of results. Two disc drives were used, one for the controlling software, and the other for storage of data and/or results. A RAM (random access memory) disc was utilized to store temporary work files for rapid access. Two output devices were used, a Panasonic dot-matrix printer and a Hewlett-Packard x–y plotter. An Apple digitizer tablet ($800) with electronic pen was used to control the on-screen targeting crosshairs. The computer determined the x–y coordinates at user-defined time intervals as determined by an onboard clock. The precision of the digitizer tablet was much greater than needed and a Koala pad ($125) or a light pen ($150–300) was used when the high precision of the tablet was not required.

Software. All controlling programs for data acquisition and analysis were written by one of the authors (C.R.M.). The integrated data acquisition consists of three discrete programs, all controlled from a master menu program (Figure 3). These include: (1) the experiment protocol program, (2) the chamber outline and distance calibration program, and (3) the track digitization program.

The experiment protocol program records information such as data; technicians initials; number, species, and life stage of animals involved; type of experiment; physical parameters (including water temperature, pH, water hardness, and calcium concentration); video tape code name and number; tape counter at the beginning and end of the experiment; and other pertinent information (Figure 3B). Analysis information for track digitization, such as video playback speed, sample interval, experimental length, and time periods to be analyzed are then recorded. These data are stored in two files, an INFO/ on data disc and PRMTRS file on RAM disc.

The master menu program then passes the user to the chamber outline and distance calibration program (Figure 3C). The user is asked to use the electronic pen to outline the test chamber, using the video-overlay system and to designate

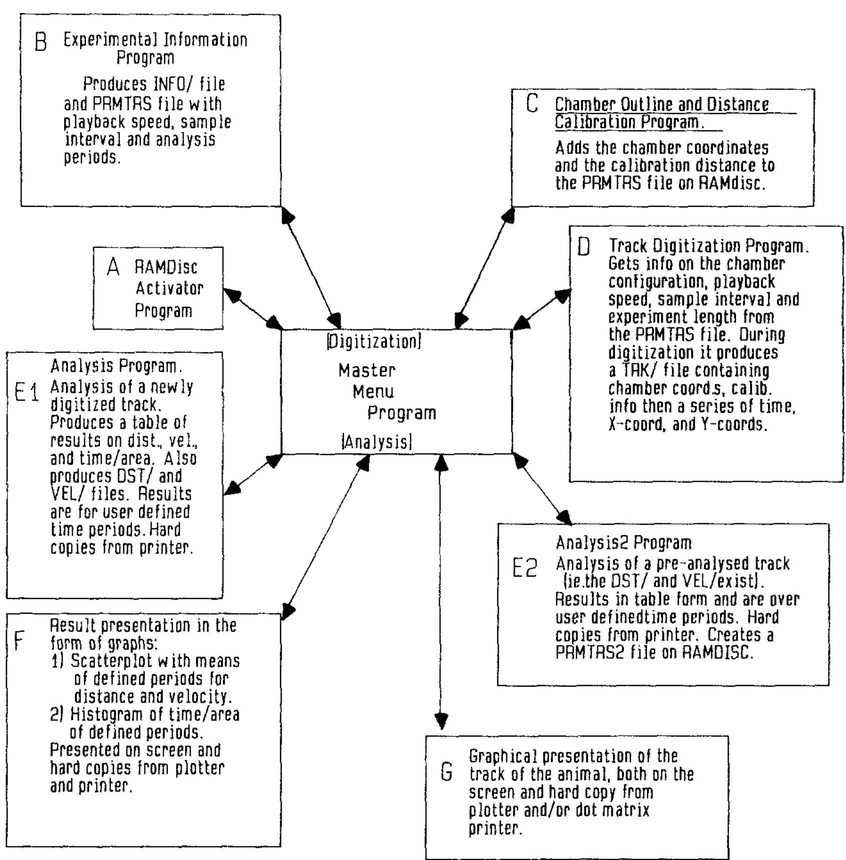

FIG. 3. ITS software block diagram. (A) The RAMdisc Activator Program first determines the availability of memory and correct system configurations. If adequate, it installs a 64K electronic disc drive (RAMdisc). (B) The Experimental Protocol Program documents the experimental and analysis parameters, then saves these to both RAMdisc and data disc. (C) Using the video overlay system, the chamber outline and calibration distance is recorded and stored on RAMdisc. (D) The Track Digitization Program, using information stored in the PRMTRS file on RAMdisc, will perform the actual track digitization with the user controlling the electronic pen. At the end of tracking, the TRK/ file is written to RAMdisc and data disc. (E1) The Analysis Program uses the TRK/ file on RAMdisc and the analysis parameters in the PRMTRS file to analyse the track. (E2) The Analysis2 Program can reanalyze a dignitzed track over new (or different) time periods. (F) The results determined in E1 or E2 can be presented graphically using the Results Plotting Program. (G) The Track Display Program can show all or any part of a digitized track on the monitor screen and hard copies can be produced on either the printer or plotter.

the ends of a 10-cm calibration rule placed in the test chamber. This information is added to the PRMTRS file on RAMdisc.

The user is then passed to the track digitization program by the master menu program (Figure 3D). Using information from the PRMTRS file, the tracking program outlines the test chamber and supplies targeting crosshairs overlayed on the video image of the experiment. The user starts the video tape and collects data simply by keeping the targeting crosshairs over the image of the fish for the duration of the experiment. Time and x–y coordinates are displayed at the bottom of the screen during data acquisition and stored in RAM (not on RAMdisc). At the end of track digitization, the user enters the stimulus source(s) position(s). The calibaration distance and the stimulus source(s) location(s), along with the time and x–y coordinates, are now written to a TRK/ file on both data disc and RAMdisc.

There are two types of analysis programs. The first (Figure 3E1) is for a newly digitized track that will create distance (DST/) and velocity (VEL/) files. The second, the reanalysis program (Figure 3E2), analyses a track for which the DST/ and VEL/ files already exist. Following analysis (either program), tabular results are displayed on the screen.

Above the table is a summary of the analysis and tracking parameters, including (1) the code name of the track analyzed and files produced and/or read, and (2) the tracking information, such as VCR playback speed, sample interval, and experiment length. A sample of such a table is shown in Figure 7. Following analysis, the data from the table can be graphically presented (Figure 7B–E). Distance and velocity are presented as a scatterplot of all data with means ($\pm$ SEM) of each period analyzed (Figure 7D,E). Time per area data appear as a histogram with separate clusters for each analysis period (Figure 7C). Finally, the actual track of the fish can be plotted over any time period(s) (Figure 7B). Hard copies of all tables, graphs, and tracks can be produced on the dot-matrix printer, and the graphs and tracks can be produced on the x–y plotter.

Analysis of Sample Populations and Statistics. Data from individual animals can be combined to form a sample population of animals responding to a given situation. For example, in our experiments, data recorded for individual fish identified by color-coded tags was stored in data files on floppy discs. Distance and velocity files for individual fish which had undergone similar experimental procedures were then combined, and composite files were created which contained the mean and variance at each sample interval. These represent the response of the sample population to the stimulus. Analysis of the results included a chi-square test to determine homogeneity of variance of replicate means. Two-way ANOVAs were used to determine if activity levels varied between treatments for individual fish.

The pH throughout each experiment was determnined from the video tape

record and transcribed into pH data files for graphic presentation along with the behavioral data (see Figure 4, bottom).

Sample Experiment

To illustrate how the system functions, a sample experiment will be outlined from its beginning to the final data presentation. Our objective is to determine the effect of pH on the response of juvenile salmonids to olfactory stimuli.

Protocol.

1. The test chamber receives water (3 liters/min) from overhead reservoirs (Figure 1), and an olfactory stimulus, in this case L-glutamine, is added to one of the inputs (chosen randomly).
2. Four fish are placed in the common area behind a barrier for a 15-min acclimation period.
3. The video camera is placed overlooking the test chamber and the pH electrode, automatic temperature compensation (ATC) probe, and pH meter are all calibrated with the probe and electrode in place at the center of the chamber. Output of the pH meter, including calibration and temperature, are overlayed on the video record of the experiment (Figure 1).
4. The experiment commences with the removal of the barrier (time = 0 sec).
5. A pH of 7.6 is maintained in the chamber for 30 min.
6. At 1800 sec (30 min), a pH change is initiated using a mixture of 50% H_2SO_4 and 50% HNO_3 (both 0.5 M). It takes 15 min to change from pH 7.6 to pH 5.1. A pH of 5.1 is held for the second 30 min.
7. At 4500 sec (75 min), the second pH change is initiated, returning the pH from 5.1 back to the original level of 7.6, over a 15-min period. A pH of 7.6 is maintained for the final 30 min.

All fish are identified with color-coded tags. At the beginning of the video tape, the experiment is given a code number, which is all the analysis technician will know about the experiment (for double-blind analysis). Pertinent data, such as stimulus type, stimulus concentration, and stimulus source location are recorded verbally at the end of the tape and in a separate notebook containing the key to the experiment's code number.

Track Digitization and Analysis of Data. Following entry of experimental information and analysis parameters, a series of calibrations begins. The first is the chamber outline procedure. The user is required to press the digitizer pen down at the corner boundaries of the chamber whose outline is then drawn on the screen and the user is asked if it is correct. If so, the distance calibration procedure follows. In this, the user is required to press the pen down at opposite ends of a 10-cm rule present in the test chamber. Again, the user is asked if

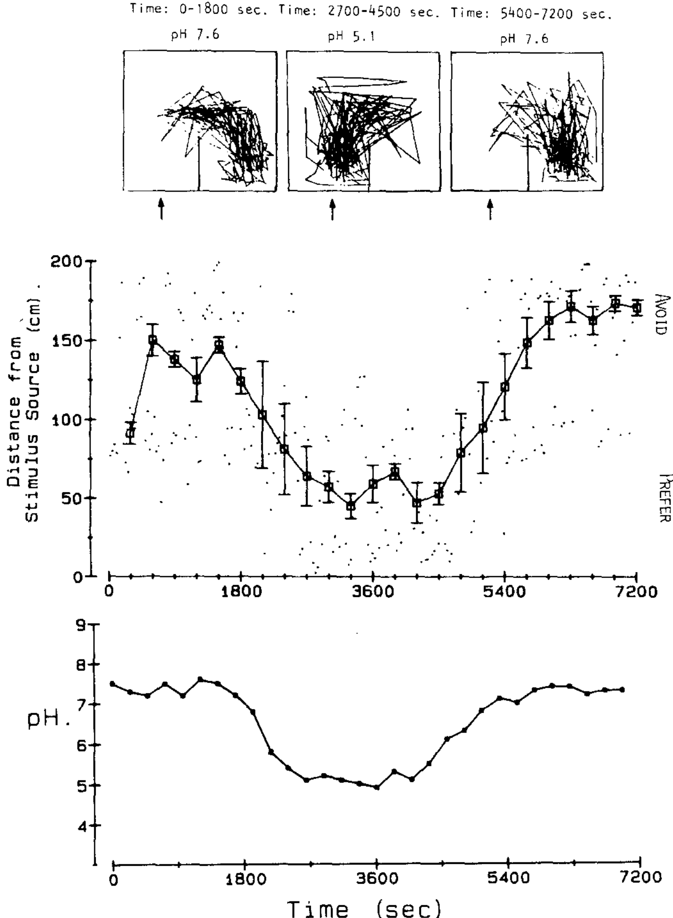

FIG. 4 Modulation of the behavioral response of twenty salmon to L-glutamine by changes in pH. Each animal was tracked for the entire experiment and mean distances (cm) from the stimulus source was calculated (see text). Top: The track of a fish during three different time periods. The arrows indicate the area receiving the L-glutamine (10^{-4} M). At pH 7.6 the fish spent most of its time away from the source of L-glutamine, but as the pH was lowered (see bottom plot), the fish's response changed to an attraction to L-glutamine. The effect was reversible with a return to pH 7.6. Middle: The mean distance from the stimulus source was determined every 300 sec for the twenty fish (squares, ± SEM). The dots represent means determined over every 30 sec, although sampled at 10-sec intervals. The closer the fish are to the stimulus, the more they prefer it. As the pH changes from pH 7.6 to pH 5.1, the avoidance changes to a neutral reaction and finally to an preference. Bottom: Record of the pH during the course of the experiment. Data was read off the video tape and entered into the computer by hand.

this is correct. All this information is placed at the beginning of a digitized track data file that will eventually contain the time, x coordinates, and y coordinates of the animal. Following this, the user begins the playback of the experimental video tape and simply tracks the animal using the digitizer pen to keep the targeting crosshairs on the image of the fish (Figure 2C). The track digitizing program accesses an onboard digital clock for time information and the digitizer tablet for the x–y coordinates of the targeting crosshairs. This information is written to RAM. The digitizer table continuously provides the computer with x and y coordinates during the tracking, but only x and y coordinates at user-defined sample intervals are recorded. This conserves memory and allows considerable flexibility in terms of track resolution. Following track digitization, the stimulus parameters are requested from the user. These include stimulus source(s) location(s), stimulus type and concentration. The user is then given the option of digitizing another track immediately or analyzing the one in memory. If the choice is the latter, the computer confirms the user's choice of time periods to be analyzed and then asks the user to wait while the analysis is conducted. Depending on the length of the experiment and the sampling rate, the analysis can take from less than 1 min for a short 30-min experiment with a data sampling rate of once every 20 sec, to 35 min for long experiments (2–5 hr) with high sampling rates (more than one sample per second). At the end of data analysis, a table summarizing the results appears on the screen. The user can then plot the results graphically. Hard copies of all or part of the data with graph can be produced by the printer and/or plotter (Figures 4–7). Following this, the track of the animal over user-specified time periods is drawn on the screen, with hard copies available (Figure 7).

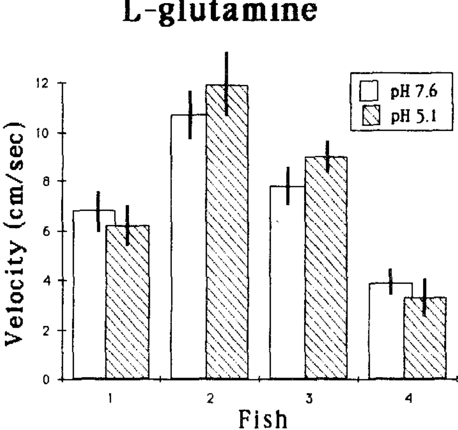

FIG. 5 Mean velocities (± SEM) of four individual fish at different pH levels with L-glutamine (10^{-4} M) present. The velocities were determined by sampling data at 10-sec intervals over 30-min periods of stable pH and then averaging these data.

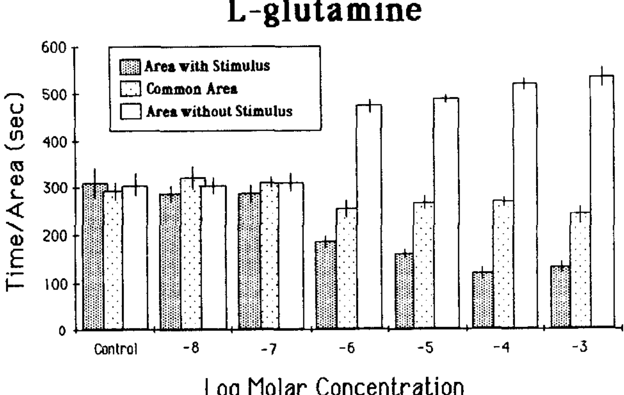

FIG. 6. Mean time (± SEM) spent per area at different concentrations of L-glutamine (N = 8 fish/concentration). The control periods did not have any stimulus present. Clearly, the avoidance of Atlantic salmon parr to L-glutamine is dose-dependent.

RESULTS

The ITS described in this manuscript was used to demonstrate that changes in acidity of water in our test chamber modified the behavioral response of juvenile Atlantic salmon (*Salmo salar*) to olfactory stimuli. We tracked each animal, in each experiment, and calculated its mean velocity, distance from the stimulus source, and time per area, every 10 sec. The data from 20 animals was compiled (15,000 data points), statistical determinations were performed by the computer, and the results plotted (Figure 4). The distance of a fish from the stimulus and time per area were used as an indication of avoidance or attraction to a given substance.

When L-glutamine (10^{-4} M) was perfused into one area of the test chamber (see Figure 1), fish spent most of their time in the area of the chamber farthest away from the stimulus (Figure 4, top), indicating an avoidance response at pH 7.6. This can be illustrated either by plotting the track of an individual fish (Figure 4, top), or by averaging the distance from the stimulus source over every 30 sec for all 20 fish (Figure 4, middle plot). The tracks at the top of Figure 4 also show that it is possible to view any portion of the experiment desired. The middle plot demonstrates that one can plot all, or part, of the data. The plot of the pH at the bottom of Figure 4 was obtained using the pH data as recorded on the original video tape of the experiment.

It is also possible to perform a number of other calculations with our software. For instance, we have determined the velocity of the animals over specific periods during control experiments (Table 1) and stimulus experiments (Figure 5). These data indicate that the acidic pH levels in these experiments do not

[b]Mean ± standard error mean.

effect the general activity of the animal. In Figure 4 (top), the tracks of the fish show that activity levels stay fairly constant between pH levels. Statistically (ANOVA), there is a significant ($P \leq 0.05$) difference in velocities among different fish, while there is not a significant ($P \geq 0.1$) difference in the velocity of the same fish at different pH levels. We have plotted a dose–response curve illustrating that the response of these salmon to a particular odor is dose-dependent (Figure 6). It is also possible to a do vector analysis over any given time period to determine an animal's orientation and/or directionality. These calculations illustrate that once the digitized tracks of all the animals are stored in appropriate data files, one can rapidly manipulate the data in a variety of different ways, depending on need.

DISCUSSION

The behavioral modification experiments described here, both in the laboratory and in the field, shown the high potential of ITS for quantitative analysis of behavior. There are similar systems on the market which track animals automatically. However, we chose not to fully automate the system for five reasons. First, we did not want to miss subtle, yet important, information that may not be recognized by a fully automated system. Second, it is not necessary to have large differences in contrast between object to be tracked and the background. Often, especially in the field, conditions were not suitable for a system that automatically tracks dark objects against a light background or vice versa. Third, although one has to repeat the analysis for each animal if there is a group of animals present, there is no problem with paths of the animals crossing. Fourth, we wanted sufficient flexibility to be able to analyze any suitable videotaped behavioral experiment. Many researchers are turning to video as a means of recording behavioral experiments. Our system (ITS) can be used to

analyze any appropriate experiments that can be recorded on video tape. Thus, a large number of researchers with varied interests can simply video tape their experiment and bring the video tape to the video–computer station in the laboratory for analysis. Finally, this arrangement allows ITS to be used for analyzing field data. We have already used it successfully to study the role of pheromones in horseshoe crab (*Limulus polyphemus*) mating behavior and the response of adult Atlantic salmon to olfactory stimuli (Figure 7).

The ITS system allows us to store data from six complete 2-hr experiments, sampled at 1-sec intervals, on a single disc, whereas other video digitizers can only store 3 min of video picture frames per disc (Kaufmann, 1983). This is because a single video frame can contain up to 52,000 bits of data and at the normal rate of 60 video frames per second, 3 min of video generates 936,000 bits of data that, when stored, will fill a data disc. While these systems need all this information in order to track a given subject automatically, our system saves memory by having a technician track the animal. The memory thus saved can then be used to store the data from a number of complete experiments in less space.

The analysis program(s) in our system can handle large amounts of data at a moderately high speed and make statistical determinations which previously would have required many man hours. This short turn-around time is beneficial because, after viewing results from one run, the investigator could rapidly modify the experimental protocol to more effectively investigate the behavior.

While there are several comparable systems available commercially or described in the literature, they tend to be much more expensive. The system we have described would cost approximately $5000 for the total assembly. However, most modern laboratories are already equipped with a microcomputer and video equipment. Therefore, the only item required would be the special-effects generator ($700) and the software. Further development of data analysis software should give rise to a wide application package that may lead to routine quantification and standardization of sensitive behavioral bioassays in the environmental monitoring field.

Acknowledgments—The authors would like to thank Dr. John J. Sasner for the use of equipment and Dave Riel and Dick Prunier of the Milford Fish Hatchery for fish and food. This research was supported by a Maine/New Hampshire Sea Grant NA-85-AA-D-FG020. Software is available to interested researchers.

Abstract—The chemical ecology of host- and mate-finding in the pine shoot beetles, *Tomicus minor* and *T. piniperda*, was studied in southern Sweden. Beetles were collected in the field from defined attack phases on Scots pine. Using gas chromatography–mass spectroscopy, a number of oxygen-containing monoterpenes, e.g., 3-carene-10-ol, myrtenol, *trans*-verbenol, and verbenone, were identified from hindgut extracts of both sexes of both species. Compared to *T. minor*, *T. piniperda* contained additional compounds and in larger amounts. The amounts were highest in both species at the time when the beetles had bored into contact with the resin-producing xylem-phloem tissue. The synthesis of (1*S*,6*R*)-3-carene-10-ol by photooxidation of (+)-(1*S*,6*R*)-3-carene is described. In comparative electroantennogram (EAG) measurements on males and females of both species, the most active of the tested compounds was *trans*-verbenol. Laboratory bioassays of walking beetles showed that *T. piniperda* was attracted to uninfested pine logs. *T. minor* was more strongly attracted to pine logs infested with females than to uninfested pine logs, indicating a female-produced aggregation pheromone. Field tests confirmed that *T. piniperda* was strongly attracted to pine logs. The attraction of *T. minor* to logs was significant only when logs were combined with racemic *trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol. *T. minor* was also

attracted to a combination of these monoterpene alcohols alone. We suggest that host and mate location in *T. piniperda* is achieved by means of a kairomone composed of host monoterpenes, while *T. minor* utilizes a primitive pheromone synergized by host odors. Evolution of host colonization strategies of the two beetles are discussed.

Key Words—Host attraction, pheromone, *Pinus sylvestris*, *trans*-verbenol, 3-carene-10-ol, myrtenol, verbenone, EAG, kairomone, *Blastophagus*, *Tomicus minor*, *Tomicus piniperda*, Coleoptera, Scolytidae, pine shoot beetles.

INTRODUCTION

The lesser pine shoot beetle *Tomicus minor* (Hart.) and the larger pine shoot beetle *Tomicus piniperda* (L.) (synon. *Blastophagus* Eich., synon. *Myelophilus* Eich.) (Coleoptera, Scolytidae) are both present in the palearctic region from Europe to Siberia and Japan. The two species are sympatric and mostly colonize Scots pine, *Pinus sylvestris* (L.), in western Europe but occasionally other trees. Both species hibernate as adults and disperse in the spring as soon as the daily temperature exceeds about 12°C. They usually establish galleries in the phloem of windthrown or otherwise weakened trees. *T. minor* is usually found in the smoother bark on the branches or higher trunk while *T. piniperda* prefers the thicker bark. Females in both species initiate galleries in the bark and are followed by a male. After two to three months, the brood emerges and flies to shoots of the current year's growth where they feed and mature. As a result of this feeding, both species cause growth losses and pruning of shoots. In addition to these effects, *T. minor* carries fungi that cause blue staining of the wood (cf. Francke-Grosmann, 1952). The bionomics of these species and their silvicultural importance have been reported by Richtie (1917), Bakke (1968), Postner (1974), and Långström (1983).

Kangas et al. (1970b) found that a volatile pine fraction, containing α-terpineol, and *cis*- and *trans*-carveol, was attractive to *T. minor* beetles in laboratory bioassays. Bakke and Jordal (personal communication) found *trans*-verbenol in hindguts of *T. minor*, and their field trapping experiments indicated that this compound may act as a pheromone component.

Earlier studies on the semiochemical system of *T. piniperda* have searched for aggregation pheromones (Schönherr, 1972; Carlé, 1978; Carlé et al., 1978; Francke and Heemann, 1976; Byers et al., 1985) with no apparent success, while evidence for a strong host attraction has accumulated (Kangas et al., 1965; Löyttyniemi and Hiltunen, 1976; Byers et al., 1985; Schroeder and Eidmann, 1986).

The aim of this study is to investigate the role of host- and beetle-produced odors in the host- and mate-finding of *T. minor* and *T. piniperda*.

METHODS AND MATERIALS

Collection of Beetles and GC-MS Analyses of Gut Volatiles. Beetles of both species were collected at Blentarp, 20 km southeast of Lund in the southernmost province of Sweden, from March 26 to April 15, 1982, while the beetles were dispersing and constructing galleries on Scots pine. *T. minor* were collected from several windthrown trees and large branches, while *T. piniperda* were taken from four windthrown trees (A–D). The diameter at breast height (DBH) of trees A, B, and C was approximately 30 cm and tree D was 15 cm. Tree C was cut into three sections, and the beetles were taken from the middle section. The beetles were treated and stored in liquid nitrogen as described by Birgersson et al. (1984).

Both *T. minor* and *T. piniperda* were separated according to the attack phase during their gallery construction in host trees (see Table 1). Attack phases were chosen in such a way that comparisons of the two species would be facilitated. However, an exact correspondence between phases in the two species was not possible to achieve because of their different behaviors (Table 1). Therefore, we divided the phase "pairs boring" into three subphases for *T. piniperda* according to the length of the tunnel made. Under favorable weather conditions, the time span between finding a suitable host (phase "walking") to egg-laying is three to six days.

Hindguts were dissected and extracted essentially as described by Birgersson et al. (1984). Females were also examined for presence of sperm (filled spermatheca) or eggs. Pentane extracts obtained from 8 to 25 guts were transferred to small glass ampoules which were sealed under nitrogen and stored at −20°C until analysis with a Finnigan 4021 gas chromatograph–mass spectrometer. GC capillary columns used were 25 m × 0.2 mm ID or 50 m × 0.35 mm ID of fused silica coated with OV-351 (Alltec Assoc.), film thickness 0.57 μm, or with Superox FA (Supelco Inc.), film thickness 0.37 μm, respectively. The terpenoid compounds analyzed in this study elute in the same order from both stationary phases. Helium was used as carrier gas at a velocity of 0.3 m/sec. The injector temperature was 210°C. After injection, the GC oven temperature remained at 50°C for 4 min and then was increased to 230°C at 8°C/min.

Heptyl acetate (30 ng/μl pentane) was added as an internal standard to the extraction solvent for quantitative calculations and comparisons of retention characteristics. Heptyl acetate was chosen as its retention time neither interferes with monoterpene hydrocarbons nor their oxygenated derivatives on the stationary phases used in this study. In our material, however, the heptyl acetate was to some extent (less than 15%) transformed to 1-heptanol and very small amounts of heptanal. For the quantitative determinations the sum of heptyl acetate, heptanol and heptanal were assumed to equal the amount of heptyl acetate originally added. A response factor of 1 was used for the quantification of the

[a] All insects collected were used both for studies of mating and egg content and for analyses of volatiles in guts.
[b] 0–3 eggs in *T. minor*, 0–2 eggs in *T. piniperda*.
[c] Attack phase "Pairs" in *T. piniperda* was separated into three subphases according to the length of the tunnel and the position of the male, as this species was sampled from thicker bark than *T. minor*. In the smaller species, formation of pairs proceeds more rapidly due to the thinner bark.

oxygenated monoterpenes relative to the internal standard. At least 0.05 ng/ extract was required for a reliable quantification of identified compounds.

Chemicals. For all identified compounds, synthetic references were available so that relative retention times and mass spectra could be compared with the compounds in the insect extracts. Myrtenal was obtained from myrtenol by treatment with chromium trioxide dipyridine complex in acetic acid (Baeckström, 1978) and analyzed immediately after synthesis. (1*S*,6*R*)-3-Carene-10-ol was obtained for reference by lithium aluminium hydride reduction of chaminic acid from the cypress *Chamaecyparis nootkatensis* (Lamb.).

The chemicals used for electroantennography, laboratory bioassay, and field trapping were 2-methyl-3-buten-2-ol, 97%; (*R*/*S*)-ipsenol, 85%; (+)-(1*R*,4*S*,5*R*)-*trans*-verbenol here called (*R*)-*trans*-verbenol, containing 12% *cis*-verbenol and <0.1% verbenone; (−)-(1*S*,4*R*,5*S*)-*trans*-verbenol here called (*S*)-*trans*-verbenol, containing <5% (*R*)-isomer and 12% *cis*-verbenol and 1% verbenone; (*R*/*S*)-*cis*-verbenol, containing 12% *trans*-verbenol; (*R*/*S*)-verbenone, 80%; (−)-*cis*-myrtanol, 95%; 2-phenylethanol, 99%; (*R*/*S*)-frontalin, >95%; (*R*/*S*)-*exo*-brevicomin, >95%; (−)-(1*S*,5*S*)-α-pinene and (+)-(1*R*,5*R*)-α-pinene here referred to as (*S*)-α-pinene and (*R*)-α-pinene, 99%; (1*S*,6*R*)-3-carene, $[\alpha]_D^{20} = +21°$; terpinolene, >99%; and myrcene, >99.8%. The chemical standards were obtained from Aldrich Chem. Comp., Steinheim, FRG, Borregaard Ind. Ltd, Sarpsborg, Norway, Chem. Samples Co., Ohio, US, or Fluka AG, Buchs, Switzerland.

Synthesis of (1S,6R)-3-Carene-10-ol for Biological Tests. Gollnick et al. (1965) and Gollnick and Schade (1966) have described a synthesis of (1*S*,6*R*)-3-carene-10-ol (7) from (1*S*,6*R*)-3-carene and their scheme was followed, although each step in the sequence was modified (see Figure 1). The photooxidation of 3-carene (1) was carried out in the presence of $TBABH_4$ according to Baeckström et al. (1982), and the crude reaction mixture was subjected to medium-pressure liquid chromatography (MPLC) on silica gel. The fractions containing monooxygenated products were combined and selectively acetylated by treatment with equal amounts of acetic anhydride and pyridine at room temperature. The acetate (5) of alcohol (4) was isolated by MPLC on silica gel and hydrolyzed with KOH in methanol. This gave the crystalline alcohol (4) which was transformed to the aldehyde (6) by an oxidative rearrangement using PCC and pTSOH in dichloromethane (Baeckström et al., 1982). Reduction of the aldehyde (6) with LAH gave the desired alcohol (7). The absolute configuration of the enantiomers of acid (8) have been determined. The (+)-(1*S*,6*R*)-enantiomer is called chaminic acid and the (−)-(1*R*,6*S*)-enantiomer is called isochamic acid (Norin, 1964). The aldehyde (6) was oxidized to the corresponding acid with sodium chlorite (Lindgren and Nilsson, 1973), and its specific rotation, [^{1}H]NMR spectrum, and melting point were found to be the same as those of chaminic acid (8) [m_p = 104.5–105.5°C, Lit. = 103–106°C, $[\alpha]_{589} = +7.2°$ (c = 3.4, MeOH), Lit. = +6 (c = 3.9, MeOH)].

FIG. 1. Reaction scheme for synthesis of 3-carene-10-ol (7) from 3-carene (1).

Electroantennography (EAG). Antennae were prepared according to Van Der Pers et al. (1984). The EAG responses were monitored on an oscilloscope, and maximum amplitudes recorded by a digital voltmeter as described by Bjostad and Roelofs (1980). The stimulation technique was essentially the same as that described by Van Der Pers (1981). A piece of filter paper (2 cm^2), with the test compound was put into a disposable 5-ml plastic syringe. No correction was made for differences in volatility among the test compounds. For each test run on an antenna the "mean response" was defined by subtracting the blank response from all measurements and then calculating the mean of the resulting amplitudes from 12 straight-chain alcohols (methanol to dodecanol), 2-methyl-3-buten-2-ol, ipsenol, *cis*- and *trans*-verbenol, verbenone, myrtenol, *cis*-myrtanol, phenylethanol, frontalin, and *exo*-brevicomin. All EAG responses are expressed as percent of this "mean response."

Laboratory Bioassay of Walking Beetles. T. minor were excise from windthrown pine trees two to three days after the first dispersal period. *T. piniperda* were picked during dispersal days while they were walking on pine trunks in a forest 30 km east of Lund, in southernmost Sweden. Beetles were

kept in the dark, 100% relative humidity, 4°C until used for testing. The open arena bioassay was as described by Byers and Wood (1981). Ten beetles at a time were released 20 ± 2 cm from the odor source on an open arena with a laminar air flow, approximately 0.6 m/sec. A beetle was recorded as attracted if it had approached closer than 1 cm from the odor source within 2 min after release. Unresponsive beetles were given a second try. Odors from pine logs for bioassay were obtained either directly by pumping air through a glass jar with a log, or indirectly after adsorption on Porapak Q and diethyl ether solvent extraction. In the latter case the adsorbed components were fractionated with capillary GC as described by Byers et al. (1985). The fractionated host compounds and the synthetic compounds were released from 5-μl glass capillaries placed in the air stream.

Field Trapping. The attractivities of a mixture of the racemic *trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol as well as host odors were tested in three field-trapping experiments. The monoterpene alcohols were used in three different baits: alone (MT-OH), together with fresh pine logs (Log + MT-OH), and together with purified host monoterpenes (MT-OH + MT). The host monoterpenes used, α-pinene, terpinolene, and 3-carene, had earlier been found to be attractive to *T. piniperda* (Byers et al., 1985).

Trapping was done in a homogeneous, evenly aged (about 70 years) pine stand 30 km east of Lund, Sweden, in April–May in 1983 and 1984. The trap logs were covered with brass nets (No. 60) to prevent arriving beetles from boring. Logs and vials with synthetic terpenes were surrounded by sticky trap, hardware cloth (No. 4), and coated with Stickem Special® (Byers and Wood, 1980). The monoterpene alcohols were each released from a 1-ml polyethylene vial (Kartell, Italy), loaded with 50 μl of the compound. The release rate of (*R*)-*trans*-verbenol from such vials was estimated by weight loss over 21 days in the laboratory to be 0.20 mg/day ($N = 8$, $r = 0.999$, hole size 4.2 mm, 20°C). The release rates of α-pinene, 3-carene, and terpinolene were each about 30 mg/day at 18°C. Treatments were assigned at random to traps placed on steel poles 1.5 m above ground and 10 m apart in a line. Rearrangement of treatment traps and collection of beetles were performed after at least 15 beetles were caught on the most attractive trap. The catches from 1984, 12 replicates, were transformed according to log (catch + 0.25) which gave homogeneous variances before ANOVA followed by Duncan's multiple-range test.

RESULTS

Attack Phases, Mating, and Egg-Laying. When walking on the host tree before entering the bark, 25% of *T. minor* and 46% of *T. piniperda* females were mated, and in both species at least 90% were mated when the nuptial chambers had been constructed (Table 1). In *T. piniperda* no fully developed

eggs could be found in the ovaries until after the nuptial chambers had been completed, while in *T. minor* some beetles contained eggs just after they had started boring ($\overline{X}$ = 0.1 eggs per female). When construction of egg galleries had begun, the mean number of eggs per female was 1.3 for *T. minor* and 0.8 for *T. piniperda*.

Volatile Compounds in Hindgut. The major volatiles found in the hindguts of the two pine shoot beetles were oxygenated monoterpenes (Table 2). In addition, smaller amounts of monoterpene hydrocarbons and sesquiterpenes were found. In *T. minor*, both the number of compounds and the amounts of detectable oxygenated monoterpenes were lower than in *T. piniperda*. Three compounds, 3-carene-10-ol, *trans*-verbenol, and myrtenol, dominated in both sexes of the two species (Table 2). Less than 2 ng per beetles of *cis*-verbenol, verbenone, and myrtenol were present in *T. minor* and less than 4 ng per beetle of verbenone, 3-carene-10-al, myrtenal, and borneol were found in *T. piniperda*. Small amounts (< 5 ng/beetle) of a few unidentified oxygen-containing monoterpenes were sometimes found, and none of these compounds were detected in both species.

In general the amounts of the oxygenated monoterpenes reached a maximum in both species when the beetles had bored through the outer bark and contacted the resin-containing phloem and xylem. In the phases following construction of the nuptial chamber, the amount of oxygenated terpenes decreased and continued to decline during egg-laying. This pattern is illustrated in Figure 2A–C for the three major oxygenated terpenes, *trans*-verbenol, 3-carene-10-ol, myrtenol, and for verbenone (Figure 2D).

Borneol	0	0	1.6 ± 0.8	1.0 ± 0.3

[a] N = number of extracts into which the beetles were divided at analysis.

The guts of *T. minor* females on the average contained more *trans*-verbenol than their conspecific males (Figure 2A). *T. piniperda* males, compared to the females, generally seemed to contain somewhat larger amounts of all the terpenes. However, it should be noted that the range of variation of samples prepared from the same sex and attack phase exceeds the differences between the sexes.

To determine the influence of various host trees on the content of oxygenated monoterpenes in *T. piniperda*, beetles were separated and extracted according to the specific tree they attacked. Table 3 shows the chemical analyses of beetles from the phase in which nuptial chambers have been formed. The insects collected from trees A and D contained significantly larger amounts of oxygenated monoterpenes than those collected from tree B and log C ($P < 5\%$, Wilcoxon signed-ranks).

Electroantennography. As a first step in determining the biological activities of the compounds identified in beetles, we recorded EAG responses in both species (Figure 3). In addition, we tested the response to some compounds attractive to other Scolytidae, as well as some host pine monoterpenes (Figure 3), and a homologous series of 12 primary straight-chain alcohols (methanol to dodecanol, not shown in the figure) was included. The straight-chain alcohols evoked a similar response pattern in both species and sexes. The responses increased with chain length to a maximum between pentanol to heptanol and then decreased with further increase in chain length. The amplitude of these responses to the alcohols were of the same order of magnitude as the other compounds tested.

For *T. minor* the strongest response was elicited by *trans*-verbenol followed by *cis*-verbenol. In *T. piniperda*, on the other hand, verbenone evoked the strongest response followed by *cis*-verbenol for the females and *trans*-verbenol for the males. However, the differences in response to *trans*-verbenol and verbenone were not significant either between the species or the sexes ($P < 5\%$, Student's t test).

Of the three major monoterpene alcohols in the beetles guts, *trans*-verbenol evoked a significantly higher response in both species and sexes compared to 3-carene-10-ol ($P < 5\%$, Wilcoxon signed rank), while myrtenol gave an intermediate response. No significant difference was observed for either species when comparing the two enantiomers of *trans*-verbenol at the same dose.

When *T. minor* antennae were exposed to different doses of (1*S*,6*R*)-3-carene-10-ol and the two enantiomers of *trans*-verbenol, both *trans*-verbenols caused signals at least twice as strong as those from 3-carene-10-ol, and they also had lower thresholds (Figure 4). The (*S*)-*trans*-verbenol was slightly more active in the tests than the (*R*)-enantiomer, but the difference was not significant.

The antennae of both species were also exposed to some major host tree

monoterpenes: (*R*)- and (*S*)-α-pinene, (1*S*,6*R*)-3-carene, terpinolene, and myrcene. The responses to these compounds were generally lower than to the oxygenated monoterpenes. No differences between sexes were found, while *T. piniperda* seemed to respond more strongly than *T. minor* to these host compounds.

Laboratory Bioassay with Walking Beetles. Behavioral tests were carried out under controlled conditions with beetle- and host-produced compounds. In the open-arena olfactometer both sexes of *T. minor* were attracted to odors from a pine log, while introduction of females into the log further increased the attraction of both sexes (Table 4, experiment 1). In contrast, *T. piniperda* beetles

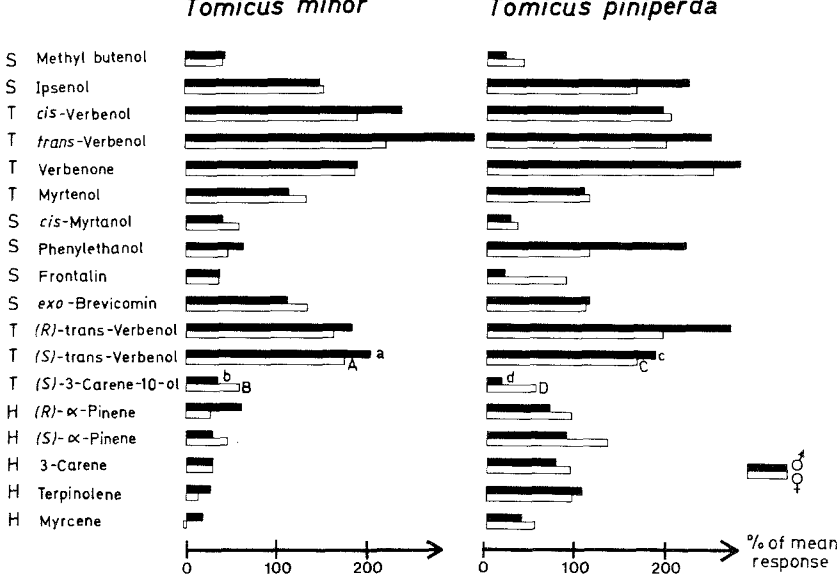

FIG. 3. EAG response of *T. minor* and *T. piniperda*, to a series of oxygenated monoterpenes produced by *Tomicus* (T), other scolytid pheromone substances (S), and host monoterpenes (H). Each insect antenna was exposed to the chemicals in the order they appear in the figure. Each compound (500 μg) was added on filter paper. For the comparison between (*S*)-*trans*-verbenol and (*S*)-3-carene-10-ol, within each species and sex, bars marked with different letters denote significantly different responses ($P < 5\%$, Wilcoxon signed-rank). Sample size was 20/16 (males/females) in *T. minor* (host compound 6/6) and for *T. piniperda* 8/15.

were strongly attracted to the pine log alone with no apparent increase in attractivity when conspecific females were present in the log. In experiment 2, Table 4, the attractiveness of the synthetic compounds, (*R*)- and (*S*)-*trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol, to *T. minor* males was compared and 3-carene-10-ol was not found to be attractive. In experiment 3 the same compounds were tested together with the monoterpene hydrocarbon fraction from pine. Again, the response to (1*S*,6*R*)-3-carene-10-ol was not significantly different from the solvent alone, but the combination of host terpenes and (*S*)-*trans*-verbenol was active. The strongest response (97%) of *T. minor* males was to a combination of a pine log and a low release of synthetic (*S*)-*trans*-verbenol (experiment 4).

Field Trapping. In the first test (Table 5, A1), performed towards the end of the flight period in 1983, indications were found that *T. minor* was attracted by the three alcohols (*R*)- and (*S*)-*trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol alone (MT-OH) and in combination with pine logs. Similarly, a subtractive

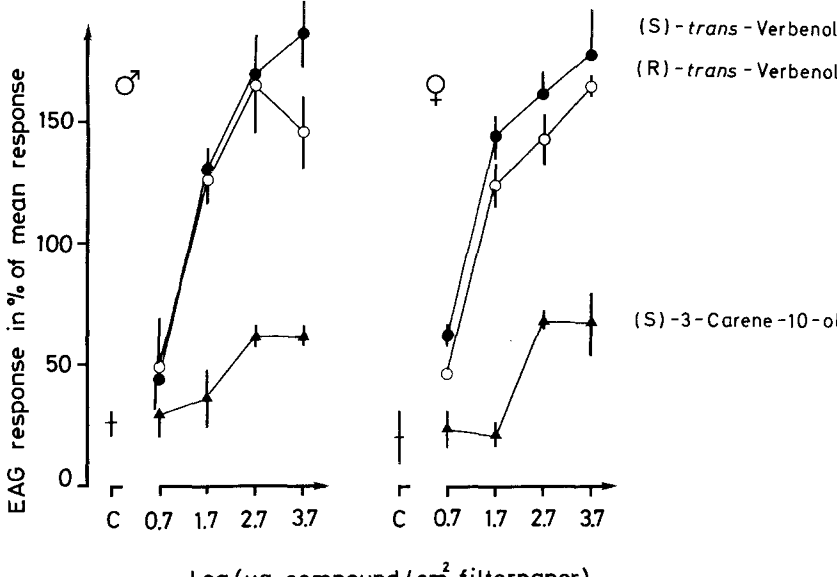

FIG. 4. Mean EAG response of *T. minor* to different doses of (*S*)- and (*R*)-*trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol applied as hexane solutions on a filter paper. Control was hexane alone. Bars represent the standard deviation.

assay of the three alcohols at the end of the 1983 flight period gave no significant differences in attraction of either species between logs baited with (1): MT-OH, (2): (*R*)+(*S*)-*trans*-verbenol, (3): (*S*)-*trans*-verbenol + (1*S*,6*R*)-3-carene-10-ol, or (4): (*R*)-*trans*-verbenol + 3-carene-10-ol. The pooled catch of *T. minor* had 68.1% males (N = 91, 95% CI-58–77), while *T. piniperda* catch was 51.2% males (N = 374).

The second test (A2) in 1984, started in the middle of the flight period, showed that traps containing *trans*-verbenols, 3-carene-10-ol, and a fresh pine log caught more *T. minor* than any of the other four treatments and was significantly different from a log alone or the blank (Figure 5). The difference in total catch between a log alone (31 beetles) and a log with the monoterpene alcohols (275 beetles) was especially prominent. For *T. minor* the baits containing the monoterpene alcohols alone differed significantly from the blank, while the log alone was not significantly different from the blank.

For *T. piniperda*, all three baits containing either pine log or the host monoterpene hydrocarbons caught significantly more beetles than the blank. The bait with the monoterpene alcohols alone did not catch more than the blank. An increase in catch was obtained when the monoterpene alcohols were added to the log, but this increase was not statistically significant.

[b] Monoterpene hydrocarbon fraction in diethyl ether after entrainment and GC fractionation.
[c] ″, §, Values followed by the same symbol are not significantly different within a species and sex by chi-square corrected for continuity at $P < 5\%$ (significance level adjusted for number of comparisons) in each experiment. Ψ, Response different between species within sex by chi-square corrected for continuity at $P < 5\%$.
[d] 40 females tested.

T. minor males were caught in a significantly higher proportion than females in the traps containing both a log and the monoterpene alcohols in all three tests (Table 4). For *T. piniperda*, on the other hand, no sex ratios significantly differed from unity.

DISCUSSION

Pheromone Activity in Tomicus. In *T. piniperda* (including *T. destruens* Woll.), Schönherr (1972) and Carlé (1974, 1978) report indications of pheromonal attraction to beetle infested logs. However, appropriate statistical tests and controls are lacking in these three studies. Kangas et al. (1970a) and Carlé

TABLE 5. SEX RATIO OF *T. minor* AND *T. piniperda* CAUGHT AT STICKY TRAPS SURROUNDING LOGS OR SYNTHETIC BAITS, SPRING 1983 AND 1984, SKÅNE, SWEDEN.

[a]Bait designations: MT-OH = (*S*)-*trans*-verbenol + (*R*)-*trans*-verbenol + 3-caren-10-ol, oxygenated monoterpenes released from separate vials at approx. 0.2 mg/day, see Methods. MT = (*S*)-α-pinene + (*R*)-α-pinene + 3-carene + terpinolene, monoterpene hydrocarbons released from separate vials at approx. 30 mg/day (Byers et al., 1985), see Methods.
[b]Sample size equal to or less than total catch, as maximum 100 individuals were sexed from each replicate and some individuals were too damaged to sex.
[c]Binomial 95% confidence interval (Byers & Wood 1980).
[d]Value significantly different from an equal sex ratio.
[e]Value calculated on less than 20 individuals.

(1978) in laboratory bioassays claimed *trans*-verbenol to be attractive, but no statistics were presented. On the other hand, field-trapping experiments by Perttunen et al. (1970) did not find that the presence of boring females (assumed to be the pheromone-producing sex) enhanced the attractiveness of logs. The results of the present study complement these results and those of Byers et al. (1985), who developed a systematic method for isolating semiochemicals from pine logs infested with *T. piniperda* (sexes together or each alone) and found no evidence for a long-range pheromone for mate and host location. Instead, pine volatiles, (*R*)- and (*S*)-α-pinene, 3-carene, and terpinolene, were found in field and laboratory experiments to be attractants (Byers et al., 1985). These three compounds were later shown to induce attacks by *T. piniperda* on vigorous trees, unsuitable for brood development (Schroeder and Eidmann, 1987). Kangas et al. (1965) and Oksanen et al. (1968) concluded from laboratory bioassays (without any statistical analysis of data) that *cis*- and *trans*-carveol

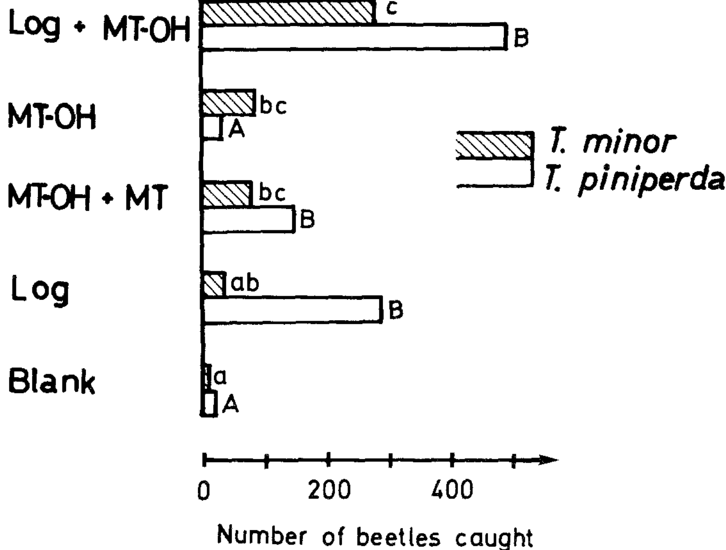

FIG. 5. Catch of *T. minor* and *T. piniperda* on sticky traps with five different baits. The lengths of the bars correspond to the total catch in 12 replicates in 1984. Bars followed by the same lower or upper case letters form homogeneous subsets [$P < 5\%$, Duncan's multiple-range test after ANOVA on log (catch + 1/4)]. Baits marked with MT-OH contain (*S*)- and (*R*)-*trans*-verbenol and (1*S*,6*R*)-3-carene-10-ol and those marked with MT contain (*S*)- and (*R*)-α-pinene, terpinolene, and (*S*)-3-carene.

together with α-terpineol were the most active host compounds and thus responsible for "primary attraction." However, their bioassays were performed in closed-choice chambers with no odor gradient at equilibrium. In our open-arena walking bioassay the odor is mixed with a stream of air. This allows both an odor gradient and a wind direction in which the beetles can orient and thus simulates the natural condition more closely.

The existence of a pheromone in *T. minor* produced by the female is indicated by the female initiated galleries, the strong bioassay response of both sexes to female infested logs, and the >50% males caught at traps baited with (*S*)- and (*R*)-*trans*-verbenol and 3-carene-10-ol. It is, however, possible that males also may contribute to the pheromonal attraction as their production of the three alcohols is almost as large as that of the females (Table 2). In a large sample of pine shoot beetles attracted to pine logs or feeding in pine shoots, Långström (1980, 1983) found an equal or slightly female biased sex ratio for both species in middle Sweden. Thus the higher percentage of males of *T. minor* at pheromone traps probably does not reflect the mean sex ratio of the population. In contrast, *T. piniperda* did not respond more to female infested logs than

to uninfested logs, and the sex ratio at traps baited with the alcohols was not different from unity.

The fact that a long-range pheromone has not been found for *T. piniperda* in this or other studies is notable, as pheromone communication in scolytid biology has almost become a paradigm (Borden, 1982; Wood, 1982). However, in at least two other cases research has failed to prove a pheromonal attraction but instead an attraction to host odors (*Pseudohylesinus nebulosus*; Ryker and Oester, 1982) or to odors of a decaying host (*Hylurgopinus rufipes*; Gardiner, 1979; Lanier, 1983). *P. nebulosus* is similar to *T. piniperda* in several respects: not only does it disperse early in spring and attacks only felled or weakened trees, but logs with male and female *P. nebulosus* were also somewhat more attractive than logs alone, parallel to the findings of Byers et al. (1985). In each of these studies the increase in attraction was attributed to a large release of host volatiles from logs with excavating beetles rather than to a weak pheromonal attraction.

Semiochemical Production and EAG Responses. Both the (*R*)- and (*S*)-isomers of *trans*-verbenol were tested in the biological experiments because the absolute configuration of the beetle produced compound was not determined. In the EAG tests with *T. minor*, *trans*-verbenol induced the largest total response and the (*S*)-enantiomer the highest dose–response. Bakke and Jordal (personal communication) also found indications that (−)-(*S*)-*trans*-verbenol acts as an attractant for *T. minor* in field-trapping experiments. When considering the activity of *trans*-verbenol, the relatively large impurity of *cis*-verbenol could be important. In fact, the amount of *cis*-isomer (about 10%) in the synthetic *trans*-verbenol used in our field tests is about as large as the ratio of *cis* to *trans* naturally found in hindguts of *T. minor*. Thus, the studies reported here do not uniequivocally support *trans*-verbenol as the only active component in the *T. minor* pheromone.

Only the (1*S*,6*R*)-enantiomer of 3-carene-10-ol was used in laboratory and field experiments since its precursor, 3-carene of the wood oil in Scots pine, is known to possess the (1*S*,6*R*)-configuration (Semmler and von Schiller, 1927; Aschan, 1928; Norin, 1964). 3-Carene-10-ol has earlier been identified in the mountain pine beetle, *Dendroctonus ponderosae* (Conn et al., 1983), but the absolute configuration was not determined and the compound was not found to have any effect on field trap catches. Our results with the laboratory olfactometer and EAG also indicate that 3-carene-10-ol is not an essential attractive pheromone component in *T. minor*.

The demonstration of the presence of *trans*-verbenol, myrtenol, and verbenone in *T. piniperda* hindguts is in agreement with earlier studies (Francke and Heeman, 1976; Carlé et al., 1978). However, Francke and Heeman's observation that virgin females and males have relatively high amounts of verbenone was not confirmed in our study. The amounts of verbenone were highest

in both sexes just before the construction of egg niches and at that time most females were mated.

The value of electrophysiology as a screening method for attractive pheromone candidates in bark beetles is probably limited. For example, it is known that bark beetles can have receptors highly sensitive to pheromone components of other species which act as allomones (Light and Birch, 1982). In fact, we found significant EAG activity in both *Tomicus* species to several bark beetle pheromone compounds that were not detected in either *Tomicus* species. Our study also showed that several monoterpenes attractive to *T. piniperda* gave smaller EAG responses than *trans*-verbenol and other oxygenated monoterpenes. These oxygenated compounds could, however, elicit other, as yet undiscovered, pheromonal activities at close range.

In the hindgut extracts, large amounts of 1-heptanol were found. When 1-heptanol, a pheromone component of *Dendroctonus vitei* (Renwick et al., 1975), and some homologs were at first included in the EAG tests, both species were almost as sensitive to these straight chain alcohols as to the oxygenated monoterpenes. However, it was later found, by addition of hexyl and octyl acetate to the gut extraction solvent, that the heptanol originated from transformations of the heptyl acetate that was used as an internal standard. Short-chain alcohols are also known to evoke EAG response in the Colorado beetle (Visser, 1979) and some lepidopteran species (Van Der Pers, 1981).

Evolutionary Considerations. How can the two *Tomicus* species be placed in a larger evolutionary framework of olfactory orientation during host colonization in bark beetles? The first "primitive" system to evolve may have relied only on host plant compounds for host location and acceptance, as in many phytophagous insects. As the use of long-range aggregation pheromones evolved, the need to utilize host attractants could have decreased in significance. In most insects, the egg-laying potential of the female is the most critical resource for reproduction, and females produce a sex pheromone attracting only males from a distance. In some insect groups, males produce pheromone and provide essential resources for reproduction like nuptial gifts in scorpionflies (Bornemissza, 1964) or announce clumped resources for reproduction, as in some stored-product beetles (Burkholder and Ma, 1985) and in polygynous bark beetles (Kirkendall, 1983). Female-produced aggregation pheromones, however, seem to be restricted to bark beetles and function in host-killing cooperation to establish a food resource after successful colonization of a tree.

Possibly, an early step in pheromone system evolution was represented by groups that modified host compounds for use as pheromone components (many *Ips*; Wood, 1982). More advanced systems have complex bicyclic ketals (*Dendroctonus*, *Pityogenes*) or tricyclic ketals (*Trypodendron*, *Scolytus*) of which the carbon skeletons are not found in the host. These compounds are, however, usually still synergized by host compounds (Borden, 1982; Wood, 1982). Other

advanced systems include loss of host synergism but with monoterpene alcohols in conjunction with short-chain alcohols (*I. typographus*; Bakke et al., 1977; *I. cembrae*; Stoakley et al., 1978). The small difference between the sexes of *T. minor* in the production of the major component *trans*-verbenol indicates a primitive system not far evolved from a simple detoxification of host terpenes.

Both *Tomicus* species apparently have a similar production and sensory perception of oxygenated compounds suitable as chemical messengers but *T. piniperda* has not acquired (or maintained) a pheromone system. The life history of the two species differs radically in the mode of feeding by the larvae. In the genus *Tomicus*, three or four palearctic species exist (Schedl, 1946), but of these *T. minor* is the only species which has evolved the fungus-feeding habit (xylomycetophagy; Kirkendall, 1983). This fungus feeding may have allowed an expansion or shift of the spatial niche to the thin-barked sections of the pine, where *T. piniperda* cannot reproduce readily. The xylomycetophagus population may have avoided gene flow from the phloem-feeding population by beginning to use a long-range pheromone. The fact that *T. minor* attacks thin bark (often <0.5 mm) and thus contacts resinous tissue more rapidly would make it easier for this species to develop a "frass pheromone" (Vité et al., 1972), which could be released comparatively quickly (within a day). In contrast, *T. piniperda* may take from one to several days during the early spring conditions (low day-time temperature) to penetrate the thicker cortex bark, and by this time most beetles have landed on the tree in response to host monoterpenes. On the other hand, *T. minor* is reputed to colonize standing, weakly stressed trees more often (Postner, 1974), presumably with the aid of its aggregation pheromone. A further evolution towards a more rapid acting pheromone system might allow *T. minor* to attack viable host trees and expand its niche considerably.

PATTERNS AND SOURCES OF LEAF TANNIN VARIATION IN YELLOW BIRCH (*Betula allegheniensis*) AND SUGAR MAPLE (*Acer saccharum*)

IAN T. BALDWIN,[1] JACK C. SCHULTZ, and DALE WARD

Pesticide Research Laboratory, Pennsylvania State University
University Park, Pennsylvania 16802

(Received January 3, 1986; accepted June 20, 1986)

Abstract—Leaves from forest-grown sugar maple (*Acer saccharum* Marsh) and yellow birch (*Betula allegheniensis* Britt.) trees were analyzed for four tannin measures (hydrolyzable and condensed tannins, total phenolics, and protein binding) at three times during the growing season. Fifteen-year-old half-sib sugar maples from four provenances, representing the geographical extremes of the sugar maple range and growing in a common garden, were examined for the same traits. We found no significant geographic or seed source component to variation in three of the four tannin measures. We found significant seasonal changes in both birch and maple leaf tannins. Within-canopy leaf tannin variation tended to obscure differences between trees in maple, but in birches between-tree differences in leaf tannin content were more readily found. We also found a significant negative correlation between leaf protein binding capacity and leaf wet weight.

Key Words—*Acer saccharum*, Aceraceae, *Betula allegheniensis*, Betulaceae, tannins, phenolics, variability.

INTRODUCTION

Tannins are polyphenolic secondary compounds that have antifeedant and toxic effects on a variety of herbivores (Feeny, 1970; Chan et al., 1978; Reese et al., 1982) as well as antipathogenic properties (Swain, 1979). Susceptibility/resistance of chestnut trees to chestnut blight has been attributed to variable tannin production (McCarroll and Thor, 1985). Tannins in sugar maple (*Acer saccharum* Marsh) bark and roots may determine tree resistance to fungal attack

(Wargo, 1972). Although their impact on defoliators is uncertain (Bernays, 1981; Martin and Martin, 1982, Lawson et al., 1984), these compounds may constitute 20% of sugar maple leaf dry weight and 10% of yellow birch (*Betula allegheniensis* Britt.) dry weight (Schultz et al., 1982) and are likely to represent a substantial metabolic investment by these trees (Mooney, 1983).

Birch and maple leaf tannins can vary substantially in space and time (Schultz et al., 1982). There are many possible causes of this variation, including increased synthesis in response of leaf damage (Baldwin and Schultz, 1983), seasonal change (Schultz et al., 1982), leaf age (Schultz et al., 1982), and individual variation arising from genotypic and/or site differences.

The last two sources of variation of other secondary compounds, e.g., monoterpenes in conifers are known to be heritable (Bridgen and Hanover, 1982; Strauss and Critchfield, 1982) and geographic variation are readily identified (Zavarin et al., 1979; Lester, 1974). Although the heritability of tannin production is well established for sorghum, where it has been employed in the development of pest-resistant cultivars (Woodruff et al., 1982), it is unstudied in trees. Understanding patterns and causes of leaf tannin variation might also help promote pest-resistance in trees.

We report here analyses of tannin and phenolic variation in two northern hardwood tree species, including maple trees grown in a common plantation from known seed and geographic sources. We find that within-tree and individual variation (related in part to leaf size) and seasonal changes are too great to permit us to identify variation arising from family, population, or even geographic sources.

METHODS AND MATERIALS

Tannin Analysis. Birch and maple leaves were collected between 8 and 9 AM and immediately placed on ice. Weighed leaves (to 0.2 mg) were flash-frozen and ground to a powder in liquid N_2 within 20 min of collection and extracted individually in aqueous MeOH (1 : 1 v/v) under N_2 for an hour at 70°C (Schultz et al., 1981). Leaf dry weights were determined gravimetrically. Extracts were filtered through Whatman No. 1 and the phenolic content was estimated by the Folin-Denis technique (Swain and Hillis, 1959). The tanning capacity of the extracts was estimated by protein precipitation; fresh hemoglobin was used as the substrate (Schultz et al., 1981). Hydrolyzable tannins were estimated with an iodate technique (Swain, 1979). These tannin values are expressed as percent tannic acid equivalents per gram dry leaf weight (%TAE) from tannic acid standard curves. Condensed tannins were measured as proanthocyanidins (Bate-Smith, 1975) and expressed as percent purified red oak condensed tannin (%ROT) per gram dry weight leaf (Schultz and Baldwin, 1982). These techniques are highly replicable; tannin and phenolic measurements made

on 20 homogeneous maple leaf samples of varying weight (75–2500 mg dry wt) had coefficients of variation below 7%.

Analysis of Geographic Variation. Fifteen-year-old half-sib sugar maples grown from seed in a provenance plantation established and maintained by the USDA-FS Aiken Sugar Maple Lab located in Millbrook, New York, were studied. Four seed sources from the approximate geographical extremes of the sugar maple range were chosen: Mille Lacs, Minnesota; Harlem County, Kentucky; Tucker, West Virginia; and Quebec City, Canada. Four trees from each seed source—one tree from each of four randomized blocks within the plantation—were sampled. Five leaves were collected 2.5 m above ground from shaded stems in the southern canopy of each tree on July 8, 1981. Selecting widely spaced individuals should have minimized intertree "pheromonal" interactions (Rhoades, 1983; Baldwin and Schultz, 1983).

Analysis of Seasonal Variation. Five 40- to 50-year-old forest sugar maple and yellow birch trees of unknown seed origin, with diameters at breast height (DBHs) of 15–22 cm, were sampled near Norwich, Vermont, on three dates during the growing season: May 19, June 10, and July 20. Five sugar maple leaves from one whorl from each tree were collected at each time period. All maple leaves were taken from the the west canopy, 2.5 m above the ground, from shaded stems, and were derived from primordia established during the previous year, thus minimizing chemical differences which might be due to leaf age or position. The first five fully expanded leaf pairs on the birch trees, at the same height and aspect as the maples, were collected. One randomly chosen leaf from each pair was selected for tannin analysis, the other was used for percent dry weight determination. The five birch leaves thus represent an age gradient. No branch was sampled twice, to avoid wound-induced changes in tannin chemistry (Baldwin and Schultz, 1983; Schultz and Baldwin, 1982), and widely spaced individuals were selected in an attempt to minimize "pheromonal" interactions (Rhoades, 1983; Baldwin and Schultz, 1983).

Statistical Methods. Many of the chemical measures were heteroscedastic between sampling dates or provenances which invalidates the use of two-way ANOVAs; thus Kruskal-Wallis one-way ANOVAs were used to compare groups (Sokal and Rohlf, 1969). A Pearson product-moment correlation matrix was calculated after the chemical data were transformed to z scores (Cooley and Lohnes, 1971). Leaf chemical values were regressed against leaf weight and dry weights and the significance of the slopes was determined with an F test (Sokal and Rohlf, 1969).

RESULTS AND DISCUSSION

Sugar maple trees grown from seeds collected at the geographical extremes of the sugar maple range showed no significant differences in leaf total phenolic

TABLE 1. TOTAL PHENOLIC CONTENTS, PROTEIN BINDING COEFFICIENTS, AND HYDROLYZABLE TANNIN CONTENTS AS PERCENT DRY WEIGHT TANNIC ACID EQUIVALENTS; PROANTHOCYANIDIN CONTENTS AS (PERCENT) DRY WEIGHT PURIFIED RED OAK TANNIN, OF SUGAR MAPLE LEAVES FROM 4 PROVENANCES IN COMMON GARDEN[a]

Provenance	Total phenolics	Protein binding	Hydrolyzable tannins	Proanthocyanidins
Kentucky	16.6 (2.3)	43.7 (8.0)	43.5 (7.7)	0.62 (0.31)
Minnesota	18.1 (2.8)	43.6 (7.7)	50.5 (11.3)	0.42 (0.12)

content, protein binding capacity, or hydrolyzable tannin content (Table 1). However, trees grown from the West Virginia seed source had higher condensed tannin contents than those from the other provenances.

Tannin measurements varied substantially among individual trees. Hydrolyzable tannin contents had between-tree coefficients of variation (CV) of 23.0%, protein binding coefficient CV of 21.1%, total phenolic content CV of 18.3%, and condensed tannin content CV of 87.5%. However, little of this variation was associated with seed source; for example, trees with both the highest and lowest mean total phenolic contents were grown from seed collected in Mille Lacs, Minnesota.

Seasonal changes were a major source of variation. Sugar maple leaf total phenolic contents, protein binding coefficients, and hydrolyzable tannin contents tended to decline from May 19 to June 23, with very little further decline by July 20 (Table 2). Together with the yellow birch results below, this is the first report of seasonal changes in hydrolyzable tannins of forest trees. Maple condensed tannin contents could not be detected in the May sampling and had reached a plateau by the June and July sampling dates (Table 2). This pattern differs from that found by Feeny and Bostock (1968) for *Quercus robur*, wherein an almost continuous seasonal increase in condensed tannins was found.

The phenology of maple condensed tannin synthesis suggests that the high condensed tannin content found in leaves from the West Virginia seed source is not a result of altered phenology in these trees; their condensed tannin content is substantially above both forest and plantation trees sampled at approximately the same time. However, only three of the four West Virginia trees displayed this high tannin content. Several nongenetic factors could have generated elevated tannin contents in some of the West Virginia trees, including previous

June 23	18.2 (2.7)	27.7 (12.6)	48.6 (11.8)	0.58 (0.25)
July 20	16.1 (1.9)	31.0 (8.5)	37.9 (26.3)	0.45 (0.18)

[a] Means (standard deviation) ND = not detected.

damage or infection. In laboratory grown maples, as little as 10% leaf area removal results in significantly increased tannin production (Baldwin and Schultz, 1983).

All plantation trees sampled at the same time as forest trees had significantly greater protein binding coefficients. Differences between the two sets of trees could derive from superior growth conditions on the plantation.

These results indicate that the chemical assays we used (with the possible exception of condensed tannin measurements) are likely to be poor markers for identifying geographic origin or seed source of sugar maples, because within-tree and seasonal variation obscure patterns in static chemical traits. However, other tree characteristics (e.g., ability to respond chemically to pest attack), could exhibit stronger geographic or family variation.

Yellow birch leaves exhibited a more complicated seasonal pattern (Table 3) than maple. Hydrolyzable tannin content decreased seasonally to a plateau

TABLE 3. as it did in maple. Condensed tannin and protein binding coefficients increased in the June sampling date and decreased in July. Birch total phenolic contents displayed the reverse pattern, decreasing in June and increasing in the July sampling.

Leaf chemistries of individual birch and maple trees, however, did not change in an orderly, parallel fashion. No forest maple tree maintained the same rank among the five individuals sampled through all time periods for any chemical measure. With a few exceptions, it is difficult to discern statistical differences between leaf tannin contents in maple trees at any particular sampling period (Table 4). Yellow birch exhibits less within-canopy variation, and statistical differences between trees are more frequently discerned (Table 4). These general seasonal patterns were similar to those found previously for both maple and birch (Schultz et al., 1982), but were temporally shifted so that plateaus were reached about three weeks earlier.

We found no consistent relationship between leaf tannin values and position in the whorl for forest maple trees or position on the branch for the forest birch trees. This was not surprising for maple because the leaves in a whorl do not differ greatly in age (Gregory, 1980). Previous studies (Schultz et al., 1982) had led us to expect higher phenolic contents in the terminal, younger leaves of yellow birch, which flushes new leaves throughout a long growing season (Sharik and Barnes, 1976). We regressed the leaf tannin and phenolic contents

TABLE 4. RESULTS OF KRUSKAL-WALLIS ONE-WAY ANALYSIS OF VARIANCE FOR TOTAL PHENOLICS, HYDROLYZABLE AND CONDENSED TANNIN, AND PROTEIN BINDING DIFFERENCES FROM 5 YELLOW BIRCH AND 5 SUGAR MAPLE TREES SAMPLED THREE TIMES DURING SEASON[a]

on leaf wet weights; results were the same when leaf dry weights were used. There were no significant differences in leaf dry weights between trees or time periods. We identified a significant negative relationship between protein binding capacity and sugar maple leaf weight for the June ($r = -0.51$, $DF = 24$, $F = 8.0$, $P < 0.01$) and July ($r = -0.61$, $DF = 24$, $F = 13.7$, $P < 0.005$) sampling dates; no other slopes differed significantly from zero. However, leaf size was found to predict protein binding in sugar maple.

In yellow birch we found similar negative correlations between leaf weight and protein binding capacity for all time periods: May ($r = -0.41$, $DF = 24$, $F = 4.66$, $P < 0.05$), June ($r = -0.51$, $DF = 24$, $F = 7.73$, $P < 0.025$), and July ($r = -0.76$, $DF = 24$, $F = 30.98$, $P < 0.001$). We also found a positive correlation between condensed tannin content and leaf weight for the July sample ($r - 0.54$, $DF = 24$, $F = 10.68$, $P < 0.001$). No other regressions for birch were significant.

The observation that smaller birch and maple leaves, regardless of their age, have higher protein binding coefficients than larger leaves suggests that tannin synthesis may be influenced by leaf expansion and growth. A similar situation was reported by Zucker (1982), who showed that the largest *Populus angustifolia* leaves had the lowest total phenolic contents. If a leaf is limited in the amount of phenolic compounds it can produce because of biosynthetic competition with growth processes, then smaller leaves should have higher tannin contents. Competition for precursors could occur at several points, including the deamination of phenylalanine (or tyrosine) at entry to the phenylpropanoid biosynthetic pathway, or between lignin synthesis and the synthesis of other phenolics. The first case would represent a direct trade-off between protein synthesis (growth) and phenolic synthesis. In the latter case, larger leaf size may result from shunting more precursors into structural lignins than into condensed tannins. However, if hydrolyzable tannins make a large contribution to the protein binding capacity of a leaf, the biosynthetic trade-offs become less clear; gallic acid, the precursor of hydrolyzable tannins, can originate from the shikimate acid pathway, as well as the phenylpropanoid pathway. The observations that many of the tannin measures decrease seasonally and that in both maple and birch the strength of the correlation with leaf weight increases seasonally are consistent with the hypothesis that lignification and tannin synthesis are competitive processes.

In their classic study of *Quercus robur* L. tannins, Feeny and Bostock (1968) reported seasonal and leaf age increases in tannin concentrations. Except for condensed tannins in maple, our results differ substantially. Although these differences may reflect differences among the species involved, several investigators have found higher tannin or phenolic concentrations in younger leaves (e.g., Coley, 1983), including oak (Faeth, 1986; Schultz and Baldwin, unpublished). Each of these studies also employed different analytical methods. We

suspect that the relationship between growth and phenolic synthesis is highly dynamic and complex in young, rapidly expanding tree leaves. Only very detailed (e.g., on a daily basis) studies of phenolic biosynthesis in expanding leaves will elucidate this interaction.

Regardless of the mechanism, the correlation between leaf size and protein binding capacity could have important ecological and evolutionary implications for maple and birch feeders. If herbivores can distinguish between leaves of different weights (or sizes), then they may be able to increase their foraging efficiency for leaves of high food quality (e.g., Zucker, 1982).

In previous work (Baldwin and Schultz, 1984), we found a significant negative relationship between individual tree leaf weight and Folin-Denis reactive phenolics for unstressed laboratory-grown yellow birch trees. This correlation was lost if the trees were damaged or shared the atmosphere with trees that had been damaged. The observation that forest-grown birches do not, as a group, exhibit the negative total phenolic content–leaf weight relationship could be due to nearby leaf damage, either on the same tree or on nearby conspecifics. Moreover, the observation that undamaged birch and late-season maple leaves exhibit a negative protein binding capacity–leaf weight relationship indicates that tannin synthesis, unlike phenolic synthesis, may be less responsive to nearby leaf damage. These results were consistent with previous work (Baldwin and Schultz, 1983) on laboratory-grown maple trees.

Calculation of a Pearson's product–moment correlation matrix allowed us to determine correlation coefficients between pairs of chemical traits of the 80 leaves analyzed from the maple plantation. Protein binding coefficients, which measure the in vitro protein binding capacity of tannins, were significantly correlated with total phenolic contents ($r = 0.65$, $P < 0.05$). Hydrolyzable and condensed tannin contents were not significantly correlated with tanning coefficients, and the three chemical measures were not significantly correlated with each other.

Correlation coefficients calculated from the forest maples differed dramatically from those in the plantation grown maples. Protein binding coefficients were not significantly correlated with any of the chemical measures. Total phenolic content was positively correlated with condensed tannin content ($r = 0.62$, $P < 0.05$) but negatively correlated with hydrolyzable tannin content ($r = -0.70$, $P < 0.01$) and condensed and hydrolyzable tannin contents were negatively correlated ($r = -0.78$, $P < 0.01$).

The relationships among the tannin measurements appear to vary from site to site and/or seasonally. These results could be caused by several factors. First, synthesis of various tannin types might not be closely coordinated in a tree; there is no reason, for example, to expect any particular relationship between hydrolyzable and condensed tannin synthesis. Second, the individual experiences of each tree could alter tannin chemistry and synthesis as the season pro-

gresses. Finally, the nature of the analyses employed here is such that the functional and synthetic relationships of the product measured are uncertain. Most of these analyses are influenced by qualitative composition of plant phenolics as well as concentration of the "target" molecules (Hagerman and Butler, 1978). Martin and Martin (1982) found a similar lack of correlation between chemical measures of tannins and functional measures such as protein binding.

Acknowledgments—We thank M. Montgomery for providing purified oak tannins and G. Hawley for access to the provenance plantation. D.B. Munson and J.B. McKoy III helped with chemical analysis, and a reviewer's comments were helpful. Supported by NSF grants DEB 80-22174 and BSR 84-00284. (Received April 24, 1986; accepted June 26, 1986)

Abstract—The cephalic extracts of two species in the stingless bee genus *Oxytrigona* were analyzed. Extracts made in diethyl ether, and then derivatized with diphenyldiazomethane, revealed large quantities of formic acid, potentially a major defensive secretion of this stingless bee group. We additionally identify several hydrocarbons, aldehydes, ketones, and acetates. Novel diketones identified by others were detected in both species.

Key Words—Defensive secretions, formic acid, *Oxytrigona*, Hymenoptera, Apidae, stingless bees, mandibular glands, Meliponinae.

INTRODUCTION

Stingless bees (Meliponinae) may react to colony disturbance by rapid and persistent attack of intruders, as do other eusocial apids, the honeybees and bumblebees (Plowright and Laverty, 1984; Sakagami, 1982; Michener, 1974). However, their primary lines of defense are biting or, in unaggressive species, concealment within the nest (Roubik, 1983). Chemical secretions play a role in eliciting defensive behavior by apids in general, often arising from mandibular gland compounds released during biting (Duffield et al., 1984; Smith and Rou-

[3] Present address: Dept. of Entomology, University of California at Berkeley, Berkeley, CA 94720.

bik, 1983; Johnson et al., 1985). In addition to an atrophied sting apparatus, meliponine bees display further unusual traits, noteworthy of which is a secretion produced by "firebees," several species of neotropical *Oxytrigona* (Camargo, 1984). The two mandibular glands of *Oxytrigona* are unusually enlarged and occupy most of the head capsule (Kerr and da Costa Cruz, 1961). Symptoms of attacks on humans range from eventual appearance of itching blisters to an immediate burning sensation if the skin is broken by a biting bee; each leaves a lasting scar (Michener, 1974; personal observation). One species of *Oxytrigona* produces chemically novel diketones (Bian et al., 1984). We examined this and an additional species of *Oxytrigona* from Panama, and applied analytic methods necessary to detect formic acid, which resembles the odor of live bees (Schwarz, 1948, p. 469). Its presence in both species suggests that it is a major defensive secretion of *Oxytrigona*.

METHODS AND MATERIALS

Live worker bees of *Oxytrigona daemoniaca* (Camargo, 1984; J.M.F. Camargo, personal communication) were collected in January 1982 from a nest found within the Atlantic coastal forest of eastern Panama. The heads of four live bees were immediately placed in diethyl ether. Foraging workers of *Oxytrigona mellicolor* (=*O. tataira mellicolor*) were collected and the heads extracted in diethyl ether on Barro Colorado Island in central Panama during April 1984. All extracts were sealed in glass vials prior to shipment; after arrival, they were stored under nitrogen gas at 10°C. Prior to analysis, the ether extracts were each divided between two vials, of which one was later treated with diphenyldiazomethane to yield the diphenyl methyl ester of the carboxylic acids in the extract (Smith and Howard, 1955). The underivatized vial of each pair was then used for comparison in the chemical analyses.

Because of odor and irritating quality, we considered the possibility that formic acid might be a component of the secretion. In order to estimate the loss of formic acid in the extracts due to its low solubility in some solvents, mixtures of synthetic formic acid in different solvents were kept at room temperature for 48–72 hr prior to analysis, as extracts would be during shipment. Using the esterification techniques outlined above, the recovery of formic acid was low from both dichloromethane and hexane (15% and 5%, respectively) but excellent from diethyl ether (95%).

For the first series of extracts in 1982, extracts of *O. daemoniaca* and mixtures of formic, acetic, propanoic, and butanoic acids in solvent were both separately and concurrently injected splitless before and after treatment with the esterification reagent onto a Hewlett-Packard HP 5092 gas chromatograph coupled to an HP 3390 data system. Final identifications of these mixtures were

made with a Girdel capillary gas chromatograph with split Ros injection coupled to a Ribermag R-10-10 quadrupole mass spectrometer and a PDP 8/A computer system in the Department of Chemistry, University of Kansas. Both instruments were fitted with 25-m vitreous silica capillary columns coated with SE-30 stationary phase. The temperature program on both instruments was from 100 to 200°C at a ramp rate of 10°C/min after a 5-min isothermal time.

For the second series in 1984, derivatized and underivatized extracts were injected splitless onto a Carlo-Erba GC and then also onto a Varian GC-MS instrument in the Department of Chemistry of the University of Tübingen, West Germany. Both instruments were equipped with a 25-m SE-54 fused silica capillary column. Temperature programming was from 70 to 200°C at 8°C/min after a 5-min isothermal time.

RESULTS

After treatment with diphenyldiazomethane, ether extracts of *O. daemoniaca* and *O. mellicolor* yielded a component which had an identical mass spectrum and retention time to those of synthetic diphenyl methyl formate formed in the ether–synthetic formic acid mixtures after similar treatment (Figures 1 and 2). In no case did any of the remaining eluted material match the retention time and/or the mass spectra of the diphenyl methyl esters of acetic, propanoic, or butyric acids. Quantification of the formate ester peak in *O. daemoniaca* by coinjection of the animal extracts on the GC together with known amounts of an internal standard demonstrated that formic acid was present in the extracts in excess of 10–20 μg per individual worker.

Other components identified from *O. mellicolor* (Figure 3) have identical mass spectra to the compounds identified in this species by Bian et al. (1984). Mass spectra and retention times of the eluted materials from our extracts were compared with those from Bian et al., with synthetic analogs when they were available, and with published mass spectra.

Two of the eluted compounds had identical mass spectra to the diketones which have been identified only in this subgenus of stingless bee (Bian et al., 1984). Peaks 2 and 4 (Figure 3) correspond to (*E*)-3-hepten-2,5-dione and (*E*)-3-nonen-2,5-dione, respectively. The three peaks under four represent different isomers and the saturated analog to nonen-2,5-dione, all of which were present in the analyses of Bian et al. We therefore provide independent confirmation of the presence of these novel compounds in the mandibular glands of a second species of *Oxytrigona*.

Additional components, most of which were identified by Bian et al. (1984) from *O. mellicolor*, are as follows with their respective peak numbers from Figure 3 in parentheses: 2-Heptanone (1) was present in large quantities and

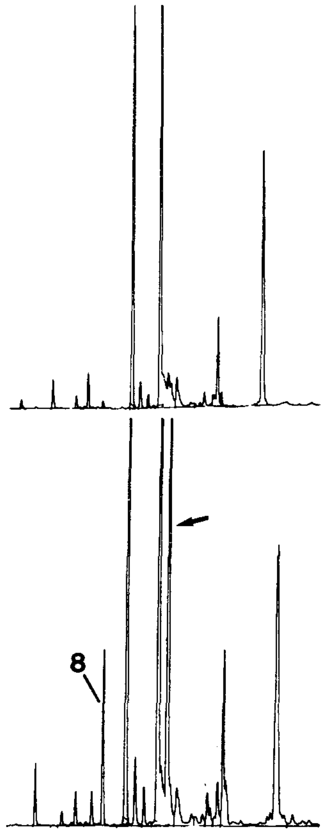

FIG. 1. Capillary gas chromatogram from an ether extract of *O. mellicolor* after treatment with diphenyldiazomethane (bottom). Chromatograms from derivatized ether extracts of *O. daemoniaca* are identical. The peak indicated (arrow) corresponds to diphenyl methyl formate, which appeared after treatment with the reagent. The other peaks have identical mass spectra and retention times to compounds found either in underivatized extracts or in the reagent (top). For reference purposes, the peak numbered eight refers to the peak of the same number in Figure 3.

may be metabolically related to the diketones. The even and odd carbon numbered saturated hydrocarbons undecane through heptadecane (3, 5, 6, 8, 11), as well as the monounsaturated pentadecene and heptadecene (7, 10), were present. Pentadecene and heptadecane were not found in *O. mellicolor* studied by Bian et al. (1984). Dodecyl-, tetradecyl-, and hexadecyl acetates (9, 12, 13) were present in the bees from Venezuela and from Panama. Additionally, hexadecanal was present in extracts of *O. daemoniaca*.

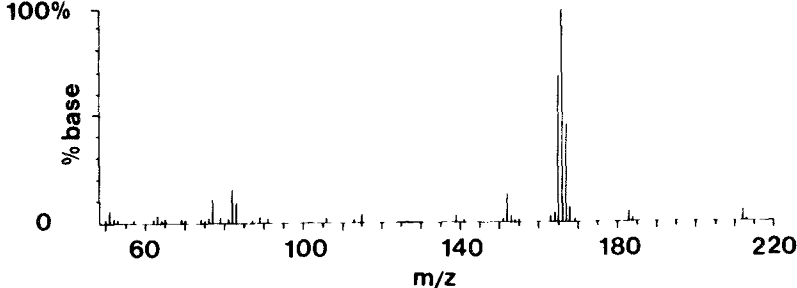

FIG. 2. Mass spectra of diphenyl methyl formate in the ether extracts of *O. mellicolor*.

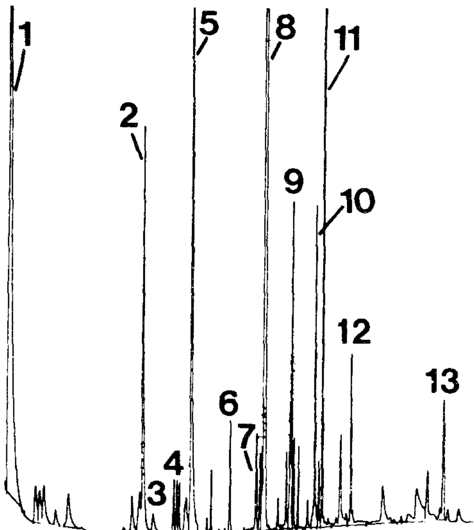

FIG. 3. Capillary gas chromatogram from head extracts of worker *O. mellicolor*. Numbers above the peaks correspond to the following substances (see text): 1, 2-heptanone; 2, (*E*)-3-hepten-2,5-dione; 3, undecane; 4, (*E*)-3-nonen-2,5-dione; 5, tridecane; 6, pentadecane; 7, pentadecene; 8, hexadecane; 9, dodecylacetate; 10, heptadecene; 11, heptadecane; 12, tetradecylacetate; 13, hexadecylacetate.

DISCUSSION

The repellent properties of formic acid, and the pain and itching it produces in humans (Eisner, 1970; Blum, 1981), demonstrate its value to *Oxytrigona* in defense of nests from vertebrate predators. Our findings provide the first evidence of employment of formic acid as a defensive substance in the Apoidea

and confirm the two observations reported in Schwarz (1948). Cederberg (1977) identified butyric acid as a major component in the mandibular gland secretion of the bumblebee *Bombus lapidarius*; low-molecular-weight carboxylic acids are commonly utilized in the Arthropoda as defensive substances (Blum, 1981). Moreover, formic acid was the first insect venom to be described (review by Schmidt, 1982) and is synthesized in vivo by deamination of serine (Hefetz and Blum, 1978). It can easily escape detection in chemical analyses because of its high volatility and low solubility in commonly used solvents. As extracts of *O. daemoniaca* were of heads, we do not show conclusively that the formic acid originates in the mandibular glands; it is conceivable that other cephalic exocrine glands produce the acid.

The combination of a highly complex exocrine secretion and persistent biting behavior must greatly enhance the defensive efficacy of the formic acid in the firebees. In many cases, acids occur in biting and/or stinging arthropods such as, for example, the formicine ants (Schmidt, 1982; Hermann and Blum, 1981). The integument of the attacked individual acts as a barrier to the penetration of the acid and must first be broken through mechanical damage; other substances in the secretion enhance the penetration properties of the acid mixture (Rembold, 1962; Eisner et al., 1968) and may account for the complexity of the cephalic secretion of *Oxytrigona* in comparison with some stingless bee species (Blum, 1981).

Occasional food robbing of apiary colonies of the honeybee *Apis mellifera* has been reported (Bian et al., 1984) and is known to us. However, nests of *Oxytrigona* can be kept together in an apiary with nests of other stingless bee species without similar robbing behavior on the part of the former. Additionally, unlike *Oxytrigona*, the four obligate cleptobiotic stingless bee species lack a pollen-carrying apparatus, have an extremely enlarged gut, and do not visit flowers (Cruz Landim and Rodrigues, 1967; Nogueira-Neto, 1970; Roubik, 1980, 1983). Therefore, food robbing by *Oxytrigona* may be a behavioral phenomenon unique to its relationship with *Apis* and not to its relationship with other stingless bee species.

Formic acid is undoubtedly responsible for some of the symptoms resulting from a firebee attack. However, other symptoms, such as blistering and other long-term effects (Michener, 1974), are not characteristically caused by formic acid. It is necessary to examine other components in the cephalic secretion of the firebees, including possible proteinaceous venoms, to determine how they may enhance the defensive efficacy of the secretion.

Acknowledgments—We wish to thank the Smithsonian Tropical Research Institute, Republic of Panama, and the Department of Chemistry, University of Tübingen, for use of the facilities. Support from the Smithsonian Institution Scholarly Studies grant 1234S001 to D.W.R. is gratefully acknowledged. Chemical analyses were facilitated by fellowships from the German Academic Exchange Service (DAAD) and NATO to B.H.S. and National Science Foundation grant BNS82-

00651 (C.D. Michener, Principal Investigator). In addition, we wish to thank C.D. Michener, J. Nicholson, A. Borg-Karlsson and an anonymous reviewer for their help and for valuable comments on the manuscript.

(Received February 24, 1986; accepted June 26, 1986)

Abstract—The Rose-of-Sharon, *Hibiscus syriacus* (L.), can be a significant alternate host plant for the boll weevil, *Anthonomus gradis* (Boh.). Boll weevils are known to be deterred from feeding and ovipositing in the buds unless the calyx is removed. This investigation was initiated to identify calyx allelochemicals that deter feeding with the eventual strategy of breeding for cotton lines high in these allelochemicals in the appropriate tissues. The feeding deterrency of calyx tissue from the buds of Rose-of-Sharon for the boll weevil was confirmed. The most active deterrent fraction was found to contain mostly fatty acids and their methyl esters. Saturated fatty acids and their methyl esters were generally found to be stimulatory, while the unsaturated species were found to be deterrent. Higher quantities of the fatty acids, particularly the unsaturated species, were found in Rose-of-Sharon calyx tissue than in the buds without calyx. This supports the hypothesis developed through the isolational work and testing of standards that the unsaturated fatty acids are significant deterrents of boll weevil feeding.

INTRODUCTION

The boll weevil, *Anthonomus grandis* Boh., is usually considered host-specific to cotton, but Coad (1914) was first to report its infestation of, and emergence from Rose-of-Sharon (ROS), *Hibiscus syriacus* L. Maxwell et al. (1965) and Parrott et al. (1966) reported that the calyx, which encloses the developing ROS bud, deterred feeding and oviposition by the boll weevil. When the calyx was removed, weevils fed on, and oviposited in buds at about the same rate as on cotton flower buds. Feeding and oviposition on the cotton buds were deterred when a water extract of the ROS calyx was applied to its surface. In subsequent chemical investigations at this laboratory, Hanny et al. (1972) identified 10 carotenoids in the bud, leaf, and flower of ROS, three of which (cryptoxanthin, chrysanthemaxanthin, and antheraxanthin) were present in ROS but not in cotton, *Gossypium hirsutum* L., while two (flavoxanthin and violaxanthin) were found in cotton but not in ROS. Additionally, the essential oils of ROS buds and flowers were found to contain at least 65 components including hydrocarbons, carbonyls, alcohols, and fatty acid methyl and ethyl esters (Hanny et al., 1973). However, no biological evaluations were conducted as part of either investigation, and, to our knowledge, no substantive information about the chemical nature of the deterrent(s) has been obtained since. The general interest in natural antifeedants, with the potential that their concentration in the host (cotton) could be enhanced by breeding selections, or eventually by gene insertions, has led to a resumption of efforts to chemically define the feeding (and oviposition) deterrents in this alternate host of the boll weevil.

METHODS AND MATERIALS

Insects. Insects used in this study were from a colony of "wild" strain boll weevils (red coloration) as defined by Bartlett (1967). The boll weevils were reared from egg to adult on a Pharmamedia®-based (Trader's Oil Mill Co.; Ft. Worth, Texas) diet prepared after the method of Lindig (1979). Male boll weevils are field collected and mated to laboratory-reared females on a yearly basis to maintain the genetic diversity present in the colony. Holding conditions are 28.3°C, 50 ± 5% relative humidity, and 14:10 light–dark photoperiod.

Four- to seven-day-old boll weevils from the rearing colony were taken three days prior to the bioassay and fed either cotton squares or artificial diet as applicable (see below). All food was removed 24 hr prior to testing to starve the males and females that had been separated from one another.

Cotton Bud Bioassays. Fresh, debracted cotton squares were rinsed in running tap water and air dried prior to bioassay. Test compounds were solubilized in an appropriate solvent, and the buds, marked with paper tags pinned in line with the stem, were dipped into the solutions. Approximately 25 μl of solution

remained on each bud. Therefore, solute concentration was adjusted to allow 1.5 mg of test material to remain on each bud after application and air drying for 1 hr. Two to six buds, depending upon the number of samples of test compounds, were placed into 10-cm Petri dishes and either 10 male or 10 female insects added. A control bud was always present in each of the dishes. The bioassays were conducted in the dark at 28°C and 50 ± 5% relative humidity. Feeding activity was determined as the number of punctures found in the cotton squares using a dissecting microscope at the end of 3 and again at 6 hr.

Plate Bioassay. The plate bioassay has been described elsewhere in detail (Bird and Hedin, 1986). Briefly, a reusable beeswax–paraffin chamber was prepared from a standard 10-cm Petri dish. Six 13-mm wells were cut into the wax layer equidistant from one another, 2 cm from the center of the dish, with a No. 9 cork borer and filled with a cooling Pharmamedia (3.0%)–agar (2.5%) solution which was allowed to solidify with a 1- to 2-mm high convex surface. Samples (100 μg for known compounds; 200 μg for extracts and chromatographic fractions) in appropriate solvents were randomly applied as 20-μl aliquots to 15-mm lens paper disks covering each feeding site. After application of the samples to the disks, the chambers were left uncovered 30 min to allow solvent evaporation. Feeding activity was determined as the number of punctures per paper disk after 3 and again at 6 hr using a dissecting microscope.

Statistical Design and Analysis. Experiments were designed as randomized complete blocks (RCB) and analyzed using analysis of variance (ANOVA) (SAS, 1982). A split plot analysis, where sex was the main unit and treatment the subunit, was incorporated if "sex × treatment" interactions were significant ($P < 0.05$). Regardless of how the treatments were analyzed, treatment means, either combined or averaged over sex, were compared by the least significant difference (LSD). After statistical treatment, the data were normalized by conversion of punctures/disk to punctures, percent of the control. A test fraction or compound was termed a feeding repellent or deterrent if feeding was reduced relative to controls or a feeding stimulant if feeding was elevated relative to control at statistically significant levels ($P < 0.05$).

Procurement and Processing of ROS Buds. Fresh buds were gathered during the summers of 1984 and 1985 and stored at −18°C until the calyxes were quickly harvested by hand and lyophilized.

For test 1, fresh ROS buds were bioassayed using cotton buds with and without calyxes removed.

For test 2, lyophilized calyx tissue (1–10 g) was Soxhlet-extracted with either water, methanol (MeOH), chloroform ($CHCl_3$), or hexane. Extracts from the specified solvent were combined and concentrated so that 25 μl, when applied to the cotton bud surface in the cotton bud bioassay, contained 1.5 mg.

For test 3, lyophilized calyx tissue (50 g) was Soxhlet-extracted 3× with 500-ml quantities of MeOH (yield of extract 6.0 g). The extract was redissolved in MeOH–water (6:4) and applied to a Polyamide® (Brinkmann Instruments

Co., Westbury, New York) column (5.0 cm diam., 30.0 cm length), and eluted with the same solvent, then MeOH–water (7:3, 8:2), and 100% MeOH (500 ml each). Eluates were concentrated so that 1.5 mg was present on the surface of each cotton bud used in bioassay.

For test 4, the MeOH–water (6:4) fraction (test 3 above; 2.8 g of solids) was partially dissolved in ethyl acetate (EtOAc) and applied to a Biosil A column (2.0 cm diam., 17 cm length). Two yellow pigmented fractions (EtOAC-1 and EtOAC-2) were collected upon extended elution of the solids from the column with EtOAC. The remaining solids not soluble in ethyl acetate (1.5 g) were dissolved in MeOH and applied to the column. Subsequent application of MeOH to the column eluted these solids in a fraction designated MeOH-3. Eluates were concentrated so that 20 μl contained 200 μg of solids when applied to the filter paper disks in the plate bioassay. Assuming uniform distribution, the concentration on the disk was 1.12 $\mu g/mm^2$.

For test 5, a number of commercially procured fatty acids and their methyl esters were evaluated by the plate bioassay at 100 μg/disk.

For test 6, palmitic acid and methyl linoleate were evaluated by the plate bioassay at 0, 0.1, 1.0, 10, 100, and 1000 μg/disk.

Mass Spectrometry. Active fractions were analyzed by GC-EI-MS employing a Hewlett Packard 5985-B® quadrupole mass spectrometer interfaced with a DB-5 fused silica capillary column (15 m $\times$ 0.322 mm ID, film thickness 1 μm, J&W Scientific Co., Cordova, California). The GC was programmed from 70 to 250°C at 10°C/min (injector temperature = 200°C, detector temperature = 250°C, carrier gas = He at 40 cm/sec). Structural assignments were made by comparison with those of commercially procured samples (Sigma Chemical Co., St. Louis, Missouri), and by comparison with standard spectra (Stenhagen et al., 1974). Eleostearic acid [(*Z,E,E*)9,11,13-octadecatrienoic acid] and its methyl ester were gifts of Mr. Martin Jacobson, USDA-ARS, Beltsville, Maryland.

Tissue Fatty Acid Analyses. ROS calyxes (10 g dry wt) and buds less calyxes (20 g dry wt) were extracted 3$\times$ with $CHCl_3$–MeOH–water (2:1:1). After filtration, the resulting chloroform layer was extracted 3$\times$ with 5% $NaHCO_3$, and the combined extracts added to the water layer. The aqueous fraction was acidified and extracted with $CHCl_3$ to yield the free fatty acids. Aliquots of the free fatty acid fraction and the $CHCl_3$ layer less free fatty acids were esterified with boron trifluoride methanol to yield the fatty acid methyl esters which were then determined quantitatively in triplicate by GC-FID employing the conditions outlined by Thompson and Sikorowski (1979). The methyl esters were isolated by chromatography on a 2 $\times$ 16-cm Biosil A® column. The methyl esters were eluted with hexane–methylene chloride (1:1) and analyzed by GC-FID. No special attempt was made to determine the *cis* or *trans* geometry of the unsaturated fatty acids except to note that the GLC retention

volumes were coincident with those of the respective *cis* standards. All standards for bioassay were of the *cis* configuration.

RESULTS AND DISCUSSION

The boll weevil demonstrated a significant ($P < 0.05$) preference (Table 1, test 1) for cotton squares over ROS buds (18–39% of control), as previously reported by Parrott et al. (1966). Their earlier findings that the feeding deterrent was a calyx-localized (ROS buds less calyx = 56–86% of control; $P < 0.05$) and water-soluble fraction (aqueous ROS extract = 17–37% of control; Table 1, test 2, $P < 0.05$) were also confirmed. Removal of the calyx resulted in a level of acceptance of the ROS buds that fell between the cotton square and the ROS bud with calyx (56–86% of control; Table 1, test 1). Exhaustive hexane, $CHCl_3$, MeOH, or water Soxhlet extracts of lyophilized ROS calyx tissues coated onto cotton squares indicated that the MeOH fraction (6–50% of control) and water fractions (17–37% of control) were both inhibitory to control ($P <$ 0.05, Table 1, test 2) at 3 and 6 hr for both males and females. The MeOH

[b] Test designed as randomized complete blocks with analysis of variance (ANOVA). Numbers in each column followed by a "D" are feeding deterrents ($P < 0.05$); "S" are feeding stimulants ($P < 0.05$); or no letter, no effect on feeding ($P < 0.05$).
[c] Five-choice bioassay conducted with 1.5 mg solute per fresh cotton bud and one untreated bud. Ten males or females per dish. The methanol fraction (Table 1) was the starting material.
[d] Biosil A fractions tested on plate bioassay at 200 μg solute per feeding site. Ten males or 10 females per bioassay chamber. The starting material was the MeOH–H_2O 6:4 fraction from polyamide 6 C column (above).

fraction was selected for further chemical work. Most of the antifeedant activity eluted from the polyamide 6C column using 60% MeOH in water as eluant (11–45% of control; Table 2, test 3).

When this MeOH–water (6:4) fraction was redissolved in ethyl acetate, and applied to a Biosil A column, two light yellow bands were eluted with ethyl acetate. These bands, designated EtOAC-1 and EtOAC-2, were found to be highly deterrent to both sexes when evaluated by the plate bioassay (0–6% of control; Table 2, test 4). The MeOH eluate, MeOH-1, was less active (35–58% of control).

GC-MS of EtOAC-1 and EtOAC-2 (Table 3) resulted in the identification of three fatty acids (pelargonic, myristic, and palmitic) and the methyl esters of palmitic, linoleic, linolenic, and stearic acids. The chromatograms were very limited in other peaks, these listed compounds accounting for 74.1 and 93.0% of the chromatographic profile, respectively. Electron impact mass spectrome-

try via solid probe suggested that some sterols and wax esters may be present in these two fractions, but the fragmentation patterns of the fatty acids and their methyl esters were prominent and accounted for most of the compounds in the fractions. IR spectra were compatible with the structural assignment of fatty acids and methyl esters, showing a strong carbonyl absorption at 1710–1712 cm^{-1}.

In order to determine the significance of these candidate compounds, a paired series of eight saturated and four unsaturated fatty acids (Table 4) and their respective methyl esters (Table 5) were evaluated by testing 100-μg quantities in the plate bioassay. Of the saturated acids, pelargonic, myristic, and palmitic acids were stimulatory (120–188% of control); capric and hendecanoic acids were deterrent (13–69% of control). The unsaturated acids (oleic, linoleic, and linolenic) were deterrent (17–35% of control) while eleostearic acid appeared to be slightly inhibitory.

With the saturated methyl esters, results were somewhat erratic. Although, methyl caprate and methyl hendecanoate were consistently deterrent (34–73% of control) and methyl laurate was highly deterrent (30–36% of control); methyl stearate and methyl arachidate were mostly stimulatory (90–237% of control). All of the unsaturated esters, methyl oleate, methyl linoleate, methyl linolenate, and methyl eleostearate, were deterrent (20–84% of control).

Finally, a representative stimulant, palmitic acid, and a representative deterrent, methyl linolenate, were tested by the plate bioassay at 0.1–1000 μg/disk. The results in Figure 1 show that the responses varied linearly with the log of the concentration, that there were no significant response differences be-

[a] Data expressed as the percent of feeding punctures observed on test sample feeding sites relative to control sites. Six-well plate bioassay disks were prepared with three randomly placed choices per dish: fatty acid, its methyl ester, and a control. Each feeding site was treated with 100 μg of the appropriate can didate or solvent, air-dried 30 min, and bioassayed with either 10 males or 10 females per dish. Puncture counts from like sites on each dish were pooled; 25 replicates were conducted for each sex.

[b] Test designed as randomized complete blocks with analysis of variance (ANOVA). Numbers in each column followed by a "D" are feeding deterrents ($P < 0.05$); "S" are feeding stimulants ($P < 0.05$); or no letter, no effect on feeding ($P < 0.05$).

tween males and females, and that the thresholds were similar at about 0.4–1.0 μg/disk in the plate bioassay.

Fatty acids and their methyl esters have previously been found to influence insect feeding. Palmitic acid was found to be stimulatory for the confused flour beetle *Tribolium confusum* (J. Du Vac) (Loschiavo, 1965). Vinson et al. (1967) reported that linoleic acid was a stimulant for the black imported fire ant *Solenopsis richteri* (Foral). Vinson et al. (1975) identified methyl myristate and methyl palmitate as repellent pheromones from the Dufour gland of the bee, *Xylocopa virginica texana*.

Considering that ROS calyx tissue was found to be deterrent while the remaining bud tissue was not, it was of interest to determine whether the fatty acid content was higher in calyxes than in buds. Accordingly, the total lipid fatty acids, the methyl ester fatty acids, and the free fatty acids were determined

TABLE 6. FREE FATTY ACIDS, FATTY ACID METHYL ESTERS, AND TOTAL LIPID FATTY ACIDS IN ROSE-OF-SHARON BUDS AND CALYXES

	Fatty acids (mg/g dry wt basis)				
Sample	Palmitic	Stearic	Oleic	Linoleic	Linolenic
Buds					
Total lipids	0.85	0.16	0.33	2.43	1.04
Methyl esters	0.08	0.01	0.03	0.21	0.18
Free fatty acids	0.02	0.01	0.01	0.05	0.02
Calyx					
Total lipids	0.57	0.05	0.14	1.31	0.67
Methyl esters	0.07	0.07	0.02	0.19	0.08
Free fatty acids	0.08	0.02	0.04	0.25	0.10

by GC-FID according to procedures described in the experimental section. The results, which are summarized in Table 6, show that while the percent total fatty acids was somewhat higher in buds than in calyxes, the free fatty acid content of calyxes was several-fold higher. The higher fatty acid content in calyxes supports the hypothesis developed through the isolational work and testing of standards that the unsaturated fatty acids and their methyl esters, present in relatively high concentrations in ROS calyx tissue, are responsible for feeding deterrency in the boll weevil.

Acknowledgments—The authors thank A.C. Thompson for methyl ester analyses, J. Robbins and L. Hepner for Rose-of-Sharon buds, and E. Sloan and M. Petty for technical support.

(Received March 25, 1986; accepted July 7, 1986)

Abstract—The pheromonal basis of the courtship behavior of two gypsy moth parasitoids, *Brachymeria intermedia* and *Brachymeria lasus*, was traced to a single component in each case. This component was isolated by a combination of absorption and gas-liquid chromatography and shown to elicit some of the courtship behavior typical of these species. Bioassays of extracts from several independent techniques for sequestering pheromones, as well as interspecific assays, support this conclusion. Comparative analyses of both male and female extracts by capillary chromatography show the uniqueness of the pheromonal peak to the female volatile profile.

Key Words—*Brachymeria intermedia, Brachymeria lasus*, courtship behavior, chromatography, sex pheromone, Chalcididae, Hymenoptera.

INTRODUCTION

The mating behavior of many parasitic insects consists of a series of discrete, highly complex courtship responses (Matthews, 1975; Leonard and Ringo, 1978). Chemical, visual, auditory, and tactile cues have been implicated. However, with the exception of two species of ichneumonids (Robacher et al., 1976; Eller et al., 1984) little is known of the pheromonal basis of parasitoid courtship behavior. Considering the wealth of evidence existing for other groups of insects (Lepidoptera, for instance), and that parasitoids account for approximately 15% of Insecta (Askew, 1971), with possibly the greatest species diversity within a group of animals, it is of obvious import to any comprehensive knowledge of pheromones that this lacuna be explored. Biocontrol programs involving

0098-0331/87/0500-1099$05.00/0 © 1987 Plenum Publishing Corporation

the release of exotic or native beneficials in new habitats require knowledge of their establishment and spread (Coppel and Mertins, 1977). This can be achieved with pheromones. Integrated pest-management programs can be better practiced by knowledge of the flight activity of parasitoids which may enable directed application of pesticides to avoid any detrimental impact on beneficials. Further, pheromone trapping of both host and its parasitoid may provide information on the degree of control exerted by the latter (Morse and Kulman, 1985).

Within this context, a study was initiated to define the pheromonal basis of the mating behavior of two species of gypsy moth endoparasitoids, *Brachymeria intermedia* (Nees) and *Brachymeria lasus* (Walker).

METHODS AND MATERIALS

Adult parasitoids were reared on the pupal stage of the factitious host, the greater wax moth, *Galleria mellonella* (L.). To this end, a small-scale mass-rearing technique was developed to provide a continuous and reliable source of the pupal stage (Mohamed and Coppel, 1983). Cocooned pupae reared singly, or in sheets of 50–100 of the wax moth were allowed to be parasitized by stock cultures of both species of parasitoids. The parasitized cocoons were placed singly in vials sealed with perforated plastic caps. They were incubated at 28.5°C, 16:8 light–dark, and 60 ± 5% relative humidity. Upon eclosion (males in 5–6 and females in 8–9 days), the adults were sexed and either treated to obtain crude pheromone or returned to stock cultures.

Several techniques were employed to collect crude pheromone samples. Some were based on literature reports on other species (Young and Silverstein, 1975) while others were designed to incorporate elements of the biology of these species. Within this framework, crude samples were collected from the parasitoids from the time of eclosion to death. Each technique was sufficiently distinct to allow several independent means of pheromone isolation and maximization of collection of crude samples. These techniques were as follows: (1) Emerging male or female parasitoids from cocoons in sheets were placed singly in 4-ml shell vials and sealed with a perforated cap; and, similarly, a male and female were placed in each vial. (2) Parasitoids emerging from singly parasitized cocoons previously held in vials were allowed to remain in these vials. The vials with parasitoids were incubated at 28.5°C and 16:8 light–dark for 24 hr. They were then removed and transferred to screened cages holding either males, females, or both sexes. The empty vials were stored until treatment to obtain crude pheromone. (3) Within these cages the parasitoids were allowed to aggregate daily on filter paper (Whatman No. 40) -lined vials (55 × 25 mm) during scotophase. The filter paper was removed and extracted monthly. (4) Dead parasitoids from all cages, of either sex, or a combination of the sexes were collected and refluxed in a solvent. (5) Virgin females from rearing cages

were placed in a glass cylinder (22.5 cm) with a tapering funnel-shaped entrance and an exit fitted with a stopcock. A heated air stream, filtered through calcium sulfate (Drierite) and charcoal was allowed to enter one end of the glass cylinder, and exit through a bed of Porapak Q at the other end, to adsorb volatiles. Approximately 5000 females and 1000 males of each species were processed.

Crude extracts from these sources were obtained in the following manner. To each vial 0.5 ml of a solvent mixture of hexane–ethyl acetate (75:25) was added and vortexed for 15 sec. Extracts from each source were then pooled separately (that is, male in vials, female in vials, male and female in vials). The filter papers from each source (technique 3) were placed separately in 250-ml Erlenmeyer flasks and agitated with the solvent mixture for 24 hr on a shaker. Volatiles from the Porapak Q were similarly desorbed. Dead bodies of each sex, or a combination thereof, were refluxed for 24 hr in the solvent mixture mentioned. The pooled extracts from each source were filtered separately over anhydrous sodium sulfate and concentrated with a Büchi evaporator. They were then transferred to 2-ml vials and stored at 0°C until further usage.

Crude extracted pheromone from each source was fractionated and/or analyzed by column, thin layer, and gas–liquid chromatography (GLC). Adsorption column chromatography was carried out on silica gel (1.1 g) packed in 40% ether–hexane in a 11.5 × 1 cm ID glass column. The elution series consisted of 4-ml aliquots of hexane; 0.1%, 1.0%, 10%, 20%, and 40% ether–hexane; and methanol. Initial separation was monitored by thin-layer chromatography using silica gel impregnated with 5% ammonium sulfate (Analtech Uniplates, self-charring) using 25% ethyl acetate in hexane as developing solvent. Further fractionation was achieved by GLC using sequentially, 1.8-m glass columns (2 mm ID), (1) 10% OV-1, and then (2) 10% OV-101, on 80/100 Gas Chrom Q and a volume flow rate (He) of 30 ml/min. The temperature program used was as follows: for column (1): 75°C (3 min), 15°C/min to 130°C (5 min); and for column (2): 40°C (10 min), 3°C/min to 65°C (10 min) with the injection port temperature at 40°C with a flash injector assembly.

Analyses of both crude and fractionated samples were facilitated with a 15-m DB-5 capillary column, using helium at a flow rate of 4 ml/min, and a temperature program of 40°C (5 min), 15°C/min to 240°C (5 min); 15°C/min to 285°C (35 min) with an injection port temperature of 195°C.

Gas–liquid chromatography was done on a Spectra Physics 7100 equipped with flame ionization detectors. The gas chromatograph was fitted with a splitter modified from Brownlee and Silverstein (1968). Components from the packed columns were shunted via the splitter to a glass capillary tubing. The tubing was encased in finely crushed Dry Ice held in place by a glass cylinder tapered at one end. The capillary tubing and tapered glass cylinder were held in place with Teflon tape. Condensed effluents within the tubing were desorbed with several washes of ether into a 4-ml vial using a 10-ml Cornwall glass syringe.

Samples were concentrated under argon and then bioassayed or further analyzed.

Bioassays were conducted on crude, column, and GLC fractions. Each sample, in concentrations from 0.5 to 2.0 female (or male) equivalents per 10 μl hexane, was applied to one spot on the perimeter of a 1.27-cm filter paper disk (Schleicher and Schuell Inc.). The disk was placed in the middle of a glass Petri dish (9 cm diam.) on a white cardboard background and the solvent allowed to evaporate for 5 min. Five male parasitoids (3–7 days posteclosion) were transferred to the Petri dish. Their behavior was observed for 15 min under a light that generated a temperature of $29 \pm 1.0°C$ at the base of the Petri dish.

The criteria for a sample's activity were based on qualitative observations on the courtship behavior of these parasitoids, and those previously described (Simser and Coppel, 1980a, b; Leonard and Ringo, 1978). The following discrete behaviors were observed and their numbers tallied on several hand counters: wing flexing (WF), wing vibrations (WV), sway (S, movement of the body from side to side, as the male moves, at a few degrees inclination from the vertical), sway in contact with another male (SCM), disk location (DL) followed by a brief antennation of the disk lasting for less than 5 sec and disk location with antennal probing of the spot where the sample was located for greater than 15 sec. Each assay, for each species, was conducted between 1 and 4 hr after the onset of photophase which was either at 0800–1100 or 1500–1900 hr depending on the incubators' light regime. Behaviors not readily quantifiable were recorded descriptively. Bioassays were conducted with samples drawn at random, or with observers who had no prior knowledge of the sample source or content.

Field bioassays were attempted with *B. intermedia*, which is established against the gypsy moth. Samples were pipetted onto 4-cm-long dental cotton wicks, air dried for 30 min, and suspended in white Pherocon II traps (Zoecon Corp., Palo Alto, California). The prepared traps were suspended at breast height on scrub oak trees (located near Otis Air Force Base, Massachusetts). This site consisted of pitch pine and a moderate understory which previously had been defoliated 50–60% by the gypsy moth. The traps were randomized and monitored daily for three weeks from mid-July to early August.

The techniques and procedure used are summarized in Figure 1. All data were analyzed for normal distribution, whereupon parametric tests were employed to assess significant differences of means. These tests include analyses of variance (ANOVA) and least significant difference (LSD).

RESULTS

The activity of crude extracts over several replicates from a given source, or between different sources, did not elicit a concerted series of discrete courtship responses in either species. However, occasional observations of male par-

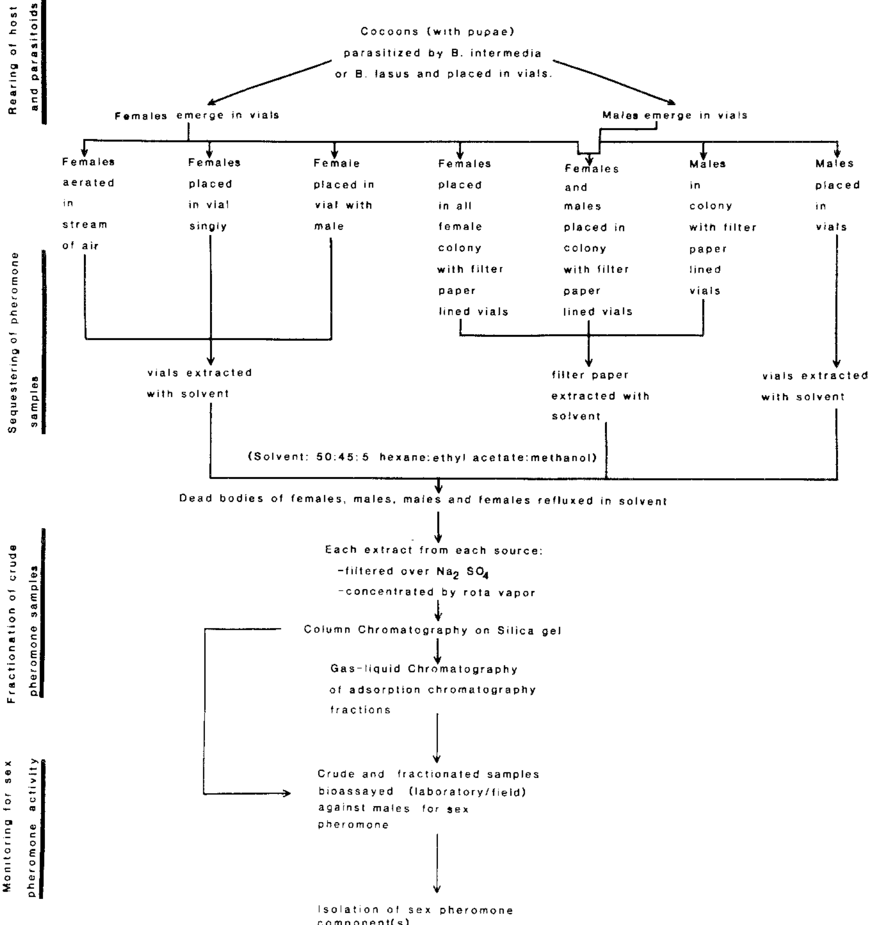

FIG. 1. Flowchart summarizing the techniques and sequence of steps used in sequestering and analyzing the sex pheromones of the parasitoids, *Brachymeria intermedia* and *Brachymeria lasus*.

asitoids locating the disk and wing pulsation on exposure to the crude fractions did allow us to infer the existence of a pheromone, with its effect possibly being inhibited by other components. This proved to be the case as adsorbtion chromatography with silica gel of the crude sample led to the isolation of a 0.1% ether–hexane fraction which was active. Responses elicited were typical of mate location such as disk location, antennation of the disk, and courtship behaviors such as wing flexing, wing vibration, and swaying of the parasitoids (Tables 1 and 2). Bioassays of this fraction in combination with other adsorption column chromatography fractions did not elicit any increased activity. Thin-layer chromatography of these active fractions, for both species, gave bands at $R_f = 0.9$.

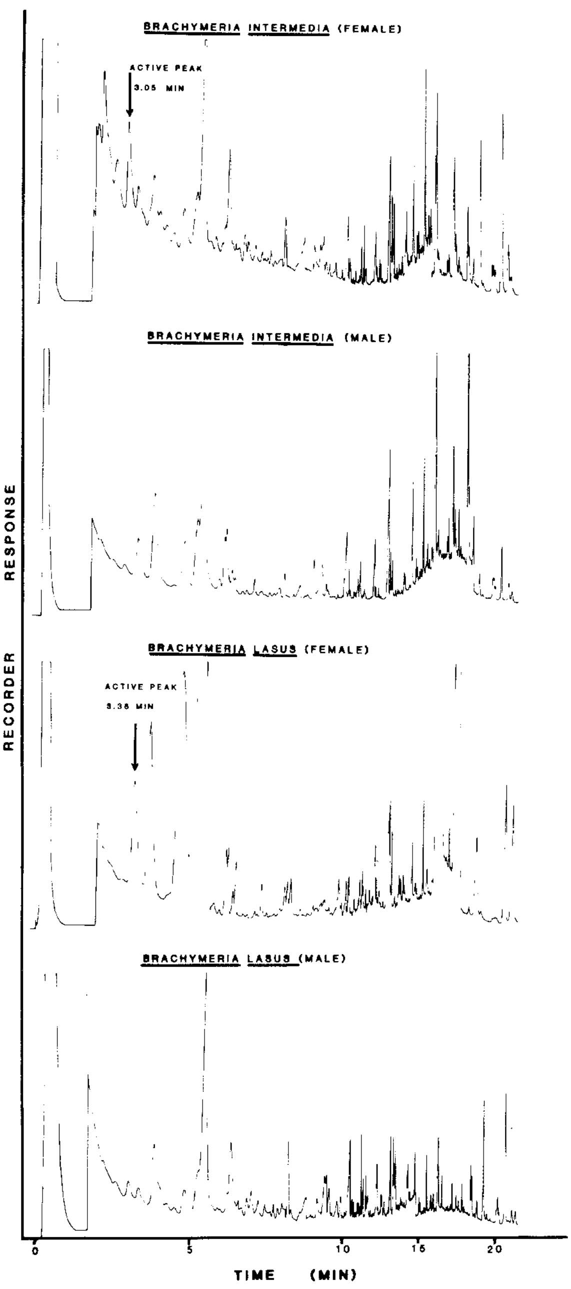

FIG. 2. Comparative analyses, by capillary chromatography of crude extracts, from both sexes of *B. intermedia* and *B. lasus*. The source was from vials in which they had enclosed from parasitized cocoons. A 15-m DB-5 capillary column was used with detector at 64 × 10^{-10} attenuation and range (1.5 min) 2 × 10^{-11} attenuation and range to the end of run.

No courtship responses could be elicited from control experiments in either species. That is, solvents, samples derived from male sources in a manner identical to that of females, and interspecific tests of males of one species against female sources of the other species yielded no responses typical of a pheromone (Tables 1 and 2). The lack of response in the latter two instances is consistent with the uniqueness of some components of the GLC profile of the female when compared to the male and that of the female of each species (Figure 2). This is further borne out by GLC analyses which revealed that the active peak was only present in the 0.1% either–hexane fraction.

Further bioassays of adsorbtion chromatography samples were conducted against *B. intermedia* in the field. Since the occurrence of the sex pheromone of this species was extremely low (ng/female), a limited number of traps was deployed. Although female-derived sources of extract did attract low numbers of male parasitoids (Table 3), further assays were not attempted so as to conserve our material for spectrometric analysis.

Preparative GLC on an OV-1 column of the active adsorbtion column chromatographic fractions yielded an active area for each species between retention times of 2.5 and 6.5 min. Separation of this region on a more polar column (OV-101) led to the isolation of an active peak for each species (Figure 3). The peaks were defined on the DB-5 capillary column (Figure 2) at 3.05 min for *B. intermedia* and 3.38 min for *B. lasus*. Courtship behavior was similar to that observed from the adsorbtion column chromatographic fraction (Table 1 and 2, GLC fraction). This component occurred in all sources of extracts, although in varying concentrations. The most productive source, extracts from vials which had newly eclosed females only, showed the component in concentrations for either *B. intermedia* or *B. lasus* at 1–3 ng/female, respectively. Other sources had concentrations ranging from 0.1 to 0.5 ng/female.

TABLE 3. FIELD RESPONSE OF *Brachymeria intermedia* TO ADSORPTION COLUMN CHROMATOGRAPHY FRACTIONS FROM SEVERAL DIFFERENT SOURCES[a]

Source of extract	Total number of males trapped[b]
Control (solvent)	0
Vials with virgin females and cocoons	4

Refluxed bodies of virgin females	2
Refluxed bodies of male and females	1

[a]Bioassays were conducted with 0.1% ether–hexane fraction obtained from adsorption column chromatography. Other fractions were also bioassayed but were inactive. Each trap was baited with 10 female equivalents.

[b]Numbers of males caught are from pooled results of three traps per source of extract.

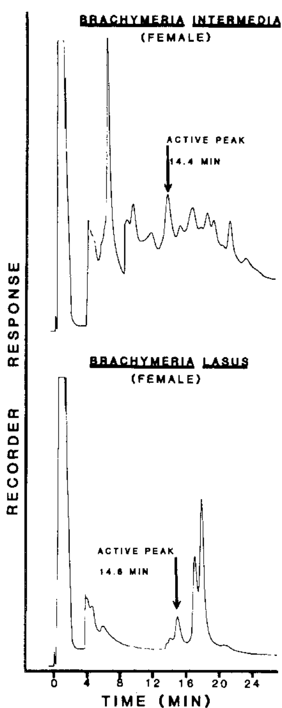

FIG. 3. Packed column chromatograms of active adsorption chromatography fraction. Analysis (and fractionation) was done with a 1.8-m, 2-mm-ID glass column with 10% OV-101. Detector was at 32×10^{-10} (3 min), and 4×10^{-11} to end of run.

DISCUSSION

It is evident that the courtship behavior of these parasitoids has a pheromonal basis, this being established in several ways. First, several independent methods of pheromone collection were used, all of which proved to be active, although to varying extents. GLC analyses and preparations of samples from the various techniques resulted in demonstrating pheromone-mediated behaviors for both species. In contrast, bioassays of other fractions obtained by these preparative methods, solvents used in various phases of sample collection, interspecific bioassays (*B. lasus* males vs. *B. intermedia* female sources, and vice versa), and male extracts (collected under similar conditions for females) all proved inactive.

Additionally, the nature of the behavioral responses was consistent with what was known of the courtship responses of males to the females of these species. This was evident in the occurrence and frequency of discrete behaviors

to the pheromone source, such as wing flexing (FW), wing pulsation (WP), disk location (DL), etc., which were clearly different from various controls. More importantly, for establishing a pheromonal basis of these behaviors, the discrete values were observed within a context of a series of mutually reinforcing responses. That is, the parasitoid, on entry to the Petri dish would first examine the dish's surface with the antennae. In the presence of an active sample, such examinations usually led to disk location, whereupon the male would antennate exactly the spot where our pheromone sample was placed (usually the diameter of 10-μl pipet). As this occurred, the body arched, and rapid wing vibration followed which usually lasted for 15–60 sec. An alternative pathway of behavior by the male on the disk was by turning 360° several times. Either behavior usually results in swaying of the body in a lateral plane as the male moves away. This sequence was repeated several times during the observation period. The sway component of the courtship behavior, in the presence of an active sample, also occurred when a male either approached the disk or as a male approached another male (SCM). Although the recorded values are apparently discrete, they are a reflection of an underlying pattern of a concerted series of behaviors which constitute the courtship response.

Several additional types of male behaviors of either species were observed but occurred infrequently. These included: kicking other males with the forelegs in what seemed an attempt to monopolize the pheromone area, swaying at the disk, attempting to antennate disk from the top of the Petri dish, and aggregation of males above the disk during and after the end of our observation period. Although infrequent, most of these behaviors have been observed in colonies containing both sexes. Given the rarity of their occurrence, no attempt was made at quantification.

The courtship responses to adsorption column chromatography or GLC fractions do have their bases in the volatile chemistry of these species. Comparison of the capillary chromatograms between sexes and species indicated that the most volatile region (first 10 min) had the most variability in both the number of components as well as the occurrence and nonoccurrence of certain peaks. This observation acquired significance as the active peaks for *B. intermedia* and *B. lasus* were found at 3.05 and 3.38 min, respectively. If a generalization is permitted from these observations, it is possible that, given active extracts, regions of variability found in comparing GLC profiles between sexes of a species could provide a clue as to where to initiate a search for a pheromone.

The field bioassays for *B. intermedia* trapped very few parasitoids but were significant against the controls and consistent with the activity to the 0.1% ether–hexane fraction observed in the laboratory. Since the pheromone components occurred in very low concentrations, and were extremely volatile, more field bioassays have been deferred until synthetic material is available.

Although our research showed clearly a single-component pheromone elic-

iting all major courtship responses for these species, we do not rule out the possibility of other minor component(s). The frequency of behaviors were designed to allow the assessment of a second component(s). However, the high variability obtained when combining fractions did not allow a definitive assessment of this possibility.

Given the size of the male parasitoids (*B. intermedia*, 4.5 ± 0.4 mg and 4.5 ± 0.1 mm; *B. lasus*, 4.2 ± 0.4 mg and 4.8 ± 0.2 mm; $N = 12$, in weight and length, respectively), the discrete nature of each behavior in the courtship sequence, the simplicity of the Petri dish for observation and manipulation, and the availability of a synthetic pheromone, it can be readily appreciated that such a combination could lead to a system that allows for developing a model of how parasitoids use chemical information against or with a background of auditory, tactile, or visual cues. The availability of pheromones for these species should allow for the rapid acquisition of information on establishment, dispersal, distribution, and abundance, which in turn can provide a more reliable picture of their impact on the gypsy moth, one of their hosts.

Acknowledgments—Much of this work was made possible by the diligent effort and care in maintaining cultures by several technicians: Steve Kratz, Jennifer Birdsall, Amy Harsha, Charles Horton, and Steve Stowell. Special thanks go to Mark Allington for making and repairing GLC parts. Additionally, we would like to thank W.W. Metterhouse and R. Chianese for supplying the original stock of both of these species. We are also appreciative of Mr. Dave Simser's effort in conducting the field bioassays. This research was supported by the College of Agricultural and Life Sciences, University of Wisconsin-Madison by Federal Hatch Support (Project No. 2116) to H.C. Coppel and by USDA, SEA.Ar Agreement No. 58-519B-1-991 to H.C. Coppel and W. E. Burkholder.

(Received April 4, 1986; accepted July 7, 1986)

Abstract—Six hydrocarbon components (2-methylhexadecane, *n*-heptadecane, 2-methylheptadecane, 2-methyloctadecane, *n*-nonadecane, and 2-methylnonadecane) were identified in sex-pheromone gland extracts and in airborne collections of *Holomelina lamae*. Low variability in the ratio of components among individuals indicates tight regulation of blend composition. Minor changes were evident in the quantity and ratio of the blend as a function of time of day. Based on gland extracts, the total quantity of the six components increased from day 1 ($\bar{X}$ = 6299 ng) to day 4 ($\bar{X}$ = 7498 ng) and subsequently decreased. No significant correlations were found between total gland contents and wet or dry weights of moths. Emission rates of *H. lamae* females were determined from pheromone adsorbed onto Porapak Q. Quantities released peaked shortly after the onset of calling and decreased rapidly as calling continued. Peak release rates ranged from 13 to 350 ng/10 min, and from 37 to 835 ng/60 min. Noncalling females did not emit detectable quantities of pheromone. Based on release rates and the rate of pulsation of the abdominal tip, the average amount released per pulse is not constant. The mean ratio of components released (0.78:7.45:84.80:2.84:2.59:1.53) was not very different from the ratio of components in gland extracts of 2-day-old females (0.70:4.19:90.12:1.65:1.91:1.42). We propose that the blend is atomized rather than volatilized from the gland, thus retaining nearly the same ratios in the female's effluvium as in her gland.

Key Words—Sex pheromone, pheromone release rates, pheromone titer, airborne pheromone collection, *Homomelius lamae*, Lepidoptera, Arctiidae, 2-methylheptadecane.

INTRODUCTION

Most moths that employ pheromones for sexual recruitment employ blends of several pheromone components. A persistent problem in research on pheromones has been the correlation of surface washes or gland extracts with volatile components. Olsson et al. (1983) summarized the problem as follows: "Discussion of the relative amounts of compounds in a pheromone blend in terms of major and minor components are generally based on the relative amounts found in extracts of female glands. When the vapor pressures of the pheromone components are significantly different, the relative amounts in the vapor phase differ from those in the liquid phase." They showed that the pheromone components of the turnip moth, *Agrotis segetum*, decyl, (Z)-5-decenyl, (Z)-7-dodecenyl, and (Z)-9-tetradecenyl acetate, which were found in a ratio of 5.7:4.3:62.7:27.3 in abdominal tip extracts, were represented as 28.6:25.5:43.2:2.7, respectively, in the vapor phase. Few studies have combined airborne collections of pheromone components with gland extracts, and few behavioral evaluations of multicomponent pheromone blends have been based on the blend actually emitted by the female. Further, little work has been directed at determining how the ratios are modulated by factors such as age and time of day.

Roelofs and Cardé (1971) determined that 2-methylheptadecane was a major component of the sex pheromone of several sibling species in the *Holomelina aurantiaca* complex. Pulsing of the abdominal tip in this group yields a higher pheromone release rate than that obtained from artificially extruded glands (Schal and Cardé, 1985), and peak pheromone release occurs soon after the onset of calling even though calling in *H. lamae* persists for several hours (Schal and Cardé, 1986). Here we report on the composition of a multicomponent blend in *H. lamae* pheromone glands and airborne collections and constituent quantities and ratios as a function of time of day and age.

METHODS AND MATERIALS

Insects. The main *Holomelina lamae* colony (MI) originated from insects collected in Manistique, Michigan (R16W, T42N, sec 14) on August 10, 1978, and was maintained in the lab for ca. 60 generations. A second colony (ME) originated from 12 females collected at Seawall Bog, Acadia National Park, Maine, on August 12, 1984; second generation females were used. Larvae were reared individually on pinto-bean diet in 30-ml clear plastic cups at 27°C and 15:9 light–dark regime until the last instar, whereupon they were transferred to 24°C and 16:8 light–dark regime. Light intensity during photophase was 1400 lux. Insects were checked daily for pupation, and female pupae and adults were kept in clear plastic cups. For airborne volatile collections, females following ecdysis were kept in screen cages in constant 40 cm/sec wind.

Pheromone Extraction. Abdominal tips of females were excised with forceps and immersed for 1 hr in 150 μl of a 0.5 ng/μl solution of 2-methylpentadecane (2me-15c, as internal standard) in redistilled *n*-hexane. A subsequent extraction of the same gland for 24 hr liberated an additional 4.7% of 2-methylheptadecane (2me-17c), the major pheromone component, but also greatly increased the amount of debris which interfered with GLC analysis. In both extracts, all six components were liberated in similar proportions. Smaller volumes of solvent increased losses associated with removal of the extracted glands from the solvent; although quantitative analysis was unaffected because an internal standard was used, we attempted to minimize these losses in order to permit quantification of minor extractable components. Samples were stored in conical glass tubes made by drawing Pasteur pipets over a flame. They were placed in hexane-containing glass vials with Teflon-lined caps and stored at −20°C.

Airborne Collections. Two types of collection devices were used. For 10-min aeration of the abdominal tip, collection tubes were modified Pasteur pipets with one flared and one constricted end; they were silanized and filled with 200 mg of preconditioned Porapak Q between glass wool plugs (Schal and Cardé, 1985). Glass beads, glass wool, and charcoal adsorbants were unsatisfactory because the short-chain hydrocarbons were not retained as well as the long-chain compounds. Conditioning of Porapak Q was modified from Byrne et al. (1975). The adsorbant was washed with redistilled *n*-hexane, N_2 dried, heated at 180°C in a N_2 stream for 24 hr, packed into tubes, and washed again with hexane. Tubes thus treated were reused after extraction without further conditioning.

Females were placed on horizontal wooden dowels (0.5 cm diameter) where they assumed vertical calling positions with the abdomen hanging below the dowel. The collection tube was positioned such that the abdominal tip was ca. 3–5 mm below the outer rim of the flared end of the tube. Thus, tubes could be exchanged readily with no disturbance to the moth. Readsorption onto the female's body was minimized by turbulence-free unidirectional flow as determined with titanium tetrachloride "smoke."

For 60-min collections, the apparatus described by Schal and Cardé (1985) was employed. Individual females with clipped wings were placed on a screen perch within the upper portion of a chamber composed of two modified ground-glass joints (14/20) whose lower portion was packed with 150 mg of preconditioned Porapak Q. The inlet was packed with glass wool (prewashed with hexane and heated at 350°C) as an air filter.

For both 10- and 60-min collections, 210 ± 10 ml/min of room air was pulled through the collection tube with a vacuum pump. Room temperature was 23 ± 2°C. Pheromone was eluted with 800 μl of *n*-hexane in 100-μl aliquots, and 100 ng 2me-15c was immediately added as internal standard.

To determine the collection efficiencies for both devices, 5 μl of a hexane

solution, consisting of 1 μg of each of the six components [2-methylhexadecane (2me-16c), *n*-heptadecane (*n*-17c), 2-methylheptadecane (2me-17c), 2-methyloctadecane (2me-18c), *n*-nonadecane (*n*-19c), 2-methylnonadecane (2me-19c); all from K & K Laboratories] was applied to the glass-wool plug above the Porapak and aerated for 10 or 60 min. No breakthrough occurred in either set-up when two collection tubes were arrayed in series for 3 hr.

Quantitative Analysis. Extracts in hexane were reduced to 2 μl with a stream of prefiltered N_2. Absolute losses of the six components ranged from 9 to 30%, but their ratio relative to the internal standard remained the same. Gas-liquid chromatographic (FID) analysis was conducted on 2-m × 2-mm-ID and 1-m × 2-mm-ID glass columns packed with 3% SP-2100 (methyl silicone) on 100–120 mesh Supelcoport. Oven temperature was 155°C for 5 min and programmed to 210°C at 3°/min. To examine for possible trace amounts of other compounds, some runs were made on a polar 2-m × 2-mm-ID Silar 10CP column (10% Silar 10C on acid-washed 100–120 mesh Chromasorb W).

RESULTS

Gland Titers. In addition to 2me-17c, the major component reported in *Holomelina* (Roelofs and Cardé, 1971), five other hydrocarbons were extracted. Abdominal tips of newly ecdysed MI females ($N = 9$) averaged a total of 6299 ng of all six components combined (Figure 1, Table 1). Quantities and ratios of components extracted from pharate adults ($N = 5$) 24 hr before eclosion were not significantly different from freshly eclosed females. Two-day-old ME females (one generation in lab) had similar ratios of the six components (Figure 1, Table 1), but the titers were significantly lower than those of 2-day-old MI females (Table 1).

Relatively small diel changes in pheromone gland titers were evident over 13 days (Figure 1). The levels of all components decreased around 10 hr after lights on, coinciding with onset of calling (Schal and Cardé, 1986), but with the exception of 3-day-old females, these changes were not statistically significant ($P > 0.05$, SNK test). In 3-day-old females, the titer of all components rose to its highest level by 14 hr after lights on (Figure 1), although calling continued until lights off (Schal and Cardé, 1986).

The ratio of the six components in the gland did not vary on a diel basis ($P > 0.05$, SNK test; Figure 1). Small standard errors indicate tight regulation of the composition of glands in different females as do significant ($P < 0.01$) correlation coefficients (Pearson) among quantities of all six components.

Quantities of 2me-16c and *n*-17c increased with age up to 13 days, based on a linear model ($P < 0.01$) (Figure 1); 2me-19c decreased with age ($Y = -0.14X + 87.0$, $P = 0.03$), while the change in other components did not differ significantly from zero. For the first four days of calling, the titer of each

component except 2me-19c, and the titer of all components combined increased with age ($P < 0.05$) (Figure 1). On subsequent days, the quantities of all components did not change significantly until day 13.

Although only small changes were seen in the ratios of components as females aged (Figure 1), significant ($P < 0.01$) increases with age occurred in 2me-16c and *n*-17c, and significant decreases ($P < 0.01$) occurred in the ratios of 2me-17c, *n*-19c, and 2me-19c; the proportion of 2me-18c did not change with time ($P = 0.30$). In the first four days, the ratios of only 2me-16c and *n*-17c increased significantly; the proportions of the other components remained unchanged (Figure 1). On subsequent days (5–13), the proportion of *n*-

[a] r_p is the Pearson correlation coefficient, P is probability level.

17c increased ($P < 0.01$), that of 2me-17c decreased significantly ($P < 0.01$), and the others remained unchanged.

To determine whether gland composition changed with the total amount of extractable material, the proportion of each component was plotted against the total amount extracted for 2-day-old females and for all females over 13 days. With the exception of *n*-19c, which decreased in representation as the total blend increased, all correlations (Pearson) were insignificant (Table 2), indicating that the composition of the pheromone blend is independent of the total titer.

Correlation with Body Weight. Pupae and newly eclosed females were

129 ± 72	1.80 ± 0.76	101 ± 39	1.65 ± 0.62	77 ± 40	3.91 ± 2.42	2.84 ± 1.40
140 ± 66	1.97 ± 0.70	123 ± 62	1.91 ± 0.65	123 ± 46	5.44 ± 0.67	2.59 ± 0.89
76 ± 49	1.06 ± 0.69	90 ± 65	1.42 ± 1.07	21 ± 10	0.90 ± 0.37	1.53 ± 0.85

weighed, their glands extracted, and the dry weights obtained after 24 hr in a drying oven (70°C). No significant relations were evident between total gland titer and either wet weight (r = 0.16, P = 0.50, N = 19) or dry weight (r = 0.61, P = 0.11, N = 8) for 2-day-old females or for 0- to 4-day-old females (r = 0.12, P = 0.15, N = 147; r = 0.11, P = 0.22, N = 136, respectively) (Figure 2A, B). Also, the quantities and proportions of all individual components did not vary significantly with body weight.

Release Rates. All components isolated from gland extracts were also collected from freely calling 2-day-old females (Table 1). Three collection tubes were changed successively every 10 min in the first 35 min of calling; subse-

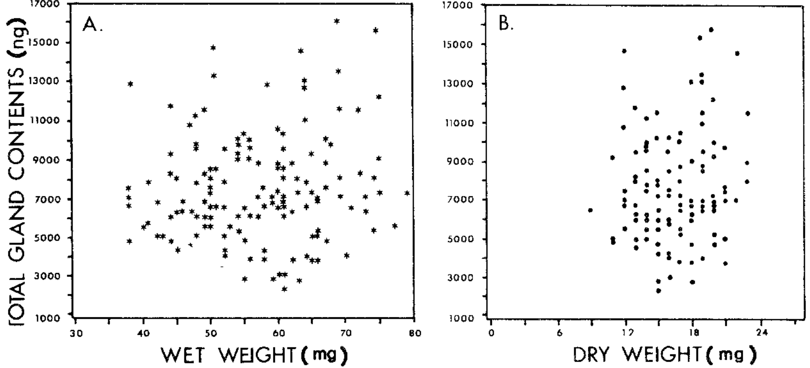

FIG. 2. Relation of total gland content of *H. lamae* with wet and dry weights.

quently, 10-min collections were made once every hour. An initial increase in the main component, 2me-17c, after the first 10 min of calling was followed by a rapid decrease, indicating that most of the material was released early in the calling period (Figure 3). This was borne out in successive 60-min collections from freely calling females where a rapid decline in the amount of pheromone released occurred after the first hour of calling (Figure 4).

The six components were represented in similar proportions in both air-

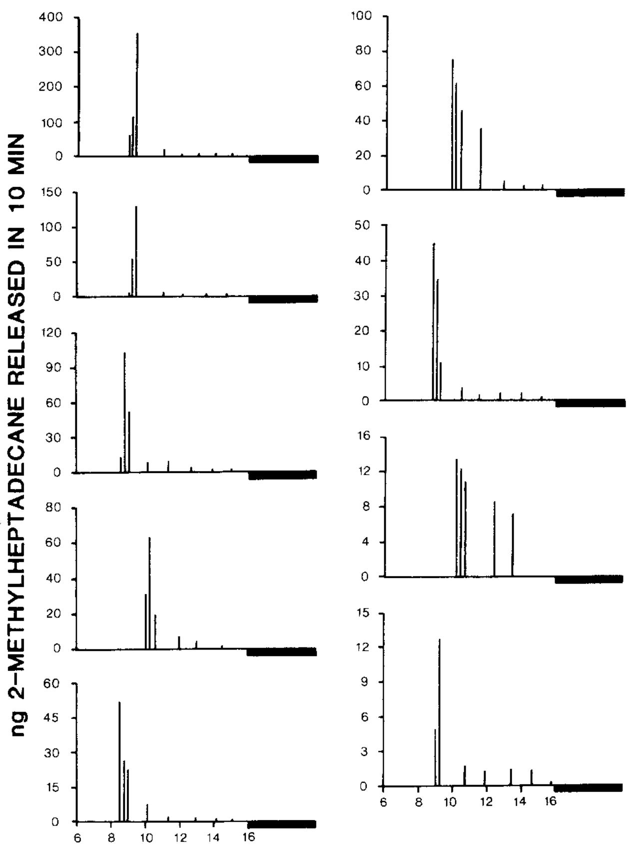

FIG. 3. Release rates per 10 min of nine *H. lamae* females throughout the scotophase (dark bars). Only 2-methylheptadecane is shown. Three collections of 10 min each were conducted in the first 35 min of calling; subsequently, 10-min collections were conducted once every hr.

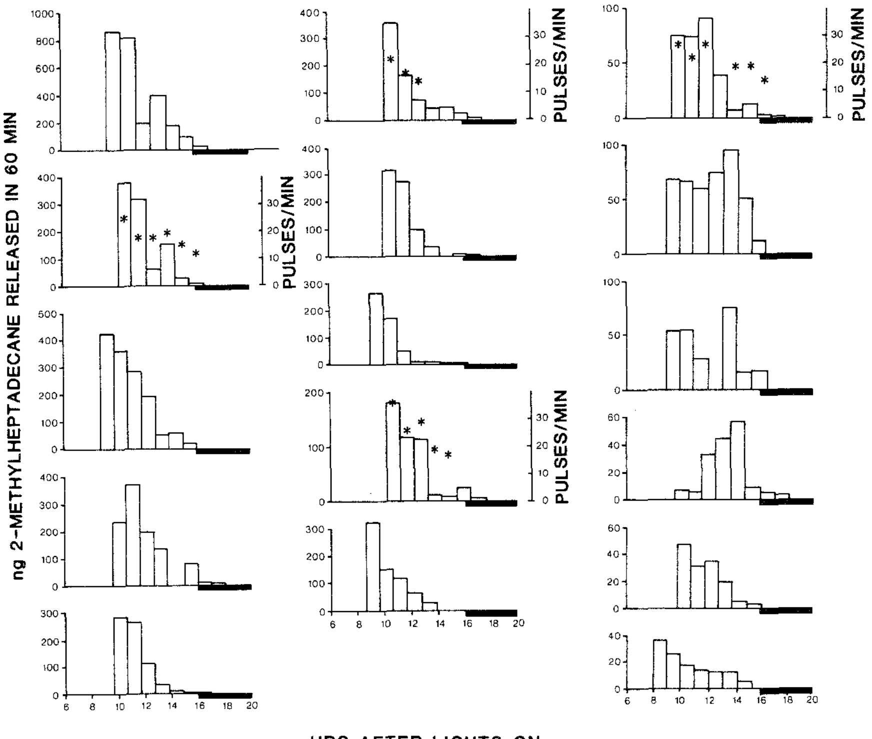

FIG. 4. Release rates per 60 min of 16 *H. lamae* females throughout the calling period. Only 2-methylheptadecane is shown. Successive 60-min collections were conducted from the onset of calling to its termination. For four females, the rates of extrusion of the terminal abdominal segments are also noted (asterisks).

borne collections and gland extracts (Table 1). Only the proportion of n-17c varied inversely with the total blend ($r = 0.36$, $P = 0.02$, $N = 39$; Table 2). The proportions of other components did not change as the total blend increased.

Pulsing Rate. H. lamae, like other arctiid moths, rhythmically extends and retracts the last two abdominal segments during calling. We determined the rate of pulsation of the abdominal tip for freely calling females in still air by counting extrusions per 1 min at 1-hr intervals throughout the calling period. At the onset of calling, pulsation frequency averaged 26/min (Figure 5) and duration of exposure of the terminal segments was long. The pulse rate rapidly peaked at 40/min where it remained for several hours. Toward the termination of calling, the pulse rate decreased gradually to a mean of 13/min (Figure 5).

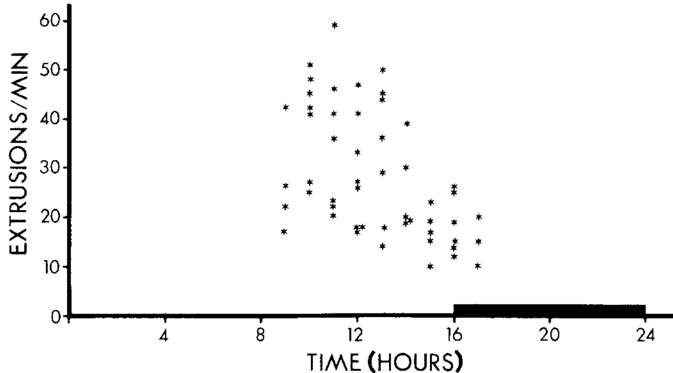

FIG. 5. Rate of extrusion and retraction of the terminal abdominal segments of *H. lamae* as a function of time of day.

DISCUSSION

Pheromone Profile. Roelofs and Cardé (1971) identified 2-methylheptadecane as the major component of the sex pheromone of a group of *Holomelina* sibling species. Males of several species were attracted to and trapped with baits of 2me-17c, but few *H. lamae* males were trapped, even though males oriented to within short distances of the traps. They suggested that missing components, greater release rates of the primary attractant, or both could be important in effecting close-range orientation (Roelofs and Cardé, 1971). We found five related components (2me-16c, *n*-17c, 2me-18c, *n*-19c, 2me-19c)[2] in gland extracts of females reared in the laboratory for ca. 60 generations and in first-generation offspring of feral females; the six components were also collected in air passing over calling females (Figure 1, Table 1). It is possible that other components are also volatilized, but at proportions below 1% of the total blend.

Among the hydrocarbon analogs of 2me-17c identified in *H. lamae* (Cardé et al., 1987), *n*-17c increases male trap catch two to threefold over 2me-17c alone, when released from separate rubber septa at charges of 1000 and 10 or 1000 and 1 μg, respectively. At charges of 100 μg with 1000 μg 2me-17c, *n*-17c diminishes trap catch twofold (Cardé et al., 1987). Thus, relative emission of *n*-17c within a range relative to 2me-17c is important to male attraction in *H. lamae*.

ME females had similar ratios of the six components in gland extracts (Table 1), but the quantity of pheromone extracted was significantly lower in ME compared to MI females ($P < 0.01$, t test). Minks (1971) reported a de-

[2] Prof. W. Roelofs and R. Cardé originally characterized these components by GLC and MS in 1970 at the New York Agricultural Experiment Station in Geneva.

crease in sex pheromone production in inbred strains of the summerfruit tortrix moth, *Adoxophyes orana*, and Miller and Roelofs (1980) showed that a lab colony of *Argyrotaenia velutinana* had significantly lower pheromone titers than field-collected moths. The differences observed in the two strains of *H. lamae* could be attributed to inherent differences in the two source populations or to inbreeding in the laboratory of the Michigan strain.

Diel and Age Effects on Gland Content. In the first four days, total gland content in *H. lamae* exhibited a diel periodicity only in 3-day-old females, decreasing abruptly at the onset of calling, but returning to its noncalling level within 2–4 hr while females still called (Figure 1). Means at different times in the diel were not significantly different from each other for 1-, 2-, and 4-day-old females. Thus, high emission rates at the onset of calling (Figures 3 and 4; Schal and Cardé, 1985) and lack of significant diel fluctuations in pheromone titer suggest rapid biosynthesis of pheromone during calling.

Similar results were found with *Trichoplusia ni* which does not have a daily rhythm in pheromone titer (Shorey and Gaston, 1965; Sower et al., 1972). However, Webster and Cardé (1982) related an abrupt drop in pheromone titer to the onset of calling in *Platynota stultana*; gland titer increased throughout the day and peaked at the initiation of calling. Similar relationships were obtained for surface washes of pheromone glands of *Plodia interpunctella* and *Ephestia cautella* (Coffelt et al., 1978), and *Heliothis zea* (Raina et al., 1986) in which peak calling coincided with maximal pheromone titer in the middle of the scotophase.

The pheromone content of virgin females changed little with age (Figure 1). However, the quantity of all components increased over the first four days, and subsequently decreased or remained unchanged. A similar pattern was observed by Lawrence and Bartell (1972) in *Epiphyas postvittana* based on male response to female extract. Miller and Roelofs (1977), Webster and Cardé (1982), and Raina et al. (1986) showed that pheromone titers in *A. velutinana*, *P. stultana*, and *H. zea* increased for the first two, four, and three days respectively, but decreased over the next few days.

The narrow coefficients of variation in the ratio of the pheromone components (Figure 1, Table 1) were independent of age (as in Miller and Roelofs, 1977) and indicate tight regulation of the blend. In *H. lamae*, although relative amounts of four of the six components changed with time, these changes are probably insignificant to behavioral response. For example, the change in 2me-16C was from ca. 0.7% on day 1 to 1.3% on day 13. Although statistically significant, it is doubtful that males detect such slight changes.

Correlations between total gland titers and proportion of individual components resulted in insignificant r values, indicating that blend composition is independent of blend quantity (Table 2).

Gland Content vs. Body Weight. Pheromone gland titer is unrelated to the wet or dry weights of pupae or adult females (Figure 2). Similar results were

obtained by Miller and Roelofs (1980) and by Charlton and Cardé (1982) for *A. velutinana.* and *Lymantria dispar*, respectively. Fitzpatrick et al. (1985) found that pupal weight did not correlate to male hairpencil contents (benzaldehyde) in *Pseudaletia unipuncta.* However, Shorey and Gaston (1965) reported that pheromone content in 4-day-old *T. ni* was correlated with the weight of females at emergence.

Release Rates and Ratios. Freely calling *H. lamae* females release all six components of the pheromone blend only during the calling period (Figure 1, Table 1); no detectable pheromone was collected from noncalling females either before or after calling. Although calling persisted for several hours in *H. lamae* (Schal and Cardé, 1986), the majority of the daily pheromone release occurred early in the calling period. A similar pattern is suggested in *Utetheisa*, in which females called for up to 200 min (Figure 6 in Conner et al., 1980), but males were attracted to calling females for an average of only 29 min, depending on the season. *T. ni* releases pheromone in calling bouts of ca. 20 min. Pheromone is released at a high rate early, but decreases asymptotically over the course of a calling bout (Bjostad et al., 1980). The strategy implicated is one of maximization of early pheromone release in some noctuids and arctiids, with concomitant rapid rates of pheromone biosynthesis as evidenced by the minor changes in gland content. Presumably, females tend to be located and mated early in the calling period or bout.

Although release rates later in the calling period may have little significance in the field because females may be mated early, they do have important implications for studies of pheromone release. Many such studies make the tacit assumption that release rates are constant throughout the calling interval, and therefore various periods of aeration of the gland can be corrected to yield a per minute or per hour release rate. The patterns exhibited by *H. lamae*, *H. aurantiaca*, and *T. ni* clearly question such extrapolations. Similarly, other studies have documented large variability in the amount and temporal pattern of pheromone emission from individual females (e.g., Morse et al., 1982).

In situations where glands are forcibly extruded (chemically or mechanically) for 10 min, and it is known that a subsequent 30 min of aeration yields little additional material (e.g., Pope et al., 1984), volatilization from the gland surface declines exponentially. Release rates (ng/min) thus obtained will differ when averaged for all 10 min or for any interval shorter or longer than 10 min. It is not known whether actual release rates approximate the maximum rate obtained from forcibly extruded glands (probably the first minute), or an average over a certain interval. For instance, the single highest 10 min rate of release for *H. lamae* was 353 ng, which would extrapolate to 2118 ng/hr or double the single highest release rate obtained from 60-min collections.

H. lamae exhibits a relatively high rate of pheromone emission (Figures 3 and 4; Schal and Cardé, 1985). Why such high release rates? An obvious explanation is to increase the distance of communication. Furthermore, high re-

lease rates may function in reproductive isolation, but ratios of components, diel activity patterns, and geographic and microhabitat distributions (Roelofs and Cardé, 1971) are probably more important partitioning factors.

The rates of emission of a single pheromone component depend upon its vapor pressure, environmental factors (e.g., temperature, wind), and the size and form of the emitting surface. Steck et al. (1984) showed that 3% of Z9-14:Ac and 97% of Z11-16:Ac provided for sustained trapping of the noctuid *Mamestra configurata* over several weeks. But, because the Z9-14:Ac was released and thus depleted more rapidly than Z11-16:Ac, its proportion in the trap declined so that the lure then attracted *Enargia infumata*. Similar effects on ratios were obtained by Olsson et al. (1983) in a study of vapor pressures of sex pheromones. The differential release of various components from artificial sources and interactions among loaded compounds suggest some important cautionary notes in formulating pheromones. First, since different substrates release materials differentially, release rates and ratios must be determined for each substrate before field tests are conducted. Second, as compounds are added or omitted from rubber septa, as in studies of the roles of each component, release rates and ratios must be determined for each new combination of components to account for interaction among components. In fact, in a comparison of three substrates, Linn et al. (1984) found that Z7-14:Ac and Z9-14:Ac were released at a much lower rate relative to the loading when compared to the 12-carbon compounds, resulting in an inappropriate ratio and poor response by *T. ni*.

A central concern is how the blend of different components is regulated. Both emitted and extracted blends of *H. lamae* contained hydrocarbons ranging from 16 to 19 carbons in length which differ in vapor pressure. Yet, the ratio of volatilized and extracted components was nearly the same, and for both, blend quality did not change with blend quantity. The remarkable similarity between the profiles of the six-component blend in the female's gland and her effluvium indicates that evaporation of the blend from the gland surface is not responsible for the ratio of components emitted. Species in the *Holomelina aurantiaca* complex examined to date possess paired tubular pheromone glands (unpublished). We propose that upon each pulse of the abdominal tip, the blend is atomized in a fine mist, thus retaining the same ratio of components as found in the gland (Cardé et al., 1987). This mechanism could also account for the conspicuously high rate of emission. This novel interpretation of blend regulation allows the ratio of components biosynthesized and present in the gland to reflect the ratio released.

Acknowledgments—The original characterization of the hydrocarbon pheromone components of *Holomelina* was a joint collaboration of Prof. W. Roelofs and R.T.C. We thank R. Collins, A. Smith, J. Tang, and R. Webster for helpful comments and suggestions throughout this study, and Mr. Carroll Schell for arranging a permit for our studies in Acadia National Park. N. Haver and

D. Root are gratefully acknowledged for technical assistance. Computer-statistical analysis of the results was conducted at Rutgers University.

(Received May 12, 1986; accepted July 7, 1986)

Abstract—The steroid hormone antheridiol has previously been shown to play a number of key roles in regulating development of the male sex organs, antheridia, of the water mold *Achlya ambisexualis*. We now demonstrate that synthetic antheridiol can inhibit both sexual (determined by oogonial counts) and asexual reproduction (determined by counts of asexual spores) in an isolate of the homothallic species *A. heterosexualis*. The implications of this dual role of antheridiol as hormone and allomone are discussed.

Key Words—*Achlya ambisexualis*, *A. bisexualis*, *A. heterosexualis*, Oomycetes, Saprolegniales, allomone, antheridiol, asexual sporulation, hormone, oogoniogenesis, pheromone, steroid, water mold.

INTRODUCTION

Sexual organogenesis in the water mold *Achlya* (Oomycetes: Saprolegniales) is initiated and coordinated by the steroid horomones antheridiol and oogoniol (Raper, 1951; Barksdale, 1969; Arsenault et al., 1968; Preus and McMorris. 1979). Most studies of this system have focused on heterothallic *Achlya ambisexualis* Raper isolates such as 734 (female) and E87 (male). Briefly, the female produces antheridiol (Figure 1) continuously under appropriate nutritional conditions. Males respond to antheridiol by producing antheridial branches and synthesizing oogoniol. This steriod in turn induces females to produce sex organs, oogonia, which attract the antheridial branches in a chem-

[1] Oomycetes: Saprolegniales.

otropic response probably involving antheridiol (Barksdale, 1967). A further stage of male sexual organogenesis, the production of the antheridium which is delimited from the remainder of the antheridial hypha by a septum, is also regulated by antheridiol (Barksdale, 1967). In this classical example of chemical communication between sexually compatible mating types, the hormonal exchange is via the intervening aqueous matrix, so that antheridiol and oogoniol have been termed pheromones.

Homothallic strains of *Achlya* can, by definition, produce both antheridia and oogonia. Conjugation tests between heterothallic and homothallic isolates have shown that these organisms use mutually similar or identical hormonal mechanisms (Raper, 1950; Barksdale, 1965).

Asexual reproduction in *Achlya* induced by nutritional stress, involves the development from vegetative hyphae of sporangia within which asexual spores are formed.

Because *Achlya* is a coenocytic (aseptate) organism capable of translocating cytoplasm to reproductive structures such as asexual sporangia (Dick, 1973) or oogonia (Hintz and Horgen, 1983), it would seem reasonable to hypothesize that the reproductive modes are mutually interrelated. In other words, conditions favoring one pathway of reproductive development might be expected to diminish the resources available for an alternative pathway. However, no such interactions between reproductive modes have been documented. Riehl and Toft (1985) commented that the asexual mode is considered to be independent of the steroid hormones.

In the course of characterizing the conjugation potential of several newly collected homothallic isolates (Thomas et al., 1984), we confirmed earlier observations (Raper, 1950) that strong females, when juxtaposed with homothallics, can suppress the production of oogonia in the latter. Barksdale (1967) reported inhibition of oogonia in homothallic *Achlya* strains by antheridiol isolated from culture filtrates of *A. bisexualis*. We now report that synthetic an-

theridiol inhibits both oogoniogenesis and asexual sporangiogenesis in a homothallic *A. heterosexualis* isolate.

METHODS AND MATERIALS

Fungus Material. Achlya ambisexualis Raper strains E87 (male) and 734 (female) were gifts of J.T. Mullins. The homothallic *Achlya* strain used (American Type Culture Collection number 52875) was isolated as strain B4 by Thomas et al. (1984) and should not be confused with the B4 isolate of Barksdale (1965). We identified the isolate as *A. heterosexualis* Whiffen-Barksdale, primarily because of the monoclinous origin of antheridial hyphae, which develop from points very near the oogonium, usually on the same hypha as the oogonium (Barksdale, 1965). The isolate produced antheridial hyphae when juxtaposed with female tester strains representing *A. ambisexualis*, *A. bisexualis*, and *A. heterosexualis*, but failed to demonstrate sexual compatibility with any of the tester females (Thomas et al., 1984). Spores were prepared by transferring agar plugs from Petri plate cultures to 100 ml peptone–yeast extract–glucose liquid medium (PYG) (Cantino and Lovett, 1960). After 24 hr incubation on a reciprocating shaker, the medium was decanted and replaced with two successive changes of 5×10^{-4} M $CaCl_2$ (Griffin, 1966). After a further 12 hr incubation on a shaker, the resulting spore suspension was decanted to a sterile receiver flask. Spore suspensions were stored at 4°C and used within three weeks.

Asexual Sporulation. Spores were inoculated to PYG and grown on a reciprocating shaker at room temperature for 24 hr. Colonies were collected by filtration, washed, and transferred to 2 ml 5×10^{-4} M $CaCl_2$ in each of 25×5-mm Petri plates with varying concentrations of antheridiol. After 24 hr, spore production was determined by hemacytometer counts of two aliquots from each dish. Treatments were in duplicate, and experiments were repeated at least once.

Sexual Reproduction. Cultures of *A. heterosexualis* 52875 were prepared and treated as described above, except that liquid M medium (Mullins and Barksdale, 1965) replaced the $CaCl_2$. After two days oogonia were counted in six colonies from each plate.

Chemicals. Antheridiol, synthesized by the protocol of McMorris et al. (1974), was applied in ethanolic solutions. All treatments including the controls, contained ethanol at a concentration not exceeding 1% (v/v) of the treatment medium.

RESULTS

In all three *Achlya* isolates, asexual spore release occurred within 4–6 hr after transfer to initiating medium. The effects of antheridiol on asexual repro-

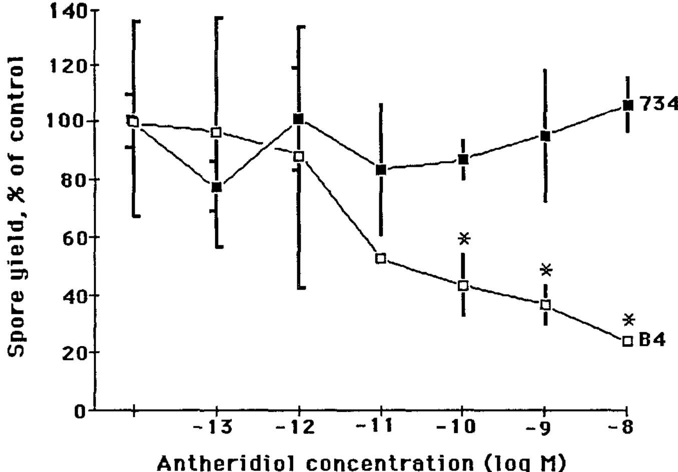

FIG. 2. The effect of antheridiol on asexual sporulation in the homothallic *A. heterosexualis* 52875 and in the female *A. ambisexualis* strain 734, which does not produce antheridial branches in response to the hormone. The vertical bars represent ± standard deviation of each mean; the asterisks denote means significantly different from the controls (two-tailed t-test, $P < 0.001$).

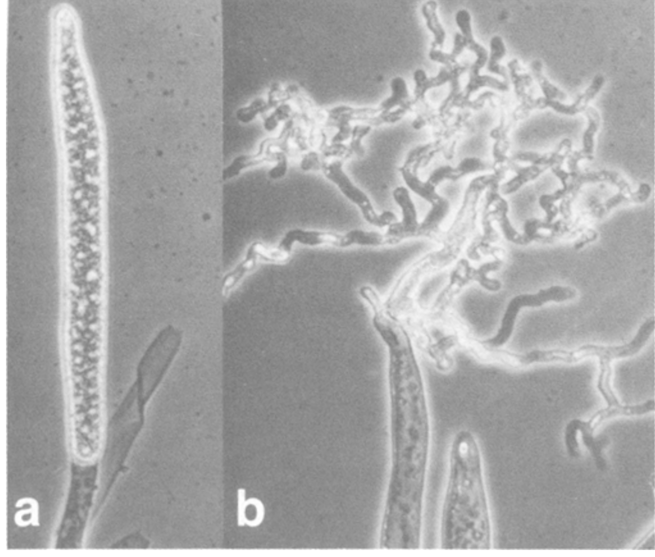

FIG. 3. Hyphal tips of *A. heterosexualis* 52875, modified to produce a terminal sporangium (a), or induced by 10^{-8} M antheridiol (b). In the presence of hormone, a hyphal tip which might otherwise have differentiated to produce a sporangium has produced numerous antheridial branches. Magnification, 300X.

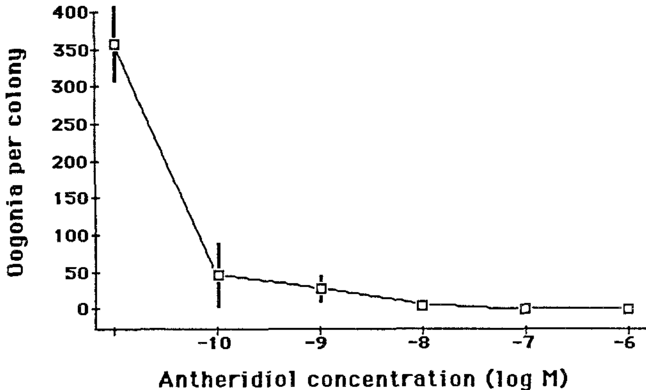

FIG. 4. The effect of antheridiol on oogonium production in *A. heterosexualis* 52875. The vertical bars representing ± standard deviation of each mean are omitted when they fall within the marker squares; treatment means are significantly different from that of the control (two-tailed t test, $P < 0.001$).

duction varied with the isolate. The homothallic isolate *A. heterosexualis* 52875, which responded to antheridiol by producing an abundance of antheridial hyphae starting 1.5 hr after treatment, showed a marked reduction of asexual spore production (Figure 2). In contrast, asexual sporulation in the *A. ambisexualis* female strain 734, which produces no antheridiol receptor (Riehl and Toft, 1985) and which shows no morphological response to the hormone, was unaffected by antheridiol (Figure 2). In the *A. ambisexualis* male strain E87, antheridial hyphal primordia became visible 3 hr after treatment and the antheridial hyphae were fewer than in *A. heterosexualis*. The effect of antheridiol on sporulation in E87 (not shown) was variable, ranging from moderate to nonsignificant inhibition. The morphological effects of antheridiol on *A. heterosexualis* 52875 (Figure 3) include massive induction of antheridial branches on hyphae which might otherwise have differentiated to produce sporangia.

In *A. heterosexualis* 52875 oogonia are produced 12–24 hr after transfer from PYG to M medium. The inhibition of oogonium production in the presence of antheridiol is illustrated in Figure 4.

DISCUSSION

Inhibition of asexual reproduction in the various strains by antheridiol appears to be directly proportional to the abundance of antheridiol receptor. The receptor is undetectable in *A. ambisexualis* 734 (Riehl and Toft, 1985), and the receptor level in *A. ambisexualis* E87 is approximately 10–20% of that present

in *A. heterosexualis* 52875 (D. des S. Thomas and T.C. McMorris, unpublished).

The vigorous production of antheridial hyphae by *A. heterosexualis* with consequent reduction of resources available for asexual and sexual spore formation may help to account for the inhibitory effects of antheridiol on asexual sporulation and on oogonium formation. These results suggest the possibility that under natural conditions females of *A. ambisexualis* or *A. bisexualis* (Coker and A. Couch), both of which secrete antheridiol, could suppress the reproduction of neighboring *A. heterosexualis* colonies. Barksdale (1965) has pointed out that these three cross-conjugating species of *Achlya* can be interpolated on a gradient ranging from low hormone productivity and high sensitivity at one end (*A. heterosexualis*) to high productivity and low sensitivity at the other end (*A. bisexualis*). Antheridiol concentrations in a culture of the *A. bisexualis* female strain T5 can exceed 5×10^{-8} M (Barksdale, 1969) and should be even higher than this near the source mycelium in an unstirred culture. The lower hormone levels shown in the present work to inhibit reproduction in *A. heterosexualis* can therefore be considered to be physiological concentrations.

Allelochemicals are chemical signals between a sender organism and a receiver belonging to a different species (Whittaker and Feeny, 1971), and include allomones, which give adaptive advantage to the sender. Among the subcategories of allomone are inductants, which modify the growth of the receiver. Where a chemical signal acts, as does antheridiol, to decrease the reproductive fitness of a member of another species, it can be classified as an allomone. The literal meaning of this term, derived from the Greek *allos* (other) and *hormon* (to excite), is appropriate in the case of antheridiol when it elicits a futile sexual response in a target organism such as *A. heterosexualis*.

The hormone/allomone duality in antheridiol function is likely to constitute an important constraint on natural selection within the genus *Achlya* and may help to elucidate observations such as the high female-to-male ratios reported in natural populations (Raper, 1950; Barksdale, 1960; Thomas et al., 1984), and the aforementioned inverse relationship between hormone sensitivity and productivity in a *A. heterosexualis*. As far as we are aware, antheridiol is unique among steroids in its potential for the dual functions of hormone and allomone within a single genus.

Acknowledgments—We thank Dr. K. Suryanarayana (Department of Medicine, University of Alberta, Edmonton) for valuable discussions, and Dr. P.A. Farnsworth (Department of Biology, University of California, San Diego) for the photomicrography. The work was supported by NIH grant AM-25625 and by the Natural Sciences and Engineering Research Council of Canada.

MISLEADING THE COLORADO POTATO BEETLE WITH AN ODOR BLEND[1]

D. THIERY[2] and J.H. VISSER

Department of Entomology, Agricultural University
P.O. Box 8031
6700 EH Wageningen, The Netherlands

(Received March 27, 1986; accepted July 11, 1986)

Abstract—Walking tracks of Colorado potato beetles, *Leptinotarsa decemlineata* Say, were recorded on a locomotion-compensator in response to wind, odors of host plants *Solanum tuberosum* L. and nonhost plants *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, and to mixtures of these plant species. Host-plant odor induced positive anemotactic responses in starved females, whereas odor of the nonhost *L. hirsutum* was neither repellent nor attractive. The attractiveness of host-plant odor, however, was neutralized in the odor blend of plant species. Masking the attractive host-plant odor will hinder the beetle's searching for host-plant patches, and this principle may be exploited in pest control by mixed cropping.

Key Words—Colorado potato beetle, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, *Solanum tuberosum*, *Lycopersicon hirsutum* f. *glabratum*, chemoattraction, masking, mixed cropping, olfactory orientation, searching behavior.

INTRODUCTION

Insect pest levels are often lower in mixed cropping systems than in monocultures, and it has been suggested that the searching behavior of phytophagous insects is disrupted by the confusion of signals from intercropped plants (Cromartie, 1981; Kareiva, 1983; Stanton, 1983). There is, however, no direct evi-

[1] The locomotion-compensator was constructed with financial support from the Foundation for Fundamental Biological Research (BION), which is subsidized by the Netherlands Organization for the Advancement of Pure Research (ZWO), grant 14-02-02. The first author was supported by a grant from the French Ministry of Industry and Research.

dence that when the odor of a nonhost plant is added to a plume of host-plant odor this will disrupt the insect's olfactory orientation. The purpose of the present study was to see whether odor blending affects the olfactory orientation of the Colorado potato beetle, *Leptinotarsa decemlineata* Say, towards its host-plant potato *Solanum tuberosum* L.

The walking Colorado potato beetle responds to potato-plant odor by an odor-conditioned positive anemotaxis (Visser, 1976; Visser and Thiery, 1985). The composition of the potato leaf odor was previously studied (Visser et al., 1979; Visser, 1983), and electrophysiological experiments revealed the characteristics of the antennal olfactory receptors (Visser, 1979, 1983).

Although in laboratory studies experimental conditions are precisely controlled, which makes a comparison with field conditions difficult, this approach is essential to study the behavioral patterns that underlie the insect's colonization of host-plant patches in the field. This paper presents data on the odor-conditioned anemotaxes of Colorado potato beetles as released by host-plant odor, and the effects of nonhost-plant odor on these responses. We used as a source of nonhost-plant odor the strong-smelling wild tomato *Lycopersicon hirsutum* f. *glabratum* C.H. Mull.

METHODS AND MATERIALS

Recordings of Behavior. Experiments were previously described on the orientation of Colorado potato beetles towards a source of windborne potato-plant odor in a low-speed wind tunnel (Visser, 1976). In the present study, behavioral responses of beetles were recorded using a locomotion-compensator in front of this wind tunnel. The insect test section of the original tunnel was removed, and the flow leaving the contraction passed over the beetle walking on the locomotion-compensator. This instrument, which was designed by E. Kramer and P. Heinecke (Max-Planck-Institut fuer Verhaltensphysiologie, Seewiesen, FRG), has been used in a number of studies on insect orientation (Kramer, 1976; Weber et al., 1981).

In brief, the locomotion-compensator operates as follows: an insect walks freely on top of a large sphere while its positional change is monitored by means of a beam of light reflected by a small mirror which is glued to its elytra. Walking activity is continuously compensated by two motors rolling the sphere in the opposite direction. The rotations of the sphere are detected by two pulse generators in contact with the sphere, and pulses are recorded and analyzed by a computer. In this way, the beetle's position was recorded every second, and walking speed and direction were calculated. Full technical details of this equipment will be presented elsewhere (Visser and Thiery, in preparation).

Insects and Plants. Beetles were obtained from laboratory stock culture.

Newly emerged females were fed for 2 hr on potato foliage and then starved for at least 12 hr prior to the experiments. At the time of the experiments, the females were about one day old. Plants were reared in greenhouses: potatoes *Solanum tuberosum* cultivar Eigenheimer, and wild tomatoes *Lycopersicon hirsutum* f. *glabratum*.

Experiments. Individual females were exposed for 10 min to each of four subsequent stimuli: (1) a clean air flow of 80 cm/sec as control, and the same air flow carrying (2) the odor of wild tomato *L. hirsutum* f. *glabratum*, (3) the odor of potato *S. tuberosum*, and (4) the odor from a mixture of the two plant species. At least 1 hr elapsed between successive exposures of individual females. For each plant species, three pots of fully grown plants were placed in the dark upwind section of the wind tunnel, and contained approximately an equal volume of foliage. The experiments were conducted at 24°C. Light intensity on top of the sphere was set at 1750 lux by means of two high-frequency illumination units (2500 Hz). The air speed was measured at the outlet of the wind tunnel. Other conditions were previously described (Thiery and Visser, 1986).

Analyses of Responses. Five variables are used to describe the beetle's responses: (1) walking speed as the mean of 599 instantaneous speeds per individual, (2) vector length as the resultant displacement from the origin after 600 sec, (3) straightness of the track as the quotient of the vector length and the total length of the walking track, (4) time spent walking upwind corresponds to the proportion of angle observations with deviations of less than 60° from the wind direction, and (5) upwind length as the upwind displacement after 600 sec. Variables were compared between treatments using nonparametric statistics (Siegel, 1956): sign test (variable 3) and Wilcoxon's test (variable 1, 2, 4, and 5). In this way the variables from the treatments were tested as related samples which compensates for the large variations in walking speeds between individual beetles.

RESULTS AND DISCUSSION

Orientation Responses. Representative walking tracks of an individual female in response to wind, nonhost-plant odor, host-plant odor, and odor of the mixture of host and nonhost plants are shown in Figure 1(a–d). Circular distributions of the beetles in the four treatments are depicted in Figure 2, and Table 1 shows the corresponding values of the variables that quantify orientation.

In a clean air flow, Colorado potato beetles walked with a weak preference for upwind directions which is manifested by their net upwind displacement (Table 1). In this stimulus condition the beetles did not walk very straight (straightness is 0.38). Odor of the wild tomato did not elicit an increase in

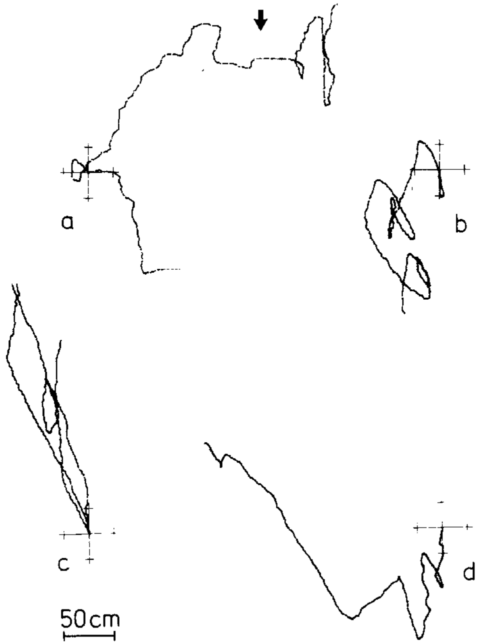

FIG. 1. Tracks of one female Colorado potato beetle in four successive treatments of 10 min each: (a) wind control, (b) *Lycopersicon hirsutum* odor, (c) *Solanum tuberosum* odor, and (d) odor blend of *L. hirsutum* and *S. tuberosum*. upwind responses of the beetles. Vector length, straightness, upwind time, and upwind length were not changed as compared with clean air. However, walking speed decreased significantly relative to that in clean air.

When stimulated by potato-plant odor, all beetles orientated completely upwind (Figure 2, Table 1). They spent most of their time walking straight upwind towards the odor source, as can be seen in an increased straightness and upwind time. The resultant vector measured about twice the vector length from the previous experiments. The upwind length equaled approximately the vector length since the latter was pointed strictly upwind.

The odor blend consisting of *L. hirsutum* and *S. tuberosum* volatiles, however, caused a decrease of all variables. Vector length, straightness, upwind time, and upwind length of the track were comparable with those in the clean air treatment. The significant decrease of walking speed did not cause a further reduction in vector length or upwind length (Table 1). The presence of nonhost-plant odor in the air flow apparently inhibits the positive anemotactic responses which are observed with potato plant odor; the beetles do not walk upwind.

Masking by Nonhost-Plant Odor. When compared with the wind stimulus

alone, wild tomato is neither repellent nor attractive. The beetle's walking speed is reduced on stimulation by both the odor of wild tomatoes, and the blend of odors. Nevertheless, in these conditions vector length and upwind length are comparable with those measured in pure wind. This implies that repellency is not involved since this term is defined as a movement being directed away from the odor source (Dethier et al., 1960), and would be directed downwind. The neutralization of orientation responses in the Colorado potato beetle is interpreted as the result of olfactory camouflage of the host plant by combining it with a different odor. An essential part of the attractive potato leaf odor consists of a complex of C_6 alcohols, aldehydes, and corresponding derivatives generally distributed in green leaves (Visser et al., 1979). The specificity of this so-

called green odor is set by the ratios of its individual components, since changing their ratios, by addition of pure volatile chemicals, interrupts the upwind movements of the beetles (Visser and Avé, 1978). In the present study it is shown that addition of the odor of wild tomato plants to the potato-leaf odor, likewise blocks the release of positive anemotactic responses in this beetle.

It is noteworthy that an accession of *L. hirsutum* f. *glabratum* that contains high levels of 2-tridecanone, is resistant to the Colorado potato beetle (Kennedy and Sorenson, 1985). In other experiments, the camouflage of potato plants was also obtained by adding the odor of cabbage *Brassica oleracea* L. var. *gemmifera* DC. (Thiery and Visser, 1986). For that reason, masking of host-plant odor is thought to be caused by the change in green odor composition, although further experiments are needed in order to exclude 2-tridecanone as a masking component.

Potato plant odor releases odor-conditioned positive anemotactic responses in females as well as in males and postdiapause beetles (Visser, 1976; Visser and Nielsen, 1977). The disruption of olfactory orientation by the mixing of odors occurs independently of the beetle's feeding experience since its emergence; the same effects were found when "naive" females were used (Thiery and Visser, 1986).

Mixed Cropping. The translation of the present findings on odor blending to field conditions requires consideration of the relevance of the beetle's walking behavior to field conditions and the extent of odor blending in the atmosphere. In Western Europe host-plant finding by the Colorado potato beetle happens mainly while the beetle is walking (the late J. de Wilde, unpublished field observations 1979, 1981). Newly emerged and postdiapause adults are unable to fly until 8–10 days of age when flight muscles are fully developed (De Kort, 1969). In the field, wind turbulence will blend volatiles from a mixed stand of plants (Stanton, 1983; Visser, 1986). It is expected, therefore, that the

beetle's range of attraction to host-plant odor is reduced in mixed cropping systems. Masking the attractive host-plant odor will then hinder the beetle's searching for host plants.

Bach (1982) reported recaptures of Colorado potato beetles which were released between small field plots containing different arrangements of host and nonhost plants. In contrast with the conclusions of the present laboratory study, she emphasized that the colonization of these beetles did not appear to be negatively affected by the presence of nonhost plants, like melon. Apart from not mentioning sex, age, and prior starvation period of the beetles, information is lacking on relevant abiotic factors such as temperatures and the prevailing wind direction. Since Bach noted that statistics were not justified with the small sample size used, this study is insufficient to conclude that plant diversity does not hinder the colonization of host plants by Colorado potato beetles.

Panasiuk (1984) and Schearer (1984) reported volatiles of tansy *Tanacetum vulgare*, that repelled Colorado potato beetles. Their studies were undertaken in order to isolate components which cause the observed reductions of beetle populations when potatoes were interplanted with tansy. These two investigations applied nearly the same methodology; however, their results differed strikingly. For example, Panasiuk reported that α-pinene attracted beetles, whereas Schearer's data suggested repellency of this compound. These observations contradict EAG data showing that the antennal receptors of the Colorado potato beetle are insensitive to this compound; small EAG responses were solely obtained to high doses that are not present in the headspace of plants (Visser, 1979). Moreover, the reports of Panasiuk and Schearer do not contain substantial data on beetle responses, and the applied doses exceeded many times their concentrations in natural plant-odor blends. The suggestion that the compounds which they identified as repellents are responsible for the reductions of beetle populations in interplantings is premature since an extreme dose of any volatile compound will be repellent (Visser, 1986).

Conclusions. Plant odors are composed of general as well as specific components (Visser, 1986). The present study shows evidence that the attractive host-plant odor is masked on blending with nonhost-plant odor. In heterogeneous ecosystems and in mixed croppings, it is expected, therefore, that host-plant odors are frequently camouflaged. This principle needs further experimentation to develop intelligent methods of intercropping for insect pest control.

Abstract—To test the hypothesis that rats (*Rattus norvegicus*) emit airborne, differential odors in response to reward and nonreward, donor rats received random sequences of rewarded and nonrewarded placements in small compartments and an airstream transported odors from these compartments to test rats in a separate chamber. When donors remained in the compartments during, or were removed just prior to, air transport, test rats utilized transported odors as discriminative cues signaling their own reward and nonreward for a lever-press response. When the airstream was passed through a clean compartment containing paper flooring extracted from donor compartments, test rats were not able to discriminate. Test trials to assess for control by food odors suggest that donor-produced odors, rather than food odors per se, provided the discriminative signals for test rats. Results confirm the existence of somewhat volatile, although apparently stable, odors emitted in response to reward and nonreward, and implicate a differential in amount and/or type of odor produced by donors to these two events as the source of discriminative control.

Key Words—Reward odor, nonreward odor, olfactometer, *Rattus norvegicus*.

INTRODUCTION

In 1966, independent reports from two laboratories suggested that rats (*Rattus norvegicus*), experiencing intermittent food reward, might emit quantitatively

0098-0331/87/0500-1147$05.00/0 © 1987 Plenum Publishing Corporation

and/or qualitatively different odors in response to reward and nonreward (McHose and Ludvigson, 1966; Spear and Spitzner, 1966). In the ensuing years, numerous studies have produced evidence for an odor differential, generated under these circumstances, as a controlling source of differences in both unlearned and learned responses of conspecifics (e.g., Bloom and Phillips, 1973; Collerain, 1978; Ludvigson et al., 1979; Ludvigson and Sytsma, 1967; Mellgren et al., 1973; Morrison and Ludvigson, 1970). Furthermore, such odor differences have been shown to control differential responding in conspecifics when: (1) the rewarding event consists of water (e.g., Davis et al., 1982); (2) food is always present, but access is sometimes prevented (e.g., Voorhees and Remley, 1981); and, (3) food is always provided, but in differing quantities (e.g., Ludvigson et al., 1985), or at differing delays (e.g., McHose and Ludvigson, 1966). Thus, the phenomenon clearly seems attributable to odors contributed by the rats experiencing intermittent differences in reward rather than the odor of the reward itself. Recently, the generality of the phenomenon was extended in a demonstration that wild wood rats (*Neotoma floridana osagensis*) both emit and respond to such odors (Davis et al., 1985). Although the ecological significance of these odors is presently unclear (cf. Davis et al., 1985; Ludvigson et al., 1985; Voorhees and Remley, 1981), an understanding of their adaptive functions would be aided by analyses of the odorants themselves as well as the reactions of conspecifics, including the basis upon which conspecifics can discriminate between the odors.

All of the aforementioned studies were conducted using alleyways, T mazes, or similar types of apparatus, and all except Voorhees and Remley (1981) brought the test rats to the odor source. Generally speaking, the most common procedure involves administering a rewarded or nonrewarded treatment to one or more food-deprived rats (donors) in the apparatus, followed by the introduction of test rats (one at a time) whose behavior is assessed for relevant response differences to the prevailing odors. Although this approach has been useful for the study of conspecific reactions to the odors, inferences about the nature of the odors and source of their discriminable differences have been less readily achieved. Relatively little is known about the olfactory stimuli themselves, aside from the fact that they accumulate as successive donors are administered treatments (Prytula et al., 1981; Taylor and Ludvigson, 1983). Since the test rats are permitted access to the location in which donors received a treatment, they could be responding to high-, low-, and/or nonvolatile components available on the surfaces or in the air of the apparatus; discriminable differences in one or more of these components could be based on qualitative, quantitative, and/or distributional differences in the components.

The present study addresses the nature of discriminable differences in the odors which rats produce to reward and nonreward. Test rats received reward and nonreward for a lever-press response contingent upon rewarded and nonre-

warded treatments given to donors in small compartments. An airstream, passed through these compartments, delivered available odors to serve as discriminative cues signaling reward and nonreward for the test rats. The acquisition of differential rates of lever-pressing to the odors, and subsequent changes in these rates as manipulations were made to alter the odors, provided the basis for inferences about the nature of and control by transported odors.

METHODS AND MATERIALS

Experiment 1

Voorhees and Remley (1981) demonstrated that an airstream passed over paper flooring extracted from an alleyway in which donors had received reward or nonreward elicits differential responses in mitral cells of test rats' olfactory bulbs as a function of the treatment received by the donors. However, in a study of Taylor and Ludvigson (1986), rats provided with an airstream passed over clean paper flooring or paper flooring from an alleyway in which donors had either received reward or nonreward were able to discriminate between the clean papers and donor-exposed papers, but gave no behavioral evidence of differentiating between papers from the reward, as opposed to nonreward, of donors. Perhaps only small quantities of odorants can be transported from the paper, and these quantities are insufficient to support a behavioral discrimination although capable of producing differences in neurological responses. If, however, test rates were allowed to sample these same odorants through direct contact with the paper, as is possible in the alleyway situation, then subtle differences might control behavioral responding in that situation. The present experiment tested the hypothesis that rewarded and nonrewarded rats provide airborne, discriminatively different odors in response to these two events.

Subjects. Eight male rats served as subjects. Upon arrival from the supplier, the rats were individually housed in wire-mesh cages and provided free access to food and water until 132 days of age. At this time they were deprived of food and gradually reduced in body weight until each rate stabilized to between 80 and 85% of its free-feeding weight. Two of the eight rats were randomly selected to serve as test rats, and the remaining six were randomly divided into two donor squads of three rats each. The test rats were randomly designated as test rat 1 and 2, and the donor squads as squads 1 and 2.

Apparatus. A small-animal olfactometer consisting of an air pump and purification system, a donor-treatment component, and a test chamber, all connected by an airstream, served as the experimental apparatus. The olfactometer is schematically depicted in Figure 1. Room air was pumped (DeVilbiss Suction Pump No. 701), via a polyethylene hose, through a series of three glass columns containing, in order, anhydrous calcium sulfate, charcoal granules, and distilled

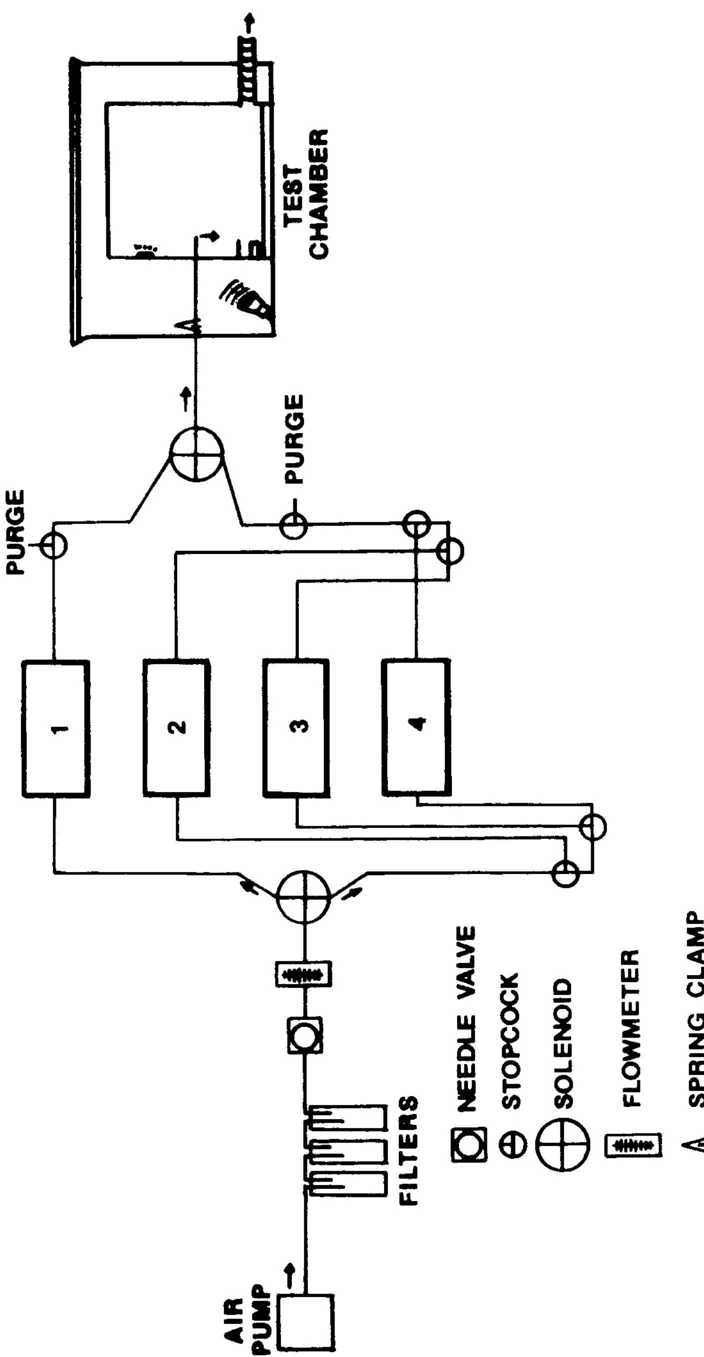

FIG. 1. Schematic diagram of the olfactometer. Room air was pumped through the filter system and the flow rate regulated before passing through one or more placement boxes (2–4) containing the odorant for delivery into the test chamber.

water. Thus, room air was dehydrated in the first column, deodorized in the second, and partially rehydrated in the third. The filtered air was carried through glass tubing to a standard needle valve and Dwyer flowmeter (RMA 16), and the flow rate regulated to 5 liters/min.

The air then passed into the donor-treatment component composed of glass tubing, Teflon couplings, glass and Teflon three-way stopcock valves, two three-way solenoid valves (ASCO No. 8320A85), and four placement boxes (box 1, 2, 3, and 4). The air flow could be directed through box 1, or through boxes 2, 3, and 4 separately or in any combination. Each placement box was made of stainless steel and measured 26.5 cm long, 8.5 cm wide, and 10.3 cm high. The top of each box was covered with a 0.64-cm-thick glass sheet extending the length and width of the box. Boxes 2, 3, and 4 were used for the placement and treatment of donors, while box 1 provided a source of clean air. Each of boxes 2, 3, and 4 was equipped with a removable, stainless-steel food cup designed to minimize the spillage of food crumbs onto the floor of the box. Each cup measured 34 mm, inside diameter, and was 29 mm deep. The base consisted of a flat trough, 10 cm × 7 cm, with edges folded up to form a 7-mm-high lip. With this design, rats would eat from the food cup and crumbs fell into the trough rather than onto the floor.

The air emerging from the donor-treatment component followed a final common path of glass tubing for delivery into the test chamber. The odor-delivery tube protruded 1.27 cm into the chamber and terminated in a 3-mm-wide opening in the bottom of the tube. The test chamber consisted of a modified Lehigh Valley Electronics operant conditioning chamber situated inside a sound-attenuating enclosure. A response lever, centered 3.81 cm below the odor-delivery tube, a food tray, and a houselight were mounted on the front wall. The length of the chamber was 22.86 cm, and the width was restricted to 10.8 cm by exchangeable glass plates which extended the length and height of the chamber. On the back wall, a round portal, 3.81 cm in diameter, allowed the chamber air to be constantly evacuated with the aid of an attached hose and exhaust fan. The sound-attenuating enclosure contained a speaker through which white noise was emitted. Together, the speaker and the exhaust fan provided a constant masking sound inside the chamber.

Preliminary Training. The donor rats were given three days of habituation to the placement boxes, consisting of four 1-min placements each day. Beginning on the fourth day, and continuing for nine days, the donors were trained on an intermittent schedule of reward and nonreward consisting of four rewarded and four nonrewarded placements each day. The order of these placements was randomly determined each day with the restriction that not more than three like events occur in succession. To administer a placement, each donor was inserted into a separate placement box at roughly the same time. Each box contained a strip of clean paper flooring and a food cup. The glass tops were

quickly placed over the boxes and weights were set on top to prevent the rats from dislodging the tops. On rewarded placements, the food cups contained fifteen 45-mg Noyes pellets which the rats were allowed 45 sec to consume; on nonrewarded placements the cups were empty and the rats were confined for 45 sec. After the 45-sec period, the tops were briefly removed to extract the food cups with needle-nose pliers and were then replaced. With the donors in the boxes, filtered air was simultaneously circulated through all three boxes for 1 min. Then donors were removed from the boxes and transported from the experimental room while preparations were made for the next trial.

During a day, each donor received all placements in the same box; however, across days, donors were systematically rotated among the boxes. Between placements, any fecal matter or traces of moisture were removed, clean flooring installed, and clean air circulated through all three boxes for 3 min. Squad 1 received all eight placements before any were administered to squad 2. The placement boxes were rinsed in hot water and dried between squads.

The two test rats were adapted to the test chamber, given pellet habituation, and trained to perform the lever-press response. Subsequently, they were trained to utilize houselight-onset as a signal for rewarded lever-pressing and houselight-offset as a signal for nonrewarded lever-pressing. Once both test rats were consistently responding during light-on periods, and showing little, or no, responding during light-off periods, the olfactory discrimination procedure was initiated.

Olfactory Discrimination Procedure. The olfactory discrimination procedure required each test rat to differentiate between two odorants, one arising from the reward of donors and one from the nonreward of donors. On any given trial, one of the two odorants was delivered by airstream during the light-on period of the trial. Across trials, for each test rat, lever-pressing was consistently rewarded in the presence of one of these odorants, but not rewarded in the presence of the other odorant. To administer a trial, the donor squad was given a rewarded or nonrewarded placement, and then the test rat was carried into the experimental room and placed in the test chamber.

Following a 5-sec delay, the houselight came on and air flowed through box 1 and into the chamber for 3 sec. The solenoid valves then switched and directed air through boxes 2, 3, and 4, and into the test chamber. Following a 2-sec delay, to ensure adequate odor transport, the differential reward period began. On a rewarded trial for a test rat, fifteen 45-mg Noyes pellets were dispensed automatically for the first lever-press response following the lapse of a variable interval which ranged from 3.75 to 36.25 sec. As the pellets were dispensed, the houselight went off and the airstream delivered into the chamber was passed through box 1. The rat was allowed 45 sec to consume the pellets before removal from the chamber. On a nonrewarded trial for a test rat, no pellets were dispensed and the rat was confined to the chamber for 45 sec.

Each test rat received four rewarded and four nonrewarded trials per day, with the order dictated by the random sequence of rewarded and nonrewarded placements assigned to the respective donor squad. Test rat 1 received a rewarded trial when its donors received a rewarded placement, and a nonrewarded trial when its donors received nonreward. For test rat 2, reward and nonreward occurred when its donors received nonreward and reward, respectively. In this fashion, odors transported from rewarded donors could serve as a signal of impending reward for test rat 1 and nonreward for test rat 2, while odors transported from nonrewarded donors could signal impending nonreward for test rat 1 and reward for test rat 2.

Between trials, a test rat was isolated in an adjacent waiting room. A white noise source in the waiting room provided a masking sound for intertrial activities going on in the experimental room. During the intertrial interval of approximately 15 min, the test chamber walls and grid floor were swabbed with clean water and dried, the two glass plates in the chamber were replaced with clean ones, and clean paper was inserted beneath the grid floor. These measures were taken to minimize the presence of residual odors from the preceding trial. Meanwhile, the donor boxes were flushed with clean air, and another placement was administered to the donors. Test rat 1 received all trials of a day before test rat 2 received any.

Experimental Manipulations. The olfactory discrimination task described above remained fixed throughout the experiment, while manipulations were made to alter the available odors delivered to the test rats in various phases as described below. In all phases, except phase B, squads 1 and 2 served as donors for test rats 1 and 2, respectively. Test rats were progressed through four distinguishable phases in the sequence A B A C D C.

During phase A, the donors remained in their boxes on each trial as filtered air was passed through all three boxes. This procedure minimized disturbance of the air in the boxes and, presumably, maximized the opportunity for transporting available donor-produced odors to the test rats. In phase B, squad 1 served as donors for test rat 2, and squad 2 served as donors for test rat 1, while all other aspects remained unchanged from phase A. This phase was introduced in an attempt to conceptually replicate observations from alleyway studies (e.g., Eslinger and Ludvigson, 1980) wherein interchanging donors appear to produce little, if any, disruption in test rats' responses to reward and nonreward odors. By inference, the controlling components of such odors would appear similar across rats rather than unique to individual rats.

In phase C, donors were removed from the boxes and the experimental room when the food cups were extracted. This phase assessed whether controlling cues remain despite removal of the donors, and thus provided for inferences about the stability of the odors and potential extraneous control by nonolfactory cues. Nonolfactory cues might include differential movements and/

or noise by the donors conducted through the glass tubing to the test rats. Continued differential responding by test rats would argue against such extraneous control and suggest a degree of stability in the olfactory cues, defined by their ability to withstand disruption during donor removal.

In phase D, manipulations were made to assess whether controlling odors are preserved on the paper flooring extracted from the boxes. On each trial of this phase, one of the three donors in a squad was given a placement in box 2 and then removed. The strip of paper flooring was transferred, with a pair of forceps, to box 4 and the box covered. After placing clean paper in boxes 2 and 3, the remaining two donors of the squad were concurrently given placements in these two boxes. The paper flooring from these boxes was subsequently added to the one previously transferred to box 4. The airstream delivered to the test rat was circulated through box 4 containing the three strips of paper flooring.

Experiment 2

This experiment was designed to further examine and clarify the ability of transferred papers to provide a functional source of discriminative cues for test rats. In order to avoid the introduction of major procedural changes when testing transferred papers, a new donor procedure was implemented for this experiment. In addition, this experiment provided a more straightforward test of potential discriminative control by food odors.

Subjects. The donor and test rats, as well as all aspects of their care and maintenance, remained unchanged from experiment 1.

Apparatus. The olfactometer remained unchanged; however, box 3 was not used at all in this experiment. The flowmeter was adjusted to yield a flow rate of 6.5 liters/min.

Olfactory Discrimination Procedure. The discrimination procedure for test rats remained unchanged from experiment 1, although each test rat only received three rewarded and three nonrewarded trials each day.

A new procedure was instituted for the treatment of donors. To administer a trial to a donor squad, the donors were successively given 45-sec placements in a single box without changing the paper flooring or cleaning the box between donors. Following the removal of the final donor, the test rat was presented with air circulated through this single box. In all phases, squads 1 and 2 served as donors for test rats 1 and 2, respectively.

Experimental Manipulations. The test rats were progressed through three distinguishable phases in the sequence A B A C. During phase A donors were given rewarded and nonrewarded placements in box 2. The performance of test rats in this phase was used as a baseline for evaluating the effects of manipulations in phase B. In phase B, donors were administered placements in box 4 in the same manner in which placements were given in box 2 during phase A.

On each trial, following the removal of the final donor in the squad, the single strip of paper flooring was quickly transferred, with a pair of forceps, to box 2. Air was circulated through this box and delivered to the test rat. This phase served as a further attempt to assess the efficacy of paper flooring as a source of controlling odors. On day 10, test trials were conducted to assess responding to air samples passed over clean paper flooring in a clean placement box. Accordingly, donors were given placements in box 4, as on the other days of phase B, but instead of transferring the paper flooring to box 2, a clean strip of paper was inserted into box 2 and the air circulated over this clean paper. Test rats were rewarded on half of these trials, with rewarded trials randomly determined.

Following a return to phase-A conditions, phase C was instituted. In phase C, donors were given placements in box 2; however, following the removal of the last donor on nonrewarded placements, two 45-mg Noyes pellets were inserted into the middle of the box onto the paper flooring. Pellets were not inserted in box 2 following rewarded placements. The two-pellet quantity was selected because inspection of the placement boxes throughout all phases of both experiments indicated that observable quantities of food crumbs were not present on the floor. Hence, two intact food pellets were judged likely to provide an odor of food in the nonreward odor sample that was at least as intense as any food odor provided by potential residual crumbs in the reward odor sample. If a food-odor differential were responsible for the test rats' discriminations, then this manipulation would be expected to eliminate, if not reverse, this differential, and hence, test rats' characteristic rates of responding to nonreward and reward odors should be reversed or, at least, differences in rate eliminated. In contrast, if a donor-produced odor differential were responsible for discrimination, then considerable differences in rate of responding to reward and nonreward odors should be maintained in this phase.

RESULTS AND DISCUSSION

Experiment 1

Total responses and total time in the presence of odors from rewarded and from nonrewarded donor treatments were computed each day for each test rat, and these values were used to calculate daily rates of responding (Figure 2). Although the two test rats displayed rather different acquisition curves, both achieved substantial levels of differential responding over the initial 16 days of phase A. Thus, test rats clearly learned to utilize differential cues as signals for their own reward and nonreward. Interchanging donor squads in phase B did not appreciably alter the degree of differential responding by either test rat, indicating that the cues utilized by test rats were rather similar across the two

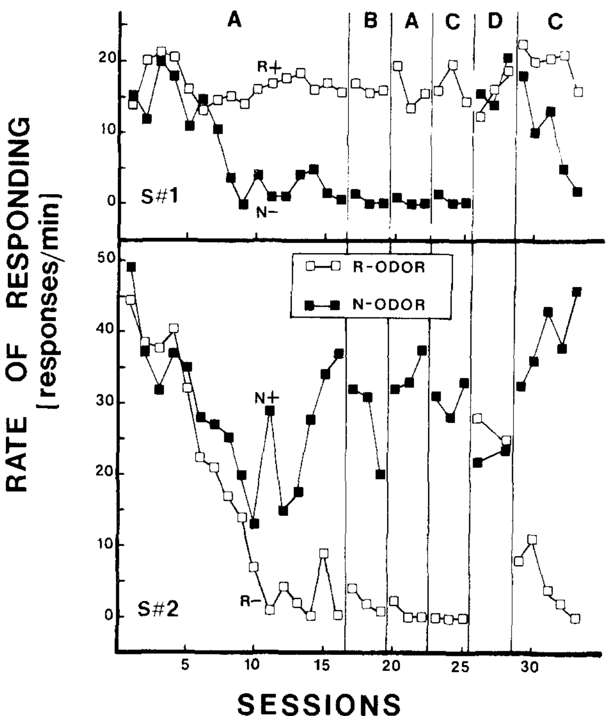

FIG. 2. Lever-presses/minute during experiment 1 by test rat 1 (top) when rewarded in presence of reward odors (R+), but nonrewarded in presence of nonreward odors (N−); and by test rat 2 (bottom) when rewarded in the presence of nonreward odors (N+), but nonrewarded in the presence of reward odors (R−).

donor squads. This serves to conceptually replicate the observations of Eslinger and Ludvigson (1980) made in the alleyway situation and to confirm their conclusion that the relevant odorants possess commonality across rats.

In phase C, the removal of donors before passing air through the boxes had little influence on the magnitude of differential responding exhibited by either test rat. Since donors were not in the boxes at the time the test rat was in the chamber, differential odors transported from the placement boxes, rather than extraneous, nonolfactory cues, must have controlled test rats' behavior. Further, although the odors are sufficiently volatile to be transported by air, they appear not to be so volatile or unstable as to be lost or altered in the process of removing donors from the boxes. Were the latter to be the case, then appreciable diminution in differential responding should have occurred.

In phase D, air passed over transferred paper flooring did not maintain differential responding. Upon returning to phase-C conditions, the test rats recovered their discriminations, although some degree of reacquisition was re-

quired. This suggests that the controlling odors are not transferable on paper, or at least not in sufficient quantity to maintain the test rats' discriminations. However, it might be argued that procedural changes introduced in phase D disrupted odor production by donors or altered the odors produced. While this seems unlikely, it cannot be ruled out. One might also argue that a food-odor differential, arising from food having been in the boxes on rewarded, but not on nonrewarded, trials, could have mediated discrimination by test rats through all previous phases, while in phase D, food odors failed to be transferred on paper from rewarded placements, resulting in the loss of the controlling cues. However, if this were true, test rat 1 should have responsed at a low, nondifferential rate to all papers presented in phase D, since according to this food-odor hypothesis, the absence of a food odor had been consistently nonrewarded during previous phases. Clearly, test rat 1 did not respond in this fashion, but rather responded at a high, nondifferential rate, suggesting control by odorants other than food.

Experiment 2

Daily rates of responding to odors from rewarded and nonrewarded placements were computed and are displayed in Figure 3. Both test rats discriminated quite well on all days of phase A. Thus, the change in the donor procedure from experiment 1 to experiment 2 did not alter the odor cues enough to interfere with discrimination. In phase B, transferred papers again failed to maintain the discriminations of test rats, but the discriminations were recovered upon a return to phase-A conditions. This observation confirms the results of phase D in experiment 1. Further, rates of responding to clean paper flooring on day 10 were similar to rates displayed to transferred papers on the other days of phase B. This supports the conclusion that no behaviorally controlling differential in reward and nonreward odors was preserved on the paper flooring upon which donors received treatments, and by inference, argues that discriminable differences are based on airborne and somewhat volatile olfactory components.

In phase C, test rats maintained substantial levels of differential responding, reflecting considerable ability to discriminate between odors from rewarded and nonrewarded donors, despite the addition of a rather strong food odor to the nonreward samples. Rates of responding to nonreward odor plus food odor were, however, elevated for test rat 1 and depressed for test rat 2, suggesting that the food odor either partially masked the typical odor from nonreward of donors or increased its similarity to the odor from reward of donors. However, assuming the odor of two intact food pellets was sufficient to cancel, or reverse, any prior and consistent food odor differential favoring reward odor, these data indicate that the airborne, controlling differences between the odor of rewarded and the odor of nonrewarded donors derive from donor-produced, treatment-engendered olfactory components.

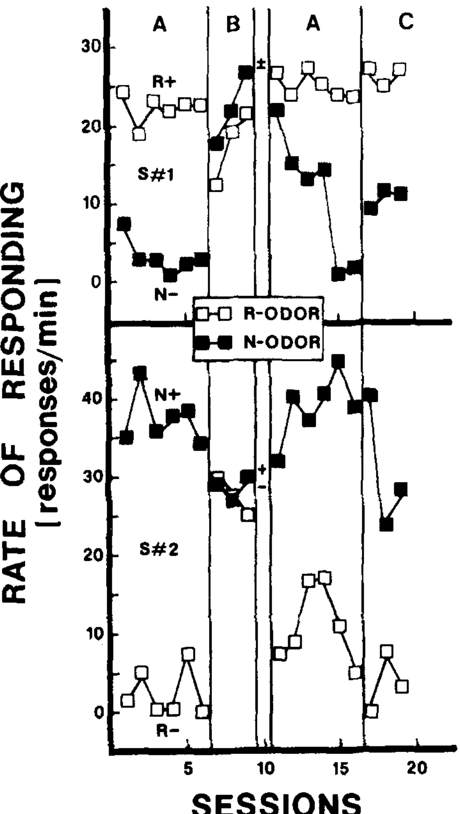

FIG. 3. Lever-presses/minute during experiment 2 by test rat 1 (top) when rewarded in presence of reward odors (R+), but nonrewarded in presence of nonreward odors (N−); and by test rat 2 (bottom) when rewarded in the presence of nonreward odors (N+), but nonrewarded in the presence of reward odors (R−). Day 10 = odor of clean paper presented and test rats 1 and 2 rewarded (+) and nonrewarded (−) on 50% of the trials.

CONCLUSIONS

Although this study leaves open the question of individual differences in, and the generality of, both odor production and odor discrimination in rats, the results do indicate that at least some rats can discriminate between the odors remaining in a location where conspecifics have found a food reward and the odors remaining when conspecifics have failed to find a food reward. The results of this study are consistent with the results of others, obtained with quite different methodologies, in showing that the relevant odorants are emitted by

the conspecifics in response to their reward and nonreward experiences. Very little has been known about the nature of these odors or the dimensions along which they are differentiated by the rat. Results of experiments reported here suggest some conclusions relevant to this void.

First, although the odors might provide various discriminable differences, depending on physical features of the location and spatial proximity of the discriminating rat, readily discriminable differences can be transported by an airstream. Thus, both reward and nonreward odors must contain volatile olfactory components which differ from one another. These components are the most likely source of olfactory cues observed to mediate discriminations in numerous alleyway studies. Other differences in the odors might arise in the alleyway, such as a differential in spatial distribution, and could be used by rats, but such differences are apparently not necessary for a discrimination to occur.

Second, the data suggest that the volatile components emitted by donor rats in response to reward and nonreward differ, at least in part, qualitatively, although quantitative differences could also exist. The differential, however, cannot simply be due to a difference in amount, or concentration, of otherwise qualitatively equal odorants. If, for example, the odorants produced in response to nonreward were simply more concentrated than those produced in response to reward, then test rat 1, for whom nonreward odor was a signal for nonrewarded lever-pressing, would have learned to inhibit responding to "high" concentrations of the odorant, while test rat 2, for whom nonreward odor was a signal for rewarded lever-pressing, would have learned to inhibit responding to "low" concentrations. This is, however, not what was observed when test rats were presented with transferred paper flooring in phase D of experiment 1 and phase B of experiment 2.

Transferred papers retain very little, if any, of the respective odorants, as demonstrated by the inability of such papers to maintain the test rats' discriminations. When presented with air passed over transferred papers, both test rats responded at a high rate similar to that typically shown to the cue signaling their reward. Since reward odor and nonreward odor served as signals for rewarded lever-pressing for test rats 1 and 2, respectively, the notion of "quantitative differences alone" would require the further, unlikely, assumption that reward odor was the less concentrated of the two when squad 1 received treatments, but nonreward odor was the less concentrated when squad 2 received treatments. In fact, phase B of experiment 1 suggests that the odorants were much the same across these two donor squads. Hence, it is more likely that a difference in type of odorant served to mediate test rats' discriminations. The fact that both test rats responded to all transferred papers, and even clean papers (day 10 of experiment 2), at a rate similar to that typically shown to the respective cue signaling reward for lever-pressing, may simply indicate relatively greater discriminative control by the cue signaling nonreward to the respective

test rat (i.e., nonreward odor and reward odor for test rats 1 and 2, respectively).

Beyond implicating the existence of some qualitative differences in the odorants, the present data do not address the nature of this qualitative difference. Odors produced in response to nonreward might contain many, or all, of the components present in reward odor, plus additional, possibly treatment-unique, components. On the other hand, reward odor, or both reward and nonreward odors, might contain treatment-unique volatile components.

Third, it is worth noting that these volatile components, whether arising from reward, nonreward, or both, must not be too highly volatile or unstable. Some degree of air disturbance was inevitable in removing donors from the boxes (phase C of experiment 1 and phases A and C of experiment 2), but this removal had little effect on the magnitude of test rats' discriminations established without removing donors (phases A and B of experiment 1).

As to the ecological significance of the odorants, several possibilities exist. Rats might emit nonreward odorants and/or reward odorants as signals for guiding the foraging activities of conspecifics, with the former odors signaling the absence of a previously available food source and the latter odors signaling the presence of a food source. In contrast, or in addition, one or both odorants might signal the emotional state of the emitting rat (e.g., "frustration" in the case of nonreward odor), thereby influencing such behaviors as social aggregation. Future work directed at further clarifying the nature of qualitative differences between reward and nonreward odors should help to identify and separate particular ecological functions of the respective odors.

Abstract—Splitless capillary gas chromatography indicated the presence of (Z)- and (*E*)-11-tetradecenyl acetate and (Z)-11-tetradecenyl alcohol in the washes of female abdominal tips of the blackheaded fireworm, *Rhopobota naevana* (Hubner). Gas chromatography combined with mass spectroscopy confirmed the presence of tetradecenyl acetate in extracts of female tips. The low levels observed in these extracts (<1 ng/female equivalent), prevented further chemical and spectroscopic identification. These materials were found to be stimulatory at low levels in electroantennogram studies. A combination of 9 μg of (Z)-11-tetradecenyl acetate and 3 μg of (Z)-11-tetradecenyl alcohol on rubber septa in wing traps provided an effective attractant. (Z)-9-Dodecenyl acetate, a previously reported attractant, did not significantly increase field trapping catches when added to the binary mixture, but was found to enhance trap catches when added to each of the primary components.

Key Words—Blackheaded fireworm, *Rhopobota naevana* (Hubner), *Rhopobota unipunctana* (Haw.), Lepidoptera, Tortricidae, Olethreutinae, sex pheromone, (Z)-11-tetradecenyl acetate, (Z)-11-tetradecenyl alcohol, (Z)-9-dodecenyl acetate.

INTRODUCTION

The blackheaded fireworm, *Rhopobota naevana* (Hubner) (=*R. unipunctana*), is a serious pest of cranberry, *Vaccinium macrocarpon* (Ait.) in the United States and Canada. Damage is caused by the larvae which web together and destroy the fruiting uprights causing cranberry bogs to have a scorched appearance. The European species, *Rhopobota* (*Acrolita*) *naevana* has been reported from Sweden to Europe feeding on holly and a variety of fruit trees, especially apple. In North America, however, *R. naevana* appears to be specific to cranberry except for one other record from evergreen huckleberry, *Vaccinium ovatum* (Pursh.) (Breakey, 1960).

The life history of *R. naevana* in British Columbia is similar to that in Massachusetts (Franklin, 1948) and Washington (Plank, 1922). It overwinters as flat, yellowish eggs on the undersides of the cranberry leaves. The eggs hatch in mid-May, and the larvae, when fully grown, pupate in the debris beneath the vines. Small silvery-grey moths emerge in late June and persist until early August. The diurnal moths make short jerky flights above the vines and lay eggs on the undersides of the cranberry leaves. A few eggs overwinter, but most give rise to a second generation of larvae in early July. Second generation moths are present from early August to late September. They also lay eggs, most of which overwinter, although some give rise to a partial third generation of larvae, which perish during the winter.

The development of an effective, pheromone-based monitoring system could considerably reduce the present high dependence on pesticide spraying to control the damage caused by this insect. Survey traps containing (*Z*)-9-dodecenyl acetate (*Z*9–12 : Ac) were reported to attract male *R. naevana* (Ando et al., 1977). Reports of damage to local cranberry farms, and the possibility of developing an effective monitoring system led us to begin investigations into the sex pheromone of *R. naevana.* This paper reports the isolation, partial identification, and field bioassay of pheromone components from female *R. naevana.*

METHODS AND MATERIALS

Pheromone Collection. Larvae of *R. naevana* were collected from local cranberry bogs, reared to pupae, and sexed. The male pupae have eight abdominal segments, whereas the females have only seven segments (Forbes, 1923). Upon emergence, adults were kept at ambient temperature and humidity under a 12 hr light–12 hr dark photoregime. Females 2–3 days old were placed in dim light to simulate dusk conditions after being in bright light for 10 hr. The abdominal tips were extruded and excised into a few microliters of heptane which had been purified by distillation followed by filtration through alumina. The tip

wash of each individual was analyzed immediately. Larger samples were obtained by combining the excised tips of 50 insects. The pooled wash was carefully concentrated by gentle warming in a narrow neck ampoule prior to analysis. An extract was also prepared by leaving 10 excised tips in solvent for three days. The extract was then washed three times with an equal volume of 5% sodium bicarbonate to remove free fatty acids, once with an equal volume of water and concentrated for analysis.

Analyses. Splitless capillary gas chromatography was performed on a Hewlett-Packard 5890 using the following fused silica capillary columns: (1) a 25-m × 0.2-mm-ID Carbowax 20 M and (2) a 25-m × 0.2-mm-ID methyl silicone, both from Hewlett-Packard, Avondale, Pennsylvania; (3) a 30-m × 0.25-mm-ID DB-1 cross-linked polydimethyl siloxane from J & W Scientific, Rancho Cordova, California; and (4) a 30-m × 0.25-mm-ID SPB-5 cross-linked 5% vinyl, 5% phenyl, polymethyl siloxane from Supelco, Bellefonte, Pennsylvania. Column 1 was programmed at 100°C for 2 min, 30°/min to 140°C, then 1.5°/min to 170°C; columns 2, 3, and 4 were programmed at 80°C for 2 min, 10°/min to 180°C, then 2°/min to 240°C. The carrier gas was helium at 1 ml/min utilizing an injector temperature of 200°C and a flame ionization detector maintained at 250°C. Selected ion mass spectra were obtained on a HP5985 GC-MS fitted with a 30-m DB-1 column using electron impact ionization.

Chemicals. All materials used were prepared by standard routes and purified as their acetates by column chromatography on silica gel impregnated with silver ion. The materials were analyzed on appropriate columns and shown to contain less than 1% of any geometric or positional isomer.

Electroantennograms. Antennal responses of male insects were measured using an electroantennographic detector similar to that described by Arn et al. (1975). The test substance, 10 ng, was applied to a small piece of filter paper as a solution in 1 μl of hexane. On evaporation of the solvent, the paper was transferred to a 10-ml disposable syringe and a 3-ml pulse was injected manually into a stream of humidified air which passed continuously over the antennal preparation at 300 ml/min. Trimmed antennae were suspended across chloridized silver electrodes, with electrical contact established with a drop of 0.8% aqueous NaCl. Fourteen separate observations were recorded for each compound with a low solvent response subtracted for each observation. The mean response and standard error was then calculated for each compound.

Field Tests. Chemicals were applied in hexane to the inside of rubber septa (Arthur H. Thomas No. 8753-D22). The septa were pinned to the upper inside of wing traps similar in design to the Pherocon 1CP trap (Zoecon Corp., Palo Alto, California), the bottoms of which were coated on the inside with Stikem Special (Seabright Enterprises Ltd., Emeryville, California).

Sites were selected which had been sprayed to provide low infestations of fireworm and thus enhance discrimination between competitive lures. Earlier

field trials in sites of high fireworm population density (Raine and Clements, unpublished) had shown very high trap catches, with little or no discrimination between lures.

The traps were suspended on stakes or on irrigation sprinkler risers about 0.3–0.6 m above the cranberry vines. The distance between traps varied from about 30 to 90 m in 1984 and from 30 to 35 m in 1985. The traps were arranged in randomized complete blocks at each of two sites in both 1984 and 1985. Eight replicates of each lure combination were tested for attractiveness to male moths at two sites within a 16-hectare commercial cranberry bog in 1984. Four replicates of each lure combination were tested at two separate bogs of 4 and 8 hectares about 2 km apart in 1985. Counts were made weekly in 1984 and twice weekly in 1985. Captured moths were scraped from the trap bottoms at each count and the bottoms were replaced when the sticky surface became dirty. Examination of the genitalia of 250 moths removed from selected traps showed that only male moths were trapped. Specimens collected were identified as *R. naevana* (=*R. unipunctana*) by P.T. Dang, Biosystematics Research Institute, Ottawa, Ontario, Canada.

Data Analysis. Variances in all experiments were significantly heterogenic as determined by the Bartlett and Hartley test ($\alpha = 0.05$) and the data were in the form of counts with some zeros. Therefore, the data were transformed into $\sqrt{x + 0.5}$ and subjected to ANOVA (Sokal and Rohlf, 1969). The analysis indicated that there was no significant difference between counts at each site in each of 1984 and 1985. Therefore, counts at both sites for each year were pooled, and the data presented as the mean number of male moths caught per trap during each trapping period. Multiple comparisons among treatment means were made using Duncan's multiple-range test ($\alpha = 0.05$).

RESULTS

Analyses. Only five of 100 individual females analyzed by splitless gas chromatography from 1981 to 1983 yielded sufficient material to be detected (>0.1 ng). The five positive traces revealed peaks corresponding to tetradecenyl acetates and alcohols. The two positive washes run on column 1 showed correspondence with *E*11–14:Ac (9.39 min, only one trace), *Z*11–14:Ac (9.55 min), and *Z*11–14:OH (10.95 min). The three traces recorded on column 2 revealed correspondence with *E*11–14:Ac (12.28 min, one trace), *Z*11–14:Ac (12.37 min), and *Z*11–14:OH (10.57 min, one trace). There were no detector responses at retention times corresponding to 12-carbon acetates and alcohols.

Subsequent investigations on a further 85 female tips, involving 25 different combined tip washes revealed the consistent presence of *Z*11–14:Ac in amounts varying from less than 0.1 ng up to almost 1 ng/female. The retention

times for Z11–14:Ac were 15.19 min on column 3, and 17.47 min on column 4. In 15 of the 25 combined tip wash traces, responses were recorded at these times. Seven traces indicated the corresponding peak for Z11–14:OH (column 4, 14.87 min), in varying amounts, averaging 30% of the quantity of Z11–14:Ac. The *E*11–14:Ac isomer (column 3, 15.06 min; column 4, 17.37 min) was represented in just three traces, averaging 10% of the peak area relative to Z11–14:Ac. A barely detectable peak corresponding to the retention time of Z9–12:Ac (column 4, 13.76 min) was observed in two traces in which the other components were clearly present. These observations, in addition to the report of Ando et al. (1977) that Z9–12:Ac was an attractant, prompted our inclusion of the 9–12:Acs in field testing.

A portion of soaked tip extract containing 10–20 female equivalents contained no detectable peaks at the retention times of the previously observed compounds when analyzed by capillary gas chromatography. No enhancement of a possible aldehyde component (Z11–14:Ald) was observed, as has been detected in other insects (Struble and Richards, 1983; Gillespie et al., 1984). A mass spectrometric analysis of 50 female equivalents of this extract, monitoring the ions of *m/e* 61, 194, and the total ion current, indicated the presence of a tetradecenyl acetate, most likely Z11–14:Ac, as judged from retention time correspondence. There was a small peak in the *m/e* 194 ion trace coincident with a very small inflection of the total ion trace at the retention time of Z11–14:OH. Ions of *m/e* 61, 166, and total ion current were monitored to examine the possible presence of Z9–12:Ac. Only the *m/e* 61 trace showed a detectable peak at the retention time of dodecenyl acetates, hardly confirming their presence in this extract.

Electroantennograms. The male antenna responded very strongly to Z11–14:Ac (0.98 ± 0.10 mV), with Z11–14:OH producing the next greatest response (0.25 ± 0.07 mV). A weak but positive response (0.15 ± 0.03 mV) was obtained with Z9–12:Ac. A moderate response (0.24 ± 0.07 mV) was obtained with *E*11–14:Ac, but all other compounds tested (*E*9–12:Ac, 0.08 ± 0.03 mV; Z11–14:Ald, 0.08 ± 0.03 mV; *E*11–14:Ald, 0.12 ± 0.02 mV; *E*11–14:OH, 0.09 ± 0.03 mV) were at best only slightly active.

Field Trapping. Trapping results in 1984 (Table 1) clearly indicated that Z9–12:Ac was not significantly more attractive to male fireworm moths than the control. The addition of Z11–14:Ac resulted in a significantly increased attraction. Addition of the corresponding *E* isomers indicated by chemical analysis to be present in the female produced no enhancement of attraction when added to the binary mixture.

Trapping in 1985 included the alcohol, Z11–14:OH, which appeared to be present in female extracts and gave a good electroantennogram response. This alcohol was as effective an attractant alone as Z11–14:Ac and strongly increased the attractancy of Z11–14:Ac. The addition of Z9–12:Ac gave sig-

[b] One to three virgin females in small cages pinned inside traps.

nificantly improved trap catches when added to either the acetate or the alcohol. Although the total number of males caught increased slightly during the last trapping period when the Z9-12:Ac was added to the highly attractive binary mixture of Z11-14:Ac and Z11-14:OH, this increase was not statistically significant.

There was no significant difference between counts in traps baited with one to three females and the controls. The concentration of pheromones as determined in female gland washes was routinely subnanogram and may well be too low to compete effectively with synthetic lures containing a few micrograms of attractant. The relative consistency of the catch in control lures compared to the substantial increase in traps containing lighter loadings suggests that low microgram loadings may be more effective. This would be consistent with the low levels of pheromones observed in the female glands.

DISCUSSION

The retention time correspondence on all capillary columns of volatiles obtained from female glands, combined with discriminating field trapping results, strongly indicates that Z11-14:Ac and Z11-14:OH are the primary pheromone components of *R. naevana.* A 3:1 mixture of these materials at low microgram levels constitutes an effective lure for the trapping of male blackheaded fireworm moths. Traps containing Z9-12:Ac in addition to the binary mixture of primary components were competitive, if not superior, to the binary mixture. Our inability to fully characterize Z9-12:Ac, if present, was due to its very low concentration in female washes or extracts. Comparison of synthetic lures with live females was hampered by the apparent short lifetime of the restrained females.

During the summer of 1985 we became aware of a very similar study (H.G. Davis and L.M. McDonough[5]) and their results are presented in the accompanying paper.

(Received April 23, 1986; accepted July 15, 1986)

Abstract—Results of field feeding preference studies with 12 species of tropical green algae of the genus *Caulerpa* showed that *C. ashmeadii* was preferred least by herbivorous fishes. Chemical investigations of *C. ashmeadii* demonstrated the presence of high concentrations of sesquiterpenoid metabolites. The chemical isolation and structural elucidation of five major *C. ashmeadii* metabolites, as well as the results of field feeding preference, antimicrobial, and ichthyotoxicity assays demonstrating the biological activities of these metabolites are reported here.

Key Words—Herbivory, chemical defense, marine algae, allelochemicals, *Caulerpa*, sesquiterpenoids.

INTRODUCTION

Some secondary metabolites from tropical algae have been implicated in chemical defense against grazing fishes and invertebrates in herbivore-rich tropical waters (Sun and Fenical, 1979; McConnell et al., 1982; Paul and Fenical, 1982, 1983). Other investigators have shown distinct feeding preferences in laboratory

0098-0331/87/0500-1171$05.00/0 © 1987 Plenum Publishing Corporation

and field feeding assays (Ogden, 1976; Hay, 1981, 1984; Littler et al., 1983; Lewis, 1985). However, few studies have tried to relate these known feeding preferences with the presence of chemical deterrents in algae (Norris and Fenical, 1982; Hay, 1984). In this study, *Caulerpa ashmeadii* was the most resistant alga to herbivorous fishes of 12 *Caulerpa* species and, in some cases, was almost completely avoided in feeding preference assays. Chemical investigation of this same alga led to the isolation of five new sesquiterpenoid metabolites which showed a high degree of biological activity in antimicrobial and ichthyotoxicity assays. The presence of these biologically active terpenoids, which have not been found in any other species of *Caulerpa*, appears to explain the resistance of *C. ashmeadii* to grazing fishes.

Other species of *Caulerpa* have been studied and found to contain terpenoid metabolites, many of which possess the novel bisenol acetate functionality unique to green algae of the related families Caulerpaceae and Udoteaceae (Blackman and Wells, 1978; Amico et al., 1978; Capon et al., 1981, 1983; Paul and Fenical, 1982, 1985). A major sesquiterpenoid metabolite, caulerpenyne (**6**) has been isolated from 10 different species of *Caulerpa* in varying concentrations (Amico et al., 1978; Paul, 1985). Other nonterpenoid nitrogenous compounds such as caulerpin (**7**) and caulerpicin have also been isolated from several different species of *Caulerpa* and have been proposed to be responsible for the biological activity of these algae (Maiti et al., 1978; Mahendran et al., 1979: Doty and Aguilar-Santos, 1966, 1970; Lobel and Ogden, 1981; Vest et al., 1983).

In this study, we posed the following questions: (1) Can the low susceptibility of *Caulerpa ashmeadii* to grazers be related to the presence of bioactive secondary metabolites? (2) How do the biological activities of caulerpenyne and caulerpin compare with the activities of the *C. ashmeadii* metabolites? (3) What are the molecular structures of the *C. ashmeadii* metabolites and can the structural features of these molecules explain the observed biological activities?

METHODS AND MATERIALS

Study Area. Looe Key (24°37′18″N, 81°24′24″W) is located 12.9 km southwest of Big Pine Key, Monroe County, Florida, and was established as a National Marine Sanctuary in 1981. Within the 18.2-km^2 sanctuary lies an inner "core" area of about 1.7 km^2 that includes rich seagrass, coral, and macroalgal assemblages. There are several distinctive habitats: (1) the seaward-most intermediate fore-reef at about 15 m depth; (2) the fore-reef including the spur and groove system (10 m deep to intertidal); (3) the reef flat (1–2 m deep); and (4) the extensive back-reef system (1–10 m deep). Spearfishing is not permitted at Looe Key and, consequently, herbivorous fish populations (especially the parrotfishes and surgeonfishes) are both exceptionally large and diverse (Bohnsack

et al., NOAA draft report). Littler, Littler, and LaPointe (NOAA draft report) were of the opinion that herbivory by reef fishes is the dominant direct controller of algal standing stocks throughout the reef flat and fore-reef slopes.

Herbivory Studies. The suspended-line bioassay method of Littler et al. (1983) was used in the grazing experiments. Clumps of 12 *Caulerpa* species (~ 10 cm^2 in area), representative of the spectrum of available forms, were placed between twists of a three-stranded, 2-mm-thick, white nylon line at 0.5-m intervals in a randomized pattern. The lines were placed in three of the major reef habitat types (intermediate fore-reef, fore-reef, and reef-flat) which have been shown to have large herbivorous fish populations (Bohnsack et al., NOAA draft report), on June 19 and 21, 1984.

The technique yields insights into the differential resistances of the various species and forms of *Caulerpa* to herbivory. For all habitats on both days, three separate lines were used, each containing three clumps per species. A fourth control line was placed in the nearby back reef, where herbivores were few, as a control for losses other than by grazing. The lines were photographed, then suspended ca. 0.3 m above the bottom with each end tied to a coral head for a 3-hr daylight period. Surgeonfishes and parrotfishes were not wary of the lines and began feeding as soon as the divers moved away. Fish typically moved from clump to clump taking small bites, becoming more persistent as they located a particularly palatable clump. After 3 hr, the lines and algae were returned to the boat, rephotographed, and subsequently quantified in the laboratory by the point intercept method (Littler et al., 1983). Losses of all control algae were negligible over the identical 3-hr period. In this technique, the percent thallus area (two-dimensional) lost to grazing for each specimen was calculated from the color slides (Kodachrome 64) by projecting the transparencies onto a grid of dots (at stratified randomized intervals) that were directly related to surface area. Results were compared using Duncan's multiple-range test (Steel and Torrie, 1960).

Chemical Analyses. Samples of *Caulerpa ashmeadii* were collected near Big Pine Key, Florida, in November 1984. The algae were placed directly into ethanol and subsequently extracted with dichloromethane. Metabolites were purified by open-column Florisil chromatography and by silica gel high-performance liquid chromatography (HPLC) with ethyl acetate–isooctane mixtures.

IR spectra were recorded with a Perkin-Elmer model 137 spectrophotometer and UV spectra were recorded in methanol with a Beckman Mk IV instrument. Proton nuclear magnetic resonance (NMR) spectra were recorded with a 360-MHz Nicolet-Oxford Magnetics FT spectrometer and [^{13}C]NMR spectra were recorded at 50 MHz with a Nicolet-200 instrument. High-resolution mass spectra were obtained through the Mass Spectrometry Service Laboratory at the University of Minnesota.

Laboratory Assays. Each metabolite was examined for antimicrobial activity against three marine bacteria and one marine fungus by standard agar plate-

assay disk methods. Zones of inhibition (clear zones) were measured for each filter disk in triplicate against each microorganism tested.

Tropical damselfishes, *Pomacentrus coeruleus* and *Dascyllus aruanus* (ca. 10–15 g average weight), were used to assay for toxicity of the algal metabolites toward marine fishes (Paul et al., 1980). For each assay, compounds were dissolved in a small amount of ethanol and stirred into seawater ($\sim 25°C$) at known concentrations (100 μl EtOH in 200 ml seawater). A damselfish was placed into the seawater and observed for 1.5 hr. A solvent control was always run simultaneously. Toxicity was measured as the death of the fish within this time. Each compound was tested against at least three fish at the minimum effective concentrations.

RESULTS

Herbivory Studies. All loss of algal material from the lines resulted from grazing by herbivorous fishes. This was confirmed by the characteristic grazing scars and by extensive observations of the suspended thalli on the lines by divers. This method measured the relative vulnerability of each species to grazing by natural populations of herbivorous fishes. We could not identify the fish species responsible for grazing nor could we determine the preference of any one fish species.

The most palatable species (Table 1, Figure 1) were *Caulerpa prolifera* v. *obovata* and *C. lanuginosa*, forms that occur cryptically among beds of the seagrass *Thalassia testidinum* which grow on sand-covered rock. The most consistently herbivore-resistant alga across all habitats was *C. ashmeadii*, with less than half of its area being grazed by fishes (Figure 1). This contrasts with a mean 89.5% loss shown by the other 11 species. *Caulerpa ashmeadii* was significantly more resistant to fish herbivory ($P < 0.05$, Duncan's multiple-range test, Steel and Torrie, 1960) than all other species (Figure 1) with the exception of *C. sertulariodes* which lost 71.3% of its thallus area during the experiments.

Chemical Analyses. The major *Caulerpa ashmeadii* metabolite, **1** (Figure 2), was isolated as 20% of the organic extract after purification by silica gel HPLC (15% EtOAc–isooctane) ($[\alpha]_D^{25} = -48°$, $c = 1.4$, $CHCl_3$). This metabolite was analyzed for $C_{21}H_{30}O_6$ by high-resolution mass spectrometry (318.1846 for M^+-HOAc) in combination with consideration of its [^{13}C]NMR spectral features. This molecular formula required seven degrees of unsaturation. The presence of the *E,E*-1,4-diacetoxybutadiene functional group was evident based upon UV absorption at λ_{max} 248 nm ($\epsilon = 17{,}000$); IR absorptions at 2940, 1720, 1440, and 1210 cm^{-1}; and characteristic [^{1}H]- and [^{13}C]NMR spectral features (see Tables 2 and 3) (Blackman and Wells, 1978; Sun and Fenical, 1979). In addition to the bisenol acetate functionality, compound **1** was recognized to possess an additional secondary acetate group and a methyl-

trisubstituted olefin as deduced by further [^{1}H]- and [^{13}C]NMR resonances (Tables 2 and 3). These functionalities accounted for six of the seven degrees of unsaturation, thus indicating one carbocyclic ring to be present in the structure. Comparisons of **1** with the *C. flexilis* var. *muelleri* metabolite **8** (Tables 2 and 3) showed both to possess similar spectral features and carbon skeletons. Proton NMR decoupling studies allowed the complete assignment of **1**, including a secure placement of the secondary acetate at C-4.

Compound **2** was isolated as 10% of the organic extract after final purification by silica gel HPLC (15% EtOAc–isooctane) ($[\alpha]_D^{25} = -98°$, $c = 1.4$, $CHCl_3$). The molecular formula of the metabolite was indicated as $C_{17}H_{24}O_3$ by high-resolution mass spectrometry ($M^+ = 276.1740$), a formula which requires six degrees of unsaturation. IR absorptions at 2940, 1760, 1680, 1650, 1440, 1210, 1110 cm^{-1} and UV absorption at λ_{max} 240, $\epsilon = 22{,}000$, when considered together with ^{1}H and ^{13}C spectral features, indicated the presence of an enol acetate, an unsaturated carbonyl, and a methyl-trisubstituted olefin.

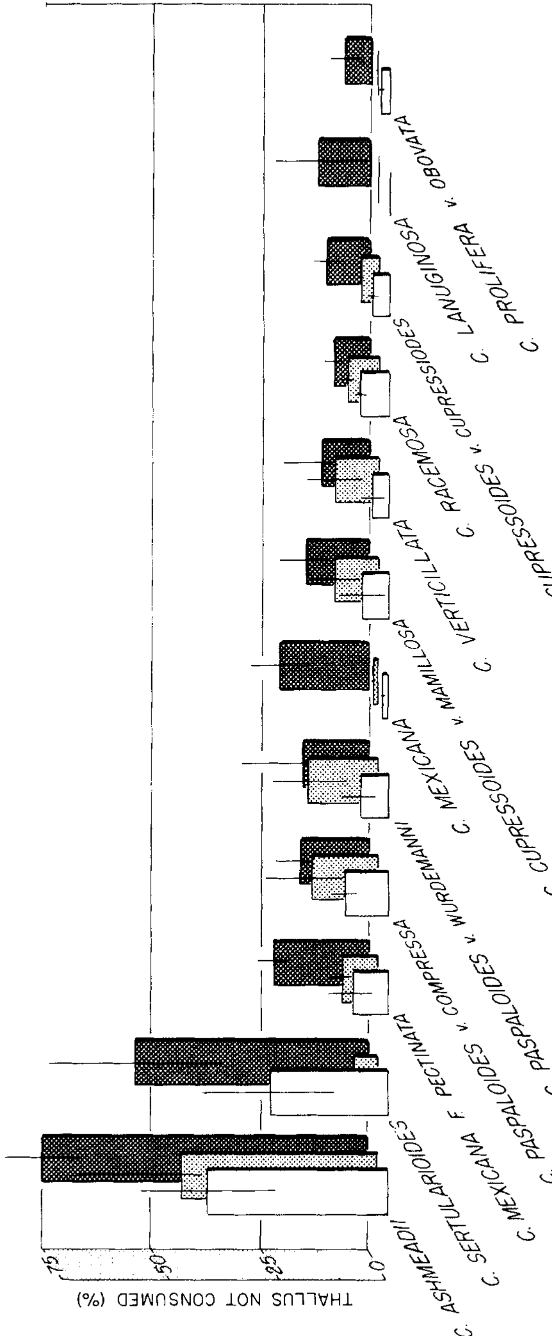

FIG. 1. Comparison of the three major habitats from deep to shallow (front, light = intermediate fore-reef; middle, gray = fore-reef; back, dark = reef flat) in terms of overall herbivory, and grazer resistance of 12 *Caulerpa* forms, in order from highest to lowest means for all habitats. Standard error is given by vertical lines.

FIG. 2. Metabolites from *Caulerpa ashmeadii* and related species of *Caulerpa*.

Spectral comparisons could be readily made with the related metabolites **1** and **8** and the known metabolite onchidal (**9**) (Ireland and Faulkner, 1978). Thus, compound **2** was assigned as a double-bond isomer of onchidal.

Sesquiterpenoid **3** was isolated as 5% of the organic extract after silica gel HPLC (15% EtOAc–isooctane) ($[\alpha]_D^{25} = -104°$, $c = 1.0$, $CHCl_3$). Compound **3** was determined to be $C_{15}H_{22}O_2$ by high-resolution mass spectrometry (234.1622 for M^+). The presence of two aldehydes (one α, β unsaturated) was readily apparent from IR absorptions at 2960, 1720, 1730, 1580, 1450, 1220 cm^{-1}; from UV absorption at λ_{max} 232, ϵ = 16,500; and by [^{1}H]- and [^{13}C]NMR spectral features (Tables 2 and 3). Full proton NMR decoupling and

spectral comparisons with the known compound rhipocephanal (Sun and Fenical, 1979) led to the final structure assignment of **3.** The geometry of the C-3–C-4 olefin was assigned as *E* based on the characteristic shielding of the C-12 aldehyde in the [^{1}H]NMR (Table 2) and on comparison with model compounds (Faulkner, 1971; Wehrli and Nishida, 1979). The saturated aldehyde showed coupling to an adjacent methylene group. The compound is a double-bond isomer of the African termite metabolite ancistrodial (Baker et al., 1978) which acts in chemical defense against ants.

Another sesquiterpenoid produced by *Caulerpa ashmeadii* was compound **4,** which was isolated as 8% of the organic extract after silica gel HPLC (10% EtOAc–isooctane) ($[\alpha]_D^{25}$ = $-111°$, c = 0.8, $CHCl_3$). Again, spectral com-

parisons with other related metabolites facilitated the structural elucidation of this compound (Tables 2 and 3). Five degrees of unsaturation were inherent in the molecular formula ($C_{17}H_{26}O_3$; 218.1653 for M^+-HOAc). These unsaturations could be accounted for by one aldehyde group, a primary acetate, two olefins, and a carbocyclic ring. These latter functionalities were identified by [^{1}H]- and [^{13}C]NMR spectral features as well as by IR absorptions at 2960, 1745, 1730, 1580, 1450, 1220 cm^{-1} and UV absorption at λ_{max} 233, $\epsilon = 2100$. Proton NMR decoupling studies showed that the aldehyde on C-1 was coupled only to a methylene at δ3.11. The methylene protons adjacent to the acetate group showed no coupling; therefore the olefin was placed at C-3–C-4. Protons on carbons C-4–C-6 were also interrelated through decoupling studies to further establish the structure of **4.**

Compounds **5a** and **5b** were isolated as a mixture as 5% of the organic extract by final silica gel HPLC (5% EtOAc–isooctane) ($[\alpha]_D^{25} = -62°$, c = 1.6, $CHCl_3$). The spectral features of these metabolites showed the presence of the familiar enol acetate functionality at C-1–C-2 and the same sesquiterpenoid monocyclic ring system as in compounds **1–4** (Tables 2 and 3). The presence of fatty acid ester residues positioned at C-12 were indicated by [^{1}H] and [^{13}C]NMR spectral features (Tables 2 and 3); IR absorptions at 2960, 1760, 1730, 1715, 1370, 1215, 1110 cm^{-1}; and UV absorption at λ_{max} 246, ϵ = 8200. High-resolution mass measurements of the acylonium ions (RCO^+) confirmed the presence of two fatty acid residues: 239.2392 for $C_{16}H_{31}O$ (17% intensity) and 237.2264 for $C_{16}H_{29}O$ (3.7% intensity). Compounds **5a** and **5b** were therefore estimated to compose 82% and 18% of the mixture, respectively. Other sesquiterpenoid esters possessing linear carbon skeletons have been reported from *C. prolifera* (De Napoli et al., 1983).

Laboratory Assays. All metabolites, except compounds **5a** and **5b,** showed antimicrobial activity toward at least one marine bacterium (Table 4). Only sesquiterpenoid **2** was active toward the marine fungus and compound **2** was the most active overall. Compounds **3** and **4** also showed activity toward all three bacteria.

All metabolites, except the fatty esters **5a** and **5b** and caulerpin **7,** were toxic to damselfish (Table 5) within 1.5 hr. The aldehydes **2, 3,** and **4** again showed the highest degree of biological activity in this assay.

DISCUSSION

This study demonstrates the strong avoidance of *Caulerpa ashmeadii* by reef herbivores and the presence of four biologically active compounds in the alga which are specific to this species of *Caulerpa* (Paul, 1985; Paul and Fenical, 1987). The unpalatability of *C. ashmeadii* relative to other *Caulerpa* species correlates with the presence of highly biologically active sesquiterpenoid

TABLE 4. RESULTS OF ANTIMICROBIAL ASSAYS FOR *Caulerpa* METABOLITES[a]

metabolites which are unique to this species. Although most species of *Caulerpa* also produce bioactive sesquiterpenoids such as caulerpenyne (**6**) and nonterpenoid metabolites such as caulerpin (**7**) (Paul, 1985; Paul and Fenical, 1987), these compounds do not show the potent activities of the *C. ashmeadii* aldehydes. Since *C. ashmeadii* is biomechanically no tougher or stronger than the more palatable species (S. Armstrong, personal communication), it seems likely that its avoidance is the result of these secondary metabolites. In addition, comparable studies on the known toxic alga *Dictyota divaricata* Lamouroux (Gerwick, 1981; Norris and Fenical, 1982), in the same habitats of Looe Key (Littler, Littler, and Lapointe, NOAA draft report), showed similar resistance to grazing. Mean loss of *D. divaricata* was 42.6% per 3 hr, which is close to the recorded 46.9% loss per 3 hr for *C. ashmeadii*.

[a] This bioassay used the tropical damselfish *Pomacentrus coeruleus* ($N = 4$ for each compound tested). Values expressed are the lowest dosages active within 1.5 hr for all four fish.
[b] + = death within time indicated; – = no death.

Several of the *Caulerpa* species examined here have been shown to be consumed at moderate to high rates in related studies (Littler et al., 1983; Hay, 1984; Lewis, 1985). The high percentage of individuals eaten (~80% for *C. ashmeadii* in Honduras (Hay, 1984) and its comparability to *C. prolifera* in palatability contrast markedly with the results of this study (Figure 1). Hay (1984) and Lewis (1985) contrastingly, noted a low to intermediate herbivore susceptibility for *C. cupressoides* which we found to be eaten readily (Table 1). These findings raise some questions regarding variation in the secondary metabolite composition of these species collected in different habitats. Alternatively, the results may indicate the presence of different herbivores with different grazing preferences or differences in grazing intensity among reefs. Paul (1985) showed that related tropical green algae (genera *Rhipocephalus*, *Udotea*, and *Penicillus*) showed between-population variation in the production of terpenoid metabolites. Concentrations of caulerpenyne (**6**) and related terpenoids may also vary in different populations of *Caulerpa* and be related to algal susceptibility to herbivory.

The nonterpenoid, nitrogenous metabolites caulerpin (**7**) and caulerpicin have often been proposed to function as chemical defenses in *Caulerpa* species (Doty and Aguilar-Santos 1966, 1970; Lobel and Ogden, 1981; Lewis, 1985). However, the sesquiterpenoid caulerpenyne (**6**), which often exists in concentrations of 40–50% of the organic extract in some species of *Caulerpa*, possesses much greater biological activity than caulerpin in ichthyotoxicity assays (Table 5). McConnell and coworkers (1982) also showed that caulerpenyne was responsible for almost all of the feeding deterrent activity of extracts of *C. prolifera* against the sea urchin *Lytechinus variegatus*. Caulerpin caused little, if any, deterrence in these assays. Similarly, Hodgson (1984) showed that caulerpenyne was primarily responsible for the antimicrobial and antineoplastic activities found in extracts of *C. prolifera*.

The *C. ashmeadii* metabolites and other *Caulerpa* terpenoid metabolites (Paul and Fenical, 1982, 1985) also show a much higher level of activity than caulerpin. Caulerpicin is a mixture of several related sphingosine derivatives which have been isolated in very small amounts from several species of *Caulerpa* (Doty and Aguilar-Santos, 1966, 1970; Maiti et al., 1978; Vest et al., 1983). Caulerpicin was not tested in these assays because it is a very minor *Caulerpa* metabolite. The major chemical defenses in *Caulerpa* species appear to be the terpenoid metabolites which contain aldehyde or enol acetate functional groups. These compounds are produced in large concentrations but are often not readily isolated because of their unstable and reactive chemical natures.

The sesquiterpenoid esters, **5a** and **5b**, showed little biological activity in our assays (Tables 4 and 5). Structurally similar terpenoid esters have been isolated from *Caulerpa prolifera* (De Napoli et al., 1983) and also from several

nudibranchs (Cimino et al., 1981, 1982, 1983; Okuda et al., 1983). The esters in the nudibranchs were also reported to be less toxic than the sesquiterpenoid aldehyde, polygodial, which was a major metabolite. The esters were found only in the digestive tract of the nudibranchs, whereas the mantle (which is more exposed to predators) contained the toxin polygodial which is reported to function in chemical defense (Cimino et al., 1981, 1983).

The molecular structures of the sesquiterpenoid aldehydes and enol acetates from *Caulerpa ashmeadii* also support the hypothesis that these metabolites are used in chemical defense. The aldehyde and enol acetate (a masked aldehyde) functional groups can be envisioned to react with proteins in a number of ways to affect or inactivate protein or enzyme function. The bioactive *C. ashmeadii* metabolites are related to numerous insect antifeedants such as ancistrodial (Baker et al., 1978), warburgenal (Kubo et al., 1976), and the iridoid aldehydes (Cavill and Hinterberger, 1960), which could function as defensive agents by identical chemical means.

IDENTIFICATION OF SEX PHEROMONE COMPONENTS OF DARKSIDED CUTWORM, *Euxoa messoria*, AND MODIFICATION OF SEX ATTRACTANT BLEND FOR ADULT MALES

D.L. STRUBLE and J.R. BYERS

Research Station, Agriculture Canada
Lethbridge, Alberta, Canada T1J 4B1

(Received April 10, 1986; accepted July 15, 1986)

Abstract—Eleven "pheromone-like" compounds were identified in excised abdomen tip extracts of calling adult females of darksided cutworm, *Euxoa messoria* (Harris). The essential pheromone components were (*Z*)-7- and (*Z*)-11-hexadecenyl acetates in a ratio of 1:40, which agreed with an attractant blend developed empirically by field testing the attractancies of synthetic blends. The pheromone component, (*Z*)-11-hexadecenol, improved the attraction of darksided cutworm males whereas the components (*Z*)-9-tetradecenyl acetate and (*Z*)-7-dodecenyl acetate inhibited their attraction. The other "pheromone-like" compounds identified in the female extracts had no obvious effect on the attraction of darksided cutworm males. Three compounds that functioned as parapheromones when substituted for (*Z*)-7-hexadecenyl acetate in the two-component blend were (*Z*)-7-pentadecenyl, (*Z*)-7-tetradecenyl, and (*Z*)-7-tridecenyl acetates. (*Z*)-11-hexadecenal was not detected in the female extracts, but it had a synergistic effect on the attraction of darksided cutworm moths and inhibited the attraction of male moths of a nontarget species, *Helotropha reniformis* (Grote). As a trap bait for monitoring purposes, we recommend a four-component blend of (*Z*)-7-hexadecenyl acetate, (*Z*)-11-hexadecenyl acetate, (*Z*)-11-hexadecenol, and (*Z*)-11-hexadecenal at 12.5, 500, 1, and 10 μg/red rubber septum dispenser containing 5 μg of antioxidant 2,6-*tert*-butyl-4-methyl phenol. This blend is effective under field conditions for at least six weeks.

Key Words—Darksided cutworm, *Euxoa messoria*, Lepidoptera, Noctuidae, sex pheromone, (*Z*)-7-hexadecenyl acetate, (*Z*)-11-hexadecenyl acetate, (*Z*)-11-hexadecenol, (*Z*)-11-hexadecenal.

INTRODUCTION

The darksided cutworm (DSC), *Euxoa messoria* (Harris), occurs across Canada and the northern United States (Hardwick, 1970; Rings et al., 1975). The larvae are a common pest of annual crops and sometimes adopt a climbing habit to cause damage of nursery stock and fruit trees. DSC is considered a major pest of tobacco in Ontario (Cheng, 1971, 1973). In western Canada, it has been considered a minor pest causing occasional damage to row crops and home gardens (Ayre et al., 1982). However, the larvae frequently occur in mixed infestations with other species, particularly redbacked cutworm, *Euxoa ochrogaster* (Guenée), and may be a more important pest in western Canada than previously recognized (Ayre et al., 1982; Beirne, 1971; Byers, unpublished data).

A synthetic sex attractant for adult DSC males was developed previously by systematically testing the attractancies of a large number of blends of synthetic chemicals (Struble et al., 1977). The attractant was a two-component blend of (Z)-7-hexadecenyl acetate and (Z)-11-hexadecenyl acetate (abbreviated as Z7-16:Ac and Z11-16:Ac) at 5 and 200 μg, respectively. It was not known whether these compounds were the same as the sex pheromone components produced by the female DSC moths. The effectiveness of the two-component blend as a trap bait for the attraction of males was comparable to two unmated female moths/trap. In a five-year test in Ontario, the blend was also much more effective than black light for the attraction of males (Cheng and Struble, 1982). It was also used to monitor DSC populations in Alberta from 1979 to 1983 (Byers and Struble, 1985) and in Manitoba from 1977 to 1979 (Ayre et al., 1982). The species specificity in these tests in Ontario, Alberta, and Manitoba was 98, 99.5, and 93%, respectively.

The behavioral responses of DSC male moths to Z7-16:AC and Z11-16:Ac have been studied in a flight tunnel and in orientation disruption experiments (Palaniswamy et al., 1984). Z11-16:Ac was found to be a long-range attractant, while Z7-16:Ac influenced the close-range flight of the moths.

In this paper, we describe the identification of the sex pheromone components in abdominal tip extracts of unmated female DSC moths and the effects of the minor pheromone components on the attraction of adult males. A more attractive and species-specific blend was developed, and it was effective for at least six weeks under monitoring conditions.

METHODS AND MATERIALS

DSC were reared on a modified pinto bean diet (Shorey and Hale, 1965). Pheromone was recovered from 4- to 10-day-old unmated adult females that exhibited calling behavior between 1 and 4 hr into the scotophase (maintained at 20°C, 80–90% relative humidity, and 16:8 light–dark). Everted abdominal

tips were removed with fine forceps and soaked (extracted) in *n*-hexane (BDH Omnisolv®, glass distilled). Extracts from 20 to 80 tips were filtered and reduced to an appropriate volume under N_2 [1.0 female equivalent (FE)/μl] for analyses without further cleanup. A total of ca. 450 females were extracted. Bioassays were done with 4- to 20-day-old adult males in a tube-type olfactometer under conditions described by Struble et al. (1980a).

The extracts were analyzed by gas chromatography (GC) using an electroantennographic detector (EAD) and a flame ionization detector (FID) simultaneously (Struble and Arn, 1984). The effluent split between detectors was ca. 1:10 (Arn et al., 1975) or 1:3 (Struble and Byers, 1985). Gas capillary columns used for the GC analyses were coated (Struble and Richards, 1983) with OV-17 (22 m × 0.35 mm ID), Silar 10C (22 and 50 m × 0.35 mm ID), Carbowax 20 M TPA (28 and 61 m × 0.32 mm ID), and SP-2340 (28 and 75 m × 0.32 mm ID). Helium carrier gas linear velocity was 30 cm/sec (at 50°C) for all analyses, and various temperature programs were used with splitless injections. GC–mass spectrometry (GC-MS) was with a Finnigan 4000 equipped with a data system and Silar 10C (22 and 50 m) capillary columns, and a Hewlett-Packard model 5985B using capillary columns of Silar 10C (22 m), Carbowax 20 M TPA (28 and 61 m) and SP-2340 (75 m).

Synthetic chemicals were either synthesized (Struble and Swailes, 1975) or purchased. All acetates were purified by argentation liquid chromatography (Houx et al., 1974) to chemical purities >99% and isomeric purity >99.8%. Purified acetates were hydrolyzed with methanolic KOH to the corresponding alcohols of similar purity. Purified alcohols were oxidized with pyridinium chlorochromate (Corey and Suggs, 1975) to yield the corresponding aldehydes which were further purified (>99% and alcohol-free) by chromatography on silica gel.

The Z11–16:Ac used throughout these tests contained <0.01% Z11–16:OH, except for the test summarized in Table 3, where the acetate was chromatographed on silica gel to remove all traces of Z11–16:OH.

Chemical blends were prepared in *n*-hexane, and red rubber septa (Arthur H. Thomas Co. catalog No. 8753-D22) were used as dispensers except for one experiment where No. 10 rubber bands (Eberhard Faber, Canada, Ltd.) were used for this purpose. An antioxidant, 2,6-*tert*-butyl-4-methyl phenol (BHT) was added (5 μg) to all blends containing aldehydes. The cone-type traps and field attractancy test procedures (1979–1984) were as previously described (Struble, 1981). Traps were spaced 20 m apart along the edge of cereal or alfalfa crops near Lethbridge, Alberta, and moth counts were recorded at least three times a week and daily in some tests. Captured moths were identified by the authors (Hardwick, 1970), with confirmation of representative specimens by Dr. J.D. Lafontaine, Biosystematics Research Institute, Agriculture Canada, Ottawa. Analyses of variance were done on transformed ($\sqrt{x + 1}$) data and treatment means were compared by Duncan's multiple-range test (SAS Institute

Inc., 1972). In all tables and text, mean catches of moths within a test (column) followed by the same letter did not differ at the 5% level ($P > 0.05$).

RESULTS AND DISCUSSION

Sex pheromone was recovered from adult females that exhibited a calling behavior which was confirmed by observing the responses that the females elicited from male moths in an olfactometer (Struble et al., 1980a). This qualitative bioassay was also used to determine the relative amount of pheromone in the female extracts.

GC and GC-MS analyses. Complete CI differential mass spectra (Struble et al., 1980b), which were comparable to those of authentic chemicals, were obtained for the following components in the female abdomen-tip extracts (relative quantities by GC-MS): 16:Ac (5.4), Z7-16:Ac (2.5), Z9-16:Ac (0.6), Z11-16:Ac (100), and Z11-16:OH (1.5). Two other components, 12:Ac and 14:Ac, were detected by their M + 1 ions in the total-ion chromatograms, but the spectra were incomplete due to the low concentrations of these components.

The total-ion chromatograms were scanned for other C_{10} to C_{18} saturated, mono-, and diunsaturated aldehydes, alcohols, and acetates. However, aldehydes and diunsaturated alcohols and acetates were not detected in the extracts.

The components detected by GC-MS all cochromatographed with authentic samples on capillary columns of Silar 10C (50 m), Carbowax 20 M TPA (61 m), SP-2340 (75 m), and OV-17 (22 m) under various temperature program conditions. Most of the positional and geometrical isomers of monounsaturated C_{10} to C_{16} acetates and alcohols with the double bond beyond carbon atom number 4 can be resolved on these liquid phases (Heath et al., 1980). The isomer assignment of Z7-16:Ac was confirmed on the OV-17 column where it eluted before 16:Ac, which was the reverse order of elution compared with the order on the more polar liquid phases. The isomer assignments of Z7-16:Ac and Z11-16:Ac were consistent with the known (Struble et al., 1977) synthetic attractant blend of these two isomers. The isomer assignments of the other pheromone components detected in the female extracts were substantiated by GC-EAD analyses and field-attractancy tests.

EAD-FID analyses. Male DSC antennae gave consistent EAD responses (Struble and Arn, 1984) to 16:Ac, Z7-16:Ac, Z11-16:Ac, and Z11-16:OH in the female extracts (Table 1). Antennal responses of comparable intensities were obtained with similar quantities of the authentic chemicals, which further supported these structural assignments. DSC male antennae did not respond to any other components in the extracts.

A special EAD technique, in which the detector antennae were from males of other species that were known to have specific responses to the DSC pheromone components, was used to further confirm the isomeric assignments of

these components (Struble and Arn, 1984). This technique was also used to prove the presence or absence of other minor "pheromone-like" components in the DSC extracts.

Antennae of male *Autographa californica*, *Loxestege sticticalis*, *Mamestra configurata*, *Euxoa tessellata*, and *Pseudaletia unipuncta* were used as detector antennae. The specific EAD responses of these antennae to DSC extract components and to the corresponding synthetic chemicals are listed in Table 1. Antennae of *E. tessellata* confirmed the presence of 16 : Ac, *Z*7–16 : Ac, *Z*9–16 : Ac, and *Z*11–16 : Ac in the female extracts, and although the antennae were highly sensitive to synthetic *Z*7–14 : Ac (0.45 mV/2 ng injected), this compound was not detected in the extracts. Antennae of *M. configurata* detected traces of 14 : Ac and *Z*9–14 : Ac and confirmed the presence of 16 : Ac and *Z*11–16 : Ac, while *P. unipuncta* antennae confirmed *Z*11–16 : Ac and *Z*11–16 : OH in the extracts. Antennae of *A. californica* detected a trace of *Z*7–12 : Ac and *L. sticticalis* detected trace quantities of 14 : Ac, *E*11–14 : Ac, and *Z*11–14 : Ac in the extracts. Antennae of *L. stricticalis* also confirmed the presence of *Z*11–16 : Ac. The components *Z*7–12 : Ac, *Z*9–14 : Ac, *E*11–14 : Ac, and *Z*11–14 : Ac were only detectable in the DSC female extracts by GC-EAD using antennae of these selected species of moths.

Based on GC (FID and EAD) and GC-MS analyses, the quantities of the pheromone components, relative to *Z*11–16 : Ac, in the DSC extracts were as follows: 12 : Ac, <0.1; *Z*7–12 : Ac, <0.1; 14 : Ac, <0.1; *Z*9–14 : Ac, <0.1; *Z*11–14 : Ac, <0.1; *E*11–14 : Ac, <0.1; 16 : Ac, 5.4; *Z*7–16 : Ac, 2.5; *Z*9–16 : Ac, 0.6; *Z*11–16 : Ac, 100; and *Z*11–16 : OH, 1.5. There was about 10 ng/FE of *Z*11–16 : Ac in the female extracts.

Attractancy Tests in the Field. The attractant developed previously by empirical testing of synthetic chemicals consisted of *Z*7–16 : Ac plus *Z*11–16 : Ac in a ratio of 1 : 20 or 1 : 40 (Struble et al., 1977). These components were identified in the female pheromone extracts by GC-MS analysis in a ratio of 1 : 40; therefore, unless otherwise stated, this ratio was used in all subsequent attractancy tests.

In the previous tests (Struble et al., 1977), rubber bands were used as dispensers; however, they deteriorated in about two weeks under field conditions and rubber septa were considered to be more suitable dispensers. To confirm this, the two-component blend was tested at a ratio of 1 : 20 (50 : 100 μg/dispenser) on (1) rubber bands and (2) rubber septa, and at a ratio of 1 : 40 (12.5 : 500 μg) on (3) rubber septa. The mean catches of DSC male moths/four replications from August 28 to September 19, 1979, were (1) 38b, (2) 119a, and (3) 137a (means followed by the same letter did not differ at the 5% level). The blends on rubber septa attracted the greatest ($P < 0.05$) numbers of moths, and the rubber septa did not deteriorate under field conditions, so they were used as dispensers throughout the remainder of these tests.

To determine the synergistic or inhibitory effects of the other components

[a] ND indicates that responses were not detectable.
[b] Responses of Z11-16:Ac in the *E. messoria* extract were also confirmed by *L. sticticalis*, *M. configurata*, and *P. unipuncta* males as detector species.

detected in the female extracts (Table 1), field-attractancy tests were done with these added singly to the two-component blend (Z7-16:Ac and Z11-16:Ac at 12.5 and 500 μg/dispenser). The components added, the quantities (μg), and the mean catches of moths for four replications from August 12 to September 3, 1980, were as follows: two-component blend, 63abc; Z11-16:OH (1 μg), 80a; Z9-16:Ac (4 μg), 56abc; 16:Ac (20 μg), 41cd; *E*11-14:Ac (2 μg), 42cd; Z11-14:Ac (2 μg), 53bc; Z9-14:Ac (0.1 and 1.0 μg), 52bc and 24d; 14:Ac (2 μg), 45bc; and Z7-12:Ac (0.1 and 1.0 μg), 23d and 7e. Three other compounds that are positional isomers of the components detected in the female extracts were also included in this test by adding them (2 μg) singly to the two-component blend. The compounds added and the mean catches of DSC males were: Z5-16:Ac, 50bc; Z9-12:Ac, 44c; and Z5-12:Ac, 41cd (throughout this test, means followed by the same letter did not differ as the 5% level). Z11-16:OH was the only component that appeared to have any synergistic effect on the attraction of DSC male moths. Both Z7-12:Ac and Z9-14:Ac were potent attractant inhibitors. The other components detected in the female extracts and their positional isomers that were included in this test tended to reduce (although

$P > 0.05$) the trap catches compared with the two-component blend, but none of these were strongly inhibitory.

The geometrical isomers of the main pheromone components, *E*7–16:Ac (2 μg) and *E*11–16:Ac (25 μg), as well as *Z*7–16:OH (10 μg) were added singly to the two-component blend in two tests (four replications) done in 1979 and 1980. These compounds had no obvious effect on the attraction of males (data are not shown). Similarly, 17 blends (four replications) containing 4–11 of the pheromone components per blend were tested during 1979, 1980, and 1981, but all of the treatments attracted fewer ($P > 0.05$) males than the two-component blend. The strong inhibitory effects of *Z*7–12:Ac and *Z*9–14:Ac were also evident whenever these components were present in the multicomponent blends.

The pheromone components *Z*7–16:Ac and *Z*11–16:Ac were essential for the attraction of DSC males, and two-component blends of *Z*11–16:Ac with each of the other components detected in the female extracts did not attract any DSC males. These results were consistent with the previous attractancy tests (Struble et al., 1977).

Two-component blends of *Z*11–16:Ac with the lower homologs of *Z*7–16:Ac, i.e., *Z*7–15:Ac, *Z*7–14:Ac, and *Z*7–13:Ac, were reported (Struble et al., 1977) to attract DSC males. These tests were repeated even though the lower homologs were not detected in the female extracts. Substitution of *Z*7–16:Ac in the two-component blend with the lower homologs resulted in the capture of smaller ($P < 0.05$) numbers of moths (Table 2). The addition of each of these compounds to the two-component blend of *Z*7–16:Ac and *Z*11–16:Ac also resulted in reduced ($P < 0.05$) catches of moths. It seems that these parapheromones must have some "fit" on the receptor for *Z*7–16:Ac, and the decrease in trap catches within this homologous series may indicate a decreasing degree of "fit." Odd-numbered carbon compounds have been reported as parapheromones for other lepidopterans (Cardé and Roelofs, 1977; Struble, 1983; Voerman et al., 1975).

In the initial attractancy tests with the minor components identified in the female extracts, addition of *Z*11–16:OH to the two-component blend of *Z*7–16:Ac and *Z*11–16:Ac appeared to enhance the attraction of DSC males. Further tests confirmed that the presence of *Z*11–16:OH at 0.1 μg resulted in a significant increase in the numbers of DSC males captured (Table 3). However, the catches of a nontarget species, *Helotropha reniformis* (Grote), also increased dramatically, as a total of 278 males were captured. In a later test, the catches of *H. reniformis* were reduced by increasing the quantity of *Z*11–16:OH to 4 or 10 μg in the three-component blend (data are not shown). These blends, however, caught large numbers of clover cutworm, *Discestra trifolii* (Hufn.), as might be expected because a blend of *Z*11–16:Ac and *Z*11–16:OH at a ratio of 9:1 is an effective attractant for this species (Struble and Swailes, 1975; Underhill et al., 1976).

[a] Four replications, August 26 to September 15, 1980. Means followed by the same letter do not differ ($P > 0.05$) by Duncan's multiple-range test.

Several compounds were added singly to a three-component blend of Z7-16:Ac (12.5 μg), Z11-16:Ac (500 μg), and Z11-16:OH (1 μg) in search of an inhibitor of *H. reniformis* that would not inhibit the attraction of DSC. Z11-16:Ald met these requirements as it not only inhibited the attraction of the nontarget species, but it also had a synergistic effect on the attraction of DSC (Table 4). The addition of 1-100 μg of Z11-16:Ald to the two-component or the three-component blends resulted in the capture of the greatest ($P < 0.05$) numbers of DSC males and the capture of only a few *H. reniformis*. The blends containing 10 μg of Z11-16:Ald captured more DSC males than blends containing 1 or 100 μg (although $P > 0.05$).

[a]Means, of four replications, followed by the same letter do not differ ($P > 0.05$) by Duncan's multiple-range test. An antioxidant, BHT (5 μg), was added to all chemical blends.

The two-component blend or the blends containing Z11-16:OH and/or Z11-16:Ald were all excellent for the attraction of DSC males. It was important, however, to determine the relative attractancies of these blends over an extended period of at least six weeks. This was done in a test (Table 5) which consisted of three parts: a comparison of the relative attractancies of the two-component blend with blends containing Z11-16:OH and/or Z11-16:Ald; the effectiveness of blends that were preexposed for 10 days in an earlier test (August 8-17, 1984, Table 4); and the effectiveness of treatments with twice the dispenser load.

The addition of Z11-16:OH to the two-component blend increased the catches of both DSC and *H. reniformis* (Table 5), which was in agreement with the earlier data (Tables 3 and 4). The addition of Z11-16: Ald to either the two- or three-component blends significantly increased the capture of DSC males and very few *H. reniformis* were caught. Increasing the dispenser load from 500 to 1000 μg (based on Z11-16: Ac) resulted in the capture of fewer DSC with all of the blends, although the reduction was not significant for the two-component blend.

The trap catches were recorded daily throughout this test and the mean catches of DSC males per three-day period from August 18 to September 17, 1984, are illustrated in Figure 1. A freshly prepared treatment of the four-component blend was added to the test on August 29 (end of interval 4, Figure 1 and Table 5) to determine the attractancy of a freshly perpared treatment relative to equivalent treatments that had been used under field conditions since August 9 and 18. The four-component blends all captured similar numbers of DSC

TABLE 5. MEAN NUMBER OF *E. messoria* AND TOTAL NUMBER OF *H. reniformis* MALES ATTRACTED TO BLENDS OF Z7-16:Ac (12.5 μg) AND Z11-16:Ac (500 μg) CONTAINING VARIOUS QUANTITIES OF Z11-16:OH AND Z11-16:ALD (FOUR REPLICATIONS, 1984)

[a] Means within a column followed by the same letter do not differ ($P > 0.05$) by Duncan's multiple-range test. An antioxidant, BHT, was added to all blends at 5 μg/500 μg of Z11-16:Ac.

males from August 30 to September 18, which indicated that the general decrease in catches throughout this period was due to a decline in the moth abundance. The three-component blend of Z7-16:Ac, Z11-16:Ac, and Z11-16:Ald consistently caught fewer moths than the four-component blend, but the difference was not significant. The attractancy of the two-component blend was previously reported to be comparable to two unmated female moths/trap (Struble et al., 1977), so the new blends containing the alcohol and/or the aldehyde would be highly competitive with females.

The beneficial effect of 1 μg of Z11-16:OH in these blends is of practical importance because trace quantities of the alcohol would not need to be removed from either Z11-16:Ac or Z11-16:Ald used for preparing the DSC attractant.

There was no analytical evidence for Z11-16:Ald in the DSC female ex-

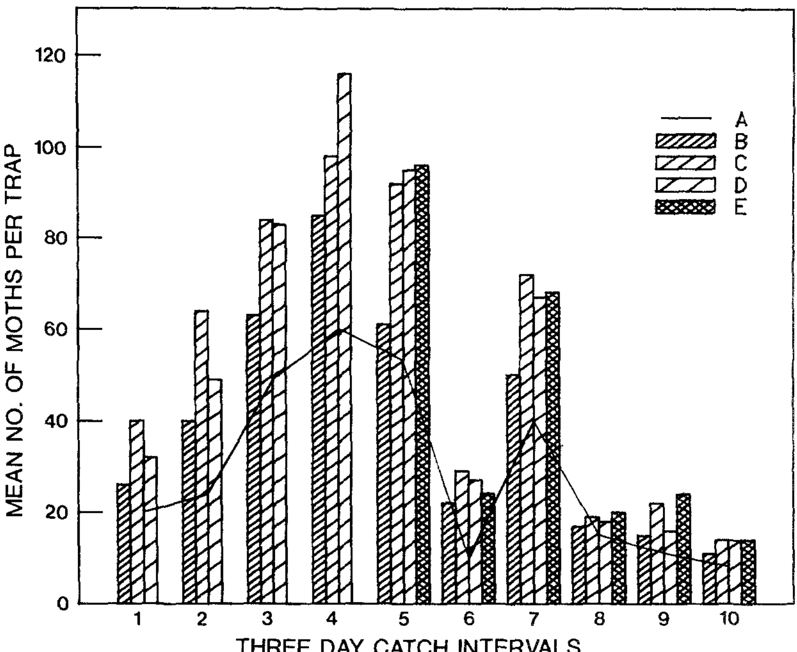

FIG. 1. Mean numbers of *E. messoria* male moths/trap/3-day intervals with four replications of five blends in an alfalfa field near Lethbridge, Alberta, from August 18 to September 17, 1984. The blends were: A, Z7-16:Ac (12.5 μg) and Z11-16:Ac (500 μg) which was the previous attractant and is represented by a line; B, blend A plus Z11-16:OH (1 μg); C, blend A plus Z11-16:OH (1 μg) and Z11-16:Ald (10 μg); D, blend A plus Z11-16:Ald (10 μg); and E, freshly prepared blend C added to the test August 29.

tracts; however, we are investigating whether it is detectable in the female effluvium.

In conclusion, for monitoring the population densities of DSC males we recommend a four-component blend of Z7-16:Ac, Z11-16:Ac, Z11-16:OH, and Z11-16:Ald at 12.5, 500, 1, and 10 μg/red rubber septum dispenser. A three-component blend without the alcohol would be nearly as attractive over at least a six-week period. Both blends contained 5 μg of BHT and are highly species-specific.

Acknowledgments—We thank Miss C. Herle, Mr. J. Elder, Mr. W. Pelham and Mr. A. Tron, Agriculture Canada Research Station, Lethbridge, Alberta, for their technical assistance; and Mr. G. L. Ayre, Research Station, Agriculture Canada, Winnipeg, Manitoba, for rearing some of the DSC moths. Part of this research was done while one of us (D.L.S.) was on a work-transfer to the

Swiss Federal Research Station, Wädenswil, Switzerland, and we thank Drs. H. Arn, H.R. Buser, and E. Städler for assistance with some of the GC-EAD and GC-MS analyses.

(Received May 12, 1986; accepted July 15, 1986)

Abstract—Postlarval lobsters (4th–7th stage) exclusively fed frozen brine shrimp (*Artemia saline*) were assayed for food-search response to extracts and metabolites from four common prey: soft clams (*Mya arenaria*), blue mussels (*Mytilus edulis*), rock crabs (*Cancer irroratus*), and sea stars (*Asterias vulgaris*). Concentrations of soluble primary amines, protein, and ammonia in prey tissues and metabolites were determined. No significant responses were observed for any prey metabolites diluted to 1 and 10%, while only *A. vulgaris* evoked a significant response at full strength, suggesting that predatorily naive lobsters have yet to develop more pronounced chemosensory responses shown by field-collected lobsters. Removal of protein with retention of small-molecular-weight polar molecules did not appear to affect response to prey extracts. EC_{50}s, as micromoles per liter amines, computed from prey extract dose–response curves indicate differences per unit amine between prey extracts, with *A. vulgaris* extract more potent as an attractant than either bivalve extract. *C. irroratus* extract was equally attractive as the other three extracts. Ammonia levels excreted into seawater over 3 hr were similar for all prey species, while soluble primary amines and proteins were undetectable. Ammonia and protein per gram whole prey varied significantly between extracts of prey species, while primary amines were similar. Lobsters may be attracted preferentially to carrion species with higher concentrations of amines and/or higher potency of attractants per unit amine.

Key Words—*Homarus americanus*, chemoreception, chemical sensing, food attractants, prey preference, attractant quality.

INTRODUCTION

The American lobster (*Homarus americanus*) is commonly considered an opportunist feeder, ingesting a wide variety of species (Herrick, 1895; Squires and Ennis, 1968; Squires, 1970; Ennis, 1973; Elner and Jamieson, 1979; Scarratt, 1980; Carter and Steele, 1982a). Although prey availability is an important dietary factor (Miller et al., 1971; Carter and Steele, 1982a), some prey selection may occur, especially as a function of lobster age (Scarratt, 1980; Carter and Steele, 1982a) and stage of molt (Leavitt et al., 1979; Scarratt, 1980; Carter and Steele, 1982a). Additionally, laboratory prey choice studies have demonstrated dietary preferences for particular species (Evans and Mann, 1977; Elner, 1980; Carter and Steele, 1982b).

Homarus americanus can sense living and dead prey from a distance via chemosensory structures. The ability to sense metabolites from living prey is considered weaker than the ability to sense prey tissue extracts (McLeese, 1973a; Hirtle and Mann, 1978; Carter and Steele, 1982b), because the concentration of the former is lower. Attractants from tissue extracts appear to consist of mixtures of amino acids and perhaps other small compounds (McLeese, 1970, 1973a; Derby, 1984; Daniel and Bayer, 1986a). Characterization of attractant components excreted from live prey has not been accomplished.

The sensitivity of lobsters to waterborne food chemicals has led to the suggestion that prey selection may be partially mediated by chemical sensing (Derby and Atema, 1981). Some evidence of discrimination between attractant solutions of prey species exists. Gravimetrically or volumetrically equivalent tissue extracts of crabs (*Cancer irroratus*) and bivalves (*Mytilus edulis*) elicited greater food-search behavior than sea stars (*Asterias vulgaris*) or sea urchins (*Strongylocentrotus droebachiensis*) (McLeese, 1973a; Carter and Steele, 1982b). However, the observed responses may have been a function of quantity of attractants in test solutions rather than quality of attractants, since prey tissues contained varying concentrations of amino acids (Carter and Steele, 1982b). The behavioral threshold of the food-search response appeared to decrease toward metabolites from live horse mussel (*Modiolus modiolus*) and to increase toward metabolites from live blue mussel (*Mytilus edulis*) after one month feeding exclusively on live *M. modiolus* (Derby and Atema, 1981). Opposite results were obtained if lobsters were fed exclusively live *M. edulis*. Thus, at least in the case of chemically mediated detection of live prey, response to prey species may vary as a function of attractant quality.

All studies of chemically mediated food-search behavior in lobsters have used field-collected individuals which have had some degree of feeding experience on live, naturally occurring prey (McLeese, 1970, 1973a,b; Hirtle and Mann, 1978; Derby and Atema, 1981; Carter and Steele, 1982b; Derby, 1984). Examination of food-search behavior in lobsters with no previous experience

with ingestion of natural prey may reveal whether there are initial prey preferences.

In the present study, postlarval lobsters (4th–7th stage) that were fed from hatching frozen brine shrimp (*Artemia salina*) were tested for food-search response to extracts and metabolites from four common prey: soft clams (*Mya arenaria*), blue mussels (*Mytilus edulis*), rock crabs (*Cancer irroratus*), and sea stars (*Asterias vulgaris*). Concentrations of soluble primary amines, protein, and ammonia were determined, providing a basis for comparison of attractant quantities of metabolites of live prey and extracts of prey tissues. Behavioral bioassays testing live prey metabolites provided information on chemical mediation of prey search by predatorily naive lobsters. Behavioral bioassays of extracts were performed as a function of primary amine concentration rather than extract weight or volume. Since primary amine concentration has been demonstrated to reflect attractant levels (Daniel and Bayer, 1986a), this allowed comparison of attractiveness of prey species extracts.

METHODS AND MATERIALS

Preparation of Prey Metabolites and Extracts. Metabolites and extracts were prepared from *Mytilus edulis*, *Mya arenaria*, *Cancer irroratus*, and *Asterias vulgaris*. These animals were obtained from intertidal areas near Southwest Harbor, Maine, or the University of Maine Darling Center, Walpole, Maine, and maintained in laboratory aquaria for no more than two days. Whole animals were weighed before preparation of solutions. Solutions containing metabolites were prepared by maintaining live prey for 3 hr at approximately 10–40 g wet weight whole prey per liter of "aged" filtered seawater, prepared by filtering natural seawater (32–35 ppt) to 1 μm (Microwynd filter, MWM Co., Meridan, Connecticut) and allowing it to stand for at least two weeks before use. Metabolites were vacuum filtered (G6 glass fiber) and stored at 4°C until behavioral bioassay within 5 hr.

Extracts were prepared by homogenizing whole animals (shells of bivalves were removed) in aged filtered seawater (100 g wet weight/liter seawater) in a Waring blender. Homogenates were centrifuged twice at 25,000*g* for 20 min at 4°C. Supernatants were combined and vacuum filtered to 0.45 μm using G6 glass fiber and 0.45 μm Nucleopore filters to make "raw extract." Extracts were halved and either stored at −20°C or used to prepare "Sm7 filtrate" by methanol extraction, rotary evaporation, and preparative Sm7 Biobeads chromatography in order to remove protein and peptides while leaving amines and other polar small-molecular-weight compounds intact [preparation described by Daniel and Bayer, 1986a; see also Rittschof et al., (1984) for discussion of rationale]. The eluent containing water-soluble amines was collected and frozen

as Sm7 filtrate at −20°C. Behavioral bioassays were performed with thawed fractions within 48 hr of preparation.

Ammonia and protein concentrations of metabolites, thawed raw extracts, and thawed Sm7 filtrates were determined by methods of Solorzano (1969) and Bradford (1976), while primary amine concentrations were determined by measurement of fluorescence of primary amines after *o*-phthaldialdehyde derivatization (Roth, 1971). However, derivatization reagent was prepared according to Lindroth and Mopper (1979). Bovine serum albumin and DL-alanine were used as standards for protein and primary amine determinations, respectively. The significance of interspecies differences in amines, ammonia, and soluble protein per gram whole prey was determined by analysis of variance and Tukey's (equal sample size) or Gabriel's (unequal sample size) comparison of means (Sokal and Rohlf, 1981).

Behavioral Bioassay. Postlarval lobsters (4th–7th stage) used in assay experiments were obtained from the Department of Fisheries and Oceans hatchery at St. Andrews, New Brunswick, Canada, and maintained in natural seawater which was recirculated through filters as described by Daniel and Bayer (1986a). Upon hatching, lobsters were fed ad libitum frozen brine shrimp (*Artemia salina*). The same group of lobsters was used for each prey metabolite or extract assay, although lobsters were randomly assigned to treatments tested for a given assay experiment. Presence or absence of food-search response of up to 200 lobsters was determined using a behavioral bioassay apparatus described by Daniel and Bayer (1986a). Lobsters, fasted for two days, were placed individually at excurrent ends of 36-cm × 4-cm-diam. clear acrylic chambers. Aged filtered seawater flowed at 0.8 cm/min (20 ml/min) through chambers. Stimulus release (2 ml/min) occurred through a 16.5-gauge needle placed 2–3 cm upstream. A positive food-search response consisted of components of the following behaviors: vigorous motions of the maxillipeds, periopod scooping, and lunging toward and/or grasping the stimulus needle.

Aged filtered seawater was used to dilute prey extracts to appropriate concentrations and as a control treatment for all bioassays. In addition, bioassays included a standard attractant containing 56 μM amine prepared from G6 filtrate of suspension of freeze-dried herring extract (preparation described by Daniel and Bayer, 1986a). Bioassay of prey metabolites included control, standard metabolites at full strength, and metabolites diluted to 1 and 10%. The significance of difference between responses to treatments and to control was determined by R × C log-likelihood test with Williams' correction (Sokal and Rohlf, 1981). Bioassay of raw extracts and Sm7 filtrates included control, standard, and extract solutions containing 0.2–560 μM amines. Responses to raw extracts and Sm7 filtrates were adjusted as described by Daniel and Bayer (1986a) to remove variability which may have been due to changes in behavioral threshold between experiments. Probit analysis was performed on adjusted responses to determine

EC_{50} values or effective concentration necessary to elicit a positive food-search response in 50% of the lobsters (Statistical Analysis System, SAS Institute, Inc., Cary, North Carolina).

RESULTS

Behavioral Bioassay of Metabolites. Generally, food-search responses to live prey metabolites were either at or slightly above levels for control seawater (Figure 1). No significant responses were observed for any of the prey metabolites diluted to 1 and 10%. Higher responses were observed for all full-strength preparations but only *A. vulgaris* solution elicited a significant response ($P <$

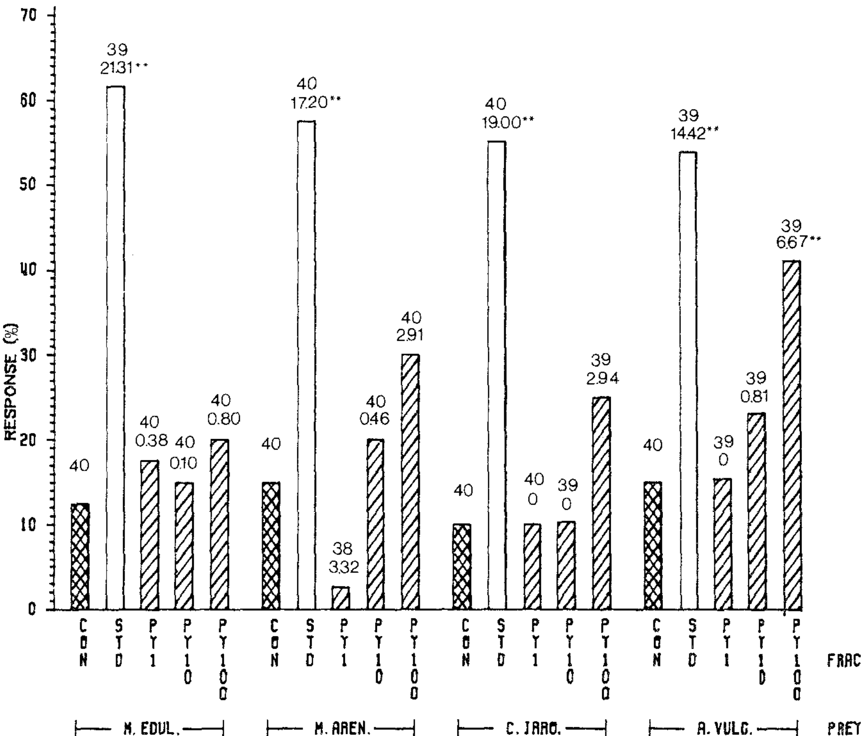

FIG. 1. Food-search response of postlarval lobsters to live prey metabolites, CON = aged, filtered seawater, STD = freeze-dried herring extract at 56 μM amines, PY1–PY100 = live prey metabolites from 1% to 100% concentration. Numbers of lobsters assayed followed by G statistic for treatment response vs. control response are given above each bar. ** = $P < 0.05$.

0.05). In contrast, response to 56 μM amine herring standard was consistently significant at 57.0 $\pm$ 1.7% ($X \pm$ SE, $N = 4$) ($P < 0.05$).

Behavioral Bioassay of Extracts. Response to filtered seawater (control) was consistent and low in extract bioassays (12.1 $\pm$ 1.45% ($X \pm$ SE), $N = 8$). In addition, responses to herring standard varied little (59.5 $\pm$ 3.57% ($X \pm$ SE), $N = 8$); thus the data transformation (Daniel and Bayer, 1986a) had little effect on probit curve estimations by affecting only slightly the y intercept. Predicted probit equations for all treatments fit these data well as determined by chi-square test for heterogeneity ($P > 0.05$).

Removal of protein with retention of most of the amines did not appear to affect the responses to prey extracts (Figure 2, Table 1). EC_{50} (as micromoles per liter amine) 95% fiducial ranges of raw extract and Sm7 filtrate of the same species showed considerable overlap. Such a comparison was not possible for *C. irroratus* since only two concentrations of Sm7 filtrate were tested; nonetheless, EC_{50} values of raw and Sm7 filtrate of *C. irroratus* were almost identical.

Some interspecific differences in attractiveness were apparent from 95% fiducial limits shown in Table 1. Responses to all raw extracts were similar, as shown by fiducial range overlap. However, EC_{50}s of Sm7 filtrates of *M. edulis* and *M. arenaria* were significantly greater than EC_{50} of *A. vulgaris* Sm7 filtrate. While the EC_{50}s for both fractions of *A. vulgaris* were quite similar, the slope of the raw extract dose–response curve was comparatively low, resulting in the largest fiducial range of any EC_{50} estimation and thus contributing to overlap with EC_{50}s for other raw extracts. Raw extracts and Sm7 filtrates of *C. irroratus* and *A. vulgaris* were probably quite similar in attractant quality, since fiducial ranges for raw extracts showed complete overlap and EC_{50}s of all preparations were very similar. Therefore, on an equimolar amine basis, *A. vulgaris* Sm7 filtrate appeared to elicit a greater food-search response than the response to bivalve Sm7 filtrates but not greater than the response to *C. irroratus* Sm7 filtrate.

Ammonia, Amine, and Protein Levels in Metabolites, Raw Extracts, and Sm7 Filtrates. Ammonia (micromoles per gram whole prey) excretion into seawater over 3 hr was similar for the four species (Table 2, ANOVA, $N = 12$, $F = 1.10$, $P = 0.4032$). Protein and primary amines were not detectable in any metabolite preparations. Protein, primary amines, and ammonia were undetectable in aged, filtered seawater. Sensitivity of assays was 50 μg/ml (bovine serum albumin equivalents) for protein, 40 μM (DL-alanine equivalents) for primary amines, and 1 μM for ammonia.

Ammonia (micromoles per gram whole prey) and protein (milligrams per gram whole prey) varied significantly between raw extracts of species (Table 2, ammonia, ANOVA, $N = 14$, $F = 14.32$, $P = 0.0006$; protein, ANOVA, $N = 14$, $F = 4.87$, $P = 0.0244$). *C. irroratus* raw extract had greater ammonia levels than all other extracts and greater protein levels than *M. arenaria* raw

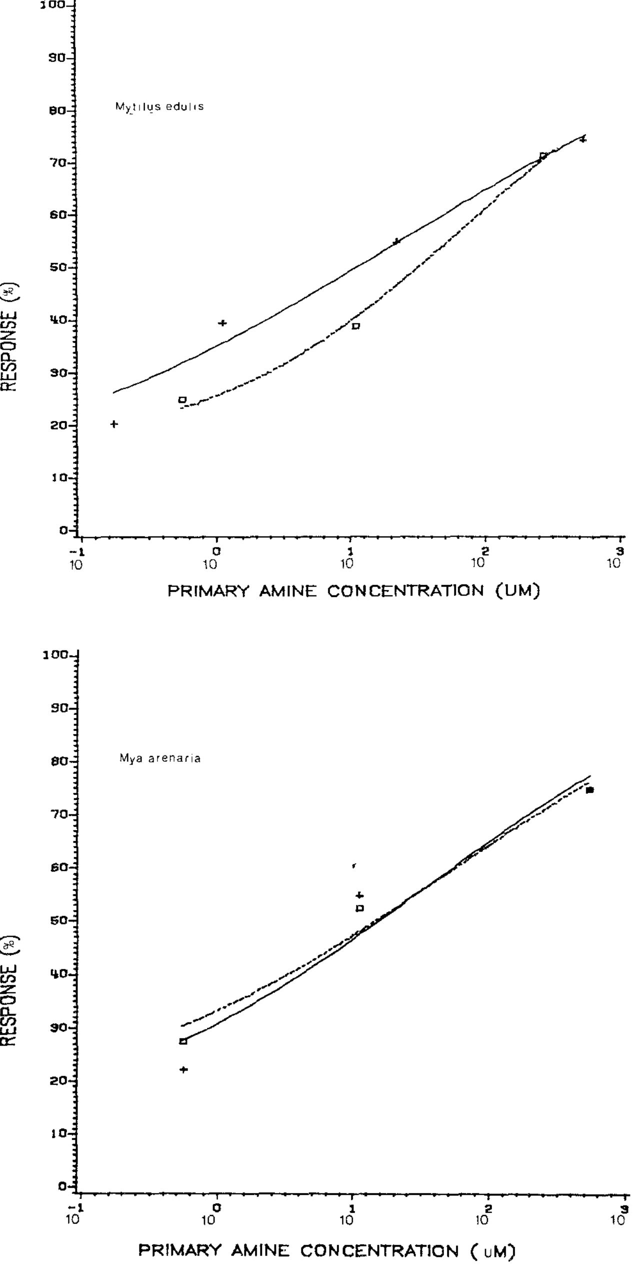

FIG. 2. Amine dose-response curves for prey extracts. Responses were normalized for variation in response to 56 μM amine freeze-dried standard. Curves generated from probit model with response to control as baseline response. Lines and data point symbols are as follows: raw extract: +, ———, Sm7 filtrate: □, - - - - - - -,.

extract. *M. edulis*, *M. arenaria*, and *A. vulgaris* raw extracts had similar ammonia and protein concentrations. All four species had similar primary amine concentrations (micromoles per gram whole prey, Table 2, ANOVA, $N = 14$, $F = 1.79$, $P = 0.2129$).

Sm7 filtrates of prey extracts retained most of the primary amines with little detectable protein remaining. Retention as percent recovered in filtrate was 81.2 ± 6.10% for amines, 0.26 ± 0.11% for proteins, and 41.9 ± 5.37% for ammonia (X ± SE, $N = 13$).

TABLE 2. CONCENTRATION OF SOLUBLE NITROGENOUS COMPOUNDS IN PREY METABOLITES AND EXTRACTS PER GRAM WHOLE PREY[a]

	Metabolites		Extracts			
Prey species	N	Ammonia (μmol/g)	N	Ammonia (μmol/g)	1° amine (μmol/g)	Protein (mg/g)
Mytilus edulis	3	1.29 ± 0.0861a	4	6.13 ± 1.49a	39.8 ± 5.48a	10.0 ± 1.09ab
Mya arenaria	3	1.62 ± 0.521a	4	3.62 ± 1.81a	30.4 ± 5.43a	7.42 ± 1.45a
Cancer irroratus	3	1.35 ± 0.295a	3	13.1 ± 1.01b	34.0 ± 9.22a	24.0 ± 7.21b

[a] Values are means ± SE. Values followed by the same letters represent similar concentrations according to 95% confidence limits computed from comparison of means test; Tukey's for equal sample sizes, or Gabriel's for unequal sample sizes.

DISCUSSION

The importance of low-molecular-weight polar compounds, such as amino acids, as major components of food attractants for *Homarus americanus* has been shown using extracts of *Mytilus edulis* (Derby, 1984), cod (*Gadus spp.*) (McLeese, 1973a), and *Clupea harengus* (Daniel and Bayer, 1986a). The present study extends the list to include *Mya arenaria*, *Asterias vulgaris*, and *Cancer irroratus* and reaffirms previous results with *M. edulis* extract (Derby, 1984).

Moreover, this is the first demonstration of differences in attractant potency of extracts of different prey species, independent of total primary amine concentration, for *H. americanus*. *Asterias vulgaris* protein- and peptide-free Sm7 filtrate was more attractive than *M. edulis* and *M. arenaria* Sm7 filtrates, although no differences in raw extracts were apparent by comparison of EC_{50}s expressed as micromoles per liter primary amines. This latter discrepancy appears to be a result of higher response variability in raw extracts since EC_{50}s of raw extracts and Sm7 filtrates were similar.

Chemically mediated prey preferences demonstrated by McLeese (1973a) and Carter and Steele (1982b) were probably due to the quantity of attractants in stimulus solutions using volumetrically or gravimetrically equivalent solutions rather than attractant potency as indicated in the present study. Unlike McLeese (1973a), Carter and Steele (1982b) measured amine concentrations in extracts. Ranking of percentage of lobsters showing food-search behavior of the extracts generally followed that of amine concentration for the extracts: response to *C. irroratus* extract, 92.0% (225 μM amine) > *M. edulis* extract, 80.0% (39 μM amine) > *A. vulgaris* extract, 66.7% (21 μM amine) > *S. droebachiensis* extract, 53.8% (26 μM amine). They concluded that there was an apparent preference of lobsters for *C. irroratus* and *M. edulis* over echinoderms. McLeese's (1973a) results showed similar trends, although the difference between response to echinoderm extracts and to bivalve extracts was more pronounced. Observed preferences were probably a result of variations in concentrations of attractants in the different prey extracts, partially due to differing proportions of hard parts which would not contribute to the weight or volume of extract after filtration. Indeed, primary amine concentrations as micromoles per gram whole prey including hard parts did not show significant variation between prey in the present study in comparison to much higher levels in *C. irroratus* in Carter and Steele's (1982b) study which did not include hard parts in concentration estimates.

Measurement of total amines by the o-phthaldialdehyde (OPA) derivatization method might lead to error due to variations in fluorescent intensity between individual amino acid derivatives. For the buffer and pH (boric acid, pH 9.5) used in coupling reagent, fluorescence of most individual amino acids is similar (10–20% variation) (Roth, 1971). However, proline and lysine are undetectable (Roth, 1971); both have been shown to produce feeding response

[proline: 53% (McLeese, 1970), 56.5% (Carter and Steele, 1982b); lysine: 9–70% (McLeese, 1970), 47.8% (Carter and Steele, 1982b)]. EC_{50}s as micromoles per liter amine (measured by OPA derivatization) of extracts with high amounts of proline and/or lysine might be expected to be less than EC_{50}s of extracts with low proline and/or lysine concentrations. Levels of lysine among prey extracts did not differ, although there were significantly higher levels of proline in *C. irroratus* than in *A. vulgaris*, and no difference in proline levels in *C. irroratus* and *M. edulis* (Carter and Steele, 1982b). This would suggest that only proline might bias conclusions based on EC_{50} values. However, the addition of proline concentration to total amines measured by the OPA method would serve only to increase the EC_{50} of the *C. irroratus* extract relative to other extracts. The hypothesis that there are differences in attractiveness (independent of primary amine concentration) between prey extracts, with *A. vulgaris* extract as the most potent attractant due to its low EC_{50}, would be either unaffected or strengthened by inclusion of lysine and proline in estimations of EC_{50}s.

Only Sm7 filtrates of prey extracts showed differences in attractant potency. Rittschof et al. (1985) have found that some amino acids, particularly arginine and lysine, are retained by Amberlite XAD-7 (similar to Sm7 Biobeads). Since both arginine and lysine are attractive to lobsters when presented singly (McLeese, 1970, Carter and Steele, 1982b), removal might reduce attractiveness of extracts containing these compounds as major components. This might lead to a modification of qualitative differences between prey species extracts. Relative loss of these amino acids from Sm7 filtrates is not known; however, Daniel and Bayer (1986a) did not measure significant retention to Sm7 Biobeads of a mixture of 20 radiolabeled amino acids including arginine and lysine.

Thus, lobsters may be attracted preferentially to carrion with higher concentrations of amines and higher potency of attractants per unit amine. Different mixtures of amino acids and other small compounds in extract mixtures may provide a basis for variations in preference. *Homarus americanus* showed variable food-search responses to single amino acid solutions, although responses were not consistent (McLeese, 1970; Carter and Steele, 1982b). Mixtures of amino acids may evoke greater food-search responses in *Homarus* spp. than single amino acids and the magnitude of response may vary with types of amino acids in the mixture (McLeese, 1970; Mackie, 1973).

Some chemosensory cells show specificity towards particular amino acids, while other cells respond to a variety of amino acids (Derby and Atema, 1982; Johnson and Atema, 1983). Neural integration of chemosensory response to attractant mixtures in the spiny lobster (*Panulirus argus*) can produce qualitative discrimination in some neurons as certain components elicit synergistic or suppressive effects (Derby and Ache, 1984a,b; Derby et al., 1985). Synergistic effects of mixtures of artificial attractants on whole behavior have been indi-

cated for feeding response in the shrimp, *Palaemonetes pugio* (Carr, 1978; Carr et al., 1984; Carr and Derby, 1986). Finally as the studies with *P. pugio* indicate, attractiveness may also be a function of low-molecular-weight compounds other than amino acids which do not react with OPA, resulting in an apparent lowering of EC_{50} estimations based solely on primary amines.

The food-finding behavior of another lobster, *Panulirus interruptus*, contrasts with our results for *H. americanus*. The spiny lobster, also an opportunistic feeder, appears to respond to high-molecular-weight compounds exuding from prey tissues (Zimmer-Faust et al., 1984). While individual amino acids are attractive to the spiny lobster, low-molecular-weight fractions of prey extracts may contain compounds which suppress attraction to the extract (Zimmer-Faust et al., 1984a). The higher-molecular-weight fractions contain the attractants, possibly peptides. Release of larger molecules from tissue occurs later than release of small molecules, causing a delay in attraction of the lobster to the food site (Zimmer-Faust and Case, 1982; Zimmer-Faust et al., 1984a). Zimmer-Faust et al. (1984a, b) argue that this prevents lethal encounters with predators which are attracted to the early-releasing solutes. A similar hypothesis has been proposed for delayed attraction of hermit crabs to gastropod predation sites (Rittschof, 1980). American lobsters are most attracted to polar solutes leaching from tissue within 3 hr of immersion in seawater (Daniel and Bayer, 1986b). Avoidance behavior is probably unnecessary since they are well-equipped for defense and, therefore, can safely approach a food site earlier.

Responses of postlarval lobsters to metabolites of live prey which they had never ingested and also had not experienced previous exposure to metabolites appeared to be even lower than reported previously for adult field-collected lobsters (McLeese, 1973a; Hirtle and Mann, 1978; Derby and Atema, 1981; Carter and Steele, 1982b). A significant response was obtained only to full-strength *A. vulgaris* metabolites, corresponding with the higher potency of *A. vulgaris* extract. Some of the discrepancy may be due to methodology used to prepare metabolites. Studies with older, field-collected lobsters either used greater prey weight per volume water (50–100 g/liter) or soaked prey for longer periods (10–24 hr). However, dilution of stimulus in behavioral assays was often 1000× or greater (McLeese, 1973a; Hirtle and Mann, 1978; Derby and Atema, 1981; Carter and Steele, 1982b). In the present study, dilution of stimulus was probably minimal due to shorter distances between stimulus needles and lobster shelters (2–3 cm) and lower volumes of water in assay chambers (300–400 ml).

It is more likely that lower responses to live prey metabolites reflect differences associated with either the age or the predatorily naive state of postlarval lobsters. Metabolites of live green crabs (*Carcinus maenus*), *C. irroratus*, *S. droebachiensis*, *M. edulis*, and *M. modiolus* appear to contain stimulants of feeding behavior in field-collected adult or juvenile lobsters (Hirtle and Mann, 1978; Derby and Atema, 1981; Carter and Steele, 1982b), while *C. irroratus*

and *M. edulis* metabolites did not evoke significant responses in postlarval lobsters. Field-collected lobsters have not been tested with *M. arenaria*, which did not elicit a feeding response in postlarval lobsters, or with *A. vulgaris*, which produced a significant response at full strength in postlarval lobsters. Interestingly, Carter and Steele (1982b) reported that measurable levels of amino acids (alanine, glycine, and histidine) were found only in tank water of *A. vulgaris* (which they did not test for attractiveness), reflecting relative levels in extracts, and not in tank waters containing equivalent concentrations of other prey species. This may account for the responsiveness of postlarval lobsters to the metabolites from *A. vulgaris*.

Acknowledgments—The authors wish to express gratitude to Drs. A.M. Mackie and C.D. Derby for provided helpful comments and criticisms of the manuscript. Technical assistance was provided by Lenora Daniel. Sam Chapman and Mike Eagles graciously provided postlarval lobsters from their hatcheries. Research described represents partial fulfillment of a Doctoral degree for the principal author and was funded by the University of Maine Sea Grant Program, grant NAB1AA-D-00035, and the Maine Agricultural Experiment Station.

(Received May 12, 1986; accepted July 15, 1986)

Abstract—Postlarval lobsters were fed live amphipods (*Gammarus oceanicus*), soft clam spat (*Mya arenaria*), or frozen brine shrimp (*Artemia salina*) for five weeks in order to determine by behavioral bioassay if chemically mediated prey-search behavior is established by feeding experience. Chemosensory responses of predatorily naive lobsters to live clam and amphipod metabolites were low and erratic. After five weeks, amphipod-fed lobsters had developed strong responses towards amphipod metabolites but not clam metabolites. In contrast, clam-fed lobsters did not develop responses to either prey. Chemical fractionation of amphipod metabolites indicated that attractants were confined to the same fraction as for prey extracts, i.e., polar, low-molecular-weight compounds. Survival (80–90%) was similar for each diet group; growth was greatest for amphipod-fed lobsters (100%), followed by clam-fed lobsters (72%) and brine shrimp-fed lobsters (18%); and feeding rates increased for amphipod-fed lobsters and decreased for clam-fed lobsters. Coloration of lobsters indicated that only amphipod diet provided desirable pigments. Differences in ingestive conditioning results between clam-fed and amphipod-fed lobsters may have been related to (1) clam metabolites being qualitatively or quantitatively less attractive than amphipod metabolites or (2) differences in the predisposition of lobsters to show ingestive conditioning to different prey and their associated metabolites as a function of quality of prey as a diet.

Key Words—*Homarus americanus*, chemoreception, predatory behavior, ingestive conditioning.

INTRODUCTION

Postlarval lobsters (*Homarus americanus*) with no previous exposure to potential prey are attracted to extracts of prey flesh but can, at best, weakly respond to metabolites exuded from living specimens of the same prey (Daniel and Bayer, 1987a). A slight but significant prey-search response was elicited only with *Asterias vulgaris* metabolites but not with *Mytilus edulis*, *Cancer irroratus*, or *Mya arenaria* metabolites. This overall lack of response to live prey metabolites by predatorily naive lobsters contrasts with stronger responses to a wide variety of prey species in field-collected juveniles and adults (Hirtle and Mann, 1978; Derby and Atema, 1981; Carter and Steele, 1982), suggesting that the establishment of sensing of metabolites for live prey may involve a mechanism dependent on age or feeding experience.

Feeding experience has been shown to be a determinant of the sensitivity of lobsters to prey metabolites (Derby and Atema, 1981). Field-collected lobsters capable of sensing metabolites of the mussels, *Modiolus modiolus* and *Mytilus edulis*, lower their threshold of detection to a given prey metabolite solution following feeding experience on that prey. This behavior, termed "ingestive conditioning" (Wood, 1968), has been observed in other invertebrates including a marine gastropod [*Urosalpinx cinerea* (Wood, 1968; Wood et al., 1981)], sea stars [*Asterias rubens* (Castilla, 1972), *Luidia clathrata* (McClintock and Lawrence, 1984), *Acanthaster planci* (Collins, 1975; Ormond et al., 1976)], a nudibranch [*Aeolidia papillosa* (Hall et al., 1982, 1984)], a terrestrial gastropod [*Achatina fulica* (Croll and Chase, 1977, 1980), and, possibly, a polyclad flatworm [*Stylochus ellipticus* (Christensen, 1972; Daniel, 1982)].

Ingestive conditioning may explain discrepancies between chemosensory responses of adult field-collected and laboratory-hatched, naive oyster drills (*U. cinerea*). Adult drills collected in areas containing only bay scallops (*Argopecten irradians*) were attracted and could ingest scallops (Ordzie and Garofalo, 1980), whereas naive drills were not attracted to scallops (Rittschof et al., 1983). Furthermore, recently hatched snails (*Achatina fulica* and *U. cinerea*) were conditioned through feeding experience to prey metabolites to which they initially showed little or no response (Croll and Chase, 1980; Wood et al., 1981). A similar hypothesis can be invoked to explain the contrast between chemosensory responses of predatorily naive, hatchery-reared versus adult, field-collected *H. americanus*.

The demonstration of the development through feeding experience of chemically mediated prey-search behavior in postlarval lobsters is obviously complicated by their small size. Natural prey species must be selected which are small enough to be handled successfully by lobsters weighing less than 500 mg. Lobsters this size have rarely been observed in nature but, according to substrate choice studies conducted in the laboratory, appear to prefer eel grass

beds (Barshaw and Atema, 1985) or rock sand substrates (Botero and Atema, 1982; Pottle and Elner, 1982; Barshaw and Atema, 1985). Small crustaceans and bivalve spat are common to these habitats. Our study used amphipods (*Gammarus oceanicus*) and soft clam spat (*Mya arenaria*) as prey items for postlarval lobsters in ingestive conditioning experiments. Live *G. oceanicus* was shown by Good et al. (1982) to constitute a suitable diet for postlarval lobsters. Initially, we selected *Mytilus edulis* spat as appropriate prey items, since Derby and Atema (1981) had fed immature lobsters adult blue mussels in their ingestive conditioning study. However, preliminary studies indicated that postlarval lobsters were incapable of opening even the smallest mussels. Soft clams were successfully opened by most of the lobsters, probably as a result of their thinner shells. Responses of prey-fed lobsters to prey metabolites were compared to responses to filtered seawater and to responses of lobsters fed frozen brine-shrimp to prey metabolites. Survival, feeding rates, and growth were monitored for determination of potential correlates between prey quality and feeding behavior.

METHODS AND MATERIALS

Source and Maintenance of Postlarval Lobsters

Postlarval lobsters were obtained from the Department of Fisheries and Oceans Hatchery at St. Andrews, New Brunswick, Canada (NB lobsters, N = 235, mean wet weight (g) = 0.065 ± 0.00078 (SE), and from the University of Maine Darling Center hatchery at Walpole, Maine (DC lobsters, N = 110, mean wet weight (g) = 0.10 ± 0.0079 (SE). NB lobsters were reared from hatching exclusively on frozen brine shrimp (*Artemia salina*) and were never exposed to any potential prey metabolites, while DC lobsters were reared through fourth stage on live brine shrimp, followed by frozen brine shrimp and filtrate from the plankton bag filtration system (240–500 μm) in the hatchery which included live barnacle larvae, bivalve larvae, amphipods, copepods, and mysid shrimp. Cannibalism probably occurred in this group as lobsters were not kept separate. Equal numbers of both groups of lobsters were randomly assigned to three tanks of natural seawater recirculated through filters and kept in individual containers (holding system described in detail by Daniel and Bayer, 1987b) for prey ingestion experiments. Group mean weights were similar at experiment initiation. However, NB lobsters in the clam-fed group were replaced after 17 days with larger DC lobsters (N = 65, mean wet weight (g) = 0.24 ± 0.015 (SE).

Source and Maintenance of Prey

Live clam spat, *Mya arenaria*, ranging from 0.0014 to 0.10 g wet weight including shell, were obtained from the Darling Center hatchery. Live amphi-

pods, *Gammarus oceanicus*, ranging from 0.0015 to 0.020 g wet weight, were collected during low tide in mean low-water intertidal pools near Bar Harbor or Pemaquid Point, Maine. Prey were maintained in a laboratory aquarium containing natural seawater and fed unicellular algae (a mixture of *Thalassiosira pseudonana* and *Isochrysis galbana* obtained weekly from Darling Center cultures, maintained in glass carboys in constant light and aeration and supplied with nutrient media) and frozen brine shrimp. Adequate populations of each prey species were kept in the aquarium to supply the requirements of the feeding regimens. Prey used for metabolite preparation were collected within one week of bioassay.

Feeding Regimes

Each group of lobsters was reared exclusively on either frozen *A. salina*, live *M. arenaria*, or live *G. oceanus* as follows:

Artemia Salina-Fed Group. Each lobster was fed ad libitum every other day. Responses of this group to prey metabolites allowed a standard of comparison with responses of prey-fed lobsters over the duration of the feeding trial.

Mya arenaria-Fed Group. Each lobster was supplied with 10 live clams every other day. Sizes of clams were generally in proportion to lobster size. Prey remaining in the container were counted and new clams were added to equal 10.

Gammarus oceanicus-Fed Group. Initially, lobsters were supplied 10 amphipods every other day. However, it became apparent that newly molted lobsters were being eaten by amphipods. After five days, further predation by amphipods was successfully prevented by reducing the daily supply of amphipods to three. Prey remaining in containers were counted and new amphipods were added to equal three. Unlike with clams, amphipods were chosen at random, independent of lobster size. Amphipod escape rates were determined by placing three amphipods in each of 10 empty containers and counting the number escaped after one day. Prey ingestion rates were corrected for escape rates (0.33 amphipods/(container $\times$ day).

Lobsters were maintained on the diets for five weeks. Two days before behavioral bioassays all prey were removed from lobster containers. Amphipods which escaped from containers into tanks were removed. Feeding regimes were reestablished immediately after completion of behavioral bioassays.

Significance of differences between the proportion of lobsters surviving after six weeks was determined for the test groups by unplanned G tests for the heterogeneity of treatments (Sokal and Rohlf, 1981). A similar test was used to determine the effect of duration of diet on frequency distribution of number of prey ingested/(lobster $\times$ day). Differences in wet weight gain of lobsters on the three diets were determined by analysis of variance and Gabriel's multiple comparison of means based on unequal sample sizes (Sokal and Rohlf, 1981).

Preparation of Live Prey Metabolites

One gram wet weight of prey per 100 ml of two weeks or older ("aged") filtered natural seawater (preparation described by Daniel and Bayer, 1987b) was lightly aerated for 10 hr for clam metabolite preparation and only 3 hr for amphipod metabolite preparation in order to eliminate mortality resulting from longer soaking time. Clams were supplied with an algae mixture at the beginning of metabolite preparation. Prey were removed and water was vacuum filtered (GF/C glass fiber) and stored at 4°C until behavioral bioassay within 4 hr.

Half of one preparation of amphipod water was passed through a Sm7 Biobeads column (bed volume = 15 ml) which was subsequently washed with seawater and HPLC-grade water. Adsorbed material, including peptides, was eluted with HPLC-grade 100% methanol. Details of chromatographic procedure were given by Daniel and Bayer (1987b). Untreated amphipod water, seawater fractions (Sm7 filtrate) and rotary evaporated methanol eluent (Me eluent) were stored at −20°C for less than 24 hr before bioassay.

Ammonia, protein, and primary amine concentrations of untreated prey metabolites were determined as described by Daniel and Bayer (1987a).

Behavioral Bioassays

Lobsters within a feeding group were randomly assigned to treatments tested for a given assay experiment. Presence or absence of prey-search response of approximately 100 lobsters was determined using a behavioral bioassay apparatus described by Daniel and Bayer (1987a, b).

Aged filtered seawater was used to dilute the stimulus solution to appropriate concentrations and as a control treatment for all bioassays. In addition, assays of unfractionated prey metabolites included a standard attractant containing 56 μM amines prepared from the G6 filtrate of a suspension of freeze-dried herring extract (preparation described by Daniel and Bayer, 1987b). Bioassay of unfractionated prey metabolites included control, standard, and prey metabolites diluted to 10% and at full strength. Bioassay of fractionated amphipod metabolites included control, untreated amphipod metabolites diluted to 10%, Sm7 filtrate and Me eluent of amphipod metabolites diluted to the same volume as 10% untreated amphipod metabolites.

Feeding groups were assayed for prey-search response as follows: (1) pretreatment test with both prey metabolites; (2) at day 15, amphipod-fed lobsters tested with amphipod metabolites, clam-fed lobsters tested with clam metabolites, and brine shrimp-fed lobsters tested with amphipod and clam metabolites; (3) at day 35, all diet groups tested with each prey metabolite solution and amphipod-fed lobsters tested with untreated and fractionated amphipod metabolites.

Significance of differences between responses to prey metabolites versus

responses to control and responses to treatments of prey-fed group versus response to treatments of brine shrimp-fed group for the same prey metabolites was determined by $R \times C$ log-likelihood test with William's correction (Sokal and Rohlf, 1981).

RESULTS

Responses of Lobsters to Prey Metabolites

Artemia salina-*Fed Lobsters.* Lobsters fed frozen brine shrimp showed some response to both prey metabolites over the five-week test period. Significant prey-search responses to 100% amphipod metabolites were observed at zero and five weeks (Figure 1). No response to 10% amphipod metabolites was apparent at any test period. A significant response to clam metabolites at both concentrations was apparent only at two weeks (Figure 2). Most of the prey-search response to amphipod metabolites at zero and two weeks was contributed by DC lobsters. Response to full-strength amphipod metabolites was 63.6% for DC lobsters ($N = 11$) and 38.9% for NB lobsters ($N = 18$) at zero days, and 50% for DC lobsters ($N = 12$) and 11.1% for NB lobsters ($N = 18$) at two weeks. A larger response of DC lobsters was not evident at five weeks with both groups having a 33.3% response ($N = 12$ for each group). In contrast to these temporal changes in responsiveness, DC and NB lobsters showed similar responses to clam metabolites independent of test period.

Mya arenaria-Fed Lobsters. No increase in response to clam metabolites occurred with feeding experience (Figure 2). Responses were not significant when compared to control for the same assay or to corresponding treatments for brine shrimp-fed lobsters. There were significant responses to 10% and full-strength amphipod metabolites compared to the control response for five-week clam-fed lobsters (Figure 1). However, responses were not significantly greater than response to corresponding treatments of five-week brine shrimp-fed lobsters.

Gammarus oceanicus-*Fed Lobsters.* There was an increase in response to amphipod metabolites with feeding experience (Figure 1). After two weeks, response to amphipod metabolites at full strength and 10% was significantly greater than control, although only the response to 10% metabolites was significantly greater than response of brine shrimp-fed lobsters at two weeks to the same metabolite solution. However, by five weeks, amphipod-fed lobsters responded as vigorously to amphipod metabolites as to herring standard. Responses were significantly greater than control and corresponding treatments of brine shrimp-fed lobsters at five weeks. After five weeks, amphipod-fed lobsters did not show a significant response to 10% or full-strength clam metabolites (Figure 2).

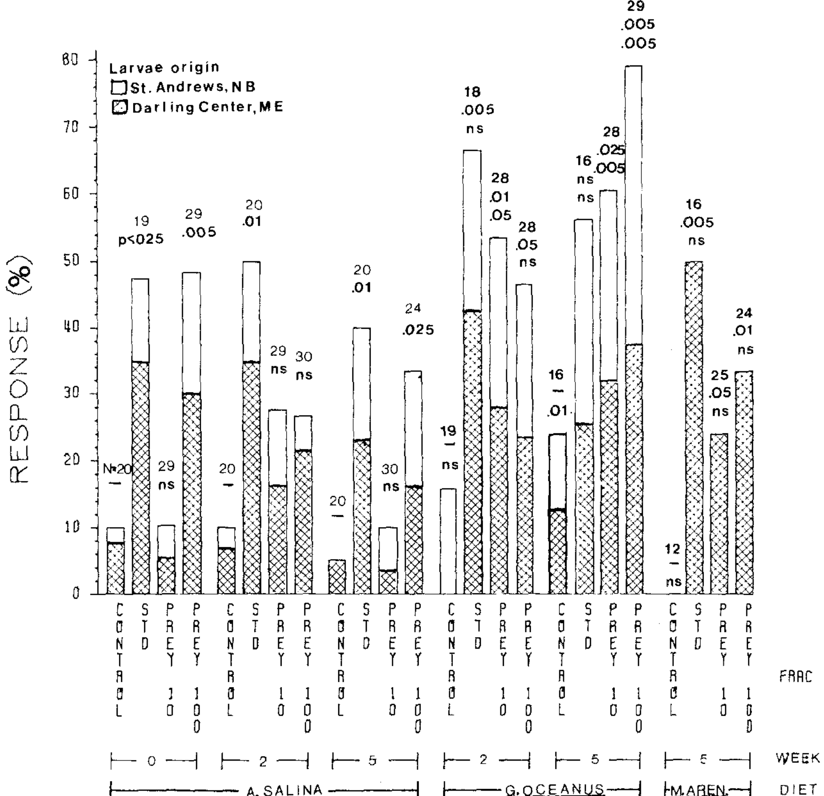

FIG. 1. Prey-search response (%) to amphipod (*G. oceanicus*) metabolites of *A. salina*-fed, *G. oceanicus*-fed, and *M. arenaria*-fed lobsters by week of feeding trial. Control = aged, filtered seawater, Std = herring freeze-dried extract at 56 μM amine; Prey 10 = 10% solution of amphipod metabolites in aged, filtered seawater; Prey 100 = full-strength solution of amphipod metabolites. Hatched areas represent proportion of response due to DC lobsters. Clear areas represent proportion of response due to NB Lobsters. Numbers above bars represent number of lobsters tested followed by (1) level of significance of log-likelihood test for stimulus vs. control and (2) level of significance of log-likelihood test for prey-fed response vs. brine shrimp-fed response to same stimulus at same feeding trial week.

Removal of peptides from amphipod metabolites did not significantly alter prey-search response (Figure 3). Responses to untreated metabolites and Sm7 filtrate were significantly greater than to the control. Response to methanol eluent was similar to control response. Response to untreated metabolites was similar to response to Sm7 filtrate but greater than response to methanol eluent.

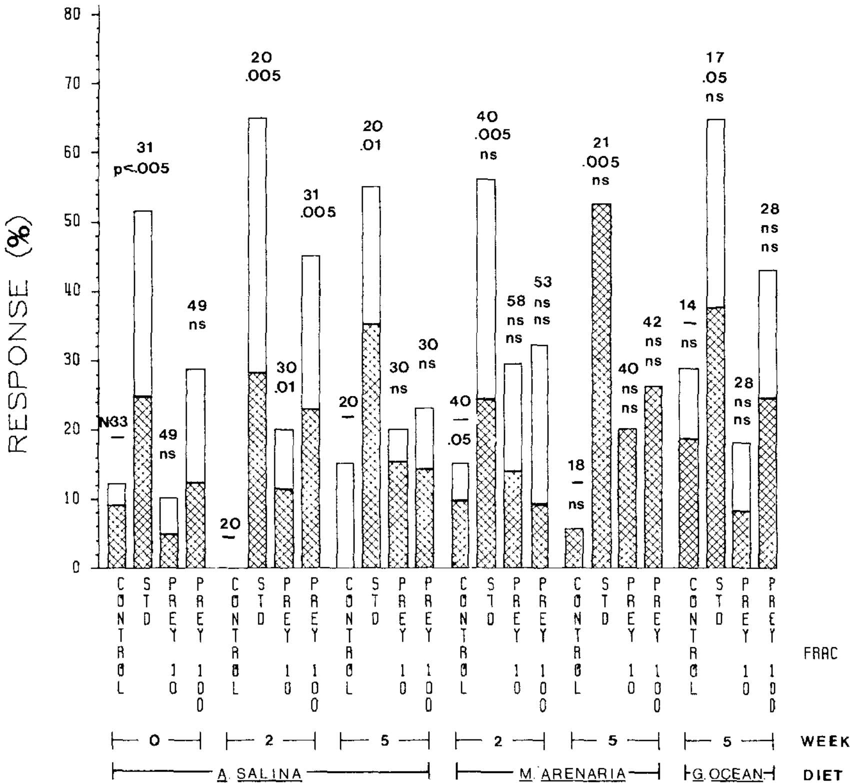

FIG. 2. Prey-search response (%) to clam (*M. arenaria*) metabolites of *A. salina*-fed, *G. oceanicus*-fed, and *M. arenaria*-fed lobsters by week of feeding trial. Control = aged, filtered seawater; Std = herring freeze-dried extract at 56 μm amine; Prey 10 = 10% solution of clam metabolites in aged, filtered seawater; Prey 100 = full-strength solution of clam metabolites. Hatched areas represent proportion of response due to DC lobsters. Clear areas represent proportion of response due to NB lobsters. Numbers above bars represent numbers of lobsters tested followed by (1) level of significance of log-likelihood test for stimulus vs. control and (2) level of significance of log-likelihood test for prey fed response vs. brine shrimp-fed response to same stimulus at same feeding trial week.

Concentration of Soluble Nitrogenous Substances in Prey Metabolites

Soluble protein and amines were undetectable in either prey metabolite preparation by the analytical methods used. Sensitivity of assays was 50 μg/ml (bovine serum albumin equivalents) for protein, 40 μM (DL-alanine equivalents) for primary amines, and 1 μM for ammonia. Ammonia concentrations of prey metabolite preparations were similar, ranging from 39 to 61 μM ($X \pm$ SE, 55 $\pm$ 8.5 μM, N = 6) for amphipod metabolites and from 46 to 80 μM ($X \pm$ SE,

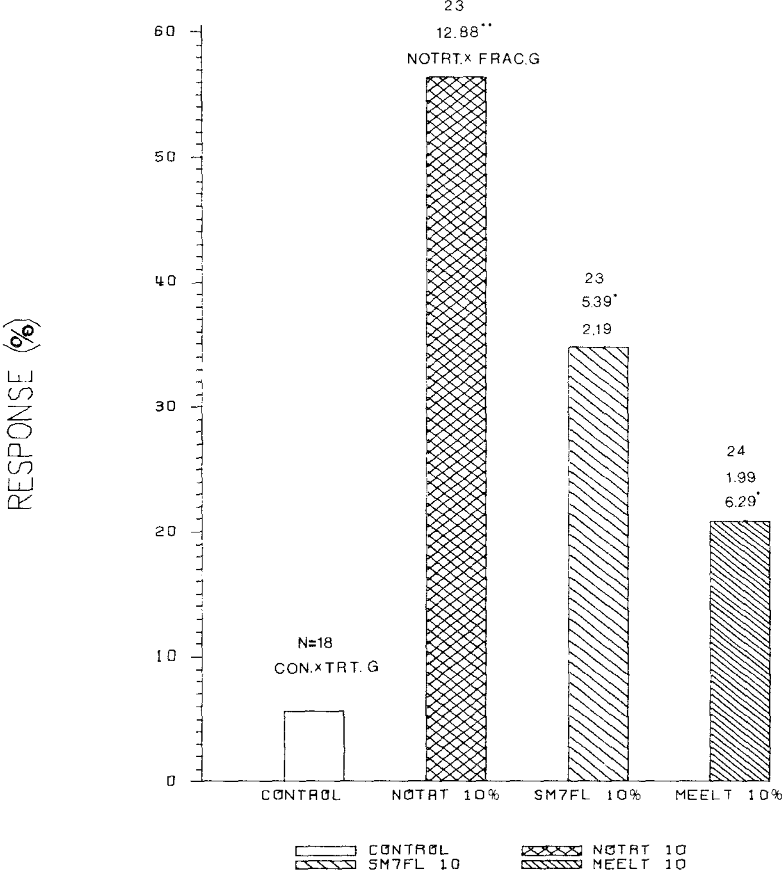

FIG. 3. Prey-search response (%) of amphipod-fed lobsters to control (aged, filtered seawater), unfractionated amphipod metabolites diluted to 10% with aged, filtered seawater, Sm7 filtrate, and Me (methanol) eluent of amphipod metabolites diluted to same volume as 10% unfractionated amphipod metabolites. Numbers above bars represent numbers of lobsters tested followed by (1) G statistic for log-likelihood test of control vs. amphipod metabolites and (2) G statistic for log-likelihood test of unfractionated vs. fractionated metabolites. $^{**}P < 0.01$, $^{*}P < 0.05$.

64 ± 8.7 μM, $N = 8$) for clam metabolites. Levels of ammonia in aged filtered seawater were undetectable.

Condition of Lobsters on Feeding Regimes

Lobsters dragged clams into shelters and broke away shell lip using chelae and maxillipeds. Lobsters under 90 mg appeared to be generally inept at open-

ing even the smallest clams while larger lobsters could open clams within a wide size range. Lobsters swam after amphipods, lunged at nearby amphipods, or tried to capture amphipods after blundering into them. Chelae were used to capture amphipods and maxillipeds were then used to improve grasp. However, even with a firm hold, amphipods were often able to squirm away. The smallest lobsters, which were unable to open clams, were capable of catching and ingesting amphipods. The most surprising observation was the disappearance of 10 of the amphipod-fed lobsters during the first week of the feeding trial. A few appendages and a recent molt shell of a lobster were often found within a large group of amphipods. Only a few molting lobsters did not disappear, leading to the conclusion that amphipods were capable of feeding on the lobsters at this vulnerable stage. By reducing prey numbers to three per day, disappearance of lobsters ceased.

Some marked color difference developed with feeding. Frozen brine shrimp-fed lobsters tended to be pale pink to blue–green, amphipod-fed lobsters were dark red, while clam-fed lobsters were pale blue to blue–green.

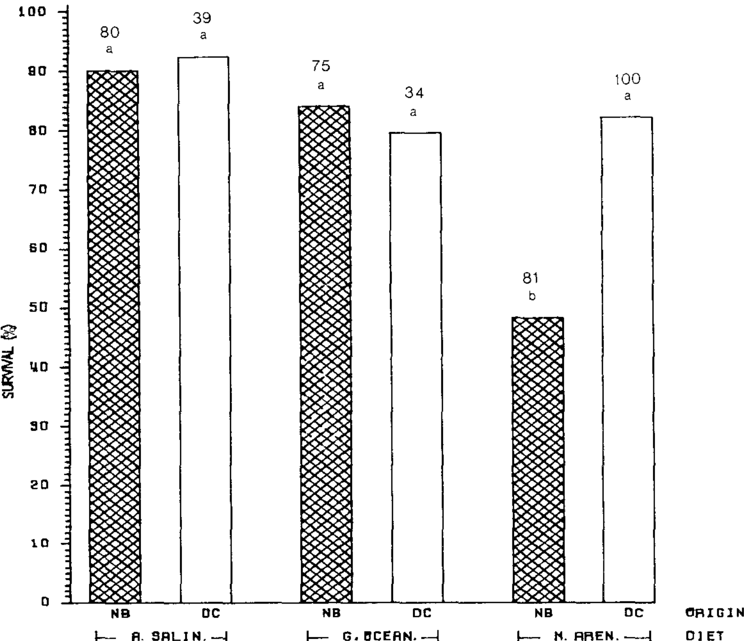

FIG. 4. Survival of *A. salina*-fed, *G. oceanicus*-fed, and *M. arenaria*-fed lobsters. NB = lobsters of New Brunswick origin. DC = lobsters of Darling Center origin. Survival is for a 35-day period with the exception of clam-fed NB lobsters which were maintained for 17 days. Numbers above bars represent numbers of animals at feeding trial initiation. Same letters above bars represent similar survival where G_h has $P > 0.05$. G test for heterogeneity ($df = 5$): all six groups = 50.9, $P < 0.005$.

Feeding rates showed that lobsters were able to capture successfully and ingest live prey over a five-week period. Survival and weight gain were similar for live prey-fed lobsters and frozen brine shrimp-fed lobsters, with the exception of clam-fed lobsters from New Brunswick which showed only 48% survival after 17 days (Figure 4). The low survival of the clam-fed NB lobsters coincided with an approximately 80% decrease in number of prey ingested/(lobster × day) after 16 days (Figure 5). In contrast, after five weeks, clam-fed lobsters

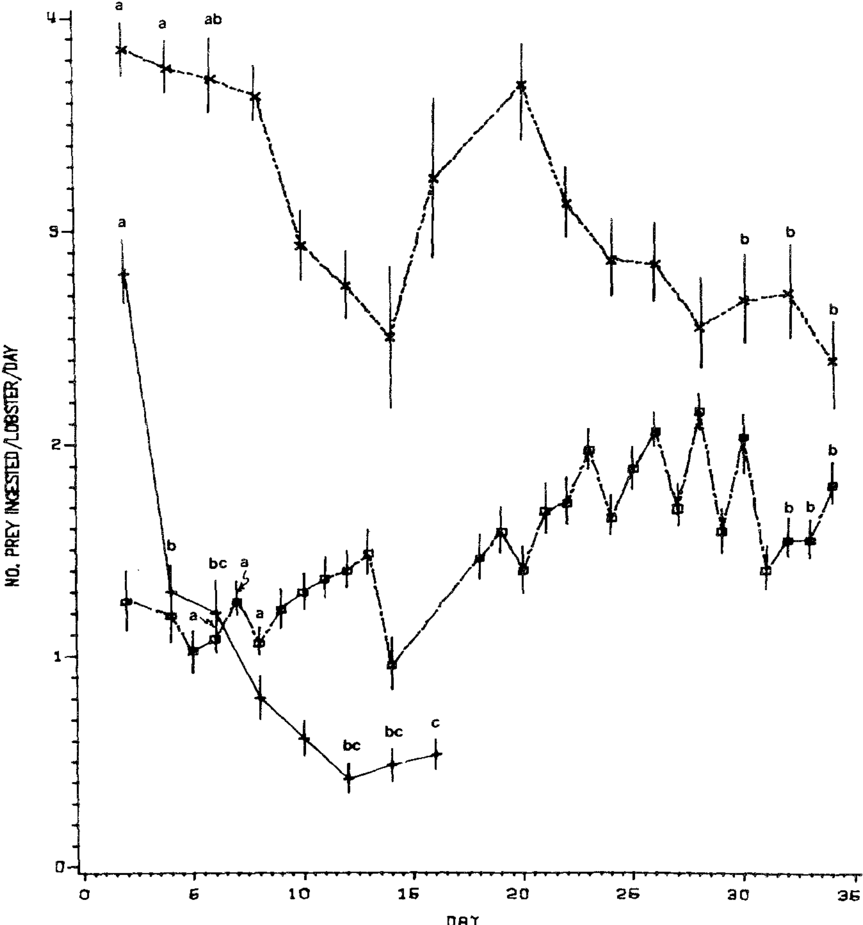

FIG. 5. Feeding rates (number of prey ingested/(lobster × day) over duration of feeding trials ($X \pm$ SE). Clam-fed NB lobsters = +, ——, N = 77–58; clam-fed DC lobsters = ×, ------, N = 100–82; amphipod-fed lobsters = □, — · — · —, N = 105–90. G tests for heterogeneity was performed on frequency distribution of first three and last three observations for each feeding group. Same letters above represent similar frequency distribution, where G_h has $P > 0.05$.

from the Darling Center showed a smaller decrease of approximately 30% and amphipod-fed lobsters appeared to increase prey ingestion rates by about 25%.

These observations were tested statistically by comparing the frequency distributions of number of prey ingested per lobster for the first three observations to that of the last three observations for each prey-fed group. After 12 days, a marked shift to lower numbers of clams ingested by NB lobsters was apparent, with no lobster consuming more than six clams in a two-day period (Figure 5, overall $G_h = 233.9$, $df = 50$, $P < 0.005$). This is a likely explanation for the high mortality observed in this group. These lobsters were smaller (0.063 ± 0.0010 g (SE), $N = 50$) than DC lobsters (0.13 ± 0.018 g (SE), $N = 35$) in the same feeding group and were placed with larger DC lobsters (0.24 ± 0.015 g (SE), $N = 65$). Still, DC lobsters showed a significant, although not as dramatic, shift toward reduced feeding rates by the end of the experiment (Figure 5, overall $G_h = 132.9$, $df = 50$, $P < 0.005$).

Since DC and NB lobsters fed amphipods showed similar ingestion rates, these groups were pooled. The first three observations could not be used for comparison with final observations since lobsters were fed initially higher numbers of amphipods. At day 6, most lobsters ingested only one amphipod per day; but, by 34 days, a majority was eating three amphipods per day, a significant increase in feeding rate (Figure 5, overall $G_h = 132.8$, $df = 50$, $P < 0.005$).

Amphipod-fed lobsters increased weight by 100% after five weeks, compared with a 72% increase for clam-fed lobsters and only an 18% increase for frozen brine shrimp-fed lobsters (Figure 6). Weight increases in amphipod-fed and clam-fed lobsters were significant, but not for lobsters fed brine shrimp. Final weights of amphipod-fed lobsters were significantly greater than final weights of brine shrimp-fed lobsters. Comparison with weights of clam-fed lobsters was inappropriate, due to the significantly higher initial weights of lobsters in that group.

DISCUSSION

These results show the development, through feeding experience, of prey-search behavior toward metabolites of live amphipods in previously naive postlarval lobsters. The results support the hypothesis that ingestive conditioning explains the discrepancies between chemosensory responses of adult, field-collected and laboratory-reared lobsters to some prey metabolites. This was demonstrated in two ways: response of amphipod-fed lobsters toward amphipod metabolites increased with feeding experience relative to response to filtered seawater and standard attractant and relative to response of brine shrimp-fed lobsters towards amphipod metabolites. Chemical fractionation of amphipod metabolites indicated that attractants were confined to the same fraction as for

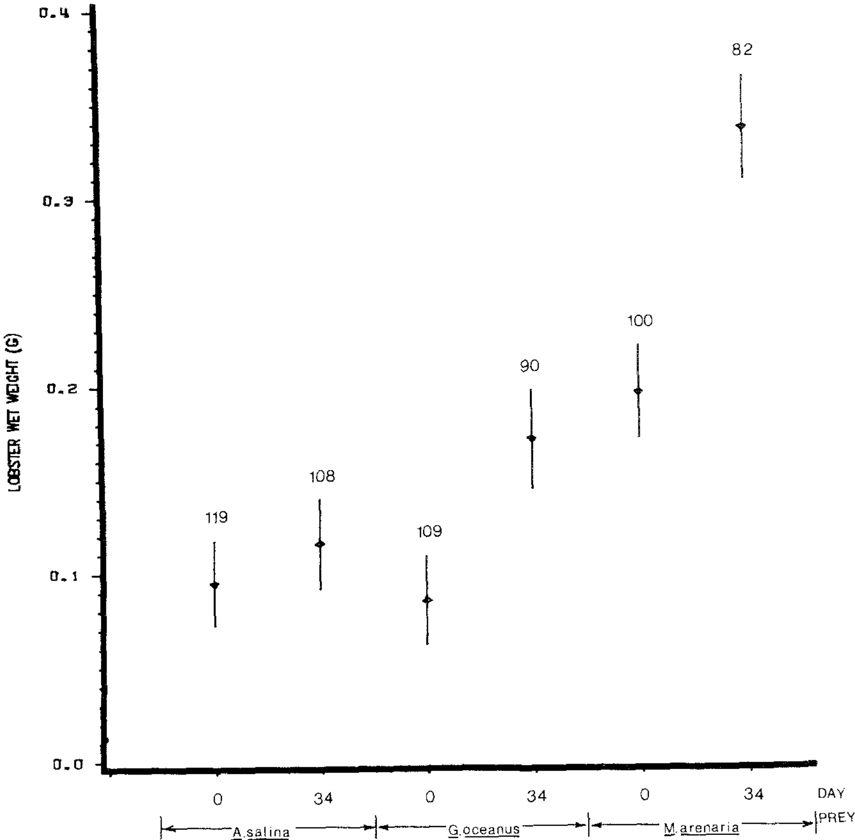

FIG. 6. Mean lobster wet weights and confidence intervals at feeding trial initiation and at termination. Numbers above bars represent numbers of animals weighed. ANOVA, $N = 608$, $F = 56.24$, $P < 0.0001$; 95% confidence intervals determined by Gabriel's multile comparison of means based on unequal sample sizes when mean square error = 0.01396, Student's maximum modulus (M) = 2.939.

food extracts, i.e., polar, low-molecular-weight compounds (Daniel and Bayer, 1987a, b). Development of response appeared to be specific for amphipod metabolites. An increase in response was not observed toward clam metabolites by amphipod-fed, clam-fed, or brine shrimp-fed groups. Responses of predatorily naive lobsters to clam and amphipod metabolites were low and inconsistent, similar to the low responses observed towards metabolites of sea stars (*Asterias vulgaris*), rock crabs (*Cancer irroratus*), soft clams (*Mya arenaria*), and blue mussels (*Mytilus edulis*) (Daniel and Bayer, 1987). Responses of lobsters which previously fed on a wide variety of prey before initiation of the

experiment (DC lobsters) appeared to have an initial response to amphipod metabolites which was lost after five weeks of feeding on frozen brine shrimp, although numbers tested were too small to be conclusive. Similar memory loss has been shown for terrestrial snails (Croll and Chase, 1977).

A confounding result was the inability of postlarval lobsters to develop responses towards clam metabolites with feeding experience. Chemical cues from other bivalve species elicit predatory behavior in older individuals; however, responses appear to be lower than towards decapod prey. Derby and Atema (1981) were able to show responses towards metabolites of two species of mussels (*Modiolus modiolus* and *Mytilus edulis*) with feeding experience. Hirtle and Mann (1978) found responses to *M. edulis* metabolites, while McLeese (1970) and Carter and Steel (1982) did not observe a significant response to *M. arenaria* metabolites. Responses to crab metabolites (*Carcinus maenus* and *Cancer irroratus*) were stronger than responses than responses to bivalve metabolites (*M. edulis*) (Hirtle and Mann, 1978; Carter and Steele, 1982).

Thus, a partial explanation of our inability to observe improved responses to clam metabolites might be that metabolites from live crustaceans are more effective attractants for lobsters than are bivalve metabolites. The difference in effectiveness of the metabolites could be due to differences in the quantity and/or quality of their components. Although the techniques used in the present study were not sufficiently sensitive to determine any such differences, this hypothesis is supported by Stephens' (1972) observations of greater excretion rates (particularly amino acids) in crustaceans relative to bivalves. However, it is clear that older lobsters can elevate their sensitivities towards bivalves with continued feeding (Derby and Atema, 1981). Differences between our results and those of Derby and Atema (1981) may be a result of the age of the lobsters, the sensitivities of behavioral assays (they counted number of times different behaviors were displayed rather than our "all-or-none" approach), or simply that lobsters are more sensitive to metabolites from mussels than from clams.

The difference in ingestive conditioning results from clam-fed and amphipod-fed lobsters might be due to differences in the genetic predisposition of lobsters to learn different chemicals. The evolution of these predispositions might be related to the food quality of prey. A central hypothesis of optimal foraging theory is that predators tend to choose prey which maximize rate of food intake while foraging (Krebs, 1978). Prey type chosen may be a function of density, size, palatability, conspicuousness, or nutrient quality. Predators may maximize intake of a preferred prey species by increasing efficiency of prey search or handling through learning (Morgan, 1972; Edwards, 1975; Lawton et al., 1974; Cunningham and Hughes, 1984; Dunkin and Hughes, 1984). For example, this might be achieved through reinforcement of a "chemical search image" which acts to focus prey-search behavior toward a particular prey (Atema et al., 1980). Animals may reinforce chemical search images

through ingestive conditioning as defined by Wood (1968). The net outcome is that feeding experience with high-quality foods tends to reinforce inherent or genetically predispositioned search images, resulting in improved detection and ultimately increased intake.

Lobsters fed amphipods showed equivalent survival, slightly greater weight gain, increased prey-ingestion rates, and more natural color than clam-fed lobsters. While both groups showed positive weight gain, amphipod-fed lobsters had an increase in prey ingestion, while clam-fed lobster ingestion rates actually decreased. Furthermore, amphipod-fed lobsters had coloration considered indicative of good health, in contrast to clam-fed lobsters. Blue color is a result of lack of suitable carotenoid pigments in diet and can be improved through supplementation of diet with crustacean tissue (Hughes and Matthiesson, 1962; D'Agostino, 1980; Good et al., 1982; D'Abramo et al., 1983). Addition of carotenoids to a formulated diet did not result in an increase in growth in *H. americanus*, but did produce coloration similar to wild lobsters (D'Abramo et al., 1983). However, greater survival was achieved with live *Artemia salina*, which, due in part to high levels of carotenoids, D'Abramo et al. (1983) argue may constitute a high-quality diet. Search image formation in lobsters may be biased genetically to those prey of higher nutritional value such as amphipods. This might result in an increase in prey-ingestion rates as predicted by optimal foraging theory. In contrast, lobsters may not be able to learn as readily, through conditioning, the chemical identity of prey of low dietary value, such as clams, resulting in low ingestion rates.

The hypothesis of a reinforcement in search image with feeding experience on a high-quality food implies a selective improvement in response toward the prey species making up the diet as demonstrated for older *H. americanus* by Derby and Atema (1981). This is in contrast to a nonselective improvement in prey-search response in which ingestion of one prey species leads to a general increase in response to a wide variety of prey species metabolites. Given the consistently subthreshold responses of postlarval lobsters to clam metabolites observed in this study, it is difficult to differentiate between selective and nonselective improvements in response to prey metabolites. Clam metabolites may be qualitatively or quantitatively less potent to preconditioned lobsters than amphipod metabolites, such that the conditioned change was still insufficient to produce an observable suprathreshold response. However, two observations support the involvement of selective improvement in some cases: the large magnitude of the increase in response observed toward amphipod metabolites after conditioning, and the lack of response to amphipod metabolites for lobsters fed clams. A convincing demonstration of one of these hypotheses would require preparation of a more potent clam metabolite solution, perhaps through concentration, or use of an alternate prey as food in which suprathreshold concentrations could be produced in preconditioned or conditioned lobsters.

Acknowledgments—The authors wish to express their gratitude to Drs. A.M. Mackie and C. D. Derby for providing helpful comments and criticisms of the manuscript. Technical assistance was provided by Lenora Daniel. Sam Chapman and Mike Eagles graciously provided postlarval lobsters from their hatcheries. Research described represents partial fulfillment of Doctoral degree for the principal author and was funded by the University of Maine Sea Grant Program NAB1AA-D-00035 and the Maine Agricultural Experiment Station.

(Received March 28, 1986; accepted July 16, 1986)

Abstract—Electroantennogram (EAG) responses of male *Rhopobota naevana* (Hübner), the blackheaded fireworm, to all of the monoene straight-chain 12- and 14-carbon alcohols and acetates implicated (*Z*)-11-tetradecen-1-ol (*Z*11–14:OH) and its acetate (*Z*11–14:Ac) as sex pheromone components. *Z*11–14:Ac produced the strongest EAG response of all compounds tested. Gas chromatography-mass spectrometry (GC-MS) analysis of extract of female sex pheromone glands (SPG) confirmed the presence of *Z*11–14:OH (125 pg/female) and *Z*11–14:Ac (600 pg/female) (all other monoenes had different retention times). In field tests, traps baited with *Z*11–14:OH alone captured males, but traps baited with *Z*11–14:Ac alone did not. Traps baited with a combination of *Z*11–14:OH and *Z*11–14:Ac in various ratios did not produce better trap catches than *Z*11–14:OH alone. (*Z*)-9-Dodecen-1-ol acetate (*Z*9–12:Ac), reported by others to be a field attractant, did not produce trap catch in our tests, but in combination with *Z*11–14:OH (98:2 in septa corresponding to 95:5 in vapor, *Z*11–14:OH to *Z*9–12:AC) produced a sevenfold increase in catch over *Z*11–14:OH alone. If *Z*9–12:AC had been present in extract of SPG at 2–5% of *Z*11–14:OH, it would not have been detected in our GC-MS experiment.

Key Words—*Rhopobota naevana* (Hübner), *Rhopobota unipunctana* Haworth, *Rhopobota naevana naevana* (Hübner), blackheaded fireworm, Lepidoptera, Tortricidae, Olethreutinae, sex pheromone, sex attractant, (*Z*)-11-tetradecen-1-ol, (*Z*)-11-tetradecen-1-ol acetate, (*Z*)-9-dodecen-1-ol acetate.

INTRODUCTION

The blackheaded fireworm, *Rhopobota naevana* (Hübner) (Brown, 1983), formerly *R. unipunctana* Haworth (Brown, 1980; Werner, 1982) and prior to that *R. naevana naevana* (Hübner) (Sutherland, 1978), is a worldwide pest. Throughout the United States it is a major pest of cranberry (Franklin, 1948). It is also noted as a pest of huckleberry (Breakey, 1960) and commercially grown holly (Swenson, 1958). In Europe and Asia, besides cranberry, it is a pest of cowberry and bird cherry (Shutova et al., 1981; Tibatina, 1976) and of fruit trees including apple, pear, plum, and cherry (Ivinskis and Pakal'nishkis, 1983).

No previous chemical studies of the structure of its sex pheromone have been reported, but in field screening studies, Ando et al. (1977) reported that *R naevana* males were caught in traps baited with (Z)-9-dodecen-1-ol acetate (Z9-12:Ac). We undertook a laboratory and field study of the structure of sex pheromone components in order to develop a lure which could eventually be used for population monitoring in control programs.

METHODS AND MATERIALS

Insects. Blackheaded fireworm larvae, in their protective leaf-ties, were collected from an abandoned cranberry bog located near Long Beach, Washington. Foliage was clipped a few centimeters below the leaf-ties which contained the larvae, placed in clear plastic shoe boxes, covered with plastic screen, transported to the laboratory, and then placed in a rearing room at 21°C, 55-60% relative humidity, and a 14:10 hr light-dark cycle. Periodically, the ties were examined for pupae which, upon formation, were transferred individually to 6 × 1½ cm corked, glass vials containing a strip of soft tissue paper to cushion the pupae. After adult emergence, each moth was sexed and females were held in small cages (25 × 20 × 30 cm). Adults were provided water via a vial containing a dental wick.

Collection of Pheromone. Female moths (2-5 days old) were collected 2 hr after the beginning of scotophase and placed in a refrigerator for 10 min to inactivate them. Abdominal tips were severed and steeped for 15 min in dichloromethane. Then the solution was removed with a syringe and stored at −20°C until used.

Electroantennogram (EAG). The technique was the same as previously described except that 60-μg charges were used (McDonough et al., 1980). Values for blanks were subtracted from values for test compounds, which were expressed as a percentage of a reference compound value.

Model Compounds Used in EAG and GC-MS Studies. All of the *n*-alkenyl alcohols and acetates possessing 12 and 14 continuous carbon atoms in the chain were prepared and purified by established synthetic methodology (Voerman,

1979). All compounds were at least 98% pure by gas chromatographic analysis and contained 1% or less of the geometrical isomer.

Gas Chromatograph–Mass Spectrometry (GC-MS). The following instrument was used to characterize model compounds and the components of the extract of female *R. naevana* sex pheromone glands: Hewlett-Packard, Avondale, Pennsylvania, model 5970 quadrupole mass selective detector with computerized data collection and a model 5790 gas chromatograph inlet equipped with fused silica capillary column (60 m × 0.25 mm ID) with splitless injection. The liquid phase was methyl silicone (DB-1).

Field Studies. Compounds used as candidate lures in field tests were dissolved in 100 μl of dichloromethane and impregnated into red rubber septa (size No. 1, West Co., Phoenixville, Pennsylvania). Septa used as controls contained only dichloromethane. A septum was placed on the bottom in the center of a Pherocon IC trap (Trece Corp., Palo Alto, California). In place of the usual 5-cm spacer between trap top and bottom, a 3.5-cm spacer was made by cutting the 5-cm spacer. Then the distance between top and bottom was about 0.7 cm at the widest points (the corners of the top and bottom touched). When the 5-cm spacer was used, large captures in blank traps were frequently obtained. The trap was suspended from a movable metal arm (an 18 × 23-cm shelf bracket) attached by a metal hose clamp to a 120-cm long wooden broom handle driven into the ground. This arrangement allowed the trap to be positioned just above the foliage where maximum flight activity was thought to occur. The traps were placed randomly throughout the bogs at approximately 16.5-m intervals. The trap data were transformed into $\sqrt{X + 0.5}$ and compared by Duncan's multiple-range test (DMRT) ($P = 0.05$). The compounds tested and their half-lives in rubber septa at 22°C were: *Z*11–14:Ac, 310 days; *Z*11–14:OH, 117 days; and *Z*9–12:Ac, 44.8 days (Butler and McDonough, 1979, 1981). These data were used to calculate dosages in the septa so that systematic changes of ratios in the vapor were obtained.

RESULTS

EAG Profile. A graph of male antennal responses of all of the monounsaturated 12- and 14-carbon alcohols and acetates is given in Figure 1. The strongest response to the tested compounds was obtained from *Z*11–14:Ac which produced a 5.8-mV response in the best antennal preparation. More typical values for *Z*11–14:Ac were about 3 mV. All the other values are expressed as a percentage of the value of this compound. Besides *Z*11–14:Ac, the compound which is the most obvious candidate for a pheromone component is *Z*11–14:OH. *E*9- and *Z*10–12:Ac and *Z*9–12:OH also produced fairly significant responses.

GC-MS. An extract of 20 female abdominal tips were analyzed in the single-ion monitor mode (SIM). The ions monitored were those characteristic of dodecenyl and tetradecenyl alcohols and acetates: 61, 166, 168, 194, 196. The

analysis showed the presence of Z11–14:Ac (600 pg/female) based on m/z = 194 (M^+-60), 166 (M^+-60-28), and 61 ($CH_3CO_2H_2$) and a distinctive retention time (t_r) of 23.32 min. During the standard runs, the nearest tetradecenyl acetates were E11–14:Ac with t_r = 23.04 and E12–14:Ac with t_r = 23.53. Retention times were reproducible within 0.04 min. Also 14:Ac was present (500 pg/female) based on m/z = 196, 168, and 61 and t_r = 23.42 min, identical to the standard. Z11–14:OH (125 pg/female) was also present based on m/z = 194 (M^+-18) and 166 (M^+-18-28) and a distinctive t_r = 18.20 min. The t_r of the closest standards were E11–14:OH, 17.98 min, and Z12–14:OH, 18.32 min. No evidence was found for 12-carbon alcohols or acetates. The sensitivity of this analysis was about 1 ng, so that if 12-carbon alcohols or acetates were present at levels below about 40% of Z11–14:OH, they would not have been detected.

Field Tests. Table 1 shows the 1983 field tests of Z11–14:OH and Z11–14:Ac. At a 1-mg dosage, Z11–14:OH evoked trap catch while Z11–14:Ac did not. Mixtures of these two compounds did not produce trap catch better than Z11–14:OH alone. In treatments 4, 3, and 2, trap catch decreased as the dosage of Z11–14:OH decreased. In a 1984 test, Z9–12:Ac (reported by Ando et al., 1977, to be a field attractant for *R. naevana*) was compared with Z11–14:OH and combinations of the two (Table 2). Z9–12:Ac alone (treatment 9) did not produce trap catch better than the control (treatment 10), while Z11–14:OH did (treatment 1). However, the best combinations were substantially superior to Z11–14:OH alone. The 95:5 ratio in the vapor of Z11–14:OH to Z9–12:Ac produced a 7.2-fold greater catch than Z11–14:OH alone. A plot of the data of tests 9–2 gave an excellent straight line: $n = 0.1517\,p + 1.138$ ($R^2 = 0.974$) where n = number or *R. naevana* caught per trap-day and p = percent of Z11–14:OH in the vapor.

[a]Total dosage was 2.0 mg/septum and there were 4 replicates.

DISCUSSION

Based on the EAG and the GC-MS studies, one would expect Z11-14:Ac to be the major sex pheromone component, that it would be required for male upwind flight, and that Z11-14:OH might be either an obligatory or synergistic component of the sex pheromone. The finding that Z11-14:Ac alone did not produce trap catch, while Z11-14:OH is a weak but significant attractant, and blends of Z11-14:OH and Z11-14:Ac were not superior to Z11-14:OH alone was surprising. The failure of Z11-14:Ac to affect trap catch in our tests does not mean it is not a sex pheromone component, but does imply that it has little effect on upwind flight. It might mediate some other aspect of male behavior.

During the summer of 1985, we became aware that Slessor et al. (1987) had also studied the sex pheromone of the blackheaded fireworm. The lure they developed used three compounds (Z11-14:Ac, Z11-14:OH, and Z9-12:Ac). It is difficult to compare our field study with theirs because the two studies used such different protocols. The dosage levels Slessor et al. (1987) used were much lower than ours. Male behavior toward different ratios of pheromone components can change substantially with dosage level (Roelofs, 1978). Clearly more extensive field tests are needed before the optimum lure can be defined with confidence.

Although the lure we developed (Z11-14:OH + Z9-12:Ac, 98:2; total dosage = 2 mg) may not be the optimum, it appears to be reasonably potent. This lure has been effective in the development of a monitoring program for cranberries in Massachusetts. A total of 2879 male *R. naevana* were captured

in 58 traps which had been placed in 58 bogs during an eight-week period in 1985. In nine of the bogs where only one male was captured, there was no subsequent evidence of infestation (Sherri L. Roberts, University of Massachusetts, personal communication).

Acknowledgments—We thank Dr. Carl Shanks, Washington State University, for supplying cranberry bogs for study, and Ms. C.L. Smithhisler, Yakima Agricultural Research Laboratory, for technical assistance.

Abstract—Factors which establish whether tannin and protein interact to form soluble complexes or precipitates were identified. The ratio of tannin to protein in the reaction mixture influenced solubility of the tannin-protein complexes. At protein-to-tannin ratios larger than the optimum ratio, or equivalence point, soluble tannin-protein complexes apparently formed instead of insoluble complexes. Several other factors influenced the amount of protein precipitated by tannin-containing plant extracts, including the length of the reaction time and the conditions of the tannin extraction. The analytical and ecological significances of soluble complexes were considered. A titration method which allows simultaneous determination of the equivalence point and assessment of the protein-precipitating capacity of any plant extract was developed. It was postulated that in vivo, tannin and protein may not only form insoluble complexes with antinutritional effects, but may also form soluble complexes which have unknown metabolic effects.

Key Words—Tannin, soluble tannin-protein complexes, digestibility-reducing substances, protein precipitation, phenolic anlysis.

INTRODUCTION

Tannin, a constituent of the leaves and stems of many plants, may defend plants from herbivores. One possible defensive function of tannin is precipitation of protein in the herbivore's digestive tract. Precipitated protein would presumably be less digestible than soluble protein, and the herbivore would thus obtain

0098-0331/87/0500-1243$05.00/0 © 1987 Plenum Publishing Corporation

inadequate dietary protein from tannin-rich plants (Fenny,1976; Rhoades and Cates, 1976). In vitro, tannin precipitates proteins from aqueous solution at moderate pH (Hagerman and Butler, 1980a; Hagerman and Klucher, 1986; McManus et al., 1981; Goldstein and Swain, 1965), and thus tannin might be expected to form precipitates in the guts of herbivores. The ability of tannin-containing plant extracts to precipitate protein is a good predictor of protein digestibility for several large mammals (Robbins et al., 1987). Some ecological studies support the hypothesis that precipitation of proteins by tannin is important in plant defense (Schultz and Baldwin, 1982; Walters and Stafford, 1984).

However, there are several reasons to think that the potential of tannin to precipitate protein is not nutritionally significant to certain herbivores. For example, the digestive tract fluids of some insects contain surfactants and are maintained at high pH, factors which inhibit precipitation of proteins by tannin (Martin and Martin, 1984; Martin et al., 1985). Some mammals also have mechanisms for preventing detrimental protein precipitation by tannins, such as the ability to secrete tannin-binding proteins (Mehansho et al., 1983). Under some conditions, tannin increases the susceptibility of proteins to proteolytic attack (Mole and Waterman, 1985). These types of evidence have stimulated a few authors to argue that tannin is a toxic defensive compound which is absorbed rather than an antinutritional compound (Zucker, 1983; Martin and Martin, 1984).

Resolution of the controversy over the defensive role of tannin calls for more comprehensive correlative studies of the chemical characteristics of tannin and the fitness of tannin-containing plants. One chemical characteristic of tannin-containing plants which is frequently measured is the protein-precipitating capacity, expressed as the amount of protein precipitated per milligram of plant tissue. Several assays are avilable for determining the protein precipitating capacity of tannin. In the radiolabeled protein-precipitation method, the precipitation of iodine-125-labeled bovine serum albumin (BSA) is measured radiochemically (Hagerman and Butler, 1980a). In the method of Martin and Martin (1982), the amount of unprecipitated BSA is measured colorimetrically. In the dye-labeled protein precipitation method the precipitation of blue dye-labeled BSA is determined colorimetrically (Asquith and Butler, 1985). BSA is used as the test protein in all three of these methods, but the methods do not give comparable results. In one recent study, the protein-precipitating capacity of a tannin-containing extract estimated with the dye-labeled protein-precipitation assay was three- to four-fold larger than the capacity as estimated with the Martin and Marin assay (Robbins et al., 1987). The differences between the assays make it impossible to directly compare experiments from labs which routinely use different tests. Futhermore, the dependence of the protein-precipitation capacity on the assay method makes it difficult to establish whether the precipitating capacity of the plant is correlated with defensive ability.

The purpose of this study was to compare these three assays and to identify the variables which affect the results obtained. It was found that the ratio of protein to tannin in the reaction mixture significantly affected the amount of protein precipitated. At ratios of protein to tannin larger than the optimum ratio, soluble tannin–protein complexes apparently formed instead of insoluble complexes. Based on the results of these studies, a recommended protocol for determining the protein-precipitating capacity of tannin-containing plant extracts was established. The tendency of tannin to form soluble complexes as well as insoluble complexes with protein supports the hypothesis that tannin may not act exclusively as a protein-precipitating agent in vivo.

METHODS AND MATERIALS

Tannin and Plant Extracts. Condensed tannin was purified from *Sorghum bicolor* grain (Hagerman and Butler, 1980b), and hydrolyzable tannin was purified from commercial tannic acid (Mallinckrodt, Inc., St. Louis, Missouri) (Hagerman and Klucher, 1986).

The plant extracts were prepared from air-dried forage samples of various high-tannin plants (Robbins et al., 1987). For most experiments, 1.5 g of the dry forage was extracted with 50 ml of 50% (v/v) aqueous methanol while sonicating for 15 min; the extract was separated from the tissue by vacuum filtration. The tissue was then extracted with 50 ml of 50% methanol at 90–95°C for 8 min. This extraction was repeated twice more with fresh 50-ml aliquots of 50% methanol. Each extraction was followed by vacuum filtration to separate the extract from the tissue. The four extracts were then combined to give a final extract volume of approximately 200 ml. Each milliliter of the extract was equivalent to 7.5 mg forage.

For a few experiments, smaller amounts of tissues were extracted following the same protocol. The four sequential extractions were applied to 100-mg samples of dry tissue, using 2.0 ml of 50% methanol for each of the four steps. The extracts were separated from the tissue by centrifugation, and the four combined to yield a final volume of eight ml. Each milliliter of the extract was equivalent to 12.5 mg forage.

Precipitation Assays. Similar procedures were used for all three of the precipitation assays. The sample volume was adjusted to a constant volume with 50% methanol in each experiment. For all experiments except the kinetics experiment, purified tannin samples were allowed to react with the protein for 15 min at room temperature and the crude plant extracts were allowed to react with the protein for 24 hr at 4°C before separating the precipitate from the supernatant. The precipitates were always separated from the supernatant by centrifugation for 15 min at 2000 *g*.

The colorimetric assay for protein-precipitable phenolics was performed as described by Hagerman and Butler (1978). The sample was added to 2.0 ml buffer containing 2 mg BSA or iodine-125-labeled BSA. After centrifugation, the tannin–protein precipitate was dissolved and the color was developed (Hagerman and Butler, 1978). The absorbance at 510 nm (A_{510}) was determined.

The radiolabeled protein-precipitation assay was performed as described by Hagerman and Butler (1980a). The sample was added to 2.0 ml buffer containing up to 12 mg iodine-125-labeled BSA. After centrifugation, the precipitate was counted in a gamma counter and the amount of protein precipitated was calculated from a standard curve relating counts per minute to milligrams BSA. If desired, the isolated precipitate could then be dissolved and the precipitated phenolic determined colorimetrically as described above.

The dye-labeled protein precipitation assay was performed as described by Asquith and Butler (1985). The sample was added to 4.0 ml buffer containing about 8 mg of the blue dye-labeled BSA. After separation of the precipitate from the supernatant, the precipitate was redissolved in 3.0 ml of sodium dodecyl sulfate–isopropanol–triethanolamine reagent (Asquith and Butler, 1985), and the absorbance at 590 nm (A_{590}) was determined. The protein concentration of the blue dye-labeled BSA was determined using the Lowry assay (Peterson, 1983). The A_{590} values were converted to milligrams protein with the calibration line obtained by diluting aliquots of the blue dye-labeled BSA solution to 3.0 ml with the sodium dodecyl sulfate–isopropanol–triethanolamine solution. Each new batch of blue dye-labeled BSA was restandardized; a typical calibration line had the equation $A_{590} = 0.292$ (mg BSA) $+ 0.035$.

The protein precipitation assay of Martin and Martin (1982), was performed essentially as described by the authors. The sample was added to 1.4 ml buffer containing 1.47 mg of BSA. After separating the supernatant and precipitate, the supernatant was applied to a gel filtration column. Either commercially prepared columns (Pharmacia PD-10 columns; Pharmacia Inc., Piscataway, New Jersey), or equivalent columns made from 10-ml disposable pipets packed with Bio-Gel P-6DG (Bio-Rad Laboratories, Richmond, California) were used; columns could not be reused. The unprecipitated protein was separated from unprecipitated tannin on the column; all the protein was eluted in the first 6 ml of eluent. The protein in the eluate was determined with a dye-binding assay (Bradford, 1976), and the amount of protein precipitated was calculated by difference. If desired, the protein-precipitable phenolics in the precipitate could be determined colorimetrically as described above.

The competitive binding assay for determining the affinity of the dye-labeled protein for tannin was performed as described by Hagerman and Butler (1981). Various amounts of blue dye-labeled BSA were mixed with the radiolabeled protein, and purified tannic acid was then added. The amount of iodine-125-labeled protein precipitated was determined by counting the precipitate with a gamma counter.

RESULTS

The formation of tannin–protein precipitates is time- and temperature-dependent. The crude extracts from tannin-containing plants formed more precipitate after 24 hr of reaction with protein at 4°C than after only 15 min of reaction at room temperature (Figure 1). More precipitate formed after 24 hr of reaction at 4°C than after 24 hr of reaction at room temperature (data not shown). The difference in precipitation at the two times depended on the tannin source; the extract of alder formed 79% more precipitate after 24 hr than after 15 min, while the extract of fireweed flower increased only 20% between 15 min and 24 hr (Figure 1). For all extracts, the precipitation reaction was complete after 24 hr at 4°C.

The data shown in Figure 1 are from an experiment in which protein precipitable phenolics were determined after the reaction between protein and tannin. Similar data were obtained if, instead of measuring precipitated phenolics, precipitated protein was measured using either the radiolabeled BSA protein-

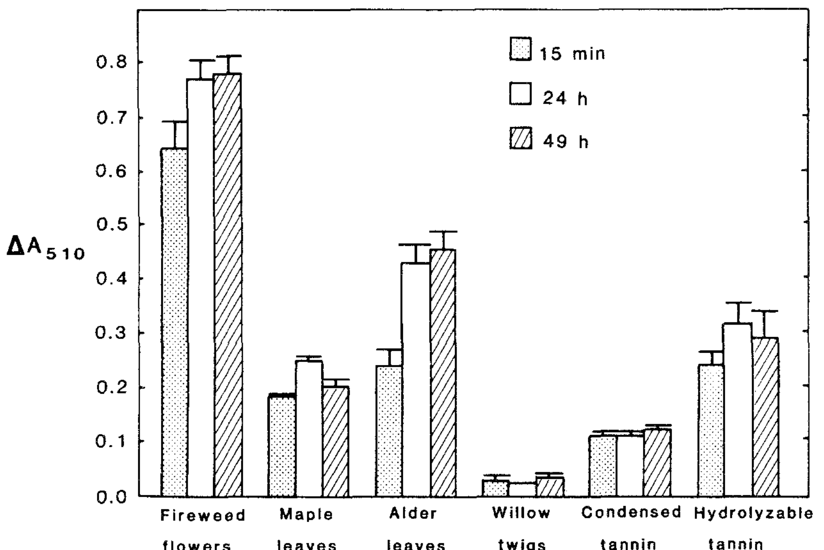

FIG. 1. Dependence of formation of tannin–protein precipitates on time. A 0.25-ml aliquot of the tannin-containing solution was mixed with 2.0 ml buffer containing 6.77 mg ^{125}I-labeled BSA. The mixtures were allowed to incubate at room temperature for 15 min (▨) or at 4°C for 24 hr (□) or 49 hr (▨). The mixtures were then centrifuged and the amount of precipitated tannin was determined colorimetrically as described in the text. The plant extracts were prepared from fireweed flowers (*Epilobium anguistfolium*), maple leaves (*Acer spicatum*), alder leaves (*Alnus rubra*), or great willow twigs (*Salix* spp.). Purified condensed and hydrolyzable tannins were prepared as described in the text.

precipitation assay, the dye-labeled protein-precipitation assay, or the Martin and Martin precipitation assay.

The precipitation of purified condensed tannin by protein was complete after 15 min, and longer reaction time or lower reaction temperature did not increase the amount of precipitate formed (Figure 1). This result is similar to the results reported in the literature, in which a 15-min reaction at room temperature was always found to be adequate for complete precipitation of protein by condensed tannin (Hagerman and Butler, 1978, 1980a; Martin and Martin, 1982; Asquith and Butler, 1985). The precipitation of purified hydrolyzable tannin by protein was significantly greater after 24 hr of reaction at 4°C than after 15 min at room temperature (Figure 1). Although 15 min of reaction at room temperature is adequate for studies of purified condensed tanning, crude tannin-containing extracts should be allowed to react with the protein for 24 hr at 4°C, before determining precipitated protein, to ensure complete precipitation.

The radiolabeled protein-precipitation assay, the dye-labeled protein-precipitation assay, and the Martin and Martin precipitation assay were directly compared by determining the amount of protein precipitated by various amounts of tannin-containing leaf extracts. Results obtained with a dogwood leaf extract are shown in Figure 2. The regions of linearity were different for each of the assays and for each of the leaf extracts tested. The protein-precipitating capacity is usually calculated from the slope of the linear portion of the results. For the Martin and Martin assay, the amount of protein precipitated was linearly related to the amount of dogwood extract added for amounts of extract corresponding to 1–2 mg forage. The slope of the linear region was 0.49 mg BSA/mg forage. For the radiolabeled protein-precipitation assay, the region of linearity corresponded to 2–3 mg dogwood leaves and the slope of the linear region was 3.6 mg BSA/mg forage. For the dye-labeled protein-precipitation assay, the region of linearity corresponded to 3–5 mg dogwood leaves, and the slope of the linear region was 1.9 mg BSA/mg forage.

Since an exhaustive extraction procedure was used to extract tannin from the tissue, the ratio of tissue to solvent used for the extraction did not affect the amount of tannin extracted. For example, extraction of 100 mg of dogwood leaves yielded extracts equivalent to those obtained from the extraction of 1.5 g tissue (Figure 2).

Each of the assays was characterized by a nonzero x intercept (Figure 2), suggesting that a threshold amount of dogwood extract was required to precipitate protein. The threshold value was different for each of the assays. Zero intercepts were reported for each of these assays in the literature (Hagerman and Butler, 1980a; Martin and Martin, 1982; Asquith and Butler, 1985). The nonzero intercepts obtained with the dogwood extract and with the other plant extracts tested made it impossible to express the protein-precipitating capacity

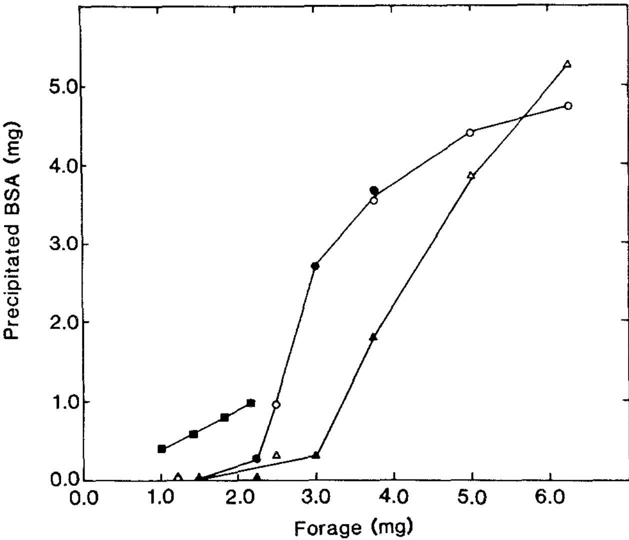

FIG. 2. Protein precipitated by an extract of dogwood leaves using three different assays. The amount of protein precipitaed by the extract of dogwood leaves was determined with the Martin and Martin assay (■); with the radiolabeled protein-precipitation assay (●, ○); with the dye-labeled protein-precipitation assay (▲, △). Each assay was performed as described in the text. In the Martin and Martin assay, the reaction mixture contained 1.47 mg BSA in a total volume of 2.0 ml; in the radiolabled protein-precipitation assay, the reaction mixture contained 6.5 mg iodine-125-labeled BSA in a total volume of 2.5 ml; in the dye-labeled protein-precipitation assay, the reaction mixture contained 7.64 mg dye-labeled BSA in a total volume of 4.5 ml. The extracts were prepared from dried samples of dogwood leaves (*Cornus stolonifera*) by sequential sonication and heating. Either 1.5 g dry tissue was extracted with 200 ml solvent (■, ●, ▲) or 0.10 g dry tissue extracted with 8.0 ml solvent (○, △).

simply as the amount of protein precipitated per gram of tissue. An accurate expression for precipitating capacity from an assay with nonzero intercepts would include not only the slope of the line but also the intercept of the line.

In an attempt to identify the sources of difference between the assays, the conditions of each assay were compared. All three assays were run at pH 4.9, the optimum pH for precipitation of BSA by condensed or hydrolyzable tannin (Hagerman and Butler, 1978; Hagerman and Klucher, 1986). Although the dye-labeled protein-precipitation assay was run at lower ionic strength than the other assays, previous work showed that the precipitation of condensed tannin by BSA was independent of ionic strength over a range of ionic strengths from 0.05 M to 5M (Hagerman and Butler, 1978). The amount of organic solvent in the assay mixture was slightly different for each of the assays, ranging from

6.5% (v/v) methanol in the final reaction mixture for the dye-labeled protein-precipitation assay to 15% methanol in the final reaction mixture for the Martin and Martin assay. In earlier studies of the effects of solvents on tannin–protein interactions, it was found that concentrations of alcohol ranging from 10% to 25% had no effect on the precipitation reaction, while lower amounts of alcohol (4.4%) suppressed precipitation slightly (Hagerman and Butler, 1980a). The low concentration of alcohol in the dye-labeled protein-precipitation assay could be partially responsible for the diminished precipitation observed with this assay. The dye-labeled protein-precipitation assay and the radiolabeled protein-precipitation assay were compared using 5.9% methanol in the reaction mixture for each (Figure 3); the dye-labeled protein was not precipitated as efficiently as was the radiolabeled BSA even when alcohol concentrations were identical. Thus, neither pH, ionic strength, nor organic solvent concentration adequately explained the differences observed for the three precipitation assays.

One significant difference between the three assays in the final concentration of protein in the assay mixture, since the recommended amount of protein and the volume of the reaction mixture are different for each method. The formation of insoluble complexes of gelatin and tannic acid is dependent on protein concentration (Van Buren and Robinson, 1969). The reaction volume used in the Martin and Martin assay was 2.0 ml, and approximately 1.5 mg BSA was used, producing a final protein concentration of about 0.75 mg/ml. The radiolabeled protein-precipitation assay was developed for a 2.5-ml reaction mixture containing about 6.5 mg iodine-125-labeled BSA, giving a final protein con-

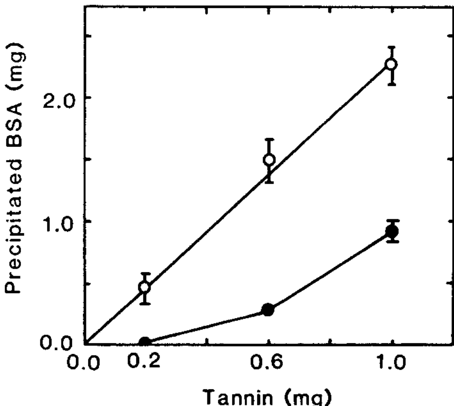

FIG. 3. Amount of iodine-125-labeled BSA and of blue dye-labeled BSA precipitated by purified tannin. An aliquot (0.25 ml) of 50% methanol containing purified condensed tannin was added to 4.0 ml buffer containing 7.64 mg blue dye-labeled BSA (●) or 7.64 mg iodine-125-labeled BSA (○). The amount of dye-labeled BSA or of radiolabeled BSA precipitated was determined as described in the text.

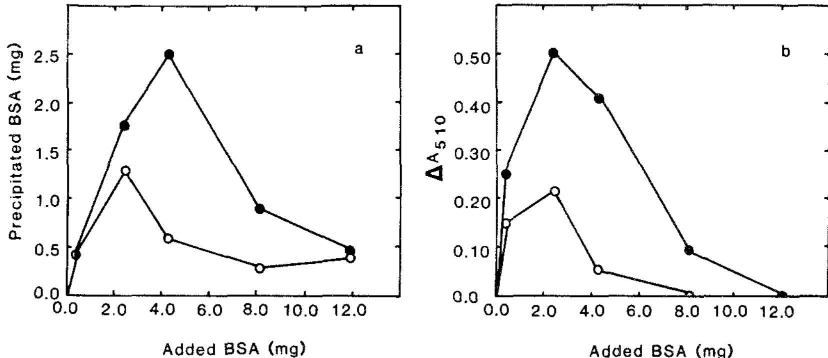

FIG. 4. Precipitation of protein and tannin by extracts of alder leaves in reaction mixtures containing various amounts of protein. An aliquot of the alder (*Alnus ruba*) extract equivalent to 2.25 mg forage (○) or to 3.75 mg forage (●) was added to 2.0 ml buffer containing between 0 and 12 mg iodine-125-labeled BSA. The amount of protein precipitated (a) and the amount of tannin precipitated (b) were determined as described in the text. The protein-precipitating capacity for alder calculated from this data is 1.31 mg BSA/2.25 mg forage = 0.58 mg BSA/mg forage (○); 2.5 mg BSA/3.75 mg forage = 0.67 mg BSA/mg forage (●).

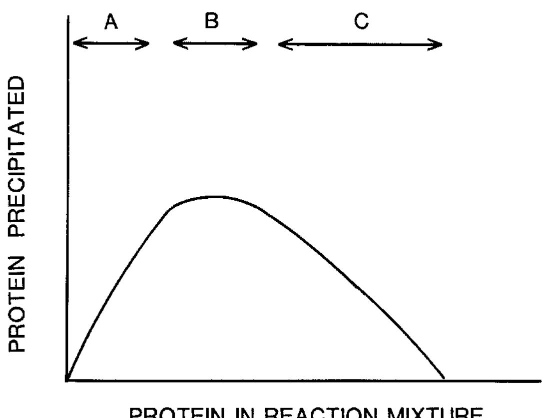
centration of around 2.6 mg/ml. In the dye-labeled protein-precipitation assay, the reaction volume was 4.5 ml, containing approximately 8 mg dye-labeled BSA, or a final protein concentration of about 1.8 mg/ml.

The effects of protein concentration on protein precipitation assays were determined by experiments with the radiolabeled precipitation assay and crude tannin-containing plant extracts. The amount of precipitable complex formed by a constant amount of tannin-containing alder extract was significantly influenced by the amount of protein in the reaction mixture (Figure 4a and b). Curves of similar shape were obtained with extracts of other plants. Each curve could be divided into three regions (Scheme 1). When very little protein was present, there was excess tannin in the reaction mixture and only a small amount of precipitate formed (region A in Scheme 1). When a moderate amount of protein was present, the optimal ratio between tannin and protein, or equivalence point, was achieved, and precipitation was maximized (region B in Scheme 1). If a large excess of protein was added, smaller amounts of precipitate again formed (region C in Scheme 1). When a large excess of protein was present, no protein-precipitable phenolics were detected (Figure 4b), but a small amount of protein was precipitated (Figure 4a). The absence of precipitated tannin suggests that insoluble tannin–protein complexes did not form when protein was present in large excess. The protein precipitated under these conditions was perhaps denatured by exposure to tannin (Mole and Waterman, 1985). Curves of similar overall shape were obtained using the dye-labeled protein-precipitation assay



SCHEME 1. Titration of tannin-containing plant extract with protein: region A, excess tannin; region B, equivalence point; region C, excess protein.

instead of the radiolabeled-BSA assay, although the maximum precipitation was obtained with different amounts of the dye-labeled BSA than of the radiolabeled BSA.

The characteristics of the curve obtained when tannin is titrated with protein may depend on the tendency of tannin from a particular species to form soluble or insoluble complexes. The amount of protein required for maximum precipitation was different for each plant extract. It was not possible to predict the concentration of protein required for maximum precipitation of an uncharacterized tannin sample. The curves obtained with some plant extracts were sharp, with narrow regions of equivalence, and the curves obtained with other extracts were broad, with wide regions of equivalence. The equivalence point was narrower when crude plant extracts were used (Figure 4a and b) than when purified tannins were used (Van Buren and Robinson, 1969; Hagerman and Butler, 1980a). With purified condensed tannin, the optimal region was extremely flat and broad (Hagerman and Butler 1980a). At values exceeding the point of limiting tannin, precipitation of protein by purified condensed tannin was independent of protein concentration. However, precipitation by crude plant extracts was always dependent on protein concentration.

The determination of protein-precipitating capacity of a plant sample was affected by the amount of protein used in the precipitation assay, as is shown in Figure 5 for a maple leaf extract. When 1.90 mg of BSA was used in the radiolabeled protein-precipitation assay, the apparent protein-precipitating capacity of maple leaf extract was 0.50 mg BSA/mg forage. If the amount of protein used in the assay was increased to 4.76 mg, the apparent precipitating capacity was 1.1 mg BSA/mg maple leaves, while with 10.9 mg of BSA in the

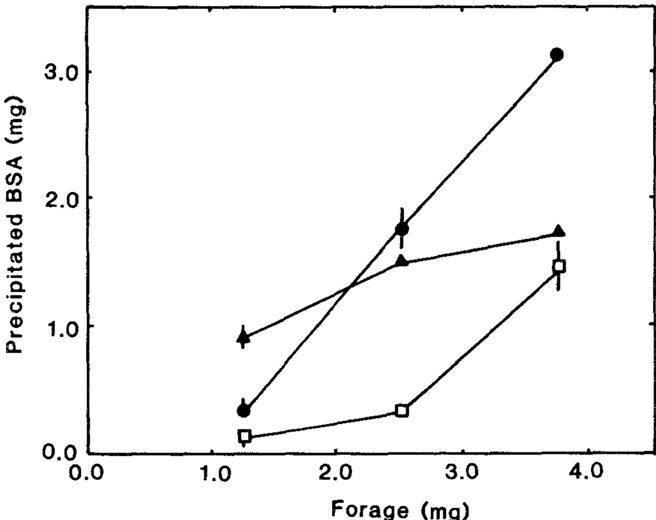


FIG. 5. Precipitation of protein by various amounts of maple extract. Aliquots of the maple (*Acer spicatum*) extract were added to 2.0 ml buffer containing 1.90 mg iodine-125-labeled BSA (▲), 4.76 mg iodine-125-labeled BSA (●), or 10.9 mg iodine-125-labeled BSA (□). The amount of protein precipitated was determined as described in the text.

assay, the apparent precipitating capacity was 0.90 mg BSA/mg maple leaves. The maximum precipitating capacity was obtained when the assay was run near the equivalence point, where neither protein nor tannin was in excess. The amount of protein precipitated per unit of tannin-containing plant tissue was diminished either in the region of excess tannin or in the region of excess protein. Thus the Martin and Martin assay, the radiolabeled protein-precipitation assay, and the dye-labeled protein-precipitation assay, which were run with different protein concentrations, gave different estimates of protein-precipitating capacity (Figure 2).

The amount of protein used in the assay also influenced the intercepts (Figure 5), giving rise to threshold effects like those observed with all of the precipitation assays (Figure 2). Zero intercepts were obtained when small amounts of protein were used in the assay, since under those conditions precipitation was favored even when only small amounts of tannin were added. With larger amounts of protein, precipitation was unfavorable for small aliquots of tannin-containing extract, and so a threshold level of tannin was necessary for precipitation to occur (Figure 5).

Apparently one source of differences among the precipitation assays is the variable protein concentration used in the methods. To further test this hypoth-

esis, the radiolabeled protein-precipitation assay and the Martin and Martin assay were set up under identical conditions, and the amount of protein precipitated was determined. It was found that the amount of protein precipitated was identical for these two assays if the same ratio of protein to tannin was used in the assays. A similar comparison was set up for the dye-labeled protein-precipitation assay and the radiolabeled protein-precipitation assay. It was found that even when identical protein-to-tannin ratios were used in these two assays, the amount of dye-labeled protein precipitated was significantly less than the amount of radiolabeled protein precipitated (Figure 3).

The competitive binding assay (Hagerman and Butler, 1981) was used to determine the affinity of dye-labeled BSA for tannic acid. The reaction conditions were set so that in the absence of competitor, 0.60 mg of the 1.0 mg of radiolabeled BSA present was precipitated by the tannic acid. The amount of competitor required to reduce precipitation of the radiolabeled protein by 50% was then determined. For blue dye-labeled BSA, 0.57 mg was required for 50% inhibition. For unlabeled BSA, 1.0 mg was required for 50% inhibition. Thus the affinity of dye-labeled BSA for tannic acid is slightly higher than the affinity of unlabeled or radiolabeled BSA for tannic acid. However, the blue dye-labeled BSA apparently forms soluble complexes with the tannin under conditions which promote the formation of insoluble complexes with the radiolabeled or unlabeled BSA (Figure 3). Insoluble complexes of dye-labeled BSA and tannin only form when the concentration of tannin is very high, so the dye-labeled protein-precipitation assay is rather insensitive.

Even after minimizing the differences between experiments or research groups by selecting common parameters for precipitation assays, problems of variability may arise. One source of such problems is the use of a variety of extraction conditions for tannin-containing tissues. Exhaustive extraction procedures like those described here are most desirable since the recovery of tannin is maximized. If only a single brief extraction period is to be used, then aqueous acetone extracts tannin more efficiently than aqueous alcohol (Bate-Smith, 1975; Fletcher et al., 1977; Hagerman, unpublished data). Using less efficient solvents for tannin extraction can significantly affect the estimate of tannin content in a plant sample (Hagerman, unpublished data). The solvent used to extract the tannin can also affect the precipitation assay. For example, even small amounts of acetone inhibit the formation of tannin–protein precipitates (Figure 6). To avoid such inhibition effects, all acetone must be removed from acetone-containing extracts before the assay is attempted, or an assay insensitive to acetone must be selected (Hagerman, 1987).

DISCUSSION

Determination of Protein-Precipitating Capacity. When attempting to determine the protein precipitating capacity of a tannin-containing plant extract,

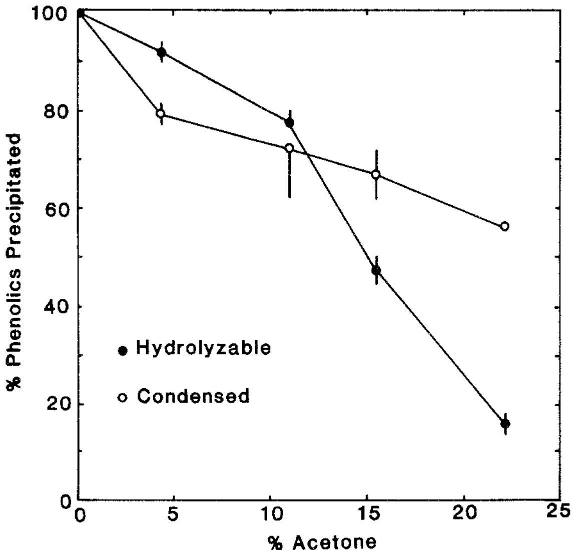

FIG. 6. Acetone inhibition of tannin–protein preciptation. Aliquots (0.25 ml) of tannin-containing solution were added to 2.0 ml reaction mixtures containing 2.0 mg BSA in buffer and up to 22.2% (v/v) acetone. After 15 min, the mixtures were centrifuged and the amount of tannin precipitated was determined colorimetrically as described in the text. The precipitated phenolics were expressed as a percent of phenolics precipitated in the absence of acetone. All of the mixtures contained 5.6% (v/v) methanol.

the conditions for precipitation and the method of analysis must be chosen with care. The effects of solvent on extractibility of the tannin from the tissue and on the precipitation reaction must be considered. Acetone is the most efficient solvent for extracting tannin, but acetone inhibits precipitation reactions except under certain conditions (Hagerman, 1987). Sufficient time must be allowed for the precipitation reaction to come to completion. Although reaction at room temperature for 15 min or less is recommended for many assays (Hagerman and Butler 1978, 1980a; Martin and Martin, 1982; Asquith and Butler, 1985), a 24-hr reaction at 4°C is required if crude plant extracts are being analyzed.

The choice of assay is dependent on the facilities available and the number of samples to be run. The Martin and Martin assay and the radiolabeled protein-precipitation assay give identical results if the precipitation reactions are run under identical conditions. With either of these assays, precipitated protein and precipitated tannin can be determined simultaneously. The radiolabeled protein-precipitation assay is simple to run, although the use of radioisotopes is required. The method is accessible to most labs since iodine-125-labeled BSA is now commercially available (ICN Radiochemicals, Irvine, California 92713). The Martin and Martin assay is technically difficult to run and would be inap-

propriate for studies involving more than a few samples. A recent modification of that assay is technically easier (Martin et al., 1985). The dye-labeled protein-precipitation assay has the advantage of being simple and not requiring any special techniques or reagents. However, precipitated tannin and protein cannot be determined simultaneously with this assay. In addition, the dye-labeled protein-precipitation assay is less sensitive than either of the other methods since the blue dye-labeled BSA preferentially forms soluble rather than insoluble complexes.

A new approach is needed for determining protein-precipitating capacity for tannin-containing samples. The capacity is presently determined as the slope of the line obtained when precipitated protein is measured as a function of the amount of tissue analyzed. The method yields variable results, depending on the amount of protein used in the precipitation assay. For each sample, the optimum ratio of protein to tannin is different and cannot be predicted. A better method for determining the protein-precipitation capacity is to titrate a single amount of plant extract with protein. The equivalence point (region B in Scheme 1) is determined by graphing the amount of protein precipitated as a function of the amount of protein added. The protein-precipitating capacity of the tannin sample is defined as the amount of protein precipitated at the equivalence point divided by the amount of tissue analyzed.

The method is illustrated graphically in Figure 4. As is seen in that example, different amounts of tannin-containing extract can be used in the assay. The equivalence point corresponds to a different protein concentration for each amount of extract. The protein-precipitating capacity, calculated as the amount of BSA precipitated at the equivalence point per milligram tissue analyzed, is approximately the same for different amounts of extract assayed (Figure 4a). The amount of tannin precipitated at the optimum ratio can also be determined using the colorimetric assay for protein-precipitable phenolics (Figure 4b). The same approach can be used with the dye-labeled protein-precipitation assay, although different values for protein precipitating capacity would be obtained since the dye-labeled protein behaves differently from BSA.

Ecological Implications. The results obtained in this study suggest that soluble tannin-protein complexes exist when a mixture of tannin and protein contains excess protein. The nutritional effects of soluble tannin–protein complexes may be relevant to the function of tannin as a defense metabolite. Formation of insoluble tannin–protein complexes is probably of little consequence to herbivores which have developed defenses against protein precipitation (Mehansho et al., 1983; Martin and Martin, 1984; Martin et al., 1985). We postulate that soluble tannin–protein complexes may form in the gut whenever protein-to-tannin ratios are favorable, despite herbivore adaptations which prevent formation of insoluble complexes. Since concentrations of tannin and protein in herbivore guts have not been measured, the frequency of occurence of soluble

complexes cannot be evaluated. However, if such soluble complexes do form, protein digestibility may be enhanced (Mole and Waterman, 1985) or absorption and metabolism of tannin may be increased (Potter and Fuller, 1968; Butler et al., 1986).

A model similar to that proposed for antigen–antibody interactions has been formulated to explain the formation of soluble tannin–protein complexes. Precipitation curves like those obtained with tannin (Figure 4) are obtained if an antibody is titrated with antigen (Kabat, 1980). At concentrations corresponding to excess antibody or excess antigen, soluble antibody–antigen complexes form rather than precipitable complexes. When tannin is present in excess, almost all of the available protein is precipitated, and no soluble complexes form. When protein is present in excess, there is not enough tannin available to form a significant number of cross-links between the protein molecules. Thus, at concentrations corresponding to excess protein, soluble tannin–protein complexes are present. At protein-to-tannin ratios corresponding to the equivalence point, crosslinking is favorable and a maximum amount of precipitable complex is formed. Thermodynamic studies of protein–phenol interactions suggest a similar model (McManus et al., 1981).

Although the characteristics of insoluble tannin–protein complexes have been extensively studied (Hagerman and Butler, 1978), 1980a, 1981; Fletcher et al., 1977; Goldstein and Swain, 1965; Van Buren and Robinson, 1969), soluble complexes have been neglected. Soluble complexes of tannin and gelatin have been detected (Calderon et al., 1968). Soluble complexes of tannin with seed proteins have been isolated (Hagerman and Butler, 1980b; Fishman and Neucere, 1980), and soluble complexes were recently detected in the aqueous extracts of pine needles (Nyman, 1985). However, little is known about features of the soluble complexes such as their size or their composition. Some proteins, such as blue dye-labeled BSA, preferentially form soluble complexes with tannin, but the general characteristics of proteins which promote formation of soluble complexes have not been identified.

There is not only a need to characterize the chemistry of soluble tannin–protein complexes, but also to study the formation of soluble complexes in vivo. Complementary nutritional and ecological studes will be necessary to elucidate the importance of soluble tannin-protein complexes in plant defense against herbivores.

Abstract—Onion fly females, *Delia antiqua* (Diptera: Anthomyiidae) laid the most eggs on ovipositional dishes having *n*-dipropyl disulfide (Pr_2S_2) release rates of 1–6 ng/sec from polyethylene capsules placed beneath a sand substrate. When dipropyl disulfide was released from the wax coating of surrogate foliage rather than from the substrate, ovipositing females again responded differentially to various concentrations, laying more eggs around stems containing 0.075 and 0.089 mg/stem. Factorial combinations of several concentrations released from surrogate foliage and substrate showed that releases from surrogate foliage stimulated four times more egg-laying than releases from the substrate. Females tended to lay more eggs around surrogate stems having Pr_2S_2 at the base rather than on the upper half of foliage. Observations of individual females performing preovipositional examining behaviors on Pr_2S_2-treated surrogate stems indicated that females tended to land on the upper portions of the foliage, but after landing, spent most of their time examining areas of soil and surrogate within 1 cm of the soil–surrogate foliage interface. Surrogate stems provide a realistic context for investigating effects of plant chemicals on host-acceptance behaviors.

Key Words—Onion fly, onion maggot, *Delia antiqua, Hylemya antiqua*, Diptera, Anthomyiidae, host selection, oviposition, dipropyl disulfide, behavior, herbivore, plant–insect interactions.

INTRODUCTION

Like many other herbivore specialists, the onion fly, *Delia antiqua* (Meigen), has a narrow host range delimited by preferences of egg-laying females. Newly eclosed larvae have limited mobility and are subject to desiccation in open areas and dry soils; therefore, eggs must be placed close to or on proper hosts (Workman, 1958).

The question of what stimuli signal "host" to ovipositing *D. antiqua* has been investigated in some detail. Because females oviposit only on a small number of species in the genus *Allium*, initial studies focused on compounds unique to this plant genus. Secondary chemicals are formed in alliums when cells are disrupted, and the normally compartmentalized cysteine sulfoxides contact the enzyme alliinase (Whitaker, 1976). The labile thiosulfinates produced by this reaction then react further at room temperatures to form thiosulfonates and other sulfur-containing compounds such as dipropyl disulfide (Pr_2S_2) and propanethiol. Secondary chemicals are also formed from intact onions when propenyl cysteine sulfoxides are exuded by roots into the soil and converted into sulfides by soil bacteria (Coley-Smith and King, 1969; Hough et al., 1981; Ikeshoji, 1984).

Host-finding and acceptance in the onion fly are stimulated by the end-products of *Allium* defensive reactions, the stable mono-, di-, and trisulfides. Increased numbers of flies are caught in traps baited with Pr_2S_2, propanethiol (Matsumoto, 1970), methyl propyl and propenyl propyl disulfide, and several other mono- and disulfides (Vernon et al., 1981). Trap catches in response to Pr_2S_2 are significant at release rates of 60 μg/hr (Dindonis and Miller, 1981). Final acceptance of oviposition sites is also influenced by onion chemicals. Propanethiol and Pr_2S_2 stimulate females to probe with their ovipositors and lay eggs (Matsumoto and Thorsteinson, 1968), as do numerous other compounds containing a sulfur atom having two unshared pairs of electrons and bonded to a saturated hydrocarbon chain three to five carbons long (Vernon et al., 1978; Ishikawa et al., 1978).

Nonchemical plant stimuli also play an important role in host recognition. Addition of surrogate foliage to oviposition dishes synergizes responses to onion slices buried beneath moist sand (Harris and Miller, 1982). Color (Harris and Miller, 1983), shape, and size (Harris and Miller, 1984) of surrogates have major effects on acceptance of oviposition sites. These foliar stimuli are sensed by females primarily during extended runs over the surface of surrogates.

While observing females engaged in these preovipositional examining behaviors, we wondered whether runs over the surface of onion foliage might expose flies to plant chemicals in addition to color, size, and shape stimuli. The importance of chemicals released from foliage was dismissed by Vernon et al. (1977), who reported that extracts from onion bulbs were more stimulatory than

extracts of foliage; however, recent work on the carrot fly, which performs similar runs over host-plant foliage, has shown that a complex mixture of chemicals in surface waxes of foliage is critical to host recognition (Städler and Buser, 1984).

Our approach to the question of whether *D. antiqua* females obtain chemical information from onion foliage was to quantify effects of releasing a range of doses of the ovipositional stimulant, Pr_2S_2, from the substrate as well as from foliar surrogates. Locations of various preovipositional behaviors were also recorded to clarify whether females examine certain areas of the foliage and substrate more thoroughly than others before committing their eggs to a host.

METHODS AND MATERIALS

Insect Rearing. Delia antiqua pupae were collected (autumn of 1981 and 1983) from onions left in harvested fields in Grant, Michigan. Adults emerging from these pupae were placed in 60 × 60 × 80-cm screened cages housed in environmental chambers (21 ± 1°C and 35 ± 5% relative humidity) illuminated by Verilux (Greenwich, Connecticut) fluorescent bulbs with a 16:8 light–dark cycle. Cages were provisioned with water, honey, dry artificial diet, and the ovipositional dishes described by Harris and Miller (1982).

Foliar Surrogates. Foliar surrogates were of two types. Surrogates used in the wind-tunnel experiment were identical to those described in Harris and Miller (1983) and consisted of sealed Pyrex tubes (8 mm diam × 9 cm long) which contained strips of yellow silk-screened paper. In all other experiments, surrogates consisted of 4-mm-diam Pyrex tubing cut into 12-cm lengths and heat sealed at one end. Color stimuli were provided by oil pigments (see Harris and Miller, 1984) mixed to match (as detected by the human eye) the green of onion foliage. Painted surrogates were allowed to dry three weeks before use in experiments, then coated with a thin layer of wax. Surrogates were placed vertically in the centers of a 4-cm-diam × 4-cm-deep plastic ovipositional dishes filled with moist white silica sand. All but 3 cm of the "foliage" stood above the substrate surface.

"Choice" Tests. Flies used in experiments were two to five generations removed from the original field-collected populations and were 7–21 days old. Flies were transferred (ca. 100 females per cage) when 7 days old to food- and male-provisioned screened cages (165 × 65 × 85 cm). Treatments (1 replicate/cage) were spaced evenly (ca. 10 cm apart) within cages and surrounded by wire-screen barriers (16 cm high × 9 cm diameter) in all experiments except those in the wind tunnel. Experimental design was randomized complete block. Eggs were separated from sand by flotation and were recorded as numbers of eggs laid per ovipositional dish per cage per sampling period. Experiments com-

paring oviposition on only two treatments were analyzed by two-way ANOVA at $P < 0.05$. All other data required transformations (log or square root) before being subjected to analysis of variance. Means were then separated by the least significant difference test at $P < 0.01$. A probability of <0.01 was used rather than $P < 0.05$ to minimize experiment-wise error rate.

Dose-Response Curves for Pr_2S_2 Released from Substrate. Six Pr_2S_2 release rates from the substrate of oviposition cups were generated by inserting size 3 BEEM polyethylene embedding capsules (Pelco Electron Microscopy Supplies, Ted Pella Co., Tustin, CA) containing 100 μl of either neat Pr_2S_2 (Eastman Kodak, Rochester, New York, 98% pure by GLC), pure peanut oil, or a mixture (range 0.05–0.9 M) of Pr_2S_2 and peanut oil (PVO International, Inc.). These capsules, which allowed outward diffusion of the Pr_2S_2 but not of the peanut oil, were set, lid-side up, in ovipositional dishes containing 2 cm of moist silica sand, then covered with 2 cm of additional sand. Color and structural stimuli were provided by the aforementioned colored glass tubing. Twelve hours after assembly, ovipositional dishes containing different concentrations of Pr_2S_2 were placed in cages. A similar set of Pr_2S_2 dosages was also tested in a cage ($60 \times 60 \times 80$ cm) placed in the wind tunnel described by Cardé and Hagaman (1979). The arrangement of ovipositional dishes in the tunnel prevented overlap of chemical plumes of different concentrations. Further details on experimental procedures are described by Harris (1986).

Because preliminary experiments showed that Pr_2S_2 is not adsorbed by sand, we estimated release rates from single ovipositional dishes by measuring the amount of Pr_2S_2 in capsules at the beginning and at the end of the experimental period (six replicates of each). Thus, one complete set of treatments was analyzed 12 hr after assembly (initiation of bioassay) and one 24 hr after assembly (termination of bioassay). Both initial and final concentrations of capsules with neat chemical were obtained gravimetrically. All other capsules were opened and placed in 8-ml vials containing 1 ml of 10 : 1 methanol–water. Concentrations in peanut oil were analyzed by injecting 1 μl of the methanol layer of the extract onto a 10% Carbowax 20 M GLC column programmed for an initial 2 min hold at 70°C, followed by temperature increases of 10°C/min and a final temperature of 160°C. Diallyl disulfide was used as an internal standard because of its similar solubility in methanol and similar flame ionization detector sensitivity. Differences in Pr_2S_2 content between the two sets of treatments (analyzed at 12 and 24 hr) were expressed as nanograms released per second, with the approximation that release rate over the 12-hr experimental period was constant.

Dose-Response Curves for Pr_2S_2 in Wax Layer on Surrogate. Various concentrations of Pr_2S_2 were formulated on the surface of surrogate foliage by adding different amounts (0.5, 1, 5, 10, 50, 100, 500, 1000, and 2000 μl) of Pr_2S_2 to 100 ml of melted paraffin wax (Cullen Industries, Huntingdon Valley, Pennsylvania). Green glass tubing was dipped in melted Pr_2S_2-containing wax so

that a 0.5-mm-thick layer was retained on the surrogate surface. Loading rates per stem were estimated to be 0.002, 0.003, 0.017, 0.033, 0.166, 0.332, 1.66, 3.32, and 6.64 mg Pr_2S_2 per stem. Temperature of the melted wax when adding Pr_2S_2 (65°C) and when coating stems (68°C) was identical for all replicates. Stems were allowed to equilibrate for 24 hr before placement in ovipositional dishes. Dishes were placed in cages for 24 hr in this and all remaining experiments. No Pr_2S_2, the optimal dose (50 μl Pr_2S_2/100 ml wax), and the highest dose (2000 μl Pr_2S_2/100 ml wax) were also compared using the same procedures used in the previous dose–response experiment.

Concentrations of Pr_2S_2 in wax layers at the initiation of choice experiments were estimated by coating glass (unpainted) surrogates with Pr_2S_2-containing wax (five replicates of each), allowing them to age for 24 hr, and then scraping the Pr_2S_2-containing wax from the surrogates directly into the vials containing 2 ml of distilled pentane. One microliter of Pr_2S_2-containing-wax in pentane (replicated three times) was then injected onto a DB-5 GLC capillary column (column temperature 130°C). Concentrations in wax were calculated by comparing peak areas with those of Pr_2S_2 (in pentane) standards containing comparable amounts of pure wax.

Interaction between Pr_2S_2 Released from "Foliage" and Substrate. Five substrate dosages (peanut oil control, 0.15, 0.5, 0.7, and 1.0 M) and five surrogate foliage dosages (untreated wax, 5, 10, 50, and 2000 μl Pr_2S_2/100 ml wax) were combined factorially to investigate possible interactions between Pr_2S_2 released from the two sites. Formulations were identical to those described previously. Another experiment with fewer treatments was also run to test again for possible interactions; stems containing optimal doses of Pr_2S_2-treated wax (50 μl/100 ml wax) were placed in dishes with capsules containing various concentrations of Pr_2S_2 in peanut oil (0.05, 0.15, 0.5, 0.7, 0.8, 0.9, and 1.0 M).

Effectiveness of Pr_2S_2-treated Stems Over Time. Onion foliar surrogates coated with an optimal dosage of Pr_2S_2 (50 μl/100 ml wax) and prepared 15, 10, 5, 3, 2, and 1 day(s) before treatments were bioassayed. Surrogates coated with wax containing no Pr_2S_2 served as controls and were also prepared 15 days before use. A final set of Pr_2S_2-stems was prepared immediately before treatments were placed in cages.

Pr_2S_2 Placement on Surrogate Stems. Effects of placing Pr_2S_2 at different locations on surrogate foliage were examined by presenting flies with surrogates coated with Pr_2S_2-treated wax (50 μl/100 ml wax) in seven different locations: on the upper 1 cm, on the upper 4.5 cm, on the upper 9 cm, on the lower 3 cm, on the lower 4 cm, on the lower 7.5 cm, and on the entire 12-cm length (see Figure 5). Areas not coated with Pr_2S_2-treated wax were coated with unadulterated wax. A surrogate covered with unadulterated wax served as a control. Surrogates were placed in plastic cups filled with moist silica sand so that 9 cm of the 12-cm surrogate stood above the sand surface.

Location of Preovipositional Examining Behaviors. Groups of 5–15 newly emerged female flies were placed along with equal numbers of males in clear plastic cages (15 cm diam × 30 cm height) provisioned with water and food. For 2 hr every day at various times between 3 and 8 PM, flies were exposed, starting at age 7 days, to an optimal surrogate stem standing upright in the center of a pot (15 cm diam × 20 cm deep) containing organic "muck" soil. This period (3–8 PM) was chosen for behavioral observations because ca. 78% of egg production occurs during this interval (Havukkala and Miller, 1987).

During each observational period, location and duration of the following stances and behaviors of individual females were noted: no movement (still), grooming, running, running with the proboscis repeatedly brought in contact with plant or soil surface (proboscis extended), running with abdomen bent and tip of abdomen (and sometimes the proboscis) touching plant or soil surface (ovipositor probing), and stationary probing with ovipositor fully extended and wedged into soil crevices (insertion and oviposition). Foliar surrogate and substrate were divided into five zones: foliage 0–1 cm from surrogate–substrate interface, foliage 1–3 cm, folige 3–9 cm, substrate 0–1 cm from stem base, and substrate 1–4 cm from stem base. Observations began when individuals entered the 1-cm-diameter zone around the base of the surrogate or flew to the surrogate. Observations of individuals were terminated after females left the surrogate area either by flying away or by walking more than 3 cm from the surrogate stem base. Behavioral observations of individuals (identified by acrylic-paint color codes on the thorax) were recorded on a Radioshack TRS 80, model 100 using a program developed by T. Bierbaum, Department of Zoology, Michigan State University.

Surrogate Onions vs. Real Onions. The best surrogate (50 μl Pr_2S_2/100 ml wax, 4-mm-diam. green cylinder) was compared to three types of onions in pairwise choice tests: (1) onion plants (grown from sets) having four leaves, a height of 14 cm, and a basal diameter of 4–5 mm; (2) onions grown from seed (Downing Yellow Globe, 6 weeks old) having three leaves, a height of 180–240 mm, and a basal diameter of 3.0–3.5 mm; and (3) a single onion leaf ca. 120 mm long cut from the foliage of onion sets (4–5 mm diam.) and positioned upright in moist sand.

Comparisons of oviposition on surrogates and onion seedlings were also made using a no-choice bioassay. Individual 7-day-old females (N = 16) were placed in cages (10 cm diam. × 30 cm height) with food, water, two males, and the surrogate or onions grown from seed. Oviposition dishes were replaced and eggs counted every 24 hr on each of the next seven days.

RESULTS

Dipropyl Disulfide Dose–Response Effects. When *n*-dipropyl disulfide was released from the substrate, females responded to a fairly wide range of release

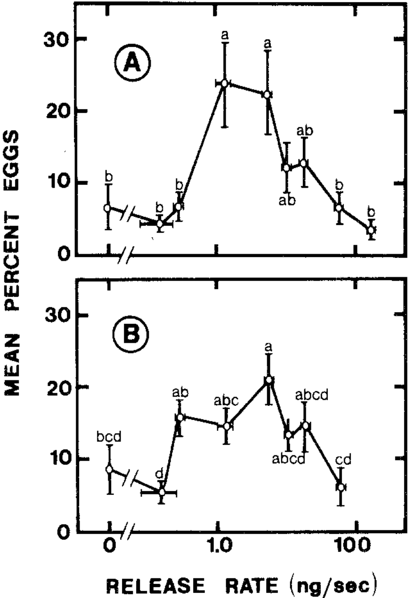

FIG. 1. Semilogarithmic plot of *Delia antiqua* ovipositional responses (means and standard error bars) to *n*-dipropyl disulfide released from the substrate using cages of flies placed in a wind tunnel (A) or in normal environmental chambers (B). Treatments accompanied by the same letter in each figure are not significantly different at $P < 0.01$ (ANOVA followed by LSD test for separation of means). Total number of eggs for 12 replicates for (A) = 22,428, for 15 replicates for (B) = 1517 eggs.

rates (Figure 1). In the wind tunnel (Figure 1A), increasing release rate from 0.32 to 1.38 ng/sec caused a significant increase in oviposition. When this same range of concentrations was tested in a cage having no rapid turnover of air (Figure 1B), significant increases in oviposition occurred at slightly lower release rates (0.32 ng/sec). A release rate of 60.8 ng/sec depressed ovipositional responses in both bioassays.

When Pr_2S_2 was released from the wax coating of surrogate foliage rather than from the substrate (Figure 2), ovipositing females again responded differentially to various concentrations. Maximal responses occurred around surrogates loaded with 0.17 and 0.33 mg/stem and dropped off sharply with the next lowest loading rate of 0.033 mg/stem. The highest loading rate of 6.64 mg/stem appeared to depress oviposition responses relative to the plain wax control. An experiment consisting of a subset of the original treatments [including the wax control, the optimal loading rate (0.17 mg/stem) and the highest rate] suggested that inhibition did occur at the highest loading rate: the high rate received a mean of three eggs vs. 16 and 55 eggs laid on the wax stem control and the optimal loading rate, respectively [eight replicates, ANOVA $F = 24.06$, sig-

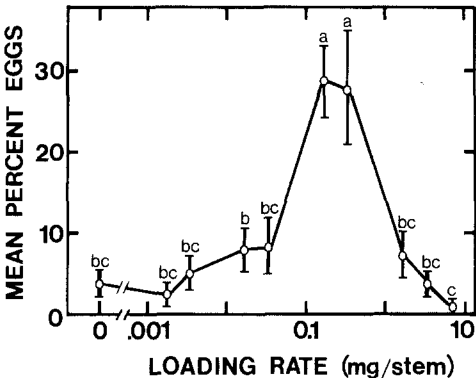

FIG. 2. Semilogarithmic plot of *Delia antiqua* ovipositional responses to *n*-dipropyl disulfide released from surrogate foliage. Treatments accompanied by the same letter are not significantly different at $P < 0.01$ (ANOVA followed by LSD test for separation of means). Total number of eggs for seven replicates = 676.

nificant at $P < 0.001$, all three treatments significantly different from each other at $P < 0.01$, least significant difference (LSD) test].

GLC analysis of actual amounts of Pr_2S_2 in wax at the beginning of the bioassay (as opposed to initial loading rates) revealed that stems with optimal loading rates of 0.17 and 0.33 mg/stem contained 0.075 and 0.089 mg/stem at the beginning of the experimental period. The next lowest dose (loading rate of 0.033 mg/stem), which stimulated no more oviposition than the wax control, contained only 0.014 mg/stem, whereas stems inhibiting oviposition (initial loading rate of 3.32 mg/stem) contained 1.83 mg/stem. The loss of Pr_2S_2 from wax from time of loading to initiation of bioassays probably occurred when Pr_2S_2 was added to heated wax during formulation.

Interactions between Pr_2S_2 Released from "Foliage" and Substrate. Females laid few eggs (Figure 3) when Pr_2S_2 was released only from the substrate. The previously determined optimal substrate dose (Figure 1B) received only 4% of the total eggs laid, hardly twice as many eggs as were received by the wax stem–peanut oil control. Flies were far more responsive to changes in concentration of Pr_2S_2 in the wax coating of surrogates. Loading rates of 0.033 and 0.17 mg/stem caused two- and ninefold increases in oviposition, respectively; these increases were similar to those seen in Figure 2.

Dose–response effects were significant both for Pr_2S_2 released from the substrate (ANOVA $F = 18.2$, significant at $P < 0.001$) and from the stem (ANOVA $F = 14.3$, significant at $P < 0.001$). A significant interaction occurred between Pr_2S_2 released from the two areas (ANOVA $F = 3.07$, significant at $P < 0.001$). Whether this interaction consisted of both synergy and interference could not be determined; however, a subsequent experiment in which a range of Pr_2S_2 substrate concentrations was presented with optimal

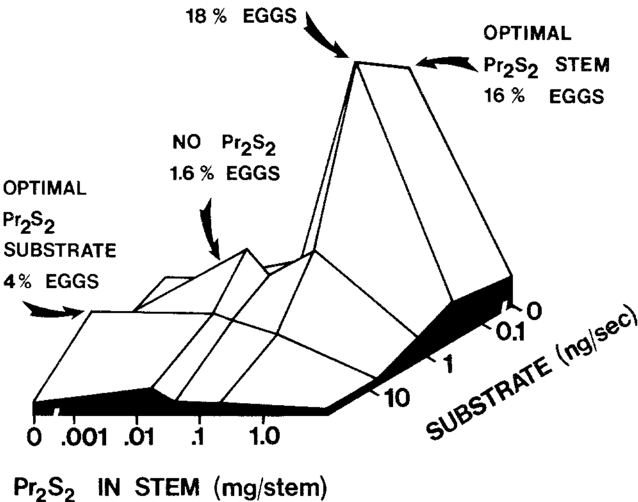

FIG. 3. Response surface generated by presenting gravid onion flies with doses of *n*-dipropyl disulfide released from substrate and surrogate foliage combined factorially (discontinuous log-log plot). Mean number of eggs laid on each of the 25 treatments is indicated by height on the vertical axis. Total number of eggs for seven replicates = 4157.

Pr_2S_2-treated wax stems (14 replicates) indicated that small concentrations of Pr_2S_2 released from the substrate did not synergize optimal concentrations of Pr_2S_2 on stems. On the other hand, higher release rates from the substrate did interfere with optimal release from the stem; release rates of 5.83 ng/sec from the substrate significantly inhibited egg-laying relative to a Pr_2S_2-treated wax control (LSD test, $P < 0.01$).

Effectiveness of Pr_2S_2-treated Stems over Time. Optimal Pr_2S_2-treated stems (loading rate 0.17 mg/stem) retained their stimulatory effects on oviposition for up to five days after being formulated (Figure 4). Stems formulated more than 10 days before exposure to females received significantly fewer eggs.

Pr_2S_2 Placement on Surrogate Stems. Stems covered both above and below the substrate with optimal doses of Pr_2S_2-treated wax, and stems with Pr_2S_2 above the substrate or on all but the upper 4.5 cm of the stem elicited the most oviposition (Figure 5). Stems having Pr_2S_2-treated wax placed on the section beneath the substrate and on the lower 1.0 cm of the stem received fewer eggs, but more eggs than the wax control or treatments having Pr_2S_2-treated wax only beneath the substrate or on the upper half of the stem. An experiment including the four top ranking treatments confirmed no significant differences in ovipositional responses (six replicates, $P < 0.01$).

Observation of Preovipositional Examining Behaviors. Encounters with Pr_2S_2-treated wax surrogates began when individual females ($N = 24$) either

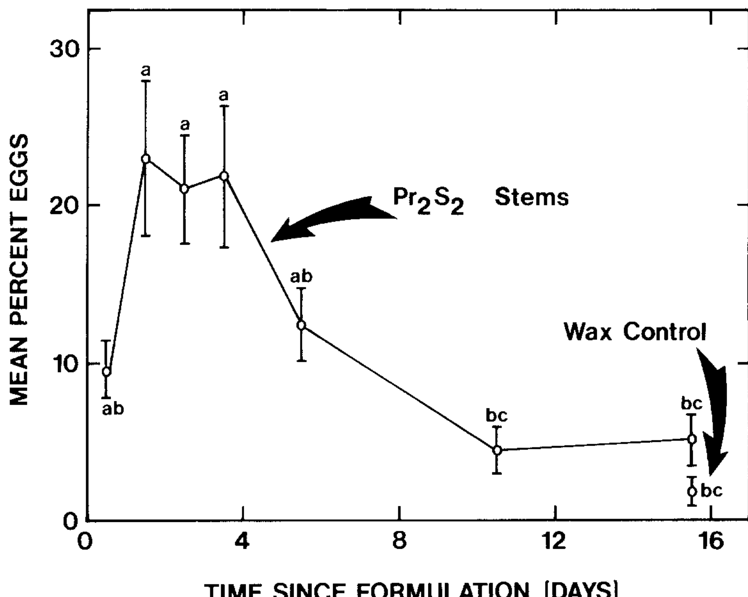

FIG. 4. Ovipositional responses of onion flies to *n*-dipropyl disulfide-treated surrogate foliage formulated 0–15 days before being used in ovipositional bioassays. Treatments accompanied by the same letter are not significantly different at $P < 0.01$ (ANOVA followed by LSD test for separation of means). Total number of eggs for 10 replicates = 2518.

flew to the surrogate ($N = 12$) or walked up to the surrogate via the substrate ($N = 12$). Females not ovipositing during these encounters ($N = 12$) stayed on the surrogate or in the immediate area of the surrogate for only 167 sec on average and spent 67% of their time grooming or sitting immobile on the surrogate. The remainder of their time was spent running over the surrogate surface and examining the surrogate with proboscis while running. These nonovipositing visitors did not proceed beyond extension of the proboscis; ovipositor probing and insertion were never observed.

Females that eventually oviposited during encounters ($N = 12$) were on the average 8.1 days old and laid 13.6 eggs (SE = 2.4). Encounters lasted ca. 17 min, 41 sec. Ovipositor insertion and oviposition accounted for the largest proportion of this time (mean ± SE = 65 ± 2.1%), with the remainder spent sitting still and grooming (3%) or examining the surrogate and substrate (32%).

Examining behaviors were primarily confined to areas of soil and surrogate within 1 cm of the soil/surrogate stem interface (mean ± SE tenure time = 253 ± 50.8 and 98 ± 16.8 sec, respectively, for substrate and surrogate, see Figure 6). Females spent significantly less time (mean ± SE tenure time = 6.2

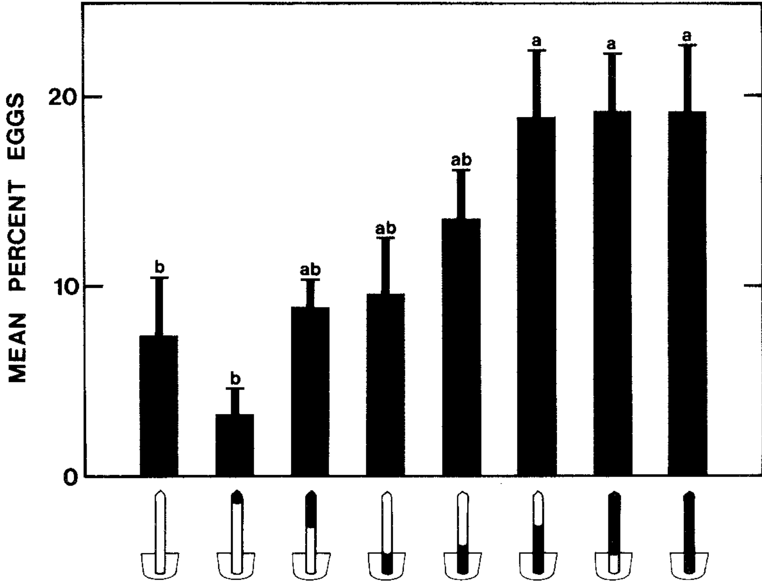

FIG. 5. *Delia antiqua* ovipositional responses to surrogate foliage with *n*-dipropyl disulfide-treated wax placed in different locations. Dark portions of surrogate foliage indicate treated areas, white areas were covered with plain wax. Treatments accompanied by the same letter are not significantly different at $P < 0.01$ (ANOVA followed by LSD test for separation of means). Total number of eggs for 10 replicates = 4312.

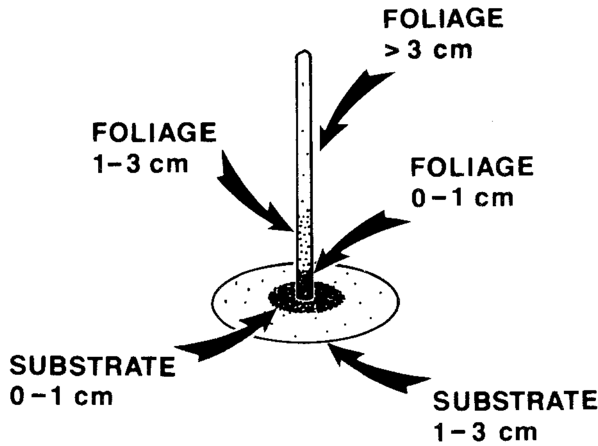

FIG. 6. Location and relative duration of *Delia antiqua* preovipositional examining behaviors on *n*-dipropyl disulfide-treated surrogate foliage. Density of shading indicates how much time is spent examining each zone.

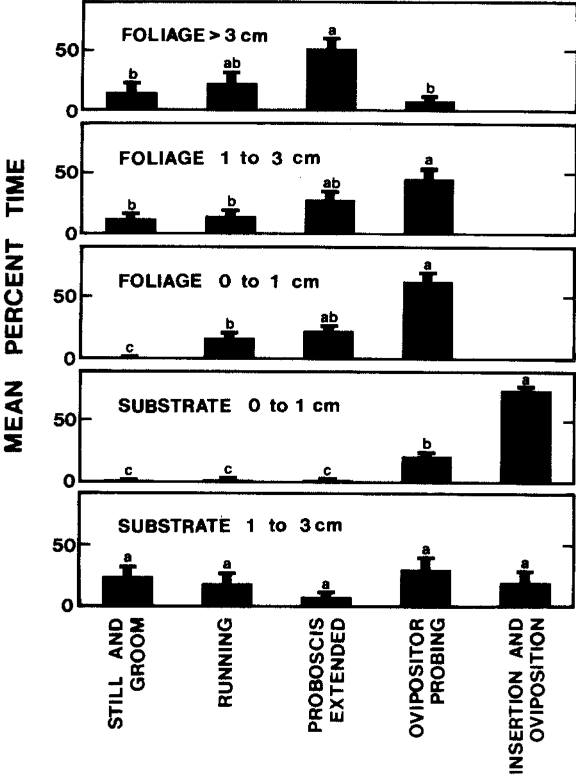

FIG. 7. Time allocated by ovipositing *Delia antiqua* females to five different behaviors in five different zones comprising oviposition sites. Values for percent time spent in behaviors within a single zone accompanied by the same letter are not significantly different at $P < 0.01$ (ANOVA followed by LSD test for mean separation).

$\pm$ 1.3 sec) examining the upper portion (foliage > 3 cm) of the surrogate. When flies did examine this area (Figure 7), it was by running over the surface or by extending the proboscis; probing with the ovipositor at this height on the surrogate occurred infrequently (mean $\pm$ SE = 0.8 $\pm$ 0.05 sec). Below 3 cm and above 1 cm (mean $\pm$ SE tenure time = 41 $\pm$ 8.7 sec), females continued to use the proboscis to examine the surrogate but were also more likely to engage the tip of the ovipositor to probe the surface. This latter form of examining was even more common at the base of the surrogate (foliage 0–1 cm).

Behaviors on the substrate differed somewhat from those seen on the surrogate itself (Figure 7). In the area immediately surrounding the base of the surrogate (foliage 0–1 cm), females spent most of their time with their ovipositors inserted into crevices in the soil. This latter behavior differed from ovi-

positor probing in that it was done in a stationary position, involved a full extension of the ovipositor, and placed the abdomen deeply within crevices in the soil surface. Ovipositor insertion was highly correlated with egg-laying; time spent in this behavior corresponded closely with the numbers of eggs laid by individual females ($r^2 = 0.90$, F for regression = 91.84, $P < 0.001$). As females moved farther away from the stem base (substrate 1–4 cm) they were less apt to insert the ovipositor into crevices and oviposit, and more apt to probe the soil with their ovipositors, sit still, or groom.

Surrogate Onions vs. Real Onions. When presented with the optimal surrogate (0.17 mg Pr_2S_2 per stem, 4 mm basal diam. × 12 cm height) and a 6-week-old onion seedling (3.5 mm diam. × 20 cm height) in a choice bioassay, females laid as many eggs around the surrogate (mean = 43 eggs) as around the onion plants (mean = 30 eggs, difference not significant at $P < 0.05$, two-way ANOVA). Significantly more eggs were laid around surrogates in no-choice bioassays (mean total eggs per female per day = 6.7 vs. 3.2 for onion seedling, significantly different at $P < 0.01$, two-way ANOVA) in which females were given access to either surrogates or onion seedlings for the first eight days of their reproductive lives. The larger number of eggs laid around surrogates was in part due to the fact that more females accepted the surrogate as an oviposition site during the eight-day test period (44 vs. 22% ovipositing per day, significantly different at $P < 0.01$).

However, when surrogates were placed in cages with 2-week-old onions grown from sets (4 mm diam. × 18 cm height), they received significantly fewer eggs (mean = 56) than did the real onions (mean = 194, $P < 0.05$, two-way ANOVA). Foliage removed from these same sets (4 mm diam. × 9 cm height) and placed upright in moist sand received fewer eggs (mean = 12) than did surrogates (mean = 47, not significantly different at $P < 0.05$, two-way ANOVA).

DISCUSSION

Because extracts of onion bulbs contain more of the stimulatory thiopropyl chemicals than extracts of onion foliage (Vernon et al., 1977, Ishikawa et al., 1978), it has been assumed that, when ovipositing into soil adjacent to onion plants, female onion flies are stimulated by volatile compounds that originate in the bulb. These assumptions have led to the design of bioassays that test effects of chemicals administered in a similar fashion; volatiles are presented either in conjunction with small holes and moistened filter paper (Vernon et al., 1977, 1978; Pierce et al., 1978) or are adsorbed onto charcoal granules and covered with moistened glass beads (Matsumoto and Thorsteinson, 1968; Ishikawa et al., 1978; Ikeshoji et al., 1980). Chemicals presented in this way never elicited more than 50% of the oviposition stimulated by onion slices.

Onion fly females, however, do not perceive onion plants solely through the chemical senses. Even when chemical stimuli are separated spatially from surrogate foliage by placing onion slices beneath the substrate, the addition of foliar surrogates synergizes ovipositional responses to odors, causing females to lay 18 times more eggs (Harris and Miller, 1982). Females respond strongly to changes in surrogate color, shape, and size and lay more eggs around yellow or green cylinders 4–8 mm in diameter and greater than 2 cm in height (Harris and Miller, 1983; 1984). These stimuli are sensed, at least in part, during runs up and down surrogate foliage.

Evidence presented in this paper indicates that acceptance of ovipositional sites may occur more readily if females perceive host-plant chemical cues in addition to foliar structural cues during runs over the plant surface. Optimal doses of Pr_2S_2 released from surrogate foliage stimulated four times as much oviposition as optimal doses released from the substrate. Placement of dipropyl disulfide on the surrogate itself also influenced oviposition. Females tended to lay more eggs around surrogates with disulfide at the base rather than on the upper half of "foliage." Observations of individual females performing pre-ovipositional examining behaviors suggested a reason for this trend: females tended to land on the upper portions of the foliage but, after landing, spent very little time in this area. The lower portions of the surrogate and areas of substrate immediately adjacent to the surrogate base were extensively examined (Figure 7) during runs with or without the proboscis and/or the tip of the ovipositor repeatedly contacting the wax surface.

During these examining behaviors, Pr_2S_2 formulated in wax could be detected by contact or olfactory receptors on the tarsi, antennae, proboscis, or ovipositor. Indeed, running over the surface of artificial or natural onion foliage may be akin to drumming in Lepidoptera (Ilse, 1937) and palpation in grasshoppers (Blaney and Chapman, 1970). Abrasion of foliage by spines or hairs located on the tarsi, proboscis, and ovipositor may increase concentrations of host-plant chemical stimuli to which the female is exposed. Antennae of *D. antiqua* are covered with trichoid, basiconic, grooved, and clavate sensilla (Honda et al., 1983) and give EAG responses to Pr_2S_2 and numerous other compounds that have stimulatory or neutral effects on oviposition (Ikeshoji et al., 1981; Guerin and Stadler, 1982). Preliminary experiments on tarsal hairs (done in the laboratory of Dr. Frank Hanson) indicate that contact chemoreceptors also respond to Pr_2S_2. Other herbivorous flies, whose examining behaviors closely resemble those of *D. antiqua*, sense host chemicals via chemoreceptors located on the antennae, tarsi, and maxillary palps (Städler, 1977; 1978; Guerin and Städler, 1982).

Since we do not know how accurately our present optimal surrogate approximates the stimuli presented by onion foliage, in-depth analyses of leaf surface chemistry and bioassays must be done to ascertain what compounds are

present and whether compounds function as stimulants or deterrents for ovipositing onion flies. For example, stimulatory chemicals such as Pr_2S_2 may be accompanied by other *Allium* secondary chemicals such as diallyl disulfide. Although this chemical does not appear to inhibit or stimulate oviposition when presented singly (Harris, 1982), it does inhibit responses when added to dipropyl disulfide (Harris and Miller, in preparation). Dimethyl disulfide may function in the same way. Both of these non-propyl-containing disulfides are more toxic than dipropyl disulfide to onion fly adults and larvae (Powell and Miller, in preparation) and are present at higher concentrations in *Allium* species (Freeman and Whenham, 1975) that are less preferred by ovipositing females and less suitable for larval development (Loosjes, 1976). On the other hand, sulfides may not be the only chemicals used in host recognition. The leek moth, *Acrolepiopsis assectella*, which also specializes on *Allium* species, responds positively to thiosulfinates in olfactometers and to thiosulfonates when ovipositing (Thibout et al., 1982). Methanol extracts of leek leaves are also highly stimulatory to ovipositing leek moths but do not contain sulfur compounds (Auger and Thibout, 1983).

Foliar surrogates and wax formulations of plant chemicals provide excellent tools for both applied and basic researchers studying insect–plant interactions. Chemicals present in resistant breeding lines can be formulated in wax coatings of surrogates and tested in lab bioassays before carrying out expensive and time-consuming field trials. The production of identical surrogates also provides realistic oviposition sites that could be used as a positive control to standardize responses to breeding lines tested at different times or in different countries. And finally, manipulation of surrogates, involving alterations of one or more plant character(s), will provide needed information on whether host acceptance is triggered by a few "key" stimuli or by interactions among a larger set of stimuli sensed by multiple sensory modalities (Miller and Harris, 1985).

KINETIC RESOLUTION OF SECONDARY ALCOHOLS WITH COMMERCIAL LIPASES: Application to Rootworm Sex Pheromone Synthesis

PHILIP E. SONNET and MARY WELCH BAILLARGEON

Animal Biomaterials Research Unit
Agricultural Research Service, USDA
Wyndmoor, Pennsylvania 19118

(Received April 28, 1986; accepted July 23, 1986)

Abstract—The relative rates of enzyme-catalyzed esterification of the enantiomers of 2-octanol with various acids were determined for several commercial lipases. Interesterifications and hydrolyses of racemic 2-octanol esters catalyzed by these enzymes were also examined. Novo's *Mucor miehei* lipase exhibited considerable enantioselectivity and was therefore employed to prepare 8-methyl-2-decanols with high configurational purity at the carbinol carbon. Esters of these alcohols had been previously identified as sexually attractive to several rootworm (*Diabrotica*) species, and the stereochemistry of those esters had been shown to be critical to the attraction. The enzymatic resolution provides a convenient method to obtain such esters in a desired state of configurational purity.

Key Words—*Diabrotica* sp., kinetic resolution, lipase, methyl carbinol, *Mucor miehei*, pheromone, western corn rootworm, Coleoptera, Chrysomelidae.

INTRODUCTION

The relationship of insect pheromone stereostructure to insect behavior has received considerable attention (Brand et al., 1979). Successful completion of a pheromone identification and evaluation of methods by which to control the behavior of an insect pest often are dependent on the ability to prepare pure stereoisomers. Therefore there is a continuing interest in the development of novel, or improved, syntheses of stereocenters that can be incorporated into structures that are commonly found in pheromone blends. Additionally, such new methodology often serves the broader interest of organic synthesis generally. Among the approaches commonly used for asymmetric synthesis, enzy-

0098-0331/87/0500-1279$05.00/0 © 1987 Plenum Publishing Corporation

matic resolution can perform quite well providing (1) a preparation is commercially available or can be reproduced easily in a laboratory, and (2) the precursor of the target stereocenter mimics the enzyme's normal substrate adequately to provide reasonable reaction rates. Enzymatic conversions that have been targeted for chiral insect sex pheromone structures include *N*-deacylation of racemic acetamido acids with an *Aspergillus acylase* (Mori and Iwasawa, 1980; Sugai and Mori, 1984), selective hydrolysis of alkynol esters by cultures of *Bacillus subtilis* var. *Niger* (Mori and Akao, 1980), reduction of β-ketoesters and ketones with Baker's yeast (*Saccharomyces cerevisiae*) (Mori, 1981; Mori et al., 1985), and the reduction of α-methyl-α, β-unsaturated aldehydes to chiral α-methylcarbinols also with Baker's yeast (Gramatica et al., 1985). In all of these cases an enzyme preparation of previously documented properties was examined with a selected group of substrates. We report here a study of a number of commercial lipases in which stereoselective hydrolysis, esterification, and transesterification of 2-octanol as a typical 2-*n*-alkanol were evaluated. The information was then used to synthesize 8-methyl-2-decanol samples in which the carbinol carbon was $\geq$97% (94% *ee*) configurationally pure. Esters of such alcohols are pheromones of various *Diabrotica* species (Guss et al., 1985).

METHODS AND MATERIALS

Gas–liquid chromatography (GLC) was performed with a Shimadzu GC-Mini-2 instrument using an SPB-1 column (0.25 mm ID $\times$ 30 m) operated at temperatures indicated below with a 50:1 split ratio and He carrier gas. Infrared (IR) spectra were obtained on a Perkin-Elmer 1310 Spectrophotometer (3% solutions in CCl_4 or $CHCl_3$). Mass spectra (MS) were recorded with a Hewlett-Packard HP-5995 GC-MS system employing an OV-1 capillary column (0.25 mm ID $\times$ 30 m). Nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ using a JEOL JNM-GX 400 FT NMR spectrometer. Free fatty acid titrations were performed with a Radiometer pH instrument comprised of an ABU-80 Autoburette module operated in "end point" or "pH stat" modes as appropriate. Lipases were obtained from commercial sources and were employed directly without any purification. Specific lipases and manufacturers are described in text and tables; additional information follows: Gist-Brocades USA, Inc., Charlotte, North Carolina 28224; Amano International Enzyme Co., Inc., P.O. Box 1000, Troy, Virginia 22974; Novo Laboratories, Inc., P.O. Box D, Wilton, Connecticut 06897-0820. The α-methylbenzyl isocyanates, both *R* and *S*, were synthesized from the corresponding amines that had been purchased from Hexcel Corp., using the method of Pirkle and Hauske (1977). The α-methylbenzylamines were 98.7% *R* and 99.4% *S*, but the analyses reported here were not corrected. The actual ratios were in fact slightly higher than those reported in this paper.

Rate ratios are calculated from the expression:

$$\frac{k_A}{k_B} = \frac{\ln (1 - C)(1 - ee)}{\ln (1 - C)(1 + ee)}$$

wherein C is fraction conversion and ee is enantiomeric excess of starting material expressed as a fraction (Martin et al., 1981). For hydrolysis the stereobias was evaluated in the product and,

$$ee_a = \frac{C(ee_b)}{1 - C}$$

wherein a and b represent starting material and product, respectively.

The 2-octanol was purchased from Aldrich Chemical Co.; other reagents and solvents were of commercial origin and employed directly except for esters of 2-octanol and 8-methyl-2-decanol. The esters were synthesized in the usual manner from the alcohols using acid chlorides and pyridine solvent. They were distilled and characterized by IR, MS, and GLC.

Initial Rate Assay. Weighed amounts of commercial lipase were allowed to react in an emulsion created by brief sonication of 10% (w/w) purified olive oil and 10% (w/w) gum arabic. Five milliliters of emulsion, 0.2 ml of 2.85 M NaCl, and 30–100 μl of aqueous enzyme were brought together at ambient temp. Free fatty acid release was measured by titration with 0.100 N NaOH using "pH stat" mode at pH 7.3 or other indicated pH (Table 1). Enzyme

TABLE 1. INITIAL RATE ASSAYS OF COMMERCIAL LIPASES ON OLIVE OIL[a]

Lipase	Manufacturer code	Rate (μmol/min/mg)	Position selectivity[b]	Fatty acid selectivity[c]
Aspergillus niger, 1	Amano-AP	0.154	1,3	18 (*cis*-Δ9)
Aspergillus niger, 2	Amano-K	11.2	1,2,3	10,12
Candida rugosa	Enzeco	9.82	1,2,3	18 (*cis*-Δ9)
	Sigma	9.70	1,2,3	18 (*cis*-Δ9)
Mucor miehei	Amano-MAP	2.67	1,3	<12
	Gist Brocades-S	40.0	1,3	<12
	Novo (powder)[d]	5.33	1,3	<12
	Nova 3A (resin)	0.095	1,3	<12
Porcine pancreatic[e]	Sigma	15.6	1,3	4
Rhizopus arrhizus[f]	Gist Brocades	33.4	1,3	8,10

[a]pH maintained at 7.3 unless otherwise indicated.
[b]Position selectivity with respect to triglyceride hydrolysis.
[c]Fatty acid selectivity (Brockerhoff and Jensen, 1974; Borgstrom and Brockman, 1984); the preferences are slight in most cases.
[d]The powder form is not currently available, although the lipase is now formulated on both an ion exchange resin sold as "3A" and as a solution as "225".
[e]pH 8.0 with 0.2 ml of 0.3 M $CaCl_2$ to 5 ml emulsion (Methods and Materials).
[f]0.2 ml of 0.3 M $CaCl_2$ to 5 ml emulsion.

solutions were prepared in distilled water with additives as indicated. The conditions were chosen to optimize activity of the lipase on the olive oil. Initial rate assays provide reproducible data by which comparisons of enzymatic activity on a given substrate may be made.

α-Methylbenzyl Carbamates. The alcohols, and reaction mixtures that were being analyzed for enantiomeric alcohol content, were derivatized by reaction with excess (*R*)- or (*S*)-α-methylbenzyl isocyanate (for example, 10 μl of neat racemic alcohol plus 20 μl of isocyanate) at 50–60°C for 0.5 hr in a screw-cap vial. The excess isocyanate was discharged by adding a few drops of methanol and warming at 50–60°C for 0.25 hr. The resulting mixture was diluted with acetone and filtered through Na_2SO_4 in a disposable pipet, if necessary, for GLC analysis. Spectral and chromatographic data for the carbamates follow: (1) 2-octanol *N*-α-methylbenzyl carbamate: IR (CCl_4) 3460, 1715 cm^{-1}; EI-MS (*m/e*) 277 $(M)^+$, 262 $(M\text{-}CH_3)^+$, 164,150; GLC (220°C) k′ 3.58 (*R*S**), 3.77 (*R*R**), $\alpha = 1.054$; (2) 8-methyl-2-decanol *N*-α-methylbenzyl carbamate: IR (CCl_4) 3460, 1715 cm^{-1}; EI-MS (*m/e*) 319 $(M)^+$, 164,150; [^{13}C]NMR ($CDCl_3$): 11.4, 19.2, 20.3, 22.6, 22.7, 27.0, 29.5, 29.9, 34.4, 36.3, 36.5, 50.5, 71.6, 116.6, 125.9, 127.2, 128.6, 155.7 ppm. GLC (240°C) k′ 3.73 (*R*S**), 4.00 (*R*R**), $\alpha = 1.072$.

Lipase Screening for Kinetic Resolution. Racemic 2-octanol (0.33 g, 2.5 mmol) was dissolved in 10 ml of nanograde hexane. The organic acid (2.5 mmol) was added as was 1.0 g of the lipase powder (2.0 g of porcine pancreatic lipase powder). The mixture (heterogeneous) was stirred for a period of time in an incubator at a specified temperature (Tables 2–5), diluted with ethanol, and immediately titrated to pH 9.5 with 0.1 N NaOH. Blanks were obtained for each lipase employed. The titrated mixture was partitioned with hexane, and

the hexane layer was washed 2× with equal volumes of water. The organic phase was dried ($MgSO_4$) and concentrated; the resulting product mixture was then derivatized for GLC analysis of residual alcohol. The esters present were also observed sometimes but did not interfere. Hydrolyses and transesterifications were conducted and analyzed in a similar manner and are reported in Tables 6 and 7. Larger amounts of enzyme were required to effect hydrolysis. The following procedures are representative.

Kinetic Resolution by Hydrolysis. (*R*)-2-octanol from racemic 2-octyl octanoate, the ester (5.12 g, 20.0 mmol) was vigorously stirred in 20 ml of distilled water at room temperature containing 1.0 g of Novo's *Mucor miehei* lipase powder. The pH was maintained at 7.0 with 2 N NaOH. After 2 days, 1.10 ml of base had been consumed (11% conversion). Ethanol (50 ml) was added, and the mixture was extracted with 3 × 50 ml of hexane. The extract was washed with 2 × 30 ml of water, dried ($MgSO_4$), and concentrated. Distillation of the residue produced 0.27 g of 2-octanol that was 98.0% *ee* (*R*): bp 90°C/30 mm. Further hydrolysis (another 12.5% conversion) gave an additional 0.1 g that was 97% (*R*).

For (*R*,*S*)-8-Methyl-(*R*)-2-decanol from racemic octanoate ester, the ester (5.95 g, 20 mmol) was stirred in 20 ml of Novo-225 after brief sonication. Novo-225 is a solution of glycerol-stabilized *M. miehei* lipase. The mixture was maintained at room temperature and at pH 7.0 until 25–30% conversion had occurred (24 hr). The product was worked up as above to give 0.67 g of 8-methyl-2-decanol that was 97.6% *ee* at the carbinol carbon: bp 54–70°C/0.2 mm.

[d] The rate was 59 for this reaction using the liquid form of the lipase, Novo-225.
[e] Novo-225.

Kinetic Resolution by Esterification. For 8-methyl-(R and S)-2-decanols, the racemic alcohol (4.51 g, 26.2 mmol) was dissolved in 45 ml of hexane containing 9.43 g (65.5 mmol) of octanoic acid. Novo's lipase 3A (5.0 g) was added, and the heterogeneous mixture was sitrred at 30°C for six weeks. The progress of the reaction was followed by GLC monitoring of the residual alcohol enantiomer content, and the reaction was worked up by filtration to recover enzyme. The filtered solution was washed with aqueous base and then water. After the organic phase had been dried, the solvent was removed and the alcohol distilled [bp 65–72°C/0.1 mm, 1.83 g of 94.6% 2(R)]. Distillation was continued until the head temperature was 120°C. This produced ca. 0.2 g that was discarded. The pot residue was saponified with 33 ml of 6 N KOH and 50 ml of MeOH under reflux overnight. The saponified material was extracted into hexane and processed as above. Distillation produced 1.88 g of 93.2% 2-(S)-alcohol.

Recovered lipase was exposed competitively with fresh Novo-3A in an esterification of 2-octanol with octanoic acid. The recovered enzyme preparation had retained ca. 85% of its activity.

RESULTS AND DISCUSSION

Lipases are a class of enzymes that hydrolyze natural triglyceride mixtures (animal fats and vegetable oils) to diglycerides, monoglycerides, glycerine, and fatty acids. Excellent reviews have been provided of their purification, char-

acterization, and catalytic action (Brockerhoff and Jensen, 1974; Borgstrom and Brockman, 1984). In addition to pork pancreatic lipase that is available as a by-product of the swine industry, a number of fungal lipases have been made available to benefit the dairy and cheese industries. Considerable interest exists in enzymatic restructuring of natural triglycerides and in enzymatic cleavages on an industrial scale. The outlook for lipase availability as catalysts for general organic synthesis therefore seems positive, although their potential has not yet been fully explored.

Triglyceride lipases are uniformly lacking in stereoselectivity in hydrolysis of triglycerides (Brockerhoff and Jensen, 1974, pp. 56–58). Nevertheless, stereobiases of varying degree are exhibited by these enzymes in esterification, transesterification, and hydrolysis of other substrates. Lipases of *Candida rugosa* (Cambou and Klibanov, 1984a,b; Langrand et al., 1985; Laumen and

Schneider, 1984; Satoru et al., 1985), porcine pancreas (Lavayre et al., 1982; Ladner and Whitesides, 1984; Wang et al., 1984), *Pseudomonas aeruginosa* (Hamaguchi et al., 1984, 1985), and *Rhizopus* sp. (Laumen and Schneider, 1984) have been variously employed to effect kinetic resolutions or to selectively esterify diols that contain stereoisotopic alcohol groups. In addition there is an indication that lipases may exhibit a stereobias in transesterification, therefore likely esterification as well, with alcohols that closely resemble diglycerides (Sonnet et al., 1986).

With this information in mind we wished to screen available lipases for possible utility in preparing 8-methyl-2-(*R* and *S*)-decanol, the parent alcohol of a pheromone structure that is common to a number of diabroticites (Guss et al., 1985). Several of these species are serious pests of corn, and the ability to monitor selectively may depend critically on the stereochemistry of the bait. Current knowledge indicates that the configuration of the methyl-bearing hydrocarbon center must be *R* for all species; the *S* configuration is inactive. Hence this center may be racemic in chemicals intended to attract with no disadvantage beyond dilution. The carbinol center, however, is species differentiating. Moreover, evidence has accrued that indicates that several percent of antipodal configuration of a pheromone can inhibit response (Brand et al., 1979). Since racemic 8-methyl-2-decanol can be readily prepared in several ways (Sonnet et al., 1985), including a procedure developed for the USDA by Zoecon Corporation,[1] an efficient enzymatic resolution of the racemic carbinol center might be a useful accessory reaction.

Initially 2-octanol and its esters were exposed to various reaction conditions using commercial lipases. The enzymes were calibrated for activity on olive oil (ca. 85% triolein) using an "initial rate assay" (Methods and Materials). The results are given in Table 1. Considerable differences exist in the lipase activity of these materials. In part this is attributable to the manner and degree of purification of each commercial preparation as well as to potential intrinsic differences. The lipase of *Candida rugosa* (previously named *C. cylindracea*) offered by Sigma is, we learned later, supplied by Enzeco, and the initial rate measurement of activity and subsequent evaluation of stereobias in resolutions were consistent with this. However, great differences in activities toward olive oil were exhibited by the several commercially available lipases of *Mucor miehei*. Moreover, the degrees of stereobias exhibited (see below) were also different. Because of the heterogeneous character of these preparations, only a more probing study of the protein content and knowledge of the (proprietary) preparation of the lipase could provide a definitive answer to questions concerning the enzymes themselves. We have opted therefore to treat these materials simply as undefined but, if reproducibly prepared, potentially useful catalysts for organic synthesis.

[1]Specific Cooperative Research Agreement No. 58-7B30-1-176, August 14, 1981.

Esterification. The alcohol, 2-octanol, was allowed to react in hexane with an organic acid at a selected temperature for a period of time in the presence of the lipases. Residual free fatty acid was determined by titration and the enantiomeric composition of the residual alcohol was determined by conversion to carbamates with (*R*)- or (*S*)-α-methylbenzyl isocyanate (Methods and Materials) (Pirkle and Hauske, 1977). Although a number of chiral derivatizing agents for secondary alcohols have been employed (Doolittle and Heath, 1985), the carbamates could be formed directly from crude reaction products, and separations of the diastereomers of 2-octanol and 8-methyl-2-decanol were excellent (Figures 1 and 2). The rate ratio, k_R/k_S could then be calculated (Methods and Materials). The results employing *C. rugosa* lipase (Table 2) were disappointing; the rate ratios were very low although they could be improved by lowering the reaction temperature. Porcine pancreatic lipase (Table 3) proved to be more selective and demonstrated the validity of varying the fatty acid as a means to optimize the selectivity. The lipase of *Mucor miehei* (Novo powder) showed only low selectivity with propanoic acid, but very high selectivity with octanoic acid (Table 4). *Rhizopus arrhizus* lipase was rather unreactive with acids of medium and long chain length as well as only modestly selective (Table 4). Other lipases were evaluated with octanoic acid only, and the results are given in Table 5.

Summarizing these results, *C. rugosa* lipase catalyzed relatively fast esterifications of 2-octanol but with low selectivity. Porcine pancreatic lipase acted more slowly (lauric acid fastest) with greater discrimination. *R. arrhizus* lipase acted slowly also (propanoic acid fastest). *M. miehei* lipase (Novo only) provided greatest discrimination between the enantiomeric 2-octanols. Temperature affects both the overall rate and the relative rate; and α-branching of the acid (see Table 2) dramatically lowers reactivity. Initial presence or absence of small amounts of water affects results as well (Table 4). Since esterification produces water, the observed results starting "dry" must be a composite. Fastest reactions may occur with shorter or longer acid chains, but stereobias (invariably $R > S$) was always poorest with shorter acid chains.

Hydrolysis. The propanoate, octanoate, and dodecanoate esters of 2-octanol were arbitrarily chosen for exposure to lipases. The pH was automatically maintained at 7.0 and the titration thereby indicated instantaneously the degree of conversion. As with the esterifications, the crude reaction mixture was derivatized and analyzed for enantiomeric excess of the alcohol, which was this time the product. Rate ratios were calculated again and the results for *C. rugosa*, *R. arrhizus*, and *M. miehei* lipases are given in Table 6. All of the lipases reacted very slowly and, although emulsifying agents were not specifically added, Novo-225, (*M. miehei* lipase intended for direct lipolysis of triglycerides) reacted no more readily with 2-octanol octanoate than did the Novo powder. This implies that the enzymes are inherently slow in their reactions with esters 2-octanol. Nevertheless, the Novo lipase (both powder and Novo-225)

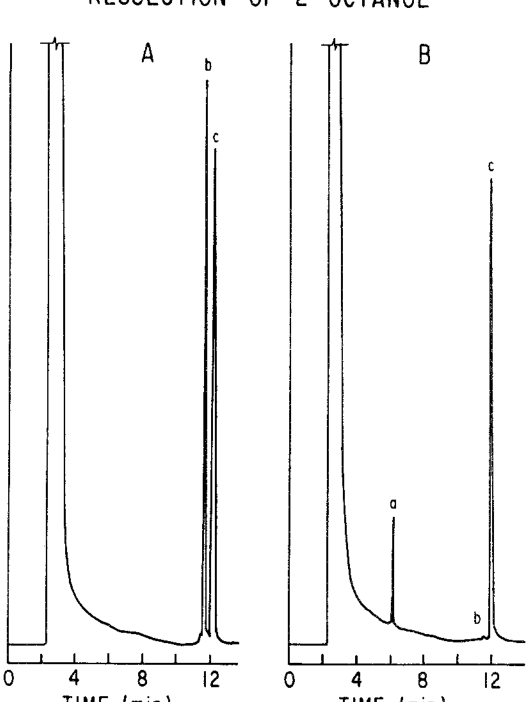

FIG. 1. (A) Analysis of α-methylbenzyl carbamates found by the reaction of (±)-2-octanol with (*R*)-α-methylbenzyl isocyanate by GLC using an SPB-1 capillary column (220°C). Peak b is the *RS* diastereomer; peak c is the *RR* diastereomer. (B) Analysis of 2-octanol obtained by hydrolysis of the racemic octanoate ester using *M. miehei* lipase (Novo, powder). Peak a is contamination by the ester, peaks b and c are the diastereomeric derivatives as in A. The major enantiomeric alcohol formed has the *R* configuration.

did show strong stereoselection, particularly for the octanoate ester; the *R*-esters reacted preferentially whenever bias was noted.

Transesterification. This process appears to be receiving considerable attention in the fats and oils industries. There the application is intended to produce new triglyceride mixtures by displacing existing acid residues with new ones to generate materials with more desirable physical properties. Stereochemistry probably plays an insignificant role in determining gross physical properties compared to positional isomerism on the glycerol moiety. However, one might use a fat or oil as a very cheap source of acid residues for kinetic resolutions in which acid residues are being transferred from glycerol to another (racemic) alcohol.

Reactions of 2-octanol with a selection of esters including triglycerides as

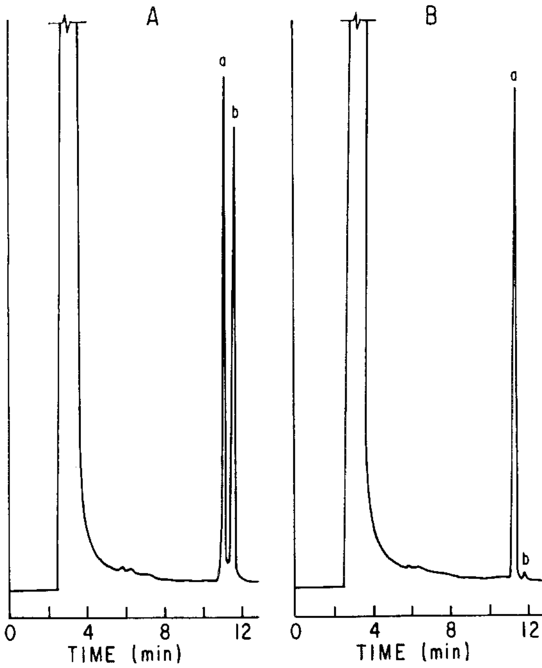

FIG. 2. (A) Analysis of α-methylbenzyl carbamates of $(\pm)$-8-methyl-2-decanol formed by reaction with *S*-α-methylbenzyl isocyanate (SPB-1, 240°C). Peak a is the *RS* diastereomer, and b is the *SS* diastereomer. (B) Analysis of 8-methyl-2-decanol obtained by hydrolysis of the racemic octanoate ester using *M. miehei* lipase (Novo-225). Peak a is the *RS* diastereomer, and the major product of lipolytic hydrolysis has the *R* configuration

sources of acid residues were conducted neat (Methods and Materials). The degree of conversion was estimated by gas chromatography and distillation to recover alcohol. Results are presented in Table 7; only the lipases of *C. rugosa* and *M. miehei* gave reasonable conversions. The most striking observation was that the addition of a small amount of water to reaction mixtures containing the Novo *M. miehei* lipase, but not the other lipases, produced a profound increase in stereoselection. It may be that in a nonaqueous medium the enzyme is deprived of water at the catalytic site, water that if present may be held in such manner that the enzyme operates stereoselectively.

Application. The transesterifications using olive oil and tallow had not shown good selectivity, even with Novo's *M. miehei* lipase. Therefore preparative reactions were limited to hydrolysis and esterification. The octanoate ester of 2-octanol was allowed to react in water at pH 7.0 to 11% conversion

using Novo *M. miehei*. The 2-octanol recovered by distillation, 10% yield (91% of theory based on conversion), was 99% *R*. Similarly, the octanoate ester of 8-methyl-2-decanol was allowed to react to 15% conversion and yielded (10%) 98.7% 2-*R* isomer. The rate ratio for this ester is therefore ca. 95. Employing the currently available liquid form of this lipase, Novo-225, a 26% yield of 98.8% 2-*R* isomer was obtained implying a somewhat improved stereobias. These reactions had been allowed to proceed at room temperature for 24–40 hr.

Esterification of racemic 8-methyl-2-decanol in hexane with octanoic acid was conducted with Novo's lipase 3A, which is derived from *M. miehei* and is formulated on an ion exchange resin. Because that rate ratio is again fairly high (ca. 100), and the resin-borne enzyme is very stable, it is possible to produce both *R* and *S* alcohols with high configurational purities and in good yields. Reactions were allowed to proceed to nearly 50% conversion and the recovered ester was saponified to *R* alcohol. Adjustments (reduction) in percent conversion can be made to provide a purer *R* ester; a higher conversion would result in an alcohol richer in the *S* configuration. In a particular experiment, 41–42% yields of each alcohol were obtained: 94.6% *R* and 93.2% *S*; in another, similar yields were obtained: 95.4% *R* and 91% *S*.

These processes represent resolutions of aliphatic alcohols that are among the more difficult structural types to resolve. Simple secondary alcohols frequently find use in organic syntheses and occasionally have important biological activity. Since the *M. miehei* lipase is commercially available, and the procedures employed are quite simple, these results should prove quite useful.

Acknowledgments—The authors express their gratitude to Dr. Edwin Piotrowski and Ms. Dorothy Hunter for mass spectral data, and to Dr. Philip Pfeffer and Mr. Thomas Boswell for NMR data. The authors also express gratitude to the Amano, Novo, and Gist-Brocades companies for generous gifts of lipase preparations.

(Received May 12, 1986; accepted July 24, 1986)

Abstract—Heterosexual intra- and interspecific chemoattraction studies were done in polycarbonate chambers without barriers using 8- to 10-week-old *Schistosoma mansoni* from mice, 10-week-old *Schistosoma japonicum* from hamsters, and 14-week-old *Schistosoma haematobium* from hamsters. Experiments were done for up to 4 hr at 37°C in a humidified incubator. Single worms were not attracted to decoys or heat-killed worms. Heterosexual intraspecific and interspecific attraction was significant at all time points with all combinations. No clear differences were apparent between intra- and interspecific attraction. Differences between same and different *S. japonicum* or *S. haematobium* pairs were not significant at any time point.

Key Words—Trematode, digenetic, *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, chemoattraction, sexual attraction, interspecific, fluke, blood.

INTRODUCTION

Using a bioassay system described by Imperia et al. (1980) to study the effects of *Schistosoma mansoni* excretory–secretory products in vitro, Eveland et al. (1982) demonstrated greater chemoattraction responses between male and female worms which were initially paired with each other, than those which were

[2]Present address: Department of Microbiology, California State University, Long Beach, 1250 Bellflower Boulevard, Long Beach, California 90840.

paired with other males or females. Eveland et al. (1983) also showed that homosexual, but not heterosexual, attraction between *S. mansoni* adults was reduced in the presence of mechanical barriers constructed from dialysis tubing with a molecular weight cutoff of approximately 12,000.

A number of investigators, including Vogel (1941), Armstrong (1965), Taylor et al. (1973), and Southgate et al. (1976, 1982) have reported cross-mating of schistosomes in vivo, but similar in vitro studies have not been done.

We report here results of studies to compare intra- and interspecific chemoattraction in our bioassay system, using *S. mansoni*, *S. japonicum*, and *S. haematobium*.

METHODS AND MATERIALS

Experimental Animals and Media. Adult 8- to 10-week-old PR-1 strain *Schistosoma mansoni* (Richards and Merritt, 1972; Fletcher et al., 1981) from CD-1 mice (Charles River, Wilmington, Massachusetts) and the albino M line of *Biomphalaria glabrata* (Newton, 1955) were used. Also used were a Chinese strain of 10-week-old *S. japonicum* from hamsters and 14-week-old *S. haematobium* from hamsters. The *S. mansoni* had been routinely maintained in our laboratory for several years and through many passages. The *S. japonicum* and *S. haematobium* were supplied by the University of Lowell (Lowell, Massachusetts) under an NIAID supply contract. Worms were recovered by perfusion of the portal and mesenteric veins and maintained until use at 4°C in Earle's balanced salt solution (EBSS) containing 0.1% glucose and 0.5% lactalbumin hydrolysate (Clegg, 1965; Imperia et al., 1980). All experiments were done using this incubation medium. The time between perfusion and the beginning of an experiment was always less than 1 hr. Distances between worms were measured in millimeters at 0.5, 1.0, 2.0, 3.0, and 4.0 hr. From 13 to 18 trials were carried out for each experimental design.

Bioassay Design. Polycarbonate chambers with 14 linear channels, each channel 3 cm long, 1 cm wide and 1.5 cm high, were used. Each channel was filled to a height of 0.85 cm with 1% agar in phosphate-buffered saline (pH 7.2). The agar was overlaid with EBSS. Experiments were carried out using nonbarrier designs (Eveland et al., 1982) at 37°C in a humidified incubator. Worms were washed in EBSS then pipetted into the chamber 15 mm apart in separate channels. This distance allowed each worm to move either toward the other, which was initially 15 mm away, or 7.5 mm in the other direction, toward the end of the channel. Distances were measured between worm cetners at each time period (i.e., 0.5, 1.0, 2.0, 3.0, and 4 hr). At each time period, the distance between a worm couple was measured, and the percent attraction determined by the formula: $(15 - D/15) \times 100$, where D = the actual distance between a worm couple at a particular time point.

Observations were based on the mean ±SE values from the summation of 13–18 individual trials. Thus, by this formula 0% attraction would indicate that worms remained at their original distance, and 100% attraction would indicate that all the worms were in contact. Attraction between *S. japonicum* or *S. haematobium* male and female worms from the same or different male–female worm pairs was tested. Also, *S. mansoni* male and female worms of opposite sex but from different pairs were compared with *S. japonicum* or *S. haematobium* worms of opposite sex for their attraction to *S. mansoni*. Tests for the significance of difference between means were performed using Student's t test, and $P < 0.05$ was considered significant.

RESULTS

All worms were alive and active after 4.0 hr in the bioassay. Results are shown in Figures 1–3. Attraction between *S. japonicum* or *S. haematobium* males and females from the same or different worm pairs was tested (Figure 1). At 0.5 hr, *S. japonicum* from the same pairs were 64% attracted, compared to 45% attraction between worms from different pairs, and at 1.0 hr, *S. japonicum* from the same pairs were 71% attracted to each compared to 53% attraction between worms from different pairs. However, the differences were not significant ($P > 0.05$). Likewise, differences between the same and different *S. haematobium* pairs were not significant at any time point.

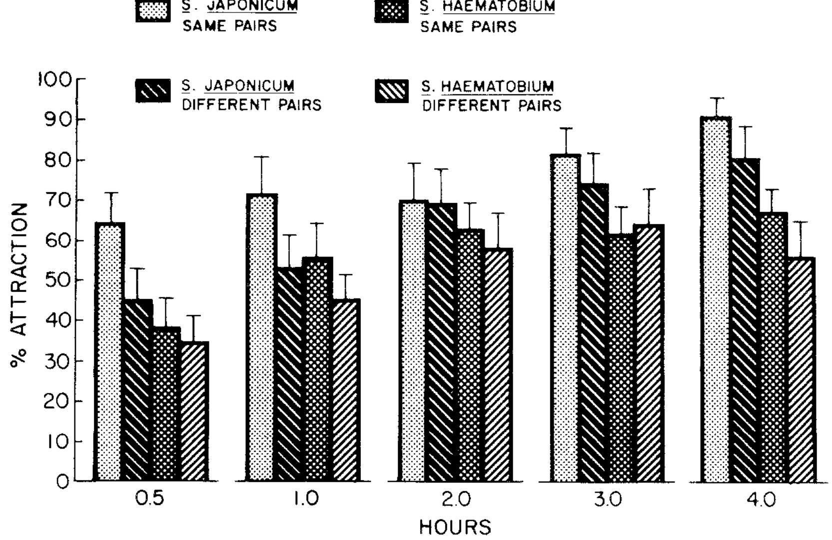

FIG. 1.

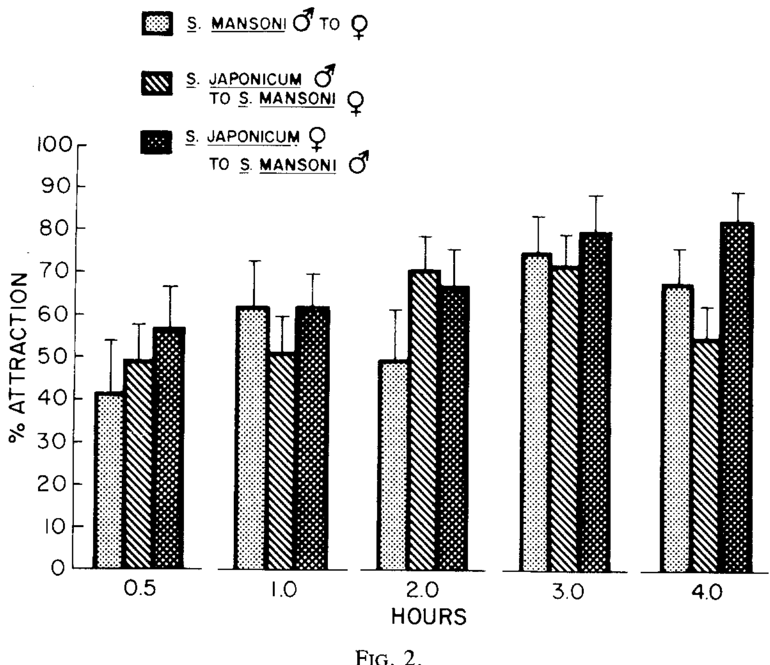

FIG. 2.

Results comparing heterosexual attraction of *S. mansoni* to *S. mansoni*, and *S. mansoni* to *S. japonicum* are shown in Figure 2. Attraction always occurred, and interspecific attraction was as great as intraspecific attraction. At some time points interspecific attraction appeared stronger than intraspecific attraction, but significant differences were not observed at any time point. In both interspecific and intraspecific attraction, 10–15% of the males and females were actually in contact at all observed time points.

Results comparing *S. mansoni* with *S. haematobium* are shown in Figure 3. Attraction always occurred, and interspecific attraction was roughly comparable to intraspecific attraction. In both interspecific and intraspecific attraction, approximately 10–15% of the males and females were actually in contact at all observed time points.

When single worms of either sex were placed at an origin in our bioassay system, they rarely migrated from that spot, although minor migrations were occasionally observed toward both sides of the origin. Likewise, net movement of single worms toward worms killed by heating at 60°C for 1-2 min or toward decoys (filter paper of approximate worm size) was zero.

DISCUSSION

In our bioassay system heterosexual attraction always occurred in the absence of barriers, and studies using *Schistosoma mansoni*, *S. japonicum*, and

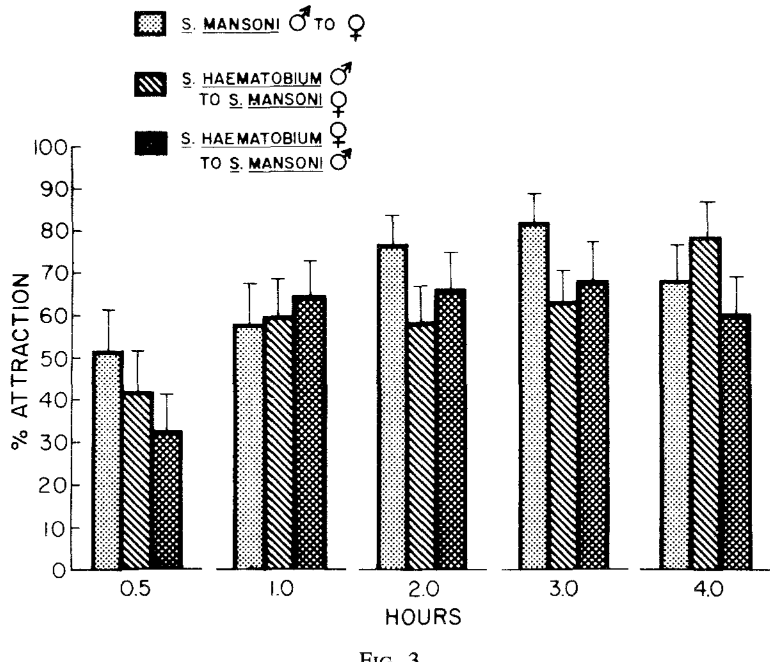

FIG. 3.

S. haematobium demonstrated no clear differences between intra- and interspecific attraction. In *S. japonicum*, slightly more heterosexual attraction between the same than different pairs may have occurred for up to 1 hr, although the differences were not significant ($P > 0.05$). This result was in general agreement with that previously reported for *S. mansoni* (Eveland et al., 1982), although in *S. mansoni* the effect was statistically significant and increased after 1 hr. Differences between worms from the same and different pairs were not observed in *S. haematobium*. The results of our studies, along with Shirazian and Schiller (1982), show that opposite sexes were attracted to each other in vitro and that, at least in *S. mansoni*, worms prefer to couple with their original partners.

In nonbarrier design experiments which we reported previously, homosexual attraction was as strong as heterosexual attraction (Eveland et al., 1982), but when barrier designs were used homosexual attraction was much weaker (Eveland et al., 1983), suggesting that more than one type of chemoattractant may be operative. It is possible that the attractants responsible for interspecific and homosexual effects were similar and differed from those responsible for the more specific effects seen in the presence of barriers. Studies are in progress to test interspecific attraction using barrier designs. In any case, these studies show that at least some schistosome chemoattractants cross species lines, and this suggests that if blocking agents can be developed against schistosome chemoattractants, they may be broadly applied.

Although the exact nature of the chemoattractants is not known, excretory-secretory products and at least their lipophilic fraction are involved (Eveland and Haseeb, 1986; Haseeb and Eveland, 1986).

Acknowledgments—This work was supported by NIH grant AI-17540. Materials used in this study were provided by an NIAID supply contract AI 02656.

TECHNIQUE FOR INJECTING INTACT GLANDS FOR ANALYSIS OF SEX PHEROMONES OF LEPIDOPTERA BY CAPILLARY GAS CHROMATOGRAPHY: Reinvestigation of Pheromone Complex of *Mamestra brassicae*[1]

A.B. ATTYGALLE, M. HERRIG, O. VOSTROWSKY, and H.J. BESTMANN

Institute for Organic Chemistry
University of Erlangen-Nürnberg
Erlangen, 8520 FRG

(Received April 1, 1986; accepted July 28, 1986)

Abstract—The structure elucidation of sex pheromones of Lepidoptera by a solid-sample injection technique in conjunction with capillary gas chromatography is described. The applicability of this method in GC and GC-MS modes was demonstrated by reanalyzing the sex attractants of females of *Ostrinia nubilalis* and *Bombyx mori*. The pheromone complex of *Mamestra brassicae* was reinvestigated and (Z)-9-hexadecenyl acetate and (Z)-11-hexadecenol were found in addition to already known pheromone components of this species. By using the solid-sample injection, the exact site of pheromone release could be determined in *M. brassicae*.

Key Words—Solid-sample injection, sex pheromone analysis, *Ostrinia nubilalis*, *Bombyx mori*, *Mamestra brassicae*, Lepidoptera, Pyralidae, Bombycidae, Noctuidae, site of pheromone release.

INTRODUCTION

In the investigations of substances present in extremely small quantities, a technique which permits direct application of the sample to gas chromatography offers a number of advantages over the more popular sample injection methods involving solutions. The most obvious advantage is that dilution of the sample

[1] Pheromones 52. Pheromones, 51: Bestmann, H.J., and Schmidt, M. 1985. *Tetrahedron Lett.* 26:6171–6174.

0098-0331/87/0500-1299$05.00/0 © 1987 Plenum Publishing Corporation

is avoided. Furthermore, no impurities from the solvent are introduced into the samples, the lifetime of GC columns is increased, and the earlier-eluting GC peaks are not masked by the solvent peak. Conformational and structural changes in a substance, which in very occasional cases can be caused by contact with the solvent, can also be avoided.

Such a procedure, often referred by chromatographers as "solid sampling," is particularly useful to analyze volatile materials present in minute quantities in samples of animal tissue. When such a tissue is extracted with a solvent, only a small portion of the extract normally can be injected into the gas chromatograph. However, if the solvent is removed before chromatography, considerable quantities of the volatile substances are lost during the evaporation process and high-boiling impurities from the solvent are concentrated in the sample. But if the tissue can be directly introduced into the gas chromatograph such problems can be avoided.

A device for crushing small samples in the injection area of a gas chromatograph had been first described by Bowman and Karman as long ago as 1958. A similar injection technique described by Morgan and Wadhams (1972) has been extensively used in the study of glandular volatiles of ants (Attygalle et al., 1983, and references therein). This method, in which the sample is sealed in a glass tube and crushed in the heated injection area, although generally used with packed columns only, has been applied recently with capillary columns (Attygalle et al., 1987; Billen et al., 1986). A method has also been described in conjunction with capillary columns, where the glandular liquid present in a reservoir is withdrawn into a glass capillary and dropped into the heated injection port (Morgan et al., 1979). Bridges and Guinn (1980) described a solid-injection method for studying bark beetle pheromones.

A commercially available solid sampler (Perkin-Elmer, MS 41) has been used in conjunction with packed columns in the study of sex pheromones of Lepidoptera, first by Weatherston and MacLean (1974) and subsequently by Descoin's group in France (Descoins and Gallois, 1979, and references therein; Frerot et al., 1984). Although a modification of this system has been used with capillary columns (Buser and Widmer, 1979), no applications in the investigations of lepidopteran pheromones have been reported. Hitherto, the advantages of the solid-injection technique and the high-resolution power of fused silica capillary columns have not been utilized simultaneously in the analysis of lepidopteran pheromones. Here, we describe such a technique and its application in the investigation of sex pheromones of Lepidoptera. The method was successfully employed also in mass spectrometry linked with gas chromatography.

METHODS AND MATERIALS

Solid-Sample Injector. A solid-sample injector was built similar to that described by Morgan and Wadhams (1972) for packed columns. The sampler

consisted of a 11-cm-long stainless-steel tube (3 mm OD, 2 mm ID; 4 in Figure 1) closed at its lower end, with an elongated hole (12 mm; Figure 1, 12) on one side, a spike (Figure 1, 13) soldered to the bottom, and a stainless-steel plunger (Figure 1, 1) fitting inside the tubing. The plunger (1) and tubing (4) were tightened together by a silicone rubber septum and a screw nut (Figure 1, 2).

The splitless injector of the gas chromatograph was modified to take the solid sampler. The regular insert liner was replaced with a larger diameter glass

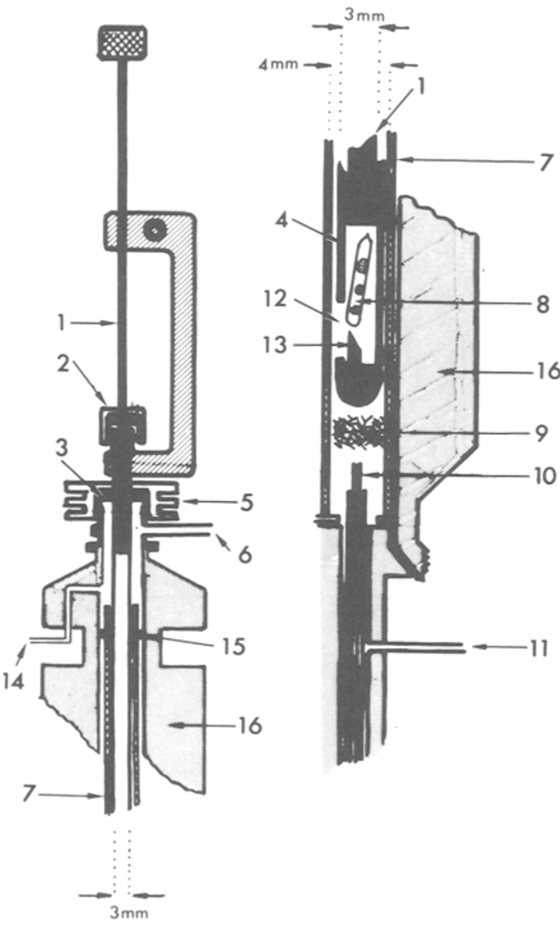

FIG. 1. Schematic presentation of the solid sample injector. 1 = plunger; 2 = screw nut; 3 = silicone rubber septum; 4 = metal tube; 5 = septum cap; 6 = septum flush line; 7 = glass insert liner; 8 = sample sealed in glass capsule; 9 = silanized glass wool plug; 10 = fused silica capillary column, 11 = split vent; 12 = elongated hole; 13 = spike; 14 = carrier gas line; 15 = rubber O ring; 16 = heated injector block.

tube (Figure 1, 7; 8 cm × 4 mm ID) that could accommodate the solid sampler. The sampler was tightened to the injection port by a silicon rubber septum (Figure 1, 3) and the septum cap (Figure 1, 5). A silanized glass wool plug (Figure 1, 9) in the glass tube (Figure 1, 7) prevented glass debris entering the GC column (Figure 1, 10).

Gas Chromatography with Solid-Sampling Technique. Gas chromatography (GC) was performed on a Packard-United Technologies-438A instrument equipped with a splitless injector, a flame ionization detector, and a Shimadzu Chromatopac C-R3A data system. A fused silica capillary column (12 m × 0.22 mm) with a chemically bonded CP-19 (≙OV-17) stationary phase of 0.2 μm film thickness was used for the analysis. The oven temperature was kept at 60°C for 2 min and increased to 270°C at 10°/min. Further analysis was carried out on a fused silica capillary column (25 m × 0.22 mm) coated with SP-2340 stationary phase, the oven temperature kept at 60°C for 2 min and increased to 195°C at 4°/min. Nitrogen was used as the carrier gas at a flow rate of 0.5 ml/min.

In use, the solid sampler was screwed tightly onto the hot injection port, the nut (2 in Figure 1) unscrewed, and the plunger (1 in Figure 1) withdrawn (under nitrogen flow). The glass capsule (Figure 1, 8; 2 cm × 2 mm) containing the sample to be analyzed was inserted, the plunger (Figure 1, 1) partly depressed, and the nut (Figure 1, 2) retightened. The capsule (Figure 1, 8) was kept in the injection port (220°C) for 2–3 min to ensure the volatilization of the substances from the tissue and allow the carrier gas flow to stabilize. The split vent was closed, and the plunger was lowered with a distinct push to crush the capsule against the spike (Figure 1, 13), thus releasing the volatile substances into the GC column. The split vent (Figure 1, 11) was opened after 0.5 min. After each injection, the sampler was removed and the glass debris was emptied from the glass insert liner.

The quantification of pheromone components was done by using a solution of (Z)-11-hexadecenyl acetate (Z11:HDA) as an external standard. All the chemicals used in this study were from our laboratory collection of pheromones.

Gas Chromatography–Mass Spectrometry. A Finnigan 9502 gas chromatograph, fitted with a split-splitless injector (Grob type), linked to a Finnigan 3200E quadrupole mass spectrometer with a Data System 6000 was used. A fused silica capillary column (CP-19, 38 m × 0.22 mm) was directly coupled to the mass spectrometer, and helium was used as the carrier gas at a flow rate of 1 ml/min. EI spectra (70 eV) were recorded at a rate of 2 sec/scan. The injection port of the GC was modified to take the solid sampler, and samples were injected as described above. The split vent was kept closed for 1 min. The oven was kept at room temperature for 3.5 min and then programmed from 120 to 260°C at a rate of 6°/min. Further analysis was performed on a fused silica capillary column (50 m × 0.22 mm) coated with SP-2340 stationary phase.

The oven temperature was kept at 60°C for 4 min and increased to 195°C at 6°/min.

Insect Rearing. The pupae of *Mamestra brassicae* and *Ostrinia nubilalis* were obtained from a laboratory colony maintained at Hoechst AG (Frankfurt/M.). The pupae of *Bombyx mori* originated from the Max Planck Institute, Seewiesen. The pupae were sexed, placed in plastic boxes containing saw dust, and maintained on a 16-hr light–8-hr dark cycle. After emergence, the insects were observed during the scotophase, under a red darkroom lamp, to study the calling behavior and period.

Encapsulation of Pheromone Glands. The samples were prepared from 2- to 4-day-old female moths. First, the abdominal tip (the last two abdominal segments) of a calling female was stripped off with a pair of scissors and the "pheromone gland" was excised carefully under a binocular microscope, using a pair of tweezers and a scalpel. For example, in *Mamestra brassicae* and *Ostrinia nubilalis*, the intersegmental glandular membrane between segments VIII and IX was excised and cleaned by removing the unfertilized eggs, gut contents, hemolymph, and other lipid material found underneath. In *Bombyx mori*, the pair of intersegmental scent sacs ("sacculi laterales") were removed and cleaned in the same way.

One to five glands prepared in this way were pushed into the bottom of a 2-cm × 2-mm, thin-walled soda glass capillary closed at one end, and the open end was sealed immediately in a micro-flame. (The thin-walled capillaries were specially made since ordinary melting point tubes are too strong for this purpose). The sealed samples were either used immediately or stored at −20°C until analyzed.

RESULTS AND DISCUSSION

Pheromone Gland Volatiles of Females of Ostrinia nubilalis *and* Bombyx mori. The two species, belonging to the families Pyralidae and Bombycidae, respectively, were selected to demonstrate the applicability of the solid sampling technique in GC analysis of sex pheromones of Lepidoptera. The glandular compositions of these two species are known.

In female European corn borers, *Ostrinia nubilalis* (Pyralidae), mixtures of geometric isomers of 11-tetradecenyl acetate have been found as the sex pheromone. The proportion of the isomers varies with the geographical origin of the moths (Klun et al., 1975). The main peak in the chromatogram of the sample investigated corresponded to (Z)-11-tetradecenyl acetate (Z11:TDA) (Figure 2), thus indicating our sample belonged to the "(Z)-strain." Furthermore, besides the main acetate, tetradecyl acetate (TDA), (*E*)-11-tetradecenyl acetate (*E*11:TDA), and (Z)-11-tetradecen-1-ol (Z11:TDOl), six hydrocar-

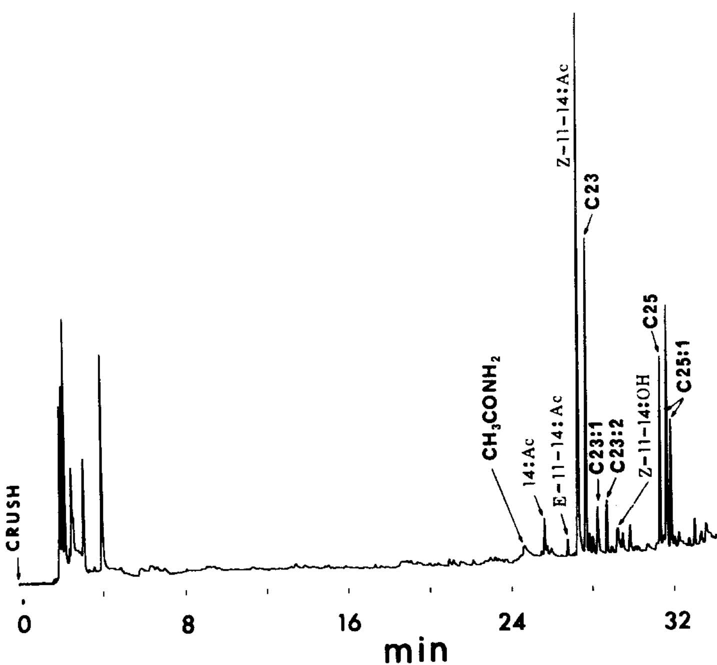

FIG. 2. GC-FID chromatogram obtained from one pheromone gland of female *Ostrinia nubilalis* by solid sampling on a 25-m × 0.22-mm fused silica capillary column SP-2340. Oven temperature was held at 60°C for 2 min and increased to 195°C at 4°/min. 14:Ac = tetradecyl acetate, *E*11–14:Ac = (*E*)-11-tetradecenyl acetate, Z11–14:Ac = (*Z*)-11-tetradecenyl acetate, Z11–14:OH = (Z)-11-tetradecen-1-ol, C23 = tricosane, C23:1 = tricosene, C23:2 = tricosadiene, C25 = pentacosane, C25:1 = pentacosene.

bons of C_{23} to C_{25} range, and the methyl esters of hexadecenoic and octadecanoic acid (not shown in the figure) were also found in the gland.

The stationary phase SP-2340, containing 100% cyanopropyl functionality, used in this study can resolve most of the positional and geometrical isomers of monounsaturated compounds found as lepidopteran pheromones (Heath and Tumlinson, 1984). The identification of the peaks was done by the comparison of retention times with those of authentic materials. Additional confirmation was provided by the mass spectrometric method described by Horiike and Hirano (1982). According to this method, the intensities of various peaks in an ion cluster of a spectrum of an unknown pheromone acetate, when compared to those obtained under the same spectroscopic conditions from a series of positional isomers of monounsaturated alkenyl acetates, can indicate the position of the double bond. The relative abundance of TDA, *E*11:TDA, *Z*11:TDA, and *Z*11:TDOl were 6, 3, 100, and 9, respectively.

In the sex gland of *Bombyx mori* (Bombycidae) (10*E*,12*Z*)-10,12-hexadecadien-1-ol (bombykol) (Butenandt et al., 1959), a trace of the isomeric (*E*,*E*)-alkadienol (Kasang et al., 1978a) and (10*E*,12*Z*)-10,12-hexadecadienal (bombykal) (Kasang et al., 1978b) have been found. However, when the composition of the gland volatiles of three *Bombyx* glands was investigated by this technique, bombykal could not be detected, by either GC or GC-MS. One major peak appeared in the chromatogram, identified as bombykol by its mass spectrum as well as retention time. A minor GC signal, with a shorter retention time (on CP-19) and mass spectrum identical to that of bombykol, was identified as the *E*,*E* isomer of bombykol by comparison with an authentic sample.

Pheromone Complex of Mamestra brassicae and Location of Pheromone. Very little is known about the exact site where the pheromones are located in female Lepidoptera. Thus, we wanted to reinvestigate the pheromone complex of *Mamestra brassicae* (Noctuidae) by the solid-sampling technique with a special emphasis on determining the exact location in the abdominal tip where pheromones are concentrated.

Mamestra brassicae has a distinct glandular region between segments VIII and IX (Otto et al., 1976) (Figure 3). During the calling period, the female insects raised their wings slightly and protruded the ovipositors, thus exposing the intersegmental glandular membrane. They do not show any calling activity during the first night after emergence (Subchev, 1983). Under our laboratory conditions most females exhibited the calling behaviour about 5 hr after the beginning of the dark period on the second night onwards. The calling period lasted about 2 hr, similar to that observed by Subchev (1980).

The present technique enabled the accurate determination of pheromone titers of individual glands. The females of *M. brassicae* use (*Z*)-11-hexadecenyl acetate (Z11 : HDA) as the main component of their specific sex pheromone (Bestmann et al., 1978; Descoins et al., 1978; Novak et al., 1979; Struble et al., 1980). The samples taken at 5 hr after the beginning of the dark period from 1-day-old females showed only traces of Z11 : HDA. Highest pheromone titers were observed in the samples taken under similar conditions from 2-, 3-, or 4-day-old females.

Figure 3 shows the amount of Z11 : HDA present in different parts of the abdominal tip of 3-day-old females sampled during the calling time. This clearly demonstrated that the pheromone components were present only in the intersegmental membrane. The traces of Z11 : HDA present in the other segments may be due to contamination during dissection or to diffusion from the membrane. It was interesting to discover the absence of any significant amounts of pheromone in the tissues beneath the glandular membrane. This proved the fact that the pheromones are concentrated in the glandular epithelium during the calling time. Hence the solid-sampling technique will be useful in biosynthetic studies in determining the fate of a precursor after a local application.

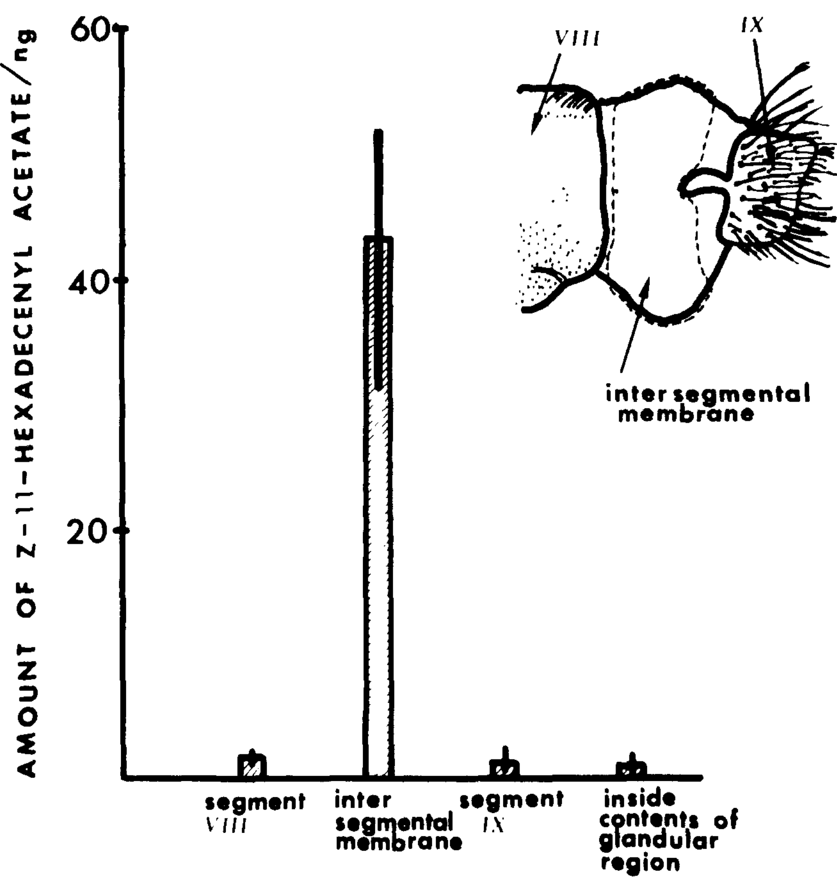

FIG. 3. The amounts of (*Z*)-11-hexadecenyl acetate present in various parts of the abdominal tip of female *Mamestra brassicae*. Each bar represents median from three determinations and the vertical line indicates the range of values. Samples were taken from "calling" insects, three days after emergence.

We also determined the pheromone titers of individual females ($N = 3$) and found a wide variation in the amount of Z11 : HDA present (31.3–51.9 ng per female on the third day). This variation may explain why certain females are more attractive to males than others. This result also shows that the term "female equivalent" (FE) often used by pheromone scientists must be treated with caution. Furthermore, the amount of pheromone found by this method was much more than that reported by Struble et al. (1980) by solvent extraction.

The solid-sampling method was compared with the solvent-extraction method. Only 20–25% of the pheromones were extracted when an excised glandular membrane was kept in 5 μl of hexane at room temperature for 20 min.

Extracting for a longer period of time introduced further impurities. This demonstrated the advantages of solid injection technique, where the "extraction" efficiency is considered very high.

This study renders obsolete the classic method of pheromone extraction, where large numbers of abdominal tips (last few segments) are disintegrated in a solvent followed by purification by liquid chromatography. As shown in Figure 3, the pheromones are located only in a small region of the abdominal tip; therefore when only this glandular region is taken, avoiding the other extraneous material, and extracted, such extracts are clean enough for direct GC examination. Figure 4 shows a chromatogram obtained by injecting one gland of *M. brassicae* by the solid-sampling technique.

The volatile substances identified from the gland of *M. brassicae* consisted of acetamide, tricosane, pentacosane, tetradecyl acetate, hexadecyl acetate, (Z)-9-hexadecenyl acetate, (*E*)-11-hexadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-11-hexadecen-1-ol (see Figure 4).

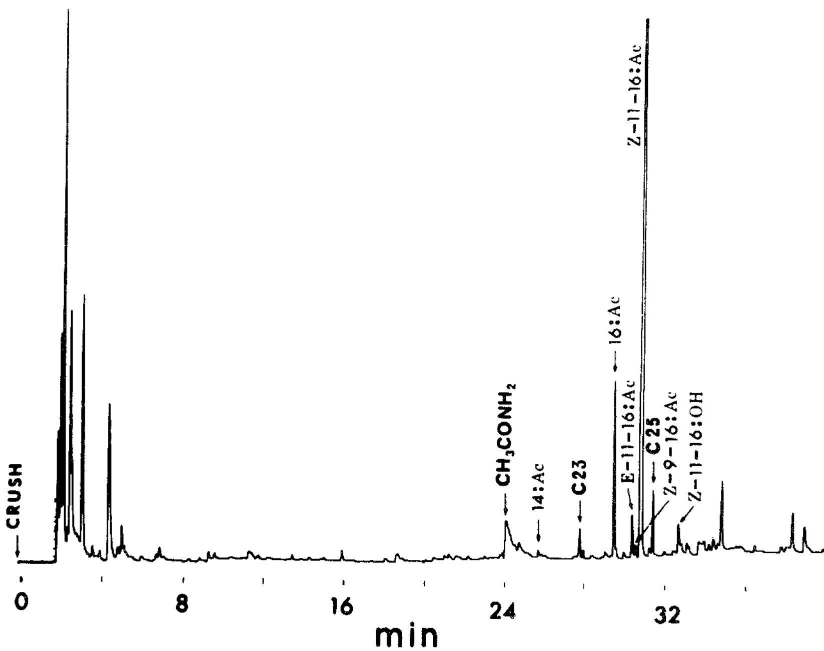

FIG. 4. GC-FID chromatogram obtained from one pheromone gland of female *Mamestra brassicae* by solid-sample injection. GC conditions given in Figure 2. 14:Ac = tetradecyl acetate, 16:Ac = hexadecyl acetate, *E*11-16:Ac = (*E*)-11-hexadecenyl acetate, Z11-16:Ac = (Z)-11-hexadecenyl acetate, Z9-16:Ac = (Z)-9-hexadecenyl acetate, Z11-16:OH = (Z)-11-hexadecen-1-ol, C23 and C25 see Figure 2.

Acetamide and the hydrocarbons are frequently found in lepidopteran glands (Attygalle, unpublished) and are therefore considered as nonspecific body contents, whereas the alkyl and alkenyl acetates and the alkenol were regarded as components of the pheromone complex or at least as biosynthetic precursors or degradation products. Of these substances, (Z)-11-hexadecenyl acetate, (*E*)-11-hexadecenyl acetate, tetradecyl and hexadecyl acetate have been identified already in *M. brassicae* (Bestmann et al., 1978; Descoins et al., 1978; Novak et al., 1979; Struble et al., 1980). The presence of (Z)-9-hexadecenyl acetate and (Z)-11-hexadecenol has not been indicated before. However, the formation of minute quantities of alcohols as artifacts from their respective acetates during sample preparation and chromatography was observed. In most of the comprehensive analytical investigations of lepidopteran sex pheromones (Tamaki, 1986), the presence of alcohols together with their corresponding acetates has been reported. Hence, it is difficult to regard unequivocally the (Z)-11-hexadecenol found as a primary gland constituent.

The solid-sampling technique can be used directly with GC-MS analysis. Figure 5 shows a reconstructed gas chromatogram (RGC) and four mass chromatograms obtained from three glands of female *M. brassicae*. The mass chromatogram of m/z = 222 ($C_{16}H_{30}^+$) has four maxima. Of them, the peaks 3, 4, and 5 have the corresponding maxima in the mass chromatogram for m/z = 61 ($CH_3COOH_2^+$), indicating these three peaks to be isomeric hexadecenyl acetates. Both saturated and unsaturated acetates yield an ion at m/z = 61 due to protonated acetic acid ($CH_3COOH_2^+$). Peak 6 has m/z = 31 and no m/z = 61; therefore it corresponds to a hexadecenol. Peak 2 has m/z = 224 and m/z = 61; therefore it corresponds to a hexadecyl acetate. Peaks 1–6 have the identical retention times to those of authentic tetradecyl acetate, hexadecyl acetate, (*E*)-11-hexadecenyl acetate, (Z)-9-hexadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-11-hexadecenol, respectively, on the SP-2340 column. The relative abundance of these compounds in the gland were 0.5, 8.9, 2.6, 0.8, 100, and 2.3, respectively.

By the applications presented, the advantages of a solid-sampling procedure in conjunction with fused silica capillary columns in the pheromone analysis of Lepidoptera could be demonstrated. There has been a lot of discussion about whether all Lepidoptera produce multicomponent pheromones. This technique is ideally suited for investigations of multicomponent mixtures consisting of compounds of different polarities because the method is not selective. Hence there is no extraction of a single compound or compounds of similar polarity which is an inherent disadvantage of the solvent-extraction technique. If a solvent extraction employing a nonpolar solvent was used, a very polar compound such as acetamide may not have appeared in the chromatogram presented in Fig. 4.

In order to identify biologically active components of the mixture, methods

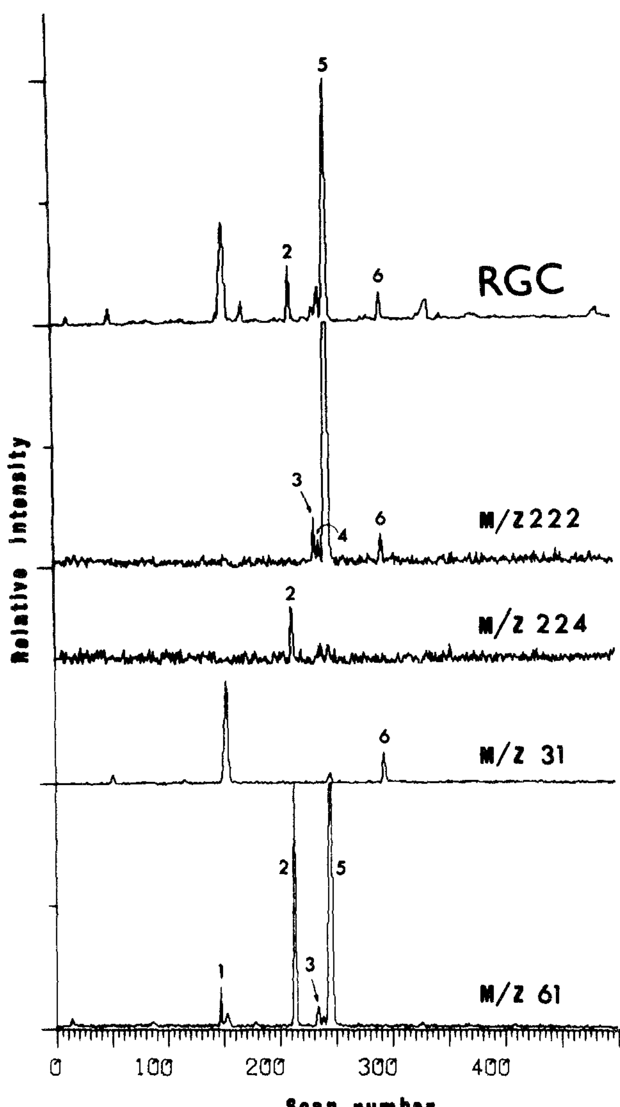

Fig. 5. A reconstructed gas chromatogram (RGC) and four mass chromatograms obtained from three glands of female *Mamestra brassicae* by solid sampling on a 50-m × 0.22-mm fused silica capillary column coated with SP-2340 linked to a mass spectrometer. The oven temperature was held at 60°C for four min and increased at 6°C/min to 195°C. 1 = tetradecyl acetate, 2 = hexadecyl acetate, 3 = (*E*)-11-hexadecenyl acetate, 4 = (Z)-9-hexadecenyl acetate, 5 = (Z)-11-hexadecenyl acetate, 6 = (Z)-11-hexadecen-1-ol.

such as electroantennography, field trials, and behavioral tests are required. This is supported by the fact that (*Z*)-11-hexadecen-1-ol is known to act as a strong attraction inhibitor for *M. brassicae* (Struble et al., 1980). Electrophysiological investigations with male antenna and the substances identified have been performed, the results of which will be published elsewhere.

Additionally, it is noteworthy that we could not detect the aldehyde component bombykal, (10*E*,12*Z*)-10,12-hexadecadienal, in *Bombyx mori* by this method. It was assumed that the aldehyde formation may take place either at a later stage of calling or perhaps is synthesized only just before pheromone release.

The application of solid-sampling technique in the studies of sex pheromones of a number of species with hitherto unknown pheromones is in progress.

Acknowledgments—We thank Dr. E.D. Morgan (University of Keele) for critical reading of the manuscript and his suggestions. This study was supported by a Fellowship from Alexander von Humboldt Foundation to A.B.A. and by the Deutsche Forschungsgemeinschaft, both of which are gratefully acknowledged.

Short Communication

EFFECTS OF NONHOST-PLANT ODORS ON ANEMOTACTIC RESPONSE TO HOST-PLANT ODOR IN FEMALE CABBAGE ROOT FLY, *Delia radicum*, AND CARROT RUST FLY, *Psila rosae*

S.F. NOTTINGHAM

(Received January 28, 1986; accepted July 16, 1986)

Abstract—An inflatable polythene wind tunnel was used for behavioral assays of female *D. radicum* and *P. rosae* in diffuse host- and non-host-plant odor, alone and in combination. Host-plant odor caused an upwind anemotactic response in both species. Changes in fly distribution, relative to wind direction, occurred when onion odor was combined with host odor for *D. radicum* and *P. rosae*, and when sage odor was combined with carrot ordor for *P. rosae*. The assay has potential for screening volatiles for their behavior-modifying effects.

Key Words—Cabbage root fly, *Delia radicum*, carrot rust fly, *Psila rosae*, Diptera, Anthomyiidae, Psilidae, odor-induced upwind anemotaxis, host-plant odor, non-host-plant odor.

INTRODUCTION

The cabbage root fly, *Delia radicum* L. (Diptera; Anthomyiidae) and the carrot rust fly, *Psila rosae* Fab. (Diptera; Psilidae) have host plants within the Cruciferae and Umbelliferae, respectively. Each plant family has a distinctive plant chemistry (Kjaer, 1976; Harbourne, 1971) that is involved in the host-plant location and oviposition behavior of *D. radicum* (Finch, 1980; Städler, 1978) and *P. rosae* (Guerin et al., 1983; Städler and Buser, 1984). Gravid female *D. radicum* responded anemotactically to host-plant odor and allylisothiocyanate

0098-0331/87/0500-1313$05.00/0 © 1987 Plenum Publishing Corporation

(Hawkes et al., 1978; Nottingham and Coaker, 1985). Propyl-benzenes from Umbelliferae attracted female *P. rosae* (Guerin et al., 1983), but anemotactic responses have not been demonstrated.

Both species were less exploitive of their host plants in diverse than simple plant plots in field experiments (Tukahirwa and Coaker, 1982; Uvah and Coaker, 1984), with onion odor being important in suppressing numbers of *P. rosae*.

The objectives of this study were (1) to establish whether *P. rosae* responded anemotactically to host-plant odor and (2) to adapt the behavioral assay (Jones et al., 1981; Nottingham and Coaker, 1985) to observe any behavior-modifying effects of non-host-plant odors.

METHODS AND MATERIALS

A series of behavioral assays presenting diffuse odor from host and non-host plants, both singly and combined, were done with female *D. radicum* and *P. rosae* in an inflatable polythene wind tunnel (Jones et al., 1981). The wind tunnel, 0.5 m diameter, with a 2-m-long flight chamber, was constructed from layflat plastic tubing supported by two metal hoops placed at each end of the flight chamber and covered with metal honeycomb (1 cm diameter), wire mesh (0.1 mm), and muslin. The tube was inflated by fans connected at each end and adjusted to give a wind speed of 0.3 m/sec. The tunnel was erected in a controlled environment room maintained at 22°C, 65% relative humidity, and illuminated by overhead fluorescent tubes providing 1500 lux within the tunnel. Ammonium chloride smoke mixed thoroughly with the air in the treatment chamber and passed uniformly through the first screen into the flight chamber.

The host plants used were cabbage (*Brassica oleracea* var. *capitata* cv. Primo) and carrot (*Daucus carota* cv. Danvers), for *D. radicum* and *P. rosae*, respectively. The non-host plants used were onions (*Allium cepa* var. Rhijneburger robusta) and sage (*Salvia officialis*). All the plants were grown under greenhouse conditions.

Ten grams of 1 to 2-month-old cabbage plants or 75 g of carrot plants of similar age were presented alone and together with the same weight of non-host plants of the same age. Odorless control treatments were included.

The plants were put into 100-ml glass beakers containing about 10 ml of water, with the foliage exposed above the rim of the beaker, and the beaker was placed on a tripod, within the treatment chamber, 20 cm from the first screen. In combined odor treatments, beakers containing host and non-host plants were arranged side-by-side on the tripod.

In each of the three replicates of the assay treatments, approximately 15 six- to nine-day-old mated and gravid female *D. radicum* or *P. rosae* were released from the center of the flight chamber after preconditioning for 2 hr in the release cage within the tunnel in the absence of odor. The release cage

consisted of a 15 × 5-cm glass tube enclosed at each end with muslin and suspended 20 cm from the tunnel floor. The flies were released 15 sec after the introduction of the treatment odor by gently removing the muslin from both ends of the tube.

The flies' response was scored by counting the number of flies in the upwind, middle, and downwind thirds of the flight chamber 5 min after their release. The data for the mean percentage of flies in each third of the flight chamber were analysed by chi-square contingency tables, done for paired treatments within each group of four treatments comprising odorless control, host odor and non-host odor alone, and host and non-host odor combined.

RESULTS AND DISCUSSION

Response to Host-Plant Odor. The odorless control elicited similar percentages of *D. radicum* in the upwind and downwind sections (18 and 21%), respectively; whereas the distribution of flies in the cabbage treatment was different from the odorless control ($P < 0.01$), with more than twice the percentage of flies in the upwind than the downwind section (44 vs. 19%) (Table 1).

This upwind anemotactic response supports previous findings that host odor stimulates upwind movement (e.g., Hawkes et al., 1978).

The odorless control elicited similar percentages of *P. rosae* in the upwind and downwind sections (18 vs. 22%); whereas the distribution of flies in the carrot treatment was different from the odorless control ($P < 0.01$), with more flies in the upwind than the downwind section (45 vs. 5.5%) (Table 1).

Host-plant volatiles attracted female *P. rosae* in the laboratory and the field (Guerin et al., 1983), and the present results suggest that they also initiated an upwind anemotactic response, which may be important in its host-finding behavior.

Effects of Non-Host-Plant Odor on Behavioural Response to Host-Plant Odor. The distribution of *D. radicum* in the onion and cabbage plus onion treatments was not different from the odorless control ($P > 0.01$). The distribution of flies in the cabbage treatment, however, was different from that in the cabbage plus onion odor treatment ($P < 0.01$), with the combined odor eliciting a lower percentage of flies in the upwind section (26 vs. 44%) and an increased percentage in the middle section (63 vs. 37%) compared to cabbage odor alone (Table 1).

The distribution of flies in the cabbage plus sage treatment, on the other hand, was not different from that in the cabbage treatment ($P > 0.01$) (Table 1).

The presence of clover odor was not thought to be an important factor causing the decreased exploitiveness of *D. radicum* when it was grown with host plants (Tukahirwa and Coaker, 1982); however, the present results suggest

TABLE 1. NUMBER OF FLIES AND MEAN PERCENTAGE OF FLIES IN UPWIND, MIDDLE, AND DOWNWIND SECTIONS OF FLIGHT CHAMBER IN DIFFUSE ODOR FROM HOST AND NON-HOST PLANTS, PRESENTED SINGLY AND COMBINED.

[a]Treatments with different letters have significantly different distributions of flies ($P = 0.01$ chi-square). ($N = 3$ for all treatments).

that certain non-host odors (e.g., onion) may be capable of modifying aspects of *D. radicum's* host-location behavior.

The distribution of *P. rosae* in the onion, carrot plus onion, sage, and carrot plus sage treatments was not different from the odorless control ($P > 0.01$). However, the distributions of flies from both the carrot plus onion and the carrot plus sage treatments were different from the carrot treatment ($P < 0.01$), with lower percentages in the upwind section in the carrot plus onion (28%) and carrot plus sage (24.5%) than in the carrot treatment (45%) and higher percentages in the middle and downwind sections (Table 1).

Onions intercropped with carrots were successful in reducing carrot fly damage only when they were young and actively growing (Uvah and Coaker, 1984) which, together with the present data, suggests that onion odor modifies aspects of *P. rosae's* host-plant-finding behavior. Sage also affected movement with respect to the wind, suggesting that other non-host odors might be effective at modifying the behavior of *P. rosae* in a similar way.

Further Development of Assay. Further work should incorporate a wider selection of non-host-plant odors together with a range of host to non-host ratios. A larger number of replicates would also be desirable.

The results of these preliminary experiments with non-host odors suggest that a behavioral assay of this type might provide a basis for screening odors for their effectiveness in modifying the behavior of insects that use host-plant odor to locate their host plants. This could not only provide a rationale for selecting intercrops to suppress certain insect pests, but, probably more importantly for future insect pest control, also identify non-host volatiles which could be used in the field to modify insect behavior.

Acknowledgments—I would like to thank Dr. T.H. Coaker for advice and Mrs. M. Free for technical assistance. This work was supported by a Science and Engineering Research Council Studentship.

(Received May 9, 1986; accepted August 1, 1986)

Abstract—A single sex pheromone component was isolated from abdominal tip extracts of female Bruce spanworm. *Operophtera bruceata* (Hulst). This was identified as (Z,Z,Z)-1,3,6,9-nonadecatetraene by capillary gas chromatography (GC), electroantennography, and mass spectrometry. In addition, hexane extracts of female abdominal tips from Bruce spanworm and the winter moth. *O. brumata* L., were analyzed by GC coupled to an electroantennographic detector (GC-EAD). The extracts of *O. bruceata* and *O. brumata* females elicited only a single response, at the same retention time, from antennae of their conspecific and reciprocal males. In field tests conducted in Saskatchewan, traps baited with the synthetic tetraene captured Bruce spanworm males. In tests carried out on Vancouver Island, British Columbia, where the two species coexist, both Bruce spanworm and winter moth males were captured. The attractancy of lures containing the synthetic pheromone alone and in combination with several structurally related analogs was field tested at both locations. One of these, an isomer of the natural pheromone, (*E*,*Z*,*Z*)-1,3,6,9-nonadecatetraene, inhibited the capture of Bruce spanworm males but had no effect upon the number of winter moth males which were taken. Thus, populations of these two very similar species can be distinguished by employing traps baited with pheromone ± the inhibitor. Cone-orifice Hara traps were found useful for field trapping males of both species.

Key Words—Lepidoptera, Geometridae, *Operophtera bruceata* (Hulst), Bruce spanworm, *Operophetra brumata* L., winter moth, sex pheromone, (*Z,Z,Z*)-1,3,6,9-nonadecatetraene, inhibitor, (*E,Z,Z*)-1,3,6,9-nonadecatetraene.

INTRODUCTION

The major, if not the only, sex pheromone component of the winter moth, *Operophetra brumata (L.), is* (*Z,Z,Z*)-1,3,6,9-nonadecatetraene (1,3Z,6Z,9Z-19:H) (Roelofs et al., 1982; Bestmann et al., 1982). Populations of this species in North America, where it has been accidentally introduced, are now known to occur in British Columbia and the Maritime provinces of Canada and in the northwestern regions of the United States (Embree, 1965; Gillespie et al., 1978). In field tests, Roelofs et al. (1982) found that the synthetic pheromone also attracted males of two closely related species, the Bruce spanworm, *O. bruceata* (Hulst) and *O. occidentalis* (Hulst). The Bruce spanworm occurs transcontinentally in Canada and in the northern United States (Brown 1962) and is very similar to the winter moth in life history, appearance, habits, and hosts. Since the winter moth is such a serious pest of fruit and shade trees and other hardwoods, and now also Sitka spruce (Stoakley, 1985), its spread in North America is of considerable concern. Thus, there is a need to develop a rapid and effective means of monitoring, separately, populations of each species. Light trapping is ineffective for such monitoring since females are wingless and males are only poorly attracted. Furthermore, adult males of these two species can only be distinguished by structural differences in their genitalia (Eidt et al., 1966). Thus, while it is possible to collect adult males of both species by field trapping with 1,3Z,6Z,9Z-19:H and to differentiate between them by dissection and examination of their genitalia, the utility of this method is severely limited.

The report of Roelofs et al. (1982) that Bruce spanworm males were attracted by the winter moth pheromone appeared while our studies to identify the Bruce spanworm and winter moth pheromones were in progress. The coattraction to traps baited with synthetic 1,3Z,6Z,9Z-19:H raises a number of questions: (1) Is 1,3Z,6Z,9Z-19:H also a component of the Bruce spanworm pheromone? (2) If 1,3Z,6Z,9Z-19:H is a component of the Bruce spanworm pheromone, is it the only component or does Bruce spanworm have a multicomponent pheromone which results in the reproductive isolation of the two species? (3) Is it possible to develop species-specific sex attractant lures for Bruce spanworm and winter moth males? In addressing these questions, we have examined and identified the sex pheromone of Bruce spanworm females, reexamined the winter moth pheromone, and have tested the effect of additions of several synthetic analogs to baits containing 1,3Z,6Z,9Z-19:H upon winter moth and Bruce spanworm male attraction in the field.

METHODS AND MATERIALS

Insects, Pheromone Isolation, and Identification. Late-instar Bruce spanworm larvae were collected from aspen near Stettler, Alberta, and allowed to pupate in cages containing aspen leaves. Pupae were sexed and stored separately in the laboratory at 22°C for three months and then at 0°C for two to three weeks to initiate adult emergence. Males were used for electroantennography and females as a source of sex pheromone. Pheromone was obtained by a 20-min pentane extraction of the terminal three to four abdominal segments from 2- to 4-day-old calling females. The extract was concentrated under a stream of N_2, fractionated by GC using an SP-2100 column (30 m × 0.25 mm ID), programmed from 40°C to 90°C at 30°C/min and then 230°C at 4°C/min. Timed fractions, 15 sec each, of the split column effluent were collected in Dry-Ice cooled capillaries and assayed by EAG (Wong et al., 1984a). The contents of EAG-active fractions were analyzed by combined gas chromatography–mass spectrometry (GC-MS) using a model 4000 (Finnigan) system equipped with an SP-2100 column (60 m × 0.32 mm ID). Both EI (70 eV) and chemical ionization (CI) (methane reagent gas) mass spectra were obtained. Spectra were acquired at 1 scan/sec over the range of 40–320 mass units. Retention times and mass spectra of components in the extract were compared with data obtained using synthetic standards.

In addition, antennal stimulatory components were detected as they eluted from a capillary column by employing a GC equipped with both a flame ionization detector (FID) and an electroantennographic detector (GC-EAD) (Arn et al., 1975). Detection of pheromone components by this technique permits the recognition of closely eluting stimulatory compounds which could have gone unrecognized using the timed collection method. Hexane extracts and surface washes of abdominal tips of Bruce spanworm and winter moth females (obtained by field collection) were prepared and analyzed using antennae from males of the same and the reciprocal species for component detection. A DB-210 column (30 × 0.32 mm ID), programmed as above, was employed in these analyses. Signals from the FID and EAD were displayed simultaneously on two Hewlett Packard model 3392A recording integrators. Two internal standards, heptadecane (17:H) and tetracosane (24:H), were added in each analysis to facilitate comparisons between analyses.

Synthetic Chemicals. Monoepoxides and other compounds used, except for the following, were synthesized as described previously (Wong et al., 1984b, 1985). The mixture of monoepoxytriene regioisomers [(CME)-1,3Z,6Z,9Z-19:H], prepared from 1,3Z,6Z,9Z-19:H, were not resolved but the three monoepoxydiene isomers, from 3Z,6Z,9Z-19:H, were separated by HPLC using a 50-cm Whatman Magnum 9 Partisil 10 silica column, eluted with 3% ether in pentane. (Z,Z,Z)-9,12,15-Octadecatrienal (9Z,12Z,15Z-18:ALD) was prepared

from linolenyl alcohol (9Z,12Z,15Z-18:OH, Nucheck Corp., Elysian, Minnesota) by treatment with pyridinium chlorochromate (Corey and Suggs, 1975). (Z,Z,Z)-1,3,6,9-Nonadecatetraene was initially prepared by a method similar to that previously described (Roelofs et al., 1982; Huang et al., 1983; Jain et al., 1983) and later, the series of $C_{18,19 \text{and} 20}$ (*Z*,*Z*,*Z*)-1,3,6,9-tetraenes and (*Z*,*Z*,*Z*)-1-bromo-3,6,9-nonadecatriene (1-bromo-3Z,6Z,9Z-19:H) were prepared by an alternate procedure (Millar and Underhill, 1986).

(*E*,*Z*,*Z*)-1,3,6,9-Nonadecatetraene (1,3*E*,6*Z*,9*Z*-19:H) was prepared as follows.

(A) Preparation of (E,Z,Z)*-2,5,8-Octadecatrienal.* (*Z*,*Z*,*Z*)-2,5,8-Octadecatrienol (Millar, unpublished) (132 mg. 0.5 mmol) in CH_2Cl_2 (0.5 ml) was added to a slurry of pyridinium chlorochromate (216 mg, 1 mmol) and sodium acetate (16 mg, 0.25 mmol) in CH_2Cl_2 (1.5 ml), and the mixture was stirred at 20°C for 3 hr under nitrogen. Ether (10 ml) was then added, and the mixture was stirred a further 10 min to allow the precipitate to coagulate. The liquid phase was decanted and passed through a column of Florisil (1 cm ID × 5 cm). The solid residues were washed with several portions of ether, and the washings were passed through the Florisil column. The combined column eluate was concentrated at reduced pressure, giving the crude aldehyde (80 mg, 61%) as an unstable yellow oil consisting of an 85:15 mixture of *trans* and *cis* isomers. The crude product was used without further purification. [^{1}H]NMR ($CDCl_3$) δ 9.51 (d, 1H, J = 7.9 Hz: H-1), 6.81 (dt, 1H, J = 15.6, 6.2 Hz; H-3) 6.13, (ddt, 1H, J = 15.6, 7.9, 1.6 Hz; H-2), 5.56 (dtt, 1H, J = 10.6, 7.2, 1.4 Hz; H-6), 5.44–5.34 (m, 2H; H-5, H-9), 5.39 (dtt, 1H, J = 10.6, 7.3, 1.4 Hz; H-8), 309 (m, 2H; H-4), 2.77 (m, 2H; H-7), 2.02 (m, 2H; H-10), 1.45–1.15 (m, 14H; H-11 to H-17), 0.86 (t,3H, J = 6.8 Hz; H-18). IR (neat): λ_{max} 3020 (m), 2960 (m, shoulder), 2935 (s), 2865 (s), 2825 (m, shoulder), 2740 (m), 1590 (s), 1460 (m), 1125 (m), 975 (m) cm^{-1}. MS (EI, 70 eV), *m/z* (relative intensity): 262 (M^+, 0.9), 218 (2.7), 208 (3.6), 149 (4.5), 135 (10,5), 121 (23.7), 109 (38.1), 96 (40.9), 95 (36.5), 93 (35.8), 92 (30.9), 91 (46.2), 81(94.5), 80 (52.2), 79 (89.3), 69 (36.1), 67 (100), 57 (42.9), 55 (90.9), 43 (90.2).

(B) Preparation of (E,Z,Z,)*-1,3,6,9-Nonadecatetraene.* To a solution of methyltriphenylphosphonium iodide (142 mg, 0.35 mmol) in THF (5 ml) at 0°C under nitrogen was added dropwise a hexane solution of *n*-butyllithium (1.4 M; 0.22 ml, 0.31 mmol). The mixture was stirred at 0°C for 30 min, followed by dropwise addition of a solution of crude aldehyde (80 mg, ≃ 0.31 mmol) in THF (2 ml). The mixture was stirred at 0°C for 20 min, then quenched by pouring into ice-water (10 ml). The mixture was extracted with hexane (1 × 20 ml, 2 × 10 ml), and the combined organic extracts were washed with brine (1 × 10 ml), dried over $MgSO_4$, and concentrated. The residue was purified by column chromatography on silica gel (1 cm ID × 20 cm), eluting with pentane, followed by HPLC on a Whatman Magnum 9 SCX column (Ag^+

form), eluting with 0.1% dimethoxyethane in hexane, giving 1,3*E*,6*Z*,9*Z*-19:H (50.4 mg, 62%) free of 1,3*Z*,6*Z*,9*Z*-19:H. [^{1}H]NMR ($CDCl_3$): δ 6.30 (ddd, 1H, J = 17.2, 10.2, $\simeq$ 10 Hz; H-2), 6.06 (br dd, 1H, J = 15.3, $\simeq$ 10 Hz; H-3), 5.67 (dt, 1H, J = 15.3, 6.2 Hz; H-4), 5.25–5.45 (m, 4H; H-6, 7, 9, 10), 5.09 (d, 1H, J = 17.2 Hz; H-1, *cis*), 4.95 (d, 1H, J = 10.2 Hz; H-1 *trans*), 2.85 (t, 2H, J = 6.2 Hz; H-5), 2.77 (t, 2H, J = 6.1 Hz; H-8), 2.03 (m, 2H; H-11), 1.1–1.6 (m, 14H; H-12 to H-18), 0.86 (t, 3H, J = 6.7 Hz; H-19), IR (neat): λ_{max} 3020 (m), 2965 (m), 2935 (s), 2865 (s), 1000 (m) cm^{-1}. The mass spectrum corresponded with that of the 3*Z*-isomer (Bestmann et al., 1982; Huang et al., 1983).

Field Trapping. Field experiments were carried out in areas containing aspen near Saskatoon, Saskatchewan, where only Bruce spanworm occurs and these were repeated approximately six weeks later on Vancouver Island, British Columbia primarily within Victoria, where both species occur, and also 50 km north near Duncan. Two types of traps were used, namely, Pherocon 1CP® (Zoecon Corp., Palo Alto, California) and Hara traps (Hara Products Ltd., Swift Current, Saskatchewan) which are similar to the cone-orifice model 3 trap described by Steck and Bailey (1978). Candidate lures were impregnated into rubber septa via dilute solutions in hexane. Traps were placed 10–15 m apart on trees or wooden stakes at a height of 1.0–1.5 m and were set out in randomized block designs. Summed trap captures were transformed ($\sqrt{X + 1}$) and subjected to analysis of variance; significantly different means were separated by Duncan's (1955) multiple-range test. In all tables, values within a column followed by the same letter are not significantly different ($P > 0.05$).

Adult Bruce spanworm and winter moth males were distinguished by the method of Eidt et al. (1966).

RESULTS AND DISCUSSION

EAG assays of 15-sec fractions collected during GC fractionation of female spanworm extracts disclosed strong male antennal stimulatory activity present in a single fraction eluting from the SP-2100 column. The activity, on repeated analyses, was consistently associated with materials which eluted at a time just before nonadecane.

The amount of pheromone recovered from the abdominal tip extracts was approximately 1 ng/female. The active compound was identified from the following information. Bromination and hydrogenation destroyed the activity, indicating the presence of double or triple bonds. The compound was not affected by basic hydrolysis conditions, indicating the lack of ester or other base-sensitive groups. The EI mass spectrum, with base peak *m/z* 79 and ions corresponding to the series $(C_nH_{2n-5})^+$, gave a small molecular ion at *m/z* 260, confirmed by methane CI, for a possible molecular formula of $C_{19}H_{32}$, corre-

sponding to four sites of unsaturation and/or rings. The lack of any fragmentations typical of heteroatom-containing groups added further credence to the molecule being an unsaturated hydrocarbon. There were two significant even-numbered rearrangement ions in the higher mass range, at *m/z* 206 and 106. The former corresponds to loss of butadiene from the molecular ion, strongly suggesting the presence of a conjugated 1,3-diene unit at one end of the molecule. As there was no major fragment corresponding to hexatriene, or the loss of hexatriene, the diene system was not further conjugated, so that the other site(s) of unsaturation were beyond carbon 5. The other fragment, at *m/z* 106, corresponding to C_8H_{10}, was identified by comparison with the spectra of 3,6,9-alkatrienes (Underhill et al., 1983, and references cited), where there is a prominent fragment at *m/z* 108 due to structure-specific cleavage between carbons 8 and 9, accompanied by a hydrogen transfer to give the even-numbered rearrangement peak. By analogy, the ion at *m/z* 106 in the unknown compound could arise from the same type of rearrangement in a 1,3,6,9-tetraene. In 1982, it was clear that the EI spectrum matched that reported by Bestmann et al. (1982) for 1,3Z,6Z,9Z-19:H and, following this, its retention times on several different columns were found to coincide exactly with those of the synthetic compound.

GC-EAD analyses showed only a single response was elicited by Bruce spanworm males to female abdominal tip extracts (Figure 1, trace b), and this corresponded in elution time to that of 1,3Z,6Z,9Z-19:H (trace a). Using the antenna of the winter moth male for detection, a similar EAD response occurred, and no additional responses, which may have indicated the presence of inhibitory components to winter moth, were detected (trace c); the large amount of material extracted from the females used for this determination was likely due to an excessive amount of tissue removed. In agreement with data reported (Bestmann et al., 1982; Roelofs et al., 1982), tip extracts of female winter moths elicited in antennae of conspecific males a single antennal response corresponding to the elution of 1,3Z,6Z,9Z-19:H (data not shown). No additional responses were observed using antennae from Bruce spanworm males. Thus all of our analytical data indicated a single and identical pheromone component present in both species.

Field-trapping experiments were carried out to determine if Bruce spanworm or winter moth male attraction to 1,3Z,6Z,9Z-19:H could be modified by additions of structural analogs of the pheromone. Our major goal was to obtain a blend which would inhibit attraction of Bruce spanworm males but remain attractive to winter moth so that populations of the latter could be specifically monitored in the presence of Bruce spanworm. In our first experiment in 1984 in Saskatchewan (3X replicated), none of nine analog additions resulted in significantly different (5% level) trap captures of Bruce spanworm males. A total of 153 Bruce spanworm males were captured in traps baited with

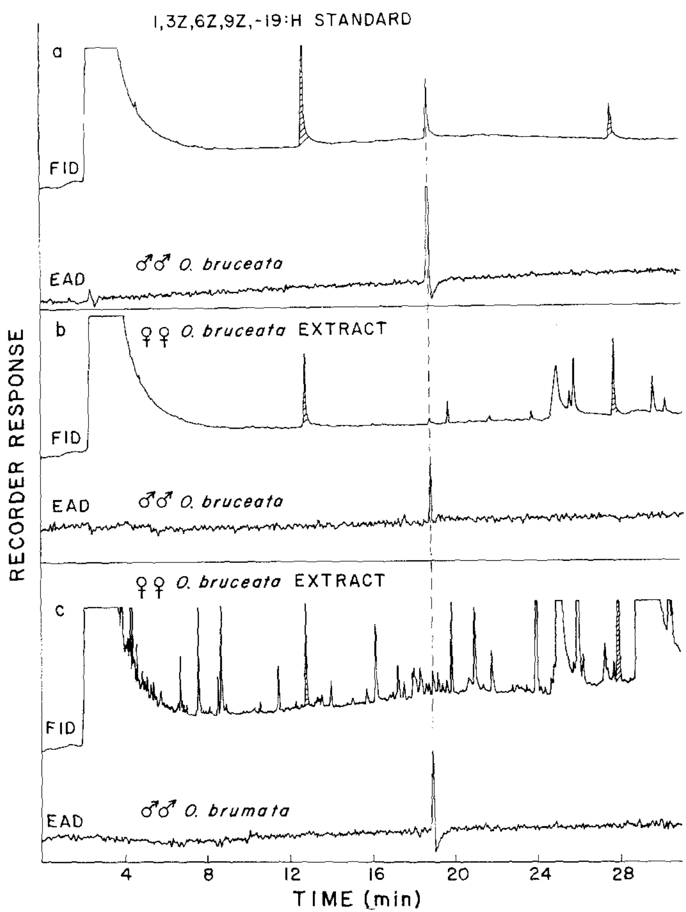

FIG. 1. Separately recorded flame ionization detector (FID) and electroantennographic detector (EAD) traces: upper pair (a) are in response in synthetic (*Z,Z,Z*)-1,3,6,9-nonadecatetraene and two internal standards (shaded); middle pair (b) to a female abdominal tip extract (1 FE) of Bruce spanworm; lower pair (c) to an abdominal tip extract of five Bruce spanworm females. EAD traces in a and b were obtained using Bruce spanworm male antennae; a winter moth male antenna was used for trace c.

1,3Z,6Z,9Z-19:H alone (100 μg) from October 6 to 9. The number of males taken in traps baited with the same amount of pheromone plus one of the nine structural analogs (20 μg each) ranged from 107 to 206. Analogs tested included nonadecane, (*Z,Z*)-6,9-nonadecadiene, (*Z,Z,Z*)-3,6,9-nonadecatriene, (*Z,Z,Z*)-6,9,12-nonadecatriene, (*Z,Z,Z,E*)-3,6,9,11-nonadecatetraene, (*Z,Z,Z,Z*)-3,6,9,11-nonadecatetraene, (*Z,Z*)-6,9-*cis*-3,4-epoxy-nonadecadiene, (*Z,Z*)-3,9-*cis*-6,7-epoxy-nonadecadiene, and (*Z,Z*)-3,6-*cis*-9,10-epoxy-nona-

decadiene. In tests at Victoria (2X replicated), where the winter moth/Bruce spanworm male population was ca. 19 : 1, there was no difference in the number of males captured by these treatments. Blank traps took no males at either location.

Additional structural analogs of 1,3Z,6Z,9Z-19:H were field tested in 1985. Data obtained from the Saskatchewan test (Table 1) showed additions of one analog, 1,3*E*,6Z,9Z-19:H, a geometric isomer of the natural pheromone, significantly inhibited Bruce spanworm captures. This was followed by a second field test where the effect of different amounts of added inhibitor on male attraction was examined. Additions from 10 μg to 300 μg significantly reduced the number of target males captured (Table 2). No males were taken in traps baited with the inhibitor alone or in blank traps. It should be noted that although the number of males taken in traps containing 100 and 300 μg of inhibitor plus 100 μg of pheromone were not significantly different from blank traps, low numbers of males were captured by at least one of the analog-containing replicates. In field tests at Victoria, none of the analog-containing lures inhibited the capture of winter moth males (Table 1): each of the lures containing increasing amounts of added 1,3*E*,6Z,9Z-19:H remained attractive to winter moth males

(Table 2). In tests similar to these, Knauf et al. (1984) also were unable to find synthetic inhibitors of winter moth male attraction to its pheromone.

Clearly, both species are attracted to the major pheromone component, but only one, the winter moth, is attracted to this component plus inhibitor. The discovery that attraction of Bruce spanworm males to 1,3*Z*,6*Z*,9*Z*-19:H is inhibited by the presence of 1,3*E*,6*Z*,9*Z*-19:H, raises the question: Is this a naturally occurring component in winter moth females which may be used for reproductive isolation? Tests were made to determine if these two isomers could be separated by GC, and four columns of differing polarity (DB-5, DB-1701, DB-Wax, and DB-210, each 30 m × 0.32 mm ID) were examined. Both isomers coeluted on the first three columns but partial separation was effected using the DB-210 column (19.14 min for 1,3*Z*,6*Z*,9*Z*-19:H and 19.21 min for 1,3*E*,6*Z*,9*Z*-19:H), the column which had been used for the GC-EAD analyses. With such a small difference in retention times it would not have been possible to detect the presence of small amounts of the *E* isomer, if indeed it did occur, in the winter moth female pheromone extract. Field evidence has confirmed that traps baited with live Bruce spanworm females from the Okanagan Valley of British Columbia attracted winter moth males in Victoria (Ring, unpublished), but the reciprocal cross-attractancy experiments using winter moth fe-

males in a known habitat of Bruce spanworm have been inconclusive to date. Furthermore, in caged experiments it was shown that winter moth females could breed successfully with Bruce spanworm males, but the reciprocal mating did not occur. The resulting progeny were viable to at least the F_2 generation (the end of the breeding experiment), and pupal cremaster characteristics were intermediate between the two species (Smith and Ring, unpublished). With the close morphological, behavioral, ecological, and phenological similarities between the two species, one could speculate that these two closely related species have been isolated by mainly geographical barriers until recent times.

The 1985 data indicated that populations of winter moth and Bruce spanworm may be distinguished by deploying two different trap baits, one with pheromone alone, the other with pheromone plus inhibitor. This was clearly demonstrated in an experiment set out in Victoria and in Duncan (Table 3). In Victoria, there was no significant difference between the numbers of male moths taken in traps baited with the two different bait compositions, indicating the presence of a predominantly winter moth population, which was confirmed by examination of captured males' genitalia. At Duncan, significantly fewer males were captured in traps with pheromone plus inhibitor than in traps with pheromone alone, indicating that Bruce spanworm dominated the population. Again, this was confirmed by examination of captured males' genitalia. It should be noted, until such time as captures of Bruce spanworm can be reduced to zero in traps containing pheromone plus inhibitor, detection of low populations of winter moth in regions of high Bruce spanworm populations will require examination of the captured males' genitalia (Eidt et al., 1966) to distinguish

between these species. However, fewer males will be required for examination since only those captured in traps with inhibitor need be dissected.

It had been noted during these investigations that captures of Bruce spanworm and winter moth males in Pherocon 1CP traps often approached or appeared to exceed saturation levels during an evening even in areas where no appreciable defoliation had been noticed during the preceding June, an indication of a moderaltely low infestation. Cone-orifice Hara traps, which have a high trap capacity, were tested for field use as they should require less frequent inspections. Tests carried out in Saskatchewan and at Victoria showed no difference in the number of Bruce spanworm or winter moth males retained by these two trap types (Table 4). In the Victoria test, Hara traps which also contained Vapona® strips, were tested, and significantly more winter moth males were recorded in these traps than in Hara traps without the insecticidal strips or in Pherocon 1CP traps. Clearly, large numbers of males can be expected to escape from Hara traps unless an insecticide is included.

(Received February 25, 1986; accepted August 3, 1986.)

Abstract—Behavioral analysis of male attraction to stereoisomers of 8-methyl-2-decyl propanoate was conducted with *Diabrotica virgifera virgifera* and *D. barberi* using a flight tunnel. *D. barberi* males were attracted to the 2*R*,8R isomer only, and the response was inhibited by the addition of 2*S*,8*R*. *D. v. virgifera* males were also attracted to the 2*R*,8*R* isomer and were neither attracted nor inhibited by any of the other isomers. Males attracted to the lures displayed a series of behaviors characterized by a slow hovering flight upwind towards the odor source. While significant numbers of males of both species landed on the pheromone lure, none attempted copulation, indicating that other cues are necessary to induce this behavior.

INTRODUCTION

The sex pheromone of the western corn rootworm, *Diabrotica virgifera virgifera* LeConte (WCR), was identified by Guss et al. (1982) as 8-methyl-2-decyl propanoate. Indirect evidence indicates that this is the compound used in pher-

0098-0331/87/0600-1331$05.00/0 © 1987 Plenum Publishing Corporation

omone communication by the northern corn rootworm, *D. barberi* Smith and Lawrence (NCR) as well (Guss et al., 1985).

The chirality of this molecule plays an important role in determining its biological activity, a phenomenon that has been documented for pheromones of other Coleoptera (Tumlinson et al., 1977, Lanier et al., 1980). Guss et al. (1982) showed that both NCR and WCR males were attracted to as little as 10 ng of racemic pheromone per lure, although NCR response was inhibited by concentrations over 0.1 μg. Trapping in the field with individual isomers revealed that the WCR was attracted to the 2*R*,8*R* isomer and, to a lesser extent, the 2*S*,8*R* isomer, while NCR was attracted to the 2*R*,8*R* isomer only. The addition of 0.1 μg of 2*S*,8*R* or 0.5 μg of 2*S*,8*S* to 1 μg of 2*R*,8*R* caused complete inhibition of the NCR response; however, the 2*S*,8*R* and 2*S*,8*S* isomers were not inhibitory to WCR males (Guss et al., 1984, 1985).

Although the isomeric specificity of 8-methyl-2-decyl propanoate was documented in the field (Guss et al., 1984, 1985), no behavioral studies have been performed under controlled laboratory conditions to verify these findings. In addition, volatility of the pheromone (i.e., release rates from rubber septa) was not examined, making it difficult to compare these results with those obtained using different systems under different climatic conditions. The following reports the results of quantitative behavioral analyses of male NCR and WCR responses to known release rates of the four isomers of 2-methyl-8-decyl propanoate in a flight tunnel.

METHODS AND MATERIALS

The four isomers of 8-methyl-2-decyl propanoate (designated 2*R*,8*R*, 2*S*,8*R*, 2*R*,8*S*, and 2*S*,8*S*) were obtained from J.H. Tumlinson (USDA, Gainesville, Florida) and were the same preparations used by Guss et al. (1984, 1985). The isomeric purity of individual isomers was as follows: 2*R*,8*R* (97.8%); 2*S*,8*S* (98.8%); and 2*S*,8*R* (97.4%). Impurities consisted of mixtures of the other isomers and are listed in Guss et al. (1984). To formulate lures, rubber septa (catalog No. 8753-D22, A.H. Thomas Co., Philadelphia, Pennsylvania) were extracted for 24 hr in a Soxhlet extraction apparatus with methylene chloride and air dried for an additional 24 hr. Individual isomers were diluted to the appropriate concentrations with hexane (Fisher Scientific Ltd., HPLC grade) and added either singly or in mixtures to the large wells or rubber septa in 200-μl volumes. After allowing 24 hr for solvent evaporation, the septa were ready to use.

Bioassays for analysis of male behavior were conducted in the laboratory at 24°C using a 1.2 × 0.5 × 0.5 m Plexiglas flight tunnel through which air was pulled at a constant flow rate. Pheromone was dispensed from a rubber septum mounted in a copper funnel 3 cm in diameter at the large end. The

narrow end of the funnel was connected to a regulated air supply via rubber tubing, and air was passed over the lures at a constant volume of 500 ml/min. Titanium tetrachloride fumes emitted from a rubber septum in the funnel were used to visualize the shape of the pheromone plume, and adjustments were made by altering the airflow entering the chamber through the funnel as well as the speed of the fan removing air (0.3 m/sec) at the other end. This enabled us to release known quantities of pheromone by regulating airflow over the lures. The plume used in all studies had a diameter of 15 cm at the downwind end. Assays were carried out between 0800 and 1130 hr using feral males collected from corn and goldenrod plants immediately prior to use.

Individual males were placed in small wire cages and allowed to acclimate for approximately 5 min prior to being tested. A septum containing an isomer or mixture of isomers to be tested was mounted in the funnel at the upwind end of the tunnel. The assay began by placing a wire cage containing a male in the downwind end of the flight tunnel on a steel platform 15 cm high with the open end of the cage facing upwind and into the pheromone plume. Subsequent behaviors exhibited by males were then tabulated in first-order, preceding–following, behavioral transition matrices and comprehensive ethograms were formulated. The assay was discontinued after 3 min or when the male landed on the lure. Statistical significance of behavioral sequences with frequencies greater than zero was assessed by calculating chi-square values as outlined by Stevenson and Poole (1976).

The probability of a particular behavioral transition occurring was significantly greater than chance if (observed − expected)/(expected)$^{0.5}$ values were greater than $(\chi^2_{0.05}, 36\ df)^{0.5}/36^{2df}$. Standard normal deviates were then calculated from significant chi-squared values, and the most probable behavioral sequences in the ethograms ($P \leq 0.05$) were determined using the binomial test (Siegel, 1956).

The rate of volatilization of 8-methyl-2-decyl propanoate from rubber septa was determined by quantitive gas chromatographic analysis of volatiles released over a period of time. Rubber septa were loaded with pheromone concentrations of 0.1, 0.25, 0.5, 1.0, 2.0 μg/lure and volatiles were collected using the technique of Tumlinson et al. (1982). Individual septa were each placed in a silanized glass aeration chamber (Teal et al., 1986) that was connected to a compressed nitrogen gas source. The other end of the aeration chamber was fitted with a small charcoal trap made by enclosing 3–5 mg of charcoal between two 325-mesh stainless-steel frits in a 2-cm section of glass tubing (6.0 mm OD) (Tumlinson et al., 1982). Volatiles evaporating from the septa were collected on the charcoal traps for a period of 2–8 hr at 24°C with nitrogen flow rates between 300 and 700 ml/min.

Following volatile collection, the charcoal traps were extracted with four 50-μl aliquots of methylene chloride and, after the addition of 15 μl of isooctane, the solution was concentrated to about 8–10 μl under a stream of N_2 gas.

An external standard was prepared by applying a known amount of 8-methyl-2-decyl propanoate onto the charcoal trap and extracting by the procedure outlined above.

Quantitative analysis of samples was done using a Hewlett Packard 5890 gas chromatograph interfaced to an Apple IIe computer via an IMI Chromatochart data analysis stream (Interactive Microwave Inc., State College, Pennsylvania). The chromatograph was run in splitless mode with a flame ionization detector. A fused silica 30-m × 0.25-mm (ID) SPB-1 (Supelco) capillary column was used with hydrogen as the carrier gas at a linear flow velocity of 38 cm/sec. Operating conditions were as follows: initial temperature = 80°C; injector purge time = 0.5 min; temperature program (at 1 min) = 25°C/min; final temperature = 140°C. Data were analyzed with the Chromatochart software package using the charcoal trap extract of a known amount of pheromone as an external standard. Results were expressed as nanograms of pheromone released per hour with a nitrogen flow rate of 500 ml/min and were plotted against the concentration of pheromone on the rubber septa.

RESULTS AND DISCUSSION

In the behavioral ethograms for NCR and WCR males (Figure 1), parentheses were used to distinguish those transitions which occurred with a frequency

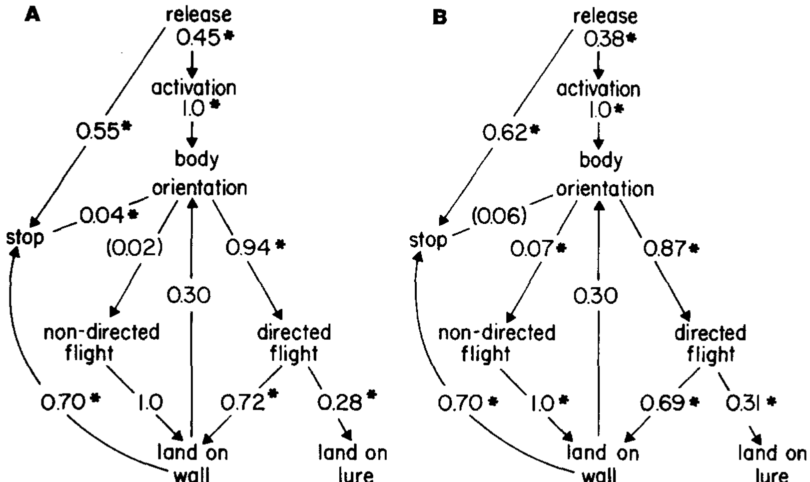

FIG. 1. Behavioral ethograms of male NCR and WCR to 1 μg of 8*R*-methyl-2*R*-decyl propanoate in the flight tunnel. Parentheses indicate those transitions not occurring with a frequency greater than chance ($P \leq 0.50$). Asterisks (*) denote the most probable transitions determined from the standard normal deviates ($P \leq 0.05$). (A) Response of NCR males ($N = 93$); (B) Response of WCR males ($N = 94$).

that was not significantly greater than chance ($P \geq 0.05$), as determined by chi-squared analysis. Among the significant transitions, those which had the highest probability of occurring, as determined by the binomial test of the standard normal deviates ($P \leq 0.05$), were indicated with an asterisk (*). Similar ethograms and statistical comparisons were made for all data given in Table I.

The ethograms produced for NCR indicated that males responded to the 2*R*,8*R* isomer of 8-methyl-2-decyl propanoate (Figure 1) but not to any of the other three isomers (Table I). When 1 μg of 2*R*,8*R* was combined in a 1 : 1 ratio with 2*S*,8*R*, response was suppressed (Table 1). However, males responded

readily to a 10:1 ratio of 1 μg 2*R*,8*R* with 0.1 μg 2*S*,8*R* (Table 2). A 10:1 ratio consisting of 10 μg of 2*R*,8*R* with 1 μg of 2*S*,8*R* again suppressed male resonse (Table 2), demonstrating that the inhibition was due to the actual amount of 2*S*,8*R* present (i.e., a threshold effect) rather than its ratio with 2*R*,8*R*. The 2*S*,8*S* and 2*R*,8*S* isomers had no inhibitory effect when each was combined with 2*R*,8*R* in a 1:1 ratio (Table 1). Although Guss et al. (1985) showed that 2*R*,8*R* was the active isomer and 2*S*,8*R* was inhibitory, their results indicated that inhibition was caused by 2*S*,8*S* as well.

The ethograms depicting the response of WCR males showed that 2*R*,8*R* was again the active isomer (Figure 1B), whereas the other three isomers exerted no effect, either alone or in combination with 2*R*,8*R* (Table 1). Guss et al. (1984) found 2*S*,8*S* and 2*R*,8*S* to be neither attractive or inhibitory in the field, but both 2*R*,8*R* and, to a lesser degree, 2*S*,8*R* attracted males in significant numbers. The attractiveness of 2*S*,8*R* in the field is difficult to explain. While a related species, *D. porracea* Harold, responds exclusively to 2*S*,8*R*, this isomer does not appear to be a component of WCR pheromone (Guss et al., 1984). The fact that no response to 2*S*,8*R* was found in the flight tunnel may have been due to the relatively low number of beetles tested (N = 35) compared to the potentially large population tested in the field. However, the possibility of attraction caused by impurities (i.e., the 2*R*,8*R* isomer) in the lures which were used in the field cannot be discounted.

In reviewing the role of chirality in the pheromone communication of Co-

leoptera, Silverstein (1979) proposed nine possible ways in which stereoisomers could mediate male response. The results presented here, as well as by Guss et al. (1985), showed that NCR pheromone was best described by category 5 (Silverstein, 1979) in which the insect produces only one enantiomer (2*R*,8*R*) and is inhibited in the presence of the other enantiomer (2*S*,8*R*). Futhermore, the data from the flight tunnel and the results of Guss et al. (1984) both suggest that WCR pheromone consists of a single enantiomer (2*R*,8*R*) and that any response to other enantiomers is an artifact (category 2, Silverstein, 1979).

Males responding to the active isomer or mixtures showed stereotyped behaviors. Although there was some variation in frequencies of behavioral transitions, the actual sequence of behaviors for both species was very similar in all cases where a positive response was observed, Upon being released, males left the cage and walked out to the upwind edge of the platform while waving their antennae in a rapid, agitated manner (activation). This was followed by ambulation back and forth along the platform edge until the body pointed directly into the odor plume. The prothoracic legs were then extended, elevating the head and prothorax (body orientation), and after taking a few steps, flight was initiated. A positive response was characterized by slow hovering flight with the body in a vertical position. Flight of this type was either upwind towards the lure (directed) or lateral with little forward motion (nondirected). The probability of the latter occurring was usually not significant.

A negative response (stop) consisted of either no flight or very fast, darting flight with no hovering, usually towards the roof of the chamber. Responses of this type could occur immediately upon release, after body orientation, or after landing on the wall.

Beetles engaged in directed flight landed on the air outlet containing the lure or, more commonly, on a nearby wall. Those individuals landing on the wall occasionally reorientated and flew to the lure, but walking out of the odor plume and "losing interest" was the most probable course of action. Males landing on the air outlet invariably located the lure, but no attempts at copulation were observed. Although attempted copulation with artificial lures is a well-documented phenomenon among other taxa (e.g., Greenblatt et al., 1976, Teal et al., 1986), apparently some other visual or chemical cues are necessary to elicit this response in *Diabrotica*.

While the behavioral responses of males to pheromone source have been well documented for several species of Lepidoptera (Bartell, 1977; Baker and Linn, 1984), few such studies have been performed with Coleoptera. An investigation by Greenblatt et al. (1976) of the mating behavior of *Trogoderma glabrum* (Herbst) revealed that male activation involved prothoracic leg extension and elevation of the head and prothorax, a feature displayed by both NCR and WCR males. In a field study of *Diabrotica balteata* LeConte, Cuthbert and Reid (1964) observed that activated males approached lures upwind in a char-

acteristic hovering flight. Attempts to elicit this response from males under laboratory conditions were unsuccessful (Cuthbert and Reid, 1964).

The success of the flight-tunnel assay for NCR and WCR males was largely dependent on the time of day when assays are done. NCR males were responsive only during morning hours on days preceded by cool nights. This period corresponded to the main response peak for males under these conditions in the field (Dobson and Teal, 1986). The response was very poor on mornings preceded by warm nights. Similarly, males did not respond in the laboratory during the nightly response period documented in the field (Dobson and Teal, 1986), despite efforts to maintain the flight chamber in complete darkness.

WCR males only responded during morning hours as well, although the response was high regardless of temperatures during the preceding night. Since WCR activity in the field was high throughout the day (Dobson and Teal, 1986), the reason for the loss of response under laboratory conditions is unknown. However, the increased agitation and "flightiness" of beetles in the field which was observed as daytime temperatures rose was no doubt an important factor. Furthermore, success of this assay was limited to feral males collected from the field immediately prior to testing. An explanation for the failure of laboratory-reared males to respond awaits further investigation.

The flight tunnel used in this investigation was a promising tool for the assay of chemicals involved in long-range attraction in other Coleoptera. Prior to this study, chemicals involved in attraction of Coleoptera have been assayed by various means including field trapping (Guss et al., 1984, Tumlinson et al., 1977), devices which permitted ambulation towards an odor source (Payne et al., 1976, Sharpas and Burkholder, 1978), and static systems which produced only close-range activation responses (Ball and Chaudhury, 1973, Guss et al., 1982). Baker and Linn (1984), however, concluded that bioassays done in a flight tunnel provide the greatest discrimination when investigating the response of insects which normally orient by flight. While there are no previous reports of the use of flight tunnel for pheromone studies with Coleoptera, there are definite advantages to using this system. In particular, use of a flight tunnel enables one to monitor, in a controlled environment, individual males performing orientation behaviors similar to those observed in the field. Previous authors assessed the attractiveness of various substances to WCR males by placing an individual in a Petri dish with a filter paper chip impregnated with the test substance. A positive response was recorded for individuals that exhibited antennal waving and orientation towards the filter paper (Ball and Chaudbury, 1973; Guss et al., 1982). The behaviors indicative of a positive response in the flight tunnel clearly provide a more objective means of assessing attraction and/or inhibition than does this latter approach.

The response threshold for both NCR and WCR males in the flight tunnel at 24°C occurred when the concentration of the *2R,8R* isomer was between 0.1 and 0.25 μg per lure (Table 2). This was considerably higher than the threshold

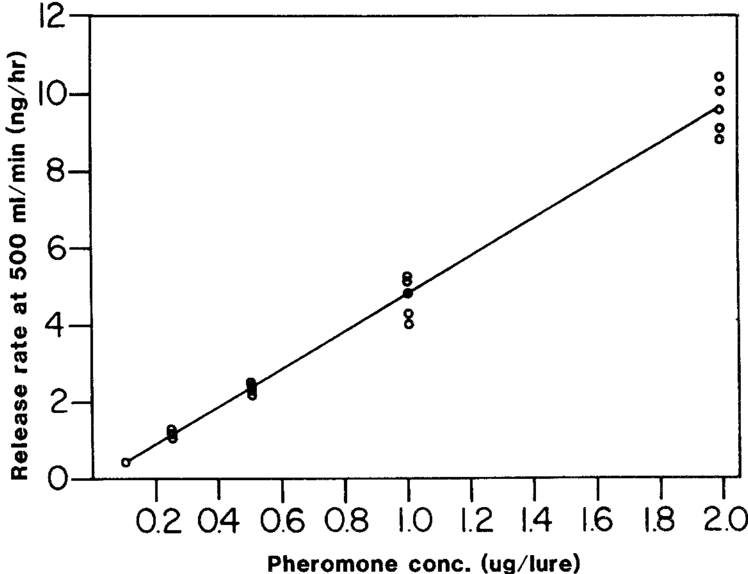

FIG. 2. Release rates of 8-methyl-2-decyl propanoate from rubber septa at 24°C in the laboratory.

value of 10 ng reported by Guss et al. (1982) in the field. This discrepancy may have been caused by different rates of pheromone release in the field and the laboratory.

A standard curve was constructed to estimate release rates for septa loaded with various concentrations of pheromone (Figure 2). The relationship between pheromone concentration and release rate was linear ($r^2 = 0.98$, $N = 25$). The relationship between release rate and airflow was also linear for flow rates within the range of 300–700 ml/min ($r^2 = 0.95$), permitting corrections for differences in airflow between tests. Consequently, a typical 1-μg lure used in the flight tunnel with an airflow of 500 ml/min at 24°C released about 4.7 ng/hr, and the lowest release rate which could elicit a positive response, as indicated by directed flight, was 0.44 ng/hr for NCR males and between 0.44 and 1.18 ng/hr for WCR males (Table 2).

In summary, this study demonstrated that both NCR and WCR males were attracted to the 2*R*,8*R* isomer of 8-methyl-2-decyl propanoate when it was released from rubber septa at levels as low as 1.18 ng/hr. Furthermore, with the exception of the inhibitory effects of the 2*S*,8*R* isomer on NCR males, none of the other isomers elicited any behavioral response in either species. Consequently, reproductive isolation of these two species is probably not achieved through differences in long-range communication using pheromones. Since the attraction of WCR males to 2*R*,8*R* was not inhibited by other isomers, racemic

mixtures of the pheromone (containing all four isomers) could be used in monitoring programs for this species. Inhibition of NCR males should be considered, however, when using pheromone preparations containing the 2*S*,8*R* isomer.

Acknowledgments—We wish to thank Dr. J.H. Tumlinson of the Insect Attractants, Behavior and Basic Biology Research Laboratory, USDA, Gainesville, Florida, for providing the enantiomers of 8-methyl-2-decyl propanoate; and Drs. J.E.. Laing and C.R. Ellis, University of Guelph, for reviewing the manuscript. This research was supported by a grant from the NSERC to P.E.A. Teal and C.R. Ellis.

(Received May 19, 1986; accepted August 4, 1986)

Abstract—The response of red deer calves (*Cervus elaphus*) to the odors of Sitka spruce (*Picea sitchensis*) and lodgepole pine (*Pinus contorta*) needles and five monoterpene constituents of their essential oils was measured by simple two-choice feeding trials. All odors were significantly rejected ($P < 0.05$) except Sitka spruce and lodgepole pine by females and Sitka spruce and alpha-terpineol by males. Females had a stronger dislike of all odors except lodgepole pine than males. Rejection of monoterpene odors weakened slightly with time. A strong logarithmic relationship between the strength of the rejection response and vapor pressure of the compounds tested suggested that the odors were rejected on the basis of concentration rather than quality.

Key Words—*Cervus elaphus*, red deer, terpenoids, monoterpenes, olfaction, *Picea sitchensis*, *Pinus contorta*.

INTRODUCTION

Monoterpenes are a group of secondary metabolites found widely throughout the plant kingdom. They are common constituents of volatile or essential oils, and individual monoterpenes are characterized by highly distinctive odors. Aromatic substances in plants, such as essential oils, may influence food selection by herbivores by acting on the sense of smell. Ruminants such as deer may have good reason to avoid plants rich in essential oils, because some are known

to inhibit the activity of symbiotic rumen microorganisms, upon which ruminants rely for the digestion of plant material. Essential oils from *Artemisia* spp. (Nagy et al., 1964; Welch et al., 1982), *Pseudotsuga menziesii* (Oh et al., 1967, 1970; Radwan, 1972; Conolly et al., 1980) and *Juniperus* spp. (Painter, 1971; Schwartz et al., 1980a) have all been shown to inhibit rumen microorganisms, Longhurst et al. (1968) reported that black-tailed deer fawns (*Odocoileus hemionus columbianus)* rejected the odor of essential oils from *Ubellularia california*, and Schwartz et al. (1980b) suggested that mule deer (*Odocoileus hemionus hemionus*) used smell to discriminate between feeds contaminated with varying levels of juniper oils. Narjisse (1981) reported that sheep also rejected the odor of essential oils of *Artemisia tridentata*. However, essential oils consist of many monoterpene constituents, and the objective of the experiment reported here was to measure the response of red deer to both whole essential oils from conifers and also to pure monoterpenes.

METHODS AND MATERIALS

Odor trials were carried out on 20 red deer calves (*Cervus elaphus*) using methods adapted from Arnold et al. (1980), in which food is contaminated by the odors of test materials absorbed in pads of cotton wool. The calves were all 3–4 months old and had been reared at Reedie Hill Deer Farm, Fife, Scotland. They had no previous experience of conifers or monoterpenes in their diet. A group of 10 males and another of 10 females were housed in separate rooms. In each room, eight buckets mounted in wall brackets 1 m above the floor were arranged in four pairs. The members of each pair were placed 2.5 m apart. Throughout the experiment, a pelleted ration (Calfrearer Cakelets, 16% protein, 8% fiber) was offered ad libitum in these buckets, which were topped up with pellets twice daily. Water and hay were available ad libitum throughout the experiment. The deer were allowed eight days to become accustomed to the system, while the effect of bucket positioning on the mass of pellets consumed from each bucket was assessed (Table 1). Seven treatment periods, each lasting

TABLE 1. MEANS AND CONFIDENCE LIMITS FOR PERCENTAGE OF TOTAL FOOD CONSUMPTION TAKEN FROM TREATMENT BUCKETS DURING ACCLIMATION PERIOD

	Food Consumption (%)			
	Initial position	Reverse position	SE	99% Cl
Females	45.7	54.3	3.3	50 ± 11.7
Males	50.8	49.2	0.8	50 ± 2.8

72 hr, then followed consecutively. The treatments were three monoterpene hydrocarbons: limonene, α-pinene and terpinolene; two monoterpene alcohols: α-terpineol and borneol (monoterpenes supplied by R.C. Treatt and Co., Bury St. Edmunds); and the crushed foliage from two conifer species: lodgepole pine (*Pinus contorta*) and Sitka spruce (*Picea sitchensis*).

The food in one bucket of each pair was contaminated by a monoterpene odor by sprinkling 1 ml of the pure compound onto three pads of cotton wool, two of which were taped to the rim of the bucket and one was loose in the food. The control bucket of each pair received three similar pads of cotton wool but with no monoterpenes applied. Borneol (a solid) and the conifer foliage were placed in bags of nylon gauze which replaced the cotton wool pads. The mass of pellets consumed from all buckets was recorded 3, 6, 12, 24, 48, and 72 hr after starting the treatment. The cotton wool pads were recharged with 1 ml of the test compounds every 24 hr. In order to eliminate the effects of bucket positioning on food consumption from each bucket, the positions of the treatment and control buckets were interchanged at 12, 24, and 48 hr.

The mass of pellets consumed from the treatment buckets was expressed as a percentage of total food consumption for each group of animals. If the deer had shown no discrimination between treatment and control buckets, this figure would have been 50%. Consumption of less than or greater than 50% from the treatment buckets would indicate rejection or preference of the test odor, respectively. During the acclimation period, 99% confidence limits were calculated for the mean mass of pellets consumed from the treatment buckets with no monoterpenes present (Table 1). During the treatment periods, significant rejection was said to have occurred when the percentage of pellets consumed from the treatment buckets was below the appropriate 99% confidence limit for the acclimation period.

RESULTS AND DISCUSSION

Over the experimental period as a whole, total consumption of pellets rose gradually as the calves grew accustomed to an ad libitum diet. Females consistently consumed significantly less than males ($P < 0.001$, 1.19 kg/day per head $\pm$ SE 0.42 for females compared with 1.67 kg/day per head $\pm$ SE 0.38 for males).

The overall responses of the calves to the odors during the 72-hr treatment periods are presented in Table 2. The odors of all pure monoterpenes were significantly rejected ($P < 0.01$) by both males and females (except α-terpineol by males). The only significant response to crushed conifer foliage was the rejection of lodgepole pine needles by males. The weakness of the rejection response to conifer foliage was probably due to weakness of the odor they emitted compared with the pure monoterpenes. Females rejected all treatments more strongly than males (except lodgepole pine).

TABLE 2. EFFECTS OF MONOTERPENE ODORS ON FOOD SELECTION BY RED DEER CALVES—CONSUMPTION FROM ODOR-TREATED BUCKETS OVER 72 HR

	Consumption (kg/head)			
	Females		Males	
Treatment	Total	From treatment (%)	Total	From treatment (%)
Sitka spruce	3.79	1.70 (44.9)	4.67	2.26 (48.4)
Lodgepole pine	3.78	1.65 (43.7)	5.01	2.25*(44.9)
Alpha-terpineol	3.96	1.18*(29.8)	5.59	2.76(49.4)
Borneol	3.86	1.46*(37.9)	5.25	2.35(44.9)
Limonene	4.33	1.20*(27.7)	5.79	2.23(38.6)
Terpinolene	3.83	0.94*(24.6)	5.42	2.30(42.4)
Alpha-pinene	3.80	0.76*(20.0)	5.33	1.96(36.8)
Nondiscrimination zones (99% CL)		(38.3–61.7)		(47.2–52.8)

*Significant rejection of treatment odor ($P < 0.01$).

Evidence of partial adaptation by the deer to some of the odors is presented in Figure 1. Between 24 and 72 hr, both males and females reduced their initially strong rejection of α-pinene, limonene, and terpinolene, and females also reduced their rejection of α-terpineol and borneol. The monoterpene hydrocarbons limonene, terpinolene, and α-pinene were more strongly rejected by both males and females than the monoterpene alcohols. α-terpineol and borneol. There was a strong logarithmic relationship between the vapor pressure of the compounds tested (vapor pressure data from Jordan, 1954) and initial response ($r = 0.95$ for males and 0.98 for females) (Figure 2).

These results suggest that deer may reject monoterpenes on the basis of odor concentration rather than odor quality. It is likely that the rejection of monoterpene odors by deer is an innate response. Since the deer in this experiment had never encountered monoterpenes or conifers in their diet before, their response could not have been based on learning from previous experience. An innate rejection of foods containing monoterpenes may have selective advantages for deer since several authors (Schwartz et al., 1980; Conolly et al., 1980; Welch and Pederson (1981) have demonstrated that monoterpenes inhibit digestion in ruminants, such as deer, by inhibiting the activity of rumen microorganisms.

Olfactory adaptation is the process whereby odors initially perceived as strong, gradually seem to weaken when exposure to them is prolonged. Originally, olfactory adaptation was thought to be due to the inability of the olfactory receptors to respond to prolonged stimulation, but now it is believed that olfactory stimuli may be suppressed at a central level (Ottoson, 1963). In domestic

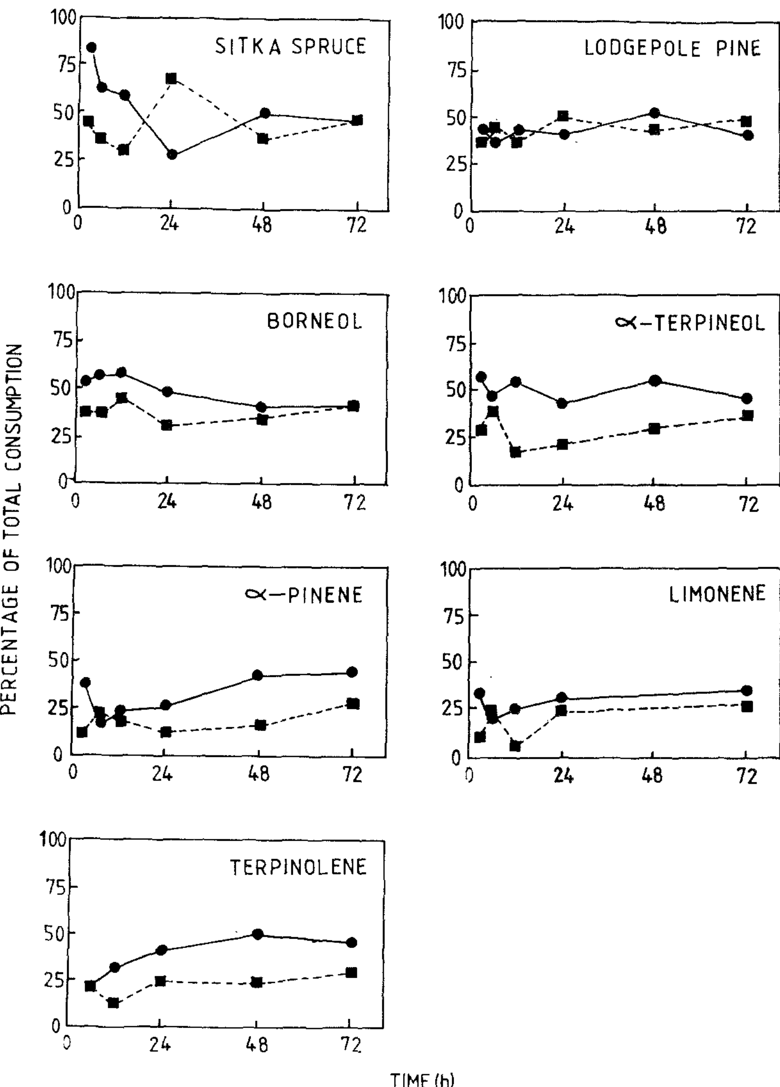

FIG. 1. Variations in response of red deer calves to odors over time. —●—, males; --■--, females.

ruminants, olfactory adaptation has been demonstrated to occur rapidly. Arnold and Hill (1972) and Arnold et al. (1980) showed that olfactory adaptation in sheep could occur within 6–24 hr, and Tribe (1949) found that sheep could adapt in less than an hour to several odors, including two which contained monoterpenes (eucalyptus and cedar wood oils). Figure 1 shows that for red deer calves, olfactory adaptation either did not occur or occurred only partially

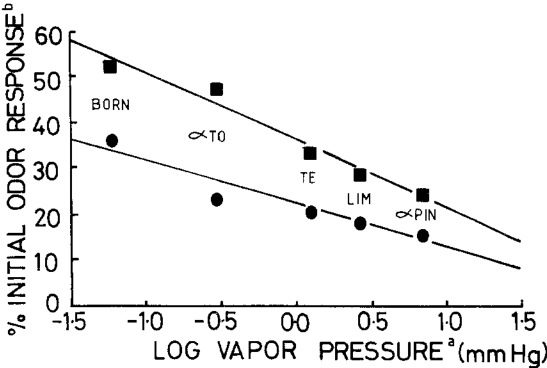

FIG. 2. Relationship between strength of rejection response and vapor pressure for five monoterpene odors: borneol (BORN), alpha-terpineol (αTO), terpinolene (TE), limonene (LIM), and alpha-pinene (αPIN). ■, males, $r = 0.95$; ●, females, $r = 0.98$. over 72 hr. The slowness with which olfactory adaptation occurred in deer compared with published data for sheep suggests that wild ruminants may rely more heavily on their sense of smell when feeding then domestic ruminants. The effect of domestication on olfaction has been demonstrated by Kruska and Stephan (1973), who found that olfactory structures in the forebrain of domestic pigs were about 30% smaller than in wild pigs. Stoddart (1980) suggested that "reductions in the olfactory part of the brain are related to the obvious behavioral changes wrought by domestication." It may be that domestication, in selecting for high productivity, has selected against those animals which reduce consumption in response to adverse olfactory stimuli.

The higher degree of rejection of food contaminated by monoterpene odors by females compared with males may have been due to bullying behavior which was common between males and may have reduced the opportunity for smaller males to select food from the preferred odorless buckets. Bullying between females was rarely observed. Alternatively, this result may reflect a genuine difference between males and females in their ability to detect and respond to olfactory stimuli. Sex differences in olfactory sensitivity have also been demonstrated in several mammals including humans (Doty et al., 1984) and black-tailed deer (*Odocoileus hemionus*) (Rice and Church, 1974). Male and female black-tailed deer differ markedly in their responses to butyric acid and putrefied fish extract.

This clear demonstration of the effects of monoterpene odors on the feeding behavior of deer may be of ecological significance in determining food selection in the wild. It is therefore important to extend these observations to feeding trials under natural conditions.

Acknowledgments—The authors would like to thank Dr. John Fletcher for allowing the use of his deer; R.C. Treatt & Co., Ltd., for supplying monoterpenes; and Dr. J. Grace and Dr. J. Milne for constructive criticism of the manuscript.

(Received June 13, 1986; accepted August 5, 1986)

Abstract—Analysis of sex pheromone glands from individual female soybean looper moths showed that in addition to the previously identified main component (Z)-7-dodecenyl acetate, the compounds dodecyl acetate, 11-dodecenyl acetate, (Z)-7-dodecenyl propionate, and (Z)-7-dodecenyl butanoate were also produced. Two of the components, 12 : OAc and 11–12 : OAc, were not detected in a single analysis of female effluvium. Flight-tunnel tests showed that the five-component and three-component blends were equal to each other and to a female extract (> 80% source contacts) and that the mixtures were superior to Z7–12 : OAc alone. Field tests indicated that the five-component blend was significantly more attractive than Z7–12 : OAc alone at a dosage of 1 mg, but that the blend was only slightly better at 3 mg.

Key Words—Sex pheromone, Lepidoptera, Noctuidae, *Pseudoplusia includens*, sustained-flight tunnel, (Z)-7-dodecenyl acetate, dodecyl acetate, 11-dodecenyl acetate, (Z)-7-dodecenyl propionate, (Z)-7-dodecenyl butanoate.

INTRODUCTION

Males of a large number of noctuid species are attracted to (Z)-7-dodecenyl acetate (Z7–12 : OAc) alone or in combination with other compounds (Steck et al., 1982). This includes many species in the subfamily Plusiinae, such as the

0098-0331/87/0600-1351$05.00/0 © 1987 Plenum Publishing Corporation

cabbage looper moth, *Trichoplusia ni* (Berger, 1966) and the soybean looper moth, *Pseudoplusia includens* (Tumlinson et al., 1972). Although both *T. ni* and *P. includens* males are attracted to relatively high release rates of Z7–12:OAc in pheromone traps, the males of both species readily distinguish conspecific females in pheromone traps (Tumlinson et al., 1972; Kaae et al., 1973; Leppla, 1983), and the presence of female *T. ni* reduces the response of male *P. includens* (Mitchell, 1972; Leppla, 1983). These results were explained in part with the identification of five additional pheromone components for *T. ni*, including 12:OAc, Z5–12:OAc, 11–12:OAc, Z7–14:OAc, and Z9–14:OAc (Bjostad et al., 1980, 1984; Linn et al., 1984). We now have investigated *P. includens* and report on its unique sex pheromone blend.

METHODS AND MATERIALS

Extracts. The insects were reared on a semisynthetic diet (Shorey and Hale, 1965), at 26°C, 70% relative humidity, 16:8 light–dark photoperiod. The sexes were separated as pupae, and males were held at conditions similar to those used in rearing. Pheromone glands were dissected from 3- to 4-day-old females at the midpoint of the 8-hr scotophase, placed in 10 μl of glass-distilled dichloromethane, and soaked for 1 hr prior to GLC analysis.

Volatile extracts were prepared as in Bjostad et al. (1984), by trapping volatiles from the gland (20 min) onto glass wool under a nitrogen stream. Collections were made during the fifth hour of the 8-hr scotophase. The volatile extract was then analyzed by capillary GLC.

Chemical Identification. Capillary GLC was conducted with a polar 45-m Carbowax 20 M column, and a nonpolar 49-m OV-101 column, used with splitless injection and programmed from 80 to 180°C at 10°/min after an initial delay of 1 min. Quantification of relative abundances of compounds was performed by electronic integration of peak areas (flame ionization detection). The packed GLC column was a 3% OV-101 (methyl silicone) on 100- to 120-mesh Gas-Chrom Q in a 2-m glass column (inside diameter, 4 mm) at 180°C. Fractions were collected with 30-cm glass capillary tubes.

Hydrolysis of the pheromone acetates was performed by adding 100 μl of a 0.5 M NaOH in aqueous ethanol solution to crude gland extract in a 4-ml vial. Hexane (0.2 ml) was added after 30 min at room temperature, and the mixture was shaken. The hexane layer was removed and reduced in volume by evaporation with a nitrogen stream, and the retention time of the hydrolysis product was determined by capillary GLC.

Acetylation was carried out on the hydrolysis products by adding a drop of acetyl chloride to a 4-ml vial in which a portion of the hexane layer from hydrolysis had been evaporated to dryness. After 1 hr, the acetyl chloride was evaporated to dryness, and a drop of hexane was added to recover the acetyla-

tion product. After concentration with a stream of nitrogen, the solution was analyzed by capillary GLC.

Mass spectra were obtained with a HP-5985 GC-MS equipped with a 25-m Carbowax 20 M glass capillary column. Chemical ionization was performed with isobutane as a reagent gas.

Synthetic compounds used for standards and for the behavioral studies were as follows: (*Z*)-7-dodecenyl acetate (Farchan Co., Willoughby, Ohio); 11-dodecenyl acetate (Nu Chek Prep, Inc., Elysian, Minnesota); (*Z*)-7-dodecenyl propionate and butanoate were prepared by reaction of (*Z*)-7-dodecen-1-ol with propionyl chloride or butyryl chloride. The compounds were found to have greater than 99% isomeric purity by capillary GLC analysis (Carbowax 20 M column).

Flight-Tunnel Tests. Individual 3- to 4-day-old males were tested in the sustained-flight tunnel described by Miller and Roelofs (1978), during the fifth and sixth hours of the 8-hr scotophase period. Males were placed in the room housing the tunnel at the beginning of the scotophase to acclimate to light and temperature conditions in the tunnel: 0.3 lux and 21–23°C. Other conditions in the flight tunnel were 70% relative humidity and 50–55 cm/sec wind velocity. Males were handled during testing as described in Linn et al. (1984). Each male was allowed 1 min to respond and was scored for the following behaviors: taking flight, oriented flight in the odor plume, initiation of upwind flight, and source contact. Males were tested only once and then discarded.

Sources for synthetic compounds in all tests were polyethylene caps, and these were prepared by adding Skelly B solutions of the synthetics to the inside of the caps with Pasteur pipets. After 1 hr, the caps were closed and left in the laboratory hood for 36 hr. Caps were held in glass vials at −10°C when not in use. In addition, pheromone gland extracts were tested by soaking three female glands in 30 μl of dichloromethane, placing 10 μl of this solution onto a 0.75-cm^2 piece of Whatman No. 1 (qualitative, lot No. 308306) filter paper, and positioning this on the end of an insect pin placed in a cork stand.

Field Tests. Field trials were conducted during the growing seasons of 1983 and 1984, at the Louisiana State Penitentiary farm, Angola, Louisiana. Pherocon 1C (Zoecon Co., Palo Alto, California) traps were baited with the desired pheromone blends or dosage of Z7–12:OAc and placed 30 m apart on aluminum poles ca. 1.5 m high. Trap height was no greater than 20 cm above the crop canopy. Tests were conducted in a variety of crops, including soybean, cabbage, and broccoli. Each treatment was replicated three times. Traps were monitored daily or on alternate days over a two-week period, and treatments were randomized each collection day. Captured specimens were returned to the laboratory and identified to species, using genitalia characteristics described by Eichlin (1975). Data for each replicate were combined over all days, and the mean trap catch for the three replicates was calculated. Treatment means were compared by Duncan's multiple-range test.

RESULTS

Chemical Identification. Analysis of single female pheromone glands by capillary GLC showed the presence of four compounds in addition to the main component Z7–12:OAc (Figure 1). The ratios of these components in eight different gland analyses is given in Table 1. The earliest eluting compound was determined to be dodecyl acetate (12:OAc) by comparison of its retention times to a standard on the Carbowax and OV-101 capillary GLC columns, and by hydrolysis to dodecen-1-ol and reacetylation to 12:OAc as determined by capillary GLC analysis.

The compound eluting just after Z7–12:OAc was found to be 11-dode-

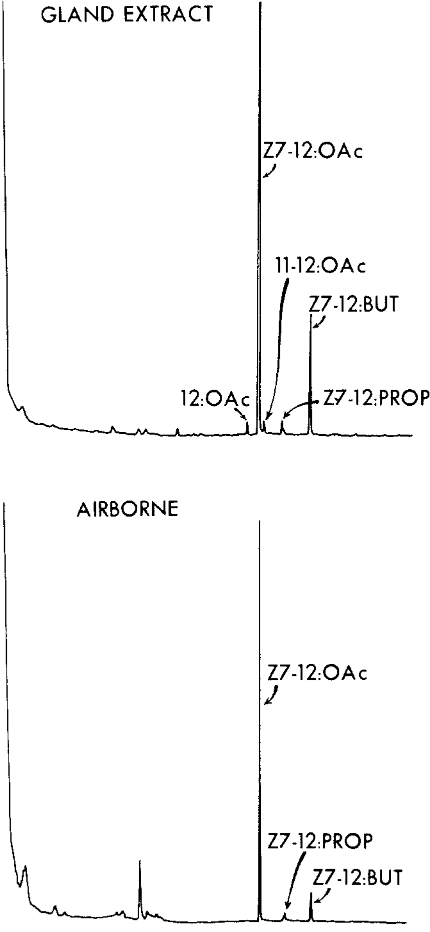

FIG. 1. Capillary GLC traces of gland extract and volatile extract of *P. includens*.

TABLE 1. PROPORTIONS OF COMPOUNDS FROM GLAND EXTRACTS AND VOLATILE EXTRACT OF INDIVIDUAL SEX PHEROMONE GLANDS OF *P. includens*

	Gland Extract								Mean	SD	Volatile
Compound	1	2	3	4	5	6	7	8			
12:OAc	0.1	6.8	0.3	0.4	0.5	0.6	0.5	0.4	1.2	2.3	—
Z7–12:OAc	95.5	93.2	95.0	89.9	93.0	91.9	93.7	93.0	93.2	1.7	88.8
11–12:OAc	0.4	0.7	0.6	1.1	0.9	0.6	0.6	0.6	0.7	0.2	—
Z7–12:Prop	0.4	1.0	0.6	2.6	0.4	0.5	1.0	0.4	0.9	0.7	3.4
Z7–12:But	3.6	5.2	3.6	6.8	5.6	7.0	4.7	5.8	0.2	1.2	7.8

cenyl acetate (11–12:OAc) by comparison of its retention times to a standard on the Carbowax and OV-101 capillary GLC columns. Although the retention times of Z9–12:OAc and 11–12:OAc are the same on Carbowax, they were separated (25.02 and 24.86 min, respectively) on the OV-101 column using a program rate of 4°C/min.

The two remaining compounds were determined to be (Z)-7-dodecenyl propionate (Z7–12:Prop) and (Z)-7-dodecenyl butanoate (Z7–12:But). Analysis of retention times for these compounds from crude extracts on the capillary GLC columns suggested that they were not standard 12- or 14-carbon acetates, alcohols, or aldehydes. Hydrolysis of the components from female extracts collected from the packed methyl silicone column, however, showed that the alcohol products had identical retention times on the capillary Carbowax column to that of the alcohol from the main component Z7–12:OAc. The alcohols were acetylated to give a product with the same GLC retention time as that of Z7–12:OAc. The propionate and butanoate moities were characterized with CI and EI mass spectral data. In addition to the fragmentation pattern expected for the long-chain alcohol portion of the compounds, the propionate compound produced a (M + 1) ion at *m/z* 241 with CI, and characteristic propionate fragmentation ions at *m/z* 75 and 57 with both CI and EI. The butanoate compound exhibited a (M + 1) ion at *m/z* 255 with CI, and characteristic butanoate fragmentation ions at *m/z* 89 and 71 with both CI and EI. All spectra were identical to those of synthetic standards.

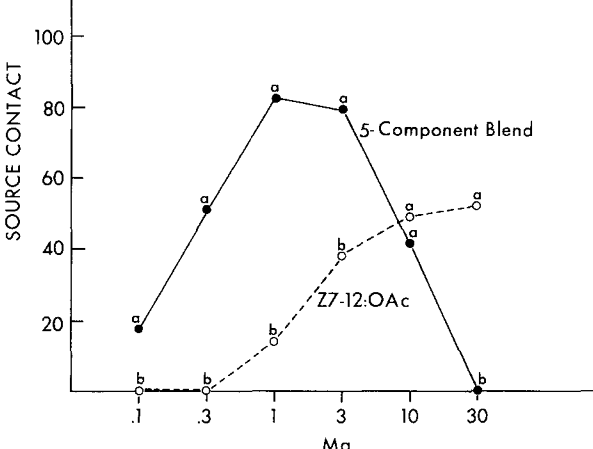

FIG. 2. Response, as proportion of males reaching source, of *P. includens* to a dosage series of the five-component blend (as defined in Figure 1 from gland extracts) versus Z7–12:OAc alone. $N = 40$ for each data point. Values for each dosage with different letters are significantly different ($P < 0.05$) according to the method of adjusted significance levels for proportions (Ryan, 1960).

Whereas analysis of gland extracts showed the presence of four additional compounds, only the Z7–12 : OAc, propionate, and butanoate components were detected in an analysis of the female effluvium (Figure 1, Table 1). Several additional airborne collections were atttempted, but the quantity of compounds trapped was too low for analysis.

Flight-Tunnel Tests. Male *P. includens* were tested in the flight tunnel to a dosage series of Z7–12:OAc, and the five-component blend identified from female glands (Figure 2). Males responded in peak percentages (80%) to the 1- and 3-mg dosages of the blend, whereas response to Z7–12:OAc at these dosages was 16 and 38% respectively.

Male *P. includens* then were tested to several treatments at the 3-mg dosage to determine the effect of removing various compounds on male flight behavior (Figure 3). Male response was >80% to the female-produced blend and the blend minus 12:OAc and 11–12:OAc, and this was not significantly different from the response level to the extract (1 FE). Removal of either the propionate or butanoate from the five-component blend, however, resulted in

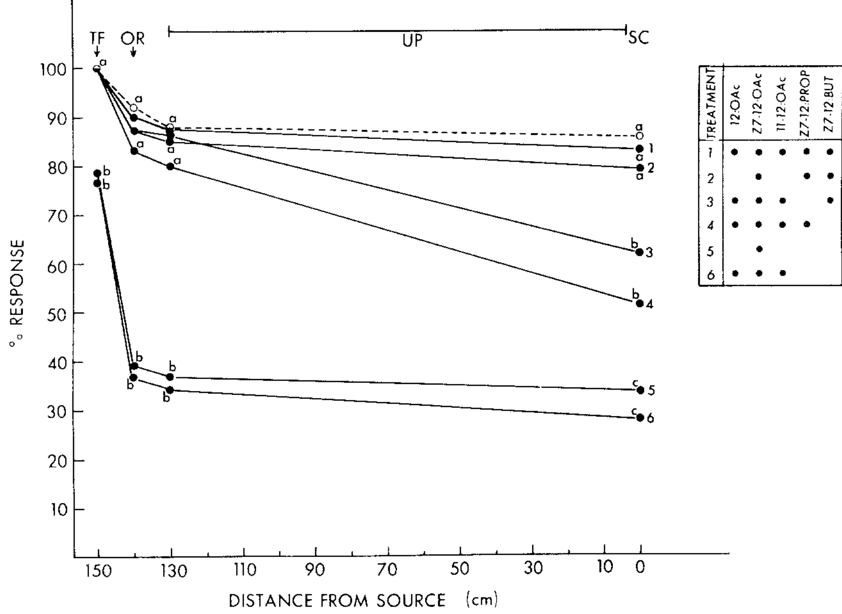

FIG. 3. Response of male *P. includens* in the flight tunnel to a 3-mg dosage of selected blends, Z7–12:OAc alone, and a 1-FE gland extract. Behaviors are: taking flight (TF), stationary orientation flight (OR), upwind flight (UP), and source contacts (SC). Dashed line represents response to 1 FE gland extract. $N = 70$ for each treatment. Values for any behavior with different letters are significantly different ($P < 0.05$) according to the method of adjusted significance levels for proportions (Ryan, 1960).

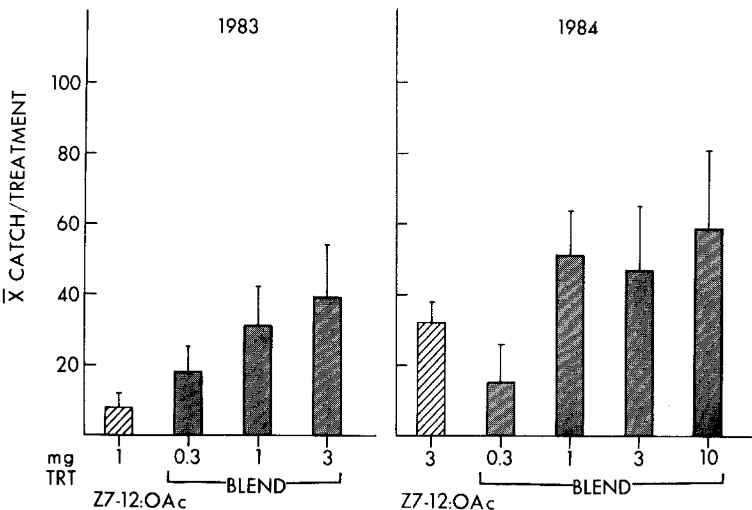

FIG. 4. Trap catch of male *P. includens* to a dosage series of the five-component blend (as defined in Figure 1 from gland extracts) versus a 1- (1983) or 3- (1984) mg dosage of Z7–12 : OAc. Values are mean + SD, N = 3 replicates for each treatment, with each replicate representing total catch over a two week period.

significantly fewer males reaching the source, as a result of arrestment of upwind flight. Male response was significantly lower at all steps in the sequence to Z7–12 : OAc alone compared to other treatments, primarily due to fewer males taking flight and orienting to the pheromone plume. The results in Figure 3 also show that addition of 12 : OAc and 11–12 : OAc to Z7–12 : OAc did not significantly affect male behavior over that observed to Z7–12 : OAc alone.

Field Tests. Field trials in 1983 showed that male *P. includens* were caught in significantly greater numbers to the 1- and 3-mg dosages of the five-component blend compared to the 1-mg dosage of Z7–12 : OAc alone (Figure 4). Tests in 1984, however, showed that trap catch with a 3-mg dosage of Z7–12 : OAc was lower, but not significantly so, compared to the 1-, 3-, or 10-mg dosages of the blend.

DISCUSSION

In addition to Z7–12 : OAc, four compounds were observed in pheromone gland extracts of female *P. includens*. These compounds were identified as 12 : OAc, 11–12 : OAc, Z7–12 : Prop, and Z7–12 : But. The mixture of five components elicited response levels in the flight tunnel that were equal to those with female extracts, and both were superior to Z7–12 : OAc alone.

Two of the minor components, 12:OAc and 11–12:OAc, found in *P. includens* gland extracts also are part of the *T. ni* sex pheromone blend. They play a questionable role with *P. includens*, however, since they were not detected in the female effluvium assay, and full activity was obtained in flight tunnel tests when they were omitted from the blend. The remaining three components, Z7–12:OAc, Z7–12:Prop, and Z7–12:But, for *P. includens* represent a unique pheromone system. Although all can be produced from the same biosynthetic route of Z11–16:acid to Z9–14:acid to Z7–12:acid to Z7–12:OH as found in *T. ni* (Bjostad and Roelofs, 1983), we are not aware of any other lepidopteran species that utilizes this interesting ester series of acetate, propionate, and butanoate.

We have shown that *T. ni* and *P. includens* both use Z7–12:OAc as a major pheromone component and that both produce two minor components in common. However, *T. ni* has three additional specific components and *P. includens* has two additional unique components. The importance of these blends in effecting specific mate recognition signals for these two species is presented in a companion paper (Linn et al. 1987).

Acknowledgments—We are grateful to Kathy Poole and Marlene Campbell for rearing the insects, and to Geoff Rule for preparing some of the synthetic blends. We also thank Rose McMillan-Sticht, Bernadine Aldwinkle, and Joe Ogrodnick for preparation of the figures.

(Received June 9, 1986; accepted August 11, 1986)

Abstract—The petroleum ether extract of *Argemone mexicana* seeds was found to possess nematicidal activity against the plant parasitic nematode *Meloidogyne incognita*. The active nematicidal compound has been isolated from the crude extract by column chromatographic techniques and purified by TLC. Chemical structure has been determined by chemical and spectroscopic methods to be that of a triglyceride, sn-glycerol-1-eicosa-9, 12-dienoate-2-palmitoleate-3-linoleate.

Key Words—Nematoda, *Meloidogyne incognita*, *Argemone mexicana*, Papaveraceae, triglyceride, nematicide.

INTRODUCTION

Recent ecological studies have shown that some plant species escape attack by plant-parasitic nematodes (Huang, 1985). The number of plant-parasitic nematodes capable of attacking a given plant species is controlled by the presence of plant defense mechanisms. The mechanisms involved in plant resistance to nematodes have been reviewed (Kaplan and Keen, 1980; Veech, 1981, 1982). Chemical investigations of plants that escape nematode attack have led to the isolation and identification of several natural nematicides (Figure 1).

FIG. 1. Selected natural nematicides isolated from plants: (**1**) cucurbitacin, isolated from cucumber (Huang, 1985); (**2**) pyrocatechol, isolated from roots of *Eragrostis curvala* (Scheffer et al., 1962); (**3**) glyceollin, isolated from soybeans (Veech, 1981); (**4**) α-terthienyl, isolated from roots of *Tagestes erecta* (Veech, 1981); (**5**) polyacetylene, isolated from safflower, *Carthamus tinctorius* (Kogiso et al., 1976); and (**6**) asparagusic acid, isolated from asparagus (Takasugi et al., 1975).

As a part of our ongoing studies on isolation and characterization of natural products which are bioactive against agricultural pests (Saleh, 1984, 1985, 1986; Saleh et al., 1984, 1986b, c; Abdel Rahman et al., 1986), we report here the isolation of a nematicidal triglyceride from *Argemone mexicana* L. (Papaveraceae). The most active nematicidal component in the crude petroleum ether extract of *A. mexicana* seeds was isolated by chromatographic techniques, with the isolation sequence being guided by a laboratory bioassay against the root-knot nematode *Meloidogyne incognita*. The active compound has been identified by chemical and spectroscopic methods.

METHODS AND MATERIALS

Isolation of Nematicidal Components. Seeds of *Argemone mexicana* were collected from the Nile Bank at Aswan, Egypt, during the spring of 1984. The seeds (400 g) were ground to a fine powder and extracted successively with petroleum ether (40–60°C), then with acetone, and finally with methanol in a Soxhlet apparatus. The extracts were dried over anhydrous sodium sulfate, filtered, and the solvents removed at reduced pressure to give 95 g (24% yield) of a light yellow viscous oil from the petroleum ether fraction, 24 g (6% yield) of a yellow oil from the acetone fraction, and 18 g (4.5% yield) of an orange oil from the methanol fraction.

The crude extract obtained using petroleum ether was chromatographed on a column containing silica gel, (AR-100-mesh, Mallinkrodt, Inc., St. Louis, Missouri) preactivated by heating for 24 hr at 110°C and packed with hexane. Major column fractions were eluted with hexane, followed by mixtures of 5%, 10%, 20%, and 50% ether in hexane, then ether and acetone, and finally methanol.

Column fractions were monitored for nematicidal activity and examined by thin-layer chromatography (TLC). The most active column fraction (10% ether in hexane) was further fractionated and purified by preparative TLC on precoated silica gel plates of 1 mm thickness (EM Laboratories, Inc., Elmsford, New York) developed three times with 10% ether in hexane. Analytical TLC was carried out on 0.25-mm silica gel plates with the solvent system hexane–ether–acetic acid (90 : 10 : 1); spots were detected in iodine vapor or after spraying with anisaldehyde reagent and heating at 100°C (Stahl, 1973).

Nematicidal Bioassay. Aqueous solutions of the crude seed extracts, column fractions, and the purified compound were prepared by solubilizing them in a solvent–surfactant–water medium that is nontoxic to nematodes (Feldmesser et al., 1983). The nematicidal activities of the crude seed extract, column fractions, and the purified compound were investigated using the wet-screen method (McBeth and Bergeson, 1953) and by final viability determination (Feldmesser et al., 1983).

Wet-screen bioassay was carried out in a multicavity dish; each cavity was filled with 5 ml of the aqueous solution containing the test compound and one drop of water–nematode suspension containing ca. 100 nematodes, *Meloidogyne incognita*. Observations were made daily for one week by microscopic examination. Normal unstressed *M. incognita* are in continuous rapid motion, and the esophageal areas are hyaline. Exposure to nematicides results in reduced motility, immotility, and death; when the nematodes are moribund or dead, the esophageal structures disintegrate and darken. When reduction or cessation of motility appeared to be the sole or major effect of exposure, nematodes were held for 24 hr or longer after the end of the exposure period to determine re-

covery of motility. Untreated control samples were run along with experimental extracts; the control mortality was $< 10\%$.

Visual examination is not completely reliable for determining mortality; therefore final viability determinations on tomato plants were carried out according to Feldmesser et al. (1983). The inoculated tomato seedlings were examined after three weeks to determine the viability of the nematode inocula expressed as root infection. Five replicates of each treatment were carried out, and the results are reported as an average of the five replicates. Infections were evaluated on an arbitrary basis (the root-knot index) by assigning values of 0 = no infection, 1 = 1–25% of the roots galled, 2.0 = 26–50% galled, 3.0 = 51–75% galled, and 4.0 = 76–100% root infection.

Instruments and Conditions. Gas chromatography–mass spectrometry (GC-MS) was performed on a Finnigan-Mat 5300 GC-MS data system equipped with a 30-m (0.25 mm ID) DB-1 fused silica capillary column. Helium was used as the carrier gas and methane as the makeup gas for chemical ionization (CI) runs. GC separations of fatty acid methyl esters were carried out at a column temperature which was started at 100°C and raised to 200°C at a rate of 5°C/min. Spectra in the EI mode were recorded at 70 eV. Mass spectra (MS) of the triglyceride were determined using direct exposure probe (DEP) techniques. High-resolution MS were recorded on a VG Zab-4F analytical instrument (DEP technique). Infrared (IR) spectra were recorded on an IBM IR/32 FT spectrophotometer. High-resolution proton magnetic resonance spectra ($[^{1}H]$NMR) were recorded in $CDCl_3$ with a Bruker 500-MHz NMR spectrometer. $[^{13}C]$NMR and two-dimensional chemical shift correlations spectra were recorded on a 300 MHz Bruker instrument.

RESULTS AND DISCUSSION

Seeds of *Argemone mexicana* were collected from the Nile Bank of Aswan, Egypt, in May 1984. The seeds were extracted successively with petroleum ether, then with acetone, and finally with methanol. All extracts were bioassayed for their nematicidal activity against the root-knot nematode *Meloidogyne incognita* as described in Methods and Materials. The nematicidal activity was found to reside in the petroleum ether extract. This extract was fractionated by column chromatography on silica gel; the fractionation and isolation sequences were guided by bioassay. The column fraction eluted with 10% ether in hexane was the most active, being four times more active than the crude extract. Final purification of this column fraction by TLC yielded the active compound which was found to be five times more active than the crude extract. Solutions of 200 ppm of the purified compound showed a strong killing effect (LC_{50} 90 ppm, LC_{90} 150 ppm) in the wet-screening bioassay. In the final viability test, solutions of 100 ppm of the purified compound prevented formation of nematode

galls or root-knots in the roots of tomato plants, corresponding to a root knot index of zero. The potency increased fivefold during isolation, but the component isolated is only 2% of the seed oil, suggesting either that considerable loss of the nematicidal principal during isolation or that a synergist component(s) is removed during the isolation process. It is interesting in this context that *A. mexicana* is known to contain several biologically active components. Sanguinarine, a liver-toxic alkaloid, also a potent inhibitor to cytochrome P-450, and benzphetamine *N*-demethylase were isolated from the seeds of *A. mexicana* (Dalvi, 1985). Norsanguinarine, herberine, protopine, and β-sitosterol were isolated from the roots and 3-methoxyquercein and vanillic acid from the flowers (Pathok et al., 1985); aqueous extract of the leaves was antiinflammatory (Sukumar et al., 1984).

The active fraction was found to be pure by TLC; its exact mass from the high-resolution mass spectrum was found to be 880.7475, suggesting a possible component(s) of $C_{57}H_{100}O_6$. The NMR, IR, and MS data are consistent with a triglyceride structure of high purity of the type sn-glycerol-1-eicosa-9,12-dienoate-2-palmitoleate-3-linoleate (Figure 3). Infrared spectrum showed absorption bands characteristic of aliphatic ester groups (1750.6 cm^{-1}) and nonconjugated *cis* C=C double bonds (3010.3, 1653.2, 750.5 cm^{-1}). The molecular formula of the active compound, $C_{57}H_{100}O_6$, indicates eight sites of unsatura-

[a] Spectra were run in $CDCl_3$, and Me_4Si was used as the internal standard. Values are recorded in parts per million (ppm) downfield from Me_4Si; coupling constants (hertz) are in parentheses. Multiplicity is designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet whose center is given; br, broad. Spectra were determined on a 500 MHz instrument for protons and on a 300 MHz instrument for ^{13}C.

tion. Three carbonyl carbons in ester form (173.35 and 172.93 ppm) together with 10 olefinic carbons (128.06–130.36 ppm) can be accounted for from [^{13}C]NMR.

The NMR data of (**1**) are shown in Table 1. The assignments of hydrogen atoms and carbon atoms in the proposed structure were confirmed by the $^{13}C-^{1}H$ and $^{1}H-^{1}H$ two-dimensional spectra shown in Figure 2. Mass spectral data (Figure 3) are also consistent with the proposed structure. The absence of the ion $[M-R_2COOCH_2]^+$ relative to the $[M-R_1COOCH_2]^+$ and $[M-R_3COOCH_2]^+$ ions suggested that the fatty acid $C_{16:1}$ is esterified at the 2-position of the glyceride. The identities of the fatty acids in the triglyceride were confirmed by GC-CIMS analyses of the methyl esters of the fatty acids obtained by saponification of the triglyceride.

The fatty acid composition of *A. mexicana* seed oil has been found to be mostly linoleic, oleic, and palmetic (Mani and Lakshminarayana, 1970; Haussein et al., 1983). Minor amounts of myristic acid, 9- and 11-keto C_{28} and C_{30} acids, and hydroxy and epoxy fatty acids were also identified (Gunstone et al., 1977; Mani and Lakshiminarayana, 1972). The present results represent the first report of a triglyceride with nematicidal effect. This may provide a lead for an investigation of a new class of nematicidal compounds. Several saturated

and unsaturated C_9–C_{16} fatty acids isolated from roots of sweet daphne, *Daphne odora* (Thymelaeceae), were shown to have nematicidal activity to rice white-tip nematode *Aphelenchoides besseyi* (Munakata, 1983); it is also interesting to note that several compounds containing oleic acid, i.e., ethylene glycol mon-oleate, 1-monoolein, oleic acid, and oleyl alcohol, were found to be attractive to pine wood nematodes (Tominaga et al., 1982).

Acknowledgments—We thank Professor E.C. Friedrich, Department of Chemistry, University of California, Davis, for his helpful discussions on the spectral data and for reviewing the manuscript.

SEX PHEROMONE COMPONENTS OF THREE SPECIES OF *Semiothisa* (GEOMETRIDAE), (*Z,Z,Z*)-3,6,9-HEPTADECATRIENE AND TWO MONOEPOXYDIENE ANALOGS[1]

J.G. MILLAR, E.W. UNDERHILL, M. GIBLIN, and D. BARTON

(Received May 9, 1986; accepted August 12, 1986)

Abstract—Adult males of *Semiothisa signaria dispuncta* (Walker) were attracted to field traps baited with (*Z,Z,Z*)-3,6,9-octadecatriene and (*Z,Z*)-6,9-*cis*-3,4-epoxy-octadecadiene. However, analyses of sex pheromone gland extracts of females of this species by GC-MS and by GC in combination with an electroantennograph detector (GC-EAD) showed the pheromone to be comprised of a mixture of the next lower homologs: (*Z,Z,Z*)-3,6,9-heptadecatriene and (*Z,Z*)-6,9-*cis*-3,4-epoxy-heptadecadiene. Blends of these two C_{17} compounds were subsequently found to be more attractive to males in the field than the corresponding C_{18} mixtures. Sex pheromones of two other *Semiothisa* species were also found to contain C_{17} components. (*Z,Z,Z*)-3,6,9-Heptadecatriene, detected by GC-EAD analysis of a female abdominal tip extract of *S. bicolorata* (Fabricius), attracted conspecific males, and this attraction was significantly reduced by additions of (*Z,Z*)-6,9-*cis*-3,4-epoxy-heptadecadiene, the major pheromone component of *S. signaria dispuncta*, to the lure. (*Z,Z*)-3,9-*cis*-6,7-Epoxy-heptadecadiene was detected by GC-EAD analysis as the primary male antennal stimulatory component present in abdominal tip extracts of *S. ulsterata* (Pearsall), and males of this species were attracted to traps baited with this epoxide. Each of these three C_{17} compounds constitute previously unknown lepidopteran sex pheromone components. Blends of (*Z,Z,Z*)-3,6,9-heptadecatriene and (*Z,Z*)-3,9-*cis*-6,7-epoxy-heptadecadiene attracted males of a fourth species, *S. delectata* Hulst, but no females of this species were obtained to permit analysis of its sex pheromone. The occurrence of (*Z,Z,Z*)-3,6,9-heptadecatriene in *S. neptaria* (Guenee) females was indicated by GC-MS analysis of an abdominal tip extract; how-

ever, no males were attracted to any of the fielded mixtures containing this hydrocarbon.

Key Words—Lepidoptera, Geometridae, *Semiothisa signaria dispuncta*, *Semiothisa bicolorata*, *Semiothisa ulsterata*, *Semiothisa delectata*, *Semiothisa neptaria*, (Z,Z,Z)-3,6,9-heptadecatriene, (Z,Z)-6,9-*cis*-3,4-epoxy-heptadecadiene, (Z,Z)-3,9-*cis*-6,7-epoxy-heptadecadiene, sex attractant, sex pheromone.

INTRODUCTION

In a previous publication (Wong et al., 1985) adult males of several noctuid and geometrid species were shown to be attracted to C_{18}–C_{21} (Z,Z,Z)-3,6,9-triene hydrocarbons (I in Figure 1), to mixtures of their corresponding *cis*-3, 4-, *cis*-6,7-, and *cis*-9,10-monoepoxydiene analogs (II, III and IV, respectively), and to blends of these trienes and their monoepoxydiene mixtures. Wong et al. (1985) also showed additional noctuid and geometrid species were captured when enantiomers of (Z,Z)-3,6-*cis*-9,10-monoepoxydienes (IV) were tested as single lure components or as blends with triene hydrocarbons. During these field tests, low numbers of *Semiothisa signaria dispuncta* (Walker) males were found to be attracted to lures containing (Z,Z,Z)-3,6,9-octadecatriene (3Z,6Z,9Z–18:H) and to mixtures of its *cis*-3,4-, *cis*-6,7-, and *cis*-9,10-monoepoxydienes. Although the larval form of this species has not been associated with serious damage (Ferguson, 1974), we were interested in determining which of the positional epoxide isomers was responsible for the attraction of these males.

We report here that the sex pheromone of *S. signaria dispuncta* consists of C_{17} compounds and that C_{18} compounds tested previously were functioning as pheromone mimics. We also report the synthesis of the C_{17} series of compounds (I–IV) and data derived utilizing them in field screening tests.

METHODS AND MATERIALS

Synthetic Chemicals

Compounds were synthesized and purified by methods previously reported (Underhill et al., 1983; Wong et al., 1985), except for (Z,Z,Z)-3,6,9-heptadecatriene (3Z,6Z,9Z–17:H) and *cis*-monoepoxydienes described below.

Preparation of (Z,Z,Z)-3,6,9-Heptadecatriene. 1-Nonyne (1.49 g, 12 mmol) was added dropwise to a freshly prepared solution of EtMgBr (13 mmol) in THF (20 ml), and the resulting solution was heated at 40–45°C for 1.5 hr. The solution was then cooled to 0°C, and CuI (95 mg, 0.5 mmol) was added. The mixture was stirred 15 min, then cooled to −15°C, and 1-tosyloxy-2,5-

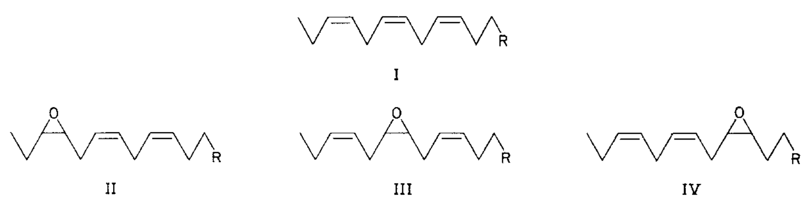

FIG. 1 Structures of some triunsaturated hydrocarbon and monoepoxydiene male sex attractants of arctiid, geometrid, and noctuid males. They include 3*Z*,6*Z*,9*Z*-trienes (I), 6*Z*,9*Z*-*cis*-3,4-epoxydienes (II), 3*Z*,9*Z*-*cis*-6,7-epoxydienes (III) and 3*Z*,6*Z*-*cis*-9,10-epoxydienes (IV) with chain lengths of 18–21 carbons. $R = C_6H_{13}$ to C_9H_{19}.

octadiyne (2.21 g, 8.0 mmol) in THF (10 ml) was added dropwise over 30 min. The mixture was warmed to 20°C over 3 hr, and stirred overnight. The mixture was then poured into aqueous 2 M NH_4Cl (50 ml), and extracted with ether (3 × 50 ml). The combined ether extracts were dried (Na_2SO_4), filtered through a short column of silica gel (2.5 × 5 cm), rinsing the silica well with ether, and the filtrate was concentrated, giving the crude triyne as a yellow oil. This was used directly in the next step.

Dicyclohexylborane (40 mmol) was prepared by the published procedure (Brown et al., 1977) from borane–dimethyl sulfide complex (10 M; 4.0 ml, 40 mmol) and cyclohexene (8.1 ml, 80 mmol) in THF (50 ml). The suspension was cooled to 0°C and the crude triyne in THF (10 ml) was added dropwise. The mixture was warmed to 20°C over 1 hr, and stirred an additional 3 hr. Acetic acid (20 ml) was then added dropwise, and the mixture was stirred overnight. The mixture was then made basic by dropwise addition of aq. NaOH (4 M, 100 ml), with efficient cooling to maintain the temperature below 10°C. Aqueous H_2O_2 (30%, 30 ml) was then added dropwise (very exothermic!), maintaining the temperature below 20°C. The mixture was then extracted with hexane (3 × 100 ml), the combined extracts were washed with brine, dried (Na_2SO_4), and concentrated. Volatile by-products were removed by warming to 50°C at 0.2 Torr. Purification was achieved by flash chromatography on $AgNO_3$ impregnated silica gel (10%; 3.5 cm ID × 20 cm), eluting with 15% ether in hexane, followed by Kugelrohr distillation (bp ≃ 140°C/0.1 Torr), giving the triene (1.08 g, 58%) as a colorless oil.

MS, *m*/*z* (relative intensity) was 234 (M^+, 1.8), 178 (14.2), 108 (42.3), 95 (32.7), 93 (35.2), 80 (52.9), 79 (100), 67 (68.6), 55 (46.2), 43 (43.2). [^{1}H]NMR (360 MHz, $CDCl_3$) δ 5.35 (m, 6H; H-3, H-4, H-6, H-7, H-9, H-10), 2.79 (br t, 4H, J = 5.9 Hz; H-5, H-8), 2.05 (m, 4H; H-2, H-11), 1.45–1.15 (m, 10H; H-12 to H-16), 0.96 (t, 3H, J = 7.5 Hz; H-1), 0.87 (t, 3H, J = 6.8 Hz; H-17). IR (neat) λ_{max}: 3020 (m), 2965 (s), 2935 (s), 2860 (m) cm^{-1}. Final confirmation of the all-*cis* structure was obtained by comparison of the

olefin region of the [^{1}H]NMR spectrum with that of a reference sample of 3*Z*,6*Z*,9*Z*–18:H.

Preparation of C_{17} cis-Monoepoxydienes. The monoepoxides were prepared from 3*Z*,6*Z*,9*Z*–17:H as previously described for the homologous C_{18}–C_{22} compounds (Wong et al., 1985). Thus, metachloroperbenzoic acid (tech. grade, 85% pure; 199 mg, 0.98 mmol) was added to a solution of 3*Z*,6*Z*,9*Z*–17:H (230 mg, 0.98 mmol) in dry CH_2Cl_2 (15 ml) at −10°C. The mixture was warmed to 20°C over 3 hr, then washed with 5% aq. $NaHCO_3$ (2 × 10 ml), dried (Na_2SO_4), and concentrated. The crude product was flash chromatographed on silica gel (2 cm ID × 20 cm), eluting with 3% ether in pentane, giving a combined monoepoxides fraction (157 mg, 63%). A portion of this was then separated into the individual monoepoxides by HPLC (Partisil M9 10/50 ODS-3, 0.9 × 50 cm), eluting with 3% ether in hexane. The elution order was 6,7-epoxide < 9,10-epoxide < 3,4-epoxide. Purified compounds were >99% pure by capillary GC (DB-5, 30 m × .25 mm ID). Baseline separation of the three isomers was obtained with this GC column. The GC elution order was 6,7-epoxide < 3,4-epoxide < 9,10 epoxide.

The EI mass spectra and the NMR spectra (360 MHz) of the isolated positional isomers were as follows: (*Z*,*Z*)-6,9-*cis*-3,4-epoxy-heptadecadiene (6*Z*,9*Z*-*cis*-3,4-epoxy-17:H) *m/z* (relative intensity): 250 (M^+, 0.2), 232 (trace), 221 (0.5), 203 (1.1), 192 (2.9), 178 (11.8), 163 (0.8), 147 (1.8), 135 (2.9), 124 (4.1), 121 (5.6), 109 (6.5), 107 (11.9), 105 (6.2), 95 (16.4), 94 (19.4), 93 (39.0), 91 (26.0), 80 (85), 79 (100), 69 (18.9), 67 (47.6), 59 (22.9), 57 (26.4), 55 (41.8), 43 (14.1). Insects, Isolation, and Identification of Pheromone Components

Antennae used for electrophysiological work (EAD and EAG) were obtained from adult males captured in field traps baited with sex attractants. Female moths, used as a source of sex pheromone, were recovered from two portable UV light traps, one located 100 km northeast of Saskatoon, Saskatchewan, the other 10 km south. Abdominal tips (terminal 3–4 segments) of field-collected females were excised and extracted with hexane for 30 min. Two internal standards, heptadecane (17 : H) and tetracosane (24 : H), were added to the extracts which were concentrated under a stream of N_2 and fractionated by GC. DB-1701 or DB-5 capillary columns were used (30 m × 0.32 mm ID). Following splitless injection at 40°C for 30 sec, the oven temperature was raised to 90°C at 40°C/min and then programmed at 4°C/min to 225°C. A Hewlett Packard 5710 GC equipped with both a flame ionization detector and an electroantennographic detector (GC-EAD) (Arn et al., 1975) was employed for the simultaneous detection of pheromone compounds. The effluent from either a DB-1701 or a DB-5 capillary column (30 m × 0.32 mm ID) was split 7 : 3 in favor of the FID detector and signals from both detectors were fed to two Hewlett Packard model 3392A recording integrators. Male antennal responses to mixtures of synthetic reference compounds and internal standards were measured and recorded in a similar manner. The reference mixture used for most species contained 17 : H and 24 : H, plus C_{17}–C_{22} 3*Z*,6*Z*,9*Z*-trienes and their corresponding *cis*-3,4-, *cis*-6,7-, and *cis*-9,10-monoepoxydienes; 2–5 ng amounts of each compound were injected. Male antennal stimulation by synthetic compounds was also measured by EAG (Chisholm et al., 1975) using 1 μg of test sample applied to filter paper discs.

Chemical ionization (CI) mass spectra were obtained using a Finnigan 3300 gas chromatograph–mass spectrometer equipped with a DB-5 column (60 m × 0.32 mm ID). Hydrogen was used as the carrier gas and methane as reagent gas. For the detection of pheromone components, the instrument was operated in the multiple-ion detection (MID) mode where a few selected ions were repeatedly scanned; the lower limit of compound detection using this method on our instrument is ca. 50–100 pg. Routinely, a "blank" sample containing only internal standards (17 : H and 19 : H) was run first, followed by the insect extract containing the internal standards, and finally a reference standard which contained 1 ng each of the C_{17} triene and three monoepoxydienes plus 17 : H and

19:H was run for retention-time purposes. Ions used for MID included $(M-1)^+$ corresponding to each of the internal standards, and $(M + 1)^+$, $(M - 1)^+$, $[(M + 1) - 18]^+$ and $[(M - 1) - 18]^+$, where applicable, for the C_{17} triene and monoepoxydienes.

Field Trapping

Field trapping was carried out approximately 100 km northeast of Saskatoon, Saskatchewan in an area containing spruce, pine, birch, aspen, and a variety of herbaceous shrubs. Pherocon 1CP traps, baited with synthetic compounds impregnated in rubber septa, were hung from branches approximately 30 m apart. Traps were set out in a randomized block design and trap captures were recorded at least twice weekly. Summed trap captures were transformed $(X + 1)$, analyzed by an analysis of variance test, and significantly different means were separated by Duncan's (1955) multiple-range test. In all tables, values within a column followed by the same letter are not significantly different ($P > 0.05$).

RESULTS AND DISCUSSION

Following earlier observations (Wong et al., 1985) of captures of *S. signaria dispuncta* in traps baited with 3*Z*,6*Z*,9*Z*–18:H and mixtures of its *cis*-monoepoxydiene analogs, traps (3× replicated) were set out containing the C_{18} triene and each of its three positional *cis*-epoxide isomers (II–IV), separately and as binary mixtures. Only traps which contained 6*Z*,9*Z*-*cis*-3,4-epoxy-18:H as a component attracted significant numbers of males of this species, and those traps which contained both the triene hydrocarbon and *cis*-3,4-epoxide captured significantly more males than any other treatment. Mixtures of the triene and 3,4-epoxide were further tested (Table 1) and optimum attraction was observed in traps baited at 9:1 and 4:1 ratios (epoxide–triene). Attraction of moths by lures at these two ratios was very species specific; all but one of 293 specimens taken were *S. signaria dispuncta* males. The results of EAG and combined GC-EAD analyses using C_{18-22} 3,6,9-triene hydrocarbons, and their derived monoepoxides were consistent with the field data in that the greatest antennal stimulation was elicited in response to 6*Z*,9*Z*-*cis*-3,4-epoxy-18:H (4.9 mV, EAG, $N = 4$). The response to 3*Z*,6*Z*,9*Z*–18:H, while only 25% as intense as that from the *cis*-3,4-epoxide, was the highest response given by the series of triene hydrocarbons.

Combined GC-EAD analysis of a hexane abdominal tip extract obtained from a field-collected *S. signaria dispuncta* female (Figure 2) disclosed no male antennal stimulation at retention times corresponding to any of these C_{18} compounds but strong activity was clearly associated with an earlier-eluting component. By extrapolation of the retention times of reference standards towards

TABLE 1. EFFECT OF DIFFERENT RATIOS OF 3Z,6Z,9Z-18:H AND 6Z,9Z-*cis*-3,4-EPOXY-18:H ON LURE ATTRACTANCY FOR *S. signaria dispuncta* MALES

Attractant formulation (μg)	Total males captured[a]
6Z,9Z-*cis*-3,4-epoxy-18:H (500)	40cd
6Z,9Z-*cis*-3,4-epoxy-18:H (500) + 3Z,6Z,9Z-18:H (5)	69cd
6Z,9Z-*cis*-3,4-epoxy-18:H (450) + 3Z,6Z,9Z-18:H (50)	154a
6Z,9Z-*cis*-3,4-epoxy-18:H (400) + 3Z,6Z,9Z-18:H (100)	138ab
6Z,9Z-*cis*-3,4-epoxy-18:H (250) + 3Z,6Z,9Z-18:H (250)	85bc
6Z,9Z-*cis*-3,4-epoxy-18:H (100) + 3Z,6Z,9Z-18:H (400)	16ef
3Z,6Z,9Z-18:H (500)	0f

[a] Each treatment 3× replicated June 4–21, 1985. Values followed by the same letter are not significantly different ($P > 0.05$).

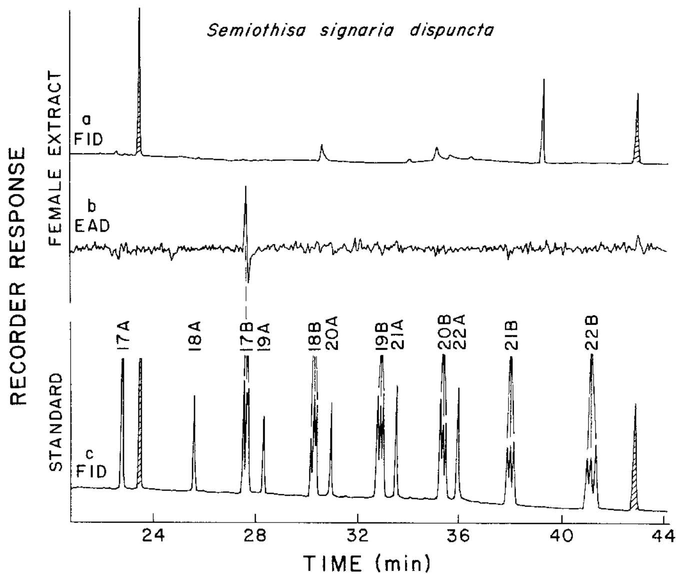

FIG. 2. Separately recorded flame ionization detector (FID) and electroantennographic detector (EAD) traces using antennae of male *S. signaria dispuncta*. Upper pair (a and b) are in response to an abdominal tip extract of a conspecific female containing internal standards, 17:H and 24:H (shaded). Lower trace (c) is the GC chromatogram of a mixture of C_{17-22} 3Z,6Z,9Z-triene hydrocarbons (designated by the letter A and preceded by the carbon chain length) and their monoepoxydiene analogs (designated by the letter B): the latter eluted from the DB-5 column in the order 6,7-, 3,4-, and 9,10-monoepoxydiene.

shorter times, the retention time of the antennal stimulatory component appeared to coincide with the postulated retention time of a 17-carbon monoepoxide. Following the synthesis of 3*Z*,6*Z*,9*Z*–17:H and the corresponding C_{17} *cis*-monoepoxydienes, it was found that the elution time of the EAD-active component corresponded exactly with that of 6*Z*,9*Z*-*cis*-3,4-epoxy-17:H. GC-MS analysis of an abdominal tip extract derived from five field-collected females provided data which supported the presence of 3*Z*,6*Z*,9*Z*–17:H; ions corresponding to $(M - 1)^+$ and $(M + 1)^+$ of this triene were simultaneously detected in the column eluate at the elution time of synthetic 3*Z*,6*Z*,9*Z*–17:H. By comparison of the intensity of the ions derived from a solution of known concentration of synthetic triene hydrocarbon with those from the female component, the amount present in the female extract was estimated to be ca. 1 ng/female. The amount of 6*Z*,9*Z*-*cis*-3,4-epoxy-17:H present in the extract was below the limits of instrument detection; we were not able to detect ions in the correct ratios and at the appropriate retention time for this component.

The attractancy of lures containing 3*Z*,6*Z*,9*Z*–17:H and 6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (Table 2) were compared with the optimum C_{18} attractant blend which had been found previously. Here also, 9:1 epoxide–triene blends resulted in the greatest number of target males captured, and these blends were significantly more attractive than the corresponding C_{18} mixture. However, the data clearly illustrate the ability of the C_{18} lures to mimic the activity of the C_{17} pheromone components. All lures (Table 2), except those containing 3*Z*,6*Z*,9*Z*–17:H alone, attracted ony *S. signaria dispuncta* males; traps baited with 3*Z*,6*Z*,9*Z*–17:H alone caught males of *S. bicolorata*. Traps (3× replicated) baited with 100-, 300-, and 1000-μg amounts of C_{17} epoxide–triene blends (9:1)

TABLE 2. ATTRACTION OF *S. signaria dispuncta* MALES TO BLENDS CONTAINING C_{17} AND C_{18} TRIENES AND *cis*-3,4-EPOXYDIENES

Attractant formulation (μg)	Total males captured[a]
6*Z*,9*Z*-*cis*-3,4-epoxy-18:H (450) + 3*Z*,6*Z*,9*Z*–17:H (50)	76b
6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (500)	58b
6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (500) + 3*Z*,6*Z*,9*Z*–17:H (5)	122ab

6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (400) + 3*Z*,6*Z*,9*Z*–17:H (100)	143ab
6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (250) + 3*Z*,6*Z*,9*Z*–17:H (250)	122ab
6*Z*,9*Z*-*cis*-3,4-epoxy-17:H (100) + 3*Z*,6*Z*,9*Z*–17:H (400)	69b
3*Z*,6*Z*,9*Z*–17:H (500)	1c

[a]Each treatment 3× replicated from June 24 to July 10, 1985. Values followed by common letters are not different ($P > 0.05$).

captured 34, 74, and 150 *S. signaria dispuncta* males, respectively, from July 12 to 26, 1985; captures at the highest dose, although significantly different from the lowest dose, were not different from those baited with 300 μg ($P > 0.05$).

Traps (2× replicated) baited with 3*Z*,6*Z*,9*Z*–17:H and its three structurally related *cis*-monoepoxydiene analogs (II–IV), as single lure components and in mixtures (Table 3), captured males of three species of *Semiothisa* in addition to *S. signaria dispuncta*. *S. bicolorata* males were attracted by several lure formulations and, although the greatest captures occurred in traps baited with 10:1 mixtures of the triene and 6,7-monoepoxydiene, the number caught was not different ($P > 0.05$) from captures by the triene alone. In a 3×-replicated test which followed (June 28–July 15 1985), the number of *S. bicolorata* males taken in traps baited with 500 μg 3*Z*,6*Z*,9*Z*–17:H alone (85 males caught) and with binary lures containing 500 μg of triene plus 10% additions of the *cis*-6,7-monoepoxydiene (94 males) and *cis*-9,10-monoepoxydiene (39 males) were not significantly different ($P > 0.05$). However, 10% additions of the *cis*-3,4-epoxide resulted in significantly reduced trap captures (three males). Both the EAG and combined GC-EAD (Figure 3) analyses using C_{17-22} synthetic 3*Z*,6*Z*,9*Z*-trienes and corresponding monoepoxydienes supported the field data; the greatest antennal stimulation was elicited by 3*Z*,6*Z*,9*Z*–17:H with lower responses given, in decreasing order, by its *cis*-6,7-, *cis*-9,10-, and *cis*-3,4-monoepoxides. GC-EAD analyses of tip extracts from two field-collected *S. bicolorata* females provided the data which supported the triene hydrocarbon as a pheromone component. Analyzed separately, a single male antennal stimulatory component was found in both extracts which eluted from the capillary column at the same retention time as 3*Z*,6*Z*,9*Z*–17:H (Figure 3). Thus, the combined analytical and trapping data provide fairly conclusive proof that 3*Z*,6*Z*,9*Z*–17:H is a pheromone component for *S. bicolorata*, and there is no evidence of any other components.

Males of a third species, *S. ulsterata*, were captured (Table 3) in traps containing 3*Z*,9*Z*-*cis*-6,7-epoxy-17:H alone or as the major lure component. In a separate field test (3× replicated), traps baited with 500 μg of 3*Z*,9*Z*-*cis*-6,7-epoxy-17:H captured 56 *S. ulsterata* males between June 28 and July 12 1985; there was no significant difference ($P > 0.05$) in the number of males taken in these traps and in those which also contained 5 μg (35 males taken) and 50 μg of 3*Z*,6*Z*,9*Z*–17:H (51 males). Species specificity was again high; of the 143 males captured in the nine-trap experiment, 142 were *S. ulsterata*. When assayed by EAG and GC-EAD using synthetic compounds, *S. ulsterata* males gave the largest response to synthetic 3*Z*,9*Z*-*cis*-6,7-epoxy-17:H and lower, but well above background, responses to the C_{18} and C_{19} 6,7-epoxydiene homologs and to 3*Z*,6*Z*,9*Z*–17:H (Figure 4). Additional data in support of 3*Z*,9*Z*-*cis*-6,7-epoxy-17:H as a pheromone component was obtained by GC-

TABLE 3. CAPTURE OF FOUR SPECIES OF *Semiothisa* IN TRAPS BAITED WITH 3Z,6Z,9Z-17:H AND ITS MONOEPOXYDIENE ANALOGS[a]

Lure composition (μg)	Total number of males caught

3Z,6Z-*cis*-9,10-epoxy-17:H (500)	0	0	0	0

[a]Each treatment 2× replicated from June 24 to August 26, 1985.

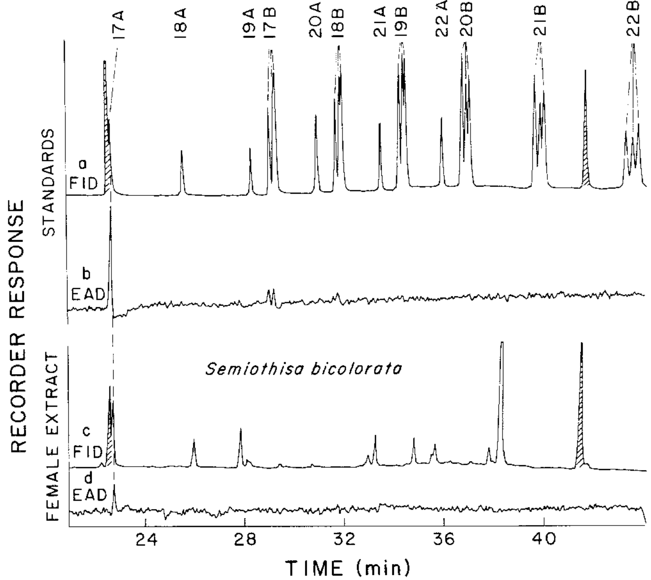

FIG. 3. FID and EAD (antennae of male *S. bicolorata*) traces: upper pair (a and b) are in response to C_{17-22} triene hydrocarbons (A), monoepoxydiene analogs (B) and two internal standards (shaded); lower pair (c and d) are in response to an abdominal tip extract (1 FE) from a conspecific female. A DB-1701 column was used; epoxides eluted in the order of 6,7-, 3,4-, and 9,10-monoepoxydiene.

EAD analyses of abdominal tip extracts from two field-collected females. These extracts were chromatographed separately on DB-1701 and DB-5 columns. In each case two antennal responses were observed, the major response occurring at the retention time of 3*Z*,9*Z*-*cis*-6,7-epoxy-17 : H and a minor response at a retention time corresponding to 3*Z*,9*Z*-*cis*-6,7-epoxy-18 : H. On the basis of the GC-EAD data, the sex pheromone of *S. ulsterata* appears to be comprised of at least two 6,7-epoxydiene components. The flight of this species had ended before mixtures of the C_{17} and C_{18} 6,7-epoxides could be properly tested.

Only a few males of *S. delectata* were captured in the survey traps (Table 3), but they also were taken in traps containing 3*Z*,6*Z*,9*Z*–17 : H, 3*Z*,9*Z*-*cis*-6,7-epoxy-17 : H, or mixtures of the two. Males of this species had also been captured earlier in the season in traps which had been set out to test C_{18-22} 6*S*,7*R*- and 6*R*,7*S*-enantiomers of 3*Z*,9*Z*-*cis*-6,7-epoxydiene hydrocarbons as lepidopteran sex attractants (Underhill et al., 1985). Of 20 *S. delectata* taken, 3*Z*,9*Z*,6*S*,7*R*-epoxy-18 : H was a lure component common to the capture of 19 and 3*Z*,6*Z*,9*Z*–18 : H was common to the capture of 15 of these. There was no indication that the 6*R*,7*S*-enantiomer was biologically active either as an at-

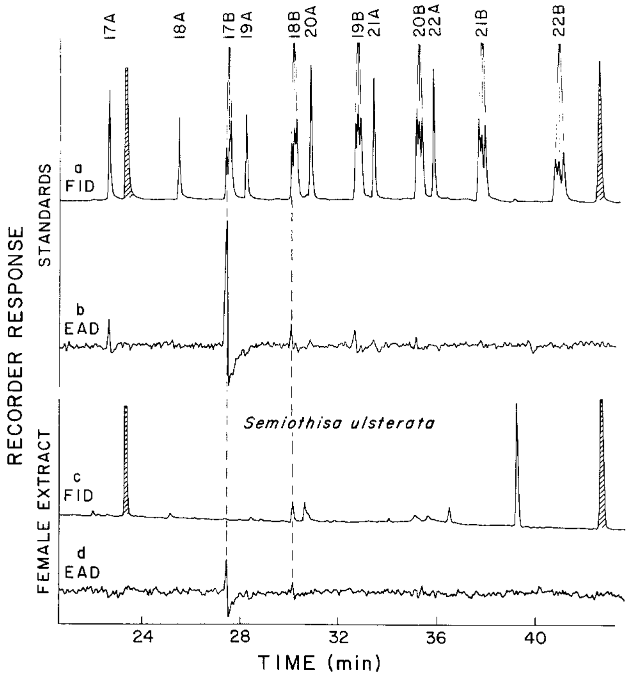

FIG. 4. FID and EAD (antennae of male *S. ulsterata*) traces; upper pair (a and b) are in response to C_{17-22} triene hydrocarbons (A), monoepoxydiene hydrocarbon analogs (B), and two internal standards (shaded); lower pair (c and d) are in response to an abdominal tip extract (1 FE) from a conspecific female. A DB-5 column was used; epoxides eluted in the order of 6,7-, 3,4-, and 9,10-monoepoxydiene.

tractant or inhibitor. At present, we have not been successful in obtaining *S. delectata* females to investigate their pheromone chemistry.

Two *S. neptaria* females were field collected and an abdominal tip extract was prepared. Lacking a conspecific male for GC-EAD analysis, the extract was submitted for CI-MS analysis by the MID technique. The presence of 3*Z*,6*Z*,9*Z*-17 : H in this extract was indicated by the appearance of ions at *m/z* 233 and 235, corresponding to $(M - 1)^+$, and $(M + 1)^+$. Both ions were present in the same ratio and occurred simultaneously at the same retention time as was found using a reference standard of this triene hydrocarbon. No evidence was obtained for the presence of the corresponding monoepoxydienes.

The foregoing field-trapping and analytical data, showing 3*Z*,6*Z*,9*Z*-17 : H and two of its structurally related monoepoxydiene hydrocarbons as sex attractants of four species of *Semiothisa*, has extended the range of geometrid sex attractants as outlined in Figure 1 to include compounds with chain lengths of 17–21 carbons. The occurrence of 3*Z*,6*Z*,9*Z*-17 : H in nature appears to be rare

and, to our knowledge, it has been only tentatively identified as a component of tomato (Garnero and Joulain, 1981). Neither 6*Z*,9*Z*-*cis*-3,4-epoxy-17 : H nor 3*Z*,9*Z*-*cis*-6,7-epoxy-17 : H have been previously reported. At the present time enantiomers of each of the three positional epoxide isomers are being synthesized in this laboratory for future field screening tests.

Acknowledgments—We thank the staff of the Biosystematic Research Institute, Agriculture Canada, for insect identifications. We also thank Lawrence Hogge for mass spectral analyses, and Leah Richardson and Ian Warkentin for assistance with field trapping.

PHEROMONAL BASIS FOR AGGREGATION BEHAVIOR OF PARASITOIDS OF THE GYPSY MOTH: *Brachymeria intermedia* (Nees) and *Brachymeria lasus* (Walker) (Hymenoptera: Chalcididae)

M.A. MOHAMED and H.C. COPPEL

(Received August 11, 1986; accepted August 14, 1986)

Abstract—The parasitoids *B. intermedia* and *B. lasus* aggregate at sites previously frequented. Extracts from filter paper conditioned by aggregated parasitoids were chromatographed (adsorption column and gas-liquid chromatography) and bioassayed. An active component that elicited aggregation response for *B. intermedia* was isolated and identified as 3-hexanone. This molecule was found in trace quantities (5–10 ng/female or male) on filter paper conditioned by either male, female or a combination of the sexes.

Key Words—Aggregation, *Brachymeria*, Hymenoptera, Chalcididae, 3-hexanone, parasitoid, pheromone.

INTRODUCTION

Intraspecific aggregations in animals are well-documented phenomena, with many known examples in Insecta. Massive aggregations of individuals have been observed in butterflies and moths (Brower et al., 1977; Capinera, 1979), aphids (Hayamizu, 1984), beetles (Crins, 1980; Faustini et al., 1982; Harris and Todd, 1980; Lee, 1980), flies (Atkinson and Shorrocks, 1984), bees (Hefetz et al., 1979), ants (Cavill et al., 1979), locusts (Gillet, 1973, 1975), and wasps (Evans and Gillaspy, 1984). The effects of such behavior include mating, host attack, defense, and thermoregulation. To orchestrate such aggregations, a system of communication, usually involving a chemical mode, has evolved to synchronize it. In one of the most studied groups, the scolytid beetles, this is achieved by pheromones. For instance, 4,8-dimethyldecanal (Suzuki and Mori, 1983), 4-methyl-3-heptanol (Gore et al., 1977; Blight et al., 1979), the tricyclic molecule, lineatin (Borden et al., 1979), and 6-methyl-5-hepten-2-ol

0098-0331/87/0600-1385$05.00/0 © 1987 Plenum Publishing Corporation

(Byrne et al., 1974) are all aggregation pheromones. Beyond this group, little is known of either the function or basis of aggregation behavior.

Overwintering aggregations of the parasitoid *Brachymeria intermedia* under bark (Waldvogel and Brown, 1978) and subsequent laboratory studies (Simser and Coppel, 1980) on *Brachymeria lasus* provide the first possibility of an aggregation pheromone in parasitoids. In this paper, evidence is provided for the existence of aggregation pheromones in both species. This is accomplished by elucidation of techniques for sequestering the pheromone, the sex(es) producing and responding to it, and some aspects of the chemistry.

METHODS AND MATERIALS

The parasitoids were reared from previously parasitized cocooned pupae of the greater wax moth, *Galleria mellonella* (L.). Parasitized pupae were reared singly in 4-ml shell vials sealed with perforated caps. Freshly eclosed parasitoids were sexed, and the species confirmed. Each sex, or a combination of the two, were transferred to large screened cages (38 × 22 × 22 cm) one side of which was made of a Plexiglas sliding door. Filter paper (Whatman No. 40) -lined vials (5.5 × 2.3 cm) were placed in each cage. Parasitoids aggregated in the vials during scotophase. This provided filter paper conditioned by either, or a combination of, the sexes. Colony sizes of 200–300 parasitoids per cage each with 10 filter paper-lined vials were maintained all year. The parasitoids were fed water and honey daily and incubated at 28.5°C, 55–65% relative humidity, and a light–dark photoperiod of 16:8.

The filter papers were replaced every two months for a three-year period, utilizing approximately 4000 parasitoids of each sex and sex combination for each species. Filter paper replacement was based on the longevity of parasitoids under our laboratory conditions and the fact that these parasitoids took at least four to five weeks to aggregate and condition it. Crude extracts were obtained by placing the conditioned filter papers in 250-ml Erlenmeyer flasks and shaking them sequentially with hexane, hexane–ethyl acetate (50:50 mix), and methanol, each for 8 hr. Pooled extracts were filtered over sodium sulfate and concentrated to a few milliliters with a Buchi evaporator.

Bioassays were conducted with conditioned filter papers under the regime mentioned above. Clean vials were lined with conditioned filter paper and placed in wooden boxes (15 × 15 × 10 cm). Conditioned filter paper from *B. intermedia* colonies of virgin females, males, or males plus females, were each tested against 25 of each sex, or a combination thereof, of the same species. Interspecific assays were also conducted with *B. lasus* adults and *B. intermedia*-conditioned filter papers. Each bioassay was replicated six times. Similar intraspecific and interspecific tests were conducted with *B. lasus*-conditioned filter paper and *B. intermedia* adults.

Attempts to isolate an active aggregation component(s) were made through bioassays of crude, absorption column chromatographic, and gas-liquid chromatographic fractions (GLC). Because of the large number of replicates involved, a different bioassay technique was developed for testing for the aggregation pheromone. It consisted of pipetting the test material or solvent (control) into a 4-ml glass shell vial lined with filter paper and with a disc (1.27 cm) at the base. Two vials thus treated, experimental and control, were placed in a glass Petri plate (9 cm diam.) and held in place with modeling clay. Ten parasitoids (virgin females or a combination of the sexes) aged 3-7 days were added to the plate. The plate was covered and incubated about 1 hr prior to the onset of aggregation, which usually took place 8-9 hr after photophase started. The vials were checked 4-5 hr later for the numbers of parasitoids aggregating. Incubator conditions were the same as those previously mentioned. Each source of pheromone (crude, absorption column, and gas chromatographic) was bioassayed for $N = 12$ replicates.

Percentage aggregation was calculated from a ratio of numbers in the experimental vial (or control) over the sum of parasitoids aggregating in both vials. Data were analyzed for normal distribution by normal probability plots. Significant differences in means were culled using Student's t test.

Crude samples were chromatographed on silica gel (1.1 g), in a glass column (11.5 × 1 cm ID), using an elution series of: hexane, 0.1%, 1%, 10%, 20%, 40% ether-hexane, with fractions taken at 3-ml intervals. The active fraction was further fractionated on a 1.8 m × 2 mm ID, 10% OV-101 on 80/100 Gas Chrom Q, with helium flow rate of 30 ml/min. The temperature program used was: 40°C (10 min), 3°C/min to 65°C (10 min), and then 20°C/min to 245°C, with injection port at 40°C. Further analyses of samples were accomplished with a 15 m × 0.32 mm ID, 1-μm film thickness, DB-5 capillary column (J&W). Conditions of use of this column were: helium at 1.5 ml/min, and a temperature program of 45°C (10 min), 15°C/min to 285°C (hold), with an injection port temperature of 95°C.

GLC was conducted with a Spectra Physics 7100 equipped with flame ionization detectors. The gas chromatograph was fitted with a splitter modified from Brownlee and Silverstein (1968). Components from the packed column were shunted via the splitter to a glass capillary tubing. The tubing was encased in finely crushed Dry Ice held in place by a glass cylinder tapered at one end. The capillary tubing and tapered glass cylinder were held in place with Teflon tape. Condensed effluents within the tubing were desorbed with several washes of 500 ml ether in a 4-ml vial using a 10-ml Cornwall glass syringe. Samples were concentrated under argon and then bioassayed or further analyzed. The latter included monitoring for purification by capillary chromatography and mass spectrometry of active isolates. Samples were subject to electron impact (70 eV) and chemical ionization with isobutane using a Finnigan 4510 GC-MS.

RESULTS

Intraspecific bioassays showed significantly different responses for any combination of conditioned filter paper and sex of either species versus controls (Tables 1 and 2). A somewhat similar result was obtained in the response of *B. lasus* females or males to *B. intermedia*-conditioned filter paper, with the one exception being to the female and male source in interspecific assays. *B. intermedia* males or females did not respond to conditioned filter papers of *B. lasus*.

Crude extracts of conditioned filter papers of either species did not elicit aggregation response from conspecifics. However, column chromatography with silica gel did allow the isolation of an active fraction (Table 3) at 40% ether–hexane for *B. intermedia*. No other fraction elicited this response. Several areas and components of the active fraction were further fractionated by preparative GLC on a 10% OV-101 column. Only the volatile region elicited any aggregation activity and, subsequently, a component at 4.4 min. Analyses by capillary chromatography from our three sources of extracts showed the presence of this component at 2.6 min in trace quantities (5–10 ng/female and/or male, approximately).

Electron impact GC-MS of of the active area and single-component isolates gave mass spectra of a compound of molecular weight of 100, which was confirmed by chemical ionization (Figure 1). The structure that fits this spectrum is 3-hexanone, which is consistent with the reported principal fragments of this molecule (Stenhagen et al., 1974). Additional rationale comes from the ion at m/z 72 $(CH_2{=}COH\ C_2H_5)^+$ and loss of $CH_2{=}CH_2$ by the McLafferty rearrangement. This is compatible only with a linear structure, and, by the same token, excludes isomers resulting from α-substitution (e.g., 4-methyl-3-pentanone). The intense peak at m/e 71 rules out another linear isomer, 2-hexanone. Our unknown spectrum, compared to that of another isomer, 2,3-epoxy-4-methyl-pentane, was incompatible. A combination of bioassays (Table 3), congruence of an authentic sample with the corresponding active peak by capillary chromatography, and the mass spectrum of 3-hexanone which was identical to our unknown, established this molecule as the aggregation pheromone of *B. intermedia*.

DISCUSSION

The basis for the aggregation behavior of the parasitoid *B. intermedia* is pheromonal. Conditioned filter paper and a chromatographic fraction elicited aggregation response consistently different from either controls or other fractions. The facts that 3-hexanone was isolated and identified from extracts of conditioned filter paper and that a positive aggregation response to it was obtained allow us to conclude that this is the major component in the aggregation

TABLE I. INTRASPECIFIC AND INTERSPECIFIC BIOASSAYS OF *B. intermedia*-CONDITIONED FILTER PAPER FOR AGGREGATION RESPONSE

Source of conditioned filter paper: *B. intermedia*	Percent aggregated ($X \pm$ SE)[a]					
	Female		Male		Male and female

Female and male	NR	NR	NR	NR	NR	NR

[a] Each bioassay (combination of filter paper source and test parasitoids) was conducted with $N = 6$ replicates, and 25 parasitoids/replicate. Significant differences between experimental (exp.) and control are indicated by different letters and vice versa. The Student's t test was used at $P < 0.025$, $df = 10$.

[b] Less than 10% of parasitoids aggregated and is indicated by NR (no response).

TABLE 3. LABORATORY BIOASSAYS FOR AGGREGATION ACTIVITY OF *B. intermedia* TO COLUMN AND GAS-LIQUID CHROMATOGRAPHIC FRACTIONS, 2-HEXANONE, AND 3-HEXANONE[a]

Test material[b]	Aggregation (%)	
	Exp.	Control
Column chromatographic fraction		
1	81.7[a]	18.2 ± 4.9[b]
2	33.7[a]	66.2 ± 5.4[b]
GLC fraction	72.3[a]	27.6 ± 2.9[b]
3-hexanone	81.3[a]	18.7 ± 3.1[b]
2-hexanone	19.7[a]	80.2 ± 3.9[b]

[a] Assays were conducted with concentrations of 5–10 ng 3-hexanone, N = 12 replicates with 10 females or male and female parasitoids per bioassay. Significant differences are indicated by different letters using Student's t test at $P < 0.001$, $df = 22$.

[b] Column chromatographic fraction 1, indicates a 40% ether–hexane fraction; fraction 2 represents other fractions from adsorption column chromatography; and GLC fraction is a component taken at 4.4 min from a 10% OV-101 column.

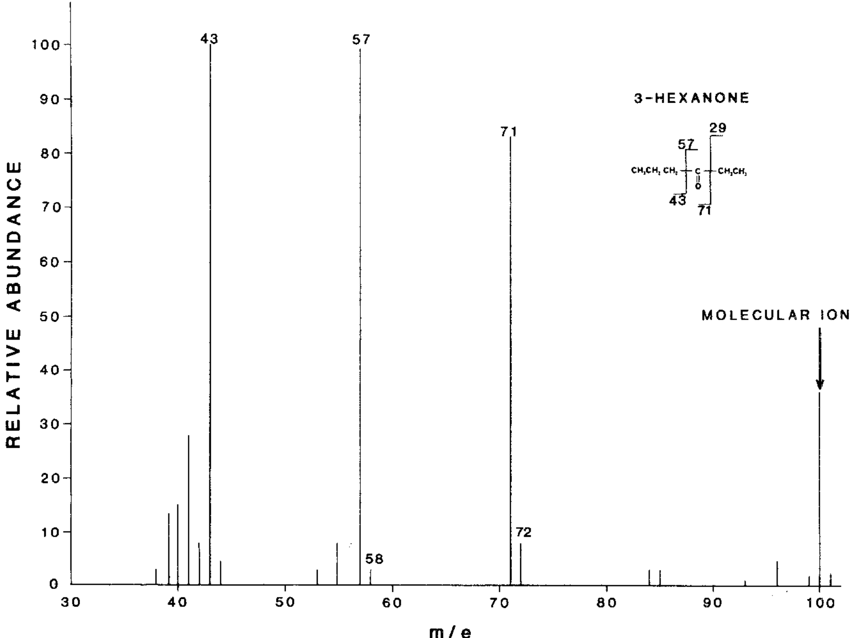

FIG. 1. Mass spectrum of the aggregation pheromone (3-hexanone) isolated from female and male plus female-conditioned filter paper of *B. intermedia*.

pheromone of *B. intermedia*. Another component suggests itself from the fact that, although *B. lasus* displays an interspecific response, it is not responsive to 3-hexanone.

The volatility of 3-hexanone (bp = 125°C) seems consistent with some aspects of the biology of *B. intermedia*. This species is polyphagous and capable of widespread dispersal, as evidenced by both sexes being strong fliers. In order to assemble at a particular site, a volatile pheromone would seem to be the best strategy. The evolution of an aggregation pheromone could have resulted from an increase in reproductive success by increasing the probability of mate location, as well as offering the possibility of mate choice.

Abstract—The male red pine sawfly *Neodiprion nanulus nanulus* Schedl responds mainly to the (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-yl acetate (2*S*,3*S*,7*S*-A) in the field. No other isomer is as effective by itself or synergizes 2*S*,3*S*,7*S*-A in this species. For *Neodiprion sertifer* (Geoffroy), however, we confirmed our earlier report that males responded significantly to a 5:0.003 mixture of 2*S*,3*S*,7*S*-A and either 2*S*,3*R*,7*R*-A or 2*S*,3*R*,7*R*/*S*-A. The 2*S*,3*S*,7*S*-A isomer was separated from 2*S*,3*R*,7*R*-A by capillary gas-liquid chromatographic (GLC) analysis using Carbowax 20 M and DB-5 columns. The latter column also separated 2*S*,3*S*,7*S*-A from 2*S*,3*R*,7*S*-A. Only 2*S*,3*S*,7*S*-A was found in the natural pheromones of *N. n. nanulus* and *N. sertifer* by GLC analysis.

Key Words—Sawflies, *Neodiprion nanulus, Neodiprion* sertifier, Hymenoptera, Diprionidae, pheromones, chiral, chirality, 3,7-dimethylpentadecan-2-yl acetate.

INTRODUCTION

The native red pine sawfly, *Neodiprion nanulus nanulus* Schedl is an important defoliator of red pine (*Pinus resinosa* Ait) and jack pine (*P. banksiana* Lamb.)

[2]Present address: Department of Plant Science, University of Ife, Ile-Ife, Nigeria.

in the Lake States. Red pine is the predominant conifer being planted in this region. One complete defoliation of red pine by sawflies caused a 21% reduction in height growth and two successive defoliations reduced height growth as much as 64% (Kapler and Benjamin, 1960). Such defoliations are uncommon in the Michigan study area.

Monitoring tools for this pest at present consist of both scouting for the larval stages and estimating the injury levels. Jewett et al. (1976) isolated and identified diprionid sawfly sex pheromone as 3,7-dimethylpentadecan-2-ol (diprionol), the acetate or propionate ester of which was active in attracting males in the field. Kraemer et al. (1983) reported that the optical isomers (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-yl acetate (2*S*,3*S*,7*S*-A) and propionate (2*S*,3*S*,7*S*-P) as well as (2*S*,3*S*,7*R*)-3,7-dimethylpentadecan-2-yl acetate (2*S*,3*S*,7*R*-A) were highly active, but that 2*S*,3*S*,7*S*-A was significantly superior to others at lower concentrations. The 2*S*,3*S*,7*S*-A thus appeared to be the major pheromone component for *N. n. nanulus* as well as for *N. pinetum* (Norton) (Kraemer et al., 1979), and *N. lecontei* (Fitch) (Matsumura et al., 1979; Kraemer et al., 1981). However, in another sympatric species, *N. sertifer* (Geoffrey), where 2*S*,3*S*,7*S*-A is also the major pheromone component, its combination with small amount of (2*S*,3*R*,7*R*)-3,7-dimethylpentadecan-2-yl acetate (2*S*,3*R*,7*R*-A) greatly increases its field effectiveness (Kikukawa et al., 1983). Here we report results of field studies to examine whether such interaction of optical isomers also occurs with *N. n. nanulus*. We also report field confirmation of our earlier studies on *N. sertifer* and GLC analyses of the natural pheromones of both species.

METHODS AND MATERIALS

Field tests. The red pine sawfly trapping was carried out in Vogel Center, Sec. 32, Aetna Loop, Misaukee County, Michigan. Some trapping was also done at sec. 7, Manistee River, Garfield Township, Kalkaska County, and at Sec. 36, Higgins Lake, Old I-27, Beaver Township in Roscommon County, Michigan. The main experimental area, Vogel Center, is about 1.2 km^2 and is surrounded by farmlands such that within a 13-km radius only scattered plots of red pine could be found. Larval colonies of *N. n. nanulus* were collected from all sites in late spring and early summer of 1981, 1982, and 1983.

All field trapping of *N. sertifer* was at Rose Lake Wildlife Research Station, Sec. 33, Bath, and at Arboretum, Lansing, Ingham County, Michigan. Larval colonies were collected at Rose Lake from scotch pine, *Pinus sylvestris* L., in an area of 8 km^2.

Pherocon II traps were hung at a height of 1.5–2.5 m and spaced no closer than 15 m within and between trap rows. Weekly or biweekly observations were made, at which time the traps were rotated randomly within and between rows.

Pheromone components were prepared in 1 ml hexane and sealed in glass ampules. At the test site, the contents were dispensed onto a 4.0 to 5.0-cm dental cotton roll which was then positioned at the center on one side inside the Pherocon trap. A randomized block experimental design was used with at least three replicates of each treatment. Data were analyzed by analysis of variance and the means compared by Duncan's multiple-range test at the 5% level.

Laboratory Rearing of Larvae and Extraction of Natural Pheromone. Female sawflies from which pheromone was extracted were reared from larvae and cocoons collected at the test sites. Larvae were reared outdoors under shade near the greenhouse. The larvae were fed fresh foliage as necessary. Mature larvae formed cocoons among the grass in the cage. These cocoons, as well as the field-collected cocoons, were sexed according to size, the large cocoons being females. Cocoons were placed singly in gelatin capsules until adults emerged. Virgin females were placed in 3 × 5-cm vials contains strips of Teflon to simulate pine needles and left for a few days before being frozen. The natural pheromone was extracted as described for *N. sertifer* (Kikukawa et al., 1983).

Synthetic Pheromones. Two groups of chemists from Japan synthesized and supplied us with the optical isomers used. Mori's group synthesized the 2*S*,3*S*,7*S*-A and the corresponding alcohol (Mori et al. 1978). These materials contained some unknown percent of optical impurities, but are believed to have been less than 1%, the approximate limit of detection by PMR assay. Tai's group synthesized the 2*S*,3*R*,7*R*/*S*-A with a known 5% erythro contamination (Tai et al., 1978). The same group later synthesized 2*S*,3*S*,7*S*-A (unpublished) and 2*S*,3*R*,7*R*-A and 2*S*,3*R*,7*R*-AG (Kikukawa et al., 1982). In this instance the 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A contained less than 1% optical impurities but 2*S*,3*R*,7*R*-AG synthesized through a Grignard reaction was greater than 99.9% optically pure.

Preparative GLC Fraction Collection. A Varian 1700 preparative gas chromatography fitted with stainless steel column, 7.2 m and 3 mm ID, packed with 10% Carbowax 20 M on 80–100 mesh Chrom Q was used for fraction collection of acetate of diprionol. A 9:1 postcolumn splitter was used which directed 90% of the injected material for collection. The retention time of natural pheromone was determined first by injecting synthetic standard and then by coinjecting the standard with natural pheromone at column temperatures of 200° and 220°C.

Capillary GLC Analysis. A Varian 3700 capillary GLC equipped with two FID was used. Synthetic standards containing 1 mg/ml of 2*S*,2*S*,7*S*-A, and mixtures at ratios 1:2, 1:1, 3:2, and 2:1 of 2*S*,3*S*,7*S*A-/2*S*,3*R*,7*R*-A and 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*S*-A were used. Natural extracts derived from the above purification were used. Concentration of natural pheromone was in the order of 5000 female equivalents (FE)/ml. Two fused silica capillary columns, one Carbowax 20 M, 30 m × 0.25 mm ID, and the other DB-5, 40 m × 0.25 mm ID (J. & W. Scientific Co., Folsom, California), were capable of resolving threo

diastereomers from erythro counterparts. Runs were made isothermally at 180°C and temperature programmed from 130 to 190°C at 4°C/min, with initial hold at 0 min, and final hold at 18 min giving a total analysis time for each injection of 32 min.

RESULTS

Field Tests. The 2*S*,3*S*,7*S*-A isomer alone was more active than any combinations of 2*S*,3*R*,7*R*/*S*-A or 2*S*,3*R*,7*R*-A as an attractant for *N. nanulus* (Table 1). At lower concentrations, 2*S*,3*R*,7*R*/*S*-A and 2*S*,3*R*,7*R*-A appeared to increase the effectiveness of the 2*S*,3*S*,7*S*-A isomer, but the increase was not statistically significant (Table 2). One possibility for this lack of synergistic effect could be that the effectiveness of the synergist may not be expressed at high sawfly populations as this particular test caught many males. Lower concentrations of 2*S*,3*S*,7*S*-A were used in 1983 to attract fewer males and thus bring on clear differences, if any, among the treatments. Additional data (Table 3) indicate that the traps baited with 2*S*,3*S*,7*S*-A alone attracted more males than did mixtures. Such results support our hypothesis that 2*S*,3*S*,7*S*-A alone is the major pheromone component of *N. n. nanulus*. These data also agree with those of Kraemer et al. (1983). However, since they found 2*S*,3*S*,7*R*/*S*-A as active as 2*S*,3*S*,7*S*-A, we have compared the two isomers in a side-by-side test in the field. With a total catch of 640 males with 2*S*,3*S*,7*S*-A-baited traps compared to 253 males with 2*S*,3*S*,7*R*/*S*-A-baited traps, we thus, proved the

(with medium populations), 14.5 ± 10.9 SD/branch; and Vogel Center (with high populations), 28.05 ± 8.7 SD/branch] were chosen to allow comparison of the field effectiveness of the synthetic and natural pheromones. At all locations, trap catches increased with increasing concentration of the synthetic compound (Table 4). This agrees with the suggestion that an attractant with the correct optical configuration shows a dose-related response (Cardé et al., 1977). Traps baited with the natural pheromone, however, caught no adults at Manistee or Roscommon, apparently due to the low population numbers. No valid comparison between the synthetic and natural pheromone can be made with the data in Table 4 because the concentration of the synthetic was not low enough.

The effectiveness of the synthetic was tested side by side with the natural pheromone and the results are shown in Table 5. Based on capillary GLC analysis, one virgin female contains about 2 ng pheromone stored as alcohol. The response to the natural pheromone was not dose-related. Catches were generally lower at higher concentrations. There is the possibility that the extracts may contain impurities which, at the higher concentration, were inhibitory. In 1982, all the natural preparations were further purified after acetylation by passing them through one extra TLC system-preparative TLC $HF_{254+366}$ and developing

with 20% ether in hexane as the mobile phase (Kikukawa et al., 1983). The synthetic 2*S*,3*S*,7*S*-A (Mori et al., 1978) was purified through a charcoal–celite column. The 2*S*,3*S*,7*S*-A prepared through different synthetic routes by Kikukawa et al. (1982) was also purified. The 2*S*,3*S*,7*S*-A from both sources indicate a threshold at 0.003 μg (Table 6). Both the synthetic and natural pheromones were comparable.

To determine indirectly the form in which natural pheromone is stored in the females, the ester and alcohol fractions of *N. n. nanulus* females were first purified by TLC and the latter fraction was acetylated and then tested for relative activity on the field (Table 7). To test whether unesterified diprionol itself might have any effect on effectiveness of synthetic pheromone, varying amounts of 2*S*,3*S*,7*S*-alcohol was added to a fixed amount of 2*S*,3*S*,7*S*-A isomer. It is clear from these data that the alcohol is inhibitory at least at higher doses (Table 8). The responses of males of *N. n. nanulus* and *N. sertifer* to different com-

binations of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-AG were different from each other (Table 9). As observed earlier (Table 2), the 2*S*,3*R*,7*R*-A isomer was neither synergistic nor inhibitory to the field effectiveness of the 2*S*,3*S*,7*S*-A isomer against *N. n. nanulus*. Males of *N. sertifer*, however, seemed to prefer the combination of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A between the ratios of 5:0.001 and 5:0.01, although the figures were not statistically significant (Table 10).

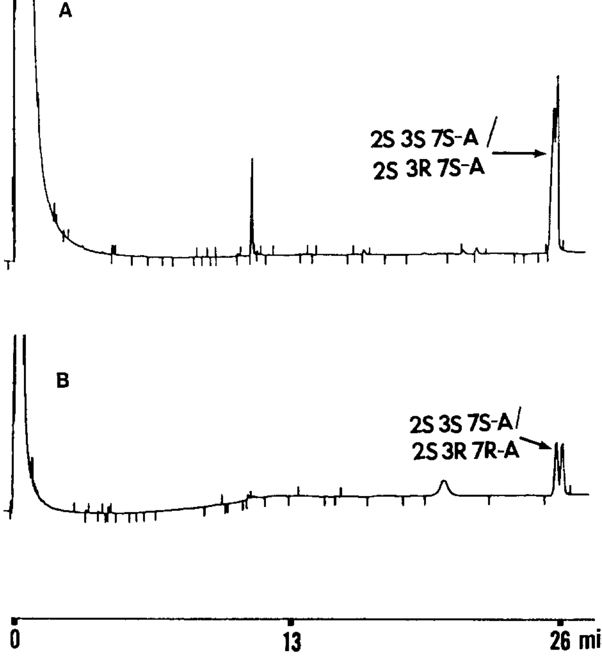

FIG. 1. Capillary GLC separation on DB-5 column temperature programmed 130–190°C at 4°/min. (A) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*S*-A mixture, 100 ng, (B) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*R*-A mixture, 50 ng.

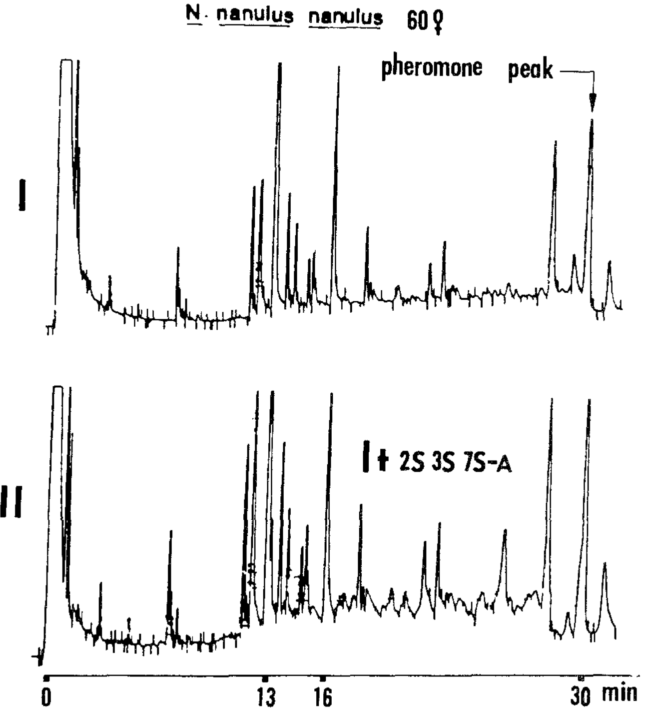

FIG. 2. (I) Capillary GLC on DB-5 recordings of acetylated natural pheromone of *N. nanulus nanulus*, 60 FE. (II) Capillary GLC recordings of acetylated natural pheromone of *N. nanulus nanulus* 60 FE, spiked with 100 ng 2*S*,3*S*,7*S*-A.

feeding on jack pines vs. red pines (Knerer and Atwood, 1973) traps baited with 2*S*,3*S*,7*S*-A and 2*S*,3*S*,7*R*/*S*-A were set in Vogel Center (red pine) and Houghton Lake (jack pine). In both locations 2*S*,3*S*,7*S*-A showed superior effectiveness over 2*S*,3*S*,7*R*/*S*-A in attracting males of *N. nanulus* (data not shown).

Capillary GLC Analysis. The two GC columns used for this analysis were capable of separating the 2*S*,3*S*,7*S*-A from the 2*S*,3*R*,7*R*-A. With the latter having a longer retention time, better resolution was obtained with the DB-5 column where the 2*S*,3*S*,7*S*-A was also separated from 2*S*,3*R*,7*S*-A (Figure 1). By matching the retention times of the standard synthetic isomers 2*S*,3*S*,7*S*-A, and 2*S*,3*R*,7*S*-A and 2*S*,3*R*,7*R*-A with the natural pheromone peaks, and by coinjection of 2*S*,3*S*,7*S*-A with the natural pheromones, it was observed that only the 2*S*,3*S*,7*S*-A isomer was detectable in *N. n. nanulus* and *N. sertifer* (Figures 2 and 3). It was determined, with the DB-5 column, that virgin females of *N. n. nanulus* and *N. sertifer* each contained 2 ng and 10 ng of pheromone, respectively.

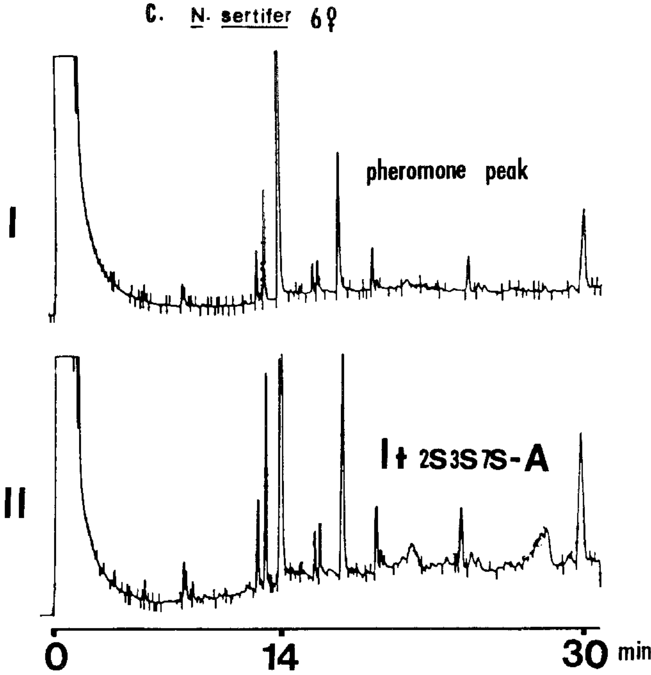

FIG. 3. (I) Capillary GLC on DB-5 recordings of acetylated natural pheromone of *N. sertifer*, 6 FE. Compare to Figure 2 for the locations of pheromones. (II) Capillary GLC recordings of acetylated natural pheromone of *N. sertifer*, 6 FE, spiked with 50 ng 2*S*,3*S*,7*S*-A.

DISCUSSION

It is clear from the current study results that 2*S*,3*S*,7*S*-A is the major pheromone component *N. n. nanulus*. The addition of 2*S*,3*R*,7*R*/*S*-A, 2*S*,3*R*,7*R*-A, and 2*S*,3*R*,7*S*-A was neither inhibitory nor synergistic to its effectiveness. The synthetic pheromone, either as 2*S*,3*S*,7*S*-A alone or as mixtures, was as effective as the natural pheromone extracted from females (Table 5).

By contrast the most effective synthetic preparation for *N. sertifer* was a mixture of 5:0.003 to 5:0.01 (μg/μg) of 2*S*,3*S*,7*S*-A to 2*S*,3*R*,7*R*-A. It must be emphasized here that adults of these two species emerge at the same time of the year (one generation per year) and that they are observed to distribute in similar areas in the Great Lakes region. Futhermore, there are two races of *N. nanulus*: one feeding on jack pine and the other on red pine. Therefore, these two species, at least the ones feeding on jack pine, must be regarded as truly sympatric. A natural question arising from the current study results is whether

the action of the small amount of synergist 2*S*,3*R*,7*R*-A on *N. sertifer* alone could offer a critical species differentiation between them.

In the area where these two species coexist (e.g., Vogel Center, Table 9) *N. sertifer* males were caught only to traps containing 0–0.03 μg synergist to 5 μg of 2*S*,3*S*,7*S*-A, whereas *N. nanulus* males were caught in all ranges of synergist concentrations. The results indicate that the males of the former species is much more sensitive to the presence of the synergist and thereby discriminatory to specific isomer ratio than the latter. Thus, such a species difference in pheromone recognition could play at least an important part in the species isolation for *N. sertifer*. How *N. nanulus* males recognize the females of their own species from others is not clear. It is possible that there are other mechanisms, particularly those involved in close-range behavioral signals, which play important roles in this regard. Much more work would be needed to clarify this point.

There is good agreement between the field studies and the GLC analyses of the natural pheromone in these two species. Assuming a 5 : 0.003 optimum blend of 2*S*,3*S*,7*S*-A to 2*S*,3*R*,7*R*-A obtained from field studies, the 36 pg of 2*S*,3*R*,7*R*-A present in the 6 FE pheromone of *N. sertifer* injected at the time was beyond the detection limit of the FID system used. This explains why only 2*S*,3*S*,7*S*-A was detected by GLC analysis for both *N. n. nanulus* and *N. sertifer*. Thus, despite the failure of reorganizing the synergist component in *N. sertifer* extract, the GLC analysis has clearly established for the first time the true chiral identity of the major pheromone for both species.

EFFICACY OF PINE OIL AS REPELLENT TO WILDLIFE

CHRISTINA M. BELL and ALTON S. HARESTAD

Department of Biological Sciences
Simon Fraser University
Burnaby, B. C., Canada V5A 1S6

(Received June 16, 1986; accepted August 20, 1986)

Abstract—Pine oil, a by-product of the pulp industry, is a feeding repellent to snowshoe hares and voles. In pen trials with snowshoe hares and field trials with voles, when given a choice between food in a pine oil-treated bowl and a control bowl, the animals fed preferentially from the control bowl. When the hares were presented with food only in a pine oil-treated bowl, two hares showed a reduced rate of food consumption and one hare did not feed at all. Pine oil contains monoterpenes which may inhibit microbial symbionts in the digestive tracts of hares and voles. The repellent action of pine oil is likely based on this interference of digestive processes, and it is of adaptive advantage for cecal digestors to avoid it. Pine oil has potential as a commercial repellent for snowshoe hares and voles.

Key Words—wildlife damage, snowshoe hare, *Lepus americanus*, Townsend vole, *Microtus townsendii*, pine oil, repellents, seedling protection.

INTRODUCTION

Wildlife can pose serious problems to intensive forest management, specifically to conifer regeneration programs. Feeding by hares and voles is responsible for substantial damage to seedlings in the Pacific Northwest (Black et al., 1979). Snowshoe hares, *Lepus americanus* Erxleben, damage seedlings by clipping the terminal and lateral shoots (Dimock, 1970) and saplings or large trees by debarking, which can result in girdling of trees (Sullivan, 1984). Volves, *Microtus* spp., debark stems and clip growing shoots of seedlings (Santamour et al., 1963; Green, 1978). Control measures can either eliminate the pest animals or protect trees from the pest. A strategy whereby the crop trees are made inaccessible or undesirable to wildlife is a more desirable approach given current

0098-0331/87/0600-1409$05.00/0 © 1987 Plenum Publishing Corporation

attitudes to wildlife. Considerable attention has been focused on chemical repellents to protect seedlings. No currently available repellent has proved completely effective against wildlife feeding damage, and there is a continuiing search for new products.

Pine oil,[1] a by-product of the pulp industry, is an oily liquid containing a mixture of terpene alcohols and monoterpenes. These terpenes are present in naturally occurring, essential oils found in foliage resistance to animal damage. Pine oil has repellent properties to forest insects (Nijholt et al., 1981; Alfaro et al., 1984; Richmond, 1985). It has been used in Scotland as a deer repellent in seedling plantations (P.R.W. Sanders,[2] personal communication). These observations and reports suggest the potential of pine oil as a repellent for wildlife. Since it is extracted from pulp waste, it is both plentiful and accessible to the forest industry.

The overall aim of this research was to determine whether pine oil had repellent properties to snowshoe hares and voles and if future research is warranted.

METHODS AND MATERIALS

Effect of Pine Oil on Penned Snowshoe Hares. Three males snowshoe hares were kept separately in adjacent outdoor pens (5.0 × 1.5m). Each pen contained two covered feeding stations, 1.1 m apart. These hares were provided with lab pellets (Purina Rabbit Chow) and fresh food (apples and carrots) between 0800 and 1500 hr (PST) each day. Food was removed from the pens 2 hr prior to the start of a trial.

Feeding preference experiments were conducted overnight between 1700 and 0800 hr, because hares are more active and consume the bulk of their daily food in take during this time. Trials were conducted between October 15 and December 10, 1985. At each feeding station, each hare was given a bowl of food containing 100 g of lab pellets (increased to 150 g when consumption rose during cold winter months). The bowls were presented in a combination of treated–control or control–control. To create a vapor "barrier" around the food, pine oil was applied by drenching 1 m of pipe cleaner in 25 ml of pine oil. The pine oil wick was then wrapped in burlap, placed around the bowl, and secured with a rubber band. Thus the smell of pine oil could permeate the atmosphere around the food but the hare could not come into direct contact with it. Control bowls were presented with the burlap and pipe cleaner but no pine oil. At the end of the 15-hr trial period, the bowls were removed and the remaining food

in each bowl weighed. Preference was determined by the relative amount of food consumed. To eliminate bias for a particular feeding station, the treated and control bowls were randomly positioned for each replicate.

Fourteen-hour, no-choice experiments began at 1700 and ended at 0700 hr. Each hare was given a single pine oil-treated or control bowl containing 50 g of lab pellets. The food was replaced every 2 hr. Each time, the food remaining in the bowl was weighed and the amount of food consumed during the 2 hr period was calculated.

Effect of Pine Oil on Voles in the Field. Experiments were conducted at a field in Richmond, B.C. (approximately 1 km north of Vancouver International Airport) inhabited by Townsend voles, *Microtus townsendii* Bachman. The field was covered with deep grass and a few shrubs. Thirty-one feeding stations, at least 10 m apart, were established near vole runways over a 1-hectare area. Each feeding station consisted of two open-ended milk cartons pegged side by side to the ground. They were baited with rolled oats in small glass dishes placed in the centers of the cartons to ensure protection from weather and foraging birds. The field was prebaited for five days to accustom the voles to oats.

During the experiment, dishes containing 5 g of rolled oats were placed in each milk carton. At each feeding station, there was a choice between a dish surrounded by a ring of pipe cleaner soaked in pine oil in one carton and a dish surrounded by a ring of clean pipe cleaner in the remaining carton. The experiment ran for 72 hr, from February 10–13 and 18–21, 1986, after which the food remaining in the dishes was collected and weighed. The presence or absence of droppings in dishes and cartons was noted at each feeding station.

RESULTS

Snowshoe Hares. When given a choice, all three hares consumed significantly more food from the control bowl than from the pine oil-treated bowl (Table 1). Two of the hares fed almost exclusively from the control bowl, while hare 1 ate some food from the pine oil-treated bowl in all eight replicates. In one replicate, it ate more than half of its nightly intake from the treated bowl. This variation in individual reaction by snowshoe hares was also observed in experiments testing predator odors as repellents (T.P. Sullivan,[3] personal communication). When the hares were given a choice between two control bowls, there was no differences in the amount of food consumed from each bowl (Table 2).

The choice experiments indicate that pine oil has significant repellency resulting from olfactory stimuli. The vapor barrier around the bowl apparently deterred the hares from feeding. The hares did not appear to become habituated

to the smell of pine oil, since there was little difference in results between the start of the experiments in October and their termination in December.

For the no-choice experiments, the nightly feeding patterns for each hare under the control and treatment regimes are shown in Figure 1. For all three hares, the mean total food consumption was greater from the control than the treated bowl (Table 3). Different hares had different feeding patterns when presented only with food in a pine oil-treated bowl. Hares 1 and 2 fed from the pine oil-treated bowl in the absence of alternative food, while hare 3 did not feed at all from the pine oil-treated bowl (Table 4). Sinclair et al. (1982) reported a one- to four-day "hunger strike" in snowshoe hares presented with

low-quality food, after which the animals resumed feeding. The duration of our experiment was insufficient to observe such behavior by hare 3.

Pine oil did not prevent feeding by two hares, although it did reduce their rate of intake. If such feeding behavior occurred in natural populations, pine oil may not prevent feeding on treated plants. If a "feeding strike" occurred, followed by a resumption of normal feeding behavior (Sinclair et al., 1982), the repellent effects on pine oil on animals such as hare 3 might be of short duration. In most field situations, however, alternative foods exist, suggesting that pine oil might have considerable practical potential for use against snowshoe hares.

Voles. When feces were present in a carton, food had always been removed. Data for six feeding stations were removed from the first experiment and four from the second because of the lack of fecal pellets and absence of feeding at treated and control dishes. These data were removed because lack of

		(Food consumed g, ($\bar{X} \pm$ SE)[a]	
Experiment	No. of replicates	Control dishes	Treated dishes
1	25	4.4 ± 0.2	1.6 ± 0.4
2	27	4.8 ± 0.1	0.9 ± 0.3

[a] Difference between consumption from treated and control dishes significant in both experiments, Student's t test, $P \leq 0.05$.

pellets likely indicates that voles did not encounter the feeding stations. At the remaining stations, voles fed from 52 of 52 control dishes and only 19 of 52 pine oil-treated dishes ($\chi^2 = 15.34$, $df = 1$, $P \leq 0.05$). There was also significantly more (3.7 times) food taken from the control than the pine oil-treated dishes (Table 4).

At 33 stations there were no droppings in the cartons containing pine oil and no food was removed, suggesting that in these cases the pine oil odor was sufficiently repellent to prevent the voles from even entering the cartons. However, at 19 stations, voles had entered the cartons and fed from the pine oil-treated dishes, taking an average of 3.4 ± 0.4 g of food. The apparent lack of pine oil repellency at these stations could be due to differences in effective concentration of pine oil or to individual variation in response to pine oil, a phenomenon also observed with snowshoe hares. At all of these 19 stations, however, the 5 g of food in the control cartons had been completely consumed. This suggests that voles may have fed from treated dishes only after food in control cartons was completely consumed. If this was the case, it indicates the need for alternative food sources when using pine oil as a feeding repellent.

At 20 stations, all of the food from the control cartons was removed but the pine oil-treated food remained untouched. This may be due to less feeding at those stations or a result of the individual variation in response of voles to pine oil. Overall, pine oil seems to be an effective repellent to voles in the presence of alternative food.

DISCUSSION

Some strains of Douglas fir are more resistant to deer and snowshoe hare damage than others, and this resistance has a genetic basis (Dimock et al., 1976; Silen and Dimock, 1978). The difference between damage-resistant clones and susceptible clones of Douglas fir is based on the essential oil (terpene derivatives obtained from plant material by steam distillation) content of the foliage, and the levels of volatile terpenes emitted by these oils (Radwen, 1978; Radwan and Ellis, 1975). More than 40 essential oils have been identified in Douglas-fir needles. It is generally believed that these oils serve a defensive purpose and deter herbivores from feeding on the foliage (Freeland and Janzen, 1974). The natural resistance of deciduous woody plants and conifers to browsing by snowshoe hares and voles has been attributed to the presence of defense compounds (Von Althuen, 1971; Bryant, 1981) and, in particular, oxygenated monoterpenes in conifers (Bryant and Kuropat, 1980). Oxygenated monoterpenes in Douglas-fir foliage have an inhibitory effect on microbial activity (Oh et al., 1967). Pine oil contains high levels of terpene volatiles, including some oxygenated monoterpenes such as α-terpineol and limnonene (Nijholt, 1980) with known antimicrobial properties (Connolly et al., 1980). The antimicrobial action of these monoterpenes may be detrimental to herbivores.

Snowshoe hares and voles are cecal digestors and are dependent on microorganisms for efficient food digestion (Robbins, 1983). The consumption of essential oils containing microbial inhibitors may disrupt the digestive process (Bryant and Kuropat, 1980). A herbivore should be able to detect physiologically detrimental defensive chemicals, or indicator chemicals, in a plant before eating it (Levin, 1976). Detection of the characteristic odor, of essential oils may, therefore, be of adaptive advantage to cecal and ruminant digestors for food selection. The use of pine oil as a repellent may exploit any ability herbivores have to recognize metabolically costly compounds by olfaction.

Foraging theory predicts that an animal will always try to maximize its rate of energy intake within the constraints of risk of predation (Krebs, 1978). The use of a chemical repellent aims to reduce or mask the quality of a high-value foraging patch or food item. The animal will mistake desirable food for food that is energetically expensive to digest and will search for an alternative food source with a ''higher'' energy value. When such an alternative food source is available, a repellent should be very effective in protecting trees (Green, 1978). In the absence of such a food source, however, the animal may be forced to eat the apparently ''low-value'' food. The field trials with voles are consistent with this hypothesis.

Despite the preliminary nature of our experiments, our results suggest a possible commercial future for pine oil as a wildlife repellent. Preliminary tests showed that it is phytotoxic to seedlings when applied topically, and an alternative method of application, such as in slow release devices, could be feasible. Our initial success with pine oil as a repellent justifies a continuation of its testing as a potentially marketable product. Field experiments with hares and voles should be performed using seedlings and wild populations of animals. Phytotoxicity tests should be conducted on different species of trees at different ages and developmental stages with different modes of application.

CHEMICAL BASIS FOR ASYMMETRIC MATING ISOLATION BETWEEN STRAINS OF SCREWWORM FLY, *Cochliomyia hominivorax*

L. HAMMACK

Metabolism and Radiation Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Fargo, North Dakota 58105

(Received May 22, 1986; accepted August 21, 1986)

Abstract—Laboratory mating tests and bioassays for a contact, mating-stimulant pheromone were conducted within and between two strains of the screwworm fly, *Cochliomyia hominivorax*. No strain or sex difference in pheromone activity occurred at emergence. However, the pheromone activity of females increased with age in one strain but declined in the other. Activity also declined in males of both strains but more steeply than in the females. Thus, sexual dimorphism in pheromone activity developed with age in both strains but to differing degrees. The decline in female pheromone activity was partly compensated for within that strain by a higher male responsiveness to pheromone. Female pheromone activity and mating success were positively correlated. Virgin females and those inseminated 24–48 hr previously were equally stimulatory. It appears that the strain differences arose from selection for reduced pheromone activity during laboratory colonization.

Key Words—Screwworm fly, *Cochliomyia hominivorax*, Diptera, Calliphoridae, sex pheromone, mating-stimulant pheromone, mating behavior.

INTRODUCTION

Female-produced sex pheromones located on the cuticle and acting on contact or at short range occur in many Diptera (see Howard and Blomquist, 1982). Most of these pheromones are hydrocarbons, usually alkenes or branched alkanes with chain lengths of 23 (C_{23}) to 37 (C_{37}) carbons. Some function as short-range attractants, such as the C_{23} alkene, (Z)-9-tricosene, of the housefly, *Musca domestica* (Carlson et al., 1971). Others, such as the C_{35} and C_{37} methyl branched alkanes that are present in tsetse flies (*Glossina* spp.), are not signif-

0098-0331/87/0600-1419$05.00/0 © 1987 Plenum Publishing Corporation

icantly volatile and function as contact aphrodisiacs (Langley et al., 1975; Carlson et al., 1984).

In the screwworm fly, *Cochliomyia hominivorax* (Coquerel), chemically mediated attraction of males to females is not known, but male copulatory behavior is released upon contact with a chemical stimulus or set of stimuli produced by the female (Mackley and Broce, 1981; Hammack, 1986). However, heterogeneity apparently exists among screwworm strains with respect to this pheromone system. Female pheromone activity estimated from male copulatory attempts directed at dead females in intrastrain tests increased significantly with age after emergence in one strain but declined in another (Hammack, 1986). The decline occurred in a long-colonized strain and began before females were old enough to mate. These features and the report by Pomonis and Mackley (1985) that cuticular lipid profiles change with colonization in female but not male screwworm flies led to the hypothesis that the declining pattern is the result of adaptation to mixed-sex holding conditions in the laboratory, where high pheromone activity might prove detrimental to female survival. Regardless of origin, sexually receptive females differing in pheromone activity could prove useful for evaluating the respective roles of female behavior and chemical stimuli in elicting male courtship. Strain heterogeneity in the pheromone system, if accompanied by mating isolation between strains, may also be relevant to screwworm eradication programs that depend on the ability of mass-reared sterile males to mate competitively with wild populations.

The purposes of this study were to (1) confirm that contrasting relationships between female age and sex pheromone activity occur in different screwworm strains; (2) determine whether or not mating affects female pheromone activity in a strain showing an age-dependent increase in pheromone activity; (3) determine when strain differences in the pheromone activity of females occur and if these are compensated for by strain differences in the responsiveness of males to a pheromone stimulus; and (4) conduct interstrain mating tests to determine the relationship between female pheromone activity and mating success.

METHODS AND MATERIALS

Insects. The screwworm strains used here were the 009 and FC-96 (hereafter FC). The 009 strain, established from multiple egg masses collected in Texas, had been colonized in the laboratory for > 100 generations. It had previously failed to show an age-dependent increase in the ability of dead females to stimulate male copulatory attempts (Hammack, 1986). The FC strain originated from a single egg mass collected in Chiapas, Mexico, and was tested after 4–26 generations in the laboratory.

Larvae were reared on a beef-based diet, and adults held on a 12:12 light–

dark photoperiod at 25 ± 1°C with access to corn syrup and water (Hammack, 1984). Breeding females of the 009 strain were held in mixed-sex colonies, whereas those of the FC strain were held without males except for the few minutes required to achieve insemination. Experiments were conducted with virgin flies 6–8 days old, unless stated otherwise. Virgins were obtained by separating the sexes within 24 hr of emergence, using CO_2 anesthesia. Flies older than 24 hr were not anesthetized when handled.

Pheromone Extraction. Extracts of cuticular components were prepared by washing 20 females for 15 sec in 1 ml of *n*-hexane (Hammack, 1986). The brief wash was retained because longer extractions in preliminary tests either had no effect on the recovery of pheromone activity (1 min) or reduced it (5 min). Extracts were concentrated in a stream of N_2 and stored up to eight days at ca. −70°C before testing.

Pheromone Bioassays. Bioassays determined whether or not test males attempted copulation with decoy insects when the males were paired with decoys for 1 min. The decoys were either whole insects fresh-killed by freezing at −20°C for 30 min (untreated decoys) or hexane-washed males treated with female extract (or solvent). The males killed by rinsing in three 0.5-ml aliquots of hexane were air dried and then treated, unless stated otherwise, with 1.0 female equivalent (FE) of extract in 5 μl of hexane.

Some decoys were mounted for assay using pins as in previous tests (Hammack, 1986), and these are identified in Tables 2 and 4. However, most were mounted with the ventral side applied to the small end of No. 6 corks via nylon thread tightened against the dorsal surface of the neck. The thread was taped to opposite sides of the cork where test males could not touch. Each cork with attached decoy was fitted in a glass test tube (15 × 150 mm) that contained one test male. Inversion of the tube forced contact between the test and decoy insects. The change in mounting method was made to avoid puncturing the body surface of decoys after loose decoys previously punctured with pins proved less stimulatory than unpunctured controls (Hammack, unpublished). Except for the altered method of mounting most decoys and the use of solvent-washed males in place of females to test pheromone extracts, bioassay procedures were as described previously (Hammack, 1986). Males were substituted here because solvent washing might not remove from females all sex-specific cues contributing to the release of male copulatory behavior.

Solvent-washed males treated with 5 μl of hexane were assayed to determine control responses. Washed males treated with female extract were assayed simultaneously to check responsiveness of the test males. Within strains, each of five decoys per treatment was tested with 10 males.

Matings were observed at four days of age among mixed-sex pairs of the FC strain, after establishing in preliminary trials that mating frequencies were identical whether determined visually or by detection of sperm in spermathecae. The inseminated females and matched virgins were extracted separately 24 and

48 ± 4 hr after mating. For each interval, responses of FC males to extracts of mated and virgin females were compared in bioassays.

Pairwise comparisons of pheromone activities were made using test males 6–8 days old and the following untreated dead decoys: (1) 0 vs. 6- to 8-day-old females within strains, (2) males vs. females at 0 and 6–8 days within strains, (3) 0 vs. 6- to 8-day-old FC males using 009 test males, and (4) FC vs. 009 females at 0 and 6–8 days using males of each strain. Six- to eight-day-old FC and 009 females were also compared by assaying their extracts with males of each strain. Finally, the responsiveness of 009 and FC males was compared using both 0 day and sexually mature female decoys of each strain. All 0 day insects were killed within 4 hr of emergence.

Females of the 009 strain that had all emerged during the same photophase interval were frozen at the following ages postemergence: 3 ± 2 hr and 1, 2, 3, 4, 6, and 8 days ± 2 hr. They were stored at ca. −70°C up to 25 days and then extracted. Extracts (one per age group) were prepared simultaneously and each tested on three decoys in intrastrain assays. The extraction and assay procedures were repeated twice.

Data were analyzed using Wilcoxon's signed-rank test or Friedman's nonparametric test for the randomized complete block design (Xr^2 statistic distributed approximately as X^2) (Steel and Torrie, 1960). Each decoy tested with 10 individually exposed males was considered a replicate.

Mating Tests. Two tests were done in which males were given the opportunity to mate with live unrestrained females. Both involved four crosses set up simultaneously: the two intrastrain and two reciprocal interstrain ones. The crosses in the first test were made by placing 20 virgins of each sex in cages (ca. 28 × 18 × 23 cm) and then isolating the females after 24 hr. Those with sperm in their spermathecae were considered mated. Mating frequencies from eight replicates per cross were analyzed using Friedman's test for the randomized complete block design.

For the second test, the sexes were combined in single pairs and forced into contact for 1 min in glass shell vials (25 × 95 mm) stoppered with foam rubber plugs. A new plug was used for 10 successive replicates and discarded. Observations were made of the number of pairs (1) in which males attempted copulation with the female and (2) that were in copula within 1 min. Insects of both sexes were tested once and discarded. One hundred twenty pairs were observed per cross using 6- to 8-day-old 009 and 12- to 14-day-old FC flies. The test was repeated using only 6- to 8-day-old insects.

RESULTS

Pheromone Bioassays. Within the FC strain, no males (0/50) attempted copulation with hexane-washed males treated only with solvent, although 84% (42/50) responded to those treated with 1.0 FE of extract. None of the 009

males responded to solvent (0/50), although 44% (22/50) did so to 1.0 FE of 009 extract. Thus, control decoys were not stimulatory within either strain.

Insemination had no effect on the pheromone activity of females of the FC strain when they were extracted for testing 24–48 hr after mating (Table 1). Data obtained at 24 and 48 hr within mating treatments were similar and have been pooled in Table 1.

Sex and strain differences in the ability of untreated decoys to stimulate male copulatory attempts were absent at 0 days (Table 2, tests 1–4). Between 0 and 6–8 days, the stimulatory ability of FC-strain females increased significantly (Table 2, test 5), whereas that of 009-strain females declined significantly (Table 2, test 6). In this respect, 009 females resembled males of both strains (Table 2; tests 2, 7, 9), although the decline was steeper among males because sexual dimorphism in pheromone activity was evident in both strains when they were tested at 6–8 days of age (Table 2; tests 8, 9). Sexually mature female decoys of the FC strain stimulated significantly more copulatory responses than those of the 009 strain, regardless of whether test males were of the FC or 009 strain (Table 2; tests 10, 11). These differences also occurred when extracts of FC and 009 females were assayed (Table 3), leaving no doubt that sex pheromone was the stimulus responsible for the greater activity of mature FC females.

The percentage of 009 males responding to extracts of 009 females varied significantly with female age and declined from 94% at 0 days to 66% at 8 days ($Xr^2 = 13.4$, $df = 6$, $P < 0.05$). This pattern is contrasted in Figure 1 with those age-dependent changes in pheromone activity already inferred for FC-strain females and males of both strains. This was accomplished by plotting all pheromone activities relative to that of insects 0 days old when sex and strain differences were lacking. The pattern of 009 females was clearly unique but, in its decline with age, more closely resembled that of FC and 009 males than that of FC females.

TABLE I. EFFECT OF MATING ON SEX PHEROMONE ACTIVITY OF FEMALE SCREWWORM FLIES OF FC STRAIN EXTRACTED 24–48 HR POSTMATING

Dose (FE)	Mean male response (%)[a]	
	Virgin females	Mated females
1.0	93	86[b]

10	6–8	F	FC	FC			91	**
	6–8	F	009	FC			2	
11	6–8	F	FC	009			96	**
	6–8	F	009	009			51	

[a] 0-day-old insects were killed within 4 hr of emergence.
[b] $N = 10$ decoys per type and mounting method, each tested with ten 6- to 8-day-old males.
[c] NS, not significant at 0.05 probability level. ** $P < 0.01$, referring to the difference within tests and mounting methods between members of a pair (Wilcoxon's signed-rank test).

Although sexually mature females of the FC strain had more pheromone activity than 009 females, the data in Table 2 suggest that males of the 009 strain were more responsive to a pheromone stimulus than FC males. This higher 009 responsiveness was demonstrable in paired comparisons and did not depend on the strain or age of females used to supply the pheromone stimulus (Table 4).

TABLE 3. EFFECT OF SCREWWORM STRAIN ON SEX PHEROMONE ACTIVITY OF FEMALES 6-8 DAYS OLD

Strain supplying 1.0 FE of female extract	Strain of test male	Mean male response (%)[a]
FC	FC	93 **[b]
009	FC	2
FC	009	95 **
009	009	29

[a] $N = 15$ decoys per strain combination, each tested with ten 6- to 8-day-old males.
[b] $**P < 0.01$, referring to the difference within strains of males between strains of females (Wilcoxon's signed-rank test).

Mating Tests. When the sexes were combined for 24 hr, significant differences in mating frequencies occurred among the four test crosses involving FC and 009 strains (Figure 2, 24-hr test) ($Xr^2 = 12.2$, $df = 3$, $P < 0.01$). However, deletion from the statistical analysis of the cross involving 009 females and FC males abolished significance ($Xr^2 = 2.4$, $df = 2$, $P > 0.25$). Thus, FC females were readily mated by males of both strains, whereas 009 females were readily mated only by 009 males.

A similar mating pattern was obtained for the four crosses when insects were observed for 1 min in mixed-sex pairs (Figure 2, 1-min test). More im-

[e] $**P < 0.01$, referring to the difference within tests between members of a pair (Wilcoxon's signed-rank test).

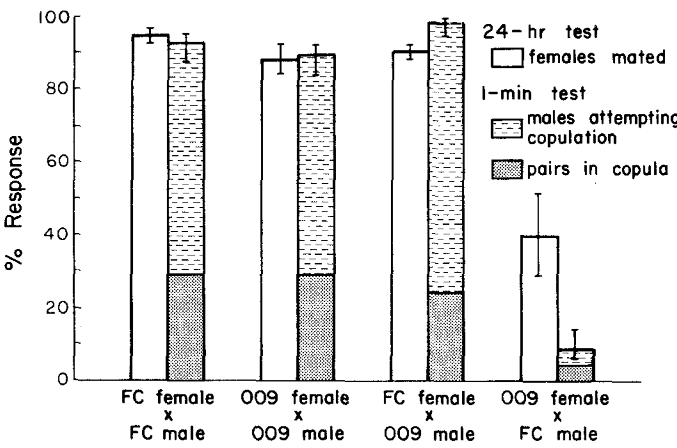

FIG. 2. Mating behaviors in intra- and interstrain crosses involving 009 and FC strains of the screwworm fly. Vertical bars represent standard errors of the mean in the 24-hr test and 95% binomial confidence intervals in the 1-min test.

portantly, the low mating frequency in the cross involving 009 females and FC males occurred because few males even attempted copulation (Figure 2, 1-min test). Data generated by 6- to 8- and 12- to 14-day-old FC insects are pooled in Figure 2. The two age groups produced homogeneous results, except that older FC females, whether paired with FC or 009 males, appeared more receptive to mating than younger ones.

DISCUSSION

The results confirmed earlier data implicating a female-produced sex pheromone in the release of male copulatory behavior in the screwworm fly (Mackley and Broce, 1981; Hammack, 1986) and more convincingly demonstrated that this stimulus is required for mating.

The contrasting relationships between female age and ability to stimulate copulation that were observed here in the 009 and FC strains, and previously in the Aricruz and DE-9 strains (Hammack, 1986), could be attributed to pheromone differences because whole females and extract of females both produced similar response patterns. Thus, the pheromone activity of females increased with age after emergence in FC and DE-9 strains but remained unchanged or declined in Aricruz and 009 strains. Interpretation of these differing ontological patterns was intially complicated by the strong responses obtained to newly emerged insects within the latter two strains. However, the interstrain comparisons done here indicate that these were due in the 009 strain to a high male responsiveness to pheromone and not to any difference between strains in the pheromone activity of newly emerged insects. The higher responsiveness of 009 males was demonstrable using pheromone from either strain and partly compensated for the lower sex pheromone activity of sexually mature females of the 009 as compared with the FC strain. This difference between mature females was demonstrable using males of either strain. The simplest explanation is that the strains differed quantitatively in the production and reception of either pheromone(s) or else in compounds interfering with responses to pheromone; however, qualitative differences were also certainly possible.

The pheromone activities obtained here and in previous behavioral tests (Hammack, 1986) correlate well with the nonpolar cuticular lipid profiles published for the screwworm fly by Pomonis and Mackley (1985). The profiles show no sex or strain differences at emergence and no strain differences among males; however, sexual dimorphism occurs after the age of 48 hr, as do differences among strains in the cuticular lipid patterns of females. These differences among females involve a shift toward lipids with shorter chain lengths as duration of laboratory colonization increases.

Interstrain variation with respect to aphrodisiac production by females as well as its reception by males is well documented in several *Drosophila* spp.

(Luyten, 1982; Jallon, 1984; Antony et al., 1985). In addition, like 009 and Aricruz strains of the screwworm fly, teneral *D. melanogaster* of both sexes or their extracts often stimulate as much male sexual activity as older females do, or even more (Cook and Cook, 1975; Jallon and Hotta, 1979; Jallon, 1984). However, even though its function is unclear, courtship of the young occurs to varying degrees in both wild and laboratory strains and is considered a normal component of *D. melanogaster* sexual behavior (McRobert and Tompkins, 1983).

The results here showed a positive correlation between the sex pheromone activity of screwworm females and their mating success when strain differences in the responsiveness of males to a pheromone stimulus were also taken into consideration. Thus, significant mating depression was only observed when females with the lower pheromone activity (009 strain) were paired with males showing the lower responsiveness to pheromone (FC strain). The failure of most FC males to even attempt copulation with 009 females indicates that the mating depression likely occurred because of an inappropriate pheromone stimulus. In addition, the sexual isolation was asymmetric in that no depression occurred in the reciprocal cross involving females of the more stimulatory strain (FC) paired with males of the more responsive one (009). Asymmetric mating patterns have received considerable attention from those interested in *Drosophila* speciation, but hypotheses as to how such asymmetries might reflect phylogeny vary (see Robertson, 1983, for discussion and references).

Richardson et al. (1982) postulated strong reproductive isolation among screwworm field populations, but subsequent cytogenetic and morphological studies have failed to uncover interspecific-level variation among strains from different habitats or localities (see Dev et al., 1986, and LaChance and Whitten, 1986, for discussion and references). Mating preference studies supported the latter, except that some mating isolation frequently occurred when newly colonized males were offered females from different long-colonized strains (C.J. Whitten, personal communication). The generality of such a pattern lends support to the hypothesis that selection during colonization led to the pheromone and mating differences observed here between FC and 009 strains.

The present tests showed no reduction in the pheromone activity of FC females within 24–48 hr after mating. Therefore, the standard method of maintaining screwworm colonies in mixed-sex groups until oviposition is stimulated would subject the monogamous female to repeated male copulatory attempts. This in turn might favor survival and reproduction of those females least stimulatory to males (Baumhover, 1965). Should mechanisms to rapidly deactivate pheromone not be available once high levels have been established, then such pressure might lead, during colonization, to selection for low pheromone activity from the time of emergence as seen here in females of 009 strain. While obviously speculative, this scenario envisions a heightened male responsiveness to pheromone to be secondary to selection for reduced female pheromone pro-

duction in an insect that nevertheless requires a chemical stimulus to release male copulatory behavior.

Even if the above scenario proves demonstrable during mass rearing of the screwworm, its consequences for population control via the sterile-insect-release method would still require clarification. The data provided no evidence that males of a long-colonized strain like the 009 would be unable to recognize or readily mate wild females; nevertheless, such males may be handicapped in their ability to recognize and terminate inappropriate interactions. For example, the observation that sexual dimorphism in pheromone activity was less marked in the 009 than the FC strain suggests potential difficulties with sex discrimination in the 009 strain. Indeed, this may account for the occurrence of copulatory behavior in all-male groups of many laboratory strains such as the 009 (Mackley and Broce, 1981), but not others such as the FC (Hammack, unpublished). Strikes were common among FC males, but homosexual interactions were terminated without the release of copulatory behavior. Colonization might also affect the ability of males to discriminate among species, but the role of the screwworm pheromone in species recognition remains to be investigated.

REPEATABILITY OF PHEROMONE EMISSIONS FROM INDIVIDUAL FEMALE ERMINE MOTHS *Yponomeuta padellus* and *Yponomeuta rorellus*[1]

(Received February 21, 1986; accepted August 22, 1986)

Abstract—The repeatability of the composition of pheromone emitted by individual female moths (*Yponomeuta*) was determined by gas chromatographic analysis. An improved technique for repeated collections of airborne volatiles from the same moth was developed. The procedure did not harm the females and allowed precise quantification of 0.05 ng of pheromone components in 30-min collections. Individual females of *Y. padellus* ($N = 10$) and *Y. rorellus* ($N = 5$) were sampled six and eight days after emergence. *Y. padellus* released, on average, 4.8 ng/30 min of tetradecyl acetate, (*E*)-11-tetradecenyl acetate, (*Z*)-11-tetradecenyl acetate, hexadecyl acetate, (*Z*)-9-hexadecenyl acetate, and (*Z*)-11-hexadecenyl acetate in the average ratio 445:38:100:494:35:421. The amount of (*E*)-11-tetradecenyl acetate relative to (*Z*)-11-tetradecenyl acetate was less variable [coefficient of variation (CV) = 15%] than the relative amounts of the other components (CV = 46–61%). The repeatability of the relative amounts of compounds released by individual females was high for all components ($r = 0.82$–0.90). The average emission of tetradecyl acetate, tetradecanol, hexadecyl acetate, and hexadecanol by *Y. rorellus* was 8.3 ng/30 min (ratio 100:8:10:2). The repeatability was low for tetradecanol ($r = 0.51$) but higher for hexadecyl acetate ($r = 0.87$) and hexadecanol ($r = 0.89$). The low interindividual variance for the (*E*)-11-/(*Z*)-11-tetradecenyl acetate ratio in *Y. padellus* might be due to its importance for reproductive isolation, i.e., it is under strong selection pressure.

INTRODUCTION

The pheromone production of individual moths has been shown to vary within populations of several species (Klun and Maini, 1979; Miller and Roelofs, 1980; Haynes et al., 1984; Löfstedt et al., 1985; for a review see Schlyter and Birgersson, 1986). There is both a quantitative variation in the absolute amount of pheromone produced and a variation in the relative amounts of different compounds in the pheromone blend. The total phenotypic variance in a population can be partitioned into variation within and between individuals. If the latter component constitutes a major proportion of the total variance, this indicates that there is a constant pheromone production in individual females. The constancy of a trait can be measured as its repeatability. This quantity sets an upper limit to the fraction of the variance of that trait which is heritable, i.e., to its heritability (Falconer, 1960). A population's potential for evolutionary change is limited by the amount of heritable variation present; hence knowledge about these quantities are necessary for our understanding of the evolutionary processes molding sex pheromone communication.

The present study was undertaken to determine the day-to-day constancy of pheromone blend emission by individual female *Yponomeuta padellus* and *Y. rorellus*. The pheromone gland of *Y. padellus* contains seven acetates of which at least (Z)-9-tetradecenyl acetate (Z9-14:OAc), (*E*)-11-tetradecenyl acetate (*E*11-14:OAc), (Z)-11-tetradecenyl acetate (Z11-14:OAc), and (Z)-11-hexadecenyl acetate (Z11-16:OAc) are important for the attraction of males (Löfstedt and Van Der Pers, 1985; Löfstedt, unpublished). The pheromone gland of *Y. rorellus* contains no unsaturated acetates or alcohols and high attractivity is achieved with tetradecyl acetate as a single component (Löfstedt et al., 1986). The repeatability of pheromone emission in these species was determined by repeated collections of airborne volatiles from individual calling females.

METHODS AND MATERIALS

Insects. Insects were collected from the field as pupae or late-instar larvae. *Y. padellus* originated from several places in the province of Skåne, southern Sweden; *Y. rorellus* was collected in the Netherlands, close to Leiden, and mailed to our laboratory as pupae. The sexes were separated and the females emerged at 23°C under a reversed light–dark 16:8 photoperiod. The adults were maintained under the same conditions and fed a 5% sucrose water solution. Most females displayed their pheromone glands in a typical calling posture at the beginning of the photophase four to five days after emergence.

Collection of Airborne Volatiles from Calling Females. To allow the repeated collection of pheromone from individual females, it was essential to

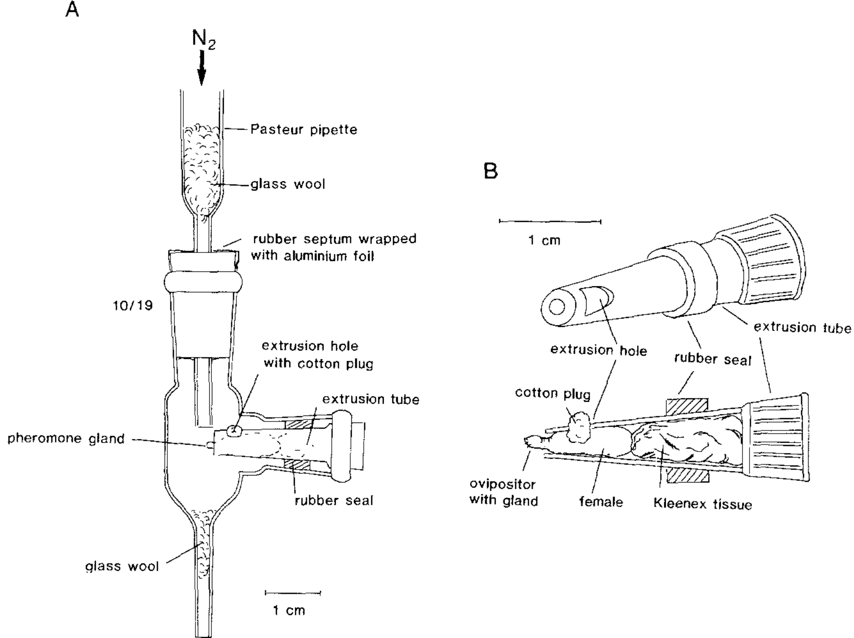

FIG. 1. (A) Device for collection of airborne volatiles from female moths, modified from Baker et al. (1981). A stream of purified nitrogen (ca. 50 ml/min) is directed to the exposed pheromone gland with a Pasteur pipet. The linear velocity at the outlet of the pipet is approximately 0.6 m/sec. (B) Expanded view of the extrusion tube with an inserted female.

employ a technique that left the females alive and in good condition after sampling. A modified version of the collection device developed by Baker et al. (1981) fulfilled this requirement (Figure 1). A calling female was placed in the extrusion tube (Figure 1B) made from a disposable plastic pipet tip (Labsystems Oy, Finland). A small piece of Kleenex tissue was inserted behind the head of the female. Then a small ball of paper was pressed into the extrusion hole, gently squeezing the female abdomen, so that the ovipositor with the sex pheromone gland was protuded. The extrusion tube with the female was placed in the holder and nitrogen, filtered through a molecular sieve and glass wool, was introduced. The carrier gas (50 ml/min) was directed towards the gland with a Pasteur pipet. The linear velocity at the outlet of the pipet, 1–2 mm from the gland, was 0.6 m/sec. Airborne volatiles were collected on glass wool during 30 min and subsequently eluted with 75 μl of hexane. The solution was condensed to 5–10 μl with a gentle stream of nitrogen in a pointed 4-cm-long × 0.4-mm-ID glass vial. All glass ware was rinsed with distilled acetone and conditioned in an oven at 300°C for at least 2 hr before use.

After collection, the female moth was immediately released in a 250-ml plastic cup, covered with a nylon screen, and kept at the same conditions as described above. The second collection was obtained two days later. Only calling females were used for the collections.

Determination of Method Error. Small pieces of rubber (3–5 mm^3) were cut out of red rubber septa (A.H. Thomas Company, Philadelphia, Pennsylvania). The rubber pieces were extracted by hexane and acetone and dried before impregnation with synthetic pheromone components. For impregnation, 10 rubber pieces were placed in a vial to absorb 100 μl of hexane containing 380 μg 14:OAc, 4 μg *Z*9–14:OAc, 45 μg *E*11–14:OAc, 100 μg *Z*11–14:OAc, 3820 μg 16:OAc, 307 μg *Z*9–16:OAc, and 2234 μg *Z*11–16:OAc. The dispensers were conditioned 2 hr at room temperature before use. Formulated in this way, one dispenser released a blend of pheromone components similar, in quantity and proportions, to the emission of an average *Y. padellus* female as determined from 30-min collections of airborne volatiles in the above-mentioned device. The overall method error was estimated by analysis of 10 airborne collections from synthetic dispensers. The precision of the GC procedure was determined by repetitive analysis of a standard solution containing one "average female *Y. padellus*-equivalent" per 3 μl hexane.

Gas-Chromatography. The concentrated solution obtained from washing of the glass wool was injected splitless (split valve opened 0.5 min after injection) on a Hewlett Packard 5880 capillary gas chromatograph equipped with a flame ionization detector. The injector temperature was 250°C and the detector temperature 275°C. The column temperature was maintained at 80°C for 2 min following injection and then programmed at 10°C/min to 230°C. A 30-m × 0.25-mm-ID Supelcowax 10 fused silica column (Supelco Inc.) was used for the separations, and hydrogen (H_2) carrier gas was supplied at 40 cm/sec linear velocity. Peak heights were used for quantification, as these provided more precise measures of standard solutions than peak areas did.

Statistical Analysis. The total phenotypic variance in the relative amounts of pheromone components (*Z*11–14:OAc = 100 by definition) was partitioned into variance within individuals and variance between individuals using a one-way analysis of variance. The repeatability (r) was calculated as r = variance between individuals/(variance between individuals + variance within individuals) (Falconer, 1960).

RESULTS

Method Error. Gas chromatographic analysis of airborne volatiles from a rubber dispenser ($N = 10$) revealed the precision of the overall method. The mean relative amounts of the respective compounds and their coefficients of variation (within parentheses) were: 14:OAc, 350.7 (2.3%); *E*11–14:OAc,

45.5 (2.8%); Z11-14:OAc, 100 (0, by definition); 16:OAc, 360.1 (7.6%); Z9-16:OAc, 50.5 (8.3%); and Z11-16:OAc, 287.3 (6.9%). The amount of Z9-14:OAc was below the limit of detection. The coefficients of variation for the 16-carbon acetates were higher than for the 14-carbon acetates. This is probably because all amounts are relative to a 14-carbon acetate. The variance in a ratio usually increases with differences in volatility between the two compounds, because of irreproducible discrimination in the split/splitless gas-chromatographic injector. Repeated analysis of a standard mixture on the GC confirmed this interpretation. The coefficients of variation of the relative amounts were 14:OAc, 2.6%; *E*11-14:OAc, 2.3%; Z11-14:OAc (0, by definition); 16:OAc, 4.8%; Z9-16:OAc, 6.3%; and Z11-16:OAc, 4.8%. Thus gas-chromatographic parameters explain most of the difference in precision between 14-carbon and 16- carbon acetates.

Females. Volatiles collected from *Y. padellus* females generally contained significant amounts of 14:OAc, *E*11–14:OAc, *Z*11–14:OAc, 16:OAc, *Z*9–16:OAc, and *Z*11–16:OAc (Figure 2). However, *Z*9–14:OAc was usually below the limit of detection. The total release rate varied between 0.7 and 16.7 ng/30 min (Table 1). However, some of this variation in absolute amounts might be due to the handling of the sample, as no internal standard was used. The quantitatively dominating constituents were 14:OAc, 16:OAc, and *Z*11-16:OAc. Upon comparison of the coefficients of variation for the different components, it appeared that the amount of *E*11–14:OAc relative to *Z*11–14:OAc was more stable (CV = 15%) than the amounts of the other compounds (CV = 46–61%) (Table 1). Most of the variation was due to between-female variation, whereas the individual females produced rather constant ratios (Table 1, Figure 2). For instance female II released low relative amounts of the 16-acetates at all four sampling occasions compared to the population means. Female IV released a high relative amount of 14:OAc, while the 16-acetates where substantially below the respective mean. Female V released low amounts of the 14-acetates. Both females VI and IX released high amounts of 16:OAc, but differed with respect to *Z*11–16:OAc and *E*11–14:OAc; female IX released a high relative amount of *Z*11–16:OAc, whereas VI was characterized by a high relative amount of *E*11–14:OAc.

The positive correlations between the composition of the pheromone emitted by individual females on their sixth and eighth day, respectively, also show the production of female-specific blends (Figure 3). The repeatability varied between 0.82 and 0.90 for the five compounds (Table 2). In the airborne collections from *Y. rorellus*, 14:OAc was the dominating constituent, as was reported elsewhere (Löfstedt et al., 1986). The total amount of 14:OAc, 14:OH, 16:OAc, and 16:OH released varied between 2.7 and 16.0 ng/30 min (Table 2). The amounts of 14:OH, 16:OAc, and 16:OH relative to 14:OAc (= 100) was 10 or lower, and the coefficients of variation were 41–50%. Only a small number of insects were available for the study, but based on five individuals, the repeatability was high for the proportions of 16:OAc and 16:OH and lower for 14:OH.

DISCUSSION

The determination of the repeatability of pheromone production is an important step in a research program on the heritability of pheromone production. The technique used by us for collection of airborne volatiles from calling females allowed two or more collections from the same female. The females were usually in such a good shape after the collections that it should be possible to mate them afterwards. Thus, the procedure is an attractive alternative to the technique used by Du et al. (1984) in their selection for abberant pheromone production in the red-banded leafroller moth. They picked only a part of the

pheromone gland for analysis to allow subsequent mating of the female. Such a technique is only applicable to high-producing moth species with easily accesible glands, whereas collection of airborne volatiles should be feasible with any moth species releasing reasonable amounts of pheromone. We were successful with female moths releasing less than 1 ng/30 min.

Measurements of the heritability of pheromone blends are rare thus far. Collins and Cardé (1985) estimated the heritability of the ratio between (Z, E)- and (Z, Z)-hexadecadienyl acetate isomers in the pink bollworm moth to be 0.35 from a breeding experiment. Working with *Argyrotaenia velutinana*, Roelofs et al. (1987) found a similar heritability for the Z11- to E11-14:OAc ratio when only females were selected. However, mating of selected females with selected males yielded a heritability twice as high (0.85), because males also contribute to the pheromone production of their daughters. This higher figure agrees with the level of repeatability observed in *Yponomeuta*. Thus *A. velutinana* seems to realize the maximum heritability that could be expected in our moths.

Ratios between Z and E isomers are generally believed to be more important for reproductive isolation than other ratios in the pheromone blend (see for instance Cardé and Baker, 1984). The results of our study seem to support this idea. The interindividual coefficient of variation for the Z/E ratio was lower

than for any of the other ratios measured. In contrast, the repeatability was equally high for all of the compounds. Thus an individual female seems to be able to control all of the ratios, not only the one between the geometric isomers, but selection for reproductive isolation might have reduced the interindividual variance in the *Z*/*E* ratio.

Acknowledgments—We are thankful to Dr. Wim Herrebout, Leiden, for the supply of *Y. rorellus* pupae and to Drs. Sigfrid Lundberg and Fredrik Schlyter, Lund, for valuable suggestions. This work was supported by grants from Swedish research councils (NFR, SJFR, FRN) to Jan Löfqvist and Christer Löfstedt. The stay of Dr. Jia-Wei Du in Lund was supported by the Swedish and Chinese Academies of Science.

Abstract—The electroantennogram (EAG) responses of both male and female *Trichoplusia ni* to two components of the female-released sex pheromone were determined over a range of concentrations of chemical and age of insect. The EAG was at a peak at a dose of 100 μg for both dodecyl acetate and (*Z*)-7-dodecenyl acetate (*Z*7–12:OAc) for both sexes. The EAG responses varied with age of the insect. Responsiveness to both components was at a maximum at three days postemergence for males followed by a fairly rapid senescence, and for females it peaked at three days followed by a rapid senescence for *Z*7–12:OAc but not for dodcecyl acetate.

Key Words—*Trichoplusia ni*, Lepidoptera, Noctuidae, (*Z*)-7-dodecenyl acetate, dodecyl acetate, pheromone, electroantennogram, age, maturation.

INTRODUCTION

Electroantennograms (EAGs) have frequently been used to show that both male and female insects can perceive many diverse odors through their antennae (Boeckh et al., 1965; Schneider, 1962; Schneider and Steinbrecht, 1968) including, in many Lepidoptera, male scent-brush secretions (Light and Birch, 1979; Seabrook et al., 1979). However, in the great majority of moths studied

0098-0331/87/0600-1443$05.00/0 © 1987 Plenum Publishing Corporation

to date, only the male antennae give EAG responses to female-produced sex pheromones (Light and Birch, 1979). In at least some of these species, the female antennae lack the sensilla trichodea associated with perception of the female-produced sex pheromone by males (Boeckh et al., 1965).

In contrast, in a few lepidopteran species such as the spruce budworm *Choristoneura fumiferana* and the cabbage looper *Trichoplusia ni*, in which there is little antennal dimorphism (Albert and Seabrook, 1973; Jefferson et al., 1970), the sex pheromone emitted by the female is detected by females of the same species (Palaniswamy and Seabrook, 1978; Ross et al., 1979; Grant, 1970; Light and Birch, 1979) and can influence the behavior of conspecific females (Palaniswamy and Seabrook, 1978; Birch, 1977). The EAGs from female spruce budworm antennae from moths of different ages and for various pheromone concentrations have been studied (Ross et al., 1979).

The major component of the pheromone produced by female cabbage loopers was first identified as (Z)-7-dodecenyl aceate (Z7–12 : OAc) (Berger, 1966). A second component, dodecyl acetate (12 : OAc) comprises 9.6% by weight of the total pheromone extracted from glands (Bjostad et al., 1980). In the present study, the effect of age and the concentration of the two major components of the pheromone on EAG response in male and female *T. ni* was investigated.

METHODS AND MATERIALS

A colony of *Trichoplusia ni* was maintained in the laboratory using a method similar to that described by Shorey and Gaston (1964). All stages were maintained at a temperature of 25°C ± 2°C. They were sexed as pupae and thereafter kept separately by sex.

The EAG recording system used in this study was similar to that described by Roelofs and Comeau (1971) with the exception that a unity gain voltage follower was used in place of the 100 × amplifer. The recording electrode was made from a Pasteur pipet containing a silver–silver chloride wire electrode and filled with Pringle's Ringer (containing 156 mM NaCl, 2.7 mM KCl, 1.8 mM $CaCl_2$, and 22 mM glucose at pH 6.8). The preparation was grounded through a third electrode to a common ground via the saline pool in which the proximal end of the antenna was placed.

Antennae were exposed to test compounds in 1-sec puffs. The compounds were carried in ultra-zero-grade bottled air (Matheson Co.) at a flow rate of 150 ml/min. The odor-delivery system was similar to that described by Albert et al. (1974). An odor-evacuation system was set up immediately adjacent to the preparation in order to prevent a possible build-up of pheromone near the antenna. This provided a flow of clean air at a velocity of approximately 1 cm/sec over the preparation between releases of test chemicals.

The 12:OAc and Z7–12:OAc (both 99+ % pure by GLC) were dissolved in ether at concentrations ranging from 10^{-5} to 10^{+3} μg per 50 μl of solvent. Fifty-microliter aliquots of the test solution were applied to 1.5 × 1.5-cm pieces of Whatman No. 1 filter paper and evaporated to dryness at room temperature. The treated filter papers were placed in glass tubes (6 mm inside diameter × 65 mm long), which were then wrapped in Parafilm until used later that same day. The control stimulus was a similar piece of filter paper, treated with 50 μl of ether and evaporated to dryness. Each stimulus source was used no more than three times.

Each antennal preparation was initially exposed to a control stimulus. This was followed by an experimental stimulus after a 3-min recovery period. It is known that in *T. ni* essentially complete recovery of antennal sensitivity to pheromone occurs within 30–60 sec at the flow rates and concentrations used (Payne et al., 1970; Mayer, 1973; Light and Birch, 1979). EAG responses to both control and pheromone stimuli were photographed directly from the oscilloscope screen on Polaroid film, and amplitude measurements were made from the resulting prints. The stimulus EAG peak voltage was calculated by subtraction of the control voltage from the voltage generated by a given compound. As there was no apparent reduction in the EAG voltage during the 1-sec test, a more sophisticated treatment of the data (Roelofs and Comeau, 1971) was not necessary.

The EAG saturation concentration, the concentration of odorant molecules beyond which there is no further increase in EAG amplitude (Boeckh, 1969), for each sex was found from a dose–response curve obtained from exposing antennae from 3-day-old insects to one of a series of concentrations for each chemical and determining the corrected stimulus EAG voltage. By this age, male *T. ni* are known to respond maximally to sex pheromone, and the percentage of males mating has reached a peak (Shorey et al., 1968b). The saturation concentration was then used as the stimulus for antennae from moths of both sexes ranging in age from 1 day postemergence to 7 or 8 days postemergence. Three replicates were carried out for each test.

RESULTS

The EAG dose–response curves for the tested compounds for both males and females are shown in Figures 1 and 2. The saturation concentration was reached at a dose of 100 μg in both sexes and for both pheromone components. At this saturation concentration, the response of the male antenna to the principal pheromone component, Z7–12:OAc, was more than three times that of the female antenna. At lower doses, the difference in magnitude of response between male and female antennae, although reduced (Figure 1), remained significant ($P < 0.01$, Wilcoxon signed-ranks test for matched pairs). As the con-

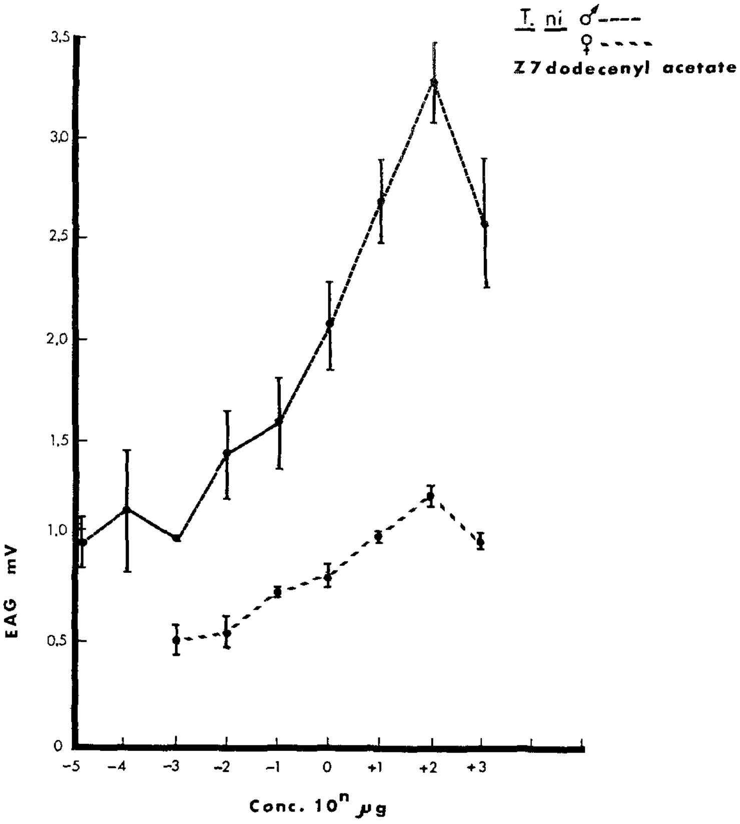

FIG. 1. Dose-response curves for 3-day-old male and female *T. ni* exposed to various concentrations of (Z)-7-dodecenyl acetate. Means are ±SEM. At doses between 0.1 and 100 μg, the regression for male response is $\hat{Y} = 2.14 + 0.570X$, $r^2 = 0.832$ and for female the regression is $\hat{Y} = 0.868 + 0.164X$, $r^2 = 0.878$.

centration of Z7–12:OAc was increased, the increase in the mean amplitude of the EAG became significant at 0.1 μg for both males and females [$P < 0.05$, Student-Newman-Keuls (SNK) test for comparison of differences among means]. In both sexes the EAG amplitude increased as concentration was increased from 0.1 to 100 μg ($r^2 = 0.832$ for male response, $r^2 = 0.878$ for female response).

In the dose-response curves for 12:OAc, male and female sensitivities are most similar (1.4 mV vs. 1.3 mV) at or near the saturation concentration, but at lower doses, females are much less sensitive than males ($P < 0.025$, Wilcoxon signed-ranks test for matched pairs) (Figure 2).

When the EAG responses of the female antennae to each component are compared, the two curves are quite similar in shape, and the peak EAG ampli-

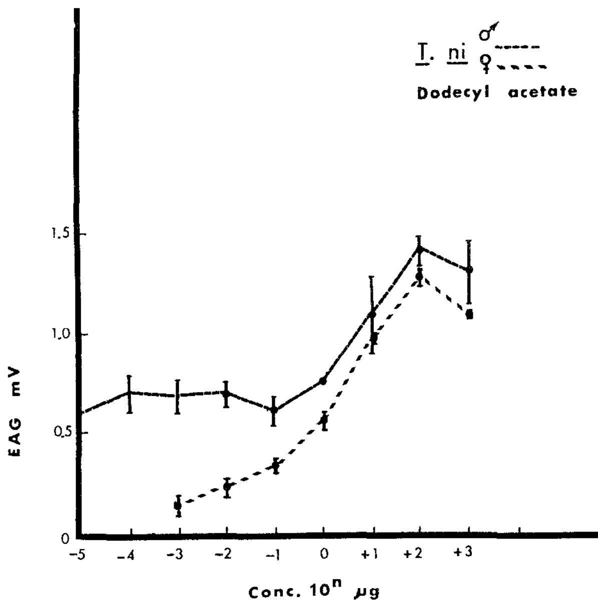

FIG. 2. Dose-response curves for 3-day-old male and female *T. ni* exposed to various concentrations of dodecyl aceate. Means are ±SEM. At doses between 0.1 and 100 μg, the regression for male response is $\hat{Y} = 0.842 + 0.274X$, $r^2 = 0.775$, and for females the regression is $\hat{Y} = 0.628 + 0.324X$, $r^2 = 0.973$.

tudes are approximately the same (1.2 mV and 1.3 mV), although at low stimulus concentrations, the female appears to be less sensitive to 12:OAc than to Z7-12:OAc.

In contrast, over all concentration ranges, the amplitude of EAGs from male antennae is two or three times larger for Z7-12:OAc than for 12:OAc. The changes in the mean EAG amplitudes of male responses to increasing doses of dodecyl acetate were not significantly different at concentrations below 10 μg ($P < 0.05$, SNK test). For females, significant increases in mean EAG responses began above 0.01 μg of 12:OAc.

The sensitivity of both male and female antennae to both pheromone components differs with age (Figures 3 and 4). In male antennae, at three days after emergence, the magnitude of response to both compounds reaches a peak significantly higher than the magnitude on day 1 ($P < 0.05$, SNK test). In females the response to Z7-12:OAc also reaches a peak on day 3 which is significantly higher than the response on either the preceding or the following day ($P < 0.05$, SNK test), but there does not appear to be a clear peak in sensitivity to 12:OAc related to age. The temporal pattern of response obtained for the maturation and senescence of the response to both chemicals is similar in males, but not in females. Senescence of the response after day 3 was fairly rapid until

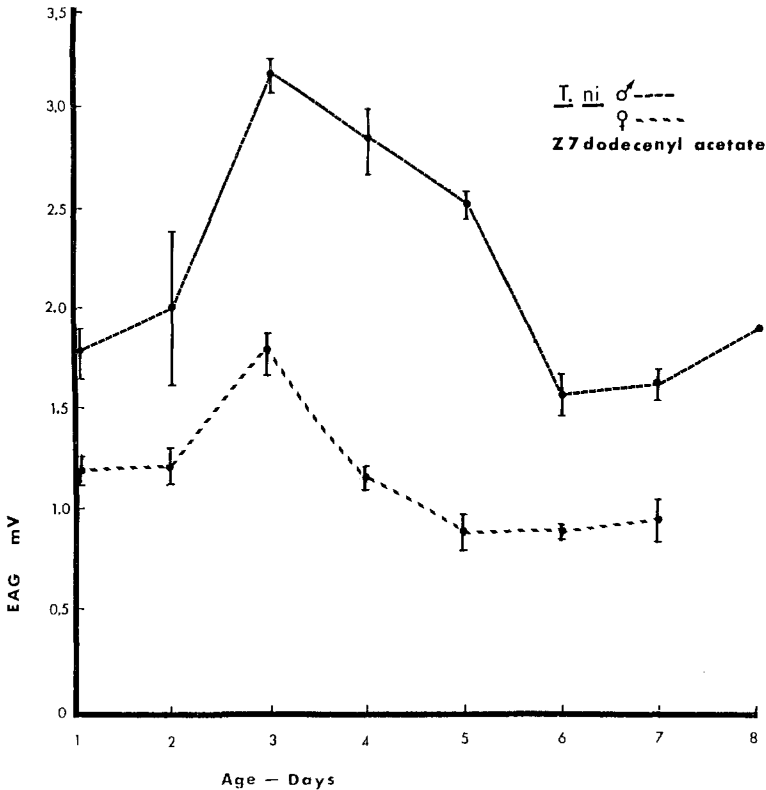

FIG. 3. Effects of age on the antennal response of male and female *T. ni* to a 100-μg source of (Z)-7-dodecenyl acetate. Means are ±SEM.

day 5 or 6, except for females to 12:OAc. The EAG voltage dropped to half of its peak value by six days postemergence for the response of males to both components and the response of females to Z7–12:OAc. Female responses to 12:OAc senesced more slowly. At ages of 6 days or over, there was no further senescence of the response.

DISCUSSION

Many aspects of the responses, both behavioral and electrophysiological, of male *Trichoplusia ni* to pheromones have been extensively studied and are probably better known than for any other species of moth. However, the responses of the females to their own sex pheromones have received much less attention. The shape of the dose–response curve obtained over the range of 10^{-3} to 10^{+2} μg of Z7–12:OAc is similar to that obtained by Mayer (1973) (Figure

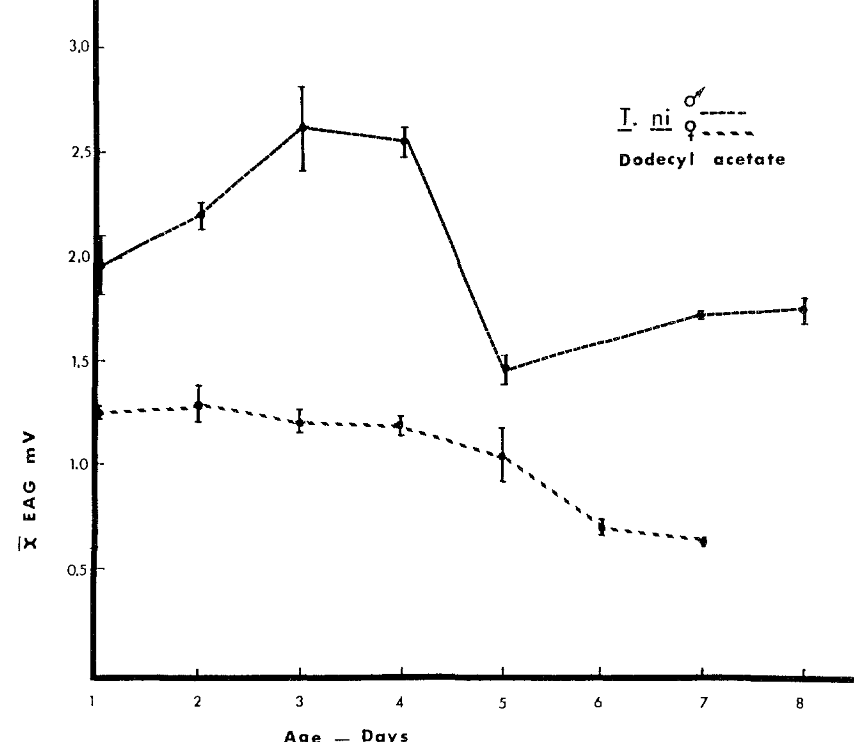

FIG. 4. Effects of age on the antennal response of male and female moths to a 100-μg source of dodecyl acetate. Means are ±SEM.

1). The dose-response curve for male *T. ni* to Z7-12:OAc reported by Alford and Hammond (1982) covered a wider range of doses and showed a similar trend, except that they did not detect a decrease in EAG amplitude at concentrations higher than 10^{+2}. On the other hand, Payne et al. (1970) and Grant (1970) did detect a reduction in male EAG amplitude at higher concentrations of Z7-12:OAc.

Mayer (1973) estimated that the EAG in response to a stimulus of dodecyl acetate indicated a sensitivity roughly 500 times less than that to looplure. The data presented in Figure 2 confirm that the EAG response of male *T. ni* to 12:OAc is lower in amplitude at all concentrations tested than the EAG produced by Z7-12:OAc by about the same amount found by Grant (1970).

The trend of the dose-response curve would indicate that male *T. ni* moths should be unable to detect a change in concentration at low concentrations of 12:OAc. This does not appear to be true of females or of Z7-12:OAc for either males or females. At a level of stimulation close to the peak of the dose-re-

sponse curve, both males and females could detect a concentration gradient, since in this range responses change with a change in stimulus concentration (Figures 1 and 2). Females are known to respond to pheromone lures (both Z7–12:OAc and virgin females) in this species (Birch, 1977), and EAG recordings have been obtained previously from female antennae exposed to Z7–12:OAc (Grant, 1970; Light and Birch, 1979). The amplitude of the female EAG response to a 2-μg standard dose of Z7–12:OAc has been found to be only 25% that of the male (Light and Birch, 1979). Although we did not use a stimulus of 2 μg, at a dose of 1 μg of Z7–12:OAc the female response was approximately 40% of the male EAG (0.82 ± 0.06 mV vs. 2.08 ± 0.22 mV), and the curves for male and female had the same general shape (Figure 1).

In the spruce budworm, the pheromone dose–response curves for males and females also have the same shape, although these curves are more obviously sigmoid (Ross et al., 1979) than those of *T. ni* to Z7–12:OAc. However, in the budworm, the difference in amplitude of the EAG between the sexes is less pronounced and disappears entirely at concentrations between 10^{-5} and 10^{-1} μg of pheromone (Ross et al., 1979).

Antennal response of *T. ni* to both pheromone components changes with the age of both females and males. In males the response to both compounds increases initially to reach a peak at three days after eclosion, remains at a high level for two or three days, then declines sharply to levels below those found on day 1 before leveling off (Figures 3 and 4). The pattern between age and mating frequency of males shows some similarities to this pattern in that mating frequency peaks between three and four days of age, and then begins to decline slightly (Shorey et al., 1968a). Shorey et al. (1968b) found that the age at which 50% of males responded behaviorally to pheromone at a dose of 10^{-3} female equivalents was 2 days, approximately the time sexual maturity was reached, but response levels remained high thereafter (Shorey and Gaston, 1964; Payne et al., 1970). Payne et al. (1970) also found that newly emerged males responded behaviorally only to high concentrations of Z7–12:OAc and responsiveness to lower concentration increases rapidly through the age of 2.5 days.

The pattern of male response over time is quite different from that reported for the spruce budworm, which showed only small and irregular changes with age (Ross et al., 1979). It bears some resemblance to the pattern of maturation and senescence in EAGs from male *Pseudaletia unipunctata* in response to the male-produced scent brush odors (Seabrook et al., 1979), but the changes in amplitude are less dramatic.

The response from female antennae to the two components over time showed different patterns. Sensitivity to Z7–12:OAc peaked at the age of 3 days, as it did in males (Figure 3), followed by a decline. The shape of the curve and the timing of the peak are quite similar to the relationship found between age and mating frequency (Shorey et al., 1968a). The peak is close to

the time of egg maturation (Shorey et al., 1968a). A similar pattern of maturation followed by senescence in female response to pheromone has been reported in spruce budworm (Ross et al., 1979) and in *P. unipunctata* (Seabrook et al., 1979).

In contrast, the sensitivity of the female antenna to 12:OAc appeared to remain fairly constant for several days, after which it began to decline slowly (Figure 4).

This difference in the pattern of maturation and senescence of the EAG response to the two pheromone components implies that the cells sensitive to Z7-12:OAc and to 12:OAc mature and senesce at different rates. This could be due to an increase followed by a decrease in the number of available acceptors, which in turn could be under hormonal control, as has been suggested for the spruce budworm (Palaniswamy and Seabrook, 1985). Such a hormone could act on different cells differentially. If the argument that at saturation concentration all available acceptor sites are occupied is correct, and if the two pheromone components are occupying the same acceptors, then one would expect the EAG response to each component to mature and senesce at the same rate over time. Since this does not happen in the case of the female EAGs, we assume that different acceptors are used to bind Z7-12:OAc and 12:OAc.

For both components of the pheromone, the sensitivity of females at all ages appears to be considerably less than that of males. This was also true in the spruce budworm at high concentration (Ross et al., 1979). In the case of the budworm, it was suggested to be due to the fact that female antennae have one third to one half the number of sensilla trichodea found on male antennae (Albert and Seabrook, 1973). In males, the sensilla trichodea are known to be the pheromone receptors (Albert et al., 1974). This explanation may also hold for *T. ni*, as there is some sexual dimorphism between male and female antennae based on the relative numbers of the sensillae trichodea (Jefferson et al., 1970). However, there also is a difference in the ability of the antennae to enzymatically degrade Z7-12:OAc, with male antennae being capable of degrading the pheromone component to an alcohol twice as fast as the female (Mayer, 1975). It is possible that this could also contribute to the observed response differences.

(Received May 14, 1986; accepted September 3, 1986)

Abstract—Abdominal volatiles of female mountain pine beetles, *Dendroctonus ponderosae* Hopkins, fed in ponderosa pine, *Pinus ponderosa* Dougl. ex Laws, and in lodgepole pine, *P. contorta* var. *latifolia* Engelmann, were analyzed by gas chromatography and coupled gas chromatography-mass spectrometry and were found to comprise host oleoresin components and beetle-produced alliylic alcohols, aldehydes, and ketones derived from host monoterpenes. Neither *exo*- and *endo*-brevicomin nor frontalin were detected. Three metabolic pathways are proposed to account for the distribution of beetle-produced monoterpene alcohols. The first pathway involves hydroxylation of monoterpene substrates on allylic methyl groups which are *E* to a methylene or vinyl group. This oxidation pathway is indiscriminate with respect to substrate and probably functions to detoxify monoterpenes. A second pathway, which hydroxylates the *endo*-cyclic methylene *E* to a vinyl methyl group of bicyclic monoterpenes to give almost exclusively the *trans* alcohol, is hypothesized to be involved in pheromone production. A third detoxification pathway involves anti-Markovnikov addition of water to the *exo*-cyclic double bond of β-phellandrene to give predominantly *trans*-2-p-menthen-7-ol.

Key Words—*Dendroctonus ponderosae*, mountain pine beetle, Coleoptera, Scolytidae, monoterpene metabolism, monoterpene alcohols, pheromones, allylic hydroxylation, anti-Markovnikov hydration, *Pinus ponderosa*.

INTRODUCTION

During the early phases of attack by bark beetles, living pine trees exude oleoresin in which the predominant volatile components are monoterpenes. To survive in galleries filled with volatile, toxic monoterpenes (Smith, 1965, 1966), these beetles must possess effective mechanisms for monoterpene metabolism. The primary products of monoterpene metabolism in pine bark beetles, especially in the genera *Ips* and *Dendroctonus*, are the corresponding allylic alcohols which may undergo rearrangement, hydrogenation, or further oxidation (White et al., 1980; Francke and Vité, 1983). It was initially proposed that these insects possessed enzymatic systems which detoxify monoterpenes by nonspecific oxidation of allylic positions (Hughes, 1973a; Renwick and Hughes, 1975). There is, however, evidence that if the oxidation products are pheromones, the process can be highly stereo- and enantioselective (Renwick et al., 1976a; Fish et al., 1979; Klimetzek and Francke, 1980; Byers, 1983).

The mountain pine beetle, *Dendroctonus ponderosae* Hopkins, successfully colonizes and kills millions of lodgepole pines (*Pinus contorta* var. *latifolia* Engelmann) and ponderosa pines (*Pinus ponderosa* Dougl. ex Laws.) each year in western North America. Such success is evidently due in part to the ability of the pioneer female beetles to metabolize host monoterpenes efficiently without discrimination and to produce aggregation pheromones which induce mass attack.

The volatile constituents of the oleoresin of these pines are acyclic, monocyclic, and bicyclic monoterpenes (Smith, 1965, 1966). Emergent female *D. ponderosae* are devoid of volatile, monoterpene-derived attractants (Pitman and Vité, 1969; Hughes, 1973b); they produce these compounds only after attacking fresh host trees. The biological activity of several of the female-produced compounds has been investigated in the laboratory (Conn 1981) and in the field (Conn et al., 1983; Borden et al., 1983, 1986; Libbey et al., 1985).

Despite the growing knowledge of volatiles produced by *D. ponderosae*, the hypothesis that these beetles efficiently metabolize a wide range of monoterpenes in detoxification reactions has not been rigorously tested. Our major objective was to investigate in detail monoterpene metabolism in female *D. ponderosae* during the initial stage of gallery construction in ponderosa and lodgepole pines.

METHODS AND MATERIALS

Instrumental Methods. A Hewlett-Packard 5830 gas chromatograph equipped with an 18835B capillary inlet system and a flame-ionization detector

was employed for analyses by gas–liquid partition chromatography (GC). Micropreparative GC was carried out with a Varian 1200 instrument fitted with a 10:1 effluent splitter, a thermal gradient collector (Brownlee and Silverstein, 1968), and a 3.05-m × 3.18-mm-OD stainless steel column packed with 10% SP-1000 on Chromosorb W AW (100/120) (Supelco, Inc., Bellefonte, Pennsylvania). For both chromatographs, injection port and detector temperatures were 260° and 275°C, respectively.

A Hewlett-Packard 5985B GC/MS/DS was employed for coupled gas chromatography–mass spectrometry (GC-MS). Glass (0.25 mm ID) or fused silica (0.32 mm ID) open-tubular columns (30 m) coated with SP-1000 or Carbowax 20 M (J & W Scientific, Inc., Rancho Cordova, California) were used. The injection port, Pt-Ir transfer line, and ion source were maintained at 260°, 240°, and 200°C, respectively. Helium was the carrier gas for GC and GC-MS.

A Varian 5000 liquid chromatograph was utilized for high-performance liquid chromatography (HPLC). Column effluent was monitored at 220 nm with a Varian Series 634S UV-visible spectrophotometer fitted with microvolume flow cells.

Reference Compounds for Gas Chromatography and Mass Spectrometry. Components were identified by comparison of their mass spectra (GC-MS) with those of authentic samples or published reference spectra. Commercially available compounds were; *exo-* and *endo*-brevicomin and (+)-3-carene (Albany International, Columbus, Ohio), α-pinene, and (+)-*p*-mentha-1,8-dien-10-ol (Aldrich Chemical Co., Milwaukee, Wisconsin), *p*-mentha-1,8-dien-7-ol (perilla alcohol) (CA Aromatics Co., Floral Park, New York), carvone, β-citronellal, geraniol (Eastman Organic Chemicals, Rochester, New York), acetophenone and 2-phenylethanol (Matheson Coleman & Bell, East Rutherford, New Jersey), *p*-isopropylbenzaldehyde, *p*-isopropylbenzyl alcohol (Pfaltz and Bower, Inc., Stamford, Connecticut) and β-myrcene (Sigma Chemical Co., St. Louis, Missouri).

Compounds generously donated were: ipsdienol and *cis*-verbenol (L.E. Browne, University of California, Berkeley, California); *cis-* and *trans*-2-*p*-menthen-7-ol, *p*-mentha-2,4(8)-dien-9-ol and *p*-mentha-2,4(8)-dien-10-ol (F. Camps, Instituto de Quimica Bio-organica, Barcelona, Spain); 3-caren-9-ol (T. Ishida, Hiroshima Institute of Technology, Hiroshima, Japan); (−)-β-phellandrene and (+)-*trans*-verbenol (B.J. Kane, SCM Organic Chemicals, Jacksonville, Florida); *p*-mentha-1,8-dien-4-ol, *p*-mentha-1,4(8)-dien-9-ol, and *p*-mentha-1,4(8)-dien-10-ol (E. Klein, Dragoco, Holzminden, Federal Republic of Germany); *m*-mentha-4,6-dien-8-ol and *p*-mentha-1,5-dien-8-ol (J.A.A. Renwick, Boyce Thompson Institute for Plant Research, Ithaca, New York); *trans*-pinocarveol (L.C. Ryker, Oregon State University, Corvallis, Oregon); frontalin (K.N. Slessor, Department of Chemistry, Simon Fraser University); and geranyl acetate (J.W. Wong, Department of Chemistry, Simon Fraser University).

Compounds synthesized by methods in the literature were: 2-caren-10-al (Büchi et al., 1969), 3-caren-10-al and 3-caren-10-ol (Gollnick et al., 1965; Gollnick and Schade, 1966a), 3-caren-5-one (Boyle et al., 1971; Burns et al., 1968), *p*-mentha-1,3-dien-7-al (Kayahara et al., 1968), *p*-mentha-1,4-dien-7-ol (Varo and Heinz, 1970a, b), (*E*)-2-methyl-6-methylene-octa-2,7-dienol (*E*-myrcenol) (Büchi and Wüest, 1967), and *cis*-3-pinen-2-ol (Whitham, 1961). 2-Caren-10-ol, 3-caren-5-ols, β-citronellol, *p*-mentha-1,3-dienol, and 1-phenylethanol were prepared by reduction of the parent aldehyde or ketone with lithium aluminum hydride in ether or sodium borohydride in ethanol. Perilla aldehyde and verbenone were prepared by oxidation of the precursor alcohols with MnO_2 and Jones reagent, respectively.

Hydroboration of (−)-β-phellandrene with borane–tetrahydrofuran complex (Aldrich Chemical) gave, after oxidative work-up, extraction, and vacuum distillation, a 1:3 mixture of *cis*- and *trans*-2-*p*-menthen-7-ols in 56% yield.

3-Thujen-10-ol. Steam distillation–continuous extraction (Flath and Forrey, 1977) of the macerated (Waring blender) foliage (2 kg) from a *Juniperus* sp. yielded 52 g of crude leaf oil. From this, a monoterpene fraction (21.7 g), containing approx. 45% sabinene, was obtained by distillation at water aspirator pressure. Redistillation of this material through a Nester-Faust annular Teflon spinning band column gave 6.1 g of sabinene with a purity >99%. Since photosensitized oxygenation of sabinene gave none of the reported hydroperoxide photoproduct (Dässler, 1959), sabinene was isomerized with potassium *t*-butoxide in dimethyl sulfoxide (Acharya et al., 1969) to a mixture of α-thujene (88%), sabinene (9%), and unidentified compounds (3%). Selenium dioxide oxidation of α-thujene (Catalan and Retamar, 1972) gave 3-thujen-10-al, in a complex mixture, which was reduced directly with sodium borohydride in ethanol. A pure sample of 3-thujen-10-ol was isolated by preparative GC from the distilled product. NMR (Varian A56/60A) (CCL_4 + 1% TMS): δ 0.005 (m, 1H, C-6 H_{endo}), 0.78 (dd, J = 4 Hz, J = 7.3 Hz, 1H, C-6 H_{exo}), 0.84 and 0.89 (d, J = 7.3 Hz, 6H, C-8 H and C-9 H), ca. 1.5 (m, 2H, C-5 H and C-7 H), 2.21 and 2.41 (AB quartet, J_{AB} = 17.9 Hz, 2H, C-2 H_{exo}, C-2 H_{endo}), 4.1 (s, 2H, C-10 H), 5.16 (s, 1H, C-3 H).

Collection and Maintenance of D. ponderosae. Beetles were allowed to emerge from caged lodgepole or ponderosa pine logs cut from infested trees obtained from interior British Columbia. Emergent beetles were collected periodically and kept at 2–4°C in jars containing moist dental cotton wicks and tissue paper.

Frass Production and Isolation of Abdomens from D. ponderosae. Female beetles were placed into entrance holes preformed in ponderosa (or in one case lodgepole) pine logs. The longer portion of a gelatin capsule was secured over each entrance hole with a loop of masking tape. After 24 hr the capsules were removed and the frass collected. Beetles were chipped from the bark and held over ice until dissection. Freezing of intact insects without or under solvent

resulted in disappearance of all volatiles upon later extraction (unpublished data). Therefore, abdomens were removed and immediately immersed in distilled pentane contained in a vial set in Dry Ice. No more than 100 abdomens were placed in each vial since in numbers more than 100, the frozen abdomens could not be crushed thoroughly. Frass and whole or crushed abdomens under pentane and frass were stored at −44°C.

Isolation of Abdominal Volatiles of Female D. ponderosae *by Codistillation with Water.* A pentane slurry of 530 crushed abdomens from female beetles fed 24 hr in ponderosa pine was placed in a 100-ml round-bottomed flask to which was added approx. 50 ml of distilled water. The magnetically stirred contents of the flask were heated to boiling, and the distillate was collected under a layer of chilled (~5°C) pentane. After approx. 35 ml of water had distilled, 30 ml of distilled water was added to the flask, and the distillation was continued until approx. 15 ml of water remained. The water and pentane layers were separated, and the aqueous layer extracted twice with pentane. The pentane extracts were dried (Na_2SO_4), filtered, and concentrated by slow distillation of solvent through a Vigreux column to a small volume (2–3 ml). The concentrated solution was made up to 5.3 ml (100 beetle equivalents/ml). A 1-ml aliquot was concentrated to approx. 10 μl for analysis by GC-MS.

Isolation of Abdominal Volatiles by Steam Distillation–Continuous Extraction. The volatiles of approx. 1000 abdomens from female beetles feeding in ponderosa pine were isolated by steam distillation–continuous extraction (SD-CE) (Godefroot et al., 1981, 1982). Aliquots (150–200 μl) of the pentane extract (1 ml) were employed for GC-MS analyses.

Isolation of Abdominal Volatiles of Female D. ponderosae *at Reduced Pressure.* The pentane extract of approx. 500 abdomens from females fed 24 hr in ponderosa pine was vacuum-distilled (0.001 mm) in a one-plate distillation apparatus (Varo and Heinz, 1970a). The cold finger of the apparatus was cooled with liquid nitrogen and the volatiles were collected for 1 hr. The cold finger was rinsed with acetone to remove the distillate. The solution was dried (Na_2SO_4) and concentrated under a stream of nitrogen to approx. 100 μl for analyses by GC and GC-MS.

Isolation of Primary Terpene Alcohols from Frass Volatiles. Steam was passed through 10 g of frass produced by female beetles feeding in ponderosa pine until 750 ml of distillate had collected under a layer of chilled pentane. The water layer was extracted with pentane (3 × 100 ml). The combined extracts were dried ($Na_2SO_4 + MgSO_4$), filtered, and concentrated by distillation. The final volume of the extract was made up to 10 ml of which 5 ml was concentrated to approx. 50 μl by evaporation under a stream of nitrogen. The concentrate was separated by HPLC on a 30-cm × 4-mm-ID MicroPak Si-10 column with hexane–isopropyl alcohol (99:1, v/v) as eluent (2 ml/min) to give three fractions: fraction 1, 0–10 min; fraction 2, 10–12 min; and fraction 3, 12–20 min. All fractions were concentrated to 1 ml under a stream of nitrogen.

Ponderosa Pine Phloem Oil. Steam was passed through 400 g of ponderosa pine phloem tissue (cut into small pieces) until 1200 ml distillate was collected. The distillate was extracted with pentane (3 × 100 ml). The combined extracts were dried ($MgSO_4$), filtered, and concentrated to ~1 ml by distillation of solvent through a Dufton column. Residual solvent was removed under a stream of nitrogen to give 220 mg of crude oil (0.055% of wet weight).

RESULTS

Abdominal Volatiles of Female D. ponderosae *Fed in Ponderosa Pine.* Typical total ion chromatograms of volatiles obtained from crushed abdomens of female beetles fed on ponderosa pine are shown in Figures 1 and 2. One sample (Figure 1) was obtained by steam distillation and subsequent pentane extraction of the distillate. A second sample (Figure 2) was obtained by steam distillation–continuous extraction. The terpene alcohol regions of the two samples reveal many of the same components, but differ markedly in the relative proportions of the components. In these two and several other samples, *trans*-verbenol (Scheme 1, 2t),[6] 3-caren-10-ol (Scheme 2, 10), and perilla alcohol (Scheme 9, 63) were the dominant terpene alcohols. *cis*-Verbenol (2c) was usually present as a minor component.

The only carbonyl compounds identified in these samples were verbenone (4), 3-caren-10-al (12), 3-caren-5-one (13), and perilla aldehyde (65). There was some evidence that metabolism of allylic alcohols to carbonyl compounds was dependent on substrate availability. For example, perilla aldehyde (65) was not detected in Figure 1, where perilla alcohol (63) was present in low relative amounts. In Figure 2, 63 was a major peak and 65 was present. Similar arguments apply to 10 and12. Verbenone (4) always accompanied 2t.

Acetophenone (18), 1-phenylethanol (19), and 2-phenylethanol (20) (Figure 3) were present in variable amounts in all samples. Neither *exo*- or *endo*-brevicomin (21 or 22) nor frontalin (23) was detected in female beetle volatiles. Compounds 18–23 were not present in the host phloem, although we found the commonly occurring natural products 24–29 (Figure 4) of phloem oil.

Verbenone (4) and *m*-mentha-4,6-dien-8-ol (11) coeluted under the analytical conditions of Figure 1. The mass spectrum of the latter was indistinguishable from that of *p*-mentha-1,5-dien-8-ol (6). Complete resolution of 4, 6, and 11 was achieved on the fused silica column (Figure 2) on which 12 eluted as a shoulder on 6. *trans*-Pinocarveol (16) was apparently the only beetle-de-

[6]The chiral structures shown in Schemes 1–3 and 5 are based upon the predominant enantiomers of α-pinene [(−)-1], 3-carene [(+)-7], β-pinene [(−)-14] and β-phellandrene [(−)-34] occurring in the oleoresins of ponderosa and lodgepole pines of the Pacific Northwest (Mirov, 1961). We did not independently determine the chiralities of the beetle-produced compounds or host monoterpenes.

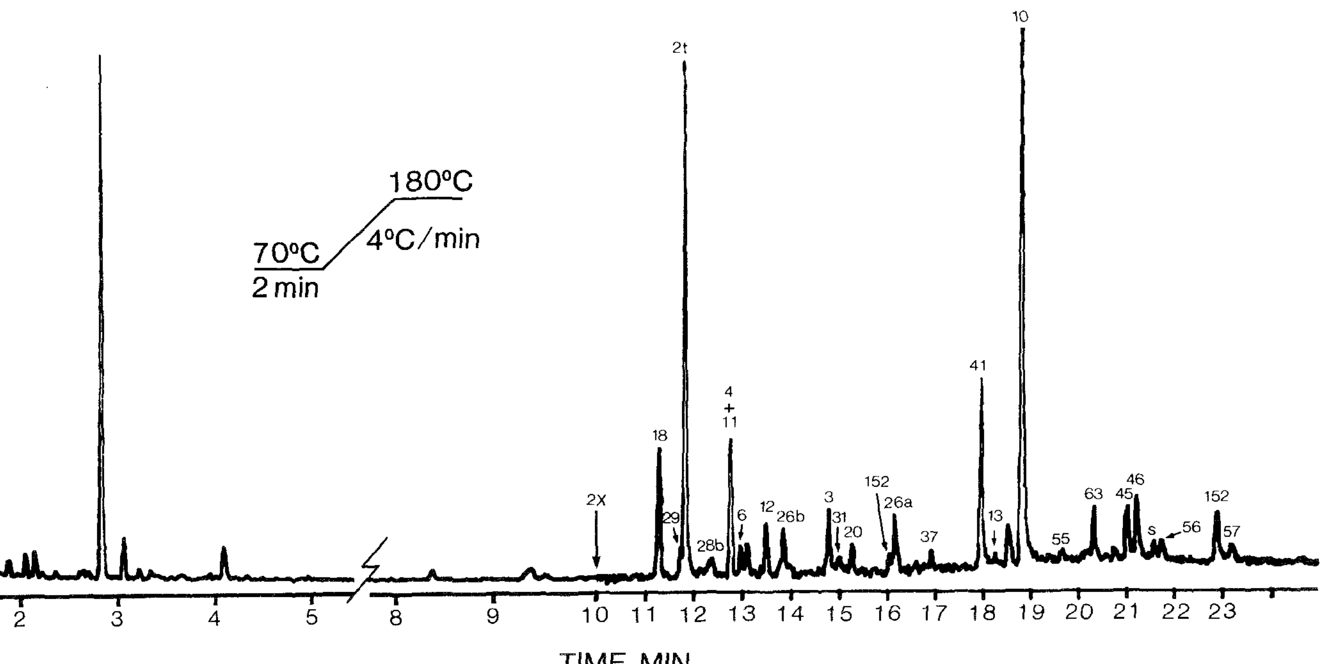

FIG. 1. Total ion chromatogram of the abdominal volatiles from female *D. ponderosae* fed 24 hr in ponderosa pine. Volatiles were isolated by codistillation-extraction and analyzed on a 30-m × 0.25-mm-ID borosilicate glass column coated with SP-1000. Note vertical scale expansion of 2× at R_t = 10 min. Intensities of peaks with R_t > 10 in are normalized on constituent 2t. See Table I for peak assignments. Molecular weights of unknown peaks are indicated by 150, 152, or 154. s = unknown sequiterpene.

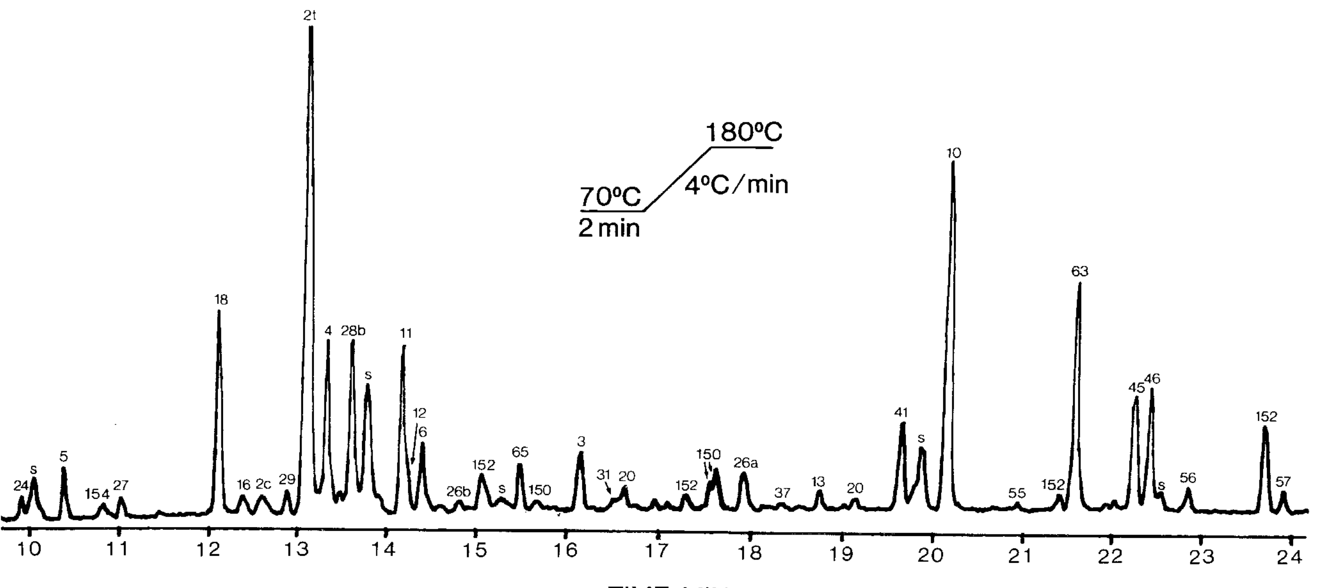

FIG. 2. Terpene alcohol region of the total ion chromatogram of the abdominal volatiles from female *D. ponderosae* fed 24 hr in ponderosa pine. Volatiles were isolated by steam distillation–continuous extraction and analyzed on a 30-m × 0.32-mm-ID fused silica column coated with SP-1000. Intensities of peaks are normalized on constituent 2t. See Table 1 for peak assignments and legend to Figure 1.

rived metabolite of β-pinene (14) encountered (Scheme 3).

3-Thujen-10-ol (Scheme 4, 31, and Figures 1 and 2) was the only confirmed metabolite of α-thujene (30), a trace component of ponderosa pine oleoresin (Smith, 1977). The mass spectra of peaks at R_t = 15.8 min (mol wt = 150) and R_t = 17.3 min (mol wt = 152) in Figure 2 were quite similar to the published spectra of 3-thujen-2-one (umbellulone, 33) and *trans*-3-thujen-2-ol (*trans*-umbellulol, 32t) (Wheeler and Shonowo, 1974). While the R_t of the earlier eluting peak was appropriate for 33, that of the second peak seemed too long for 32t. Until authentic samples of 32 and 33 are available for measurement of their mass spectra and R_t's, the status of these oxidation products of α-thujene (30) remains undetermined.

The compound eluting directly after 26a in Figures 1 and 2 could be identified only as a 2-*p*-menthen-7-ol (37) (Scheme 5) since authentic samples of the *cis* and *trans* isomers were unavailable at the time the spectrum was recorded for R_t measurements. Although 37 was present only in small amounts

in female beetles fed in ponderosa pine, it was a major constituent of a female from lodgepole pine (Figure 4).

(*E*)-Myrcenol (41) was the only metabolite of myrcene (38) found in female beetle volatiles (Scheme 6). Although no authentic sample of the known *Z*-isomer (40) (Granger et al, 1972) was available, analysis of synthetic (*E*)-myrcenol (41) by GC-MS did reveal the presence of a minor component (presumably 40, $E:Z = 98:2$) with an identical mass spectrum which eluted slightly before 41. Examination of Figures 1 and 2 in the region between geraniol and (*E*)-myrcenol (41) in these preparations failed to detect *Z*-myrcenol (40).

Of the possible primary alcohols derivable from allylic oxidation of terpinolene (Scheme 7, 44), only dienols 45 and 46 were confirmed in female

SCHEME 4. Allylic oxidation products derived from (+)-α-thujene (30).

SCHEME 5. Allylic oxidation and hydration products of (−)-β-phellandrene (34).

volatiles. The mass spectrum and gas and liquid chromatographic properties of the component eluting at R_t = 22.9 min in Figure 1 and at R_t = 23.8 min in Figure 2 suggested that it was *p*-mentha-1,4(8)-dien-7-ol (47). Its mass spectrum was similar to that of 45, and the compound was produced in an amount comparable to 45 and 46. Perilla alcohol (63), 45, 46, and 47 were the most prominent of the beetle-produced primary *p*-menthadienols, while those derived from α-phellandrene (51), α-terpinene (52), and γ-terpenine (53) were present in low amounts or absent (Scheme 8). Other possible products of limonene, the

SCHEME 6. Allylic oxidation and hydration products of myrcene (38).

SCHEME 7. Primary allylic alcohols derived from terpinolene (44) and isoterpinolene (48).

carveols (61), *p*-mentha-1,8-dien-4-ol (60), isopiperitenols (64), and 59 were not detected by GC-MS (Scheme 9).

Steam distillation would have caused rearrangement of *cis*- and *trans*-3-caren-5-ols (9c and 9t) to *m*-mentha-4,6-dien-8-ol (11) (Gollnick and Schade, 1966b). Therefore, the volatile constituents were removed from female beetles (fed on ponderosa pine) under reduced pressure and condensed on a liquid N_2-filled cold finger. The concentrated condensate was analyzed by GC and GC-MS. The terpene alcohol region of the chromatograms was similar to Figure 2 and was devoid of 9t. Detection of 9c was not possible due to overlap with peaks eluting after *trans*-verbenol (2t).

Precursors of 1,5-dienol (6) might have been the verbenols (2) or 3-caren-2-ols (8) (Schemes 1 and 2). Absence of carveols (61) suggests that oxidation of 3-carene at C-2 probably did not occur in the beetles (Renwick and Hughes, 1975). Rearrangement of the verbenols (2) directly to 6 or via *cis*-3-pinen-2-ol (5) upon steam distillation or in the beetles (Renwick and Hughes, 1975) also accounts for the formation of 6.

Primary Alcohol Fraction from Female Frass Volatiles. Since a sesquiterpene eluting near 19.9 min interfered with measurement of the mass spectra of several metabolites eluting between components 41 and 10 (Figure 2), the primary terpene alcohols from steam-distilled female frass volatiles were isolated by HPLC (fraction 3) and analyzed by GC-MS (Figure 5, Table I). Although their mass spectra were not recorded, on the basis of retention times structures of *trans*-2-*p*-menthen-7-ol (37t), *p*-mentha-1,5-dien-7-ol (54), *p*-mentha-1,3 dien-7-ol (55), and *p*-mentha-1,8-dien-10-ol (62) were assigned to the small

peaks as shown in Figure 5 (see Schemes 5, 8, and 9). Comparison of Figure 5 to Figures 1 and 2 reveals that many of the primary terpene alcohols found in the volatiles of female beetles were also present in the frass. In particular, there were substantially greater quantities of host geraniol (26a), 3-caren-5-one (13), and perilla alcohol (63), and a lesser amount of 3-caren-10-ol (10). As mentioned above, only (*E*)-myrcenol (41) was detected in female volatiles, and there is no suggestion in Figure 5 of the Z-isomer (40). Neither component possessing a molecular weight of 154 and eluting near 17.2 min and 19.1 min in Figure 5 was γ-geraniol (43), nor were the mass spectra of these components suggestive of an acyclic structure such as 42. 3-Caren-9-ol (Scheme 2, 67) was identified by comparison of its mass spectrum to that of a specimen isolated

SCHEME 9. Allylic oxidation and hydration products of limonene (58).

from the neutral metabolites of (+)-3-carene administered to rabbits (Ishida et al., 1977, 1981). 2-Caren-10-ol (66) was not detected in frass or beetle volatiles. Analysis of ponderosa pine phloem oil by GC-MS revealed a complete absence primary monoterpene alcohols eluting beyond geraniol (Figure 4). Hence, peaks in this region were produced by female beetles.

Abdominal Volatiles of Female Beetle Fed in Lodgepole Pine. Extraction of a single female beetle fed in lodgepole pine for 24 hr (Conn, 1981) was sufficient to show the presence of *trans*-2-*p*-menthen-7-ol (37t) and *p*-mentha-1,5-dien-7-ol (54) in the terpene alcohol region (Figure 6). Analysis of the sample on a different column indicated a *trans–cis* ratio of 8 : 1. Oxidation of 37 to an aldehyde and oxidation of β-phellandrene at C-6 to yabunikkeols (35) (Fujita et al., 1970) did not occur to any appreciable extent. The areas of unidentified peaks were < 10% of that of 54. Due to poor resolution and the presence of numerous sesquiterpenes, fewer peaks in Figure 6 could be identified (Table 1), than in Figures 1 and 2. The numerous sesquiterpenes eluting before and after *trans*-verbenol precluded detection of any 2-*p*-menthenols (36).

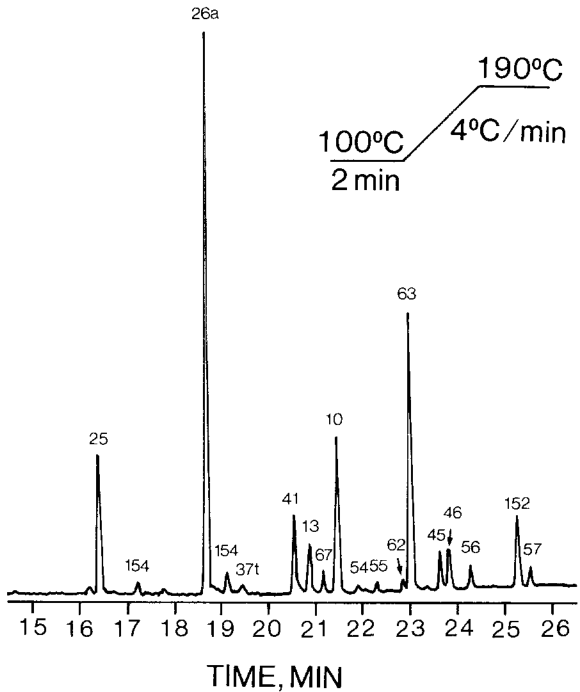

FIG. 5. Total ion chromatogram of the primary terpene alcohols isolated from steam-distilled female frass. See legend of Figure 1 for description of column and Table 1 for peak assignments. Molecular weights of unknown peaks are indicated by 152 or 154.

DISCUSSION

The discovery of acetophenone (18) and 1-phenylethanol (19) in the abdomens of feeding female *D. ponderosae* (Table 1) constitute the first record of these compounds in insects, as they have not previously been reported (Bradshaw, 1984). Renwick et al. (1976b) found 2-phenylethanol (20) in *Ips* and *Dendroctonus* spp. The absence of the brevicomins (21, 22) and frontalin (23) is in agreement with Ryker and Libbey (1982) and Libbey et al. (1985). Female *D. ponderosae* are atypical among other *Dendroctonus* which usually contain one of these bicyclic ketal pheromones upon emergence (Borden, 1985).

Allylic Alcohols: Precursor–Product Relationships. Monoterpenes are traditionally classified as acyclic, monocyclic, and bicyclic. Myrcene (38), the only prominent acyclic monoterpene in pine oleoresin, was exclusively oxidized by female *D. ponderosae* in ponderosa and lodgepole pine logs to (*E*)-myrcenol (41). However, female *D. ponderosae* exposed to myrcene vapors produced both (*E*)- and (*Z*)-myrcenol (*E*:*Z* = 49:1) (Scheme 6), while males produced approximately equal amounts of (*S*)-(+)-ipsdienol (97% ee) and (*E*) and (*Z*)-myrcenol (*E*:*Z* = 9:1) (Hunt et al., 1986). Male and female *D. brevicomis*

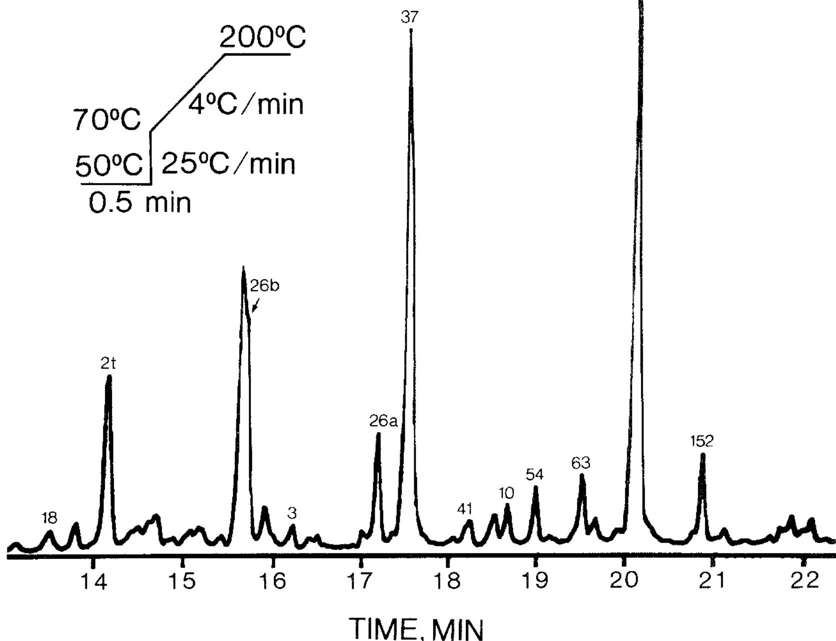

FIG. 6.. Terpene alcohol region of the total ion chromatogram of the abdominal volatiles extracted from a single female *D. ponderosae* fed 24 hr in lodgepole pine. See legend of Figure 2 for description of column. Splitless injection was used for sample introduction. See Table 1 for peak assignments and legend to Figure 1.

also convert myrcene to (*E*)-myrcenol (Renwick et al., 1976c),[7] while males produce *S*-(+)-ipdienol (Byers, 1982). Thus in these cases of myrcene oxidation to primary alcohols by *Dendroctonus* spp., the process is specific for the *E* methyl. Oxidation of the C-1 methyl group and C-6 of 1-methyl-1-cyclohexene (71) in male *D. frontalis* (Renwick and Hughes, 1975) occurred in approximately the same ratio (10 : 1) as oxidation of the (*E*)- and (*Z*)-methyl groups of myrcene by male *D. ponderosae*.

Monocyclic terpenes terpinolene (44) and limonene (58), α-phellandrene (51), and the isomeric terpinenes 52 and 53 were all oxidized at the allylic methyl groups to give primary alcohols. As for myrcene, the allylic methyls of these monocyclics which were *E* to a vinyl methylene group were oxidized.

[7] Although Renwick et al. (1976c) undoubtedly identified correctly the beetle-produced compound as the *E* isomer (41), the structure was drawn as the *Z* isomer (40). We attribute this error to an improper transcription of the structure given by Büchi and Wüest (1967). Granger et al. (1972) isolated from the essential oils of certain chemical races of *Thymus vulgaris* L., (*Z*)-myrcenol (40) and showed by NMR spectroscopy that it was the geometrical isomer of synthetic (*E*)-myrcenol (41).

Female *D. pondersoae* evidentally do not possess the ability to oxidize the *endo*-cyclic allylic methylenes of these monoterpenes, since anticipated metabolites such as 61 and 64 were not detected.

Primary allylic alcohols resulting from the oxidation of allylic methyl *E* to a ring methylene are encountered for α-pinene, 3-carene, and α-thujene. The relative proportions of the alcohols myrtenol (22), 3-carene-10-ol (10), and 3-thujene-10-ol (31) are close to the proportion of the monoterpene precursors in host volatiles.

The only prominent secondary alcohol in female volatiles is *trans*-verbenol (2t). We assume that verbenone (4), 5, and 6, are secondarily derived from *trans*-verbenol. Thus the oxidation of a α-pinene at the *endo*-cyclic allylic methylene occurs with the same high stereoselectivity as in other female *Dendroctonus* spp. (Hughes, 1973a; Byers, 1983).

Metabolic Pathways for Allylic Alcohol Formation. To account for the allylic oxidations (White et al., 1980; Francke and Vité, 1983) which would produce the distribution of allylic terpene alcohols found in the female volatiles, we propose two metabolic pathways.

Pathway MP-I (Figure 7) oxidizes any allylic methyl group which is *E* to

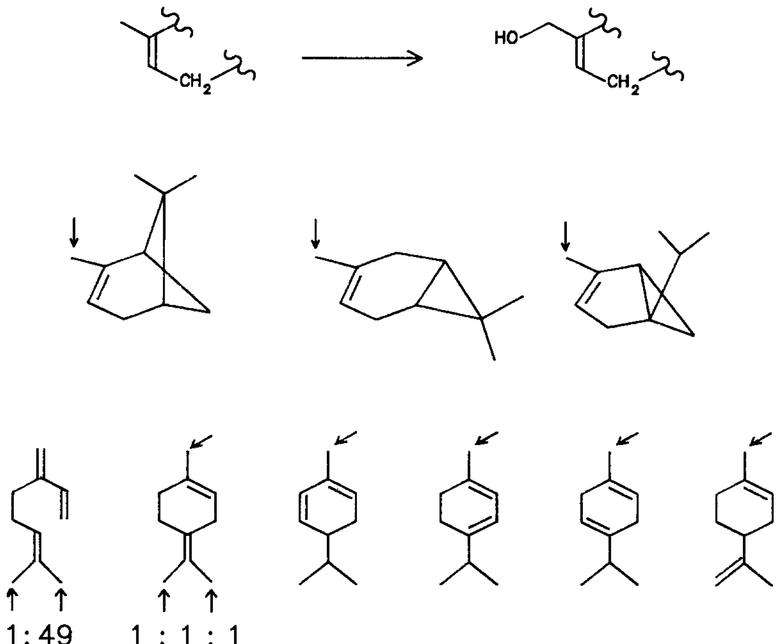

FIG. 7. Regiospecific oxidation (MP-I) of monoterpenes to primary alcohols in female *D. ponderosae.*

an allylic methylene or vinyl group (e.g., 52 → 55). It does not discriminate between different methyl groups in the same substrate as long as they possess the requisite geometry with respect to the olefin (e.g., 44 → 45:46:47, 1:1:1). Furthermore, MP-1 does not differentiate between substrates (1, 7, 30, 38, 44, 51–53, 59). The formation of 3-caren-9-ol (67), a minor metabolite of 3-carene (7), involves oxidation having the same stereochemical relationship to the carene cyclopropane as the methyl of myrcene oxidized during conversion to *E*-myrcenol has relative to the myrcene double bond. We hypothesize that both oxidations are mediated by the same system.

No discrimination between the enantiomers of α-pinene was found for oxidation to myrtenol (3) in *I. paraconfusus* (Renwick et al., 1976a). By analogy, MP-I would not discriminate between enantiomers of chiral substrates. Thus the board substrate specificity of MP-I and conversion of substrates to primary allylic alcohols, which can be oxidized to more polar metabolites, ideally suit this pathway for the detoxification of monoterpenes.

MP-II (Figure 8) mediates the oxidation of *endo*-cyclic allylic methylenes *E* to a vinyl methyl of bicyclic substrates. This pathway is responsible for the conversion of α-pinene (1) to *trans*-verbenol (2t), 3-carene (7) to 3-caren-5-ol (9t detected as 11), and possibly α-thujene (30) to 3-thujen-2-ol (32t). The greater amount of 2t compared to 3 in the volatiles of female *D. ponderosae* indicates that the relative rate of conversion of a substrate to product alcohol by MP-II is considerably greater than that of MP-I.

We suggest that MP-II is selective for enantiomers of bicyclic substrates which are structurally related to (−)-a-pinene (1). This suggestion is based on the observation that the *trans*-verbenol (2t) to myrtenol (3) ratio is large, whereas the *m*-mentha-4,6-dien-8-ol (11) to 3-caren-10-ol (10) ratio is small. Since the MP-I system responsible for formation of 3 and 10 operates on each of its

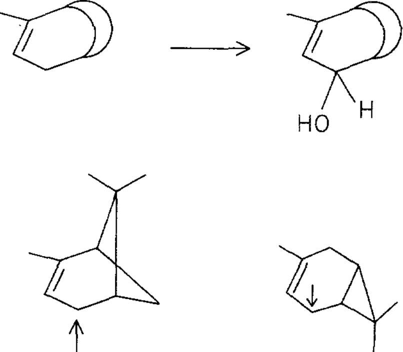

FIG. 8. Stereospecific oxidation (MP-II) of bicyclic monoterpenes to *trans* alcohols in female *D. ponderosae*.

substrates (in this case α-pinene and 3-carene) with equal facility, one would expect the ratio of 2t : 3 and 11 : 10 to be similar if α-pinene and 3-carene were oxidized at equal rates by MP-II to 2t and 11, respectively. The ratio of oxidation products observed suggests that 2t is produced by MP-II in much greater efficiency from α-pinene than is 11 from 3-carene. This would be expected if (−)-α-pinene were the preferred enantiomer of α-pinene for MP-II.

As shown in Figure 8 the stereochemical difference between (−)-1 and (+)-7 is that the *gem*-dimethyl group is above and below the plane of the double bond, respectively. The skeleton of (+)-1 is actually closely related to (+)-7. Thus, if oxidation of (+)-1 by MP-II is not as facile as oxidation of (−)-1, then oxidation of (+)-7 by this system should also be slow compared to oxidation of (−)-7. Since (+)-7 is the predominant enantiomer in ponderosa pine oleoresin (Mirov, 1961) and the proportion of MP-II-derived product from this substrate is small with respect to MP-I-derived 10, we infer that MP-II is specific for the (−)-enantiomer of α-pinene (1). Thus MP-II is enantioselective and is probably of little or no importance in monoterpene detoxification; however, it would be of importance in the production of (−)-2t, the major female-produced aggregation pheromone in *D. ponderosae* (Libbey et al., 1985; Borden et al., 1986).

Several studies have examined the stereochemistry of the conversion of α-pinene to *trans*-verbenol by *Dendroctonus* spp. Plummer et al. (1976) found that natural 2t isolated from the Porapak Q-trapped volatiles produced by female *D. frontalis* boring in short leaf pine logs for 96 hr was a 60 : 40 mixture of (+)-2t and (−)-2t, but they did not determine the enantiomeric composition of the host α-pinene. It is thus not possible to assess whether preferential oxidation of enantiomers occurred. Byers (1983) exposed male and female *D. brevicomis* to (+)-α-pinene (87.4% ee) and (−)-α-pinene (79.4%ee). Both sexes produced (+)-*trans*-verbenol (62% ee) from the (+)-*α-pinene, (−)-trans*-verbenol (53-54% ee) from (−)-α-pinene, and little *cis*-verbenol from either α-pinene.[8] While *D.brevicomis* and *D. frontalis* convert either enantiomer of α-pinene to *trans*-verbenol, the allylic oxidation of C-4 of chiral α-pinenes in *I. paraconfusus* proceeds by stereospecific replacement in the *pro*-(4*S*) hydrogen with hydroxyl. The process is amazingly insensitive to the steric effect of the bulky *gem*-dimethyl group since beetles exposed to (±)-α-pinene produced a 1 : 1 mixture of *cis*- and *trans*-verbenols (Renwick et al., 1976a). *I. amitinus* and *I. typographus* also metabolize the isomers of a α-pinene in a similar fashion (Klimetzek and Francke, 1980).

The metabolism of 3-carene by *I. paraconfusus* and *I. pini* is probably similar to that of α-pinene. The unstable 3-caren-5-ols (9) were not detected but rearranged in vivo to *m*-dienol 11, which was actually isolated by GC from

[8] A rotation of 168.75° (Schulz and Doll, 1944) was used for calculating the enantiomeric excess (ee) of the *trans*-verbenols produced by male and female *D. brevicomis*.

the hindguts of *I. pini* (Renwick et al. 1976c). The in vivo instability of 9 is somewhat puzzling since alcohol 9t was synthesized by Gollnick and Schade (1966b). Renwick et al. (1976c) proposed that ring opening occurred during the oxidation of 7. That 9 can survive for at least some time is suggested by the detection of its oxidation product 3-caren-5-one (13). Trace amounts of organic acids in the insect gut may catalyze the rearrangement of 9 to 11. We failed to detect 9 even when female volatiles were isolated at reduced pressure from pentane extracts of crushed abdomens by condensation on a liquid nitrogen-filled cold finger.

Metabolism of β-Phellandrene. Neither MP-I nor MP-II can metabolize β-pinene or β-phellandrene. In ponderosa pine, β-phellandrene is a minor compound. However, in lodgepole pine, female *D. ponderosae* encounter up to 70% (−)-β-phellandrene (34) in the oleoresin monoterpene fraction (Mirov, 1961; Smith, 1964). MP-III is specific for conversion of (34) to *trans*-2-p-menthen-7-ol (37) by anti-Markovnikov hydration of the *exo* double bond (Scheme 5). Being deficient in its ability to oxidize the allylic position α to an *exo* double bond (e.g., 14 → 16 and 58 → 62), *D. ponderosae* has apparently develop this hydration process for detoxification of β-phellandrene. Although β-pinene, myrcene, and limonene are abundant in lodgepole and ponderosa pines (Smith, 1964, 1977), hydration of these terpenes to the corresponding primary alcohols does not occur to detectable levels in female *D. ponderosae*.

It is of interest that male *Polygraphus poligraphus* (L.) contain *trans*-4-thujanol (69) and *cis*-4-thujanol (70) apparently produced by the Markovnikov hydration of sabinene (68) or α-thujene (30) (Scheme 10) (Francke and Vité, 1983). The hydration of sabinene would be mechanistically similar to that of β-phellandrene by MP-III.

Metabolic Pathways and Host-Insect Ineraction. Pine bark beetles may have adapted initially to their hosts by development of metabolic pathways that detoxify monoterpenes and later by exploiting the resultant metabolites as pheromones (Hughes, 1973a). The results of our study are consistent with this hypothesis. They have led to three proposed metabolic pathways that are adapted in *D. ponderosae* to overcome the host's chemical defense system.

OR [H_2O] + OH OH

68 30 69 70

SCHEME 10. Hydration products of sabinene (68) or α-thujene (30).

MP-I oxidizes most monoterpenes commonly occurring in the host and is apparently the general pathway for terpene detoxificiation. MP-III appears to be specific for detoxification of β-phellandrene. It would permit *D. ponderosae* to colonize lodgepole pine or similar species with high β-phellandrene content.

The relatively high rate of conversion of α-pinene to *trans*-verbenol by MP-II suggests that it is a specialized pathway utilized by female beetles to produce pheromone. Thus it is a critical process in initiating the complex series of semiochemical-mediated events (Borden et al., 1986) that result in the successful colonization of a living host tree.

SOLUTION VOLUME AND SEED NUMBER: Often Overlooked Factors in Allelopathic Bioassays

JEFFREY D. WEIDENHAMER, TIMOTHY C. MORTON, and JOHN T. ROMEO

Department of Biology
University of South Florida
Tampa, Florida 33620

(Received May 9, 1986; accepted September 3, 1986)

Abstract—Cucumber seeds were germinated under various combinations of solution volume and seed number with a range of ferulic acid concentrations. At each concentration, radicle growth decreased as the relative amount of ferulic acid available per seed increased from x (25 seeds/5 ml) to $5x$ (5 seeds/5 ml) to $19x$ (25 seeds/95 ml). With 2.0 mM ferulic acid in buffered solution, radicle lengths after 48 hr ranged from 71 to 47% of control. The amount of ferulic acid remaining in 2.0 mM solution after 48 hr was directly proportional to the amount initially available per seed, and ranged from 9 to 91%. Solution volume and seed number also significantly affected inhibition by vanillic acid, caffeic acid, and juglone. With 0.1 mM juglone, radicle lengths after 48 hr were 88% of control with 25 seeds/5 ml, 68% with 5 seeds/5 ml, and 56% with 25 seeds/90 ml. The data demonstrated that lower phytotoxin concentrations can produce equivalent or greater inhibitory effects than higher concentrations when the amount available per seed for uptake is greater. Equivalent inhibition of radicle growth was observed with 1.0 mM (5 seeds/5 ml) and 2.0 mM (25 seeds/5 ml) ferulic acid. Available literature on herbicides indicates that similar effects occur in greenhouse and field studies.

Key Words—Ferulic acid, vanillic acid, caffeic acid, juglone, cucumber, *Cucumis sativus*, allelopathy, competition, interference, seed bioassays.

INTRODUCTION

Allelopathy is a factor in determining vegetation patterns and community structure and has important implications for agriculture and forest management (Rice, 1984). Various bioassay techniques have been used to assess the biological activity of suspected phytotoxins (Stowe, 1979; Putnam and Duke, 1978;

0098-0331/87/0600-1481$05.00/0 © 1987 Plenum Publishing Corporation

Einhellig et al., 1985). A common method is to test plant extracts or pure compounds for inhibition of seed germination or radicle elongation. Factors known to affect the results of such bioassays include high osmotic pressures (Anderson and Loucks, 1966; Bell, 1974; Stowe, 1979) and pH (Reynolds, 1975; Blum et al., 1984, 1985).

Ferulic acid is one of several simple phenolic acids with demonstrated phytotoxic activity. Conditions for germination and radicle elongation bioassays with ferulic acid have varied substantially. Guenzi and McCalla (1966) used 10 wheat (*Triticum aestivum,* L.) seeds in 6 ml solution; Lodhi (1975), 30 seeds each of little bluestem (*Andropogon scoparius*) and brome grass in an unspecified volume; Lodhi (1979), 25 seeds each of *Salsola kali* L. and radish (*Raphanus sativus*), thinned to 10 seedlings at 24 hr, in an unspecified volume; Liebl and Worsham (1983), 15 seeds of morning glory (*Ipomoea lacunosa* L.) and 10 each of corn (*Zea mays* L.) and soybean (*Glycine max* L.) in 10 ml solution; Blum et al. (1984), 25 seeds of cucumber in 5–7 ml solution; and Cameron and Julian (1980), 2 seedlings of lettuce in 2 ml solution. Similar variability of experimental conditions is seen in the literature for other compounds.

Blum et al. (1984) showed that the concentration of ferulic acid in a bioassay with cucumber declined approximately 80% (at high concentrations) to 100% (at low concentrations) during the 48 hr of the bioassay. This was due to a combination of plant uptake and microbial breakdown. The decrease in phytotoxin concentration over time suggested to us that solution volume and seed number may be of crucial importance in allelopathic bioassays. We hypothesized that the degree of inhibition caused by an allelopathic compound will depend upon both phytotoxin concentration and the total amount of phytotoxin available for uptake. Since solution volume and seed number determine the amount of phytotoxin available per seed, greater toxicity will be observed at a given concentration if there are fewer seeds per dish or a large solution volume. Lower phytotoxin concentrations may actually produce greater inhibitory effects than higher ones, if the total amount available per plant for uptake is greater. The experiments reported here were conducted to test these hypotheses and assess the magnitude of these effects in radicle elongation bioassays.

METHODS AND MATERIALS

Source of Materials. Cucumis sativus cv. Early Green Cluster seeds were purchased from Wyatt Quarles Seed Company, Raleigh, North Carolina. Ferulic acid, caffeic acid, vanillic acid, juglone and MES [2-(*N*-morpholino)ethanesulfonic acid] were obtained from Sigma Chemical Company, St. Louis, Missouri.

Experimental Design and Methods. Seeds were placed in plastic Petri dishes

(100 × 15 mm or 100 × 25 mm) which contained Whatman No. 1 filter paper and specified volumes of the test solution. The seed number–solution volume combinations were 25 seeds/5 ml, 5 seeds/5 ml and 25 seeds/90 or 95 ml. At a given concentration, the relative amount of phytotoxin available per seed ranged from x (25 seeds/5 ml) to $19x$ (25 seeds/95 ml). Replication gave 75–100 seeds per treatment.

The larger 100 × 25-mm Petri dishes were used for the 90-and 95-ml treatments, with the seeds and filter paper placed on a plastic platform inside the dish. The platform's height was adjusted so that seeds were not immersed but were in contact with approximately the same levels of solution as in other treatments. The platform and filter paper were perforated to allow free flow of solution.

Initial experiments were conducted according to the method of Blum et al. (1984), with ferulic acid dissolved in 15 mM MES and the pH adjusted to 5.8 with 1.0 N NaOH. These workers reported osmolalities of up to 25 mosm for 15 mM MES plus 3 mM phenolic acids and saw no inhibition of cucumber radicle growth over this range. In our experiments, however, 15 mM MES inhibited growth of controls compared to distilled deionized water (34.5 vs. 40.9 mm for 25 seeds/5 ml controls, and 37.5 vs. 46.6 mm for 5 seeds/5 ml controls, significantly different at the 0.05 level). Therefore, additional studies were conducted using distilled deionized water as solvent. Sterile techniques (filter sterilization, autoclaving) were not used since preliminary experiments showed no effect on the results (radicle lengths of seedlings in 2 mM ferulic acid, 25 seeds/5 ml, were 23.5 mm in nonsterile solution vs. 21.6 mm in sterile solution, not significantly different at the 0.05 level). Because of concern about oxygen depletion by seed respiration, Petri dishes were opened to ambient air for approximately 5–10 sec every 24 hr. Growth of aerated controls actually was decreased slightly (2–4 mm) compared to nonaerated controls (data not shown).

Seeds were germinated in the dark in a growth chamber at 25–27°C. Radicle lengths of germinated seed were measured in mm after 48 or 72 hr. Seeds were considered to be germinated if the radicle protruded at least 2 mm. The germination rate was approximately 95%.

Chemical Analyses. Chemical analyses were performed on a Bio-analytical Systems Inc. high-pressure liquid chromatograph (HPLC) (West LaFayette, Indiana), using a reverse-phase (C_{18}) column (150 × 4 mm) and detection at 254 nm. A Shimadzu Chromatopac C-R3A (M. B. Nathanson and Associates, Loudon, Tennessee) was used for peak integration and retention time measurements. Compounds were eluted isocratically at 1.5 ml/min with water–methanol–acetic acid (55:45:1, v/v). For analysis, the solution remaining in a Petri dish at 48 or 72 hr was pipetted off, and the dish, filter paper and germinated seeds were rinsed thoroughly with distilled deionized water. The amount of phenolic acid in the resulting solution was then determined.

Data Analysis. All data were subjected to standard analysis of variance procedures. A significance level of $P < 0.05$ was used for all multiple comparison tests.

RESULTS

Radicle growth is a function of both concentration and the amount of phytotoxin available per seed (Figure 1 and 2). Greater inhibition was observed as the amount of ferulic acid available per seed at a given concentration increased. Radicle lengths after 48 hr in buffered 2.0 mM ferulic acid were 71%, 49%, and 47% of controls for the 25 seeds/5 ml, 5 seeds/5 ml, and 25 seeds/95 ml treatments, respectively. The same trends occurred at concentrations of 0.5 and 1.0 mM, with values for the 5 seeds/5 ml treatment intermediate between the 25 seeds/5 ml and 25 seeds/95 ml treatments. No differences in the relative degree of inhibition were noted between 48 and 72 hr (Figure 1). Solution pH remained between 5.6 and 5.8 for all treatments.

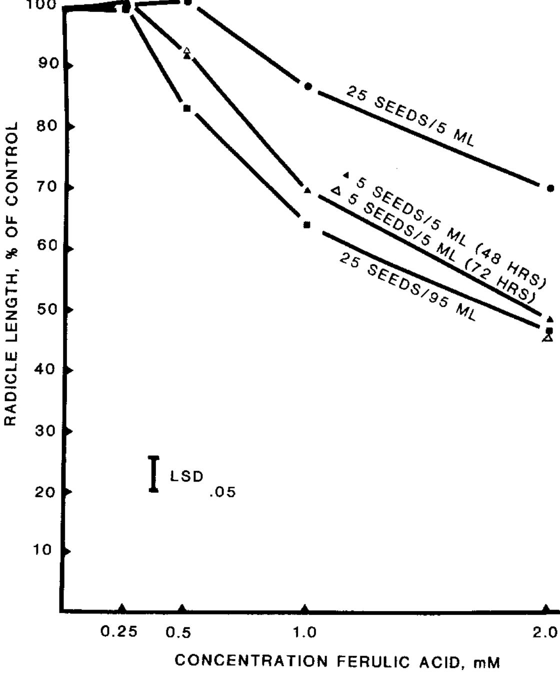

FIG. 1. Effect of seed number and solution volume on inhibition of cucumber radicle growth by ferulic acid in 15 mM MES at pH 5.8.

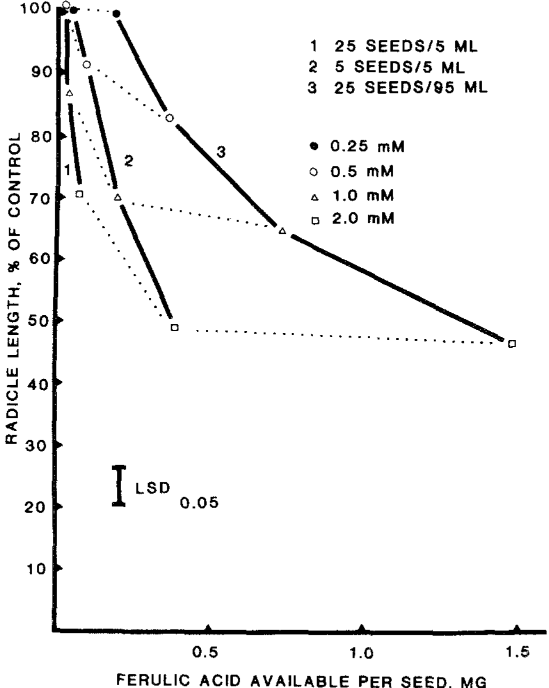

FIG. 2. Effect of the amount of ferulic acid available at pH 5.8 on inhibition of cucumber radicle growth.

In distilled deionized water, inhibition of radicle growth by ferulic acid was greater and differences between the seed number/solution volume treatments more pronounced than in buffered solutions (Figure 3). The initial pH of unbuffered 2.0 mM ferulic acid was 3.0. No inhibition of radicle growth was seen in controls at this pH range (data not presented). The toxicity of phenolic acids, however, is known to decrease as pH increases (Harper and Balke, 1981; Blum et al., 1985), and the final pH values for the 2.0 mM ferulic acid solutions were 5.4, 3.9, and 3.1 for the 25 seeds/5 ml, 5 seeds/5 ml, and 25 seeds/90 ml treatments.

Radicle lengths of 25-seed controls were slightly shorter than the 5-seed treatments in both MES and distilled deionized water. In MES, control radicle lengths at 48 hr were 40.8, 49.1, and 45.4 mm for the 25 seeds/5 ml, 5 seeds/5 ml, and 25 seeds/95 ml treatments. In distilled deionized water, they were 36.8, 43.4, and 40.7 mm for the corresponding treatments.

Ferulic acid concentrations diminished greatly over 48 hr for the 25 seeds/5 ml treatment, with only 9% remaining at 2.0 mM (Table 1). The percentage

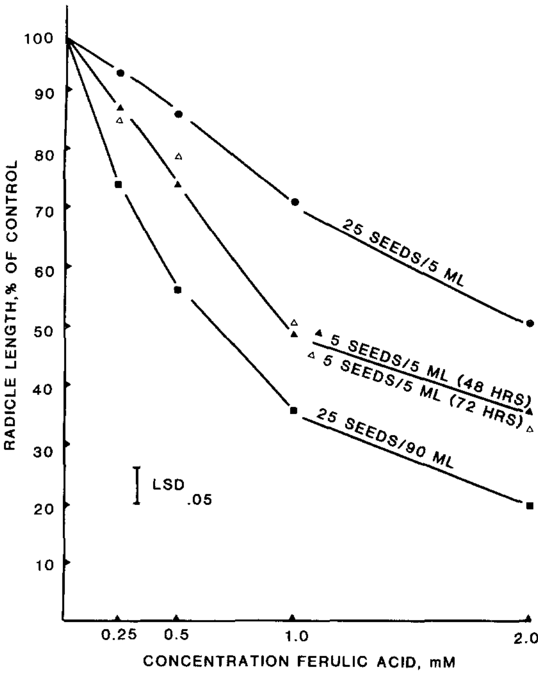

FIG. 3. Effect of seed number and solution volume on inhibition of cucumber radicle growth by ferulic acid in distilled, deionized water.

TABLE 1. PERCENTAGE OF FERULIC ACID REMAINING IN SOLUTION AT 48 AND 72 HOURS FOR TREATMENTS IN 15 mM MES

Initial conc. (mM)	% remaining after 48 (72) hr ± SE[a]		
	25 seeds/5 ml[b]	5 seeds/5 ml[c]	25 seeds/95 ml[b]
0	0	0	0
0.25	0	0	35.1 ± 21.7
0.50	0	1.5 ± 1.0	59.1 ± 14.0
1.0	0	38.9 ± 6.6	81.1 ± 8.1
2.0	8.6 ± 2.5	50.0 ± 2.4 (39.3 ± 8.3)	90.6 ± 1.0

[a] Detection limits were 25 ng/10 μl injection. Values in parentheses are for 72 hr.
[b] $N = 2$.
[c] $N > 5$.

remaining was higher for the 5 seeds/5 ml treatment (50% at 2.0 mM) and highest for the 25 seeds/95 ml treatment (91% at 2.0 mM). As expected, the 95 ml volume stabilized the concentration of ferulic acid relative to the other treatments. After 72 hr, 39% of the ferulic acid remained for 5 seeds/5 ml 2.0 mM treatment. In general, levels of ferulic acid remaining after 48 and 72 hr were lower with distilled deionized water than in buffered solutions (Table 2).

There was significant loss of ferulic acid over 48 hr in water controls with no seeds. This loss increased at 72 hr. Small amounts were lost by physiochemical degradation, and additional amounts could not be recovered due to adsorption on the filter paper. For 2.0 mM ferulic acid, the percentage remaining after 48 hr was 84.4 ± 7.0% (nonsterile) and 85.4 ± 0.5% (sterile) for 0 seeds/5 ml controls. In sterile controls without filter paper, the amount remaining was 92.6 ± 3.1%.

In agreement with the results of Blum et al. (1984), small amounts of metabolic products were detected in Petri dishes of germinating cucumber seedlings containing ferulic acid solutions. These included vanilic acid, protocatechuic acid, and an unknown compound. No differences were apparent in the metabolic products formed in 15 mM MES and distilled deionized water.

In tests with vanillic acid, caffeic acid, and juglone, radicle growth also decreased as the amount of available phytotoxin increased from x (25 seeds/5 ml) to $18x$ (25 seeds/90 ml) (Table 3). Striking results were seen with juglone, a quinone for which pH effects would not be expected to complicate results. With 0.1 mM juglone, radicle lengths were 88% of control with 25 seeds/5 ml, 68% with 5 seeds/5 ml, and 56% with 25 seeds/90 ml.

DISCUSSION

Effect of Volume and Seed Number in Radicle Elongation Bioassays. The data demonstrate that solution volume and seed number are important factors in radicle elongation bioassays. For any given concentration, larger solution volumes or lower seedling densities increase the amount of phytotoxin available per seed and thereby increase the amount of inhibition observed. Similarly, lower phytotoxin concentrations can produce equivalent or greater inhibitory effects than higher concentrations when the amount available per seed is greater. In the experiments with ferulic acid, radicle lengths 70% of control were observed at 1.0 mM with 25 seeds/95 ml, while with 25 seeds/5 ml, approximately the same level of inhibition was not reached until the greater concentration of 2.0 mM (Figure 1), roughly a twofold difference in initial concentration. Similar doses of phytotoxin, taken up under different conditions of total amount available and concentration, can be expected to result in equivalent levels of inhibition. This is implied by Figure 2.

Our interpretation attributes the disappearance of ferulic acid and the resulting inhibition of growth primarily to uptake of ferulic acid by the germinating seedlings. While there may be some microbial breakdown of ferulic acid to more or less phytotoxic substances (Liebl and Worsham, 1983; Blum et al., 1984), the relative stability of ferulic acid concentrations in our 25 seeds/95 ml treatment argues against this as a complicating factor in these experiments.

Although effects observed in water solution were greater than in buffer, the interpretation of the data is complicated somewhat by pH changes which occurred during the course of the experiment. These results emphasize the importance of buffering pH when conducting bioassays with phenolic acids.

Reasons for differences in control radicle lengths with various seed number–solution volume combinations are not clear. Water did not appear to be limiting in any treatment. At least 0.5 ml of liquid could be removed by pipet at the end of the assay for all treatments. Increasing the solution volume in high-seed-density controls did not increase growth (data not presented). Some cucumber accessions are allelopathic (Putnam and Duke, 1974; Lockerman and Putnam, 1979, 1981a, b). The shorter radicle lengths of high-seed-number controls thus may be due to autotoxic inhibitors produced by cucumbers which accumulate to higher concentrations when there are more seedlings per dish.

In light of our results, most current assays would seem to be conservative in assessing possible allelopathic effects. The 48-hr 25 seeds/5 ml treatment is representative of many current experiments. Greater inhibition, however, was observed with both the 5 seeds/5 ml and 25 seeds/95 ml treatments. Results with 0.5 mM ferulic acid (Figure 1, radicle lengths 83–101% of control) and 0.1 mM juglone (Table 3, radicle lengths 56–88%) suggest that phytotoxic compounds possibly are being overlooked when extracts are screened. While seed number and solution volume have been a concern in designing appropriate growing conditions for assay species, effects of seed number and solution volume on the magnitude of inhibition must be considered in standardizing conditions for bioassays. For cucumber and seeds of similar size, the 5 seeds/5 ml treatment, requiring only 75 ml solution for 15 replicates, may represent a good compromise between conditions of maximum inhibition (25 seeds/90 ml, 270 ml for three replicates) and availability of very small amounts of experimental material.

Possible Implications to Greenhouse and Field Studies. Analogous to any nutrient necessary for plant growth, plants compete for available phytotoxins. The observed effects of volume and seed number in radicle elongation bioassays result from this competition. Numerous herbicide studies have shown similar effects, with greater phytotoxicity in greenhouse and field studies as plant density is decreased (Skipper, 1966; Burrill and Appleby, 1978; Hoffman and Lavy, 1978; Andersen, 1981; Winkle et al., 1981; Khedir and Roeth, 1981; recently reviewed by Appleby, 1985). Hoffman and Lavy (1978), using ^{14}C-labeled atrazine, showed that uptake per plant decreased 50% as soybean density increased, demonstrating competition for this phytotoxin. In one field study, no phytotoxicity was seen at higher densities, while dry-weight reductions of 75% occurred at low density. Effects of similar magnitude were seen when the amount of soil per pot was increased from 225 g (no growth reduction) to 900 g (>90% dry weight reduction) at constant plant density.

Clearly, the phenomenon of competition for phytotoxins should be considered in greenhouse and field studies of allelopathy. High seedling densities and/or small pot volumes may yield results which do not support a hypothesis of allelopathy when, in fact, phytotoxins are present in significant concentrations. In the field, similar effects due to differences in plant density may occur. This suggests that allelopathy may be more important ecologically in situations where overall plant densities are lower because of environmental and other constraints. In these cases, phytotoxin concentrations which cause inhibitory effects in the field may be considerably lower than those shown to be toxic in laboratory assays, especially if soil concentrations are replenished by some mechanism such as daily input of toxins by rains or a continual input from microbial breakdown of plant residues. It has long been supposed that if only small amounts of a phytotoxin are present in the soil, these could be inhibitory if the concentration is high enough in a localized area such as a litter or mulch layer (see Guenzi and McCalla, 1966). This hypothesis is also supported by Figure 2.

Finally, decreased plant growth as plant density decreases is a reversal of effects normally observed when plants compete with one another (see Kira, 1953; Dekker et al., 1983; Harper, 1977). Such results strongly imply the presence of a toxic substance in the soil. Assuming similar effects can be demonstrated for naturally occurring phytotoxins, experiments in which plant density is varied could provide a tool for demonstrating the presence of allelopathic compounds in the soil and separating allelopathic from competitive interference. Further experiments to test these hypotheses are being designed.

Acknowledgments—Chris Miller provided technical assistance with the HPLC analyses. Helpful suggestions were made by Glover B. Triplett, Jr., and David C. Hartnett.

ORIENTATION BEHAVIOR AND EFFECT OF EXPERIENCE AND LABORATORY REARING ON RESPONSES OF *Cotesia melanoscela* (RATZEBURG) (HYMENOPTERA: BRACONIDAE) TO GYPSY MOTH SILK KAIROMONE

RONALD M. WESELOH

Department of Entomology
Connecticut Agricultural Experiment Station
New Haven, Connecticut 06504

(Received July 3, 1986; accepted September 5, 1986)

Abstract—*Cotesia melanoscela* responds the same way to the silk of its host, gypsy moth larvae, *Lymantria dispar* L., whether or not it has previously been exposed to hosts. Parasites maintained in the laboratory for six or 25 generations also responded similarly, suggesting that orientation behavior is not modified by laboratory rearing. Details of silk-related orientation behavior were analyzed by tracing paths of female parasites when on or off silk-covered substrates. Females made 31° average turns every 0.5 cm whether or not they were examining silk. They tended to turn back onto a silked area when encountering a border, and their speed of movement when not examining silk was about three times higher than when examining silk.

Key Words—*Cotesia melanoscela*, gypsy moth, *Lymantria dispar*, Lepidoptera, Lymantriidae, orientation behavior, silk kairomone, Hymenoptera, Braconidae.

INTRODUCTION

The gypsy moth, *Lymantria dispar* (L.) (Lepidoptera: Lymantriidae), parasite *Cotesia* (=*Apanteles*) *melanoscela* (Ratzeburg) is known to respond to a kairomone on gypsy moth silk by intensely examining areas which have silk strands on them (Weseloh, 1976). Kairomone-mediated behavior increases contacts with hosts and oviposition attempts (Weseloh, 1977), and responses to silk decrease over several minutes due to habituation (Weseloh, 1980).

0098-0331/87/0600-1493$05.00/0 © 1987 Plenum Publishing Corporation

Other aspects of the interaction remain unexplored, however. For example, while many natural enemies respond to host kairomones (Weseloh, 1981), little is known about their actual orientation mechanisms in most cases. Waage (1978) has suggested that most kairomones perceived on contact cause a decrease in locomotory movement (inverse orthokinetic response) and/or an increase in the rate of turning, either at the edge of the kairomone "patch" or randomly within the patch itself. Strand and Vinson (1982) found that the parasite *Cardiochiles nigriceps* Vierick (Hymenoptera: Braconidae) increased its rate of turning inside a kairomone patch, but also increased rather than decreased its rate of locomotion. Sabelis et al. (1984) showed that starved predatory mites, *Phytoseuilus persimilis* Athias-Henroit (Acarina: Phytoseiidae), walked slower and turned more often than fed mites in a kairomone plume and that both fed and starved mites tended to turn back toward an odor source if they happened to leave it. Another predator, *Coccinella septempunctata* Bruchii (Coleoptera: Coccinellidae), did not respond directly to prey kairomone with such behaviors, but after consuming a prey aphid increased its rate of turning and decreased its locomotory rate (Nakamuta, 1985). Such changes in orientation behavior caused by kairomone perception might also cause specific changes in the orientation movements of *C. melanoscela*.

Another area in which little work on *C. melanoscela* has been done is the effect of previous experience on subsequent parasite behavior. *Pseudeucoila bochei* Weld (Hymenoptera: Cynipidae), for instance, cannot discriminate between parasitized and unparasitized drosophilid hosts until it has had an opportunity to attack unparasitized ones (Van Lenteren, 1976). The already-mentioned *C. nigriceps* recognizes a kairomone patch much more readily after it has parasitized hosts than before so (Strand and Vinson, 1982). Similarly, *Nasonia vitripennis* (Walker) (Hymenoptera: Pteromalidae) changes its host preference depending on the particular species of muscoid host puparia that it had previously been exposed to (Cornell and Pimentel, 1978). Even responses to host and microhabitat stimuli change depending on preconditioning, as Vet and Opzeeland (1984) found for two *Asobara* spp. (Hymenoptera: Braconidae: Alysiinae) which attack drosophilids.

A third factor which could affect the behavior of *C. melanoscela* is the number of generations it has been reared in the laboratory. Hoy (1975) showed that reared *C. melanoscela* had slower development, lower progeny production, and lower sex ratios (female–male) than forest-collected parasites. Thus the possibility of behavioral changes is very real.

The present study was undertaken to investigate these areas of research. In particular, differences in host-related behavior of naive and experienced *C. melanoscelus*, responses to silk of parasites reared for different lengths of time in the laboratory, and detailed orientation behavior of *C. melanoscela* when it encounters areas of gypsy moth silk were measured.

METHODS AND MATERIALS

Insects. The *C. melanoscela* adults in these experiments were originally reared from gypsy moth larvae collected in Connecticut forests, and the colonies were maintained on gypsy moths fed an artificial wheat-germ diet (Yamamoto, 1969). One colony was started from gypsy moths collected in spring 1984 (old colony) and one from gypsy moths collected in spring 1985 (new colony).

Naive vs. Experienced Females. This test was run in September 1984 using the old colony when it was ca. five generations old. Female parasites which had emerged and presumably mated the day before were placed in 473-ml, 8-cm-high by 11.5-cm-diam. paper cups with clear plastic lids and honey and water. Parasites were considered experienced after being held for one hr with ca. 20 first and second gypsy moth instars in such containers, while naive insects were held with no hosts. Both groups were then held at least 2 hr without hosts before testing.

Silk substrates were made as follows: a 1.5-cm square of parafilm was wrapped with 1, 5, or 10 strands of silk by dropping a first or second gypsy moth instar and winding the resulting silk strand around the parafilm for the required number of times. The parafilm square was fastened to the bottom of a 9.5-cm glass Petri dish by pressing on the four corners with forceps. The dish was inverted over a mirror so the insect could be easily watched. An experienced or naive *C. melanoscela* female was introduced and observed for 10 min, and the number of contacts with the parafilm, examinations of silk, and total time examining silk were recorded (see Weseloh, 1976, for description of silk-related behavior). Experienced and naive females were alternated in successive tests. Ten replicates were run. The number of contacts and examinations, percentage of contacts leading to examinations, and total time spent examining were each analyzed by two-way analysis of variance and selected treatment comparisons (Ostle, 1963).

Old Colony vs. New Colony. This test was similar to the first one except that all females were naive, the old colony females which were in culture for ca. 25 generations were compared to new colony females in culture for ca. six generations, and only two silk "concentrations" (1 and 10 strands) were used. Ten replicates were run from October 23, to November 21, 1985.

Orientation Behavior. Orientation behavior of *C. melanoscela* females was studied by tracing their paths in the presence or absence of silk. Squares (1.5 cm) of parafilm were wrapped with either 0, 1, 5, or 10 strands of silk and fastened on the bottom of a 95-cm-diam. glass Petri dish, the outside bottom of which was frosted by wet-grinding with No. 600 carborundum grit. The dish was inverted over a glass plate extending over the edge of a counter. A thin 12-cm-diam. plastic disk was fixed to the underside of this glass plate by an arrangement of slides so disks could be quickly exchanged. The whole apparatus

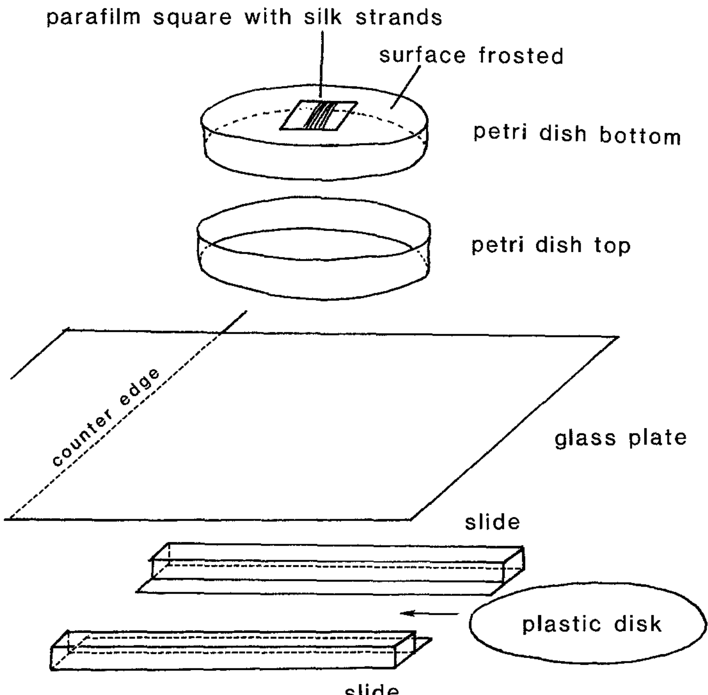

FIG. 1. Exploded diagram of apparatus used for tracing paths of *C. melanoscela* females (drawing by Wilhemina Smith).

(Figure 1) was illuminated from below, and the position of the parafilm and the silk on the parafilm was marked on the plastic disk from below with a felt pen. This was easy to do because the shadow of the pen projected onto the frosted glass bottom of the chamber. A female *C. melanoscela* was introduced, and her path was marked on the plastic disk for 0.5 min, the disk was exchanged for a new one, position of parafilm and silk quickly marked on it, and the female's path was traced for another 0.5 min. This continued for 5 min total. The first group of tests was run in May and June 1985 and used only old colony females (ca. 18 generations in culture). Four replicates for each silk "concentration" were run. Angle changes which occurred when parasites were on or off silk were measured by dividing each traced path into 0.5-cm straight segments (cords), starting from the beginning of the path. The angular changes in direction from one such straight line segment to another were the data recorded (Figure 2).

Angle changes occurring off silk were analyzed by multiple regression analysis (analysis of variance was not used because some females did not move during some time periods, with resulting missing data). The two independent

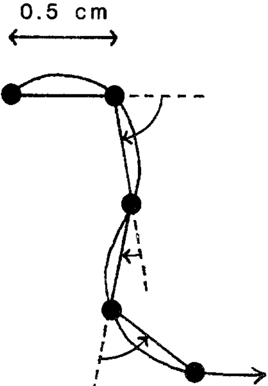

FIG. 2. Diagram of traced path of a *C. melanoscela* female, showing 0.5-cm cords (straight sections) and angular changes in direction as measured by successive cords.

variables were number of silk strands (x_1) and time period (x_2). The dependent variable (y) was the average angle change for one female at a particular time period and number of strands (model: $y = b_0 + b_1x_1 + b_2x_2$). T tests were used to determine differences in angle changes when on or off silk for each time and silk amount combination (46 in all). Jones (1984) pointed out that t tests can be used to make such multiple comparisons if the rejection regions for making a type-I statistical error are modified. This is because when the null hypotheses are true in a many-comparison situation, the probability of rejecting the null hypothesis in one or more of the comparisons can be quite high simply due to chance if the usual probability levels ($P = 0.05$ or 0.01) are used. In order to be 95% confident that the null hypothesis is false in 46 t-test comparisons, one must use a probability level of $1 - (0.95)^{1/46} = 0.001$ for each individual test (Jones, 1984). This was the level used in each comparison.

The above tests were also analyzed to determine the tendency of females to turn back from boundaries associated with silk-covered areas. To generate more replicates, additional tests were run in fall 1985 with new and old colony females. For analysis, results for different colonies and 0 and 1 strands were so similar that these were pooled. The variable analyzed was the proportion of times a female turned back when she went from parafilm to the background Petri dish surface, minus the proportion of times she turned back when going from the background to the parafilm, i.e., the net proportion of turnbacks on parafilm was determined. This was done for each time period for each female. Results for 10 and 20 strands were not pooled, and the proportion of boundary contacts resulting in turnbacks when going from silk to parafilm minus the proportion going from parafilm to silk (net proportion of turnbacks on silk) was also determined for each time period.

To determine trends and significance of data, an iterated, locally weighted regression procedure was used (Cleveland, 1979) to give smoothed scatterplots of net proportion turnbacks vs. time period. Estimates of smoothed value variabilities were made using the bootstrap procedure (Efron and Gong, 1983). In this resampling scheme, random selections with replacement are made from the original data and the weighted regression procedure used on the selections to get a new set of smoothed values at the various time periods. This was done 100 times, giving a range of artificially generated, smoothed net turnback proportions. Using the procedure for finding bias-corrected confidence intervals (Efron and Gong, 1983), 95% confidence intervals could be placed around the original net values. If the confidence interval did not include zero, the true net value could be said to be different from zero with 95% confidence, and thus that the insects tended to turn back most often when approaching the border from a particular side.

To determine how fast females move, the path-tracing apparatus was used with a parafilm square on which 20 silk strands were wrapped. At instances where a female was either examining silk or not, her path was traced as long as possible and the elapsed time measured with a stop watch. The path length was later measured by rolling a plastic, circular protractor marked in degrees over the entire tracing and converting the number of degrees covered to linear distance. Thus speed of movement could be calculated. Thirteen path lengths on silk and 20 off silk from 21 females were so measured (an attempt was made to get both kinds of path lengths from each female, but this was not always possible). The parasites' speeds on and off silk were compared by t test.

RESULTS AND CONCLUSIONS

Naive vs. Experienced Females. There were few differences in parameters whether or not female *C. melanoscela* had been preconditioned by exposure to gypsy moth larvae before tests (Table 1). Experienced females may have been more active, because they contacted the parafilm at a greater frequency than did naive females, but no differences in other parameters occurred. There were some differences in responses to different amounts of silk, but only for the percent of contacts leading to examinations and total examination time. A significant interaction occurred only between silk amount and female type for number of contacts ($F = 3.478$, 2 and 54 df, $P < 0.05$).

Old Colony vs. New Colony. Few differences occurred between old and new colony females in their responses to silk (Table 1). Old colony females spent less time examining than did new colony females, but that was the only difference. No differences occurred between results for different silk amounts, even though trends were what one would expect (i.e., more silk, more activity). All interactions between female type and silk amount were not significant. Thus

TABLE 1. EFFECT OF EXPERIENCE AND LENGTH OF COLONIZATION ON RESPONSE OF *Cotesia melanoscela* TO DIFFERENT QUANTITIES OF SILK, GIVING AVERAGES FOR EACH TREATMENT LEVEL AND VARIABLE AS DETERMINED FOR KIND OF FEMALE AND SEPARATELY FOR SILK CONCENTRATIONS (10 REPLICATES)[a]

Treatment	No. contacts	No. exams.	Contacts leading to examinations (%)	Total time examining (sec)
Experiment 1. Effect of experience				
Female type				
Naive	10.1a	4.0a	37.3a	28.7a
Experienced	15.9b	4.9a	38.4a	42.3a
Silk concentration				
1 silk strand	15.5a	3.1a	20.6a	17.0a
5 silk strands	10.2a	4.0a	43.6b	33.0ab
10 silk strands	13.2a	6.3a	49.3b	56.4b
Experiment 2. Effect of colonization				
Female type				
Old colony (25 gen.)	8.9a	2.3a	22.7a	4.25a
New colony (6 gen.)	12.0a	4.25a	30.1a	15.4b
Silk concentration				
1 silk strand	8.1a	2.2a	23.9a	7.75a
10 silk strands	12.8a	4.35a	28.9a	11.9a

[a] Numbers in each column and each treatment followed by different letters are significantly different at $P < 0.05$ by two-way analysis of variance and selected treatment comparisons.

the old colony females may have been less active than new colony ones, but behavioral differences between the two colonies were small.

Detailed Orientation Behavior. The multiple regression of average angle change away from silk (y) on number of silk strands (x_1) and time period (x_2) was $y = 30.957 + 0.229x_1 - 0.014x_2$, $N = 118$. Using a t test (Ostle, 1963), the coefficients for the x values were not found to be different from 0 (t value for coefficient of $x_1 = 1.707$, 115 *df*, $P < 0.1$, t value for coefficient of $x_2 = -0.018$, 115 *df*, $P > 0.5$). Thus the amount of turning when females were not on silk was not influenced by either the amount of silk present or the passage of time, and averaged $31° \pm 11.7°$ (square root of residual mean square) per turn. When t tests were run to compare rates of turning off silk with rates of turning on silk, only one t value of 46 compared was significant ($t = 3.794$, $P < 0.001$, 35 *df*). Thus with these data there is no reason to expect the parasite to have different turning behaviors when on or off silk.

A different situation exists concerning turnbacks at borders. Figure 3 gives the net proportion turnbacks when on parafilm for all silk concentrations and the net turnbacks when on silk for 10 and 20 strands of silk. For 0 and 1 strands,

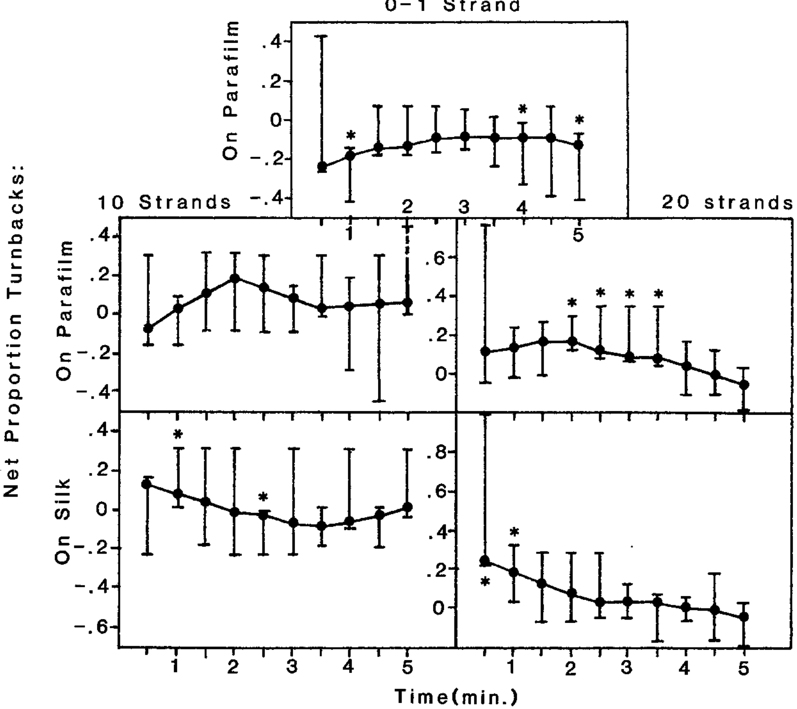

FIG. 3. The relationship between turnbacks at borders for *C. melanoscela* females at different time periods and with different amounts of silk. Data are locally weighted regression values for net proportion turnbacks on parafilm and on silk. Brackets are the 95% bias-corrected bootstrap confidence intervals for each net value. Asterisks highlight values where the confidence interval does not include 0.

all values are below 0, and some are significantly below 0 (i.e., confidence interval does not include 0) with no evident trend over time. This suggests that in the absence or undetectability of silk, females tend not to turn back at borders when they are on parafilm. When silk is detected (10 and 20 strands), many of the net values for on parafilm and silk were positive and, especially for 20 strands, some were significantly so. The net values also tended to decrease with time. Thus females tend to turn back into areas which have silk when they encounter a border, even if that border is somewhat beyond the edge of the substrate which has silk (i.e., at the background-parafilm border). This response decreases with time and could be an important factor in causing the habituation already referred to when *C. melanoscela* females are exposed continuously to silk (Weseloh, 1980).

The speeds of movement of females when on and off silk, respectively,

with 95% confidence intervals, were 0.66 cm/sec ± 0.70 and 2.10 cm/sec ± 1.17. These values were significantly different ($t = 8.392$, 31 *df*, $P < 0.001$). Thus, as with other parasitoids (Waage, 1978), *C. melanoscela* has an inverse orthokinetic response when examining silk.

DISCUSSION

This study suggests that, unlike other parasites mentioned in the introduction, *C. melanoscela* does not learn to recognize gypsy moth silk. The response of *C. melanoscela* to gypsy moth silk is a highly specific one, for the silk of even other lymantriids is examined rather little (Weseloh, 1976). Learning may be more important for parasites which attack a variety of hosts than it is for *C. melanoscela*.

Differences in the behavior of old and new colonies was not evident, but these insects should actually be different in a variety of ways. The ease with which diapause can be altered in laboratory cultures of this species (Hoy, 1975) hints at its genetic plasticity. Possibly the behaviors investigated here are so basic that even under prolonged rearing conditions, they are not greatly changed. The results suggest that the evaluation of these behaviors in the laboratory has some relevence for wild parasites.

Concerning orientation behavior, *C. melanoscela* appears to behave differently from other natural enemies tested (Strand and Vinson, 1982; Sabelis et al., 1984; Nakamuta, 1985) because its rate of turning does not noticably increase when it has detected kairomone. The reason may be related to the natural distribution of kairomone on leaves. When first and third gypsy moth instars which *C. melanoscela* attacks feed on oak leaves, they deposit strands of silk diffusely over the whole surface (personal observation). To find the caterpillar that spun the silk, *C. melanoscela* must thoroughly search all of a rather large leaf. Being a small (ca. 2 mm long) parasite, it can probably do this most successfully if it does not turn so often that it is restricted to one small section of the leaf. By responding to boundaries by turning back, it is able to quickly examine the leaf. By moving slowly, the parasite has time to recognize a host when contacted. Finally, the decrease in the turnback response ensures that the parasite will eventually stop searching if a host is not found.

The orientation behavior of *C. melanoscela* can be broken down into various, simpler behaviors, some of which differ from similar behaviors of other parasites. The differences are related to the host specificity shown by *C. melanoscela* and the distribution of kairomone in relation to the host in nature. When these factors are accounted for, the parasite is seen to be well adapted to find hosts efficiently.

Acknowledgments—I thank Wilhemina Smith for her help in carrying out this study and her large contribution to designing the apparatus used for path tracing.

ATTRACTION TO PHEROMONE SOURCES OF DIFFERENT QUANTITY, QUALITY, AND SPACING: Density-Regulation Mechanisms in Bark Beetle *Ips typographus*[1,2]

FREDRIK SCHLYTER, JOHN A. BYERS, and JAN LÖFQVIST

Department of Animal Ecology

(Received February 18, 1986; accepted September 10, 1986)

Abstract—The density of bark-beetle colonization of a tree could be regulated by a quantitative effect of the pheromone signal from beetles in the tree (cessation of release of attractive pheromone) or by a qualitative effect (production of pheromone components inhibiting attraction). The quantitative hypothesis was tested on *Ips typographus* by varying the release rate of the two known attractive compounds, 2-methyl-3-buten-2-ol (MB) and (4*S*)-*cis*-verbenol (cV). The highest number of beetles were captured at traps with the highest release rates. The catch was nearly proportional to the release of MB and cV at a distance between traps of 12 m or more. At 6-, 3-, and 1.5-m distances between traps deployed in a triangular arrangement there was still a good discrimination between release rates, but relatively more beetles, especially males, were caught on the blank. The lower release rates caught an equal sex ratio while the highest release rate caught only about 30% males. The qualitative hypothesis was tested by releasing the suspected inhibitors ipsdienol (Id) and ipsenol (Ie), from traps in the same amounts as cV. Only small effects were noted for *I. typographus*. However, the competitor *I. duplicatus* was attracted to Id and inhibited by Ie, while the predator *Thanasimus formicarius* was attracted to both compounds. On the other hand, when the ratio of Id or Ie to cV was 10:1 or 0.1:1 rather than 1:1, they affected the numbers of *I. typographus* attracted. A small amount of Id combined with the attractants increased trap catch, while large amounts of Id or Ie decreased attraction, especially when combined. Attack density regulation is modeled as an effect of both quantitative and qualitative mechanisms acting in sequence.

INTRODUCTION

Regulation of colonization density is a crucial factor in the population biology of the spruce bark beetle, *Ips typographus* (L.). At high population levels the beetle is able to reach attack densities sufficient to overcome the resistance of a healthy tree by a mass attack involving several thousand beetles and governed by aggregation pheromones (Thalenhorst, 1958; Bakke and Riege, 1982). However, the high densities found on trees killed by mass attacks, 3–15 egg galleries/100 cm^2 (Thalenhorst, 1958; Lekander, 1972; Anderbrant, 1986), are often at a level where severe larval competition results in a low number and quality of offspring per female (Botterweg, 1983; Anderbrant et al., 1985). Consequently, the bark bettle needs not only a pheromone mechanism to initiate a mass attack to reach a sufficient attack density, but natural selection would also promote a system telling arriving individuals that a patch is occupied (Alcock, 1982). Arriving beetles may then colonize nearby patches, such as other parts of the tree or adjacent trees. Such "switching," where the attack first focuses on one tree but, in a few days, switches to other trees in the vicinity, has frequently been observed at high "epidemic" population densities both in *Dendroctonus frontalis* (Coulson, 1979), *D. ponderosae* (Geiszler et al., 1980), and in *I. typographus* (J.M. Hoff, unpublished; O. Anderbrant et al., unpublished).

Little is known about variation in pheromone production and response in bark beetles during the colonization phases and how pheromones may be used in regulation of density (Byers et al., 1984). Byers (1983) suggested that colonization density in *Ips paraconfusus* Lanier along the trunk of a felled tree was regulated in part by sex-specific responses to quantitative changes in the rate of pheromone release. Males appeared to avoid higher pheromone concentrations emanating from the densely colonized patches and thus settle in adjacent areas where their pheromone production spreads the area of aggregation and colonization. Schlyter and Löfqvist (1986) showed in the laboratory that walking *I. typographus* females were more attracted to stronger sources of natural pheromone than were walking males. 2-Methyl-3-buten-2-ol (MB) and (4*S*)-*cis*-verbenol (cV) are the essential components of the aggregation pheromone of *I. typographus* (Bakke and Riege, 1982; Schlyter et al., 1987b). The quantity of these two compounds in hindguts is maximal when the unmated male constructs his nuptial chamber under the bark (Birgersson et al., 1984). Later, when the males are mated and females are laying eggs, MB and cV decrease substantially, while ipsdienol (Id) and ipsenol (Ie) reach the same order of magnitude as cV. Id has been indicated as a synergist (Bakke et al., 1977) and Ie as an inhibitor (Bakke, 1981) of the aggregation pheromone.

In *I. typographus*, regulation of density and tree-switching by pheromone could then be hypothesized to take place by one or both of the following mechanisms:

1. *Quantitative Hypothesis.* Initially, males attack in relation to the amount of attractant odor. As the release increases, some of the males attracted to the initial attack site are deflected by high concentrations of pheromone when they reach the source and so attack patches (adjacent bark areas or trees) a short distance away. After mating, the males in the first patch produces less attractant, and the aggregation would switch to the newly attacked areas.

2. *Qualitative Hypothesis.* The higher amounts of inhibitors such as Id and Ie released in the later phases by the earliest arriving males cause an inhibition of attraction, especially in males. Surrounding areas would receive the new attacks and the colonization activity would switch.

From the quantitative hypothesis follows at least two predictions: First, beetles should discriminate between sources of different release rate, and males, compared to females, should be relatively less attracted to the highest rates. Second, discrimination should be significant even when sources are only a few meters apart (as are mature trees in a forest).

From the second, qualitative hypothesis, it follows that the presence of Id and Ie should, especially at the higher release rates or ratios, lower the number of beetles attracted.

In order to test these hypotheses, we have in the field studied beetles landing on sticky traps deployed in triangular arrays at four spacings with three release rates of MB and cV. We have also studied the attraction to pipe traps at constant spacings baited with a concentration range of attractants (MB and cV) with and without Id or Ie, or both, in different proportions.

METHODS AND MATERIALS

Synthetic Substances, Dispensers, and Release Rates. The synthetic substances were released from polyethylene (PE) vials with different sizes of openings (MB, cV, and high rates of Id and Ie) or from glass capillaries (low rates of Id and Ie). Release rates from PE vials were determined from weight loss in a mini wind tunnel, 0.70 m/sec, at 20°C. Weights were taken on a balance to the nearest microgram and corrected for weight changes of empty control vials. The slope with its 95% confidence interval of the regression of weight (y) on time (x) gave the estimated release rate, Table 1. The release rates of Id and Ie from capillaries were measured in a similar wind tunnel. The capillaries were 12 mm long, fused at one end, and filled from the bottom through an inserted thin capillary (Löfqvist, unpublished). The loss of liquid from the capillaries was measured by the change of the position of the meniscus under a stereomicroscope.

MB and cV were released in the field experiments at three release rates

each at a ratio of about 50 : 1, which is close to or larger than that found in male hindguts (Birgersson et al., 1984). The lowest release rate of cV was somewhat higher (about 0.03 mg/day) than intended (0.01) and the medium was lower (0.052 mg/day) than intended (0.10). This altered the target MB–cV ratio somewhat as MB was released at evenly spaced decadic steps. However, the ratio of MB to cV changes the sex ratio very little and it is the MB release that is the most critical in determining the total number caught (Schlyter et al., 1987a). The highest rate, 50 mg MB and 1 mg cV per day, corresponds to the release from 1 m of commercial Borregaard/Hercon Ipslure® dispenser, aged one week (Schlyter et al., 1987b).

Triangle Experiment: Variation of Pheromone Release Rate and Spacing. Three traps arranged in an equilateral triangle constituted a trap group. Each group had a blank trap and various combinations of two of the three possible decadic release rates of MB and cV (Tables 1 and 2). Randomization between replicates took place only within groups, as it was impractical to change the positions of whole trap groups. This means that comparisons of absolute catches between groups are not valid. However, comparisons can be made between groups based on relative catches within a group.

The chemical dispensers were housed in 30-cm sections of commercial drain pipe traps, suspended on 1.5-m-long steel pipes. The black dispenser housing was surrounded by a tubular sticky trap (31 × 19 cm diam.) of No. 4 hardware cloth coated with Stikem Special®.

For the first trapping period (six replicates between the days May 16 and 31), the traps were spaced at 3-, 6-, and 12-m distances in nine trap groups (three baitings × three spacings) (Figure 1). Since the blank caught few beetles even in groups with 3-m spacing, we decided to arrange all nine trap groups in a 1.5-m spacing distance for a second trapping period (eleven replicates between May 31 and June 12, 1982).

The test area was in a clear-cut at 160 m altitude, near Torsby, province of Värmland, Sweden, with a moderately high beetle population (more than 100 trees killed the previous year within 0.7 km). The trap groups were placed in a grid with equal distance between groups (50 m) on a gentle west slope (maximum elevation difference was 20 m).

Quantitatively and Qualitatively Different Baits at Constant Spacings. In the 1982 test, four qualitative combinations of either Id or Ie, both, or neither were released with three rates of MB and cV yielding 12 different baits (Tables 3 and 4). The release rate of Id and Ie was varied to correspond approximately with that of cV.

Black pipe traps with a white funnel at the base (''N 79 with funnel'' in Regnander and Solbreck, 1981) were used at a spacing of about 50 m. Treatment (trap with a bait) positions were randomized after each replicate. The Ie in PE vials was replaced after the first replicate as it began to polymerize.

One set of 12 traps was used in each of two widely separated sites near

TABLE 1. CHEMICALS, RELEASE RATES, AND DISPENSERS FOR 2-METHYL-3-BUTEN-2-OL, *cis*-VERBENOL, IPSDIENOL, AND IPSENOL USED FOR FIELD TRAPPING OF *Ips typographus* IN 1982 AND 1984

[b] Value significantly different from the catch of the high bait (*$P < 5\%$, **$P < 1.0\%$, ***$P < 0.1\%$ by chi-square).
[c] Values in parentheses calculated on less than 15 beetles.

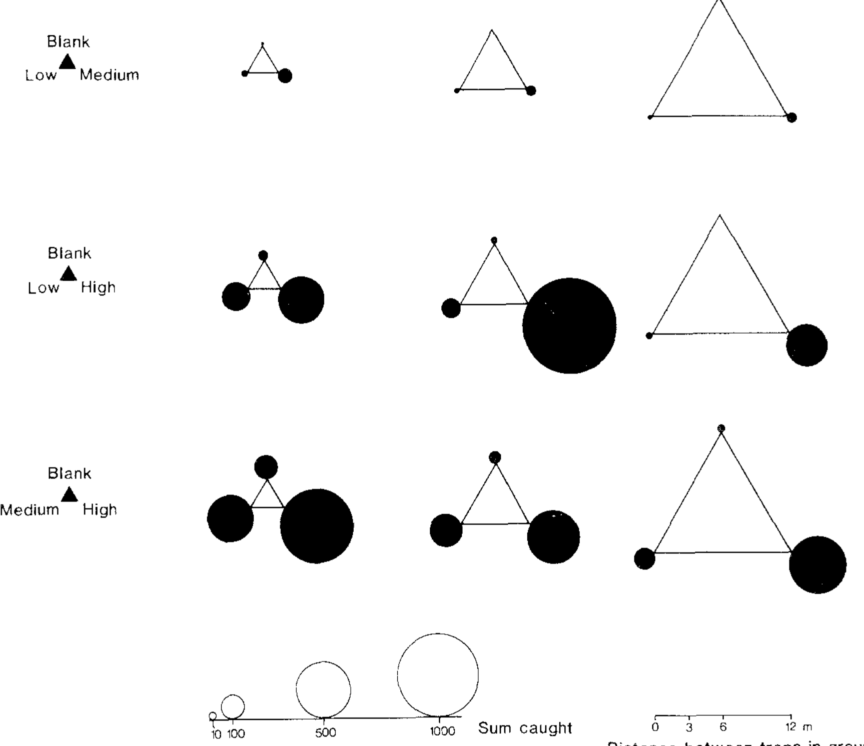

FIG. 1. Total catch on sticky traps with quantitatively different baits at different spacings within triangle trap groups during the first trapping period. Catch data from the 1.5-m spacing during the second period and release rates of baits are shown in Table 2. The different baits are indicated at the black triangles at left. Baits were randomized within trap groups and distance between trap groups was 50 m.

Torsby, province of Värmland, Sweden. Site L, a 3-year-old clear-cut area at 145 m altitude, had a low local beetle population, with no standing trees attacked the previous year within 0.5 km. Site T, a fresh clear-cut at 105 m altitude, had a high local population because many standing trees were killed within the cutting area the previous year, so that a high density of beetles were probably wintering in the duff close to the traps. Trapping was done between May 16 and June 9, 1982.

In the 1984 test, nine combinations of Id/Ie, with MB + cV at a constant medium dose, as well as MB + cV alone as a control (ten different baits) were tested (Table 5).

MB and cV were released with the same type of dispensers as used for the medium release rate in the 1982 test.

TABLE 3. BAITS AND PERCENT MALES IN CATCH OF *Ips typographus* AT THREE GROUPS OF RELEASE RATES AND FOUR QUALITATIVE COMBINATIONS OF ATTRACTANTS AND INHIBITORS, IN PIPE TRAPS, VÄRMLAND, SWEDEN 1982

1–12	Site T, all baits					37.6	35.7–39.6	2382

[a] Less than total catch, see Methods and Materials. Samples from sites L and T pooled unless otherwise stated.

Black pipe traps without exterior funnel ("N 79" in Regnander and Solbreck, 1981) were used in two rows with all spacings 10 m and randomized in an incomplete Latin-square design, i.e., a bait could occupy a position only once during a test. Two sets each of 10 traps were placed on two 3- to 4-year-old clear-cuts 1.5 km apart at 50 m altitude, in Esrum forest distinct, Grib skov, northern Sjaelland, Denmark. The beetle population was judged to be fairly high, with about 100 trees killed within 0.5 km the year before but none closer to traps than 100 m at both sites. Trapping was done between May 14 and June 26, 1984.

Statistics. Raw catch data, individual trap catches per replicate (trapping period of one half to several days depending on flight activities), were subjected to a series of transformations, including log, square root, and arcsin $p^{0.5}$ to achieve homogeneous variances before ANOVA (Sokal and Rohlf, 1981). The transformation which yielded homoscedacity for the catches of each treatment in different experiments, as tested by both Cochran's C and Bartlett-Box tests with $P > 5\%$, along with the highest F ratio was chosen and used in ANOVA and MANOVA on each experiment. All beetles from the sticky traps were sex separated. From pipe traps, 260 beetles (or the whole catch if less than 260) from the total catch of each bait on a site, proportionally sampled from the different replicates over the whole trapping period were separated by sex.

RESULTS

Attraction to Sources of Attractive Pheromone of Different Quantity at Different Spacings. The ability of the beetles to discriminate between pheromone sources of different strengths and spaced at various "close" distances was studied in the triangle experiment. The beetles discriminated well between pheromone sources of different strengths (Figure 1), the response being highly dependent on the release rates of MB and cV (Table 2). Even at 3-m spacing, the strongest sources had 65–83% of the beetles caught by a triangle trap group, while the blank caught only a few percent (Figure 2). There was, however, a significant increase in the catch on the blank with decreasing triangle size, and at 1.5 m spacing as much as 17% of the trap group catch was found on the blank trap (Figure 2). Also low and medium release rates had an increased catch at smaller distances when tested in trap groups with a stronger bait present. For the highest release rate, the increase in its proportion of the trap group catch with increased distance was highly significant (Figure 2).

The sex ratios of catch on the blank and low-bait traps were not significantly different from 50% at 3-, 6-, and 12-m distances (Table 2). The percent males caught was significantly less than 50% at the highest release rate at all four distances on all eight traps.

Attraction to Pheromone Sources of Different Quantity and Quality at Con-

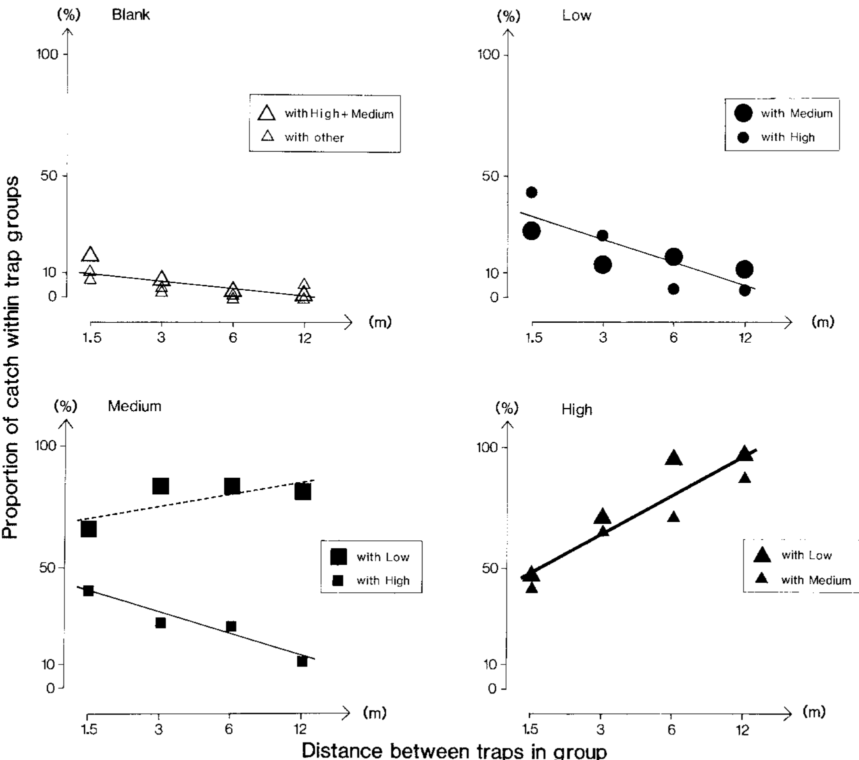

FIG. 2. Relative catches (means) within trap groups as a function of distance between traps. Significance of regression estimated by the slope confidence intervals difference from zero (thick regression line: $P < 1\%$; thin: $P < 5\%$; dotted: $P > 5\%$). Combinations not significantly different when only one line is shown. Release rates and sex ratio statistics shown in Table 2.

stant Spacing. I. typographus catch correlated well to three decadic steps in release rates of MB + cV from pipe traps spaced 50 m apart. At the site with a low local beetle population in the 1982 experiment (site L), the catch was directly proportional (slope close to unity) to the quantity of pheromone released (Figure 3). The addition of Ie, Id, or both in combination to these baits at about the same release rates as cV had very little effect. Multiple ANOVA of the first experiment showed that quantity (amount of MB + cV released) had by far the largest *F* ratio of the main effects. Quality (addition of Ie and/or Id or none) had a smaller but significant effect (Table 4). The interactions between quantity and site could be due to the more direct proportionality between bait and response at site L (Figure 3). One-way analysis of variance showed that baits with the same release of MB + cV usually formed homogeneous subsets (Figure 4).

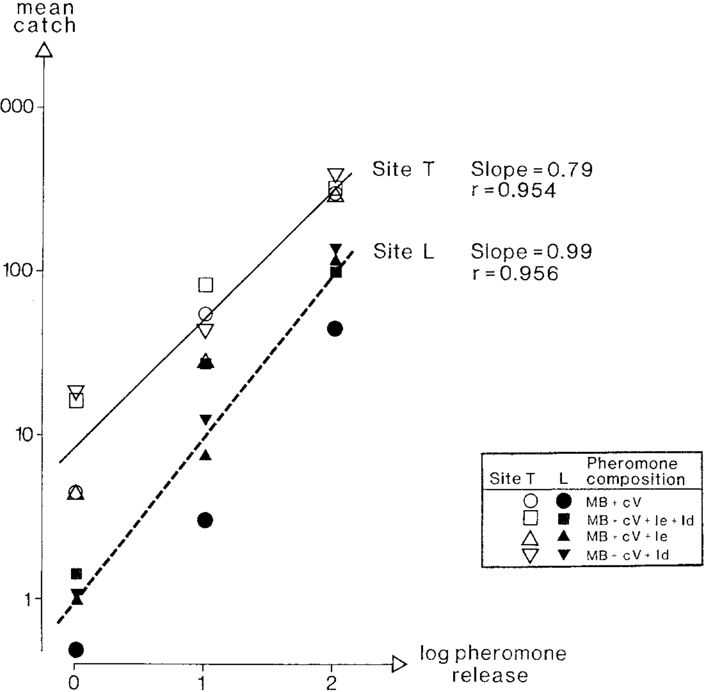

FIG. 3. Dose (log pheromone quantity) and response (untransformed mean trap catches) at sites with a high (T, 8 replicates) and a low (L, 8 replicates) local beetle population. Regression coefficient (slope) different from zero at $P < 1\%$ for both sites. Slope of regression line for site T significantly different from unity at $P < 5\%$. Release rates of the components (MB, cV, Ie, Id) of qualitatively different baits as shown in Table 3.

For the second experiment (1984) multiple ANOVA showed highly significant first-order effects when Ie, Id, or both were tested with cV at either 10 : 1 or 0.1 : 1 ratios (Table 4). The highest ratio of Ie and the combination Ie + Id, decreased the catch significantly as judged by one-way ANOVA (Figure 5). In contrast, the lower amounts of Id, the same as 1 : 1 or a tenth (0.1 : 1) that of cV, increased the catch slightly but significantly compared to the control.

Sex Ratios. An increase in bait strength caused a decrease in the proportion of catch that were males from 50% at the low dose to 30% at the high dose, similar to the ratios caught in the triangle experiment (Table 3). In fact, at the high bait, the pipe traps and the sticky traps caught an almost identical percentage of males, 32.9 and 33.4%, respectively (Tables 2 and 3). The addition of Ie/Id in amounts similar to cV did not give any significant difference between the sex ratio in the catch of the individual baits in the 1982 experiment. However, the three baits with only MB + cV had a higher percentage of males (38.5) than the three baits with both Ie and Id added (31.8%, Table 3). This

TABLE 4. FACTORIAL MANOVA ON EFFECTS ON CATCH IN PIPE TRAPS OF *Ips typographus* OF VARIATION OF MB AND cV AND ADDITION OF Ie AND Id AT CONSTANT RATIO, VÄRMLAND, 1982; AND ADDITION OF Ie AND Id AT DIFFERENT RATIOS TO CONSTANT MB + cV, GRIB SKOV 1984[a]

[a] For abbreviation of compounds, see Table 1.
[b] 1982 test, 16 replicates, variable analyzed was log (catch per replicate + 1/2)
[c] 1984 test, 11 replicates, variable analyzed was arcsin (proportion of catch per replicate + 1/100)$^{0.5}$

difference is mainly due to the low male ratio, 26.0%, in the traps with the highest release of MB, cV, Ie, and Id.

Similarily, in the 1984 experiment, the higher amounts of Ie plus Id added together seemed to reduce the percentage of males (Table 5). However, the sex ratios in 1984 were confounded by a constant decrease in the proportion of males caught during the trapping period. During the nine replicates between May 15 and June 8, the percent males (y) in the total catch fell steadily at about 1% per day (x), following the regression equation: $y = 38.2 - 1.20x$ ($r = 0.92$, slope different from zero at $P < 0.1\%$). A similar trend was noted in

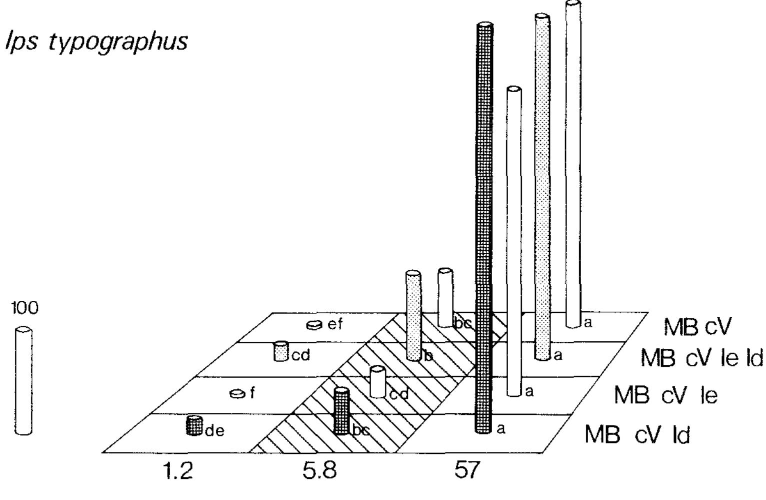

FIG. 4. Response of *Ips typographus* (untransformed mean catches of 8 replicates) towards quantitative variation of MB + cV and addition of Ie and/or Id in well-spaced pipe traps (1982 experiment, site T). Bars with the same letter are not significantly different [$P > 5\%$ by Duncan's multiple range test after ANOVA on catch transformed by log (catch + 1/4)]. Squares with parallel hatching contain baits used in both 1982 and 1984 experiments. Bars with stippled hatching indicate baits with both Ie and Id added, while cross-hatching indicates addition of Id. Sex ratio statistics and release rates are shown in Table 3.

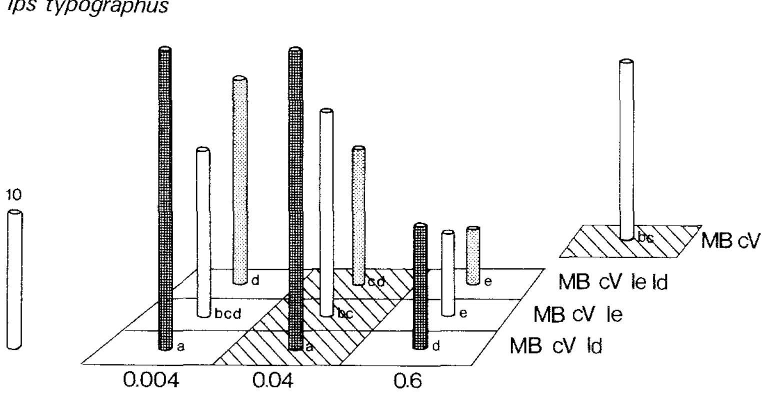

FIG. 5. Response of *Ips typographus* (untransformed means) to addition of Ie and/or Id (1984 experiment, 11 replicates, two sites pooled) to MB + cV at 5.8 + 0.05 mg/day. Statistics and hatchings as in Figure 4, except that arcsin (proportion of catch per replicate + $1/100)^{0.5}$ was used in ANOVA.

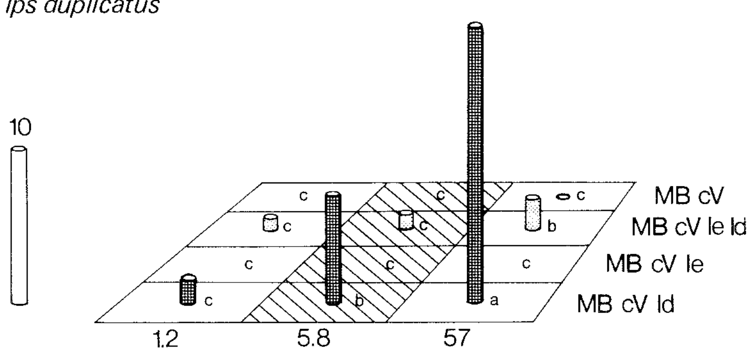
[a] Equal to total catch, see Methods and Materials. Samples from the two test sites pooled as sex ratio of total catch on each site showed no significant difference.



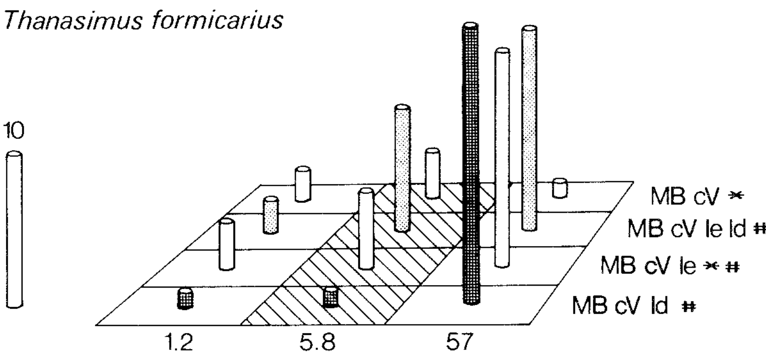


FIG. 6. Response of *I. duplicatus* (untransformed mean catches) in 1982 experiment, sites pooled. Statistics and hatchings as in Figure 4. Response of *Thanasimus formicarius* (total sums caught, sites pooled) in 1982 experiment. Hatching as in Figure 4. Qualitative bait combinations followed by the same symbol (*, #) are not significantly different ($P > 5\%$, Wilcoxon matched-pairs signed-ranks test).

1982 in Värmland, but the smaller number of replicates during this period makes a statistical analysis less valid.

Other Species. In contrast to *I. typographus*, *I. duplicatus* (Sahlb.) did not react to a change in MB + cV release, but responded only to addition of Id and/or Ie and was attracted strongly only to baits containing high levels of Id (Figure 6). Inclusion of Ie reduced the catch clearly and significantly at all release rates. The predator *Thanasimus formicarius* (L.) (Coleoptera: Cleridae) was attracted predominantly towards baits with high amounts of Ie and/or Id (Figure 6). The smaller predator *T. femoralis* (Zett.) was attracted in a similar pattern but in very small numbers.

DISCUSSION

Methodology and its Relationship to Natural Behavior. In order to arrive at meaningful biological interpretations of results from trapping with synthetic compounds, three elements of the methods must be scrutinized in particular: trap design, purity of chemicals, and release rates of chemicals.

The traps used in this study were either a sticky trap with silhouette, which require beetles to land in order to be trapped, or pipe traps with holes which require a beetle both to land and enter a hole to be trapped. Thus, both trap types reflect the landing rate, which is one of the most important parameters in the host colonization process (Byers et al., 1984). The two trap types also had very similar sex ratios in their catches, both here and in a parallel study (Schlyter et al., 1987a).

The chemicals used in this study were all of fairly high chemical purity (Table 1), and the cV was of correct ($>94\%$ *S*) enantiomeric composition while Ie and Id were racemic (50/50 *R/S*). The natural composition of Ie and Id in *I. typographus* is probably not racemic (Francke et al., 1980). Attractive synergistic properties of these compounds could thus have been concealed by the presence of an unnatural enantiomer (Wood, 1982; Vité et al., 1985). Possible inhibitory properties of a compound might also be hidden by an incorrect enantiomeric composition.

The release rates of the different pheromone components are very critical in a study of this kind, because they must ultimately be compared to natural pheromone sources. It is difficult to determine the actual release rate during attraction in the field and so we must rely on laboratory estimates until further studies are done (see Table 1). *I. typographus* males produce high amounts of MB when initiating the nuptial chamber, while production of cV is dependent on the amount and enantiomeric composition (optical purity) of α-pinene in the bark (Birgersson et al., 1984; unpublished). For males attacking a resin-rich standing tree, the release of MB and cV per male has been estimated by air entrainments to be on the average about 100 μg/day and 1–2 μg/day, respectively, per male (Schlyter et al., 1987b; Birgersson et al., unpublished). Typically, as more than 1000 males might attack a standing tree, this would yield a release of at least 100 mg/day of MB and 1–2 mg/day of cV per tree, which corresponds to the highest dose used per trap in the present study.

Quantitative Hypothesis. There was a dramatic effect on the response of *I. typographus* with a change in dose of attractive pheromone components. In two of three sites the catch was directly proportional to the release rate. This finding is in contrast to the generally held concept that in pheromone studies one usually gets only a doubled response with a 10-fold increase in dose. The nearly proportional relationship could be related to the MB component of the pheromone, which has an unusually steep dose–response curve both in EAGs and in field tests (Dickens, 1981; Schlyter et al., 1987a). The beetles were able to differ-

entiate between pheromone sources of different strengths only 1.5 m apart. This indicates they can sense which area is likely to provide the better habitat in terms of avoiding competition. However, "low" attractant releasing areas could not be identified as either a beginning or terminating colonization site based on the quantitative hypothesis alone.

The almost equal sex ratio obtained both on sticky traps and in pipe traps with the low releasing baits as compared to female biased sex ratios on higher releasing baits indicates that an area with low numbers of males in the earliest attack phases, producing a weak pheromone signal (Figure 7A, B), would then attract relatively more males and result in a mass attack (Figure 7C).

The nearly equal sex ratio obtained on weak baits in pipe traps with funnel in our study indicates that the low proportion of males always found in pipe traps in mass trapping (Bakke et al., 1983) is not only due to an intrinsic property of the pipe traps, but is mainly due to the high pheromone doses used. Males are proportionally less attracted to strong pheromone sources than females. They may well be deflected from a strong pheromone source, such as a tree under mass attack (Figure 7C, D) and start colonization in a patch with lower amounts of pheromone (Byers, 1983). In a Y-tube walking bioassay, Schlyter and Löfqvist (1986) showed that females chose stronger sources of natural male pheromone more often than males did. At a strong pheromone source, flying males may reach a threshold concentration releasing landing or avoidance further away than at a weaker source. The reason for the sexual differences could then be that, although both sexes are equally attracted from a distance (Schlyter et al., 1987a), males are physiologically more sensitive to the pheromone (Dickens, 1981). Males might respond further away than females by entering the "landing step" in the attraction sequence and so land in less populated areas and expand the colonization area (Schlyter et al., 1987a).

The quantitative mechanism, if invoked alone, would predict that males be attracted to completely colonized trees (where all males are mated, Figure 7E) with a low release of attractive pheromone, something which would be nonadaptive.

Qualitative Hypothesis. Males could separate a new and weak pheromone source from an old and weak source of MB and cV by the release of Id and Ie from the older source. More specifically, it could be of interest for a male to assess the ratio of Ie and Id to MB and cV. Addition of Ie and Id in the same quantity as cV (Ie + Id : cV = 0.9 : 1) had no effect in the 1982 test, even at the high release rate (0.9 mg/day). When these compounds were added in the 1984 test at approximately the same release rate (1.3 mg/day), but at a much higher ratio to cV (25 : 1), a clear reduction in catch resulted.

As reported by Bakke (1975), the competitor *I. duplicatus* is strongly attracted to baits containing Id, and this was also shown in our test in Värmland (species not present in Denmark). *I. duplicatus* was also inhibited by Ie at much lower doses than *I. typographus*, an effect also found in Norway (Bakke, per-

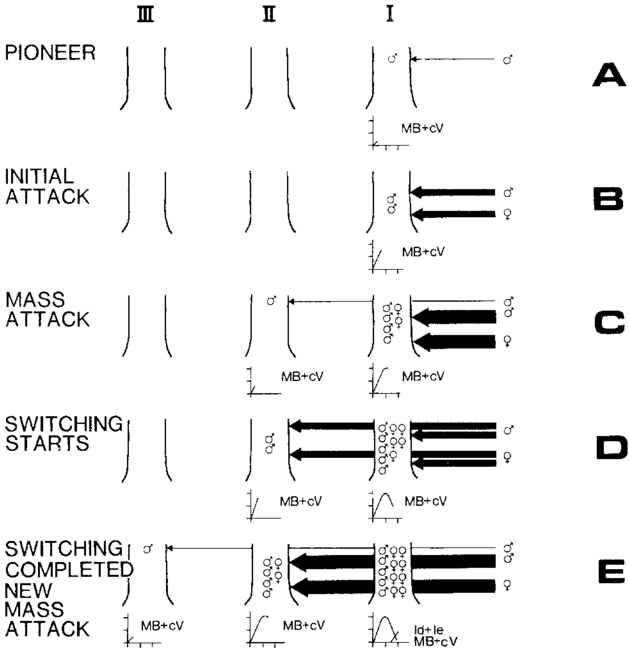

FIG. 7. (A) At the low densities in the *pioneer stage*, density is increased by recruiting more beetles by the increased release of aggregation pheromone (MB + cV). (B) If the first pioneering males are not killed by the resin flow in a short time (hours–1 day), they will produce large amounts of pheromone, and if the beetle population is high, the attracted beetles will start an *initial attack* to exhaust the defensive resin flow. (C) In the *mass attack* phase the tree (I) is taken over, and large numbers of females and males are attracted. A small proportion of males are deflected and land on an adjacent tree (II). (D) While attraction declines towards the first tree as a result of the decline in production of attractive pheromone components, attraction increases towards the second tree, which starts a *switch* in attraction. (E) The first "*switching*" is now *completed* as very few beetles are attracted to the first tree, which now produces only small amounts of attractants (MB + cV) but increasing amounts of inhibitory compounds (Ie + Id and others). The second tree (II) has now become the focus of attraction, where a *new mass attack* starts, while a small fraction of males again is deflected and lands on a third tree (III). At high population levels, this kind of density regulation behavior could mean the death of hundreds or thousands of standing trees, while at lower normal population levels, the colonization may proceed only along patches on a single fallen tree. The small graphs under tree trunks represent log pheromone release and are a simplification and condensation of Figures 3 and 4 in Birgersson et al. (1984). The marks on the x axis represent the attack phases 1, 3, and 6, corresponding to males boring in cortex bark (1), having completed nuptial chamber (3), and being joined by egg-laying females (6).

sonal communication). As *I. duplicatus* is the weaker competitor for breeding substrate when attacking at the same time as *I. typographus* (Anderbrant and Schlyter, unpublished), it is surprising that *I. duplicatus* is attracted to a blend of chemicals (MB, cV, and Id) produced by *I. typographus* in an already colonized patch. This question can probably not be resolved before we gain a better understanding of the quantity and chirality of Id and Ie produced by these two competing species in different phases.

The two *Thanasimus* species were little attracted to baits with MB and cV, but baits with addition of Ie and Id were attractive kairomone sources, which corresponds well to the results of Bakke and Kvamme (1981).

Addition of Id alone showed an interesting effect on *I. typographus*: at low release rates and proportions (0.1 : 1 and 0.8 : 1 of Id to cV) it increased the catch somewhat, while at the higher rate (12 : 1. Id : cV) it decreased the catch (Figure 5). This multifunctional (Rudinsky, 1973) effect of Id is not shared by Ie, which seems to decrease attraction in all baits where it is added alone (Figures 4 and 5). The reason for this difference between the compounds might be that Id is produced somewhat earlier than Ie (Birgersson et al., 1984; unpublished). Verbenone, reported by Bakke (1981) as an inhibitor of trap catches and often produced in considerable quantities in galleries in later phases (Leufvén and Birgersson, 1987) could also contribute to the message of an "old patch."

Other means of communication than pheromonal, such as acoustic, could also affect the colonization density by producing spacing patterns (Byers, 1984). However, the stridulation in *I. typographus* is of low amplitude (Rudinsky, 1979) and would result in a short communication distance (millimeters–centimeters) and could contribute little directly to the switching between patches of the scale discussed here.

Conclusion. Using the chemical data from Birgersson et al. (1984), biological data from Schlyter and Löfqvist (1986), and this study, we propose a combined hypothesis in a graphic model of how attack density could be regulated by the aggregation switching to other trees (areas) at a high population level, as shown in Figure 7. The switching is effected by both the quantitative and qualitative mechanisms acting in sequence. A high quantity of MB and cV is the mass attack signal and also enlarges the area of attack as many of the males land on adjacent trees. The aggregation switching to new areas or trees is completed by a decrease of MB and cV in combination with an increase of the proportion of Id and Ie and possibly other later-occurring substances at the initial colonization area.

Acknowledgments—Chemicals (cV, Id, and Ie) were provided by Borregaard, Sarpsborg (L. Riege) and cV was purified by P. Baeckström, KTH, Stockholm. Study areas were generously supplied by Billerud (M. Sjölander) and valuable field information by Skogsvårdsstyrelsen (I. Olsson) 1982 in Torsby, Sweden. Statskovvesenet in Grib skov, Esrum forest district, Denmark. provided the 1984 study areas which were located with the help of H.P. Ravn, Landbohøjskolen,

Copenhagen. Dedicated field assistance was given by E.V. Jirle, M. Appelgren, G. Birgersson, E. Marling, and K. Persson. The extensive effort of sample preparation and measurements of dispensers was done by E. Marling, B. Bartosch, J. Börnfors, and E. Wijk. The mini wind tunnel was designed and built by J. Jönsson. The drawings were made by E.V. Jirle. We thank them all for their professional help and commitment.

Funding was provided by Swedish Research councils (NFR, FRN, SJFR, STU).

Abstract—The response of the sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), and the merchant grain beetle, *O. mercator* (Fauvel), to synthetic racemic and chiral macrolide aggregation pheromones was assessed in pitfall olfactometers. *O. mercator* utilizes the *R* enantiomers of (*Z*)-3-dodecen-11-olide and (*Z,Z*)-3,6-dodecadien-11-olide. *O. surinamensis* utilizes the *R* enantiomers of (*Z,Z*)-3,6-dodecadien-11-olide and the synergist (*Z,Z*)-5,8-tetradecadien-13-olide in combination with achiral (*Z,Z*)-3,6-dodecadienolide. For both species, the racemates of the respective chiral pheromones were effective attractants. The respective *S* enantiomers were inactive for both species and had no effect on the biological activity of the active antipodes. No diel periodicity in responsiveness to pheromones was detected in *Oryzaephilus* spp. reared either on a 12:12 light–dark photoperiod or in darkness. Nonpheromone macrolides, naturally released in trace amounts by *Oryzaephilus* spp., did not affect the aggregation response of either species to its pheromones when these additional macrolides were combined with the pheromone mixtures.

Key Words—*Oryzaephilus surinamensis*, *Oryzaephilus mercator*, aggregation pheromone, macrolide lactone, (Z)-3-dodecen-11-olide, (*Z,Z*)-3,6-dodecadien-11-olide, (*Z,Z*)-5,8-tetradecadien-13-olide, (*Z,Z*)-3,6-dodecadienolide, (*Z*)-5-tetradecen-13-olide, enantiomers, racemate, chirality, aggregation behavior, Coleoptera, Cucujidae.

INTRODUCTION

The sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), and the merchant grain beetle, *O. mercator* (Fauvel), are long-lived pests of stored food products throughout the world. In the United States, *O. surinamensis* was ranked first in importance as a pest of stored products and processed food and second as a problem on raw grain, whereas *O. mercator* was listed as an established pest of processed food in general (Mueller, 1982). Utilization of pheromones for suppression and monitoring of insect populations could contribute to the development of integrated control programs (Burkholder, 1981, 1982) for these economically important species.

Seven male-produced, macrolide lactone aggregation pheromones have been identified for grain beetles in the genera *Oryzaephilus* and *Cryptolestes* in the family Cucujidae (Oehlschlager et al., 1987, and references therein). In the genus *Oryzaephilus* (Figure 1), the pheromones have been identified as (Z)-3-dodecen-11-olide (I) and (Z,Z)-3,6-dodecadien-11-olide (II) for *O. mercator*, and II, (Z,Z)-3,6-dodecadienolide (III), and (Z,Z)-5,8-tetradecadien-13-olide (IV) for *O. surinamensis* (Pierce et al., 1985). An additional compound, (Z)-5-tetradecen-13-olide (V), a pheromone synergist in *C. turcicus* (Millar et al., 1985a) and *C. pusillus* (Millar et al., 1985b) is produced in trace amounts by *O. surinamensis* and *O. mercator* (Oehlschlager et al., 1987), but has not been tested in *Oryzaephilus* spp. In laboratory bioassays utilizing the natural products, *O. mercator* responded best to a mixture of I and II, while IV synergized the response to a mixture of II and III for *O. surinamensis* (Pierce et al., 1985). Macrolides I, II, and IV each possess one chiral center and thus could exhibit biological activity as the *R* or *S* enantiomers or some combination thereof.

Our objectives were: (1) to determine the biological activities of the *R*, *S*, and racemic forms of the macrolide aggregation pheromones for both *Oryzaephilus* spp.; (2) to determine the biological activities of additional macrolide lactones released in trace amounts by males of both species (Oehlschlager et al., 1987); and (3) to assess whether or not either or both species show any diel periodicity in pheromone response.

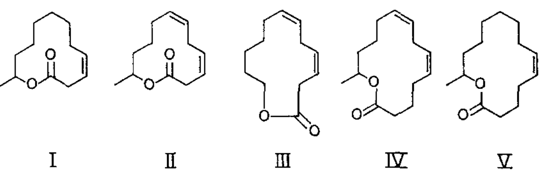

FIG. 1. Structures of macrolides I, II, III, IV, and V.

METHODS AND MATERIALS

Experimental Insects. O. mercator and *O. surinamensis* were reared on large-flake rolled oats and brewer's yeast (95 : 5, w/w) at 28–30°C and 40–60% relative humidity in darkness (Pierce et al., 1981). Additionally, beetles used for some bioassays were reared as above but on a 12 : 12 hr light–dark cycle (lights on from 0600 to 1800 hr).

Macrolide Lactones. Macrolide lactones used for bioassays were as follows: (*R*,*S*)-I, (*R*)-I, and (*S*)-I were synthesized by Oehlschlager et al. (1983). Racemic II was synthesized by Millar and Oehlschlager (1984). (*R*)-II was isolated from volatiles of feeding *O. mercator* (see below), enantiomeric excess >99.5% (Oehlschlager et al., 1987). (*S*)-II was synthesized by the method of Millar and Oehlschlager (1984). III was synthesized by Millar and Oehlschlager (1984). (*R*,*S*)-IV, (*R*)-IV, and (*S*)-IV were synthesized by Millar and Oehlschlager (1984). (*R*,*S*)-V, (*R*)-V, and (*S*)-V were synthesized by Millar et al. (1983).

Collection of Natural II. Beetle-produced volatiles for preparative separation of (*R*)-II were obtained by aerating *O. mercator* adults of mixed sex and age maintained on rolled oats in all-glass systems for periods of seven days (Pierce et al., 1981, 1985). Charcoal-filtered, humidified air was drawn by aspiration through the culture contained in a vertically oriented chamber and then through a trap filled with Porapak Q® (50–80 mesh, Applied Sciences Division, Milton Roy Laboratory Group, State College, Pennsylvania). Volatiles were recovered by extraction of the Porapak Q with purified pentane in a Soxhlet extractor for 24 hr and concentrated by distilling off the pentane through a Dufton column.

Instrumental Methods. A Hewlett-Packard 5830A gas chromatograph equipped with a 18835B capillary inlet system and a flame-ionization detector (FID) was employed for analyses by gas chromatography (GC). Samples were analyzed on a 50-m × 0.5-mm-ID open-tubular glass column coated with Superox 4 (Alltech Associates, Deerfield, Illinois). The temperature program for analytical GC was 70°C for 2 min, then 4°C/min to 180°C, holding for 30 min or less. A Varian 1200 gas chromatograph equipped with a 10 : 1 effluent splitter, FID, and thermal gradient collector (Brownlee and Silverstein, 1968) was used for isothermal (175°C) micropreparative separation of II from Porapak Q-trapped volatiles of feeding *O. mercator*. The column was a 3-m × 3.17-mm-OD stainless-steel tube packed with 5% OV-101 on Chromosorb G (80–100 mesh). Before micropreparative separation, an aliquot of the pentane extract was concentrated to 30–50 μl by evaporation under a gentle stream of nitrogen at −10°C. For both chromatographs, helium was the carrier gas, and the injection port and detector temperatures were 260°C and 270°C, respectively.

Quantification of macrolides in purified pentane for bioassay was done using methyl myristate as an internal standard.

Mass spectra were determined on a Hewlett-Packard 5895A GC/MS/DS fitted with a 30-m × 0.25-mm-ID fused silica column coated with Carbowax 20 M (J & W Scientific, Rancho Cordova, California) with helium as the carrier gas.

Bioassay Procedures. A two-choice, pitfall olfactometer (Pierce et al., 1981) was utilized to test macrolide attractiveness. Filter paper disks treated with a 10-μl aliquot of either an experimental stimulus in purified pentane or purified pentane as a control were put singly into the bottoms of two glass vials suspended from holes in the bottom of a plastic Petri dish arena. Twelve beetles of mixed sex were released into the dish, and the lid was replaced. Bioassays for each test solution were replicated 12 times simultaneously (i.e., 12 olfactometers). After 2 hr in darkness, the numbers of beetles in experimental and control vials were recorded. The raw data were analyzed with a t test for correlated, paired data. Results were expressed as the mean percent response of the total number of beetles per treatment.

Bioassays were conducted at 23°C and 60% relative humidity using test beetles 5–12 weeks posteclosion. Except for bioassays examining the effect of photoperiod on pheromone response, test insects had been reared in darkness. To ensure a uniform state of preconditioning for *O. mercator*, each replicate of 12 beetles was held in a 60-ml glass vial without food for 20 hr at 23°C in darkness prior to a bioassay. To obtain maximum responsiveness from *O. surinamensis*, up to 1500 beetles were preconditioned without food for 48 hr at 23°C in darkness in a 6-liter Erlenmeyer flask, through which charcoal-filtered, humidifed air was drawn at 1.5 liters/min. Since response of *O. surinamensis* in the two-choice olfactometer was extremely sensitive to population density (Pierce et al., 1983), test beetles were maintained at a reduced population density of 1000 beetles/kg medium for at least one week before bioassays commenced.

RESULTS AND DISCUSSION

O. mercator. Olfactory response by mixed-sex *O. mercator* to racemic I and II and the *R* and *S* enantiomers thereof over a 10,000-fold dose range is presented in Figures 2–4. It was previously shown (Pierce et al., 1985) that response by *O. mercator* to a 1:1 mixture of natural I and II was numerically superior to that to either compound alone, although the beetles responded well to either pheromone. The 1:1 mixture of I and II approximated the natural ratio produced by the bioassay beetles. Good aggregation response was shown to the *R* enantiomers of macrolides I (Figure 2C), II (Figure 3C), and the 1:1 mixtures

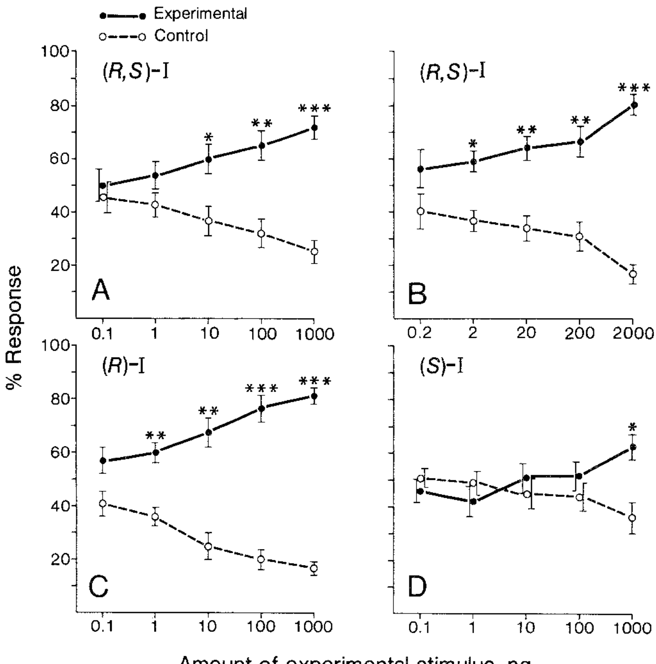

FIG. 2. Response ($\bar{X} \pm$ SE) by mixed-sex *O. mercator* in two-choice, pitfall bioassay to macrolides (R,S)-I, (R)-I, and (S)-I. Significant response (t test) to experimental stimulus indicated by the following: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$. $N = 12$ replicates.

of (R)-I and (R)-II (Figure 4C), with the thresholds for significant positive response at 1–2 ng of experimental stimulus. A similar response occurred to equivalent amounts each of (R)-I (Figure 2B) and (R)-II (Figure 3B) presented as the racemates and to the 1 : 1 mixture of racemic I and II (Figure 4B). These response patterns were equivalent to those shown towards natural I and II by mixed-sex *O. mercator* (Pierce et al., 1985). Based on the same weights of macrolides bioassayed, however, lower aggregation responses were demonstrated towards racemic I (Figure 2A), II (Figure 3A), and the 1 : 1 racemic mixture (Figure 4A) compared to the responses shown to the *R* enantiomers thereof (Figures 2C–4C).

No significant positive response was shown to the *S* enantiomers of I and II alone (Figures 2D, 3D) or combined (Figure 4D) except at high doses. These moderately positive responses can be explained by small optical impurities in (S)-I and (S)-II (enantiomeric excess >99%) (Oehlschlager et al., 1987).

Recently, *O. mercator* was found to produce chirally pure I and II in the

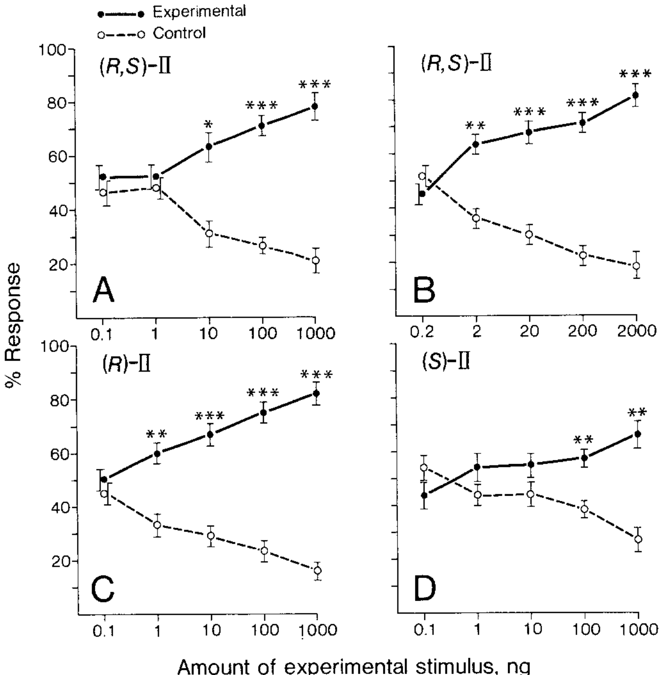

FIG. 3. Response ($\bar{X}$ ± SE) by mixed-sex *O. mercator* in two-choice, pitfall bioassay to macrolides (*R*,*S*)-II, (*R*)-II, and (*S*)-II. Significant response (*t* test) to experimental stimulus indicated by the following: *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$. $N = 12$ replicates.

R configuration (Oehlschlager et al., 1987). Figures 2–4 indicate that the inactive *S* enantiomers of I and II had no effect other than dilution on the biological activity of (*R*)-I and (*R*)-II.

O. surinamensis. Moderate amounts of (*R*,*S*)-II (Figure 5A) or achiral III (Figure 5B) elicited a low aggregation response from mixed-sex *O. surinamensis*; the positive response was enhanced when (*R*,*S*)-II and III were combined in a 2:1 mixture (Figure 5C). The racemate of the synergist IV elicited no significant response when bioassayed alone over a 6-ng to 6-μg dose range (data not shown). When combined with either (*R*,*S*)-II (Figure 5D) or III (Figure 5E), (*R*,*S*)-IV enhanced the positive response to either of the former two macrolides and extended the ranges of positive response at the highest experimental doses. The 2:1:6 mixture of (*R*,*S*)-II, III, and (*R*,*S*)-IV (Figure 5F) evoked the strongest aggregation response from mixed-sex *O. surinamensis* over the 10,000-fold dose range. The natural pheromone ratio of II, III, and IV produced by the bioassay beetles was approximately 1:1:3 (Pierce et al., 1985).

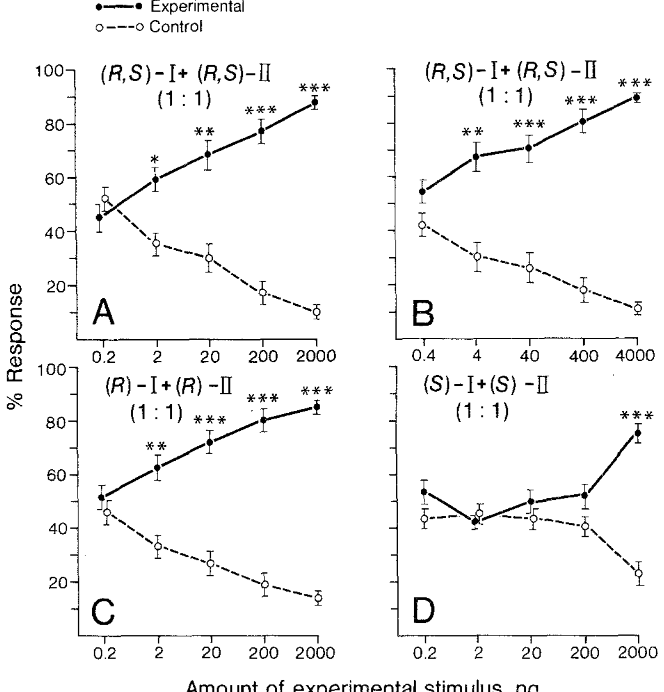

FIG. 4. Response ($\bar{X}$ ± SE) by mixed-sex *O. mercator* in two-choice, pitfall bioassay to 1 : 1 mixtures of macrolides I and II in the racemic, *R*, or *S* forms. Significant response (*t* test) to experimental stimulus indicated by the following: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$. $N = 12$ replicates.

When bioassayed individually over a 3-ng to 3-μg dose range, the *R* or *S* enantiomers of IV elicited no significant response (data not shown), as was found for racemic IV. The addition of (*R*)-IV to the 2 : 1 mixture of (*R*, *S*)-II and III to give a 2 : 1 : 3 mixture (Figure 6A) elicited a strong aggregation response, similar to that elicited by the 2 : 1 : 6 mixture of (*R*, *S*)-II, III, and (*R*, *S*)-IV (Figure 5F). The substitution of (*S*)-IV for (*R*)-IV in the 2 : 1 : 3 mixture resulted in a low response (Figure 6B) like that shown towards the 2 : 1 mixture of (*R*, *S*)-II and III (Figure 5C). Therefore, the *R* enantiomer of IV appears to be the active synergist. No inhibition of response by the *S* enantiomer of IV is indicated.

Figure 7 illustrates the response by *O. surinamensis* to either (*R*)-II and (*R*)-IV or (*S*)-II and (*S*)-IV in combination with achiral III. The response patterns to (*R*)-II, (*R*)-II + III, and (*R*)-II + III + (*R*)-IV over a 10,000-fold dose range (Figures 7A–C) were similar to those when equivalent amounts of (*R*)-II and (*R*)-IV as racemates were tested (Figures 5A, C, F). Likewise, these aggre-

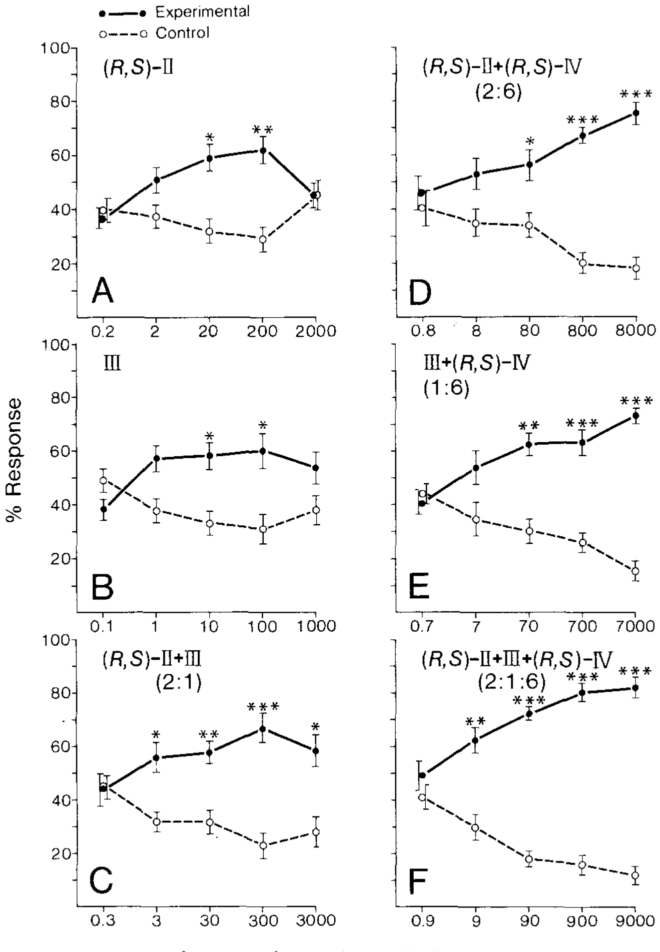

FIG. 5. Response ($\bar{X} \pm$ SE) by mixed-sex *O. surinamensis* in two-choice, pitfall bioassay to macrolides (*R*,*S*)-II, III, and (*R*,*S*)-IV. Significant response (*t* test) to experimental stimulus indicated by the following: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$. $N = 12$ replicates.

gation responses also agreed with those exhibited earlier by *O. surinamensis* to the natural pheromones (Pierce et al., 1985). Solitary (*S*)-II was inactive except at the 1-μg dose (Figure 7D), which can be explained by a small optical impurity (enantiometic excess >99%) (Oehlschlager et al., 1987). The addition of III (Figure 7E), or of III and (*S*)-IV to (*S*)-II (Figure 7F) elicited response patterns resembling that to solitary III (Figure 5B).

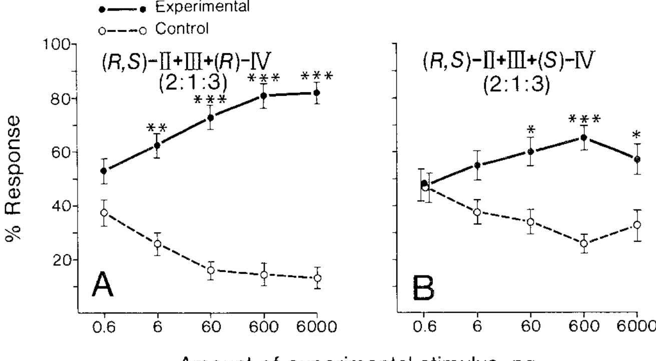

FIG. 6. Response ($\bar{X} \pm$ SE) by mixed-sex *O. surinamensis* in two-choice, pitfall bioassay to macrolides (*R*, *S*)-II, and III combined with (*R*)-IV or (*S*)-IV. Significant response (*t* test) to experimental stimulus indicated by the following: $^*P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$. $N = 12$ replicates.

O. surinamensis produces chirally pure II and IV in the *R* configuration (Oehlschlager et al., 1987). Taken together, Figures 5, 6, and 7 indicate that *O. surinamensis* utilizes the *R* enantiomers of II and IV. The *S* enantiomers appear to be inactive alone and do not inhibit or affect response to the *R* enantiomers.

Additional Macrolides. Feeding males of both *Oryzaephilus* spp. produced trace amounts of additional macrolide lactones as detected by GC-MS (Oehlschlager et al., 1987). For *O. mercator* these trace macrolides were III, IV, and V, while *O. surinamensis* produced trace amounts of V. When these compounds were bioassayed individually over a 0.1- or 0.2-ng to 1- or 2-μg dose range, III and the *R*, *S*, and racemic forms of IV and V elicited no response from mixed-sex *O. mercator*, and (*R*)-, (*S*)-, and (*R*, *S*)-V elicited no response from mixed-sex *O. surinamensis* (data not shown).

The five macrolides (I–V) were bioassayed in five-part mixtures (Table 1). For either *Oryzaephilus* spp. the presence of additional macrolides in the respective pheromone mixtures did not affect response to the aggregation pheromones over a 10,000-fold dose range (compare Table 1 with Figures 4B and 5F).

Interspecific Communication. Since both *Oryzaephilus* spp. utilize (*R*)-II as a common pheromone, solitary (*R*)-II and the pheromone mixture of the other species were tested to further investigate possible interspecific communication between *O. mercator* and *O. surinamensis* (Table 2). Solitary (*R*)-II elicited strong aggregation response from *O. mercator* and comparatively lower response from *O. surinamensis*. For either species, response to (*R*)-II was not affected by the pheromone(s) of the other species.

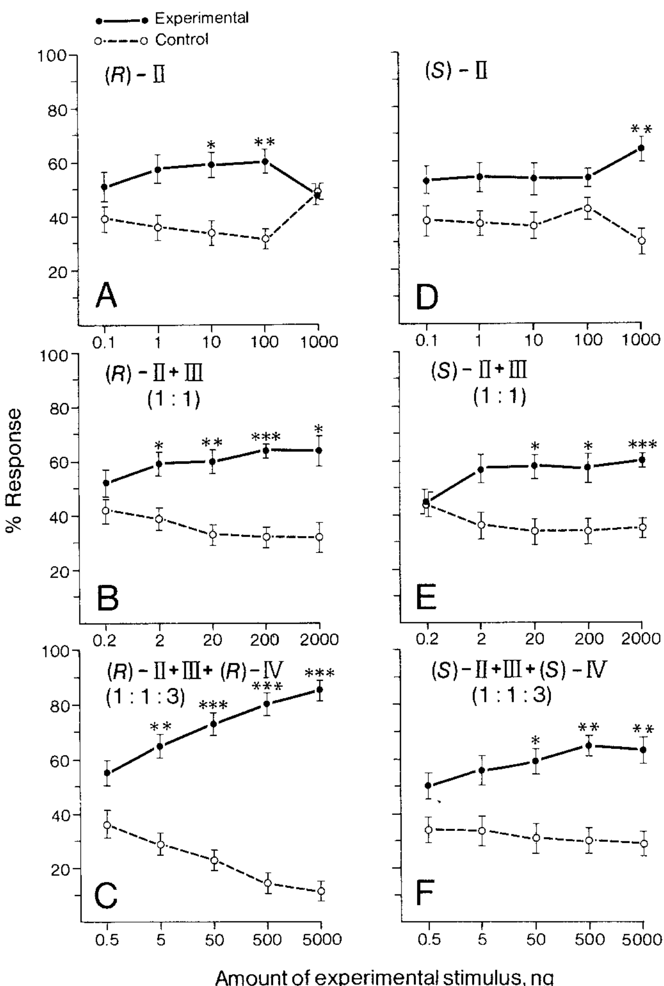

FIG. 7. Response ($\bar{X} \pm$ SE) by mixed-sex *O. surinamensis* in two-choice, pitfall bioassay to macrolides: chiral II, III, and chiral IV. Significant response (*t* test) to experimental stimulus indicated by the following: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$. $N = 12$ replicates.

Diel Response Patterns. For both *Oryzaephilus* spp., there was no apparent diel rhythm in pheromone response to moderate amounts of the respective pheromone mixtures tested in mid-photophase and mid-scotophase (Table 3). Beetles reared in darkness showed no difference in pheromone response when compared to beetles reared on a 12 : 12 hr light–dark photoperiod. *Oryzaephilus* spp. and the maize weevil, *Sitophilus zeamais* Motsch. (Walgenbach et al., 1983),

are similar in their lack of diel periodicity in responsiveness to pheromones. However, another long-lived, stored-product beetle, the granary weevil, *Sitophilus granarius* (L.), definitely exhibits such periodicity (Faustini et al., 1982).

Practical Implications. Response to attractive volatiles in *O. mercator* and *O. surinamensis* appears soon after eclosion and apparently extends throughout the long, adult lives of these beetles (Pierce et al., 1983). Moreover, neither species showed any diel periodicity in responsiveness, despite the photic conditions under which they were reared. Therefore, macrolide lures for *Oryzaephilus* in field traps might be effective under variable conditions of photoperiod throughout adult life.

Our results also indicate that the cost-effective racemates of the chiral macrolide pheromones could be used in biomonitoring programs for *Oryzaephilus* spp. Similarly in cucujid beetles of the genus *Cryptolestes*, the inactive antipodes of the chiral macrolide pheromones were not inhibitory (Wong et al., 1983; Millar et al., 1985a,b). Nonpheromone macrolides (Tables 1 and 2) naturally produced in trace amounts had no effect on response by *Oryzaephilus* spp. to their respective pheromones. Since these trace macrolides as well as the *S* enantiomers of I and IV are aggregation pheromones of other cucujid beetles (Oehlschlager et al., 1987), lures might be formulated to trap *Cryptolestes* spp. together with *Oryzaephilus* spp. In this regard, it was possible to monitor simultaneously for both a cucujid and tenebrionid grain beetle using pheromones for both species together in the same field trap (Lindgren et al., 1985). Such combinations of lures for several species would greatly reduce the cost of pheromone-based monitoring programs.

Taxonomic and Ecological Implications. The fact that *O. mercator* and *O. surinamensis* utilize the common pheromone (*R*)-II reflects the close taxonomic relationship of these two species (Slow, 1958). Although they are distinct species that do not interbreed (Slow, 1958), they are morphologically very similar (Loschiavo and Sabourin, 1982). On the other hand, chromosomal studies revealed that the genera *Oryzaephilus* and *Cryptolestes* are not very closely related (Robertson, 1959). Differences in pheromone complexes provide chemotaxonomic evidence in support of this distant relationship. *Cryptolestes* spp. use as aggregation pheromones either macrolides that are unique to the genus, macrolides released in trace amounts by *Oryzaephilus* spp. and not used as pheromones by the latter spp., or macrolides of the *S* configuration (Oehlschlager et al., 1987). The chiralities of the nonpheromone, trace macrolides in *Oryzaephilus* spp. are unknown, however. Enzymatic specificities for macrolide biosynthesis most likely differ in the two genera.

Since our bioassay data indicated that *O. mercator* could be significantly attracted to *O. surinamensis* aggregation pheromone (Table 2), other semiochemicals such as sex pheromones (Burkholder, 1982), so far unknown for these two species, ultimately might be involved in species recognition. How-

[d] Significant response (*t* test) to experimental stimulus indicated by the following: $^{***}P < 0.001$; $^{**}P < 0.01$; NS, not significant. $N = 12$ replicates per treatment, 12 adults per replicate.

ever, in a large, three-dimensional habitat such as stored grain, cross-attraction to (Table 2) or tolerance of (Table 1) the pheromones of a coinhabiting species might be expected. Similar cross-attraction and tolerance occurs among ambrosia beetles that inhabit another spacious host resource, the sapwood of coniferous trees (Borden et al., 1981). In contrast, mutual inhibition of response occurs between two species of bark beetles, *Ips pini* (Say) and *I. paraconfusus* Lanier, that compete for an essentially two-dimensional resource, the inner bark of trees (Birch and Wood, 1975).

Aggregation pheromones in Coleoptera are thought to have arisen initially as mechanisms to cause aggregation at a suitable food source (Shorey, 1973). In many bark beetles (Borden, 1985) and grain beetles (Burkholder, 1982), aggregation pheromone production is dependent on food and is thought to signal the presence of a food-rich habitat. Although pheromone production was enhanced in the presence of food in all *Cryptolestes* spp. investigated to date (H.D. Pierce, Jr. et al., 1984; Millar et al., 1985a,b), macrolide aggregation pheromones may serve as especially critical signals of food reserves for *Oryzaephilus* spp. since only trace amounts of pheromones were released by either *O. mercator* or *O. surinamensis* deprived of food (unpublished observations). Furthermore, *Oryzaephilus* spp. prefer food of high oil content, and fatty acids are hypothesized to be precursors of the macrolide pheromones (H.D. Pierce, Jr. et al., 1984).

One mechanism contributing to the maintenance of species specificity is differential resource utilization. In this regard, a model for the colonization of new habitats by *Tribolium* spp. (Tenebrionidae) (Ghent, 1963; Ziegler, 1976) has also been applied to *Oryzaephilus* spp. (Pierce et al., 1983). The more dispersive *O. surinamensis* may be a primary colonist suited to exploit widely distributed, sparsely populated, and very fresh habitats, whereas *O. mercator* may be a secondary colonist better able to invade and persist in habitats already occupied by populations of the same or different species (Pierce et al., 1983). In support of this model, young, reproductivity vigorous *O. surinamensis* (but not *O. mercator*) were extremely sensitive to overcrowding by conspecifics, as evidenced both by decreased pheromone production (A.M. Pierce et al., 1984) and perception (Pierce et al., 1983). The strong attractiveness of (*R*)-II to *O. mercator* which allows it to be attracted to habitats already colonized by *O. surinamensis* is consistent with the proposed roles for *O. surinamensis* and *O. mercator* as primary and secondary colonists, respectively, of temporary habitats.

(Received April 28, 1986; accepted September 22, 1986)

Abstract—The chiralities of macrolide lactone aggregation pheromones of five species of economically important grain beetles have been determined by capillary gas chromatographic separation of the diastereomeric (*S*)-*O*-acetyllactate derivatives of the hydroxy methyl esters derived from boron trifluoride-catalyzed cleavage of the macrolides in methanol. Chirally pure (*Z*)-3-dodecen-11-olide (I) is produced in the *S* configuration by *Cryptolestes ferrugineus* (Stephens) and in the *R* configuration by *Oryzaephilus mercator* (Fauvel). (*Z,Z*)-3,6-Dodecadien-11-olide (II) is produced in the *R* configuration by both *O. mercator* and *O. surinamensis* (L.). (*Z,Z*)-5,8-Tetradecadien-13-olide (IV) is produced in the *R* configuration by *O. surinamensis* and as a 85 : 15 mixture of *R* and *S* isomers by *C. turcicus*. (*Z*)-5-Tetradecen-13-olide (V) is produced in the *S* configuration by *C. pusillus* (Schönherr) and as a 33 : 67 mixture of the *R* and *S* isomers by *C. turcicus* (Grouvelle). The results indicate that in these cucujids, species specificity in pheromone response is maintained at least in part by pheromone chirality.

Key Words—Chiral semiochemicals, pheromones, enantiomeric composition, enantiomeric synergism, *Cryptolestes ferrugineus, Cryptolestes pusillus, Cryptolestes turcicus, Oryzaephilus mercator, Oryzaephilus surinamensis,* Coleoptera, Cucujidae, (Z)-3-dodecen-11-olide, (Z,Z)-3,6-dodecadien-11-olide, (Z)-5-tetradecen-13-olide, (Z,Z)-5,8-tetradecadien-13-olide.

INTRODUCTION

Since the first discovery of an aggregation pheromone response in cucujid grain beetles (Borden et al., 1979), our investigations in the genera *Cryptolestes* and *Oryzaephilus* have yielded a new class of aggregation pheromones, the macrolide lactones. In the five economically important species studied, we found seven macrolide pheromones (Table 1) (H.D. Pierce, Jr. et al., 1984). Laboratory bioassays revealed that for each species, insects of mixed sex are attracted best to those mixtures of macrolides produced by feeding males (H.D. Pierce, Jr. et al., 1984). In four species, superior attraction was achieved with binary mixtures (Wong et al., 1983; Millar et al., 1985a, b; A.M. Pierce, et al., 1984; Pierce et al., 1985), whereas for *Oryzaephilus surinamensis* (L.), a ternary mixture of macrolides was maximally attractive (A.M. Pierce et al., 1984; Pierce et al., 1985). The males of some species produce macrolides that are pheromones for other species (Table 1). In some instances, different species share common pheromones. Maintenance of species recognition in this sympatric group must therefore involve several mechanisms.

We report the determination of the chiralities of the male-produced macrolides in five species of cucujids. This information, in combination with previously reported bioassay data, allows delineation of the role of chirality in maintenance of species recognition.

METHODS AND MATERIALS

Synthetic Macrolides. Synthetic I in both its racemic and chiral forms was available from previous studies (Oehlschlager et al., 1983). Synthetic racemic II and IV and synthetic chiral IV were prepared as described by Millar and Oehlschlager (1984). Racemic and chiral V were prepared as described by Millar et al. (1983). The remaining macrolides (III, VI and VIII) in Table 1 are achiral and were previously prepared in the references mentioned above.

Insect-Derived Macrolides. Pentane extracts of Porapak Q collected volatiles from feeding adults of each species were prepared as previously described (H.D. Pierce, Jr. et al., 1984). The macrolide composition as determined by gas chromatography (GC) of each extract is given in Table 1.

Derivation of Macrolides and Analysis. Synthetic macrolides or Porapak Q extracts of beetle-produced volatiles (0.5–5.0 μg) were dissolved in methanol (50–100 μl) containing 5% boron trifluoride etherate at −20°C and sealed in glass ampoules. The reactions were maintained at 70°C overnight. This process yielded the corresponding hydroxyl methyl esters, which were isolated by dilution of each reaction with pentane (100 μl) and washing with water (3 × 50 μl). The pentane solution was dried over finely powdered sodium sulfate and filtered through glass wool. A portion (30 μl) of the filtrate was derivatized by treatment in a clean ampoule with pyridine (15 μl of a 50 mg/ml solution in

TABLE 1. DISTRIBUTION OF MACROLIDES IN *Cryptolestes* AND *Oryzaephilus* SPECIES[a]

	Distribution (%)						
	I	II	III	IV	V	VI	VII
C. ferrugineus	34 P	2	—	0.5	3.5	—	60 P
C. pusillus	—	—	1.5	—	2.5 P_{syn}	96 P	—

[a] Analysis by coupled gas chromatography–mass spectrometry as previously described (Slessor et al., 1985) confirmed the identity of the observed peaks as the desired *O*-acetyllactate diastereomers (major fragment ions at m/z 115, 87, 43).
[b] Gas chromatographic conditions: Column DB-1: 30 m × 0.25 mm ID fused silica column programmed as follows: (1) 60°C for 2 min, 7°C/min to 180°C, 2°C/min to 240°C; (2) 80°C for 2 min, 10°C/min to 180°C, 2°C/min to 220°C. Column SPB5: 30 m × 0.25 mm ID fused silica column programmed as follows: (1) 100°C for 2 min, 10°C/min to 180°C, isothermal for 2 min, 10°C/min to 215°C.
[c] ND = not detected
[d] Average of three determinations.

ether) and (*S*)-*O*-acetyllactyl chloride (30 μl of a 25 mg/ml solution in methylene chloride), as described by Slessor et al. (1985).

The *O*-acetyllactyl methyl esters derived from synthetic and naturally occurring macrolides I, II, IV, and V were analyzed by capillary gas chromatography on Hewlett-Packard 5890 and 5880A instruments fitted with flame-ionization detectors. The injector and detector temperatures were 250°C. Helium was the carrier gas. Columns and oven temperature programs are listed in Table 2.

Microhydrogenations were performed by placing 30–50 μl of the hexane solution of the macrolides under one atmosphere of hydrogen in the presence of a few milligrams of 5% Pd on $BaSO_4$. The solution was separated from catalyst by syringe prior to treatment with $BF_3 \cdot CH_3OH$.

The chirality of I in *C. ferrugineus* (Stephens) was determined by comparison of the retention times (Table 2) for the *O*-acetyllactate derivatives (IX) derived from synthetic (*R*,*S*)-I (entry 1) and synthetic (*S*)-I (entry 2) with the *O*-acetyllactate derived from natural I produced by *C. ferrugineus* (entry 3). The same procedure was used for the determination of the chirality of IV in *C. turcicus* (Grouvelle) (entries 13–15), and of V in *C. turcicus* (entries 19–21) and *C. pusillus* (Schönherr) (entries 22–24).

Both I and II reduce to the same saturated macrolide. The determination of the chirality of I in *O. mercator* (Fauvel) involved reduction of natural I, isolated by micropreparative GC, to its dihydro derivative followed by the usual derivatization. Comparison of the retention times of the *O*-acetyllactate derivatives of synthetic racemic tetrahydro II (entry 11), synthetic dihydro (*S*)-I (entry 10) and dihydro (entry 8) derived from *O. mercator* yielded the configuration of the natural material. The retention values obtained above (Table 2) for the *O*-acetyllactate derivative of tetrahydro II (entry 11) enabled us to determine the chirality of tetrahydro II derived from reduction of II produced by *O. mercator* (entry 9) and *O. surinamensis* (entry 12). Likewise, both IV and V reduce to the same saturated macrolide. Knowledge of the chirality of V in *C. pusillus* (entry 24) from the experiments described above allowed assignment of the chirality of the corresponding *O*-acetyllactate of the dihydro derivative (entries 25, 26). This in turn can be used to assign chirality in the *O*-acetyllactate of tetrahydro IV derived from *O. surinamensis* (entry 18).

RESULTS AND DISCUSSION

Chirality of Macrolides I, II, IV, and V. Conversion of macrolides I, II, IV, and V to the corresponding hydroxyl methyl esters (VIII) and thence to *O*-acetyllactate derivatives (IX) is not accompanied by any apparent racemization of the chiral center or double bond isomerization as evidenced by the conversion of synthetic chiral macrolides to single diastereomers (Figure 1). Diastereomers

I,II,IV,V VIII IX

FIG. 1. Conversion of macrolide pheromones to *O*-acetyllactate methyl esters.

(IX) obtained from each racemic macrolide were baseline-separated by the chromatographic systems used. In all cases, the diastereomers (IX) derived from macrolides possessing the *R* configuration eluted prior to those derived from the corresponding macrolides possessing the *S* configuration. From previous work on this method, it is known that errors due to kinetic resolution during formation of the *O*-acetyllactates (IX) and to differential weight response of the diastereomers are less than 3% (Slessor et al., 1985). The enantiomeric compositions calculated for each macrolide in Table 3 are therefore not corrected for either of these variables.

Cross-Attractancy in Cucujids. The aggregation pheromone of the rusty grain beetle, *C. ferrugineus*, consists of I and VII (Wong et al., 1983). These two macrolides, each attractive alone, also act synergistically. One would not expect the rusty grain beetle to be cross-attracted (Table 4) to other cucujids in Table 1 for two reasons. First, *C. ferrugineus* is the only species that produces VII. Second, although both *C. ferrugineus* and *O. mercator* share I as a pheromone, the former produces (Table 3) and responds (Wong et al., 1983) only to (*S*)-I, whereas the latter produces (Table 3) and responds (Pierce et al., 1987) only to (*R*)-I.

The macrolide pheromones produced by *C. pusillus* are V and VI (Table 1) (Millar et al., 1985a). Macrolide V acts to synergize response to the second component, VI, which is active alone. Although *C. pusillus* produces (*S*)-V of high chiral purity (Table 3), no preference for one enantiomer of V acting as a synergist for VI was detected by laboratory bioassays (Millar et al., 1985a). Cross-attraction (Table 4) of *C. pusillus* to other cucujids in Table 1 is not expected since VI, a singly active pheromone component for this species, is not produced by any other species. Although V is common to all cucujids investigated, it is not attractive alone to *C. pusillus*.

The flour mill beetle, *C. turcicus*, utilizes IV and V as its aggregation pheromone (Table 1). As with *C. pusillus*, V is inactive alone but synergizes response to IV which is attractive alone (Millar et al., 1985b). Both IV and V are produced by *C. turcicus* as mixtures of *R* and *S* enantiomers and with opposite chiral enrichments. Macrolide IV is rich in *R* enantiomer (85 : 15, *R*:*S*)

TABLE 3. CHIRALITIES OF MACROLIDES OF *Cryptolestes* AND *Oryzaephilus* SPECIES[a]

	I	II	IV	V

O. surinamensis		*R*	*R*	

[a] Single *S* or *R* indicates >99% one enantiomer.

and V is rich in *S* enantiomer (33:67, *R*:*S*). Careful analysis of the responses of *C turcicus* to the chiral isomers of the singly active macrolide, IV (Millar et al., 1985b), reveals that mixtures of IV containing both *R* and *S* isomers are more attractive than either chiral isomer alone. This is the only known case of enantiomeric synergism in the cucujids. Synergism between enantiomers also occurs in the scolytids, *Gnathotricus sulcatus* (Borden et al., 1976) and *Ips pini* (Lanier et al., 1980).

It is probable that *C. turcicus* would not be cross-attracted to *C. ferrugineus*, even though both IV and V are produced by the latter. In *C. turcicus*, the V:IV ratio is 0.38, whereas, in *C. ferrugineus*, it is 13.0. Furthermore, IV and V are only minor components of *C. ferrugineus* volatiles. Attraction of *C. turcicus* to *C. pusillus* would not be expected since both share only V which is inactive alone in both species. Attraction of *C. turcicus* to *O. mercator* is unlikely because both IV and V are produced by the latter only as minor components (Table 1). Attraction of *C. turcicus* to *O. surinamensis* would not be expected for two reasons. The ratio of IV to V produced by *O. surinamensis* (>510) is drastically different from that emitted by *C. turcicus*. Secondly, IV produced by and attractive to *C. turcicus* is a mixture of *R* and *S* enantiomers, whereas *O. surinamensis* produces (*R*)-IV of high chiral purity (Table 3).

The merchant grain beetle, *O. mercator*, utilizes macrolides I and II as its aggregation pheromone (Table 1; A.M. Pierce, et al., 1984; Pierce et al., 1985). Both I and II are active alone and additively (A.M. Pierce et al., 1984; Pierce et al., 1985). *O. mercator* produces (*R*)-I and (*R*)-II in high chiral purity (Table 3), and this species responds only to the *R* enantiomer of each component of its aggregation pheromone (Pierce et al., 1987). This species would not be expected to be attracted (Table 4) to *C. ferrugineus* because the latter produces only *S*-I (Table 3) (Wong et al., 1983). Cross-attraction of *O. mercator* to *O. surinamensis* is possible since both species produce (*R*)-II (Table 3) which is attractive alone to *O. mercator* (Pierce et al., 1987).

The sawtoothed grain beetle *O. surinamensis* utilizes only three macrolides (II, III, and IV) as pheromones (A.M. Pierce, et al., 1984; Pierce et al., 1985). Macrolides II and III are attractive alone and additively in 1:1 mixture, whereas IV is not attractive but synergizes response to II and III (H.D. Pierce, Jr. et al., 1984; Pierce et al., 1985).

O. surinamensis produces (Table 3) and responds (Pierce et al., 1987) to the *R* isomers of II and IV. Cross-attraction (Table 4) of *O. surinamensis* to *C. ferrugineus* due to the production of minor amounts of II and IV by the latter is not likely since the II:IV ratio in *C. ferrugineus* does not approximate that found in *O. surinamensis* (Table 1). Cross-attraction of *O. surinamensis* to *C. pusillus* is not likely since the only *O. surinamensis* pheromone produced by *C. pusillus* is III and this is a minor component in the volatiles of the latter. Attraction of *O. surinamensis* to *C. turcicus* would not be expected to occur

TABLE 4. CROSS ATTRACTION OF *Cryptolestes* AND *Oryzaephilus* SPECIES[a]

Responding species	Emitting species				
	C. ferrugineus	*C. pusillus*	*C. turcicus*	*O. mercator*	*O. surinamensis*
C. ferrugineus	+	– [1]Emits no VII	– [1]Emits no VII	– [1]Emits no VII [3]Emits *R*-I	– [1]Emits no VII
C. pusillus	– [1]Emits no VI	+	– [1,2]Emits no VI	– [1,2]Emits no VI	– [1,2]Emits no VI
C. turcicus	– [2]Emits insufficient IV relative to V Insufficient amounts of IV and V	– [1,2]Emits no IV	+	– Emits insufficient IV and V	– [2,4]Emits only *R*-IV
O. mercator	– [3]Emits only *S*-I	– [1]Emits no I or II	– [1]Emits no I or II	+	+ (moderate-good) Emits no I
O. surinamensis	– [1]Emits insufficient II	– [1]Emits no II or IV Insufficient III	– [2]Emits no II or III	+ (low) Emits insufficient IV, III relative to II	+

[a] 1 to 4 refer to corresponding mechanisms of species recognition as given in Conclusion. Macrolides listed refer to pheromone components identified as being required for response by responding species that are missing in emitting species. + = responding species is expected to be attracted to emitting species; – = responding species not expected to be attracted to emitting species.

even though these two species produce major amounts of IV. This component of the *O. surinamensis* pheromone blend is not attractive unless II and III are present (H.D. Pierce, Jr. et al., 1984; Pierce et al., 1985). Both of the latter components are absent in *C. turcicus* volatiles. Attraction of *O. mercator* to *O. surinamensis* is likely since each species uses (*R*)-II as an active pheromone component. In addition, *O. mercator* produces a minor amount of III which is singly a pheromone of low activity for *O. surinamensis*.

CONCLUSION

The only cucujid investigated to date likely to exhibit significant cross-attraction is *O. mercator* to *O. surinamensis* (Table 4). The group of insects investigated utilize several mechanisms for species recognition. The major mechanisms identified are: (1) presence of a unique pheromone (*C. ferrugineus*, VII; *C. pusillus*, VI); (2) use of synergistic pheromones that are inactive alone but synergize response to other pheromones (*O. surinamensis*, IV; *C. pusillus* and *C. turcicus*, V); (3) response to only one chiral isomer of a pheromone (*C. ferrugineus* and *O. mercator*, I); and (4) synergism between enantiomers of a pheromone (*C. turcicus*, IV).

Abstract—In field experiments in Sweden, the constituent 2-methyl-3-buten-2-ol of the aggregation pheromone of the spruce bark bettle *Ips typographus* (L.) was effectively replaced by 2-methyl-3-butyn-2-ol.

Key Words—*Ips typographus*, spruce bark beetle, Coleoptera, Scolytidae, pheromones, aggregation pheromone, methylbutenol, methylbutynol, (*S*)-*cis*-verbenol, ipsdienol, traps.

I. INTRODUCTION

Bark beetle pheromones may contain several components. One or several constituents are necessary and considered to be irreplaceable; others may contribute more or less to the overall attractive effect and are not essential. Little is known about the specific behavioral functions of the individual constituents of bark beetle pheromones.

The spruce bark beetle *Ips typographus* (L.) produces a number of substances in varying proportions (Birgersson et al., 1984). (*S*)-*cis*-Verbenol and

2-methyl-3-buten-2-ol are claimed to be essential for eliciting aggregation response (Bakke, 1976; Bakke et al., 1977). Varying results have been obtained by the addition of ipsdienol to the essential compounds to increase attraction (Bakke et al., 1983; Schlyter, 1985; Regnander, personal communication).

Recent studies in Czechoslovakia have indicated that it is possible to replace 2-methyl-3-buten-2-ol with another substance, and patent applications for effective blends have been filed (Konečný et al., 1984, 1985). It has been claimed (Ozols et al., 1982) that methylbutenol as well as ipsdienol can be replaced by other substances, but the identity of those substances has not been revealed. To our knowledge, until now there are no documented cases in which essential bark beetle-produced pheromone components have been effectively replaced by a compound of different structure.

In this paper we present evidence from field experiments conducted in Sweden in 1985 that 2-methyl-3-butyn-2-ol can effectively replace 2-methyl-3-buten-2-ol in baits for trapping *Ips typographus*.

METHODS AND MATERIALS

Chemicals. As standards for the field experiments, commercially available Celamerck plastic bag dispensers containing 1500 mg 2-methyl-3-buten-2-ol, 70 mg (S)-*cis*-verbenol, and 15 mg ipsdienol were used. The release rate of the blend was expected to be about 50 mg/day, but it was ca. 30 mg/day in the experiments.

The experimental blends of the following substances were prepared in the laboratory: 2-methyl-3-buten-2-ol (ME), 2-methyl-3-butyn-2-ol (MY), (*S*)-*cis*-verbenol (CV), and ipsdienol (ID).

ME and MY were purchased from Fluka A.G. The identity of the compounds was checked by NMR and the purity by GC. None of these alcohols contained any detectable trace of the other compound (secured detection level 1/1000), either at the start or at the end of the experiments. MY gave only one peak in the GC trace, while ME contained 22% of an impurity most probably consisting of 2-methyl-3-butan-2-ol, which appears to be a by-product formed in the manufacturing process. Racemic ID was synthesized according to Baeckström et al. (1983). The CV was a gift from Borregaard (95% ee) and was purified by liquid chromatography to >99% chemical purity. The main impurity removed was verbenone.

Immediately before the field tests, special glass dispensers of our own design were prepared with the experimental blends. All blends contained CV combined with either ME or MY, in some blends ID was also added. The substances were used in the following proportions by weight: ME and MY 100, CV 5, and ID 1.

Sufficient chemical (5 ml or more) was added to each dispenser to last the

duration of the experiments. Release rates were determined gravimetrically. In three- to five-week experiments release rates varied between 34 and 79 mg/day (two faulty dispensers released 115 and 202 mg/day). The mean release rate was 56 mg/day ($N = 18$). In the long-term experiment (see below) the mean release rate was 35 mg/day, and the dispensers were still effective after more than three months.

Field Experiments. The attractiveness of the chemicals was tested in two experiments of similar design, one 18-day experiment (replacement) in which ME was replaced by MY and another three-month experiment (long-term) in which the long-term attractiveness of MY + CV was studied. In the replacement experiment, 1979 model Swedish traps with collecting funnel were used; in the long-term experiment, 1979 model Norwegian traps without funnel were used (cf Regnander and Solbreck, 1981).

The traps were placed in fresh clear-cuts 35 km north of Uppsala which contained slash and stumps of predominantly Norway spruce. The traps were set up in groups of three with distances of 6 m between traps and 50 m between groups. Each trap in a group was baited with one of three treatments (see below). All traps were placed in a single row strung parallel to the southern forest edge of the clear-cuts at a distance of 50–75 m from the forest.

The replacement experiment was conducted for 18 days. The treatments (baits) were: Commercial lure, MY + CV, and ME + CV. Five groups with three traps in each were used. The catches were collected when a nearby monitoring trap indicated that there had been sufficient flight activity. After each collection, the positions of the traps within each group were interchanged randomly. The catches were collected five times. The five groups and the five trapping periods yielded a total of 25 replicates.

The long-term experiment, at a distance of 5 km from the replacement experiment, was conducted for 102 days. The treatments were: Commercial lure, MY + CV, and ME + CV + ID. A randomized block design with 10 replicates (groups) was used. The treatments within each block remained in the same position during the entire experimental period. The catches were collected at various intervals.

RESULTS

Replacement of Methylbutenol with Methylbutynol. A total of 40,630 *Ips typographus* was caught in this experiment. Table 1 summarizes the results of the comparison between the methylbutynol blend and blends containing methylbutenol. A two-way analysis of variance (3 treatments, 25 blocks) confirmed that there were no significant differences in catch efficiency between the three pheromone blends ($F = 0.98$).

The results show that methylbutynol can effectively replace methylbutenol

TABLE 1. COMPARISON OF ATTRACTIVENESS OF THREE PHEROMONE BLENDS: MEAN CATCHES OF *Ips typographus* PER REPLICATE FOR SUCCESSIVE TRAPPING PERIODS (N = 5) AND ENTIRE EXPERIMENTAL PERIOD (N = 25).

Trapping period 1985	No. of beetles		
	Commercial lure (ME + CV + ID)	MY + CV	ME + CV
May 15–19	538.4	439.0	400.8
May 20–27	519.2	441.0	661.8
May 28	631.4	604.6	597.4
May 29	799.0	747.0	721.0
May 30–June 2	376.6	303.4	336.4
Mean catch ± SD (25 replicates)	572.9 ± 224.4	507.0 ± 234.1	543.5 ± 275.6

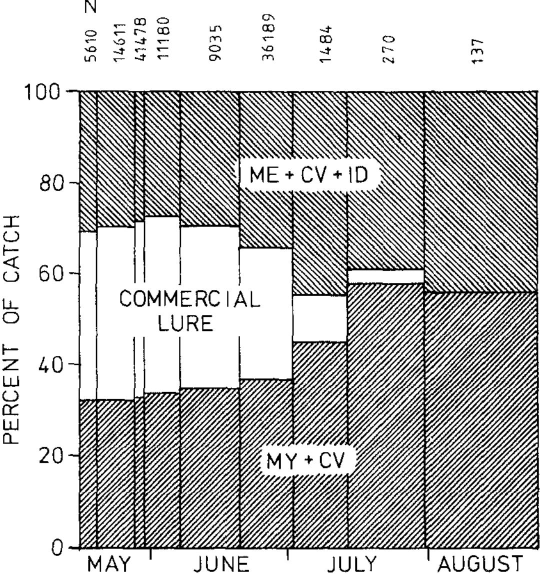

FIG. 1. Relative trap catches of *Ips typographus* in three treatments with different pheromone blends during successive trapping periods. The catches are given as each treatment's percentage of the total catch during each period (N on top of figure = total number of beetles in period = 100%).

in the attraction of *I. typographus*. The commercial lure was not significantly more attractive than the other blends, despite the addition of ipsdienol.

Long-Term Performance of Methylbutynol. A total of 119,994 *Ips typographus* was trapped between mid-May and late August, giving a mean of 4000 beetles per trap. After one and a half months of the experimental period, the trap catches decreased sharply (Figure 1, N).

The attractiveness of the three treatments to *I. typographus* differed towards the end of the experimental period (Figure 1). Higher catches for the traps baited with commercial lure were recorded during the initial three to four weeks. However, two-way analysis of variance did not reveal any significant differences between the three treatments for trap catches up to 35 days. Later, attractiveness of the commercial dispensers decreased strongly, while the experimental glass dispensers remained attractive until the end of the experiment. MY with CV was at least as attractive as the blend containing ME, CV, and ID over a 102-day period.

The results indicate that 2-methyl-3-butyn-2-ol can effectively replace 2-methyl-3-buten-2-ol in blends for trapping *Ips typographus* over long time periods. Ipsdienol was obviously not required for effective trapping in late season.

DISCUSSION

The experiments show that 2-methyl-3-buten-2-ol can be replaced by 2-methyl-3-butyn-2-ol. We are, however, aware of the impurity of the methylbutenol used (see Methods and Materials).

Several thorough studies have been made on substances produced by *Ips typographus*. It is unlikely that 2-methyl-3-butyn-2-ol would have been overlooked. In any case, it can hardly be expected to be released in nature by the beetles in such amounts that it may act as an effective component in combination with (*S*)-*cis*-verbenol to attract the beetles. A possible release of 2-methyl-3-butyn-2-ol by the host plant has not been studied, but such release is improbable.

In the replacement experiment, no significant differences in catches were found between the three mixtures containing methylbutynol or methylbutenol. In the long-term experiment, MY plus CV was not less attractive than the blend ME + CV + ID. Thus, the usefulness of adding ipsdienol to baits for *I. typographus* can be questioned, particularly since it is so attractive for clerid beetles which prey upon *I. typographus* (e.g., Bakke and Kvamme, 1981; Schlyter, 1985).

The release rate of our glass dispensers was adjusted to the expected release rate of the commercial lure used as the standard. In the experiments the actual release rates of the standards were, on average, lower than those of our glass dispensers. According to studies by Sauerwein (1981), Bakke et al. (1983),

and Regnander (personal communication), this difference in release rates is not expected to significantly affect trap catches. This appears confirmed by the first 35 days of the long-term experiment, during which similar blends in the two types of dispenser gave similar catches, while the drop in catch of the commercial dispensers after these 35 days seems to signify a drastic drop in release and attraction.

Interaction between neighboring treatments could be a source of experimental error in trapping experiments, in our case an overestimation of the least attractive treatment. However, the results of Schlyter (1985) indicate low interaction at a 6-m trap distance.

Acknowledgments—We gratefully acknowledge financial support from the Commission of the European Communities and Keno Gard AB and the supply of *cis*-verbenol from Borregaard Industries Limited. Dr. David Tilles kindly corrected the language.

(Received June 13, 1986; accepted September 29, 1986)

Abstract—Behavioral observations of the rice moth (*Corcyra cephalonica*, Pyralidae, Galleriinae) in the laboratory have shown that a male wing-gland pheromone induces attraction of female moths. This pheromone was identified as a blend of (*E,E*)- and (*Z,E*)-farnesal. Wing-gland extracts or synthetic compounds were shown to be attractive to females by inducing walking.

Key Words—Male pheromone, olfactometer, identification, synthesis, farnesal, Lepidoptera, Pyralidae, Galleriinae, *Corcyra cephalonica*, rice moth, 3,7,11-trimethyl-2,6,10-dodecatrienal.

INTRODUCTION

The rice moth, *Corcyra cephalonica* Stainton (Pyralidae, Galleriinae), is a major pest of stored products in subtropical countries (Balachowsky, 1972). In India, the biology of this insect has been extensively studied and different aspects of the sex pheromone-mediated behavior were reported by Singh and Sidhu (1976). They concluded that: (1) the female emits a sex attractant; (2) "calling" females or abdominal-tip extracts were able to stimulate both males and females; and (3) the male produces an aphrodisiac pheromone.

These results suggest that the pairing system in the rice moth is little different from that found in more widely studied genera such as the tortricids and noctuids. However, although female-emitted pheromones are well-known in

0098-0331/87/0700-1561$05.00/0 © 1987 Plenum Publishing Corporation

pyralid subfamilies like the Phycitinae, Pyraustinae, and Crambinae, they have not previously been found in Galleriinae. In this subfamily, male pheromones emitted from wing glands (Vöhringer, 1934; Barth, 1937; Atkinson, 1982; Farine, 1983) evoke a searching behavior in females (Zagatti, 1981; Flint and Merkle, 1983; Greenfield and Coffelt, 1983). It seems that the female responds to male pheromone by walking rather than by flying toward the male, as was originally proposed (Röller et al., 1968; Dahm et al., 1971; Finn and Payne, 1977).

The reported occurrence of female-emitted pheromones in the rice moth led us to reconsider its communication system, since it could represent a step in the evolution of mating behavior in this subfamily.

METHODS AND MATERIALS

Insects. In France, a laboratory-reared strain, fed on *Sorghum*, was obtained from India (G.B. Pant University of Agriculture and Technology), and this strain was compared with "wild" moths found on stored cacao pods in southwestern France. Larvae were fed on rice and vegetables (complementary diet for dogs: MacAni KC 62) and kept in a warm room (27°C, 70% relative humidity) under a 16:8-hr light–dark cycle. Adults were sexed as soon as they emerged (generally half an hour prior to scotophase), and maintained separately thereafter.

Behavioral observations were conducted in a dark room at 25–27°C, with only illumination from a red lamp (Osram 5463; 40 W). Calling and courtship behavior were analyzed using a video-tape recorder (Sanyo VTR 7100) and video camera (Sanyo VC 510). All observations and tests were done between the second and third hour of the scotophase. Moths were 0 (3 hr), 1, or 2 days old when tested.

In England, moths from a laboratory culture originating in Malawi were used. Larvae were fed on a medium of wheat feed (10 parts), dried yeast (1 part), and glycerol (2 parts). Cultures were maintained at 25°C under constant light, and moths were sexed and separated each day.

Olfactometric Tests. Our previous work on galleriine moths (Zagatti, 1981), led us to reconsider the bioassay of pheromones, especially as sex attraction was never quantified for such walking insects. Bioassays were performed in a glass-tube olfactometer (Sower et al., 1973). The tube (70 cm long, 3.5 cm in diameter with an airflow of 1.5 liters/min) was divided into seven sections, each 10 cm in length (Figure 1). Section 0 was at the downwind end and section 6 at the upwind end of the tube.

From 6 to 11 moths were released into section 0 of the tube 30 min before the test, and clean air was passed over them continuously.

Either living insects (A) or hexane extracts (B) were used as pheromone

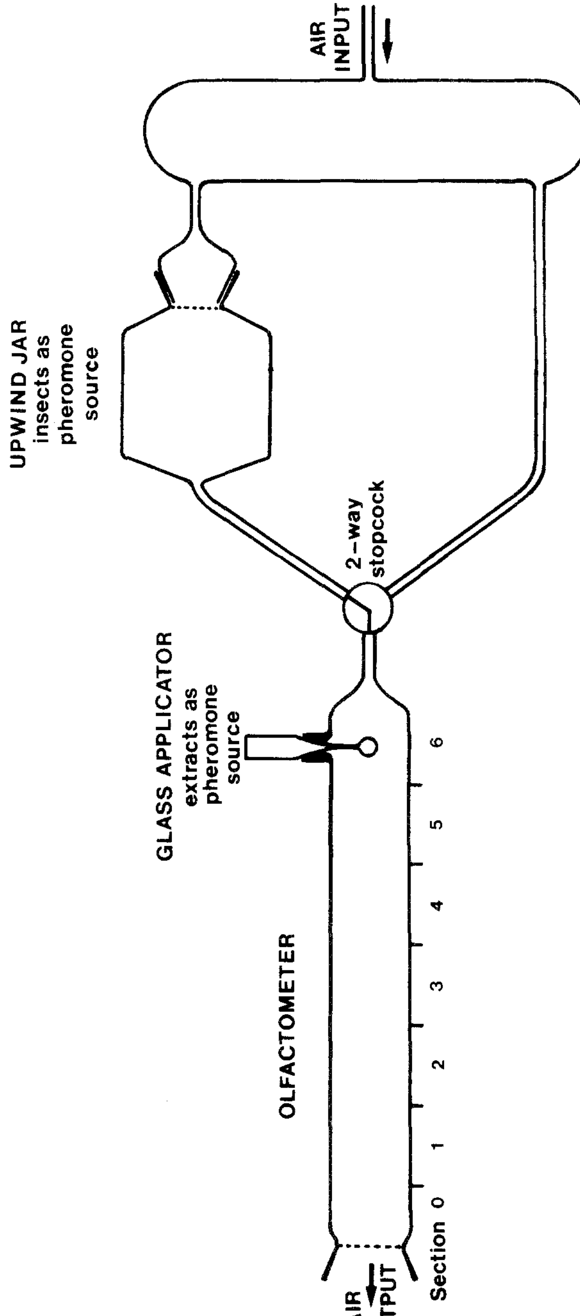

FIG. 1. Diagram of the olfactometer developed for testing the attractiveness of living insects or hexane extracts.

source. (A) The airflow passed through a glass jar containing five males or six females, upwind from the olfactometer tube (Figure 1). (B) The extracts were placed onto an applicator, which consisted of a ground glass rod ending in a small ball (6 mm in diameter). When in place, the ball was situated in the center of the tube, in section 6.

Computation of Results. During a test period of 5 min, the number of moths in each section is recorded every minute, and the position of the moths is given by the formula:

$$X_t = \sum_{i=0}^{6} i\,(n_i)$$

where n_i is the number of moths in section i at the time t. The movement of the moths at each minute is:

$$S_t = X_t - X_0$$

where X_t is the position of the moths at the time t and X_0 the position of the moths at the beginning of the test.

Since the value of S_t depends on the initial distribution of the moths in the tube (X_0), it has to be balanced by the maximum attraction: S_{max} (i.e., the value of S_t if all moths are attracted toward section 6).

$$S_{max} = \sum_{i=0}^{6} (6 - i)n_i$$

where n_i is the number of moths in section i at $t = 0$.

Finally, we define D_t as the index of relative attraction at the time t:

$$D_t = \frac{S_t}{S_{max}} \times 100$$

The tests were not considered when S_{max} was lower than 20.

Statistical analyses were performed using nonparametric tests (Mann-Whitney test, Siegel, 1956); each treatment was repeated eight times.

Pheromone Collection. In France, forewings of 53 males from the Indian strain were clipped and soaked in 1 ml hexane for 2 hr at room temperature. The crude extract was then filtered through glass wool and reduced to ca. 100 μl under N_2 flow. This extract was kept at −30°C until use. An extract of 21 males from the French strain was used for comparison.

For the olfactometric tests, 5 μl of the extract, which correspond to 2.5 male equivalents (ME) were applied to the applicator.

In England, volatiles emitted by male moths were collected on activated charcoal or Porapak Q resin. From one to four virgin male moths were placed in a silanized glass vessel (15 × 4.5 cm). Laboratory air was drawn into the vessel through a filter containing activated charcoal (12 × 2.5 cm; 10–18 mesh)

at 2 liters/min, and out through a collection filter for up to 8 hr. Activated charcoal collection filters contained 5 mg of activated charcoal (0.05–0.1 mm) held between stainless-steel screens (300 mesh) fused into Pyrex glass tubing (6 mm OD, 4 mm ID). Adsorbed volatiles were removed by eluting with dichloromethane (20 μl and then two 10-μl portions) as described by Grob and Zürcher (1976). Porapak collection filters contained 100 mg Porapak Q (50–80 mesh) held between glass wool plugs in a Pasteur pipet (5 mm ID). Adsorbed volatiles were eluted with dichloromethane (200 μl and then two 100-μl portions). Both types of filter were washed well with dichloromethane before use and dried with a nitrogen stream. Dodecyl acetate (1 μg) was added to the solutions of volatiles as internal standard for GC analysis.

Pheromone Identification. In France, male wing-gland extracts were analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). GC analyses were performed on a Carlo Erba Fractovap 2900 with flame ionization detector (FID), equipped with a nonpolar column (50 m WCOT SE-52, 0.2 mm ID; Girdel, Suresnes, France) heated from 45 to 160°C (25°/min) and from 160 to 210°C (5°/min) and with a Girdel 300 chromatograph (FID) equipped with a polar column (34 m WCOT Carbowax 20 M, 0.3 mm ID; Girdel), operated isothermally at 180°C. GC-MS was performed on a Girdel 32 gas chromatograph coupled to a Nermag R 10-10C quadrupole mass spectrometer (electron impact at 70 eV). The chromatograph was fitted with a fused silica capillary column (25 m WCOT CPSil 5 CB, 0.22 mm ID; Chrompack, Middelburg, The Netherlands) and operated isothermally at 180°C. Chemical ionization–mass spectrometric data were obtained using ammonia as reactant gas at 92.5 eV.

In England, the original work was carried out in 1977 on a Varian 7200 gas chromatograph (FID) using packed GC columns (1.8 m × 2 mm ID glass columns packed with 2.5% SE-30 + 0.25% Carbowax 20 M on 100–120 mesh Chromosorb G AW DMCS, or 1.5% Carbowax 20 M on 100–120 mesh Chromosorb G AW DMCS; temperature programmed from 120° to 220°C at 4°C/min; nitrogen carrier gas at 25 ml/min). GC-MS was carried out with a Pye 104 gas chromatograph coupled to a Varian CH5 DF mass spectrometer via a double-stage Watson-Biemann separator (5-ft × $\frac{1}{4}$-in. glass column packed with OV-225 nonextractable polymer-coated column operated isothermally at 130°C with helium gas at 40 ml/min as the carrier). The results were later checked on fused silica capillary columns coated with CPSil 5 CB (chemically bonded methyl silicone; Chrompack) and CP Wax 57CB (chemically bonded Carbowax 20 M; Chrompack) (25 m × 0.32 mm ID columns; splitless injection; oven temperature 70°C for 2 min, then programmed at 20°C/min to 100°C and then at 2°C/min to 200°C; helium carrier gas at 0.4 kg/cm^2).

Synthesis. For synthesis of (*E,E*)- and (*Z,E*)-farnesyldiphenylurethanes (Bates et al., 1963), a mixture of commercial (Janssen; Beerse, Belgium) far-

nesol (9 ml) [containing (*E*,*E*)-, (*Z*,*E*)-farnesol, and nerolidol], diphenyl-carbamyl chloride (10 g), and anhydrous pyridine was heated at 60°C under Ar for 4 hr. After cooling, the resulting reaction mixture was dissolved in ether and the organic phase was extracted with 2 N HCl, $NaHCO_3$, and brine and dried over Na_2SO_4. The brown oil obtained after evaporation of the solvent was treated with MeOH and left in the cold. White crystals formed which were recrystallized several times from MeOH to provide pure (*E*,*E*)-farnesyldiphenylurethane ($C_{28}H_{35}O_2N$, F = 60–61°C, M^+ at *m/z* 417, base peak at *m/z* 169).

The combined mother liquors were purified by column chromatography (Silicagel 60 Merck). Pure (*Z*,*E*)-farnesyldiphenylurethane was isolated as a colorless liquid by repeated preparative HPLC (Jobin-Yvon Miniprep, hexane–ethyl acetate 9:1). $C_{28}H_{35}ON$: M^+ at *m/z* 417, base peak at *m/z* 169.

For synthesis of (*E*,*E*)- and (*Z*,*E*)-farnesol (Bates et al., 1963), in a typical experiment, 680 mg of farnesyldiphenylurethane are dissolved in a mixture of 3.5 ml EtOH, 0.1 ml H_2O, and 0.4 g KOH, and heated at 60°C for 5 hr. After cooling, the mixture was extracted with Et_2O, and the organic phase was washed with H_2O and dried over Na_2SO_4. The pure alcohols were obtained after column chromatography over Silicagel (Merck) with hexane containing increasing amounts of ethyl acetate. Yield: 310 mg (85%). $C_{15}H_{26}O$: M^+ at *m/z* 222, base peak at *m/z* 69.

(*E*,*E*)-Farnesol was further identified by GC-MS comparison with an authentic sample provided by Dr. W. Pickenhagen, Firmenich S.A., Geneva, Switzerland.

For synthesis of (*E*,*E*)- and (*Z*,*E*)-farnesal, pure (*E*,*E*)-farnesal was obtained from the corresponding alcohol by oxidation with a 100-fold excess of freshly prepared MnO_2 in hexane solution according to Corey and Achiwa (1969), followed by Kugelrohr distillation (3 mm Hg/120°C bath temperature).

When (*Z*,*E*)-farnesol was treated in the same manner, (*Z*,*E*)-farnesal containing slowly increasing amounts of (*E*,*E*)-farnesal was obtained. Therefore, it is recommended to prepare farnesal immediately before use.

RESULTS

Observation of Mating Behavior. The mating behavior of *C. cephalonica* occurs a few hours after the emergence of adults. When kept separately, both male and female moths have a similar behavior; they display rhythmic wing-fanning although it seems more constant and frantic with males. This behavior is observed at the beginning of the scotophase and lasts 3 or 4 hr until copulation.

When male and female moths are kept together in small cages, sexual encounters seem to occur at random. Moths are very agile and continuous walk-

ing or jumping results in frequent contacts; therefore it is difficult to evaluate the significance of such movements for sexual behavior.

Before mating occurs, the wing-fanning male tries to mount the female from behind, then to grasp her with his labial palpi. After copulation, the male releases his grip and rests motionless in a tail-to-tail posture.

Cross Attraction. The results of cross-attraction tests are summarized in Figure 2; five males were used to attract females and six females to attract males (eight replicates each).

Females were obviously attracted by males (Figure 2a), but males also were attracted by females (Figure 2b) although the observed indexes D_t were

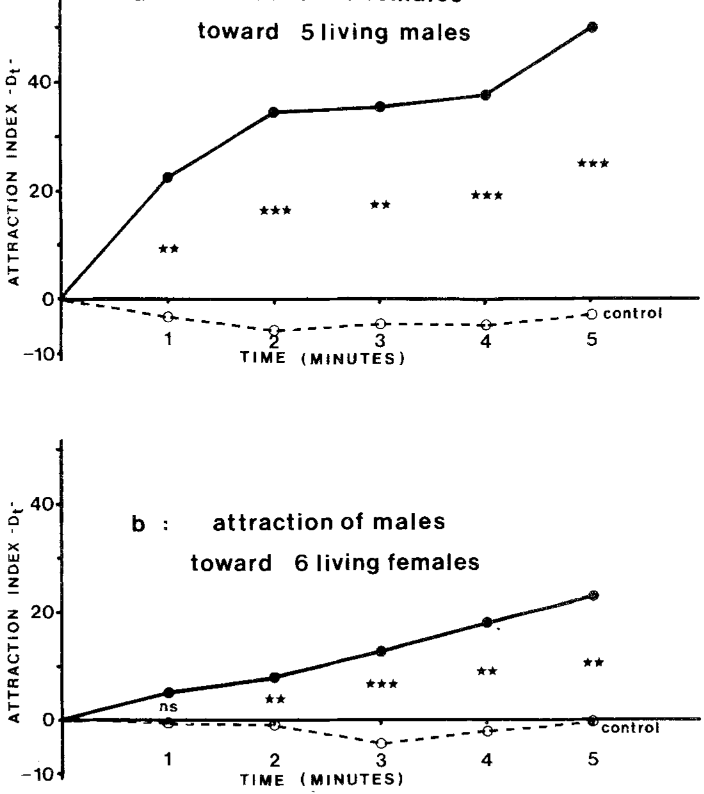

FIG. 2. (a) Relative attraction of 58 females by five males; (b) relative attraction of 69 males by six females. Statistical analysis (Mann-Whitney test): difference with respect to the control (test carried out with 76 females and 68 males, the chamber being empty). ns: not significant; $**P < 0.01$; $***P < 0.001$ for eight replicates.

lower. When males are placed upwind, the females exhibit: (1) raising of the antennae, (2) increase in wing-fanning, and (3) upwind orientation by walking. Attraction is easy to observe with females, which begin to walk only after the stimulation, but is more difficult with males, which are constantly moving.

Attraction of Females toward Male Wing-Gland Extract. The results (Figure 3) are in agreement with cross-attraction tests: virgin females are attracted by male wing extract when tested with 2.5 ME. The attraction of males toward female extract is discussed in a subsequent paper (Hall et al., 1987).

These results clearly show that, in this species, sexual attraction is mediated at least in part by olfaction. As in other Galleriinae, a male pheromone attracts females.

Chemical Identification. GC analyses of extracts from the forewings of the Indian and French strains showed two peaks in a 79:21 ratio. GC-MS data in electron impact mode revealed two sesquiterpenic isomers, with characteristic ions at *m/z* 69 ($C_5H_9^+$) and *m/z* 84 ($C_5H_8O^+$). Chemical ionization mass spectrometry with ammonia indicated a molecular weight of 220 (*m/z* 238).

The computerized spectra library (Sidar data acquisition system) strongly suggested farnesal [(*E*,*E*)-3,7,11-trimethyl-2,6,10-dodecatrienal] as the main compound.

This structure was confirmed by GC comparison of synthetic (*E*,*E*)-farnesal with the natural extract. The minor compound was identified as (*Z*,*E*)-farnesal, which can also be produced by spontaneous isomerization of (*E*,*E*)-farnesal.

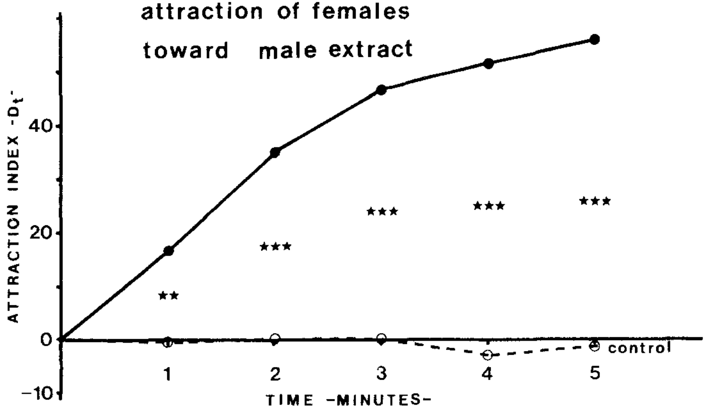

FIG. 3. Relative attraction of 67 females by the male forewing extract (2.5 ME). Statistical analysis (Mann-Whitney test): difference with respect to the control (test carried out with 61 females using 5 μl hexane). $**P < 0.01$; $***P < 0.001$ for eight replicates.

TABLE 1. RETENTION DATA FOR FARNESAL ISOMERS ON FUSED SILICA CAPILLARY COLUMNS

	ECL^{a}	
Isomer	CP Sil 5 CB	CP Wax 57CB
Z,Z	12.60	14.91
Z,E	12.87	15.35
E,Z	12.90	15.49
E,E	13.13	15.81

[a] Equivalent chain lengths relative to retention times for straight-chain acetates.

Analyses of volatiles collected from male moths in England showed two components with no other component more than 1% of the major peak. These components were identified as (*E,E*)- and (*Z,E*)-farnesal by GC-MS and co-chromatography of the natural and synthetic materials on packed and capillary GC columns. All four isomers of farnesal could be distinguished even on packed GC columns, and they were completely resolved on the CP Wax 57CB capillary column. Retention data for the isomers are shown in Table 1.

The *EE/ZE* ratio varied between 95:5 and 89:11, and extraction of the forewings of the moths after entrainment, according to the French procedure, gave ratios identical to those obtained by entrainment of the same moths. The ratio did not seem to vary consistently with age of the moths or time of collection. Addition of a catalytic amount of iodine to the natural extract or entrainment and exposure of the solution to sunlight for 10 min changed the ratio to 77:23.

When male pheromone was collected in the dark, approximately 5 μg of (*E,E*)-farnesal was obtained from four moths over 6 hr. When collections were carried out under low light intensity (approx. 20 lux), the male moths exhibited much more vigorous wing-fanning and 25 μg of (*E,E*)-farnesal could be collected from four moths over 6 hr. Extraction gave approx. 0.5 μg (*E,E*)-farnesal per male moth.

A blend of synthetic farnesal isomers (70% *EE* to 30% *ZE*) evoked a strong attraction of virgin females in olfactometric tests (Figure 4a). The responses obtained with "pure" isomers (Figure 4b) were rather inconclusive. Both (*E,E*)- and (*Z,E*)-farnesal attracted females, but a GC quantitation of the test compounds showed a rapid increase in the relative amount of the minor compound after three or four replicates (10 days), soon reaching an equilibrium.

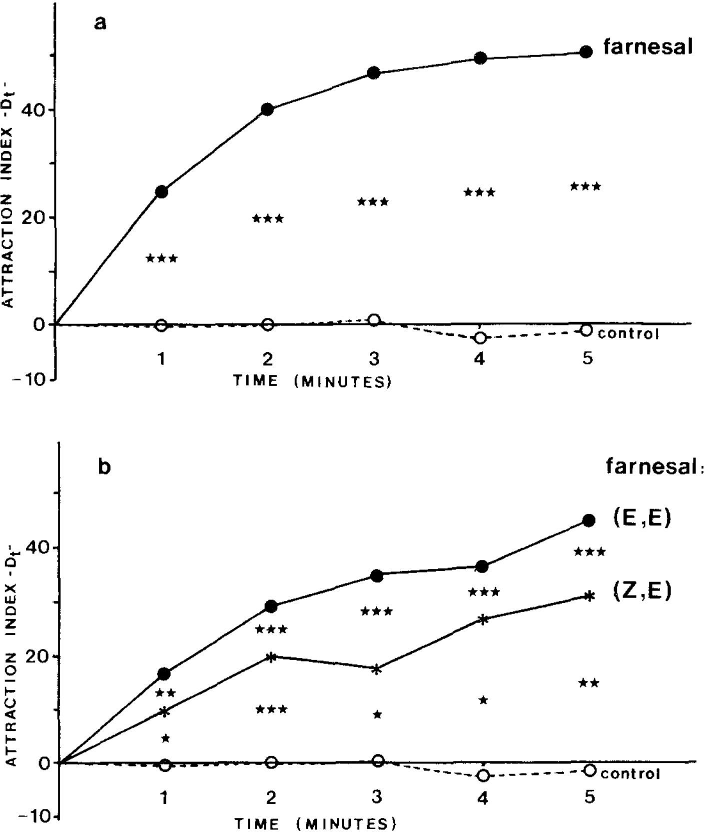

FIG. 4. Relative attraction of females by synthetic farnesal. (a) 50 μg of a 70/30 blend of (*E,E*)- and (*Z,E*)-farnesal (N = 69, eight replicates). (b) (*E,E*)- and (*Z,E*)-farnesal tested separately (25 ng) (N = 42 and 45 respectively, five replicates). Statistical analysis (Mann-Whitney test): difference with the control (61 females, 5 μl hexane, eight replicates): $^*P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$. The differences between (*E,E*)- and (*Z,E*)-farnesal are not significant.

DISCUSSION

As in other Galleriinae, males of *C. cephalonica* emit a pheromone in order to attract females. Their calling behavior consists of wing-fanning which can be observed from the beginning of the scotophase. By gently abrading the male forewings, scales are easily removed to reveal a pouch located along the costal vein very close to the wing articulation and filled with a yellowish liquid. This pouch is similar to the wing gland of *Galleria mellonella* (Barth, 1937) or *El-*

dana saccharina (Atkinson, 1982; Farine, 1983), and is likely to be the site of male pheromone production.

The first study dealing with *C. cephalonica* (Singh and Sidhu, 1976) implied that males were attracted by females as in the Phycitinae, which represent a pyralid subfamily closely related to Galleriinae (Minet, 1981). The results of our cross-attraction tests show that males actually attract females, and although a pheromone is also produced by females, it is not the primary attractant pheromone mediating the sexual communication of this species (see following paper in this issue).

All our observations suggest that female *C. cephalonica* moths walk rather than fly to calling males, and this would seem to be a general characteristic of Galleriinae. Observations have shown the occurrence of walking behavior in *Eldana saccharina* (Zagatti, 1981) and *Achroia grisella* (Greeenfield and Coffelt, 1983). In trapping experiments with *Galleria mellonella* (Finn and Payne, 1977) and with *Achroia grisella* (Dahm et al., 1971; Spangler, 1984), it was necessary to position sticky traps baited with male moths or synthetic pheromone on the ground in order to catch female moths. It is thus likely that in the Galleriinae the females mate close to the emergence site.

To our knowledge, farnesal has only been reported once before in an insect secretion: in the mandibular glands of the ant *Lasius fuliginosus* (Bernardi et al., 1967). Terpenoid compounds of any sort have only rarely been found to be produced by moths. 6-Methyl-5-hepten-2-one and the corresponding alcohol were found in the abdominal brushes of the noctuid, *Phlogophora meticulosa* (Aplin and Birch, 1970), and pinocarvone in the brushes of another noctuid, *Apamea monoglypha* (Aplin and Birch, 1970). More notably, the monoterpene lactone (3*S*,4*R*)-*trans*-3,7-dimethyl-6-octen-4-olide, is produced in the wing glands of the male galleriid, *Eldana saccharina* (Kunesch et al., 1981; Vigneron et al., 1982), and the diterpene, (*E*)-3,7,11,15-tetramethyl-2-hexadecen-1-ol [(*E*)-phytol], is produced in the wing glands of the male phycitid, *Ephestia elutella* (Phelan et al., 1986).

The biosynthetic origin of the farnesal produced by male *C. cephalonica* moths is unknown. It could possibly be derived from farnesol or farnesyl pyrophosphate in the diet, although it is more likely to have been biosynthesized from mevalonate in the insect tissue. The juvenile hormone JH3, the methyl ester of 10,11-epoxyfarnesoic acid, has been shown to be biosynthesized from mevalonate (Schooley et al., 1973), and both farnesal and farnesol were found in cultures of corpora allata from the tobacco hornworm, *Manduca sexta*, where they are probably precursors of JH3 (Baker et al., 1983).

Acknowledgments—The INRA authors thank Drs. K.R. Kanaujia and F. Fleurat-Lessard for the supply of insects, Dr. M. Renou and Mr. P. Witzgall for helpful discussions, and Mrs. M.F. Commeau for the English translation. The TDRI authors are grateful to Dr. Rick Hodges of TDRI Storage Department, Slough, England, for supply of insect cultures, and to Dr. Fred Mellon and

Dr. Margaret Blight, formerly of the ARC Unit of Invertebrate Chemistry and Physiology, University of Sussex, England, for the GC-MS measurements.

(Received June 13, 1986; accepted September 29, 1986)

Abstract—Laboratory investigations of mating behavior in the rice moth, *Corcyra cephalonica* Stainton (Lepidoptera: Pyralidae; Galleriinae) showed that male moths are attracted at short range to live, virgin female moths and to female abdominal-tip extract. Volatiles collected from virgin female moths contained one component eliciting an electroantennographic (EAG) response from the male moth, and the chemical, spectroscopic, and chromatographic data on this component were consistent with that of synthetic 6,10,14-trimethyl-2-pentadecanol. This compound caused an EAG response from the male moth and attracted male moths in the bioassay. The pheromone is thought to play a role in courtship, and the synthetic material was shown to cause the male moths to search for a mate and attempt copulation.

Key Words—Rice moth, *Corcyra cephalonica*, Lepidoptera, Pyralidae, Galleriinae, female pheromone, courtship pheromone, olfactometer, electroantenogram, 6,10,14-trimethyl-2-pentadecanol.

INTRODUCTION

Studies of mating behavior in the rice moth, *Corcyra cephalonica* (Lepidoptera: Pyralidae; Galleriinae) have shown that female moths are attracted to male moths, and male moths are attracted to female moths (Zagatti et al., 1987). The male moths were found to produce (*E*,*E*)- and (*Z*,*E*)-farnesal (3,7,11-trimethyl-2,6,10-dodecatrienal) from glands in the forewings, and the synthetic

0098-0331/87/0700-1575$05.00/0 © 1987 Plenum Publishing Corporation

compounds were shown to attract walking female moths (Zagatti et al., 1987). This paper describes identification of the female-produced pheromone and studies to establish its role in the mating behavior of this species.

METHODS AND MATERIALS

Insect Material. Laboratory cultures of *C. cephalonica* were maintained as described by Zagatti et al. (1987). The identification work in London was carried out with moths from cultures of Malawi origin. Moths from cultures originating in India were used for the bioassay work in France.

Pheromone Collection and Purification. For bioassay work, the abdominal tips (three posterior segments including ovipositor) of 38 virgin female moths were excised 2 hr into the scotophase. The tips were extracted in 1 ml hexane for 2 hr and the extract filtered through glass wool and reduced to 100 μ under nitrogen.

For the identification work, ovipositor or whole-body washes from virgin female moths were made under a variety of conditions: age 0–7days; at various times throughout a 12 hr–12 hr light–dark cycle or under constant low light; in heptane, ether, or dichloromethane.

To collect pheromone by entrainment, 20–30 virgin female moths were placed in a silanized, 3-liter, bolt-head flask with two paper tissues. Laboratory air was drawn at 1 liter/min into the bottom of the flask through a charcoal filter (12 $\times$ 2 cm; 10–18 mesh) and out through two glass filters (1.5 cm ID) packed with 2.5 g Porapak Q (50–80 mesh) purified by washing well with dichloromethane. Pheromone was collected continuously under natural lighting conditions at 20–25°C. Twice per week, the Porapak filters were extracted with a total of 25 ml dichloromethane, and dead moths were replaced with freshly emerged ones.

After seven weeks of entrainment, the Porapak filter extracts were combined and evaporated to 5 ml on a rotary evaporator at or below room temperature. Florisil (0.5 g, 100–200 mesh) was added and the remaining solvent removed on the rotary evaporator. The coated Florisil was deposited on the top of a column of 9.5 g Florisil (30 $\times$ 1 cm) made up in pentane. This was then eluted with 50-ml aliquots of diethyl ether–pentane mixtures containing 0, 2, 5, 10, 20, 30, 50, 75, and 100% ether. Fractions of 10 ml were collected.

Gas Chromatography (GC). Columns packed with SE-30 or Carbowax 20 M and fused silica capillary columns coated with CPSil 5 CB or CP Wax 57CB were used as described in Zagatti et al. (1987). Retention data are given as the equivalent chain length (ECL) relative to the retention times for straight-chain saturated acetates.

Electroantennography (EAG) and Linked Gas Chromatography-Electroantennography (GC-EAG). Male *C. cephalonica* moths were prepared for

EAG recording as described by Beevor et al. (1986), except that the glass microelectrodes were inserted into the interstitial membrane between annuli of the intact antennal flagellum. The recording electrode was inserted into the distal end of one antenna, and the reference electrode into the proximal end of the other. The microelectrodes were filled with saline (Roelofs and Comeau, 1971) with 0.2% w/v agar added in order to reduce evaporation and avoid crystallization of dissolved salts in the microelectrodes.

Test samples were syringed onto the inner walls of a disposable Pasteur pipet and blown over the antennal preparation with a pulse of nitrogen, as described by Beevor et al. (1986). Typically, an interval of 5 min was allowed between successive stimuli for the preparation to recover fully.

Linked GC-EAG analyses with packed and fused silica capillary GC columns were carried out as described by Moorhouse et al. (1969) and Beevor et al. (1986). The GC column effluent was split 1 : 1 between the EAG preparation and the flame ionization detector. The GC columns used were as described above.

Microchemical Reactions. For bromination, a dilute solution of bromine in carbon tetrachloride (5 μl) was added to the sample dissolved in carbon tetrachloride (5 μl), and the mixture analyzed after 20 min at room temperature. The carbon tetrachloride was purified by passage through neutral alumina.

Reductions were carried out by adding a few grains of lithium aluminium hydride to the sample dissolved in dichloromethane (15 μl).

Oxidations were carried out with a saturated solution of pyridinium chlorochromate in dichloromethane for 20 min at room temperature. The pyridinium chlorochromate was washed with ether before use, and the dichloromethane was passed through neutral alumina.

In all microchemical reactions, blanks for assay by GC or EAG were prepared under identical conditions using pure solvent instead of the test solution.

Mass Spectrometry (MS). Linked GC-MS analyses of natural and synthetic materials were carried out in EI mode at 70 eV with a VG Micromass 7070F instrument and VG 2000 data system. This was coupled via an all-glass jet separator to a Pye 104 gas chromatograph fitted with a glass column (2.5 m × 2 mm ID) packed with 15% Carbowax 20 M on Chromosorb W and operated isothermally at 200°C.

Synthesis. 5,9,13-Trimethyl-2-pentadecanol (compound A) was prepared by a sequence starting with three successive Julia reactions (Julia et al., 1960) as shown in Figure 1. The "one-pot" modification (Biernacki and Gdula, 1979) was used in these reactions. The yields became progressively poorer, but intermediates were available from a preparation of 4,8-dimethyldecanal, the aggregation pheromone of *Tribolium* spp. (Breuer et al., 1982). The yields are quoted for products purified by chromatography if necessary and distillation.

6,10,14-Trimethyl-2-pentadecanol (compound B) was prepared from far-

FIG. 1. Synthesis of 5,9,13-trimethyl-2-pentadecanol (A). Reagents: (i) Mg/Et_2O; cyclopropylmethyl ketone; H_2SO_4; (ii) $KOAc/CH_3CN$/Adogen 464; (iii) $K_2CO_3/MeOH$; (iv) $H_2/PtO_2/EtOH$; (v) pyridinium chlorochromate/CH_2Cl_2; (vi) CH_3MgI/Et_2O. Yields are for chromatographically homogeneous products after distillation.

nesol by standard reactions involving two-carbon homologation with ethyl acetoacetate, as shown in Figure 2.

Bioassays. The olfactometric bioassay used was that described by Zagatti et al. (1987) and consisted of a glass tube olfactometer divided into seven sections. The positions of moths released into the olfactometer were recorded every minute for 5 min, and the attraction index (D_t) calculated as described by Zagatti et al. (1987).

In order to determine the range of action of the female pheromone, the responses of individual male moths to female extract (1 female equivalent, FE) were recorded. In all, 99 male moths were observed in the olfactometer for 3-min periods, and the time and direction of their first shift were recorded along with their initial position. As controls, 28 males were observed under the same

FIG. 2. Synthesis of 6,10,14-trimethyl-2-pentadecanol (B). Reagents: (i) $H_2/PtO_2/EtOH$; (ii) $CBr_4/PPh_3/CH_2Cl_2$; (iii) ethyl acetoacetate/Na/EtOH; (iv) 150°C/DMSO/H_2O; (v) $NaBH_4/EtOH$. Yields are for chromatographically homogeneous products after distillation.

conditions with hexane (5 μl) on the applicator, and there was no significant difference between the numbers of moths moving upwind and downwind after 3 min ($\chi^2 = 3.7$ with 4 *df*). The percentages of moths making an initial upwind shift after periods of 30 sec, 1 min 30 sec, and 3 min were calculated for different initial positions, and these were compared with the corresponding results in the control tests using a 2×2 χ^2 analysis.

The precise role of the female-emitted pheromone in mating behavior was investigated using the synthetic pheromone. A solution of the pheromone (100 ng) in hexane (1 μl) was deposited onto the inner walls of a disposable Pasteur pipet, and air was blown at 200 ml/min through the pipet and over a pair of male moths caged in a small cylindrical box (5×8 cm diameter). A total of 15 pairs of males was tested with the pheromone and 15 pairs with hexane (1 μl) as controls. The results were recorded as the percentages of moths showing the following types of behavior within a 2-min observation period (Table 3): (1) calling posture (stationary, fanning wings); (2) search for females (walking, fanning wings); and (3) copulation attempts (moths circling and trying to mount one another).

The test and control results were totally different, obviating the need for statistical analysis.

RESULTS

Evidence for Female-Emitted Sex Pheromone. During initial studies of pheromone-mediated behavior in *C. cephalonica*, it was shown that live virgin female moths can attract male moths (Zagatti et al., 1987). A crude hexane extract of female abdominal tips (2.5 FE) was also shown to be attractive (Figure 3), demonstrating the olfactory nature of this phenomenon.

In these tests, it seemed that male moths close to the pheromone source were markedly more stimulated than those further downwind. By recording the responses of individual male moths at different distances from the pheromone source it was shown that the percentage of moths responding to female extract (1 FE) by an upwind shift decreased sharply at distances greater than 13 cm from the source (Figure 4). At distances greater than 33 cm from the source, there was no significant difference between the responses in the presence or absence of the pheromone.

Pheromone Identification. Whole-body washes or ovipositor washings from virgin female *C. cephalonica* moths caused EAG responses from the male moth, and linked GC-EAG analyses suggested that a single EAG-active component was present. Amounts of this component obtained under a variety of conditions were much less than 1 ng/female, and purification of these solvent washes by GC or liquid chromatography did not remove large amounts of impurities which prevented further analytical work.

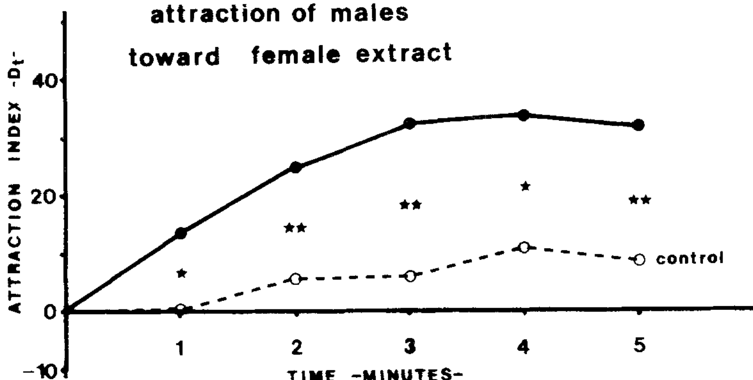

FIG. 3. Attraction indices for male *C. cephalonica* moths to female abdominal tip extract (2.5 FE; 68 males) and hexane (5 μl; 64 males) as control (eight replicates). Statistical analysis by Mann-Whitney test: difference between treatment and control significant at $^{*}P = 0.05$; $^{**}P = 0.01$.

Aeration of virgin female moths and collection of the volatiles emitted on Porapak Q gave significant amounts of pheromone that could be purified by liquid chromatography on Florisil. Assay of the fractions by EAG showed that essentially all the activity was eluted with 20% ether in pentane. Thus the crude Porapak extract (0.5 μl from 5 ml) gave an EAG response greater than 0.8 mV; the two active fractions (0.5 μl from 10 ml) each also gave an EAG response greater than 0.8 mV with no other fractions giving responses greater than 0.29 mV.

Linked GC-EAG analysis of the crude Porapak extract on a GC column packed with Carbowax 20 M showed only one EAG-active component at ECL 15.36 (total response 1.0 mV; no other response greater than 0.15 mV). Analysis of the active fractions from liquid chromatography similarly showed one active component at the same retention time (total response 1.9 mV; background response 0.20 mV), and these fractions were sufficiently pure for carrying out microchemical reactions and GC-MS analysis on the active component. Approximately 5 μg of this purified material was obtained after seven weeks of entrainment (1000–1500 moth days).

When microgram quantities of synthetic long-chain hydrocarbons, aldehydes, acetates, and alcohols were chromatographed on Florisil under the same conditions, hydrocarbons were eluted with pentane, aldehydes with 2–5% ether in pentane, acetates with 5% ether in pentane, secondary alcohols with 10–20% ether in pentane, and primary alcohols with 50% ether in pentane. The elution behavior of the active component was thus consistent with that of a long-chain, secondary alcohol.

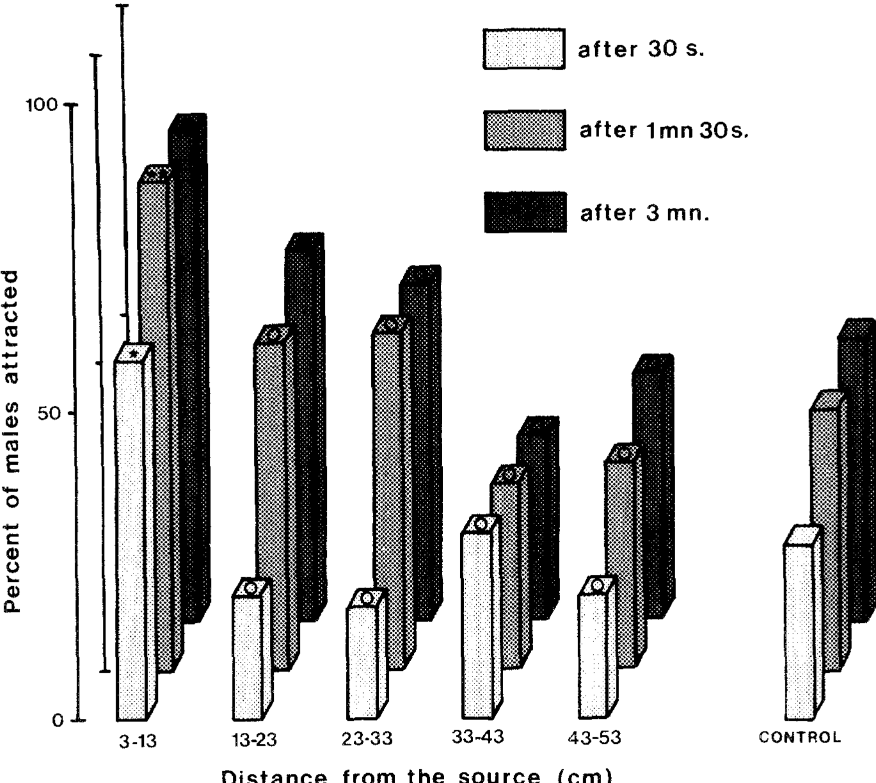

FIG. 4. Responses of male *C. cephalonica* moths to female abdominal tip extract (1 FE; 99 males) and hexane (1 μl; 28 males) as control, relative to their initial distance from the source and the time after the start of the stimulation. The vertical axis represents the percentage of males which moved at least one section upwind in the olfactometer. Statistical analysis by χ^2 test: difference between treatment and control not significant, o; significant at $*P = 0.05$; $**P = 0.01$.

Bromination of the crude Porapak extract caused no loss in EAG activity. GC analyses on a GC column packed with Carbowax 20 M showed that the purified active component was unaffected by bromination. Bromination of standard synthetic compounds showed that unsaturated compounds and aldehydes reacted but saturated acetates, alcohols, and ketones were unchanged.

On treatment of the crude Porapak extract with lithium aluminium hydride in dichloromethane, EAG activity was lost, but the activity was completely restored when the reaction mixture was hydrolyzed with water. These results were consistent with the active component being a saturated alcohol.

Reaction of the purified active component with pyridinium chlorochromate

was monitored by GC analysis on columns packed with SE-30 and Carbowax 20 M. The active component at ECL 14.44 and 15.36 on the two columns reacted to give a product at ECL 14.30 and 14.33. These shifts in ECL on the two GC phases of −0.14 and −1.03, respectively, were consistent with a methyl carbinol-to-methyl ketone conversion (Table 1).

The mass spectrum of the active component (Figure 5a) showed ions of highest mass number at *m/z* 255 and 252, interpreted as loss of CH_3 and H_2O from a saturated, 18-carbon alcohol of molecular weight 270. The remainder of the spectrum suggested an aliphatic rather than alicyclic structure. The GC retention times for the active component on fused silica capillary columns (Table 2) indicated that, if the component was a saturated 18-carbon alcohol with the alcohol in the 2 position, it must have several branches in the aliphatic chain. These branches would be favored fragmentation points in the mass spectrum (e.g., Carlson et al., 1978), and 5,9,13-trimethyl-2-pentadecanol (A) was prepared as a model compound. This compound had a mass spectrum (Figure 5c) significantly different from that of the active component and slightly longer GC retention times (Table 2). In view of the known shorter retention times of

iso-branched fatty acid methyl esters relative to the *anteiso*- isomers (e.g., Body, 1984), 6,10,14-trimethyl-2-pentadecanol (B) was then prepared. This compound had a mass spectrum (Figure 5b) that was essentially identical with that of the active component, and identical retention times on fused silica capillary GC columns (Table 2). The latter were confirmed by cochromatography of the natural and synthetic materials. The GC peak for the synthetic mixture of four diastereoisomers was broadened relative to that for the natural component on both columns (Table 2), suggesting that the natural component consisted of only one or a few of the possible diasteroisomers.

Compound B elicited a significant EAG response from male *C. cephalonica* moths, while compound A showed no activity. Responses from the same moth to 3.5 ng of material delivered through the GC-EAG link were 2.31, 1.23, and 0.0 mV for the natural pheromone component, compound B, and compound A, respectively. The lower EAG response to the synthetic mixture of diastereoisomers and enantiomers also suggests that the natural material consists of only one or a few of the possible isomers.

Bioassays of Synthetic Pheromone. Both candidate compounds A and B were tested as attractants in the olfactometer. At the 200 ng level, compound B was highly attractive to the male moths whereas A was inactive even at the 400 ng level (Figure 6a). The attraction indices for 200 ng of B were considerably higher than those evoked by 2.5 FE of female abdominal tip extract (Figure 3), and the tests were repeated with lower amounts of the synthetic material (Figure 6b). Male moths were significantly attracted to 2 ng of compound B.

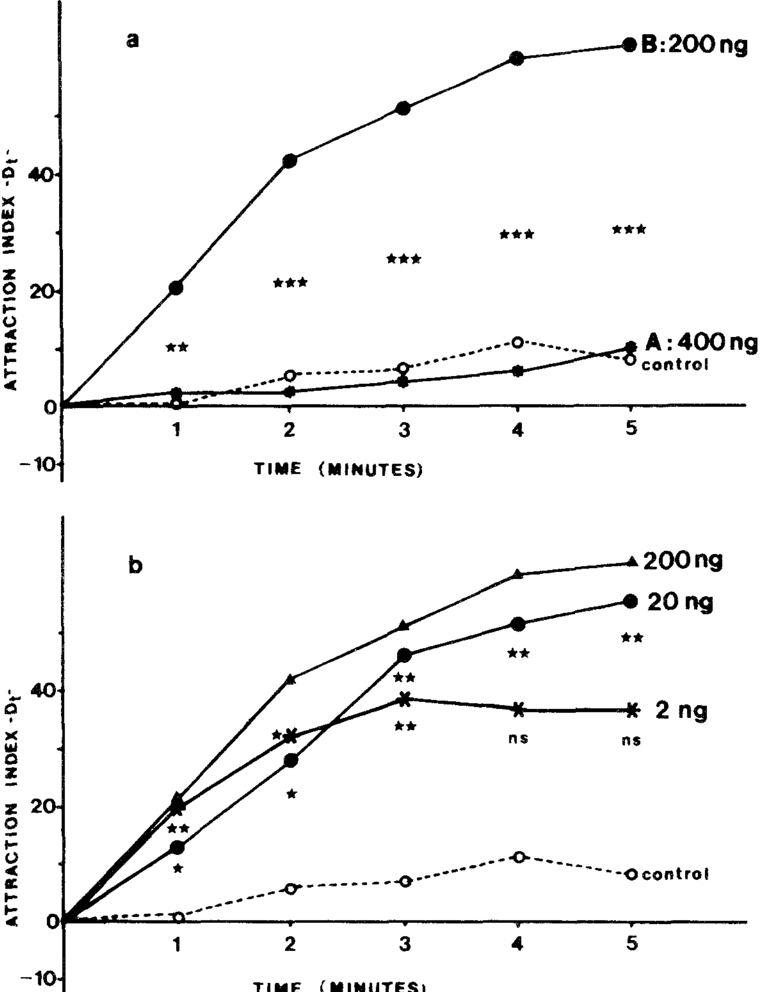

FIG. 6. (a) Attraction indices for male *C. cephalonica* moths to compound A (400 ng; 67 males), compound B (200 ng; 67 males), and hexane (5 μl; 64 males) as control (eight replicates). (b) Attraction indices for male *C. cephalonica* moths to compound B (20 ng, 30 males; 2 ng, 27 males) (four replicates). Statistical analyses by Mann-Whitney test: difference between treatment and control not significant, ns; significant at *P = 0.05; **P = 0.01; ***P = 0.001.

The synthetic compound B was used to investigate further the effect of the female pheromone on male behavior. Table 3 shows the results of exposing pairs of virgin males in small cages to compound B. Before the test, 50% of the males were essentially stationary and fanning their wings. The male pheromone is emitted during wing-fanning (Zagatti et al., 1987), and it is assumed

TABLE 3. EFFECTS OF SYNTHETIC PHEROMONE ON BEHAVIOR OF MALE *C. cephalonica*

	Observed behavior (%)[a]				
	Before stimulation		After stimulation

100 ng (B)	50	0	0	87	53
1 μl hexane	57	0	47	0	0

[a]2 × 15 pairs of male moths observed within a 2-min period.

that this is "calling" behavior. In less than 2 min after stimulation with compound B, 87% of the moths tested started to walk sinuously while continuing their wing-fanning. This behavior seems to indicate searching for a mate, and homosexual copulation attempts were observed in 53% of the pairs. During control tests with pure solvent, the initial percentage of calling males decreased slightly, possibly due to the air disturbance. Neither searching for a mate nor copulation attempts were observed.

In the same experiment run with a dead female moth replacing one of the pair of live males, no copulation attempts were observed, showing the importance of visual and/or auditory cues in the courtship behavior.

DISCUSSION

Virgin female *C. cephalonica* moths have been shown to produce a pheromone that acts as a short-range attractant for the male moths. Volatiles collected from virgin female moths contain one component that elicits EAG responses from male moths, and the available chemical, chromatographic, and spectroscopic data on this component are consistent with that of synthetic 6,10,14-trimethyl-2-pentadecanol (B). In support of this identification, compound B causes an EAG response from male *C. cephalonica* moths and is highly active in the bioassays. Furthermore, the closely related compound, 5,9,13-trimethyl-2-pentadecanol (A) is biologically inactive.

No attempt has been made to determine which of the four diastereoisomeric pairs of enantiomers of B is (are) produced by the female moth, but there is chemical and biological evidence that only one or a few of the isomers is involved. Thus the GC peak width for the natural pheromone component is narrower than that for the synthetic mixture of isomers, and the natural phero-

mone causes a greater EAG response than that to an equal amount of the synthetic.

It is also possible that other pheromone components are present, although these must be present in much lower amounts and/or cause a smaller EAG response than the major component.

When this work was carried out, 6,10,14-trimethyl-2-pentadecanol (B) had not previously been found in an insect secretion. However, Burger et al. (1985) recently reported this compound to be a major component of the material produced in the male abdominal brushes of *Eldana saccharina*, another galleriid closely related to *C. cephalonica*. No biological function was reported.

In most lepidopterous species, the female produces a long-range attractant pheromone. It has also been demonstrated in many of these species that the male produces a short-range courtship pheromone. Butler (1967) used the general term "aphrodisiac" for these, but this is inadequate to describe the many roles they may play (Boppré, 1984). Short-range attraction of female *Grapholitha molesta* (Lepidoptera: Tortricidae) by the male was demonstrated by Baker et al. (1981), and the pheromone emitted from the male abdominal brushes was fully identified by Nishida et al. (1982). The bioassay was carried out over a distance of 2 cm.

Ephestia elutella (Lepidoptera: Pyralidae; Phycitinae) is more closely related to *C. cephalonica*. The female produces a long-range attractant, and the males have been shown to produce a pheromone from glands in the forewings that causes the female moth to stop calling, flex the abdomen downwards, and turn (Krasnoff and Vick, 1984). This pheromone was characterized chemically by Phelan et al. (1986) and shown to contain several γ-lactones and (*E*)-phytol [(*E*)-3,7,11,15-tetramethyl-2-hexadecen-1-ol], a compound not unrelated to the 6,10,14-trimethyl-2-pentadecanol (B) found to be produced by female *C. cephalonica* moths.

By contrast, in the Galleriinae it seems that the long-range pheromone is typically produced by the male moths, evoking a searching behavior in the females (Zagatti et al., 1987, and references therein). This necessitates a cue from the female for the male to change behavior from passive calling to courtship directed towards the female. In *Eldana saccharina* it was shown that this cue is auditory in nature (Zagatti, 1981). In *C. cephalonica* the female moths emit a courtship pheromone that acts over a short distance to attract the male and cause him to attempt copulation.

The site of production of the female pheromone has not been established, and histological examination has failed to show any glandular structures on the female abdomen. In the females of most Lepidoptera, the pheromone-producing glands are modifications of the intersegmental membranes between abdominal segments VIII and IX (Percy and Weatherston, 1974). In *C. cephalonica* it is possible that secretory cells are disseminated along the abdomen. Thus analyses

of female cuticular washes suggested that more pheromone was obtained when larger portions of the abdomen were taken, and collection of volatiles from female moths was found to be a better source of pheromone than cuticular washing.

It is uncertain how useful the synthetic pheromones will be in monitoring or control of *C. cephalonica*. The female-emitted pheromone is probably too short-range in action to be used alone. The male-emitted pheromone could be used to bait traps or to disrupt mating if it causes a directed, anemotactic response in the female moth, rather than a searching response as is the case with *E. saccharina*. Work to investigate this further is in progress.

(Received June 24, 1986; accepted September 29, 1986)

Abstract—In a trapping experiment, wood chips from freshly cut Scots pine trees attracted flying adults of the bark beetle *Tomicus piniperda* (L.) Healthy Scots pine trees, which usually are not attacked by *T. piniperda*, were baited with chips from freshly cut trees. In other experiments trees were baited with a mixture of (−)-α-pinene, (+)-3-carene, and terpinolene; the individual monoterpenes; or with ethanol alone. All baited treatments were attacked by *T. piniperda*. Most of the attacks resulted in short egg galleries and in larval galleries which were only a few millimeters in length. In trees from which a new generation of beetles emerged, net reproduction was well below 1.0. Unbaited control trees remained unattacked or received a few isolated attacks.

Key Words—Gallery initiation, host volatiles, monoterpenes, ethanol, reproductive success, bark beetle, pine shoot beetle, *Tomicus piniperda*, Coleoptera, Scolytidae.

INTRODUCTION

The pine shoot beetle *Tomicus piniperda* (L.) is one of the most important forest insects of Scots pine, *Pinus sylvestris* L., in northern Europe. At high population levels of beetles their feeding in shoots of healthy trees can result in considerable growth reduction (Mattson-Mårn, 1921; Nilsson, 1974, 1975; Långström, 1980; Ericsson et al., 1985).

In early spring the beetles leave their hibernation sites in the bark at the base of living pine trees. Under favorable weather conditions the main flight period and the main period of gallery initiation last for only a few days (Bakke,

0098-0331/87/0700-1591$05.00/0 © 1987 Plenum Publishing Corporation

1968; Eidmann, 1965, 1974). The beetles reproduce in logs, stumps, and pines that are windbroken, windthrown, or otherwise weakened. Field studies have failed to demonstrate the occurrence of an aggregation pheromone in *T. piniperda*; instead, this species uses host volatiles to locate breeding substrate (Kangas et al., 1967; Perttunen et al., 1970; Jordal, 1979; Byers et al., 1985). Byers et al. (1985) demonstrated that *T. piniperda* is strongly attracted to several major monoterpenes isolated from Scots pine: (+)-α-pinene, (−)-α-pinene, (+)-3-carene, and terpinolene. Subsequently, Vité et al. (1986) showed that the addition of ethanol to a mixture of α-pinene and terpinolene strongly increased the attraction of flying *T. piniperda*.

The influence of host volatiles on gallery initiation by *T. piniperda* has not been demonstrated earlier. The biodegradation product ethanol has been shown to induce attacks by some bark and ambrosia beetles (Kerck, 1972; Roling and Kearby, 1975; McLean and Borden, 1977; Moeck, 1981). In this study we addressed four questions: (1) Do naturally occurring blends of host volatiles induce gallery initiation? (2) Do the same monoterpenes that attract the beetles also induce gallery initiation? (3) Can single monoterpenes have this effect? (4) Can ethanol induce gallery initiation?

METHODS AND MATERIALS

All experiments were conducted in Scots pine stands in the province of Uppland in central Sweden except for the induction-of-attack test with monoterpenes, which was conducted in the province of Dalarna.

Attraction to Pine Chips. Attraction of beetles to traps with and without chips from freshly cut Scots pine trees was monitored by means of sticky traps during 1983. The beetles were caught on wire net cylinders (6.5 mm mesh, 50 cm high, 30 cm diam.) coated with Stickem-Special®. The traps were attached to plastic tubes at a height of 1.5 m. Inside each wire net cylinder one metallic cylinder (20 cm high, 8 cm diam.) covered on both ends with wire-netting was attached. In seven traps the cylinders were filled with chips of Scots pine, and in the seven control traps empty cylinders were used. Every 24 hr the cylinders were refilled with fresh chips. The traps were placed in two parallel rows, every other trap being a control. The distance between traps was 15 m while that between rows was 40 m. Captured beetles were collected after each day of flight, and catches were pooled for each trap in the analysis.

Induction of Attack with Pine Chips. Healthy trees in a 55-year-old pine stand with a mean height of 13 m were baited with chips from freshly cut Scots pine trees during 1983. Twelve trees were selected and four of these were randomly assigned to the treatment. During the first day of beetle flight (April 16), these four trees were provided with fresh pine chips in cylinders of the same model as described above. Fourteen cylinders were attached around the trunk

TABLE 1. MEAN NUMBER OF ATTACKS BY *T. piniperda* ON SCOTS PINE TREES BAITED WITH CHIPS AND ON UNBAITED CONTROL TREES

Treatment	Replicates (No.)	Tree diam. (cm)		Attacks per tree (No.)	
		$\bar{X}$	Range	$\bar{X}$	Range

Chips April 20	4	13.6	9.0–16.3	35.3[a]	24–54

[a]Treatment is significantly different from control ($P = 0.05$, Mann-Whitney test).

of each tree, seven at a height of 0.5 m and seven at a height of 1.2 m. The eight remaining trees served as controls and were left untreated. The following day (April 17), boring dust was found on the four baited trees. To obtain more replicates, four additional trees were baited with chips on the second day of beetle flight (April 20). The distance between selected trees was at least 4 m. Mean diameters at 1.3 m are given in Table 1.

In September 1983, all 16 trees were felled. The trunks were then totally debarked and inspected for bark beetle attacks. A *T. piniperda* attack was defined as any penetration through the bark that reached the phloem, even if no gallery was formed, with the exception of the penetrations at ground level caused by hibernating beetles during previous years. Attacks just reaching the phloem could be identified as *T. piniperda* attacks by the dimension of the entry holes and by the localization of the attacks to the rough bark.

In this and the following experiments we expressed our data as number of galleries per tree since entire trees were inspected for attacks. Attack densities expressed, e.g., as galleries per square meter, are of minor interest in the present context.

Induction of Attack with Monoterpenes. Healthy trees in a 130-year-old pine stand with a mean height of 12 m were baited with monoterpenes during 1984. On a 0.5-hectare plot, eight groups of five trees each were selected. The distance between selected trees was at least 5 m. Mean diameters at 1.3 m are given in Table 2. The trees in each group were randomly assigned one of five treatments. On the first day of beetle flight (April 28), three trees in each group were baited individually with commercial samples of either (−)-α-pinene (Fluka 99.5%, $[\alpha]_D^{20}$ −42 ± 1°), (+)-3-carene (Fluka 99%, $[\alpha]_D^{20}$ +17 ± 0.5°), or terpinolene (92% GC), and one tree in each group was baited with all three chemicals (Table 2). The remaining tree in each group was left as an unbaited control. Monoterpene baits were selected with respect to their attractivity to *T. piniperda* (Byers et al., 1985).

The chemicals (50 μl) were individually released from open conical vials

TABLE 2. MEAN NUMBER OF ATTACKS BY *T. piniperda* ON SCOTS PINE TREES BAITED WITH MONOTERPENES AND ON UNBAITED CONTROL TREES[a]

	Tree diam. (cm)		Attacks per tree (No.)	
Treatments	$\bar{X}$	Range	$\bar{X}$	Range
Control trees	11.7	10.3–13.4	0	0
(−)-α-Pinene	12.3	8.9–14.4	174.5[b]	121–237
(+)-3-Carene	11.6	9.5–14.2	52.4[b]	8–89
Terpinolene	12.5	11.0–14.2	116.5[b]	0–312
(−)-α-pinene, (+)-3-carene, and terpinolene	12.2	10.4–13.5	208.1[b]	121–298

[a] Eight replicates in each treatment

(upper diam. 5 mm) which were attached to the trunk at 1.2 m height. Each tree was baited with two vials containing the same compound, one on each side of the trunk. The release rates of the compounds during the experiment were not measured. In the laboratory at 15°C the monoterpenes were released at about 5 μl/hr from each vial. The sequence of application was α-pinene, 3-carene, and terpinolene with about 30 min application time for each chemical. Because of this time lag in application and since the beetle flight had already started by the time the chemicals were applied, no comparison between baited treatments was made in the analysis. On the morning of the following day (April 29), boring dust was found on each of the 32 baited trees except for one of the eight trees baited with terpinolene, while none of the eight control trees had apparently been attacked.

During September 1984, all trees were felled and inspected for bark beetle attacks in the same way as described above. The data were subjected to a Friedman's test followed by a nonparametric Dunnett's test (one-tailed) (Zar, 1984). To evaluate reproduction with regard to attack densities and to compare our results to those of other authors, the data from this experiment were converted from galleries per tree to galleries per surface area. The surface area was estimated as square meters rough bark on each tree, since *T. piniperda* usually does not attack the smooth bark found higher up on Scots pine trees.

The number of offspring was estimated from the number of emergence holes, since in *T. piniperda* every beetle makes its own emergence hole, i.e., very few beetles emerge through already existing holes (Salonen, 1973; Saarenmaa, 1983).

Induction of Attack with Ethanol. Healthy trees in a 40-year-old natural regeneration of pine with a mean height of 8.5 m were baited with ethanol or

TABLE 3. MEAN NUMBER OF ATTACKS BY *T. piniperda* ON UNBAITED SCOTS PINE TREES AND ON TREES BAITED WITH ETHANOL OR (−)-α-PINENE[a]

Treatments	Tree diam. (cm)		Attacks per tree (No.)	
	$\bar{X}$	Range	$\bar{X}$	Range
Control trees	10.6	9.5–11.5	0[b]	0
(−)-α-Pinene	10.4	7.3–13.8	10.8	1–19
96% ethanol	9.9	8.6–11.5	4.2	0–11

[a] Six replicates in each treatment.
[b] All treatments were significantly different (P =0.05, Newman-Keuls test).

α-pinene during 1985. Eighteen trees (diameters are given in Table 3) were randomly assigned one of three treatments: (1) unbaited controls, (2) 96% ethanol, and (3) (−)-α-pinene (Fluka 97%, $[\alpha]_D^{20}$ −42 ± 3°). The distance between selected trees was at least 3 m. The α-pinene-baited treatment was included to ascertain whether responsive beetles were present in the area at the time of the test. The ethanol (2 ml) and α-pinene (100 μl) were released from open vials (9 and 5 mm diam., respectively). Each tree was baited with two vials as described in the previous experiments. The beetle population in the area was apparently low. Therefore the trees were baited daily from May 8 to May 13, except for one day when no beetle flight occurred. Vials were supplied with fresh compounds daily just as the beetle flight started. In the afternoon, after having been open for about 4 hr, the vials were refilled. The release rates during the experiment were not determined. In the laboratory at 15°C, ethanol was released at about 75 μl/hr, and α-pinene was released at about 10 μl/hr.

Late in June 1985 all trees were felled and inspected for bark beetle attacks as described above. Data were subjected to a Kruskal-Wallis test with tied ranks followed by a nonparametric multiple comparison similar to the Newman-Keuls test (Zar, 1984).

RESULTS

On traps baited with chips from freshly cut Scots pine trees, a mean of 13.1 *T. piniperda* (range 6–28) was caught while a mean of 1.1 *T. piniperda* (range 0–3) was caught on unbaited control traps. The difference is statistically significant (P = 0.001 level, Mann-Whitney test).

When healthy Scots pine trees were baited with chips, significantly more *T. piniperda* attacks were found on these trees than on unbaited control trees, which only received a few isolated attacks (Table 1). Only in one of the baited

trees did the attacks result in emergence of a new generation of beetles. In all other baited trees and in the control trees, attacks resulted in short egg galleries with an average length of 2.3 cm and, in the few cases where progeny developed, in larval galleries which were only a few millimeters in length. In two of the trees we also found a few larvae of *Pissodes* spp. (Curculionidae).

All trees baited with either α-pinene, 3-carene, terpinolene, or all three compounds were attacked by *T. piniperda* except for one tree baited with terpinolene (Table 2). No attacks were found on the control trees.

Reproduction success was low. In 23 of the baited trees, the attack density was higher than 100 galleries/m^2 ($\bar{X}$ = 167; range 101–302). In six of these trees, a new generation of beetles emerged. The mean attack density in these trees was 194 galleries/m^2 (range 153-221), and the net reproductivity (number of offspring per parent beetle) was 0.27 (range 0.05–0.47). In all other attacked trees, the attacks resulted in short egg galleries with an average length of 3.8 cm and in larval galleries which were only a few millimeters in length. In 14 of the baited trees we also found larvae of *Pissodes* spp.

Of the six trees baited with ethanol, five were attacked by *T. piniperda* (Table 3). The trees baited with α-pinene in the same experiment received a higher number of attacks than the trees baited with ethanol. All attacks were unsuccessful and resulted in short egg galleries with an average length of 1.3 cm. No attacks were found on the control trees. No attacks of other insect species were found on the trunks.

DISCUSSION

Host volatiles released by chips from freshly cut Scots pine trees both attracted *T. piniperda* and induced gallery initiation in healthy trees (Table 1). Attraction of beetles to host volatiles from pine logs was also observed by Byers et al. (1985), who demonstrated that several Scots pine monoterpenes, (+)- and (−)-α-pinene, (+)-3-carene, and terpinolene were strongly attractive to *T. piniperda*.

Trees baited with any one or all of these monoterpenes [(+)-α-pinene not tested] were attacked (Table 2). This induction of attack by several compounds may have resulted as an adaption to the great variation between pines in monoterpene composition (Tobolski and Hannover, 1971; Thorin and Nommik, 1974; Hiltunen, 1975).

The attacks of *Pissodes* spp. found on some of the baited trees should not have influenced gallery initiation by *T. piniperda* since the flight period of these species occurs later in the season than the flight period of *T. piniperda* (Saalas, 1923; Eidmann, 1974; Löyttyniemi and Uusvaara, 1977).

Trees baited with ethanol were also attacked by *T. piniperda* (Table 3). Since anaerobic metabolism in deteriorating tree tissue can result in the for-

mation of ethanol (Graham, 1968; Cade et al., 1970; Moeck, 1970; Ikeda et al., 1980), its presence may indicate a weakened tree that would provide suitable breeding substrate for *T. piniperda*.

A new generation of *T. piniperda* emerged from only six of the 31 monoterpene-baited trees that were attacked, and net reproductivity was well below 1.0. Reproduction failed despite the relatively high attack densities in most of the trees: in 23 of these trees the densities were higher than 100 galleries/m^2. These attack densities correspond well with those generally found in suitable breeding substrate, and good reproduction is often observed in weakened trees with attack densities lower than 100 galleries/m^2. The highest densities found in nature are usually less than 300 galleries/m^2 (Salonen, 1973; Saarenmaa, 1983, 1985; Långström et al., 1984). From this the following conclusions can be drawn: (1) gallery initiation induced by host substances does not necessarily lead to successful reproduction; and (2) *T. piniperda* is adapted to breed in dead or severely weakened trees and is usually unable to reproduce in trees of good vigor.

Our study demonstrates that monoterpenes as well as ethanol, eventually together with terpenes, can induce gallery initiation by *T. piniperda* on apparently healthy trees, which generally are not suitable for reproduction. Responses to the two different classes of compounds may reflect the various kinds of breeding substrate utilized by this species. In trees broken or windthrown during winter, ethanol production may not have reached levels high enough to be detected by the beetles during their flight period in early spring; however, high amounts of terpenes may be released from resin exuding from injuries on these trees. In contrast, weakened and dying pine trees lacking external injuries (e.g., suppressed trees) would not be expected to release high amounts of monoterpenes. Instead, metabolic processes resulting in detectable quantities of ethanol may guide beetles to attack these trees.

Acknowledgments—We are indebted to R. Axelsson, H. Bylund, and H. Nordenhem for technical assistance. We also thank K. Sjödin for the terpene samples. O. Anderbrant, Dr. F. Schlyter, and Dr. D. Tilles commented on the manuscript, and Dr. Tilles also made the linguistic revision. We gratefully acknowledge the financial support to the project Odour Signals for Control of Pest Insects by the research councils FRN, NFR, and SJFR.

(Received July 3, 1986; accepted September 29, 1986)

Abstract—A sex pheromone produced by female banded cucumber beetle adults, *Diabrotica balteata* LeConte, was isolated from volatiles trapped on Porapak Q and identified as 6,12-dimethylpentadecan-2-one. The structure was elucidated by spectroscopic analyses and confirmed by synthesis. The synthesized racemic compound was equal to the purified natural pheromone in eliciting responses by banded cucumber beetle males to field traps. A dose-response characteristic was demonstrated for the racemic material formulated on filter paper or rubber septa and placed in field traps. The absolute configuration at the C-6 and C-12 positions was not established.

Key Words—Sex pheromone, 6,12-dimethylpentadecan-2-one, ketone, banded cucumber beetle, *Diabrotica balteata*, Chrysomelidae, Coleoptera, attractant.

INTRODUCTION

The banded cucumber beetle (BCB), *Diabrotica balteata* LeConte, an economic pest of vegetable and field crops, particularly sweet potato and seedling

cucurbits (Pitre and Kantack, 1962; Saba, 1970; Teng et al., 1984; Young, 1961), occurs from southern United States to Colombia, Venezuela, and Cuba (Krysan, 1986).

Since the use of broad-spectrum insecticides to control BCB often causes outbreaks of secondary pests, a number of studies on host performance of BCB adults have been conducted in efforts to develop noninsecticidal methods to manage this pest (Melhus et al., 1954; Cuthbert and Jones, 1972; Overman and MacCarter, 1972; Risch, 1976). The presence of a BCB female-produced sex pheromone, which should be useful in monitoring and possibly in controlling this species, was reported by Cuthbert and Reid (1964). Later Schwarz et al. (1971) reported that the BCB pheromone molecule included *n*-dodecenyl, ethylene epoxy, and methyl ketone moieties, but they were unable to complete the structure elucidation.

We report here the isolation, identification, and synthesis of a sex pheromone, collected from BCB female-produced volatiles, that attracts males of the species in the field.

METHODS AND MATERIALS

Pheromone Collection and Bioassay

The insects were from a laboratory colony maintained at the Northern Grain Insects Laboratory, Brookings, South Dakota, by the method of Jackson (1985). The colony was begun in Brookings, in August 1981, with eggs obtained from a laboratory colony at the USDA, ARS, Vegetable Insects Research Laboratory, Charleston, South Carolina. Virgin females were isolated from males within 24 hr of emergence and held in screened cages (30 × 30 × 30 cm) for three days before being placed in the pheromone collection chamber.

The pheromone collection system and methods were the same as those used to collect volatiles from the southern corn rootworm (SCR), *Diabrotica undecimpunctata howardi* Barber (Guss et al., 1983b). The collection was performed at 24°C with a 12-hr photophase and the pheromone was collected on Porapak Q (Byrne et al., 1975).

During the initial isolation stages, a laboratory bioassay similar to that used for the SCR (Guss et al., 1982) was employed. In this array, four or five virgin male beetles were placed in a Petri dish (150 × 15 mm) and allowed to acclimate for 15 min. A test extract or fraction in 1–5 μl of hexane was applied to a 5-mm^2 piece of filter paper, the solvent was evaporated for about 10 min, and then the paper was placed into the dish. Responses of beetles toward the treated paper, antennal waving, and copulatory behavior were considered evidence of the presence of the pheromone.

Field bioassays were conducted with synthesized putative pheromone and crude and purified natural material from the Porapak Q collectors. Wing traps (Pherocon 1C-type, Trece, Inc., Salinas, California) were baited with various doses of these materials applied (in 200 μl of hexane) to 5.5-cm filter paper circles or to methylene chloride-extracted rubber septa (A.H. Thomas, Philadelphia, Pennsylvania, No. 8753-D22).

The first test was conducted in a field of sweet potato in the vicinity of Homestead, Florida, on November 6, 1985. On the morning of the test, the air temperature was about 18°C at 9:00 AM with winds about 6–10 mph and increasing. The afternoon temperature was about 20°C with winds 10–15 mph.

The traps were baited with filter paper formulations of 1 μg of the purified natural pheromone, a crude extract that contained 1 μg of the natural pheromone, and 1, 4, 10, 100, and 1000 μg of synthetic racemic 6,12-dimethylpentadecan-2-one and a hexane blank. Treatments were assigned randomly to traps within each replicate. Traps were placed 25 m apart in a row across the field perpendicular to the prevailing wind. Two replicates (16 traps in a row) were conducted beginning at 8:45 AM and terminating at 11:30 AM. The experiment was then moved 400 m upwind in the field and two replicates were conducted with rebaited traps in a new random order from 1:40 PM until 9:00 AM the next morning. An observer was assigned to each replicate, and the cumulative total males captured in each trap was recorded at 15-min intervals from 8:45 to 9:30 AM (morning test), from 1:40 to 2:30 PM, at 5:00 PM, and from 8:30 to 9:00 AM the next morning. Tests were conducted during the day because preliminary trapping observations indicated that night temperatures during this period were too cool for BCB flight.

The second test was conducted in a field of mature yellow crook-neck squash in the vicinity of Gainesville, Florida, from November 14 to November 20, 1985. Traps were placed 50 m apart in a row across the field and perpendicular to the prevailing wind. Treatments were 0.03, 0.1, 0.3, 1.0, 3.0, 10, and 30 mg of racemic 6,12-dimethylpentadecan-2-one, and a hexane blank formulated on rubber septa. The baits were not renewed during the test. The traps were checked daily and captured males were removed and counted, at which time the trap and bait were moved to the next trapping location in the line.

Release rates of synthetic pheromone were measured by collecting volatiles released by the septa and analyzing them by gas–liquid chromatography (GLC). Septa were loaded with the same doses used in the field tests and aired at room temperature for 24 hr prior to release-rate measurement. Then a septum was placed in a 15-mm (ID) × 20-mm-long stainless-steel tube, and compressed air, purified by passage through a charcoal filter, was passed over it at 1 liter/min for 1 hr. Volatiles entrained in the airstream were trapped on a small charcoal filter that was subsequently extracted with methylene chloride. After addition of internal standards, the extract was analyzed by capillary GLC.

Pheromone Purification

Volatiles were extracted from Porapak Q filters with 50 ml of ether–hexane (60:40) by agitation for 24 hr. The extract was concentrated with a stream of N_2, and the concentrate was subjected to preparative GLC without further treatment.

Micropreparative GLC was performed with a Varian model 1400 gas chromatograph equipped with a flame ionization detector. The pheromone was purified using two packed columns: 10% OV-101 on 60–80 mesh Chromosorb W (glass column 2 × 2 mm ID) and 7.5% Carbowax 20 M on 60–80 mesh Chromosorb W (glass column 2 m × 2 mm ID). The injection port and column temperatures were both 200°C when operating the OV-101 column and 180°C when operating the Carbowax 20 M column. Detector temperature was 250°C. The carrier gas (He) flow rate through each column was 20 ml/min.

The chromatograph was modified to accommodate a 90:10 effluent splitter and an external, Dry Ice–acetone-cooled fraction collector (Brownlee and Silverstein, 1968). Fractions were collected in 1.5-mm (ID) × 305-mm glass capillary tubes and eluted with about 10 μl of hexane.

Synthesized pheromone was purified by preparative high-performance liquid chromatography (HPLC) using a 4.6-mm (ID) × 25-cm stainless-steel column packed with Adsorbosphere C18 (5 μm) (Alltech/Applied Science, Deerfield, Illinois). The methanol–water (90:10) mobile phase was pumped through the column at 1.0 ml/min, and the eluting components were detected with a Waters model R401 differential refractometer. The 6,12-dimethylpentadecan-2-one eluted from this system in 17.5 min.

Pheromone Analysis and Identification

Natural and synthesized pheromone was analyzed on 50-m × 0.25-mm-ID fused silica capillary columns in a Hewlett-Packard 5790 gas chromatograph equipped with a split–splitless injector system (30-sec split delay) at a carrier gas (He) linear flow rate of 18 cm/sec. The OV-101 column was operated at 60°C for 1 min after injection, temperature programmed at 30°C/min to 200°C, and then operated isothermally. The Carbowax 20 M column was operated at 60°C for 2 min after injection, programmed at 30°C/min to 210°C and then operated isothermally.

Mass spectra were obtained with a Nermag R10-10 mass spectrometer equipped with a chemical ionization (CI)/electron impact (EI) source and interfaced with a Varian Vista model 6000 gas chromatograph equipped with a split–splitless injection system. Samples were introduced into the mass spectrometer source through a 50-m × 0.25-mm-ID fused silica OV-101 column operated at 60°C for 2 min, then programmed at 32°C/min to 230°C and operated isothermally. The linear flow velocity of the carrier gas (He) was 18 cm/

sec. The spectrometer was interfaced with a Digital PDP 11/23 computer for collection and analysis of the data.

Hydrogenoloysis in the inlet of the GC interfaced to the mass spectrometer was performed by the method of Beroza and Sarmiento (1963, 1964). About 6 cm of a glass insert (1 mm ID) was filled with 1% neutral Pd catalyst on Gas-chrom W and placed in the injection port ahead of the OV-101 column. The catalyst was maintained at 285°C for the hydrogenolysis, and H_2 was used as the carrier gas at a flow rate of 20 ml/min.

PMR analysis was performed with a Nicolet 300 MHz Fourier transform NMR spectrometer interfaced to a Nicolet model 1280 data system (16K data points, 10 μsec pulse). Samples purified by micropreparative GLC (about 3 μg total pheromone) were transferred from the glass capillary, using benzene-D6, into an NMR tube, the top of which was 5 mm (OD), with a 50 × 2-mm (OD) coaxial extension on the bottom (Wilmad Glass Co., Buena, New Jersey, catalog No. 507 with WGS-5BL stem).

Synthesis

1-Bromo-4-methyl-3-heptene (1). This was reported previously by Guss et al. (1983b), and its preparation has been described in detail by Kulesza et al. (1969). It was prepared in 79% yield; bp 68–70°C at 7 mm (Kuleza et al. reported bp 51–52°C at 2 mm). Its IR and NMR spectra were in complete agreement with its assigned structure.

1-Bromo-4-methylheptane (2). This was prepared from (1) in 70% yield by hydrogenation over platinum oxide in glacial acetic acid (Guss et al., 1983b); bp 67–70°C at 8.5 mm. Its IR and NMR spectra were in agreement with the assigned structure and reported values (Guss et al., 1983b).

8-Methyl-undecan-2-one (3). The lithium reagent was prepared from 9.66 g (0.05 M) of bromide (2), and 0.853 g (0.123 M) of lithium metal in 50 ml of dry ether at −150°C and 100 μl of methyl iodide was used to start the reaction. This lithium reagent was converted into an organocopper reagent and reacted with freshly distilled methyl vinyl ketone in the presence of tri-*n*-butylphosphine by the method of Suzuki et al. (1980). Distillation afforded 80% yield of product; bp 58–60°C at 0.5 mm; CI-MS (CH_4) *m/z*, 185 (M + 1); IR (CCl_4), 2960(s), 2940(s), 2880(s), 2860(s), 1723(s), 1468(m), 1380(m), 1358(m), 1160(m); NMR ($CDCl_3$), 0.84 (6H, m), 1.1–1.4 (11H, m), 1.57 (2H, m), 2.12 (3H, s), 2.41 (2H, t).

4-Oxo-pentane Ketal Triphenylphosphonium Bromide (4). The phosphonium salt was prepared in 60% yield by the method of Sonnet et al. (1986); IR ($CHCl_3$), 2950(s), 1438(s), 1110(s), 1030(m), 690(m), 660(m), NMR ($CDCl_3$), 1.22(3H, s), 1.58 (2H, bds), 1.75(2H, m), 2.05(2H, t), 3.9(4H, s), 7.8(15H, m).

6,12-Dimethyl-5-pentadecen-2-one Ethylene Ketal (5). A hexane solution

of *n*-butyllithium (19.0 ml, 0.038 M) was added dropwise at 0°C to a suspension of 20 g (0.038 M) ketal phosphonium bromide (4) in dry THF and stirred for 30 min. The reaction mixture was brought to room temperature, and 3.6 g (0.02 M) of 8-methylundecan-2-one (3) in ether was added dropwise and the mixture was stirred for 6 hr. The reaction mixture was poured into ice water, and the mixture was extracted with hexane. The hexane solution was washed with water and saturated NaCl and dried over Na_2SO_4. Distillation furnished 870 mg (15% yield) of 6,12-dimethyl-5-pentadecen-2-one ethylene ketal (5); bp 120–130°C at 0.7 mm Hg; CI-MS (CH_4) (*m/z*), 297(M + 1); IR(CCl_4), 2960(s), 2940(s), 2880(s), 1467(m), 1380(m), 1240(m), 1160(m), 1220(m), 1090(m), 1060(m), 950(m), 900(m); NMR ($CDCl_3$), 0.85 (6H, m), 1.1–1.7 (17H, m), 1.68 (3H, s), 2.05 (2H, m), 2.13 (3H, s), 3.95 (4H, bds), 5.10 (1H, m).

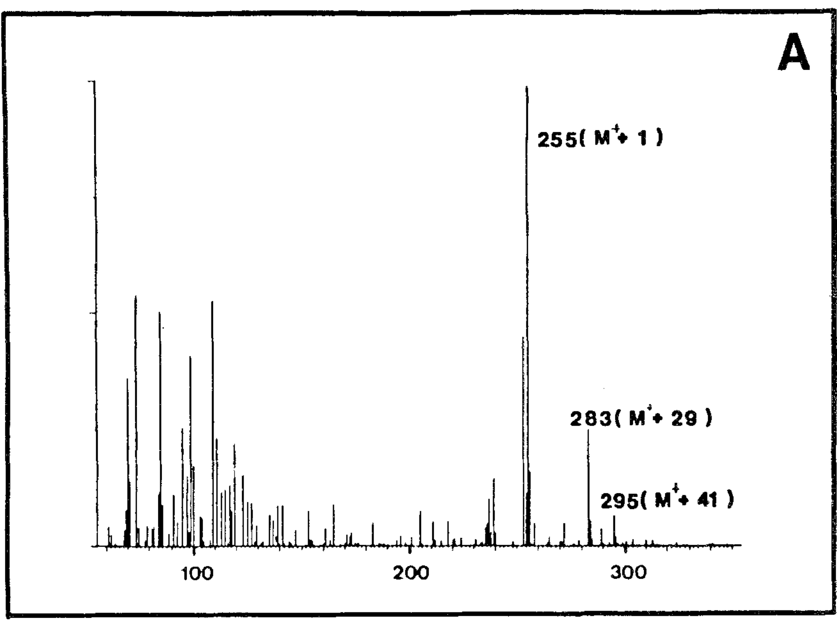
6,12-Dimethylpentadecan-2-one Ketal (6). The unsaturated ketal (5) (870 mg, 0.003 M in absolute ethanol) was hydrogenated over 50 mg of palladium on charcoal to yield 832 mg of 6,12-dimethylpentadecan-2-one ketal (6); CI-MS (CH_4) *m/z*, 299(M + 1).

6,12-Dimethylpentadecan-2-one (7). A solution of 832 mg (0.003 M) of ketal (6) in acetone–10% H_2SO_4 was stirred for 3 hr. It was then extracted with hexane and the extract washed with saturated aqueous NaCl, dried over Na_2SO_4, and concentrated in vacuo to yield 695 mg (98%) of 6,12-dimethylpentadecan-2-one (7); CI-MS (CH_4) *m/z*, 255(M + 1); EI-MS (*m/z*), 43(100), 58(82), 59(38), 71(42), 85(24), 95(13), 97(8), 109(10), 110(15), 123(3), 137(2), 151(1), 152(0.5), 153(0.5), 165(1), 196(3), 211(2), 236(6), 254(M+, 0.9); IR (CCl_4), 2960(s), 2930(s), 2850(s), 1735(s), 1460(m), 1375(m), 1360(m); NMR (C_6D_6), 0.875 (3H, d, J = 8.1 Hz), 0.895 (3H, d, J = 8.1 Hz), 0.905 (3H, t, J = 6.2 Hz), 1.1–1.4(20H, m), 1.64(3H, s), 1.91(2H, t, J = 7.3 Hz).

RESULTS AND DISCUSSION

The hexane–ether extracts of Porapak Q filters from the collection chamber elicited behaviors from BCB males in the laboratory bioassay that indicated the presence of the female sex pheromone. Laboratory assay of the fractions obtained by preparative GLC indicated that the pheromonal activity was confined to a single peak eluting at 11 min on OV-101 under the experimental conditions. Further micropreparative chromatography on the Carbowax 20 M-packed column yielded a compound with a purity of greater than 99.5% by analysis on the OV-101 and Carbowax 20 M capillary columns. The retention indices (Kovats, 1965) of this compound, relative to paraffin hydrocarbons, on the OV-101 and Carbowax 20 M capillary GLC columns were 1787 and 2114, respectively.

The methane CI mass spectrum (Figure 1A) established that the molecular weight of the compound was 254 with diagnostic peaks at *m/e* 253(M − 1),



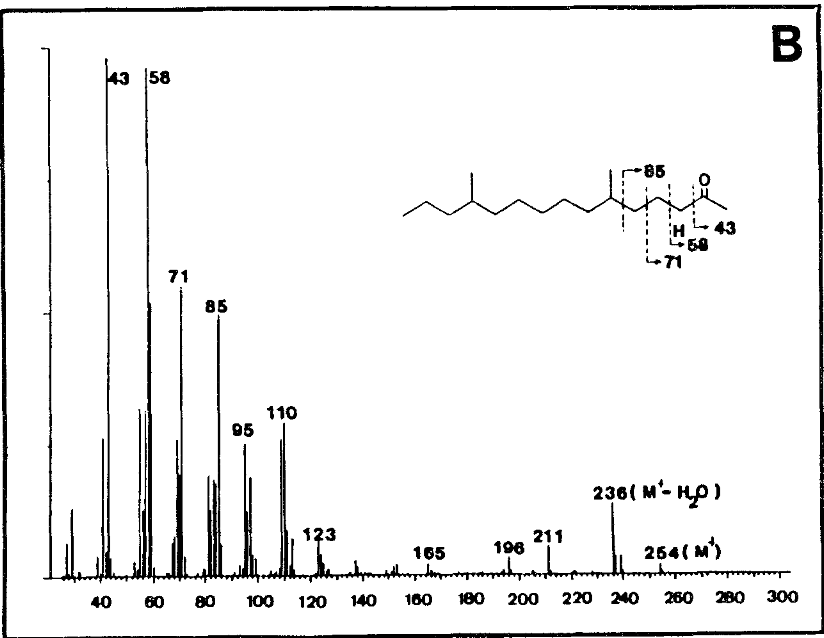


FIG. 1. (A) Chemical ionization (CH_4) and (B) electron impact mass spectra of *D. balteata* pheromone.

255(M + 1), 283(M + 29), and 295(M + 41). In the EI mass spectrum (Figure 1B), the peak at *m/e* 254(M+) confirmed the molecular weight. Furthermore, the EI mass spectrum of this pheromone is very similar to that of the SCR pheromone, 10-methyl-2-tridecanone (Guss et al., 1983b) with a peak at *m/e* 236 indicating the loss of H_2O, and the strong peaks at *m/e* 43 and 58, the weak peak at *m/e* 57, and the moderately strong peak at *m/e* 71 strongly suggesting a methyl ketone with no substitution on the carbons α or β to the carbonyl (Budzikiewicz et al., 1967).

The [^{1}H] NMR spectrum of the purified natural pheromone (Figure 2) supported the above assignment. The signals at δ 1.64 ($\underline{CH}_3CO-$; 3H, s) and 1.92 ($-CO\underline{CH}_2$-CH_2-; 2H, t) confirmed the presence of a 2-oxobutyl moiety in the pheromone molecule. Furthermore, when expanded, the group of peaks from δ 0.86 to 0.91 appeared to consist of three overlapping signals, δ 0.875 (3H, d, J = 8.1 Hz), 0.895 (3H, d, J = 8.1 Hz), and 0.905 (3H, t, J = 6.2 Hz) which suggests the presence of two methyl branches and a terminal methyl in the molecule.

Hydrogenolysis of the pheromone in the GC injector leading to the mass spectrometer source and EI mass spectral analysis of the product yielded the

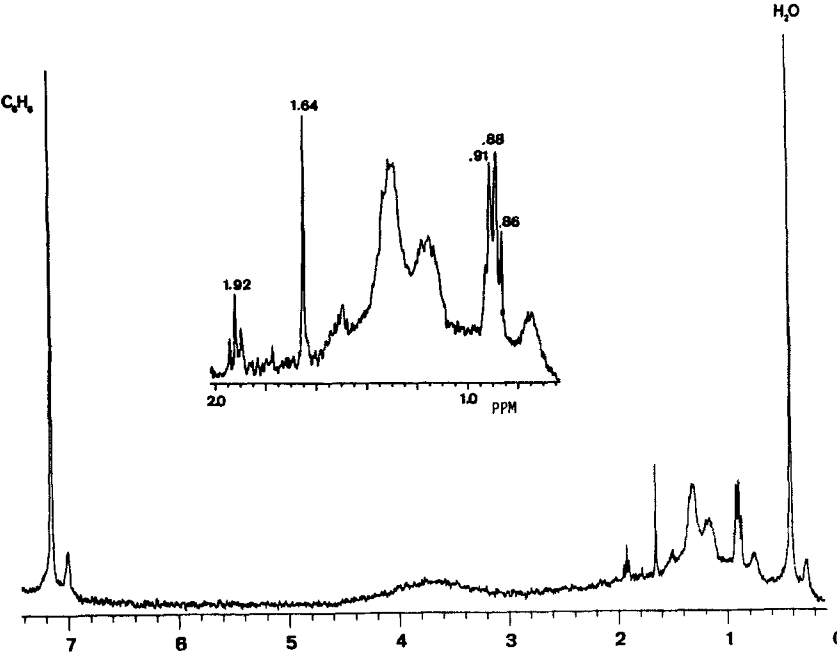

FIG. 2. 300-mHz proton magnetic resonance spectrum of approximately 3 μg of the purified natural *D. balteata* pheromone.

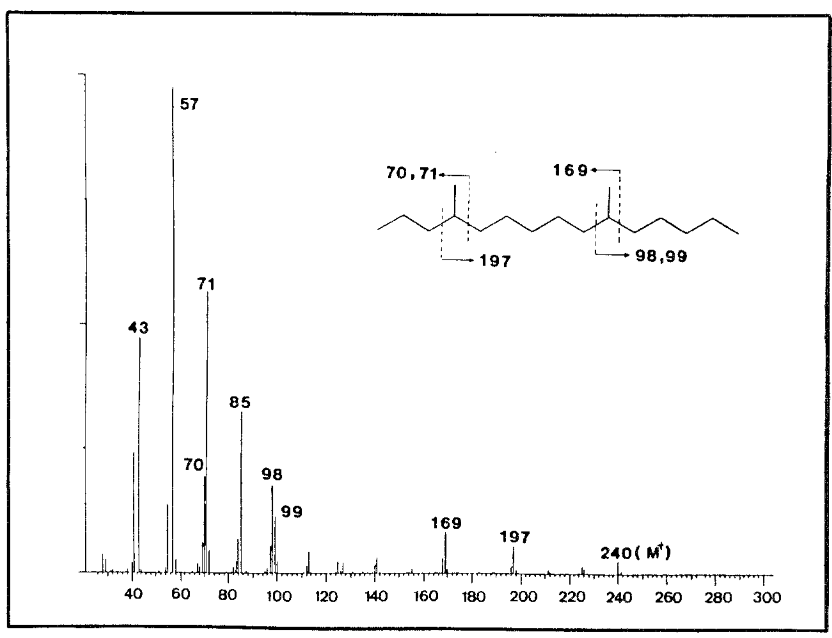

FIG. 3. Electron impact mass spectrum of hydrogenolysis product of *D. balteata* pheromone.

spectrum shown in Figure 3. The peak at 240(M+) confirms the 17-carbon skeleton indicated by mass spectra of the parent compound. The peaks at *m/e* 70, 71, and 197 and at *m/e* 98, 99, and 169 are of greater intensity than would be expected in a normal hydrocarbon and represent preferred cleavage on either side of two methyl branches. These data support a structure with methyl branches on carbons four and ten as indicated in Figure 3. The only other possible structure, with methyl branches on carbons 4 and 6, was ruled out because of the relative intensities of the peaks at *m/e* 98 and 99. The greater intensity of the peak at 98 is consistent with cleavage of the bond between carbons 9 and 10 in 4,10-dimethylpentadecane, with the fragment ion containing only one methyl branch. Cleavage between carbons 6 and 7 of 4,6-dimethylpentadecane yielding a fragment ion containing two methyl branches would be expected to produce peaks at *m/e* 98 and 99, but the peak at 99 should be of greater intensity (Nelson et al., 1972; Nelson and Sukkestad, 1970, 1975; Pomonis et al., 1980; Pomonis and Hakk, 1984). Thus the structure of the hydrogenolysis product was established as 4,10-dimethyl pentadecane. Since the EI mass and PMR spectra of the pheromone indicated that the carbons α and β to the carbonyl must be unsubstituted, the only possible structure is 6,12-dimethylpentadecan-2-one.

Synthesis. The synthesis of racemic 6,12-dimethylpentadecan-2-one (Figure 4) was analogous to that for the sex pheromones of the western corn rootworm (WCR), 8-methyl-2-decanol propanoate, *D. virgifera virgifera* LeConte (Guss et al., 1982), and the SCR (Figure 5) (Guss et al., 1983b). Methylcyclopropyl ketone was allowed to react with *n*-propylmagnesium bromide. The intermediate tertiary carbinol was isomerized to the homoallylic bromide (1) with hydrobromic acid (Julia, 1961). The allic bromide (1) was reduced to 1-bromo-4-methylheptane (2) by hydrogenation with PtO_2. The saturated bromide (2) was converted to the corresponding organocopper reagent which was reacted with methyl vinyl ketone in the presence of tri-*n*-butyl phosphine (Suzuki et al., 1980) to produce 8-methylundecan-2-one (3). A Wittig reaction between the C-12 methylketone (3) and ethylene ketal pentan-2-one phosphonium salt (4), produced a mixture of the *Z* and *E* isomers of the ethylene ketal of 6,12-dimethyl-5-pentadecen-2-one (5) (15% yield). The unsaturated ethylene ketals were hydrogenated and then subjected to acid hydrolysis to produce 6,12-dimethylpentadecan-2-one (7). The final product was purified (>99%) by HPLC and GLC.

The CI and EI mass spectra and the PMR spectrum of pure synthetic racemic 6,12-dimethylpentadecan-2-one were identical with those of the isolated natural pheromone. Additionally the synthetic and natural pheromones cochromatographed, producing only one peak, on each of the two capillary GLC columns.

Field Tests. The mean number of males captured in traps baited with filter paper formulations of natural and synthetic materials are summarized in Table 1. Since the purified natural pheromone attracted more males into traps than the crude natural material, the crude material may have included substances that either reduced the release rate or inhibited the response of the males. The captures for 1 μg natural, 4 μg synthetic, and 10 μg synthetic were not statistically different, but were different from all other means. While the number of males captured increased with increasing dose for synthetic pheromone treatments from 1 to 10 μg, linear regression analysis yielded correlation coefficient values slightly less than required for significance at the 5% level of probability (nontransformed data $r = 0.9945$, 1 *df*; the coefficient did not increase with log-transformation). The responses of males to doses > 10 μg was greatly reduced.

The observed captures for the first 2 hr of each replication of the test with filter paper formulations are shown in Table 2. The captures were not dose related for all periods and reveal a complex pattern that is probably related to nonlinear release rates from the filter papers coupled with trap interaction and the depletion of males available to react to each trap. This field was infested heavily with BCB, and reaction to the baits was nearly instantaneous. Males were seen immediately in the vicinity of the 100- and 1000-μg-baited traps but did not enter these traps immediately as they did the other treatments. Again, a dose-response relationship is evident, and regression analysis yields very high correlations for the synthetic treatments 1-10 μg ($r = 0.983$ for the total captures at 2 hr). The increase in captures at the 100-μg level, beginning 30 min after the traps were baited, suggests a decreasing release rate with time.

Apparently the 10-μg dose on filter paper provided a near optimum release

rate of the racemic synthetic material. The effect of the stereoisomers cannot be determined clearly at this time, but the similar responses to the 1 μg pure natural and the 4 μg and 10 μg synthetic material suggest that one of the stereoisomers of 6,12-dimethylpentadecan-2-one is a pheromonal constituent.

The response of males to traps baited with rubber septa formulations are summarized in Table 3. Again, a relationship of increasing capture with in-

TABLE 3. MEAN NUMBER OF *Diabrotica balteata* MALES CAPTURED IN TRAPS BAITED WITH RUBBER SEPTA FORMULATIONS OF RACEMIC 6,12-DIMETHYLPENTADECAN-2-ONE

10000	9.2 ± 1.1	1322
30000	5.8 ± 1.2	4369

[a]Means of two measurements; flow rate 1 liter/min, ca. 25°C.

creasing dose is evident for traps baited with 30–300 μg of synthetic racemic pheromone ($r = 0.998$ for linear regression of log dose vs. log response). Trap captures declined for treatments above 300 μg. This is the same response pattern observed with the filter paper formulations (Table 1).

The results of the study of release rates of the synthetic pheromone from rubber septa (Table 3) indicate that the release rates continue to increase as the dose is increased over the dose range studied. Thus, the leveling off and decline of trap captures at doses higher than 300 μg/septum cannot be attributed to a leveling off or decrease in the release rate. A similar phenomenon was observed for captures of *D. barberi* Smith and Lawrence, the northern corn rootworm (NCR), in traps baited with racemic 8-methyl-2-decanol propanoate (Figure 5) (Guss et al., 1982). Later this was explained when it was discovered that the NCR is attracted to the 2*R*, 8*R* isomer but that attraction is inhibited by the 2*S*, 8*R* and 2*S*, 8*S* isomers (Guss et al., 1985). On the other hand, the dose–response relationship reported here may be more like that of the WCR, in which rubber septa loaded with 0.25–1000 μg of the 2*R*, 8*R* isomer produced highly correlated captures of males; however, many WCR males ceased their upwind response to the 1-mg bait and attempted to copulate with nearby males (Guss et al., 1984). Thus, BCB males respond positively to one or more of the stereoisomers of 6,12-dimethylpentadecan-2-one and are either inhibited by other stereoisomers of the same compound or, with higher doses, their response to the locus of the active material is diminished. The use of stereoisomers to achieve specificity in their chemical signals is common among the *Diabrotica* studied thus far (Krysan et al., 1986).

The SCR was present in the test areas, and a pheromone of this species, 10-methyl-2-tridecanone, was evaporated from rubber septa baits using doses similar to those formulated in the BCB baits. Neither BCB nor SCR were captured in traps baited with the synthetic racemic pheromone of the other species.

We conclude from the congruence of chemical analytical data and demonstrated field activity in traps with doses equivalent to that of natural material that 6,12-dimethylpentadecan-2-one is a sex pheromone of female BCB. The active enantiomer(s) and the complete role of this chemical in premating communication remain to be determined.

This identification adds to our knowledge of the pheromonal communications systems of the *Diabrotica*: a pattern of chemical structures is beginning to emerge that appears to be related to the taxonomy of this genus. The species of *Diabrotica*, for which the chemical structures of sex attractants are known, fall into two groups (Wilcox, 1972). Those in the *fucata* species group have pheromones characterized by the methyl ketone functionality and a methyl branch on the fourth carbon from the hydrocarbon end of the chain. By contrast, all those taxa is included in the *virgifera* species group are attracted to one or more stereoisomers or analogs of 8-methyl-2-decanol propanoate (Figure 5).

The genus *Diabrotica* includes some 338 species (Wilcox, 1972). It will be interesting to see if these patterns prevail as pheromones from additional species are identified and knowledge accrues on phylogenetic relationships within the genus.

THEORETICAL RANGE OVER WHICH BACTERIA AND NEMATODES LOCATE PLANT ROOTS USING CARBON DIOXIDE

Atlanta, Georgia 30332

(Received June 16, 1986; accepted September 30, 1986)

Abstract—A theory used to estimate the smallest relative chemical gradient that is potentially detectable is given approximately by $G > (DCRv^2t^3)^{-1/2}$ where D is the diffusion constant and C the concentration of the stimulus chemical, R is the effective radius of the receptor, v the velocity of the organism, and t the time period within which the organism measures the concentration. Of these factors, time has the strongest influence. Combining this result with available information on gradients of carbon dioxide around roots and behavior of bacteria and nematodes leads to several conclusions. Bacteria can potentially detect carbon dioxide gradients in the layer of water in contact with the root but not further away. In contrast, plant-parasitic nematodes can potentially detect gradients one meter from a single long root fiber and over 2 m from a plant root mass using klinokinesis. A direct approach using klinotaxis can start a few centimeters from a single root fiber and half a meter from a root mass. These differences are due to differences in the time available to measure the concentrations. Increasing the length of a bacterium could increase its ability to detect gradients by reducing its rotational diffusion. Collimating stimuli that serve to maintain a straight path may provide a means of improving chemotaxis by permitting concentration to be measured for longer times during klinokinesis. More accurate predictions can be made when more precise data are available. The analysis is applicable to a wide variety of other organisms and stimuli.

Key Words—Theory, chemotaxis, rhizosphere, soil, klinokinesis, klinotaxis, nematode, bacteria, carbon dioxide, root.

INTRODUCTION

An important question in soil ecology is how animals find their way in this complex environment. A specific question of particular importance to plant

0098-0331/87/0700-1617$05.00/0 © 1987 Plenum Publishing Corporation

ecology and agriculture is how plant-parasitic nematodes and root-colonizing bacteria locate plant roots. Carbon dioxide is an attractant for several phytoparasitic nematodes (reviewed by Prot, 1980). Some are very sensitive to it (Pline and Dusenbery, 1987). While CO_2 is quantitatively the most important root exudate, its relative importance as an attractant under natural conditions is debatable. The suggestion has been made that CO_2 may attract nematodes toward host roots, but that its influence does not extend further than 1 or 2 cm from the roots (Klinger, 1963; Prot, 1980). It has recently been demonstrated that the bacterium *Pseudomonas* can migrate 1 cm toward seeds (Scher et al., 1985).

Because it is very difficult to observe the behavior of organisms in soil and to measure concentration gradients over small distances, an experimental approach to the problem is difficult. Consequently, a theoretical approach was taken. A relatively simple theory is presented that can place more specific limits on what is physically possible. Using existing data, some rough estimates are made.

METHODS AND MATERIALS

Berg and Purcell (1977) present a theoretical treatment of the sensory limits of bacterial chemotaxis. Their theory is based on the fact that for organisms the size of bacteria, the forces of viscosity completely dominate those of inertia, i.e., the Reynolds number is very low. In these circumstances, diffusion limits the rate at which molecules can be detected. The same considerations should apply to plant-parasitic nematodes, which move at about the same speed as bacteria and have sensory openings about the same size as bacteria.

Assume a receptor has an effective radius of R, that it measures the concentration of a stimulus chemical with diffusion constant D for a time t, and that the true concentration is C. Berg and Purcell provide several arguments that, ignoring factors of order unity, the relative error (noise) will be given approximately by $\Delta C/C \sim (tDCR)^{-1/2}$ where C is in units of molecules per cubic centimeter. For a 1 M solution, C is $6.0 \times 10^{20}/\text{cm}^3$. For a pure gas at standard temperature and pressure, C is $2.5 \times 10^{19}/\text{cm}^3$.

If an organism is moving with a velocity v along a relative concentration gradient $G = (1/C)\ (dC/dx)$ for a time t, the change in true concentration or signal will be $\Delta C/C \sim vtG$. In order to be detected, the signal must be larger than the noise. Thus, $vtG > (tDCR)^{-1/2}$. Rearranging this gives $t > [DCRv^2G^2]^{-1/3}$.

This provides a minimum time required to detect a gradient. Note that any gradient can be detected if sufficient time is allowed, including the lifetime of the gradient and adaptation time. The optimal orientation to the gradient was assumed since the result will be used to estimate the maximal range of attraction. If the organism responds by klinokinesis (Fraenkel and Gunn, 1940), the

limit on the time available is the time within which the organism maintains a straight course. If the organism responds by klinotaxis, the limit is the time the receptor is held to one side of its path.

If an estimate of t is available, the minimum gradient that can be detected is approximated by $G > [DCRv^2t^3]^{-1/2}$. Note that there is a relatively strong dependence on the time taken for measurement and somewhat less on the velocity.

RESULTS

Carbon Dioxide. To describe the distribution of CO_2 around roots, simplifying assumptions must be made. Close to a root fiber, the situation can be modeled as a line source in which the root is assumed to be infinitely long and straight. In practice, the root need only be long compared to the distance from the root to the point of interest. At distances that are large compared to the average separation between individual root fibers but small compared to the separation between plants, the situation can be modeled as a point source. In this case, the CO_2 produced by the entire root mass of one plant is treated as emanating from a small volume. This approach should be reasonably accurate for distances that are several times the diameter of the volume occupied by the root mass. In all cases, the effect of the soil–atmosphere surface will be ignored. This approximation will have little effect if the distance to the root is small compared to the distances to the surface. Where roots are shallow compared to the distance under consideration, the surface will cause distortions, and the calculations will only provide rough indications of the CO_2 distribution.

Nye (1981, Appendix) provides data for CO_2 production from roots in a typical case. The relevant parameters are: C is the concentration of CO_2 in the air space of soil (typically 0.5% v/v $= 1.3 \times 10^{17}$ mol/cm^3); $a = 0.037$ cm, the radius of a typical root; $F = 1.59 \times 10^{-6}$ ml/cm^2/sec, rate of CO_2 produced per unit of root surface; $L_v = 1.0$ cm of root length/cm^3 of soil volume; and D is the diffusion constant of CO_2 and is equal to 0.065 cm^2/sec in soil, 0.163 cm^2/sec in gas phase, and 1.66×10^{-5} cm^2/sec in water.

In soil, carbon dioxide can diffuse through both gas and liquid phases. Since the diffusion constant differs by a factor of 10^4 between the two phases, the appropriate value must be used. Over distances larger than the gas spaces between soil particles, diffusion is dominated by movement through the gas phase. In this case, the gaseous value is used but corrected for the volume of soil occupied by gas. Conversely, on a size scale of a bacterium, diffusion in the liquid phase is more appropriate.

In the case of the line source, in the steady state, the rate at which CO_2 diffuses across a cylinder centered on the source must equal the rate of production. Thus, in Nye's terms $2\pi rD\ (dC/dr) = 2\pi aF$ or $dC/dr = aF/rD$.

Substituting in the above values with $r = a$ and using D for water, the

maximum gradient in the film of water on the root is 9% CO_2/cm. Since this is several times larger than the typical concentration in soil, the relative gradient $(1/C)(dC/dr)$ will be > 1/cm. More precise estimates require knowledge of the thickness of the water film.

Beyond this thin layer, diffusion takes place mostly through the gas phase and the gradient is much shallower. The maximum gradient, near the root surface, is 0.0025% CO_2/cm or a relative gradient of 0.005/cm. The gradient is extremely shallow because of rapid diffusion through the gas phase—so shallow that at a distance of 10 m the concentration drops only one part per thousand. Thus, in determining relative gradients, the average concentration can be used in the denominator.

The relative gradient for a line source with the above parameters is $G = (1/C)(dC/dr) = aF/(CDr)$, where C is in units consistent with F. Using the above values for bulk soil, the maximum range of chemotaxis can be determined if the minimum detectable gradient is known: $r = 1.8 \times 10^{-4}/G$.

At greater distances, the gradient around the root mass of an isolated plant is better modeled as a point source. The rate of CO_2 production (P) by the root mass must equal the rate of diffusion through any surrounding sphere. Thus, $F2\pi aL_vV = P = 4\pi r^2D(dC/dr)$, where V is the volume of soil occupied by the root mass. The relative gradient is $G = (1/C)(dC/dr) = aFL_vV/(2r^2DC)$. Assuming a typical root mass occupies 1000 cm^3 of soil, 3.7×10^{-4} ml/sec of CO_2 are produced and $r = 9.1 \times 10^{-2}/G^{1/2}$. Thus, far from the root mass, the square root of the threshold gradient is inversely proportional to the range rather than the first power of the gradient.

Bacteria. The chemotaxis of *Escherichia coli* and *Salmonella typhimurium* have been studied extensively. These bacteria respond to chemical gradients by klinokinesis (Carlile, 1980). They swim in relatively straight paths for about a second. These runs are separated by tumbles in which the orientation of the bacterium is altered erratically but is not biased with respect to the gradient (Berg and Brown, 1972). A change in stimulus concentration alters the length of the runs in such a way that runs up a gradient of attractant, or down a gradient of repellent, are longer than those in the opposite direction. Thus, the organism works its way along the gradient by a biased random walk. In this case, the time for sampling the concentration is limited to the length of a run, since directional information is lost in a tumble. There is also a physical limitation on the length of time a direction can be maintained due to rotational diffusion. For ordinary rod-shaped bacteria like *E. coli*, the period is a few seconds. Thus, the time available for measuring the concentration is about 1 sec (Berg and Purcell, 1977).

The speed with which the bacteria swim during a run is about 15 μm/sec

or 1.5×10^{-3} cm/sec. The effective radius of the receptor is estimated as 0.8 μm (Berg and Purcell, 1977). Using these values for bacteria, the concentration of CO_2 for bulk soil, and the diffusion constant for liquid water, the minimum detectable gradient is estimated as 0.06/cm. Since the gradient in the bulk soil near the root is less, bacteria cannot use this mechanism to move toward roots from distances beyond the thin film of water on the root.

In an actual experiment, bacteria responded to a relative gradient of 0.7/cm (Berg and Purcell, 1977). Thus, there is sufficient sensitivity to respond to the much larger gradient in the thin film of water on the root surface.

Nematodes. The major chemosensory organs in nematodes are a pair of amphids. In infective juveniles of *Meloidogyne incognita*, the opening of the amphids to the outside is about 0.2×0.8 μm (Wergin and Endo, 1976). Let $R = 5 \times 10^{-5}$ cm for the effective radius of the receptor. The question then arises as to the appropriate value of the diffusion constant. Since nematodes are covered by a thin layer of water, the stimuli must be in water at the time of detection. However, if the layer is sufficiently thin, diffusion through it will be rapid compared with diffusion through soil. The characteristic time for diffusion is L^2/D. For a distance, L, of 40 μm the time for diffusion in water is about 1 sec. This time is sufficiently short so that no significant behavior occurs in plant-parasitic nematodes (Goode and Dusenbery, 1985). *Meloidogyne* infective juveniles are only 15 μ in diameter (Bird, 1979) and the layer of water covering them should be much less than their thickness. In addition, movement of the nematode will have the effect of stirring the media in its vicinity, which is equivalent to an increased diffusion rate. Since the effect of stirring will not be considered elsewhere, the rate of diffusion limiting measurement of concentration is assumed to be that of bulk soil: $D = 0.065$ cm^2/sec.

Like bacteria, nematodes are capable of responding by klinokinesis (Dusenbery, 1980; Goode and Dusenbery, 1985). The rate of locomotion of *Heterodera schachtii* (Wallace, 1958) is about 10 μm/sec and that of *Meloidogyne incognita* is about the same (Pline and Dusenbery, 1987). Free-living nematodes generally move about 10 times faster (Goode and Dusenbery, 1985). From tracks left by *Meloidogyne javanica* (Prot, 1978), the distance over which they maintain a straight course in the apparent absence of external stimuli can be estimated as 0.1 cm. Thus, the time available to measure concentration is on the order of 100 sec. These values yield a minimal detectable gradient of about 2×10^{-6}/cm. The gradient falls to this level at a distance of 90 cm from the single root fiber and 210 cm from the root mass.

Nematodes are also thought to be capable of chemotaxis via klinotaxis (Klingler, 1963; Prot, 1978). In this mechanism, the nematode moves its head (carrying the receptors) from side to side as it moves along and thus samples the gradient with each swing of the head. When a concentration difference is detected, the nematode turns in the appropriate direction. In this case, the time available for measuring the concentration is the time the head is bent to one

extreme and the velocity is that of swinging the head from one extreme to the other. Tethered *M. incognita* immersed in water undulate with a period of 5 sec (Goode and Dusenbery, 1985). However, movement is usually less rapid when nematodes are in a thin film of water than when immersed. From published tracks (Prot, 1978), the wavelength appears to be about 0.01 cm. At a speed of 0.001 cm/sec, the undulations would occur with a priod of about 10 sec. Let us take 10 sec as a maximum time for testing the concentration at each extreme of head motion. During locomotion, the velocity of head swinging will be about the same as the forward velocity. Thus, the main difference between the two mechanisms is that klinotaxis allows about 10-fold less time to sample the concentration. Since the minimal gradient depends on $t^{-3/2}$, the threshold gradient is increased by a factor of $0.1^{-3/2} = 32$. For the single root fiber, the maximum range of detection is proportional to the threshold gradient, so it will be reduced to about 3 cm. For the root mass, the range is reduced by the square root of the threshold gradient and is about 40 cm.

DISCUSSION

The analysis indicates that the time available for measurement of concentration is the most important factor limiting response. Shallower gradients can be detected if an organism can maintain a straight course for longer periods. For example, a bacterial cell that is elongated would have a larger rotational diffusion time, which would permit a longer time for collecting the signal. Another possibility is the use of collimating stimuli. It has been suggested that nematodes might use thermal gradients simply as a guide for maintaining a straight path (Diez et al., 1987). Using such a stimulus, a nematode could maintain a straight course over longer distances than without such a guide. Thus, the presence of a thermal gradient might aid chemotaxis. Another possible example would be motile algae. They can follow the direction of light (Foster and Smyth, 1980), and this could permit them to measure concentrations over longer times than their rotational diffusion would otherwise permit. Nematodes sometimes cease locomotion and wave their heads back and forth (Green, 1977). This may provide a mechanism of extending the sampling time without losing direction.

This analysis explains different ranges for klinokinesis and klinotaxis. A number of observations have indicated that klinotaxis occurs when a nematode gets sufficiently close to a target, and it has been proposed that klinokinesis occurs when the stimulus is weaker. The analysis developed above explains this difference in sensitivity on the basis of the time available to determine concentration. The theory predicts that the ratio of threshold ranges for the two mechanisms is the ratio of available times to the 3/2 power. This is roughly estimated

to be about 30-fold for plant-parasitic nematodes. Burr (1984) has previously pointed out the difference in threshold for klinokinesis and klinotaxis, emphasizing differences in sample distances instead of sample time.

The analysis suggests that gradients of carbon dioxide emanating from roots in soil can potentially be detected at much greater distances than previously believed possible. It remains to be seen whether nematodes actually have this level of sensitivity. Recent experiments with *M. incognita* demonstrated responses to gradients that were lower than 0.01% CO_2/cm or a relative gradient of 0.01/cm (Pline and Dusenbery, 1987). Shallower gradients could not be produced in the apparatus used. The threshold demonstrated seems very low, but it is about 10^4 times larger than the limiting threshold predicted by the theory.

Several of the assumptions used in the above calculations are subject to modification. The value of $D = 0.065$ (Nye, 1981) is at the high end of the range of commonly measured values (Wesseling, 1962), and a value of 0.03 may be more typical. Using the latter value, the ranges of detection would increase by about 50%. The concentration of CO_2 found in soil also varies a great deal. Values from 0.1 to 5% are common (Boynton, 1941; Wesseling, 1962). On this basis, the range for nematode klinokinesis to an isolated root fiber could theoretically vary between 5 and 500 cm.

Another potential limitation is that the time required to establish a gradient over such large distances might be limiting. Gradients will be disrupted by rainwater percolating through the soil. The characteristic time, L^2/D, for diffusion equals a day for a distance of 75 cm in soil. Thus, gradients form relatively rapidly, and this limitation is not likely to be important.

The theory assumes that the root source is surrounded by soil without other roots for distances greater that those of interest. For the large distances of potential attraction determined here, these assumptions will not normally hold in real situations because of the proximity of other roots and the soil surface. However, the assumptions may apply well to recently planted fields where young plants are often well separated and vulnerable to nematodes. In any case, the calculations demonstrate that the sensory abilities of nematodes need not be limiting. If nematodes have the theoretically possible sensitivity, they can follow the gradients normally present in soil to the nearest source.

It is an open question whether soil organisms actually utilize CO_2 gradients to locate plant roots. In the natural soil environment, there are many sources of CO_2 besides plant roots. If CO_2 were the only stimulus utilized, these sources could lead to dead ends. On the other hand, there is certainly a concentration of sources at the root surface. Dead ends might be sufficiently rare so that such losses would not interfere with effective infection. Other chemical stimuli are probably also utilized, especially by parasites with a narrow host range. In support of this view, the species of phytoparasitic nematodes that have been reported as attracted to CO_2 mostly have a wide host range.

INTRASPECIFIC PHEROMONE DISCRIMINATION AND SUBSTRATE MARKING BY ATLANTIC SALMON PARR

OLE B. STABELL[1]

Institute of Zoophysiology
University of Oslo
Oslo, Norway

(Received June 16, 1986; accepted September 30, 1986)

Abstract—Attraction and preference behavior patterns shown by Atlantic salmon (*Salmo salar* L.) parr towards intraspecific odors were measured. Salmon parr were attracted to tank water in which relatives of their own strain were held but were also attracted to tank water containing another strain of their species. When given a choice between the two types of tank water, water containing their own strain odor was significantly favored over water containing conspecific but nonfamiliar odor, revealing that pheromones are present at intraspecific levels in salmonid juveniles. Competitive experiments with various extracts suggest that the active compounds are most likely produced in the liver and are voided via the intestinal tract, as determined by presence of attractants in intestinal contents and bile. Intraspecific discrimination was not detected with extracts from either skin surface mucus or blood plasma. Extracts from gravel that had been kept below the fish in their rearing tanks, however, induced a strain-related preference behavior. This suggests an ability for substrate marking by salmonid fishes, presumably mediated by deposition of fecal material. Strain discrimination and substrate marking are discussed in relation to stationary behavior and homing of fishes within discrete populations in natural systems.

Key Words—*Salmo salar*, olfaction, pheromones, substrate marking, feces, bile, skin mucus.

INTRODUCTION

Salmonid fishes living in streams demonstrate a substantial degree of regional stability throughout their life, (Miller, 1954; Saunders and Gee, 1964; Edmundson et al., 1968; Hesthagen, 1978; Cargill, 1980; Harcup et al., 1984).

[1] Present address: Fisheries Department, Nordland College, Box 6003, N-8016 Mørkved, Norway.

When moved from their "home area," most of the fishes will return to that area whether displaced upstream or downstream. Downstream displacement, however, was found by Miller (1954) to result in a more precise homing in cutthroat trout (*Salmo clarki* L.). Accordingly, it was suggested that the sense of smell was the most important factor in homing since fish displaced downstream could smell their home area continuously.

Regional stability and homing after displacement in streams have also been demonstrated in several nonsalmonid species of fishes (Gerking, 1953, 1959; Stott, 1967). In sensory deprivation experiments, using longear sunfish (*Lepomis megalotis megalotis* Raf.), Gunning (1959) demonstrated that fishes with an impaired olfactory sense moved at random in the stream, whereas blinded individuals homed as quickly and accurately as controls. The precision of intact fish homing in the upstream direction was also found to be greater than that of those moving downstream. Homing was therefore concluded to be maintained by olfactory mechanisms.

The above summary indicates that fishes within streams search for their home range through rheotactic behavior mediated by olfaction, and they apparently recognize their "home area" by some characteristic odor. The question then arises: what is the origin of the characteristic odors used by fishes when homing and when maintaining regional stability?

Hasler and Wisby (1951) suggested that because of local differences in soil and vegetation of the drainage basin, each stream has a unique chemical composition. During smolt transformation and seaward migration, the young salmon were presumed to become "imprinted" to the distinctive odor of their home stream (see also: Hasler et al., 1978; Hasler and Scholz, 1983). When returning as mature adult salmon, they would proposedly remember this "imprinted" odor and use it as a cue for homing when migrating through the homestream network. The "imprinting" hypothesis, however, has been closely associated with the process of smolt transformation (Hasler and Scholz, 1983) and does not, therefore, explain the phenomena of regional stability and homing after displacement in juvenile fishes (Stabell, 1984).

The pheromone hypothesis for anadromous salmonids (Nordeng, 1971, 1977) proposes that homing migrants return to their home area by detecting population-specific pheromones secreted by downstream migrating smolt and young relatives resident in the stream. The hypothesis has been supported through behavior studies with mature anadromous char (*Salvelinus alpinus* L.) by Selset and Døving (1980), demonstrating that char have the ability to detect the odor of young relatives and that they prefer the odor of relatives to that of nonrelated conspecifics.

By positive rheotaxis olfactometry, it has recently been demonstrated that Atlantic salmon (*Salmo salar* L.) parr are also able to discriminate between substances secreted by strains of conspecifics (Stabell, 1982). Accordingly, it was suggested that intraspecific odors could be responsible for the regional sta-

bility of juveniles in streams and that these odorants could well be identical to those attracting mature migrants to the spawning grounds. Studies of positive rheotactic behavior in parr towards conspecific odors could therefore provide insight into adult homing behavior.

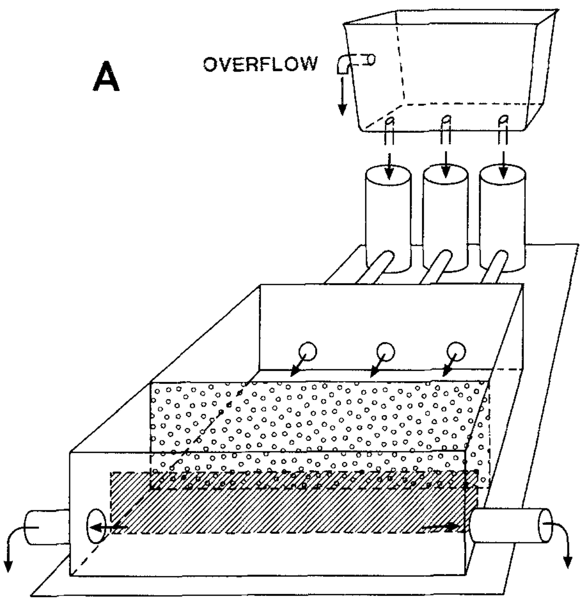
The intention with the present study was to further investigate the preference and attraction phenomena of Atlantic salmon parr towards conspecific odors. In particular, it was of interest to evaluate possible pathways for the secretion of the intraspecific signal substances and to test for substrate marking by fishes related to regional stability and homing.

METHODS AND MATERIALS

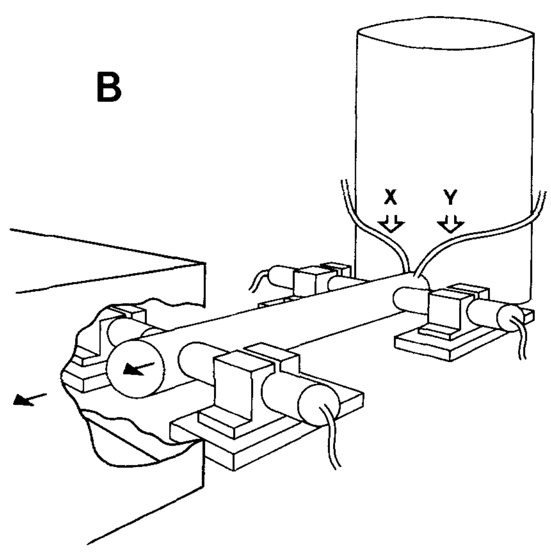
Study Animals. Atlantic salmon (*Salmo salar* L.) parr were used in the study. The parr originated from the river Sandvikselv, Akershus County, southeastern Norway; the river Imsa, Rogaland County, southwestern Norway; and from the river Altaelv, Finnmark County, northern Norway. After artificial fertilization, the eggs were hatched and the fish raised at the Research Station for Freshwater Fish, belonging to the Directorate for Wildlife and Freshwater Fish, at the Imsa River. The fishes were subsequently transported to aquarium facilities at the University of Oslo, where the experiments were conducted. The Altaelv parr were all siblings of the brood year 1981 and were transported to Oslo in May 1982. The parr from Sandvikselv and from Imsa were of the brood year 1982 and arrived at the University in September 1982. Of these fish, the Imsa parr belonged to one sibling group, while the Sandvikselv parr came from a group where ova and milt from several spawners had been mixed. The three strains of fish were reared in separate tanks supplied with tap water and fed with commercially available dry pellets from automatic feeders.

Test System. A fully automated test system was used in the experimental series to measure preference behavior and upstream movement aroused by chemical stimuli. The aquarium part of the system was of the two-choice, parallel-entrance type, as described by Selset and Døving (1980). In the current study the aquarium part was slightly modified with regard to water-flow characteristics and test sample injections, according to the description by Stabell (1982).

The system involves a main chamber with three freshwater inlets, of which the fish were allowed to choose between the two outermost (Figure 1A). The middle inlet was used to ensure good separation of water flow within the main chamber, and fish were prevented from entering that inlet by a plastic net cover. Tap water was introduced from an overflow reservoir into three separate chambers in the upstream end of the system, ensuring equal flow from each of the inlets (3×3 liters/min). A water level of 8 cm was used in the system, giving a main chamber volume of 28.3 liters.



A
OVERFLOW



B
X
Y

The test substances were introduced to the system at the upper end of the inlet tubes, as shown in Figure 1B, and added by hydrostatic pressure to the background flow through solenoid valves at an approximate ratio of 1:60 in volume. When a test sample (X) was introduced to one of the inlets, a reference sample (Y) was introduced to the other and vice versa. Movements of fish into the inlets were registered by photocells (IR light) located at the lower and upper end of each inlet (Figure 1B). Test performances were controlled and monitored by a microcomputer connected to an interface with in–out ports and a printer.

Odor Sampling. Fish odors were sampled by siphoning water from fish rearing tanks (volume: 500 liters, flow: 10 liters/min) containing approximately 100 fish that had been undisturbed for more than 12 hr. Skin mucus was sampled from the surfaces of the fish using an aspirator flask, according to the description by Stabell and Selset (1980). Skin mucus, intestinal contents, blood plasma, and bile were all sampled from the same fish. Each type of material was pooled from five fish and subsequently divided for use in two 4-hr test series. Material not used for immediate testing was frozen and stored at −20°C.

Test solutions from skin mucus as well as intestinal contents were prepared by adding 20 ml of tap water to each of the sampled materials. After careful mixing, the solutions were centrifuged and the supernatant pipetted off. Another 20 ml of tap water was added to the residue and the procedure repeated. The supernatants from both water extracts were then pooled for use in the tests. Ethanol extracts from each type of material were prepared in a similar manner to that described for water extracts. Before using in the tests, however, ethanol was removed in a rotary evaporator and the residues redissolved in tap water.

Gravel retained by a 2-cm sieve and washed in water was introduced under the fish in the rearing tanks upon arrival of the 1982 brood years. Approximately 20 liters of gravel were used in each tank. After two months, the gravel was removed from the tanks and washed carefully with running water to remove food residues and feces. It was then spread out on water-absorbing paper on the laboratory bench to dry. After a week, methanol extracts were made from the

FIG. 1. (A) Overview of the aquarium part of the test system; flow directions are shown by solid arrows. City tap water is introduced to the upper overflow tank, ensuring equal flow from each of the three inlets. Entrance by the fish into the middle inlet is prevented by a grid. A perforated wall in the downstream end of the main chamber prevents fish from moving downstream, and an overflow wall (hatched) secures a constant level of water in the system. (B) Close-up of a freshwater inlet showing positions of photocells in the downstream and upstream ends. Positions of tubes for test sample injections, denoted X and Y, are shown by open arrows in the upstream end of the inlet. Test samples are introduced through solenoid valves, and test performance is controlled and monitored by a microcomputer.

material covering the gravel surface. Five liters of methanol was used to wash the gravel from each tank. Methanol extracts were subsequently treated in the same manner as that previously described for the ethanol samples.

Experimental Procedures. Test samples were introduced to the inlet tubes for periods of 20 min followed by pauses of 10 min. Every half hour the samples were switched between the inlets in order to balance possible preferences of the fish for a particular side of the aquarium. Because of possible side preferences, two subsequent half-hour test periods were treated pairwise in the evaluation of data.

Four hours of testing, consisting of four pairs of half-hour test periods, were run as a series. This time limitation for each test series was because of the storage capacity of the test-sample reservoirs. Several 4-hr test series were usually necessary to obtain a satisfactory number of choices within each type of test. Ten fish were used simultaneously in the test system, and no fish were ever used in more than two successive 4-hr test series.

Data Evaluation. The two photocells used for each inlet allowed two different events to be evaluated: (1) search: only the beam of the downstream photocell is broken, i.e., the fish enters the lowermost part of the inlet and then backs out; (2) ascent: the beam of the downstream photocell is broken followed by that of the upstream cell, i.e., the fish moves all the way up through the inlet tube.

In random choices, the fish will choose equally between the two inlets (Selset and Døving, 1980; Stabell, 1982), and the binomial model can therefore be used for probability calculations (Siegel, 1956). The activity score (AS) obtained for each event (ascents or search) is given by the expression:

$$AS = \frac{N_t - N_r}{N_t + N_r} \times 100$$

where N_t and N_r are the number of choices in favor of the test substance and the reference substance, respectively (Olsén, 1985). The data are presented as column graphs for the two events, each representing the activity score for the total number of trials performed.

Probabilities for random choice are given in the figures. The probabilities are given as the lowest score obtained for each experiment at the 5, 1, or 0.1% levels. All probabilities given are one-tailed. The results were regarded to be within significant levels of attraction or repulsion when the probability of being generated by random choice was found equal to, or less than, 5%.

RESULTS

Fish Odors in Tank Waters. The results obtained from tests with fish odors in tank waters are presented in Figure 2. Fish from the Sandvikselv strain were

used as test fish in all three experiments of this type, which took place from October 10 to November 3, 1982. When water from the tank containing fish of the Sandvikselv strain was tested against tap water without any salmon odor, the fish significantly preferred the tank water (Figure 1A). The results refer to both parameters tested. Of 93 ascents performed, 55 were in favor of the tank water, giving an activity score (AS) of +18.3. This result represents a significant level of attraction ($P = 0.0495$). For search behavior, 468 of 820 trials performed were in favor of the tank water containing the related fish, giving an AS of +14.2, which is highly significant ($P < 0.00003$).

The test fish also demonstrated a preference for tank water over tap water when water from a tank containing an unfamiliar strain of salmon parr was used (Figure 1B). Of 122 ascents recorded, 77 were in favor of the tank water, giving an AS of +26.2 ($P = 0.0025$); from a total of 1333 searches, 725 were also in favor of the tank water (AS = +8.8; $P = 0.007$).

When tank water containing the related Sandvikselv strain of fish was tested against tank water containing the unfamiliar Imsa strain that had previously been found attractive, the Sandvikselv fish highly favored water from the related strain to that from the unfamiliar one (Figure 2C). Of 92 ascents recorded altogether, 61 were in favor of the familiar odor (AS = +32.6; $P = 0.0013$). For search, 806 of 1290 trials were in favor of the familiar odor (AS = +25.0), demonstrating that this result was also at a highly significant level ($P \ll 0.00003$).

Odorants in Excretion Products from Fish. Competition experiments with extracts from skin mucus of the Sandvikselv strain versus similar extracts of the Imsa strain are presented in Figure 3A. Fish from the Sandvikselv strain were used as test fish. In the middle of November 1982, fish from the Sandvikselv strain were found to discriminate between water extracts for the search parameter only. Of 70 ascents recorded, only 32 were in favor of the related strain (AS = −8.6; $P = 0.274$), whereas 470 of 880 searches were directed towards the familiar strain (AS = +6.8; $P = 0.023$).

In the middle of June 1983, however, no significant preferences for either strain was found in competition experiments with water extracts from skin mucus (Figure 3A). Fish from the Imsa strain were used as test fish this time. Sixty-one ascents from a total of 128 were in favor of the related strain (AS = +4.7; $P = 0.33$), and 258 of 514 searches were similarly directed (AS = +0.4; $P = 0.484$).

Ethanol extracts from skin mucus of the two strains mentioned above, tested in July 1983 with the Sandvikselv strain as test fish, elicited neither of the preference behaviors (Figure 3A). Only 33 ascents were registered in total, of which 15 were in favor of the material from the related strain (AS = −9.1; $P = 0.36$). Of 199 searches, 96 were in favor of the related strain (AS = −3.5; $P = 0.334$).

Experiments with extracts from intestinal contents are presented in Figure

3B. When water extracts from intestinal material were run in the middle of November 1982 with fish from the Sandvikselv strain as test fish, no preference behavior was detected (Figure 3B). Seventy-seven ascents were recorded; 35 of them were in favor of the related strain (AS = −9.1; P = 0.248). Of 963 searches, 464 were in favor of the related strain (AS = −3.6; P = 0.138).

When tested in June 1983, however, an ability among the Sandvikselv parr for intraspecific discrimination of water extracts from intestinal material was revealed (Figure 3B). Although a significant level was not found among ascents, 28 of 45 trials were in favor of the familiar odor (AS = +24.4; P = 0.068). For the search parameter, 124 of 205 trials were in favor of the related strain, revealing a highly significant level of preference (AS = +21.0; P = 0.0017).

Ethanol extracts from intestinal contents also elicited preference behavior of the Imsa fish towards material from the familiar strain (Figure 3B). Twenty-eight ascents of 42 were found in favor of the familiar strain, giving a significant level of preference (AS = +33.3; P = 0.022). For the search parameter, however, a repellent effect from the familiar strain was found. Of 1460 trials, only 633 were directed towards the native material, revealing a highly significant repellent effect (AS = −13.3; $P \ll 0.00003$).

Origin of Odorants. Results from competition experiments using bile from two genetic strains of parr are presented in Figure 4A. Fish from the Sandvikselv strain were used as test fish. Very few ascents were recorded during the experimental period which took place in June 1983. Only 28 trials were registered in total, and 16 were in favor of the extracted material from the familiar strain (AS = +14.3; P = 0.284). For search, however, 254 trials were recorded, of which 142 were directed towards the familiar material (AS = +11.8; P = 0.034). This result suggests that the strain-specific substances demonstrated in tank water and intestinal contents of fish may originate from the liver.

Experiments with extracts from blood plasma elicited no preference behavior of the fish from the Imsa strain (Figure 4B). Only 14 ascents were recorded in total in June 1983, with four in favor of the familiar strain (AS = −42.9; P = 0.092); 355 searches of 680 were directed in a similar manner (AS = +4.4; P = 0.134). This suggests that the attractant material found in the bile is secreted through the intestinal tract and not transported in the blood to be secreted elsewhere.

The Imsa parr demonstrated preference behavior when extracts from gravel were tested in June 1983 (Figure 4C). Of 892 searches recorded, 487 were in favor of the extract from gravel kept below their strain (AS = +3.2; P = 0.0034). For ascents, 49 of 95 trials were in favor of the gravel extract from the tank containing familiar fish (AS = +9.2; P = 0.417). Since the gravel used in the tanks originated from the same source, the results suggest that each strain of fish is able to mark the substrate of its living environment.

Activity of Fish. All experiments presented in this paper were performed within the relatively narrow temperature range of 7.3–9.3°C (Table 1). Activity of the fish, however, as shown by the data, appears to be independent of temperature. This suggests that variations obtained in activity of the fish must be related to parameters other than temperature.

When tank waters were used, the activity per hour of ascents ranged from 7.7 to 15.3, and for search from 107.5 to 166.6 (Table 1). Activity was found to be at the highest level when water containing an unfamiliar strain of fish was used. When waters from tanks containing fish were introduced to both entrances in competition tests, the activity was found to be at the lowest level. Regardless of the test type performed with tank waters, the ascents-to-search ratio remained relatively stable.

In tests with water extracts from skin mucus and intestinal contents (Table 1) a higher activity in search seems to have been present in November than in June. In general, test samples made from extracts also resulted in a lower activity than tank waters in the tests. For skin mucus, tests with ethanol extracts appear to have reduced the overall activity compared to tests with water extracts, whereas similar extraction from intestinal contents apparently had the opposite effect. Ethanol extracts from bile and blood plasma (Table 1) induced a very low activity in ascents, while search did not deviate apparently from that found for other organic solvent extracts. For gravel extracts, the fish demonstrated a behavior that did not deviate from normal activity.

DISCUSSION

The data presented in this paper reveal that Atlantic salmon parr demonstrate preference behavior towards, and are attracted to, water conditioned by conspecifics. In competition experiments they favor water conditioned by their

related strain to that conditioned by another genetic strain of their species. The findings reveal that salmon parr secrete substances specific for their strain and that they are able to discriminate between these chemical cues.

The secretion of signal substances seems restricted to the gastrointestinal tract and appears to originate from the liver, the largest "chemical factory" in the vertebrate body. Evidence has also been provided for substrate marking by salmonid fishes, presumably mediated by deposition of fecal material. In the following sections, the behavior towards chemical signals will be considered, together with aspects of physiology and ecology related to the ability of strain discrimination and substrate marking in salmonid fishes.

Determination of Chemically Mediated Rheotaxis. Fish denied olfaction demonstrate a preference for directing the body towards water currents (Høglund and Åstrand, 1973), i.e., positive rheotaxis is maintained in the absence of olfactory cues. In blind tests related to preference experiments, fish will also move upstream in the absence of any known chemical stimulus (Selset and Døving, 1980; Stabell, 1982). It is therefore difficult to give a direct measure for attractive responses due to chemical stimuli in the determination of fish behavior. The problem has been solved indirectly in behavior experiments by comparing the rate of activity of the fish to stimulants added simultaneously. In the current study, it has been possible to separate the behavior towards chemical stimuli into two events by using a double set of photocells in each tube (Figure 1B).

When held under abnormal and crowded conditions, it has previously been demonstrated that salmon parr secrete substances to which their relatives demonstrate an avoidance response when given an alternative and unscented choice of water (Stabell, 1982). Furthermore, confronted with a choice of odors from two stressed groups of fish, the parr demonstrated a preference for chemical cues secreted by their related strain. Both search and ascents were found within significant statistical levels of preference in the report mentioned, even when "repellent" substances were present in the samples tested. Tests with sample extracts in the current study, however, apparently produced a shift in preference behavior towards the search parameter. When organic solvents were used for sample extractions, ascents were found to work only once as a functional parameter in the tests. The shift in preference behavior was also found to coincide with a general decrease in activity when sample extracts were used, the decrease being greatest after treatment with organic solvents, while the ratio of ascents to search was not found to be systematically affected. A decrease in attractive responses in mature char, probably similar to the one obtained here, was also reported by Selset and Døvig (1980) when test samples had been treated by chemical means. Therefore, the extraction procedure rather than the presence of repellents seems responsible for the decrease in activity and the shift in preference behavior found in this study.

All pretreated samples in the present study were dissolved in small quantities of water before testing. In order to function as substrate markers, as will be discussed in a subsequent section, water solubility of the topical signal substances must be expected to be very low. The small volumes of water used for extraction of the active material may, therefore, have been a determining factor for the observed shift in behavior because of the low concentrations of the applied stimulus. Additional "trapping" of active compounds within precipitated material when organic solvents were used for extraction may possibly explain the special behavioral effects found following such treatment. Accordingly, both ascents and search must be viewed as parameters suitable for detecting preference behavior. While the ascent parameter is probably that which most strongly expresses attractive properties, it is suggested that search may work alone as a functional parameter in determination of chemically mediated rheotaxis when dealing with low stimulus concentrations.

Production and Secretion of Odorants. Preference tests with tank waters, each containing a separate genetic group of salmon parr, demonstrate that the fish secrete odorants specific for their strain. The observation that salmonid juveniles secrete intraspecific pheromones supports the results from several earlier reports in the field (Nordeng, 1971, 1977; Selset and Døving, 1980; Quinn and Busack, 1985; Quinn and Tolson, 1986; Olsén, 1985, 1986). Skin mucus was initially suggested to be the source of salmonid pheromones (reviewed by Stabell, 1984), but the origin of the attractive chemical components was questioned by Stabell and Selset (1980) because of a demonstrated contamination by intestinal juices of mucus collected in the customary way. Selset and Døving (1980), who found no behavioral response in mature Arctic char to "pure" skin mucus, also questioned skin mucus as a source for salmonid pheromones.

In the current study, ascents were never found below the 5% probability level in tests with water extracts from skin mucus. As for the search parameter, on one occasion only, in late autumn, an intraspecific preference for skin mucus was obtained. Since intestinal contents gave no behavioral responses at that time of the year, the result is difficult to interpret. Comparative physiologic indicators for presence of attractive substances in vertebrate skin mucus are, however, given in the literature. In female garter snakes (*Thamnophis sirtalis parietalis*), blood plasma has been shown to contain pheromones arousing sexual behavior in males (Garstka and Crews, 1981). As in this study, the pheromones from the mentioned reptiles are produced in the liver but are transported in the blood and secreted by mucus glands present between the surface scales. Extracts from blood plasma in the current study, however, revealed no preference or attractant properties. If mucus cells in salmonid fishes secrete attractant substances, the production must consequently be suggested to take place within the same cells. Possible attractant properties of skin mucus in salmonid fishes obviously await further investigation. Altogether, however, the data reported here appear to sup-

port the preliminary conclusion that the topical signal substances do not originate from skin mucus.

Tests with water extracts from intestinal contents of different salmon strains presented here demonstrate that the fish are able to discriminate among various compounds found in the gastrointestinal tract. The observed variation in odorants secreted cannot be attributed to food ingested, since the different strains of fish were fed by food pellets of common origin. Secretion of intraspecific pheromones through the intestinal tract by juvenile Atlantic salmon is in accordance with earlier observations with Arctic char (Selset and Døving, 1980). The experiments performed with ethanol extracts from intestinal contents in the present study were found to result in a significant preference level for ascents, while repellent effects were obtained for the search parameter. This was the only time during the study that contrary results were found for the parameters used, and an interpretation would therefore appear futile. Ethanol extracts from the bile, however, gave significant preference levels in search towards the familiar strain, supporting the conclusion by Selset (1980) that salmonid pheromones may originate from the liver and could be of a steroid nature.

Substrate Marking and Regional Stability. Atlantic salmon parr apparently mark their living environment with scents of an intraspecific nature, as demonstrated in this study. The odorants in question are most probably secreted within fecal material and may be deposited passively on the substrate by the bottom-dwelling parr. The chemical compounds representing the specific odors have been demonstrated to withstand dried-up conditions for at least a period of time, but they must also hold properties of low solubility due to the continuous flow of water in natural environments. Since the holding tanks in the current study were continuously exposed to flowing water, and the gravel washed by water before drying, a low solubility of the compounds in question seems to have been confirmed.

It has been suggested by some authors that salmonid fishes may leave residual scent on the spawning site long enough to secure homing by returning migrants (Larkin, 1975; Kristiansen, 1980; Selset, 1980; reviewed by Stabell, 1984). Foster (1985) also demonstrated in tank experiments that lake trout (*Salvelinus namaycush*) would preferently spawn on artificial reefs scented with material taken from eggs and excretion products of young fish. It would seem unlikely, from the point of view of energy costs, that juvenile fish have developed several parallel systems of pheromone production. The above reports, therefore, together with the data presented here, strongly indicate a common chemical basis for regional stability in juveniles and the mechanisms underlying homing of adult migrants to specific spawning grounds.

Ecological Aspects of Olfactory Recognition. Intraspecific recognition among juvenile siblings of Atlantic salmon, originating from different river strains, was demonstrated by Stabell (1982). It was suggested that the events

observed among the parr were based on the same mechanisms of recognition as the one attracting mature migrants to the spawning grounds. Quinn and Busack (1985) also demonstrated an ability among juvenile coho salmon (*O. kisutch*) to recognize and prefer chemical cues secreted by siblings. They suggested that the most obvious adaptive values of kin recognition were to encourage schooling and thereby improve predator avoidance. Facilitated inbreeding avoidance among adults was also suggested as a possible resulting effect. The conclusions reached by Quinn and Busack (1985), however, appear to contradict the events generally observed in nature, since bottom-dwelling, territorial behavior in juvenile stream-living salmonids, together with specific return to native spawning grounds by adult maturing fish, are well documented phenomena. In the current study, fish other than pure sibling groups were used, indicating that strain recognition may work on additional levels to that of siblings and suggesting that a hierarchic order of chemical recognition may be at work within discrete populations of salmonids.

The fish in this study were able to discriminate between intestinal water extracts in June but not in the middle of November. This finding may result from a late autumn decline of the behavioral response, the olfactory sensitivity, or the secretory activity of the fishes. Since, however, high behavioral activities were still recorded in November, and olfactory sensitivity in electrophysiological recordings have been found present also during the winter (G. Thommesen, Department of General Physiology, University of Oslo, personal communication), it is suggested that the results are due to a decline or absence of pheromone secretion outside the migrating season.

Selset and Døving (1980) reported an ability of mature Arctic char to discriminate between conspecific odorants secreted within the intestinal contents of juvenile fish. The present study reveals that juvenile salmonids also have the ability to discriminate between conspecific odorants of intestinal origin from juveniles. An olfactory-dependent intraspecific recognition in young fish, together with substrate marking in the "home" area by juveniles, thus extends the view of the functional role of pheromones in the ecology of salmonid migration.

Acknowledgments—The experimental fish were kindly donated by the Directorate for Wildlife and Freshwater Fish. In particular, I am grateful to Jon G. Backer, Research Station for Freshwater Fish at Ims, for his professional help regarding packing and transport. I am also indebted to Øystein Aasen, University of Oslo, for performing the electronic modifications necessary for interfacing the peripheral equipment with the microcomputer used in the study. Hans Nordeng and Georg Thommesen, both University of Oslo, gave critical comments on earlier versions of this manuscript; and Karen Mackenzie, University of Oslo, performed the necessary English corrections. I want to thank them all. This study was supported by The Norwegian Fisheries Research Council.

DIET MANIPULATION AFFECTS SOCIAL BEHAVIOR OF CATFISH:
Importance of Body Odor

BRUCE P. BRYANT[1] and JELLE ATEMA

Boston University Marine Program
Marine Biological Laboratory
Woods Hole, Massachusetts 02543

(Received July 17, 1986; accepted October 6, 1986)

Abstract—Diet manipulation, an habituation test, and chemical analysis of urinary free amino acids were used to demonstrate that bullhead catfish (*Ictalurus nebulosus*) naturally detect the body odors of conspecifics and respond to them in a predictable fashion. These signals are used in dominance and territorial relationships and lead to increased aggression toward chemical "strangers." The results support the general notion that nonspecific metabolites, as well as specific pheromones, are important in chemical mediation of social behavior.

Key Words—Pheromones, body odors, catfish, diet, *Ictalurus nebulosus*, social behavior, amino acids, urine.

INTRODUCTION

Body odor is the sum of all perceivable compounds in excreta and secreta. Pheromones represent a specialized portion of this odor complex and play an important role in the formation and maintenance of many vertebrate social relationships (Müller-Schwarze, 1974; Doty, 1976). They represent the social chemical "sign stimuli" (Tinbergen, 1951; Brown, 1975) which tend to be of discrete chemical composition and are usually associated with stereotyped physiological or behavioral responses (Wilson and Bossert, 1963; Wilson, 1975). These latter responses are generally thought not to be dependent upon learning. Commonly, pheromone synthesis is glandular and release is under voluntary control (Albone, 1984; Liley, 1982). Body odors, on the other hand, are typi-

cally chemically complex (Müller-Schwarze, 1969; Beruter et al., 1973; Evans et al., 1978; Preti et al., 1977) and consist of general metabolic waste-products rather than specifically synthesized compounds. It has been suggested that at least in mammals, chemical complexity in social stimuli may be common (Beauchamp et al., 1976). In addition, these types of stimuli tend to be used in behavioral contexts which allow or depend upon considerable plasticity or variation in response (Beauchamp et al., 1976).

In fish, a role for social chemical stimuli has been demonstrated primarily in behavior leading to spawning (Liley, 1982). These chemical stimuli function as sex- or species-specific attractants (Keenleyside, 1955; Kendle, 1968; Gandolfi, 1969; Mainardi and Rossi, 1968; Newcombe and Hartman, 1973; Chen and Martinich, 1975; Ingersoll and Lee, 1980; Teeter, 1980) or as indicators of reproductive status (Tavolga, 1956; Partridge et al., 1976; Crow and Liley, 1979; Honda, 1979, 1980a, Ingersoll and Lee, 1980; Crapon de Carpona, 1980). In addition, population-specific odors are implicated in home stream recognition (Selset and Døving, 1980). Equally important and less well studied are those chemical stimuli associated with pair-bonding (MacGintie, 1939) or dominance and territorial behavior (Todd, 1968; Todd et al., 1967). MacGintie (1939) demonstrated that mated blind gobies (*Typhlogobius californiensis*) chemically perceive gender, evicting nest intruders of the same sex. Similarly, in dominance and territorial behavior, the recognition of traits such as gender, individuality, or physiological or social status may also be mediated by chemical stimuli.

Todd et al. (1967) and Richards (1976), using sensory ablation (cautery) and behavioral conditioning methods, inferred that olfaction is important in the dominance and territorial behavior of several ictalurid catfish species. Their experiments, while demonstrating sensory capabilities, do not demonstrate which stimuli or biological traits the fish actually respond to during normal unconditioned behavior. In addition, sensory ablation can cause confounding effects by affecting aspects of behavior that are not normally mediated by the ablated sense, i.e., general motivation (Alberts, 1974). An attractive alternative to manipulation of the sensory system is to manipulate the stimulus and observe unconditioned responses to it. By altering a portion (chemical, visual, etc.) of a stimulus complex, it is possible to determine if and how that portion contributes to behavior.

We were interested in determining the importance of nonpheromonal metabolites in social behavior. To this end, we examined the chemosensory basis of bullhead catfish social behavior by changing the chemical output of one of a pair of socially interacting fish by diet manipulation. Behavioral observations indicated that changing the diet of one of the fish resulted in altered behavior of the other fish. That the observed change in behavior was due to chemical stimuli was supported by two lines of evidence. First, results from a behavioral bioassay based on habituation comparisons indicated that urine from donor fish,

a potential source of social stimuli in fish (Barnett, 1981; Richards, 1974) was perceived as different following a change in diet. Second, diet-related changes in urinary amino acids, which are known to be effective behavioral (Little, 1977, 1981; Atema, 1977; Holland and Teeter, 1981) and electrophysiological stimuli (Caprio, 1975, 1977; Suzuki and Tucker, 1971), suggested that amino acids may act as social chemical stimuli in catfish. Together, these results indicate that nonpheromonal chemical stimuli are important in the natural territorial and dominance behaviors of bullhead catfish.

METHODS AND MATERIALS

Animals. Brown bullheads, *Ictalurus nebulosus*, were caught in local (Cape Cod, Massachusetts) ponds and maintained in 680-liter tanks in groups of five to eight fish. The fish were held for one to four months before use, during which time they were fed Purina Trout Chow twice weekly. These fish were used in the two behavioral experiments and as urine donors.

Diet Manipulation. Pairs of males were kept in 680-liter (1.2 × 0.9 × 0.6-m) tanks for two to four weeks before behavioral observations began. The fish, matched to a weight difference of 20% or less, had been maintained on Purina Trout Chow for at least one month and were fed every three days before the experiment. Individual fish were identified by unique coloration patterns and fin and barbel morphology.

At the start of the experiment, most pairs of fish had established in the home tank either a territorial or dominance relationship in which the larger fish was dominant and/or held a larger territory. During the establishment of the relationship, the dominant fish frequently displayed at or nipped the subordinate fish. This aggressive behavior was not returned by the subordinate fish which avoided the dominant one. This resulted in restricted access by the subordinate fish to shelters and most areas of the tank.

In this experiment, the diet of the smaller fish was manipulated. After two days of preliminary behavioral observations, the smaller fish was transferred from the home tank to a 38-liter tank (Figure 1). Each fish was fed 2% of its body weight with trout chow. Thirty-six hours later, the smaller fish was returned to the home tank. This manipulation is referred to as the control (C) introduction. Observation of the pair was resumed. Two days later, the smaller fish was again removed and this time fed beef liver (2% body weight) while the resident fish received trout chow. Thirty-six hours later, the smaller fish was returned to the home tank. This is referred to as the experimental (E) introduction. To control for possible serial effects of reintroduction, two, rather than one, control introductions preceded the experimental introduction in seven experiments. Thus, experiments 1 to 6 (Table 1) are C followed by E introductions (C-E), while experiments 7 to 13 are denoted C-C-E.

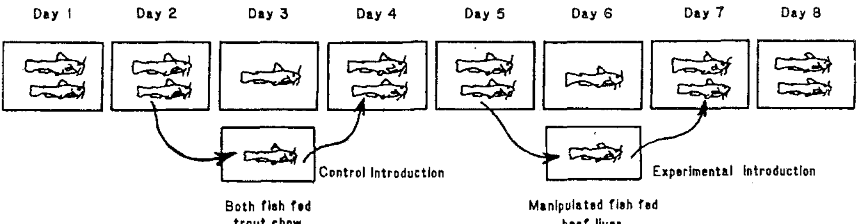

FIG. 1. Schedule of experiment. After two days of observation, the smaller fish was removed to a 38-liter tank and both fish were fed trout chow; 36 hr later the smaller fish was returned to the resident tank. This is a control introduction. Two days later the smaller fish is again removed and fed beef liver; the larger fish received trout chow. Thirty-six hours later, the smaller fish was returned to the resident tank. This is an experimental introduction. Behavioral observations were conducted in both the morning and the afternoon.

Data Collection and Analysis The location and behavior of each fish was recorded verbally on tape during observation periods of 30 min (daily morning and afternoon). Behavioral data consisted of a repertoire of discrete behavioral displays and acts modified after Todd (1968). For behaviors which lasted for more than a few seconds, only the onset was recorded. The location of each behavior was recorded by noting in which of eight areas in the tank it occurred. Activity of each individual was defined as the total number of behavioral acts regardless of type, occurring in an observation period.

Analysis of aggressive behavior and activity was based on frequencies of behavioral acts by the resident (dominant) fish during the introduction periods. Territorial behavior was analyzed by comparing the frequencies of territorial intrusions during the two observation periods preceding and following feeding. Aggressive behavior was considered to have changed between introductions only if there was either a change in the intensity of behaviors observed (e.g., "nips" escalating to "bites") or in the frequency of any aggressive act (chi-square, $P < 0.05$). Similarly, a change in the pattern of territorial behavior was registered if there was a significant change (Friedman Two-way ANOVA, $P < 0.05$) from one introduction to the next, in the frequency of intrusion by the resident fish.

Chemical Analysis of Urine. To demonstrate that the diet manipulation affected the chemical composition of urine, urine from male fish was collected and the free amino acid composition determined. Urine was obtained from chronically placed catheters which emptied into rubber sacs. Up to 15 ml of urine was collected every 24 hr from isolated fish which were fed either trout chow or beef liver. Urine samples were centrifuged at 1000 g for 15 min and stored at $-10°C$. Urinary free amino acids were determined either using a Beckman amino acid analyzer or as N-heptafluorobutryrl isobutyl esters by gas

chromatography (Pearce, 1977). In several cases, the catheter remained patent for eight days, allowing collection or urine samples corresponding to each day of the diet manipulation experiment (Figure 1). These cases included both trout-chow and beef-liver feedings.

Habituation Test. To demonstrate that urine was perceived as different following the dietary manipulation of a urine donor, urine samples taken before and after manipulation were compared using a habituation test. Urine samples were collected during the 24 hr after trout-chow and beef-liver feedings (corresponding to control and experimental introductions) using the method described above. Fifty-microliter aliquots of post-trout-chow urine (i.e., urine corresponding to "day 4" of the behavioral experiment) were introduced into the tanks of individually held male fish every 3–7 mins. This was continued until the swimming response returned to control (tank water) levels. To test the similarity of post-trout-chow urine and post-beef-liver urine, the response to 50 μl of post-beef-liver urine (corresponding to "day 7"), was then measured.

RESULTS

Diet Manipulation Experiment. Of the 13 pairs of fish observed, five pairs displayed intense aggressive behavior (actual biting and damage to one of the fish), five pairs were moderately aggressive (aggressive displays only), and three pairs were nonaggressive (Table 1). Of the 10 pairs displaying aggressive behavior, nine pairs established clear territorial and/or dominance relationships.

Since the particular set of behaviors displayed by each pair of fish varied considerably, direct comparison of specific behavioral acts across all pairs was impossible. However, for each pair, comparisons could be made of the frequencies of specific acts within the general classes of behavior (aggressive, territorial, or activity) occurring during successive introduction periods. These comparisons are shown in Table 1 and selected examples of the time course of several of the behaviors are illustrated in Figure 2. Eleven of the 13 pairs showed significant differences in at least one of the behavioral categories between control and experimental introductions (chi-square tests, $P < 0.05$). Of these, two pairs also showed significant differences between successive control introductions. For five pairs of fish, the intensity of resident aggression increased from post-trout-chow (C) to post-beef-liver (E) periods as indicated by a significant increase ($P < 0.05$, chi-square test) in either frequency of aggressive acts (dislays, nips, or bites) or escalation (displays and nips during the control period being replaced by bites and actual damage during the experimental introduction period). In addition, the activity of both the resident and manipulated fish increased significantly during the experimental period in five pairs. This was accompanied by increased "approach" behavior by the resident (pair 12) or an increase in the behavior "fast swim" for both fish (pairs 4 and 7). Significant

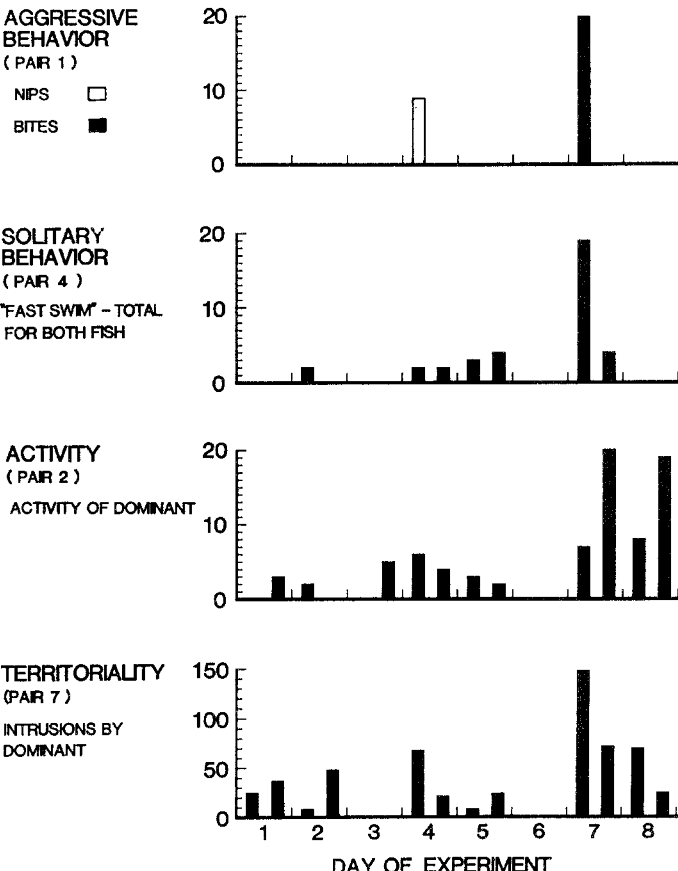

FIG. 2. Frequencies of selected behaviors observed during the course of the experiment. Behavioral observations were conducted in the morning and afternoon. Fish were fed on days 3 and 6. The smaller fish was reintroduced into the resident tank on day 4 following trout-chow feeding (control introduction) and on day 7 following beef-liver feeding (experimental introduction).

decreases in activity of the resident fish occurred in two pairs, one of which (pair 5) was a complete cessation of behavior, both social and solitary, during only the experimental introduction period.

In four instances during or following the experimental introduction period, the manipulated fish lost territory as measured by the number of intrusions, either aggressive or not, by the resident fish. In no cases did the resident fish lose territory or did the size of the smaller fish's territory increase. In those experiments in which a control introduction was followed by another control

introduction, an increase in aggressive behavior during the second introduction occurred twice (pairs 12 and 13).

Other than the loss of territory and changes in activity, no significant changes in the frequency of any specific behaviors of the smaller fish were detected.

To summarize, a comparison of experiments 1 through 6 (C followed by E introductions) with experiments 7 through 13 (C followed by C introductions) (Table 1), indicates that an effect of diet manipulation, regardless of the type of effect observed, is associated with the E introduction (Fisher exact probability test, $P < 0.02$).

Urine Chemistry. Analysis of urinary free amino acids (UFAA) indicated that concentrations of most UFAA increased following feeding. Both beef-liver (Figure 3) and trout-chow meals cause a net increase in amino acid excretion. The relative amino acid composition of urine, when each amino acid was expressed as moles per 100 moles of total FAA, was also affected by feeding. This is summarized in Table 2. Although there appeared to be no diet-related pattern of change which was common to all fish, individual fish did exhibit diet-

[a] Changes in mole percentage of each amino acid are registered if the change from the prefeeding urine sample to the postfeeding urine sample is greater than a twofold increase or decrease. + or − indicates the sign of the change.

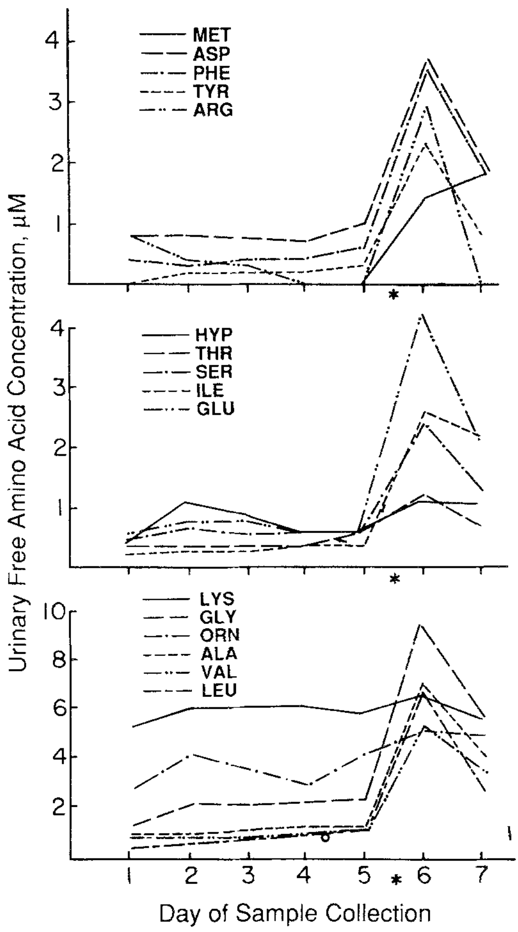

FIG. 3. Effect of feeding on urinary free amino acid (UFAA) concentration. Urine was collected from isolated fish and amino acids determined as described in Methods and Materials. The fish were fed beef liver (2% body weight) after the urine collection on day 5. Asterisk indicates the feeding.

related changes in UFAA. A selected example is shown in Figure 4. Although several amino acids varied randomly (not shown), many showed changes in composition which were directly related to feeding. The mole percentage of several amino acids increased after both types of feedings (isoleucine, serine and histidine), while others (alamine, valine, leucine, and tyrosine increased only after beef liver feedings. Because dietary amino acids affect plasma amino acid levels in carp (Kaushik and Luquet, 1979) and trout (Nose, 1972), the difference in amino acid composition between trout chow (higher L-glutamine

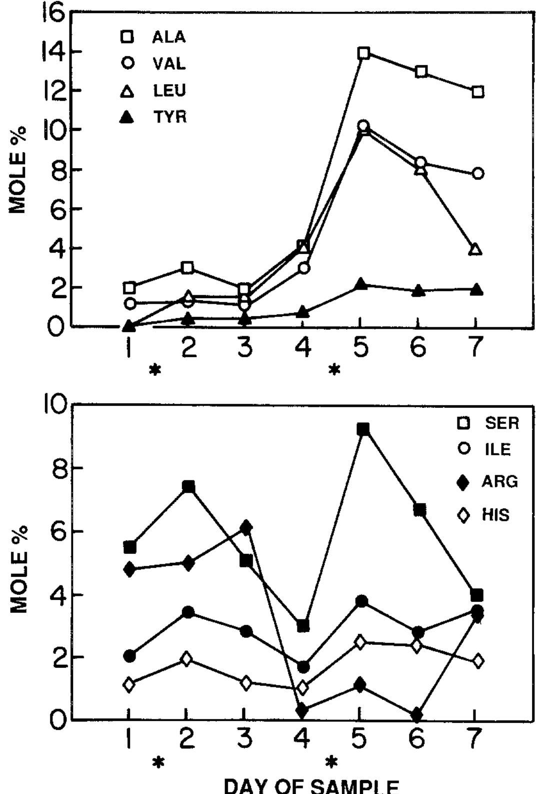

FIG. 4. Effect of trout chow and beef liver meals on urine composition. Urine was collected from isolated fish and amino acids determined as described in Methods and Materials. The fish were fed trout chow (2% body weight) on day 1 following urine collection and beef liver (2% body weight) on day 4 following urine collection. Asterisks indicate meals.

+ L-glutamatic acid and L-proline) and beef liver (higher L-methionine and L-aspartic acid) (Table 3) might be expected to be directly reflected in the UFAA composition following feeding. However, these amino acids did not increase differentially following each type of feeding.

Comparison of Urines by Habituation Test. Individual fish responded to the introduction of post-trout-chow urine by moving from a resting position and swimming around in the tank. Depending on the individual, between 14 to 33 introductions of post-trout-chow urine were required to habituate the swimming response. During the last 13 introductions of post-trout-chow urine, the mean duration ($\pm$SE) of the swimming response decreased from 69 ($\pm$16) sec to 5 ($\pm$4) sec (Figure 5). The subsequent introduction of post-beef-liver urine caused

[a] Samples of food were hydrolyzed in 6 N HCl, 110°C, 18 hr, and amino acids were determined as described in Methods and Materials. The values represent the mean of two determinations. Asterisks indicate amino acids in which there is at least a 50% difference between the two foods.

a significant increase ($P < 0.05$) in the mean duration ($\pm$SE) of the swimming response to 75 $\pm$ 16 sec.

DISCUSSION

This study demonstrates that a change in the diet of one of a pair of socially interacting catfish results in changes in the behavior of the other fish. Because these social interactions are sensitive to a relatively minor manipulation, such as a change in diet, these results provide support for the hypothesis that the stimuli used during dominance and territorial behavior are not specialized pheromones.

The social relationships which develop within different pairs of fish are not identical. Therefore, responses to experimental manipulation can take different forms. Indeed, the particular type of change in behavior that occurred varied from pair to pair but can be categorized as being either increased aggression on the part of the resident fish or else a change in activity, possibly searching behavior, of the resident fish. The aggression observed during the control introductions shows that a one-day separation (Figure 2) causes an increase in

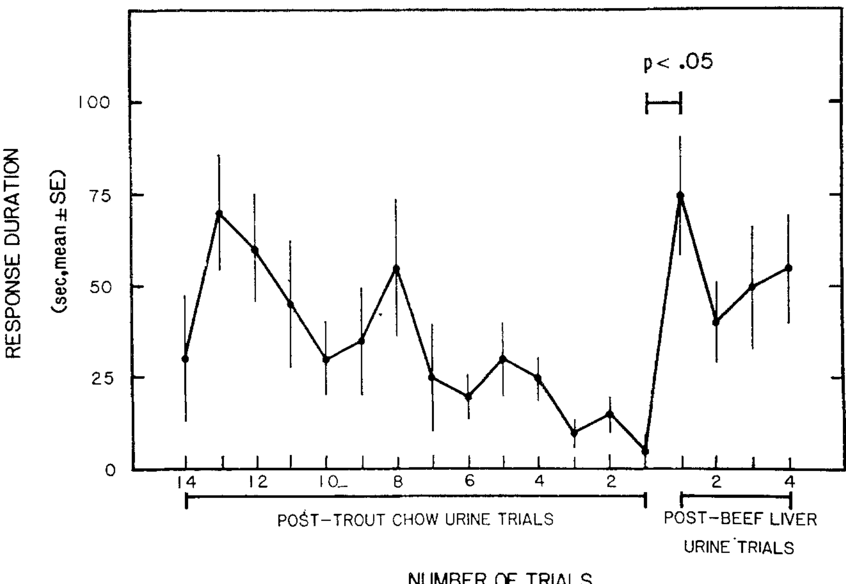

FIG. 5. Behavioral comparison of urines collected before and after diet manipulation. Individual fish were tested for their response to repeated introductions into their tanks of conspecific urine collected after donors had fed on Purina Trout Chow. After the responses had waned to that of control introduction (tank water), aliquots of urine collected after a beef-liver feeding were introduced and the response observed.

activity or aggressive behavior in some resident fish. A similar effect of separation has been demonstrated in such territorial and visually dominated fish as sticklebacks (Iersel, 1958) and cichlids (Peeke et al., 1971) and is interpreted to be the loss of recognition of previously familiar territory holders. In catfish, such territorial responses are transient and differ from those observed when the effect of separation is compounded with diet manipulation. The more intense territorial response following diet manipulation suggests that some of the cues serving territorial recognition have changed and that the manipulated fish is perhaps no longer recognized as the same fish.

Urine stimuli taken before and after diet manipulation were shown to be different using both chemical analysis and behavioral assay. Consequently, the simplest hypothesis is that diet manipulation changes the chemical output of the manipulated fish and thus its chemical identity. This change in identity disrupts a previously stable dominance or territorial relationship which is normally maintained by continuing chemosensory familiarity. Because the observed effects on behavior were specific to the beef-liver feeding, the fish may not have been responding only to quanititative changes in chemical output associated with

feeding on any diet, such as the observed increase in amino acid excretion. Since the fish were maintained on trout chow, they had already experienced the type of change in chemical output associated with trout-chow feeding and presumably had habituated to such changes. Instead, the fish may be responding either to the presence of specific compounds in the new body odor or to relative changes in an overall body odor complex caused by the beef-liver feeding.

A more complex hypothesis is that behavioral rather than chemical cues from the fish whose diet was manipulated caused the increase in resident aggression or activity. A change in diet might affect the behavior of the subordinate either directly, by affecting neurotransmitter levels (Lajtha et al., 1963), or indirectly, through a perceived difference in its own odor. While it is not possible to rule out the possibility of behavioral cues, there are some data which favor the simpler hypothesis: behavioral acts (territorial intrusions and sudden flight movements) by the subordinate which are known to induce attack by a dominant (Todd, 1968; Atema and Labeyrie, unpublished) occurred infrequently and did not increase after the diet manipulation.

Amino acids are good candidates as nonspecific social signals in catfish. Importantly, they are present in urine at concentrations that are suprathreshold using both behavioral (Atema, 1977; Holland and Teeter, 1981; Little, 1977) and electrophysiological (Caprio, 1975, 1977) criteria. Because there were changes in amino acid composition which are specific to beef-liver feeding, it is possible that specific amino acids contribute to the perceived chemical difference following diet manipulation. The possibility remains, however, that other compounds specific to beef liver were responsible for both the chemical and the perceived differences in body odor and the concomitant changes in behavior.

As in other vertebrates, fish territorial behavior is based on recognition of neighboring territory holders (Keenleyside, 1979). Such recognition allows for the discrimination between familiar neighbors and strangers, thereby reducing aggression between neighboring territory holders. Strange catfish are attacked by resident dominant fish in aquaria (Todd, 1968) and by nest holders in the field (Blumer, 1982). In these cases, the fish are discriminating resident from nonresident and mate from all other conspecifics, respectively. The results of the present study, together with these examples, are also consistent with the hypothesis that the fish are responding to chemically unfamiliar cues rather than specific aggressive stimuli. Social recognition in catfish may thus be based in large part on chemosensory habituation to tank- or nestmates. As is observed in visually mediated aggressive responses in sunfish (Colgan et al., 1977), aggression or searching behaviors in catfish may result when other, chemically different conspecific stimuli appear. Similarly, the unconditioned preference of a fish for its own odor (Richards, 1976) may result from habituation to one's own odor along with avoidance of strange conspecific odor.

Experimental changes in diet have been demonstrated to have an effect on social investigating behavior (Beauchamp, 1976) and on material odor imprinting (Galef, 1981; Porter, 1977; Leon, 1975). Although it is doubtful that natural changes in maternal diet would perturb maternal recognition in any animal, daily variation in diet may make individual recognition based on diet impossible except for those species that are specialist feeders. Chemosensory recognition of traits other than individuality may be influenced less by such daily variation. It is well known, for example, that catfish of different sizes eat different diets (Raney and Webster, 1940; Moore, 1972; Imamura, 1975; Keast, 1985). Because of this and size-related differences in metabolism (Gerking, 1955), size-related odors may be produced that are based in part on diet. In catfish aggressive encounters, size is an important determinant of the outcome (Bryant and Atema, unpublished). While visual and mechanical stimuli are more likely to be used by fish to determine size at close range (Partridge and Pitcher, 1980; Dijkgraaf, 1963), odor could be a useful indicator of size at greater distances, particularly in turbid water. Thus, size-related odors may be used during the establishment and maintenance of territories.

These experiments demonstrate that general body odor, as well as specific pheromone signals, must be considered important in the regulation of social behavior. Indeed, it is possible, perhaps likely, that many so-called pheromones in vertebrates will turn out to be rather nonspecific metabolites, exerting their influence by virtue of chemical habituation and familiarity.

PLANT-DERIVED SYNERGISTS OF ALARM PHEROMONE FROM TURNIP APHID, *Lipaphis (Hyadaphis) erysimi* (HOMOPTERA, APHIDIDAE)

G.W. DAWSON, D.C. GRIFFITHS, J.A. PICKETT, L.J. WADHAMS, and CHRISTINE M. WOODCOCK

Harpenden, Herts., AL5 2JQ, U.K.

(Received June 16, 1986; accepted October 8, 1986)

Abstract—The turnip aphid, *Lipaphis (Hyadaphis) erysimi*, responds weakly to (E)-β-farnesene, the main component of the alarm pheromone, but the response is substantially increased by incorporating plant-derived isothiocyanates, identified in aphid volatiles by coupled gas chromatography–single-cell recording.

Key Words—Aphid, pheromone, alarm pheromone, plant components, electrophysiology, single-cell recording, isothiocyanate, *Lipaphis erysimi*, *Hyadaphis erysimi*, Homoptera, Aphididae, (E)-β-farnesene.

INTRODUCTION

The turnip aphid, *Lipaphis (Hyadaphis) erysimi*, has been reported to respond well to its own alarm pheromone but not to the pheromones from a series of other aphids, even though these responded well to pheromones from each other (Nault and Bowers, 1974). Pheromone from these aphids, including *L. erysimi*, contained the sesquiterpene (E)-β-farnesene (I, Figure 1). This compound elicited a high response for each aphid except *L. erysimi*. It was proposed that the alarm pheromone from *L. erysimi* contained other components, and the presence of another sesquiterpene was suggested (Nault and Montgomery, 1979; Nault and Phelan, 1984). The objective of the present study was to identify the compounds necessary for full alarm response by *L. erysimi*.

FIG. 1. Structures of (*E*)-*β*-farnesene (EBF) (I), 4-pentenyl cyanide (II), allyl isothiocyanate (III), 2-butyl isothiocyanate (IV), 3-butenyl isothiocyanate (V), 4-pentenyl isothiocyanate (VI), and 2-phenylethyl isothiocyanate (VII).

METHODS AND MATERIALS

Compounds. Farnesene, prepared by the method of Dawson et al. (1982) containing 40% of the active isomer, (*E*)-*β*-farnesene (EBF), was employed at a concentration of 4 μg/ml EBF in ether, or 1 μg/ml in water, and stored in glass ampoules under N_2. 4-Pentenyl cyanide (II), allyl isothiocyanate (III), 2-butyl isothiocyanate (IV), 3-butenyl isothiocyanate (V), 4-pentenyl isothiocyanate (VI), and 2-phenylethyl isothiocyanate (VII) were obtained commercially or synthesized by conventional methods. When tested in behavioral bioassays, the concentrations of these compounds were 0.2 μg/ml in ether or 1 mg/ml in water.

Insects. Lipaphis (Hyadaphis) erysimi (Kaltenbach), obtained on shepherd's purse [*Capsella bursa-pastoris* (L.) Medic.] in Hertfordshire in 1981, were maintained on turnip (*Brassica campestris* var. *rapifera* Metz.) unless otherwise stated, at 16 hr daylength and 20 ± 5°C.

Isolation of Volatiles. L. erysimi were extracted with ether and the extract dried and concentrated down from a fivefold dilution to give a solution equivalent to 1 g aphids/ml ethereal extract. The extract was then vacuum distilled as described previously (Pickett and Griffiths, 1980).

Aerial parts of turnip, Chinese cabbage [*Brassica campestris* var. *chinensis* (L.) Makino], and shepherd's purse, grown under glass, were cooled under N_2, broken up finely, covered, and allowed to stand for 85 min so that conversion of glucosinolates to volatile metabolites could take place. The volatiles were then isolated by condensation as described previously (Pickett and Stephenson, 1980) and the condensate extracted into ether to give a concentration equivalent to 20 g of plant material/ml ethereal extract. Solutions were sealed in glass ampoules under N_2 and stored at −20°C.

Bioassays. Colonies of third- to fourth-instar *L. erysimi* were established on leaves of Chinese cabbage by confining adults in clip cages on the plants for

three days. The adults were then removed and the young allowed to develop for a further two to three days before testing. Single aphids were reared in a similar manner, excess nymphs being removed at the same time as the adults. Numbers of aphids responding by moving from their feeding sites were recorded 60 sec after application of the test material (colonies of 50–60 insects, five replicates; single aphids, ten replicates).

Test materials were either air (20 ml) from above *L. erysimi* crushed in a glass syringe (20 aphids containing a total amount of ca. 1 ng EBF by GC), blown slowly (ca. 10 sec) from the syringe, or ethereal or aqueous solutions (0.2 μl) applied as a single droplet to the leaf on which the aphids were settled. Thus, EBF was applied at 0.8 ng in ether or 0.2 ng in water and the isothiocyanates at 0.04 ng in ether or 0.2 μg in water. Ethereal *L. erysimi* extract and volatiles (1 μl) were also applied as single droplets to leaves at ca 0.3 ng of EBF.

Gas Chromatography (GC). GC employed fused SiO_2 columns, 24 m $\times$ 0.3 mm, with a bonded OV-101 stationary phase at 30°C (2 min), 20°/min to 100°C, 6°/min to 200°C. Confirmation of identity was by coinjection with authentic compounds.

Gas Chromatography-Mass Spectrometry (GC-MS). Ionization was by electron impact at 70 eV, 200°C, with the GC capillary column directly coupled to the source of an MM 70-70F mass spectrometer and the integrated data system 2025 (VG Analytical, Altringcham, U.K.). Spectral enhancement by means of the data system was used to produce mass spectra for regions of the chromatogram associated with electrophysiological activity but where peaks in the total ion current were not clearly discernible. Tentative identification was by comparison with published spectra (Kjaer et al., 1963).

Electrophysiology. Recordings from the cells associated with the olfactory receptors on the primary rhinaria of *L. erysimi* alates were made using tungsten microelectrodes (Boeckh, 1962). The indifferent electrode was placed in the first antennal segment, and the recording electrode was then brought into contact with the multiporous plate of the rhinaria until impulses were recorded. Permanent copies of the action potentials generated by the receptor cells were obtained by standard methods (Wadhams et al., 1982).

Most recordings showed the presence of a number of cells since there are up to 14 olfactory cells in the rhinarium (Bromley et al., 1979). Only those recordings in which the responding cells could be readily distinguished were used in these experiments.

Stimulation. The stimulus (2 sec duration) was delivered into a purified airstream (800 ml/min) which flowed continuously over the preparation. The delivery system, employing a filter paper strip in a disposable Pasteur pipet cartridge, has been described previously (Wadhams et al., 1982). Compounds III–VI in pentane (10 μl) were applied to the filter paper and, after evaporation of solvent, were presented twice to each preparation at intervals of 2–15 min;

the exact interval was dependent upon the concentration of the previous stimulus. Impulse frequency was determined as the number of impulses elicited during the first 1 sec after stimulus initiation.

Gas Chromatography-Single-Cell Recording (GC-SCR). The coupled GC-SCR system has been described previously (Wadhams, 1982). After each experiment, records of the flame ionization detector response and of the action potential frequency were obtained by detecting the impulses with a level discriminator and plotting them by means of a voltage/frequency converter.

RESULTS AND DISCUSSION

Alarm pheromone released by crushing turnip aphids, *L. erysimi*, caused most aphids to move away from feeding sites (Table 1). The presence of EBF was confirmed by GC and GC-MS studies, but no other major terpenoid component was detected. However, synthetic EBF elicited only a weak response at a level comparable to the amount produced by the aphid. Ethereal extract of *L. erysimi* gave rise to a good response, and the activity was found to be largely in the volatile fraction obtained by vacuum distillation.

The alarm pheromone is thought to be perceived principally by the rhinaria on the fifth (proximal) and sixth (distal) antennal segments (Nault et al., 1973; Wohlers and Tjallingii, 1983), and Bromley and Anderson (1982) implicated the former in host-plant volatile reception. Although olfactory cells which responded strongly to EBF were found on the distal rhinarium, it was not possible to elicit a similar response from the receptors associated with the proximal rhinarium.

Cells on the proximal rhinarium responded strongly to *L. erysimi* volatiles. Coupled GC-SCR of the *L. erysimi* distillate revealed the presence of a number of active components which, with the exception of VIII, were perceived by one cell type A in this rhinarium (Figure 2). These compounds were identified by

GC and GC-MS as 4-pentenyl cyanide (II), allyl isothiocyanate (III), 2-butyl isothiocyanate (IV), 3-butenyl isothiocyanate (V), and 4-pentenyl isothiocyanate (VI) (Figure 1). 2-Phenylethyl isothiocyanate (VII), a major component of the extract, was inactive, and peak VIII, which was detected by cell type B, was not identified. Isothiocyanates are well-known components of cruciferous plants, including the turnip; they arise from enzymic decomposition of glucosinolate precursors (Ju et al., 1982) and were therefore considered likely to have arisen from the host plant.

To investigate further the activity of the newly identified compounds, the bioassay was modified to employ single aphids, thus avoiding release of isothiocyanates through leaf damage caused by large numbers of feeding aphids. Results (Table 2) again showed that the pheromone and the volatiles isolated from *L. erysimi* were more active than synthetic EBF alone. It was also demonstrated that the pheromone from *L. erysimi* bred on Chinese cabbage was equally active. 3-Butenyl isothiocyanate alone elicited only a weak response, but when it was applied together with EBF, all the test aphids responded. Allyl isothiocyanate and 2-butyl isothiocyanate gave a similar increase in the alarm response when applied in admixture with EBF. Dose–response data for these compounds were established using the electrophysiological bioassay and showed that, at the receptor level, allyl and 3-butenyl isothiocyanates were significantly more active than the 2-butyl and 4-pentenyl isothiocyanates (Figure 3). The

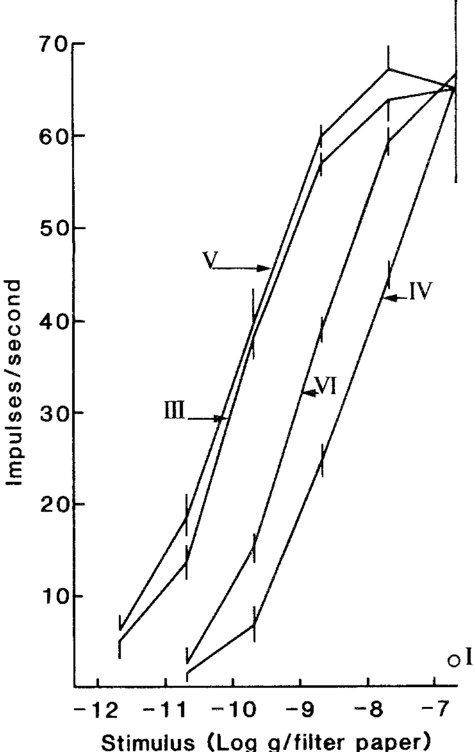

FIG. 3. Dose–response curves of *L. erysimi* olfactory cells to (*E*)-β-farnesene (I), allyl isothiocyanate (III), 2-butyl isothiocyanate (IV), 3-butenyl isothiocyanate (V), and 4-pentenyl isothiocyanate (VI). The cells were recorded from the primary rhinarium on the fifth antennal segment. Each point is the mean response (five preparations) ± SE. Where standard errors overlap only half the SE bar is shown.

olfactory receptor exhibits considerable selectivity towards these compounds: no response was observed to either EBF or the common leaf volatiles (*Z*)-3-hexenol, (*Z*)-3-hexenyl acetate, and linalol when tested at high stimulus concentrations (2×10^{-7} g per filter paper).

Although the volatiles obtained from turnip, Chinese cabbage, and the weed host of *L. erysimi* in the U.K., shepherd's purse, increased activity of EBF (Table 2), only the turnip volatiles contained relatively large amounts of 3-butenyl and 4-pentenyl isothiocyanates. However, the relative proportions of these compounds obtained from *L. erysimi* bred on Chinese cabbage were similar to those from *L. erysimi* bred on turnip. This suggested that *L. erysimi* plays an active role in the production of these compounds. Indeed, when sinigrin, the glucosinolate precursor of allyl isothiocyanate, was added to an homogenate of

L. erysimi, allyl isothiocyanate was released at 37% of the theoretical amount after 5 hr. It is interesting to note that while the glucosinolate, sinigrin, serves as a feeding deterrent for non-Cruciferae feeding aphids, it serves as a powerful phagostimulant for *L. erysimi* (Nault and Styer, 1972). Thus, the glucosinolates or their isothiocyanate products play a dual key role in the biology of this species.

When sinigrin was added to an homogenate of *Myzus persicae*, a closely related aphid also in the Aphididae, release of allyl isothiocyanate was negligible. Also, the isothiocyanates III, IV, and V did not significantly increase the response of this aphid to the alarm pheromone.

EBF can be used to improve the efficiency of contact pesticides and biological control agents against aphids (Pickett et al., 1986), but the response of aphids to aqueous formulations of EBF is very weak. Indeed, only special formulations containing hydrocarbon propellents, applied using electrostatic spraying systems, have so far given good results (Pickett et al., 1984). However, the readily available allyl isothiocyanate, when applied together with EBF in water, causes a good response from *L. erysimi* (Table 2). Further studies on such alarm pheromone synergists may lead to the use of aqueous formulations of EBF against other aphids in the field.

(Received May 15, 1986; accepted October 9, 1986)

Abstract—Previous studies demonstrated the existence of a waterborne pheromone secreted by receptive females of the amphipod crustacean *Microdeutopus gryllotalpa* which attracts males. The data were obtained by using a bioassay apparatus based on a two-choice test paradigm. The present study reports the results of additional tests employing this apparatus which have shed some light on the chemical nature of the pheromone. The bioactive substance was isolated from receptive female waters with anion exchange resin columns, but not with C-18 reverse-phase columns. This suggests that the substance is polar. Another finding of the present study was that effluents from the green alga *Ulva lactuca* inhibit males' responses to the pheromone.

Key Words—Pheromone, crustacean, amphipod, *Microdeutopus gryllotalpa*.

INTRODUCTION

The pheromones of numerous terrestrial arthropods have been chemically characterized (reviewed by Blomquist and Dillwith, 1983). However, although recent studies have demonstrated the existence of waterborne sex pheromones in many Crustacea (summarized by Dunham, 1986), the nature of crustacean pheromones has not been demonstrated for any species.

Until recently, the existence of pheromones in amphipod crustaceans was

0098-0331/87/0700-1673$05.00/0 © 1987 Plenum Publishing Corporation

disputed. For example, Dahl et al. (1970 a, b) reported that pheromones are produced by receptive female *Gammarus duebenii*, but Hartnoll and Smith (1980) could not confirm the former workers' behavioral observations. Dunham (1978) suggested that some confusion in the literature might be due to different workers' definitions of sex pheromones. He suggested that waterborne secretions should be considered sex pheromones if they serve one or more of the following distinct functions: (1) intersexual attraction; (2) stimuli for courtship; and/or (3) stimuli for mating.

With this in mind, the effects of receptive female secretions on male conspecifics' behavior was tested in two other amphipods (*Microdeutopus gryllotalpa* and *Gammarus palustris*, Borowsky, 1984, 1985, respectively), and each potential function of a pheromone was considered separately. It was learned that (1) pheromones do exist in the two species and (2) they attract males. However, subsequent work (Borowsky and Borowsky, 1985, and in preparation) showed that waterborne pheromones do not influence courtship or mating behavior after males have located females.

The effects of receptive female secretions as male attractants were demonstrated using Y-tube behavioral assay systems modified to mimic each species' habits. It was reasoned that the systems could facilitate the isolation and ultimate identification of the active substance(s). The present report presents the results of some experiments which employed the Y-tube apparatus to shed light on the general nature of the pheromone of *Microdeutopus gryllotalpa*.

METHODS AND MATERIALS

All animals were taken from the filter beds of the cold-water tanks of the New York Aquarium. They were supplied with *Ulva lactuca* thalli ad libitum for food and tube-building materials, and maintained in seawater of 29 ppt Cl^- taken from wells that supply the aquarium. All animals were maintained at 20°C. Females were maintained in individual 10-cm-diameter glass culture dishes and examined daily to determine the day they molted. Females six days past their molt were considered "receptive," and females two days past their molt were considered "nonreceptive" on the basis of previous studies (Borowsky, 1980). Males were isolated from females, and maintained communally in 20-cm-diameter glass culture dishes for one week until they were tested in the bioassay apparatus.

The bioassay apparatus is designed to mimic field conditions while testing animals' responses to waterborne substances in a standard two-choice paradigm (see Fig. 1). The apparatus is based on a glass Y-tube (Y). The base of the Y is connected to a 1-liter aspirator bottle (the departure bottle (DB) by Tygon tubing (7 mm ID), while each of the arms is similarly connected to two 2-liter aspirator bottles in series. The distal bottles (DAB) are elevated about 1 m

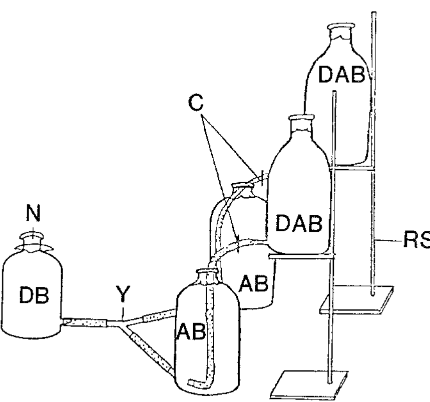

FIG. 1. Apparatus employed for testing *Microdeutopus gryllotalpa* males' responses to receptive females' secretions after the secretions were passed through columns containing different types of absorbents. Receptive females were placed in one of the distal aspirator bottles (DAB), and nonreceptive females in the other. Males were placed in the departure bottle (DB). Water was introduced into the distal aspirator bottles, passed through the absorbent columns (C), then entered the arrival bottles (AB), and finally entered the departure bottle. Males could leave the departure bottle, travel to the Y tube (Y), then pass freely to either arrival bottle. Censuses of the number of males in the arrival bottles and departure bottles at the end of each test indicated whether males responded to the receptive females' secretions after they were exposed to the absorbants. All Tygon tubing is stippled; N = nylon mesh netting, to prevent washing males out of the departure bottle RS = ring stand, to elevate distal aspirator bottles and establish a head of water to force secretions through the column. *C* = site of insertion of clamps (Experiments I and II) or absorbent columns (Experiments III and IV).

above the proximal, or arrival bottles (AB) on ring stands (RS). This establishes a pressure sufficient to force water through the columns containing the absorbents (placed at points C).

Thirty receptive females were placed in one of the distal aspirator bottles, and 30 nonreceptive females were placed in the other one. Fresh sea-water dripped into the tops of these bottles at the rate of 100 ml/hr each and continued out at the same rate through their spouts. Thus, water flowing out of these bottles had bathed the females. The water then passed through two 1-m lengths of tubing, which led into the spouts of the arrival bottles. The water flowed out of the arrival bottles' spouts through 8-cm lengths of tubing and continued into the arms of the Y-tube. A single 13-cm length of tubing carried the water from the base of the Y to the spout of the departure bottle. The water exited the system through the top of the departure bottle. To prevent individuals from

passing between the distal and arrival bottles, the ends of the connecting tubes were covered with nylon mesh netting, which did not impede the flow of water.

At the beginning of each test, the water was turned off, and the current halted. Then 15 males were placed in the departure bottle, and its mouth was capped with nylon mesh netting (N) to prevent males from leaving the apparatus. Each test was begun by starting the flow of water through the system. During a test, males could pass freely among the two arrival bottles and the departure bottle. Each test lasted 1 h. At the end of each test, the number of males left in the departure bottle as well as the number in each arrival bottle was counted. Four tests were conducted for each experiment. For each experiment receptive females were placed in the right distal aspirator bottle and nonreceptive females in the left one for two tests, and the females' sides were switched for the other two tests. Hypotheses were tested using χ^2 and binomial statistics. The overall significances of the experiments (each consisting of four tests) were obtained by combining probabilities from separate replicates using the method of Fisher (1946). Individual probabilities for each replicate were obtained from the binomial distribution (one-tailed test) and -2 times the sum of their natural logarithms was taken as χ^2 with eight degrees of freedom (referred to in the text as the aggregate χ^2).

The objective of the experiments was to learn whether the removal of polar or nonpolar substances from females' water by isolation techniques would eliminate the males' responses to the waters. It was reasoned that if the pheromone was a lipid, for example, then receptive female waters passed through a lipid adsorbent would remove bioactivity from the waters, and males would not be attracted to it.

Four experiments were conducted. In experiment I, *Ulva lactuca* thalli were provided as substrate for females in the distal bottles. In experiment II, conditions were identical to the first, but beach sand, boiled in distilled water and then dried, rather than *U. lactuca*, was used as a substrate. In experiment III, C-18 reverse-phase columns (Sep-Paks, Waters Associates, Milford, MA) were introduced into the tubes leading from the distal to the arrival bottles. (The columns were inserted at C in Figure 1; in experiments I and II clamps were inserted at these sites to reduce the flow to the rate of experiments III and IV). Experiment IV was identical to the third, except that columns containing anion exchange resin, rather than Sep-Paks were introduced into the tubes. The resin was a strongly basic quaternary ammonium (polystyrene type $RN(CH_3)_3^+Cl^-$; Mallinckrodt Chemical Works, Amberline CG-400, 100–200 mesh, chromatographic grade).

RESULTS

There was no significant difference between males' responses to receptive and nonreceptive females when the females were maintained on *U. lactuca* (Ta-

[a] $\bar{X}$ = mean, SD = standard deviation.

ble 1, Exp. I: aggregate $\chi^2_8 = 7.40$, $P > 0.05$). However, in the second experiment, which substituted sand for the *U. lactuca*, males traveled significantly more often to receptive than to nonreceptive females' waters (Table 1, Exp. II: aggregate $\chi^2_8 = 40.82$, $P < 0.001$). In addition, fewer males left their departure bottles in the first than in the second experiment (Mann-Whitney U test; U = 0.5, $P < 0.05$, two-tailed). This suggests that the presence of *U. lactuca* inhibits the males' response to female secretions.

The insertion of the C-18 reverse-phase columns in the flow of water from the females did not interfere with the attractiveness of the receptive females' secretions to males. Males traveled to receptive females' sides significantly more often than to nonreceptive females' sides (Table 1, Exp. III: aggregate χ^2_8 =

31.99, $P < 0.001$). This suggests that the pheromone was not removed from the water by this absorbent. In contrast, when the anion exchange columns were inserted, only a few males left their departure bottles, and those that did showed no preference for either type of female secretion (Table 1, Exp. IV: aggregate $\chi^2_8 = 3.34$, $P < 0.05$). Thus, the bioactive substance was isolated from the females' waters by the resin. This suggests that the pheromone is a polar substance.

DISCUSSION

Female waters exposed to anion exchange resins lost their ability to attract males, but female waters exposed to C-18 reverse-phase columns did not. These observations indicate that the anion exchange columns isolate the bioactive substances from female waters, and thus the pheromone is polar. The substance may be an amino acid or derivative or a charged organic conjugate.

These results are consistent with the results of most other investigations of the chemistry of crustacean pheromones. The pheromones of the crab *Portunus sanguinolentus* and the crayfish *Procambarus clarkii* appear to be polar (Cristofferson, 1970, and Ameyaw-Akumfi and Hazlett, 1975, respectively). In addition, although Kittridge et al. (1971) hypothesized that crustecdysterone is the pheromone of most Crustacea, three species failed to respond to this substance or its metabolites: the lobster *Homarus americanus* (Atema and Gagosian, 1973; Gagosian and Atema, 1973), the crab *Carcinus maenas* (Seifert, 1982), and the crab *Callinectes sapidus* (Gleeson et al., 1984). The idea that the pheromone is an amino acid or derivative is not unreasonable, because some species respond to water-borne amino acids (summarized in Ache, 1982).

The data suggest that *Ulva lactuca* placed in the distal bottles with the females inhibits the males' responses to receptive female secretions. Males were attracted to receptive females' secretions significantly more often than to nonreceptive females' secretions when the substrate was sand, but not when the substrate was *U. lactuca*. In a previous study, under conditions similar to experiment I, males did respond to receptive female secretions (Borowsky, 1984). However, the previous tests were conducted for 5.5 h, as compared to the 1-h tests conducted for the present study. This suggests that the presence of *U. lactuca* lengthens the males' response time, but does not eliminate their ability to distinguish between receptive and nonreceptive females.

There are two ways to explain these observations. First, it is possible that females secrete more pheromone on a sand than on an *U. lactuca* substrate. Second, it is possible that *Ulva* effluents interfere with the males' perception of the pheromones (perhaps competing for receptor sites on sense organs), or even that the effluents repel males. Some support for the latter explanation comes from the recent observations of Johnson and Welsh (1985), who found that the by-products of the deterioration of *Ulva* were lethal to some crab larvae.

The present study suggests that this experimental approach can lead to the ultimate isolation and identification of the pheromone. For example, preliminary tests have been conducted in which anion exchange resins exposed to either receptive female water, nonreceptive female water, or waters with no animals were eluted with HCL, neutralized, then diluted in seawater. These diluted extracts were then tested on males in the Y-tube apparatus. The results demonstrated that males were not repelled by the extracts and, further, that they exhibited a positive response to extracts of receptive female but not to the other types of waters. These results were not statistically significant, but were sufficiently promising to warrant further investigations. These investigations are currently under way.

ISOLATION OF 24-METHYLENECHOLESTEROL-DERIVED OXIDATION PRODUCTS FROM QUEEN HONEYBEE OVARIES (*Apis mellifica* L.)

MICHEL BARBIER

Institut de Chimie des Substances Naturelles
CNRS, 91190 Gif sur Yvette, France

(Received March 25, 1986; accepted October 13, 1986)

Abstract—The bioecological situation of 24-methylenecholesterol, the main sterol of many pollens and previously isolated from larvae, workers, and queens of the honeybee *Apis mellifica* L., is reviewed. A search for steroids in queen honeybee ovaries has led to the isolation of three compounds occurring in minute amounts: 24-methylenecholest-4-en-3-one (1), 24-oxocholesterol (2), and 24-oxocholest-4-en-3-one (3), which were identified by direct comparison with authentic samples prepared from 24-methylenecholesterol. These three substances have not been detected in lipids from other parts of queen or from worker honeybees, and their presence may reflect a particular oxidizing capability of the ovaries. The results so far observed are discussed in relationship with previous observations reported on honeybees.

Key Words—*Apis mellifica*, Hymenoptera, Apidae, honeybee, queen, ovaries, 24-methylenecholesterol, 24-methylenecholest-4-en-3-one, 24-oxocholesterol, 24-oxocholest-4-en-3-one.

INTRODUCTION

During the isolation of queen substance, the honeybee queen pheromone, 24-methylenecholesterol (Barbier et al., 1960b; Barbier and Lederer, 1960; Barbier, 1960, 1986), was obtained from the residual neutral fraction (Barbier and Schindler, 1959). This sterol was later found in many pollens, the main source of proteins for the honeybee (Barbier et al., 1960a; Hügel et al., 1964b; for a review see Barbier, 1966), mixed with the usual series of C_{27}, C_{28}, and C_{29} sterols (Standifer et al., 1968). 24-Methylenecholesterol was obtained in purer form from the queens than from worker honeybees or pollens, as if a kind of biological discrimination was accomplished between the food and tissue accu-

0098-0331/87/0700-1681$05.00/0 © 1987 Plenum Publishing Corporation

mulation. This was emphasized by the isolation of nearly pure 24-methylenecholesterol from queen honeybee larvae collected at an early stage of development, that is, fed with royal jelly only (Barbier and Bogdanovsky, 1961). Svoboda et al. (1980, 1986) noticed a unique selective transfer mechanism of 24-methylenecholesterol from workers to developing brood, which is in agreement with this preliminary observation. During a systematic search for possible steroid hormones within the honeybee world, the existence of three 2,4-dinitrophenylhydrazine-reacting substances, present in trace amounts, was observed in the queen ovaries. At that time, due to the minute amounts existing in comparison with the mass of lipids and of sterols, only the main component was identified to 24-oxocholesterol, the two others being kept for further investigations. Later, while searching for queen substance, the queen honeybee pheromone (*E*)-9-oxo-2-decenoic acid, in the queen ovaries (Barbier and Pain, 1981), these experiments were developed to confirm the preceding result and to identify the as-yet-unidentified substances. These products were found to belong to the same biosynthetic series, 24-methylenecholest-4-en-3-one and 24-oxocholest-4-en-3-one, corresponding to successive oxidations of 24-methylenecholesterol. We subsequently completed this work by comparing the presence of these products in worker honeybees and in queens with ovaries removed, in which they have not been found within the limits of sensitivity of the methods. We now report these results.

The presence of 24-methylenecholesterol in the honeybee has been discussed (Svoboda et al., 1983, 1986; Svoboda and Lusby, 1986) in relationship to biochemical transformations and food requirements. 24-Methylenecholesterol is not transformed into C_{27} sterols, in agreement with reports about its accumulation in tissues. A discrepancy appears in the literature concerning the dealkylation of C_{29} sterols into cholesterol by honeybees (Allais et al., 1971; Svoboda et al., 1981). Allais observed an 18% transformation of labeled sitosterol into cholesterol, while 24-methylenecholesterol was recovered unlabeled after these experiments (Svoboda reported no dealkylation at position C-24 by using different conditions). Allais used the sitosterol propionate, and it may be that esterification of sterols is a prerequisite for further metabolism of the substance by honeybees following the usual dealkylation process (Allais and Barbier, 1971).

In pollen, the bioecological situation of 24-methylenecholesterol is related to an incomplete biosynthesis, a characteristic of these cells also noticed with pollinastanol (a 14-methyl-9,19-cyclostanol) in the rare pollen where cholesterol is the main sterol (Hügel et al., 1964a; Barbier, 1966; Devys et al., 1969). Corresponding 24-derivatives such as 24-methylene pollinastanol have also been isolated from pollen (Thompson et al., 1978).

Thus, the situation found in honeybees is rather particular concerning their sterols, as these insects are able to metabolize steroids (Veith et al., 1974) but

selectively accumulate 24-methylenecholesterol or, as shown here, oxidize it in their ovaries.

METHODS AND MATERIALS

Honeybee queen ovaries (800) were obtained through dissection from 400 queens (they are accessible even to nonspecialists by removing the sternites to uncover the ovaries as masses that occupy nearly all of the abdomen and are separated from the accessory glands. These ovaries were crushed in ethanol, filtered, and successively extracted by ethanol–ether 1 : 1 and ether. The collected extracts were dried in vacuo, the residue taken up by hot acetone, and the insoluble phospholipids discarded. The acetone-soluble lipids, after evaporation, were further saponified according to the usual procedure: 1 : 1 mixture of benzene with a 2 N methanolic KOH solution, 2 hr reflux under nitrogen, extraction by ether after addition of water, and crystallization from methanol. In these conditions, no noticeable oxidation of the 24-methylenecholesterol present in lipids from worker honeybees was observed by TLC of the mother liquors. Repeated crystallizations from MeOH led to 90% pure 24-methylenecholesterol (according to the mass spectrum of the acetate) and to a series of mother liquors which were collected. Substances 1, 2, and 3 (Figure 1) were isolated by preparative TLC of the residue from the mother liquors redissolved in ether for application to the SiO_2 layer (fluorescent films, Schleicher-Schüll, development with hexane–ethyl acetate 85 : 15 or 7 : 3, UV observation at 254 nm with a Desaga lamp for TLC, or 2,4-DNP spray, also comparing with standards on lateral position). All substances were extracted from the scraped SiO_2 by ether. The 2,4-DNP derivatives were obtained directly from the sprayed TLC plate and further submitted to control chromatography with a standard. The acetates were prepared for TLC and MS by action of acetic anhydride in pyridine (1 : 1), 20 hr at 20°C, and direct drying in vacuo previous to control TLC and developing with hexane–ethyl acetate 95 : 5. Observation of non-UV-absorbing, non-2,4-DNP-reacting sterols was by means of H_2SO_4 50%, 200°C by infrared lamp, red colorations. MS determinations were carried out on an AEI MS9 spectrometer, and UV spectra were obtained on an automatic Leres apparatus S-66 in ether.

RESULTS AND DISCUSSION

The lipids were extracted from the ovaries of 400 honeybee queens obtained through dissection, and the acetone-soluble fraction was saponified. The repeated crystallizations of the unsaponifiable fraction in methanol gave about 10 mg of a sterol fraction consisting mainly of 24-methylenecholesterol, R_f 0.45 (hexane–ethyl acetate 85 : 15), mp 139–142°C, acetate mp 132–134°C,

FIG. 1. A, 24-methylenecholest-4-en-3-one; B, 24-oxo-cholesterol; C, 24-oxocholest-4-en-3-one.

MS, *m/z* 380 (M-60), 296 (McLafferty rearrangement), 255, 213, (Barbier and Schindler, 1959; Barbier et al., 1960a; Hügel et al., 1964b). The mother liquors of the crystallizations were collected (46 mg) and studied through fluorescent SiO_2 TLC, showing the presence of two steroids in UV, reacting with 2,4-DNP. This reagent also gave a yellow color with a third component which could not be detected under the UV lamp in the reported conditions. After isolation, these three substances were identified by direct comparison with authentic samples prepared by oxidation on a standard of 24-methylenecholesterol. They all gave the McLafferty elimination of the side chain in MS because of the presence of a methylene group or an oxo function at position 24 (1, 3: 312, at 296 for 2).

Substance 1. UV λ_{max} 240 nm (ϵ 15,000 in ether), R_f 0.60 SiO_2 TLC (hexane–ethyl acetate 85:15), mp 77–84°C, 0.6 mg, MS *m/z* 396. This substance was identified as 24-methylenecholest-4-en-3-one by comparison with the authentic substance obtained from 24-methylenecholesterol through Oppenauer oxidation. The 2,4-DNP is orange, R_f 0.55 in the same developing solvent.

Substance 2. This product cannot be observed in UV on TLC, R_f 0.40 (hexane–ethyl acetate 85:15), reaction with 2,4-DNP or with H_2SO_4 200°C on a lateral deposit, mp of the acetate 122–127°C, MS 382 (M-60). Substance 2 was identified as 24-oxocholesterol by direct comparison with an authentic sample prepared from 24-methylenecholesterol acetate through ozonolysis. This substance is the major component in these oxo derivatives of 24-methylenecholesterol (0.8 mg). The 2,4-DNP is yellow, R_f 0.30 in the developing system mentioned.

Substance 3. R_f 0.55 (hexane–ethyl acetate 85:15), UV 240 nm (ϵ 15,000 in ether), mp 65–70°C, MS *m/z* 398. The compound was identified as 24-oxocholest-4-en-3-one by direct comparison with the authentic product prepared by Oppenauer oxidation of 24-oxocholesterol. This substance represents the minor component in the mixture of these oxo derivatives (0.4 mg). The corresponding 2,4-DNP (bis, according to the MS carried out on the standard) is orange and has an R_f of 0.45 in hexane–ethyl acetate (85:15). It has not been possible to carry out MS on the isolated 2,4-DNP because of the very small amount.

These substances (1, 2, and 3) occur in small amounts in queen honeybee ovaries, and it has not yet been possible to detect any of them in the lipids obtained from 320 carcasses or from 500 g of worker honeybees.

About the origin of these compounds, two hypotheses are possible: They may result from a systematic accumulation of traces present in food (pollen) or they may be produced in situ by the oxidizing capability of the ovaries. As far as we know, these substances have not been reported from pollen, and we failed to detect traces in the mother liquors of crystallization of the sterol fractions. A similar case has been found with makisterone A, a molting hormone detected in nanogram amounts in queen honeybee ovaries (Feldlaufer et al., 1986) which also probably results from the metabolism of 24-methylenecholesterol. Makisterone A is a 24-methyl derivative (Kaplanis et al., 1975) which could result from a reduction of the 24-methylene group. Highly active metabolites are often present in insect ovaries; for example, the ecdysteroid bombycosterol from *Bombyx mori* (Fujimoto et al., 1985). Organs often stock food products as demonstrated by the presence of a food contaminant, methyl *p*-hydroxybenzoate (Barbier and Schindler, 1959), introduced into the beehive with industrial molasses and accumulated in mandibulary glands of queens in high quantity. In the present case, the biological significance of the three oxo compounds 1, 2,

and 3 in the queen honeybee ovaries is not obvious. It could mean that these insects have adapted enzymatic systems, such as 3β-hydroxydehydrogenase, Δ_5-isomerase, Δ_4-reductase, that are able to transform a sterol into a steroid.

IDENTIFICATION OF TRITERPENOID FEEDING DETERRENT OF RED PUMPKIN BEETLES (*Aulacophora foveicollis*) FROM *Momordica charantia*

M.V. CHANDRAVADANA

Indian Institute of Horticultural Research
Hessaraghatta,
Bangalore, 560 089,
India

(Received June 13, 1986; accepted October 15, 1986)

Abstract—The triterpenoids isolated from the leaves of *Momordica charantia* Linn (bitter gourd) were found to elicit feeding-deterrent activity against red pumpkin beetles (*Aulacophora foveicollis* Lucas). The most abundant triterpenoid which deterred feeding was identified as momordicine II, 23-*O*-β-glucopyranoside of 3,7,23-trihydroxycucurbita-5,24-dien-19-al. A concentration of 3200 μg/ml and above of the triterpenoids caused significant reduction of feeding by red pumpkin beetles in in vitro bioassay experiments, which compared favorably with the levels of triterpenoids in *M. charantia* leaves found in nature.

Key Words—Feeding deterrents, *Aulacophora foveicollis*, red pumpkin beetles, Coleoptera, Chrysomelidae, *Momordica charantia* (bitter gourd), cucurbitane triterpenes, momordicine, Cucurbitaceae.

INTRODUCTION

The chemical basis of insect feeding responses has been well established, and secondary plant substances are implicated as attractants, repellents, or deterrents (Schoonhoven, 1972, 1982). Cotyledons and leaves of *Momordica charantia* Linn (Cucurbitaceae) are unacceptable to red pumpkin beetles (*Aulacophra foveicollis* Lucas, coleoptera) which feed voraciously on the cotyledons and leaves of most of the other cucurbitaceous crops (Ramakrishna Ayyar, 1984). Efforts to establish the chemical basis for this phenomenon led to isolation of a feeding deterrent of red pumpkin beetles from leaves of *M. charantia* which was tentatively identified as a triterpene glucoside (Chandravadana and

0098-0331/87/0700-1689$05.00/0 © 1987 Plenum Publishing Corporation

Pal, 1983). The chemical structure of the feeding deterrent and the optimum level at which it acts are reported in the present paper.

METHODS AND MATERIALS

Triterpenoids were isolated from leaves by the procedure reported earlier (Chandravadana and Pal, 1983). In this procedure dried and powdered leaf material was extracted with 90% methanol, concentrated under reduced pressure to $\frac{1}{10}$ the volume, extracted with petroleum ether (60–80°C) to remove the lipids, concentrated to dryness, suspended in water, and finally extracted with ethyl acetate. The concentrated ethyl acetate extract was passed through a column of alumina (neutral), washed thoroughly with ethyl acetate, and the triterpenoids were eluted in methanol. Thin-layer chromatography of this eluent on silica gel-G (0.25 mm) with the solvent system ethyl acetate–methanol–water (16 : 1 : 1) revealed eight distinct triterpenoid spots when sprayed with Liebermann-Burchard (LB) reagent (acetic anhydride–sulfuric acid, 19 : 1) followed by heating to 110°C for 10 min. Of the eight triterpenoids, the major triterpenoid alone was isolated in sufficient quantity for characterization. For its isolation, the crude mixture of triterpenoids (100 mg) was applied on a column of silica gel (60–100 mesh, 10 g) using ethyl acetate as an eluent. The fraction collected between 225 and 800 ml contained the major triterpenoid, and it was crystallized from the same solvent. Its [^{1}H]NMR and [^{13}C]NMR spectra were measured in pyridine-d_5 with tetramethylsilane as the internal standard on Hitachi-Perkin-Elmer (90 MHZ) and JEOL/FX-100 (25 MHZ) spectrometers, respectively. The infrared spectrum was recorded on a Perkin-Elmer IR spectrophotometer as a KBr pellet.

Bioassay. Adult red pumpkin beetles of mixed sex and age groups were collected from field-grown plants of bottle gourd (*Lagneria siceraria*) and pumpkin (*Cucurbita Maxima*). They were starved for 24 hr before using for bioassay. Excised, fully expanded cotyledons of pumpkin, which is an acceptable food for beetles, were used for bioassay.

Triterpenoid in 80% ethanol was applied uniformly on both surfaces of the cotyledon and the solvent was removed quickly by air drying. Cotyledons treated with 80% ethanol were used as control. Treated and control cotyledons were kept separately in Petri dishes, exposing their lower surface, for a no-choice test. Beetles were released at the rate of two per cotyledon. After 24 hr, the extent of feeding was assessed by measuring the area of cotyledon damaged, using a graph sheet. The number of fecal pellets was also counted. Evidence for feeding deterrence was construed based on reduction in the extent of feeding damage and number of fecal pellets in the treated one as compared to control. Bioassays were separately conducted for major triterpenoid, minor triterpenoids, and the crude mixture of triterpenoids extracted from leaves.

Concentrations. Five concentrations of the major triterpenoid (300, 800, 1600, 3200, and 6400 μg/ml) were prepared in 80% ethanol. On each cotyledon, with a mean area of 4.8 ± 0.50 cm^2 and a mean weight of 300 ± 28 mg, 0.3 ml of one of the above solutions was applied. This corresponds to an average triterpenoid concentration of 19, 50, 100, 200, and 400 μg/cm^2 or 0.03, 0.08, 0.16, 0.32, and 0.64% w/w of fresh cotyledon. There were five replicates for each treatment, and the statistical significance of the data was assessed using analysis of variance according to Snedecor and Cochran (1967).

The minor triterpenoids were isolated by resolving 20 mg of the crude mixture on a thin-layer chromatogram. After development with the solvent system ethyl acetate–methanol–water (16:1:1), a portion of the plate was sprayed with LB reagent for visualization of triterpenoids, and the corresponding bands from the unsprayed portion of the plate were eluted in ethanol and evaporated to dryness. The quantity of each triterpenoid so obtained was bioassayed in duplicate.

The crude mixture of leaf triterpenoids which eluted together from the column of alumina was bioassayed at 300, 800, 1600, 3200, and 6400 μg/ml levels.

Triterpenoid Estimation in Vivo in M. charantia Leaves. Leaves collected from 10 plants at flowering and fruiting stages were pooled and dried. Triterpenoids were extracted by the procedure described earlier. The extract from 1 g of dried leaves was passed through a column of alumina (2 g) and washed with ethyl acetate (50 ml). The triterpenoids were eluted in methanol (100 ml), concentrated, and dissolved in methanol (1 ml). An aliquot of 0.25 ml was evaporated to dryness, mixed with 4 ml of LB reagent, and the optical density was measured immediately at 545 nm. The standard curve was prepared using the major triterpenoid. The concentration was computed based on estimations of 10 pooled samples.

RESULTS AND DISCUSSION

The [^{1}H]NMR, [^{13}C]NMR, and IR spectral data of the major triterpenoid feeding deterrent isolated from *M. charantia* has been obtained. [^{1}H]NMR revealed methyl group signals at 0.90, 0.92, 1.18, 1.51, 1.70, and 1.78 ppm, olefinic proton signals at 5.6 and 6.28 ppm, formyl proton at 10.6 ppm; and protons on carbon-bearing hydroxyl groups between 3.8 and 5.1 ppm. [^{13}C]NMR revealed hydroxymethine carbons at 104.1, 78.82, 78.21, 75.53, 75.29, 71.76, 65.66, and 62.92 ppm; formyl carbon at 207.8 ppm; carbons for two trisubstituted double bonds at 124.20, 129.01, 132.18, and 145.64 ppm; and quaternary carbons at 41.7, 45.9, and 48.2 ppm. During the course of the present study, Yasuda et al. (1984) reported the identification of the major bitter principle in the leaves of *M. charantia* as momordicine II, 23-*O*-β-glucopyr-

FIG. 1. Momordicine II.

anoside of 3,7,23-trihydroxy-cucurbita-5,24-dien-19-al ($C_{36}H_{58}O_9$, Figure 1). A comparative study of the spectral data revealed a close correspondence of the [^{1}H]NMR and [^{13}C]NMR peaks of momordicine II and the deterrent we have isolated. Furthermore, the IR spectrum of the feeding deterrent was superimposable on that of standard momordicine II. The present study therefore establishes that the major feeding deterrent of red pumpkin beetles is momordicine II, which was reported as the bitter principle by Yasuda et al. (1984). The method used for isolation of the bitter principle by Yasuda et al. is, however, different from that employed here.

The in vitro bioassay carried out in the present study with starved beetles was aimed at determining the effective levels of the major leaf triterpenoid (identified as momordicine II) as a feeding deterrent. Among the five concentrations tested (Table 1), 3200 μg/ml (0.32% w/w) and 6400 μg/ml (0.64% w/w) levels caused significant feeding inhibition (81% and 94%, respectively), in terms of the reduction in area damaged by beetles. Reduction to the extent of 80% and 94% in the number of fecal pellets produced by beetles at these two concentrations also corroborate the above observation. At lower concentrations of the triterpenoid (300–1600 μg/ml), the observed reduction in feeding damage was not statistically significant.

It was considered desirable to check the feeding deterrency of the other minor triterpenoids, as they might elicit additive or synergistic effects in vivo. Among the eight fractions distinguished on the basis of R_f values (Table 2), five of them (including momordicine II) exhibited feeding deterrent activity. All the above five fractions probably elicit additive effects in vivo, since a bioassay involving the naturally occurring mixture of triterpenoids recorded significant feeding-deterrent activity at 3200 μg/ml (0.32% w/w) and above, levels at which the major triterpenoid alone deterred feeding. It is interesting that the levels of feeding-deterrent activity of the naturally occurring mixture of triterpenoids were

at par with momordicine II alone, even though the mixture included triterpenoid fractions 4, 5, and 6 with no feeding-deterrent activity (Table 2). It will be worthwhile to identify the minor triterpenoids and ascertain their threshold concentrations for feeding-deterrent effects.

The in vivo concentration of triterpenoids in leaves of *M. charantia* was estimated, and it ranged from 0.31% to 0.36% w/w on a fresh weight basis.

TABLE 2. FEEDING DETERRENCY OF LEAF TRITERPENOID COMPONENTS

Component number[a]	R_f^b	Feeding inhibition (%)[c]
1	0.24	94.2
2 (major triterpenoid)	0.34	96.4
3	0.40	90.0

5	0.54	0.7
6	0.64	00.0
7	0.80	92.1
8	0.90	94.2

[a]The concentration of the components in 0.3 ml of 80% ethanol, used for bioassay, corresponds to the quantity of each obtained by resolving 20 mg of the crude mixture of triterpenoids on a thin-layer chromatogram and their subsequent elution.
[b]R_f: relative mobilities with respect to solvent on silica gel-G (0.25 mm) in solvent system ethyl acetate–methanol–water (16 : 1 : 1).
[c]Refer table 1.

This concentration compared favorably with the effective levels established by in vitro bioassay, which suggests that the natural levels of triterpenoids in leaves of *M. charantia* are adequate to cause inhibition to feeding by red pumpkin beetles.

The above results provide evidence for resistance imparted by triterpenoids in leaves of *M. charantia* against red pumpkin beetles. The levels at which the feeding-deterrent activity of the triterpenoids was discerned may not truly reflect the situation in vivo where it may be effective even at a lower concentration. This is primarily because, unlike in *M. charantia*, cotyledons of *C. maxima* used in bioassay studies contain cucurbitacins B and E (Enslin et al., 1957) which are known to stimulate feeding by red pumpkin beetles (Sinha and Krishna, 1970; Vashista and Choudury, 1971). Momordicine and cucurbitacins, both of which are cucurbitane triterpenes, seem to cause a contrasting feeding response by red pumpkin beetles which might be due to difference in their structure. Momordicine II is unique in having an aldehyde group at C-19 and a 23-*O*-β-glucopyranosyl unit and in not having a carbonyl function at C-11. The effect of momordicine on feeding behavior of other insect pests of cucurbits merits further study.

Acknowledgments—I thank Dr. K.L. Chadha, former director, and Dr. T.R. Subramaniam, present director, for providing facilities. I am grateful to Dr. Okabe (Fukuoka University, Japan) for measurement of [^{1}H]NMR and [^{13}C]NMR spectra and for sending the IR spectra of momordicine II. Also I thank Dr. R. Krishnan for critical reading.

FEMALE SEX PHEROMONE OF THE COMMON FURNITURE BEETLE *Anobium punctatum* (COLEOPTERA: ANOBIIDAE): Extraction, Identification, and Bioassays

PETER R. WHITE and MARTIN C. BIRCH

Department of Zoology
South Parks Road, Oxford OX1 3PS, U.K.

(Received August 25, 1986; accepted October 15, 1986)

Abstract—Observations and reports on the common furniture beetle *Anobium punctatum* suggested that, on emergence, females use a sex pheromone to attract males. GLC analysis of ovipositor extracts showed the presence of a single component, which was found to be active by EAG and coupled GLC-EAG techniques, and to attract males in both walking and flying assays. The pheromone was identified by GC-MS as 2,3-dihydro-2,3,5-trimethyl-6-(1-methyl-2-oxobutyl)-4H-pyran-4-one (stegobinone), which is the sex pheromone of another anobiid, the drugstore beetle, *Stegobium paniceum*. Male *A. punctatum* responded equally to ovipositor extracts of either species, at both the sensory (EAG) and behavioral levels, which poses the question as to how species specificity in mate attraction is achieved.

Key Words—Common furniture beetle, *Anobium punctatum*, drugstore beetle, *Stegobium paniceum*, Coleoptera, Anobiidae, sex pheromone, stegobinone, 2,3,dihydro-2,3,5-trimethyl-6-(1-methyl-2-oxobutyl)-4H-pyran-4-one, behavior, electroantennogram, species specificity.

INTRODUCTION

Anobium punctatum de Geer, the common furniture beetle, is a widespread and destructive pest of seasoned wood. Indigenous to northern Europe and Asia, it has been distributed by man on a worldwide scale and is now found in Australasia, South Africa, and the eastern coast of North America (Hickin, 1963).

The damage is done by the larvae—known as woodworm—which can feed on soft and hardwoods, pulpboards, plywood, and even cardboard, and as a result, both structural timbers and furniture are subject to attack. The female

0098-0331/87/0700-1695$05.00/0 © 1987 Plenum Publishing Corporation

lays her eggs in cracks in the surface, and the larvae tunnel into the wood. After pupation, the adults cut their way out, leaving a characteristic flight hole (Hickin, 1963).

Surprisingly, despite the economic importance of *A. punctatum*, little attention has been paid to its reproductive behavior or that of anobiid beetles in general. A recent review (Tumlinson, 1985) listed only two identified pheromones from this family: the drugstore beetle, *Stegobium paniceum* L. (Kuwahara et al., 1975, 1978) and the cigarette beetle, *Lasioderma serricorne* F. (Chuman et al., 1979).

Several observations, however, have suggested the presence of a female sex pheromone in *A. punctatum*. Kelsey et al. (1945) reported "swarming," and on examining a swarm found it to contain 167 males clustered around three females! R.W. Berry reported that males, which emerge first, locate females as they emerge from their flight holes. Our own observations have noted female "calling" behavior, which has previously been reported in *A. punctatum* (Cymorek, 1964) and in another anobiid beetle—*Ptilinus pectinicornis* L. (Cymorek, 1960): The female stands with the abdomen raised and periodically protrudes the ovipositor.

This paper describes the extraction, identification, and bioassay of the sex pheromone of *A. punctatum* and provides comparisons with other anobiid pheromones.

METHODS AND MATERIALS

Insect Material. Cultures of hazel twigs infested with *A. punctatum* larvae and pupae were obtained from the Building Research Establishment, Princes Risborough, Buckinghamshire, U.K., and were kept at 22°C in constant darkness. Emerging adults were removed daily and sexed using the presence or absence of a depression on the ventral surface of the male's terminal abdominal segment (Kelsey et al., 1945). The sexes were kept separately in glass tubes on moist filter paper until use. *S. paniceum* was kept in a mixed-sex culture on rabbit pellets at 22°C.

Extraction Procedure. Ten newly emerged female *A. punctatum* were dissected and the ovipositors removed and extracted in 0.5 ml of pentane for 24 hr at 4°C. Three replicate extractions were made. Ovipositors of *S. paniceum* were extracted in a similar manner.

Gas Chromatography. Both extracts were analyzed using a Varian 3700 GLC (Walton-on-Thames, Surrey, U.K.) fitted with a 50-m × 0.32-mm ID fused silica column coated with chemically bonded OV-1 (Phase Separation Ltd. Queensferry, Clwyd, U.K.). Samples were injected in splitless mode with the oven at 50° C for 1 min, then programmed at 5°C/min to 250°C, using helium carrier gas at 1.5 kg/cm^2. Quantitative analyses used naphthalene as a standard.

Gas Chromatography-Mass Spectrometry (GC-MS). GLC of the *A. punctatum* and *S. paniceum* extracts each showed the presence of a single major component which was identified using a Finnigan 1020 GC-MS.

Electroantennography (EAG). Initial EAG recordings showed that male *A. punctatum* antennae gave a strong EAG response to the conspecific ovipositor extract. An EAG experiment was therefore conducted to determine whether males and females are equally responsive to female *A. punctatum* extract, and whether they respond differently, at the EAG level, to extracts of *A. punctatum* and *S. paniceum.* EAG responses were recorded from isolated furniture beetle heads mounted on a cork stage using double-sided adhesive tape. The indifferent glass microelectrode was inserted into the base of the head, and the opening sealed with petroleum jelly. The recording microelectrode was inserted into a small hole punched in the terminal antennal segment using a finely etched tungsten needle. Electrodes were filled with saline and connected, using chloridized silver wires, to a Grass P-16 DC (Quincy, Massachusetts) preamplifier and a Tektronix 5223 oscilloscope.

The odor delivery system was similar to that described by Payne and Dickens (1976), using a two-way solenoid valve to divert the filtered (activated charcoal) and humidified airflow via a test cartridge into a glass Y delivery tube. The airflow was maintained at 1000 ml/min with a pulse length of 1 sec. Cartridges consisted of a strip of filter paper impregnated with 10 μl of the test extract, inside a Pasteur pipet. Parallel series of dilutions of female *A. punctatum* and *S. paniceum* extracts were made, giving matched pairs containing equal concentrations of the major component. The two series were checked for concentration by GLC and stored at $-80°C$ before use. Test cartridges were presented pairwise in ascending order of concentration. Control presentations of solvent were interspersed between test presentations, and the response subtracted from the test response before analysis of the results.

Six individuals of each sex of *A. punctatum* were tested in this way. Results were analyzed using a split-plot analysis of variance to identify differences between the sexes and between the responses to the two extracts.

Coupled Gas Chromatography-Electroantennography (GC-EAG). This was carried out to confirm that the EAG responses recorded to the ovipositor extracts were due to the single major component rather than to any trace components. The GC-EAG system was essentially similar to that described for GC-single cell recordings by Wadhams (1984). The GLC and OV-1 column were as described above, using a temperature program of 150–230°C at 5°C/min. The column effluent was split 1 : 1 between two lengths of an OV-1-coated capillary column using a glass lined T piece. One arm led to the FID detector while the other ran via a heated jacket (maintained at 220°C) to the airflow impinging on the antenna.

Behavioral Assays. Bioassays were conducted to determine the response of male and female *A. punctatum* to conspecific ovipositor extract and to test

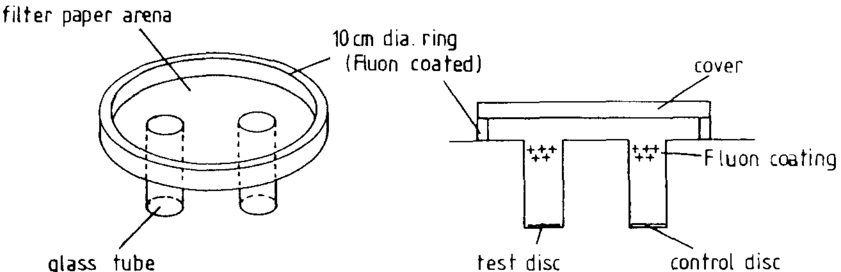

FIG. 1. Two-choice pitfall bioassay apparatus.

whether the response of *A. punctatum* to this extract differed from that to *S. paniceum* ovipositor extract.

A two-choice pitfall assay was used to compare the response of the sexes (Figure 1). Two 5 × 2.5-cm glass tubes with necks coated in Fluon were glued below holes cut in an 11-cm-diameter filter paper disc, which was supported on a metal baseplate. A 10-cm-diameter Perspex ring coated with Fluon was placed on the filter paper and covered with a glass plate.

The insects (3–15 per test) were introduced into the arena and allowed 10 min to settle. Test and control stimuli were then introduced, consisting of 10 μl of female extract (0.2 female equivalents), and 10 μl of pentane, respectively, applied to a 1-cm filter-paper square. The assay was left for 1 hr at 25°C, and then the number of beetles in each tube was counted. Five replicates were conducted for each sex, using each individual once only. Results were combined to give totals of each sex trapped in the test or control tubes. Differences between test and controls were tested for significance using a chi-square test.

A preliminary assay was also conducted in a wind tunnel 160 cm long × 75 cm high × 70 cm wide, using a wind speed of ca. 0.2 m/sec. The test stimulus (0.4 female equivalents of ovipositor extract) was placed on a filter paper strip at the upwind end of the tunnel, and either males or females placed on a platform 1.5 m downwind of the source, and their behavior observed.

An open arena assay was employed to compare the behavioral response of male *A punctatum* to the two extracts. The arena again consisted of a 10-cm-diameter ring coated in Fluon placed on an 11-cm-diameter filter paper and covered by a glass plate. Males were released singly into the arena and allowed 10 min to settle. The test extract was then applied to a 1-cm filter paper square as described above, the paper placed in the center of the arena, and the arena covered. Each individual was observed for up to 5 min, and the time taken for it to reach the center of the arena (defined as crossing a 2-cm-diameter circle drawn around the test paper) recorded. Beetles not responding in this period were given the default time of 5 min. Three concentrations plus a control were

tested for each of the extracts, with 10 replicates of each, in a randomized design. Results were analyzed using analysis of variance to determine whether the response time differed between the two extracts.

RESULTS

GLC. Analysis of the *A. punctatum* ovipositor extract showed the existence of a single major peak with a retention time of 27.5 min using the OV-1 column and the conditions described (Figure 2). Quantitative GLC showed that the mean (N = 10) amount of this material per female *A. punctatum* was 240 ng. Analysis of the *S. paniceum* extract also showed a single major peak with an identical retention time, which was confirmed by coinjection.

GC-MS. The electron impact spectra for the major components of *A. punctatum* and *S. paniceum* ovipositor extracts were found to be identical (Figure 3). They suggested a compound of molecular weight 224, this being the highest ion of significance in both spectra. The spectra were also identical to that published for stegobinone, the sex pheromone of *S. paniceum* (Kuwahara et al., 1975, 1979). Therefore, on the basis of identical spectra and retention times, the major component of the *A. punctatum* ovipositor extract was identified as stegobinone, or 2,3-dihydro-2,3,5-trimethyl-6-(1-methyl-2-oxobutyl)-4H-pyran-4-one (Figure 4).

EAG. Results of the EAG experiment (Figure 5) showed that the EAG response of males was significantly greater than that of females to both *A. punctatum* and *S. paniceum* extracts ($P < 0.001$). However, within each sex, there

FIG. 4. Structure of 2,3-dihydro-2,3,5-trimethyl-6-(1-methyl-2-oxobutyl)-4H-pyran-4-one (stegobinone).

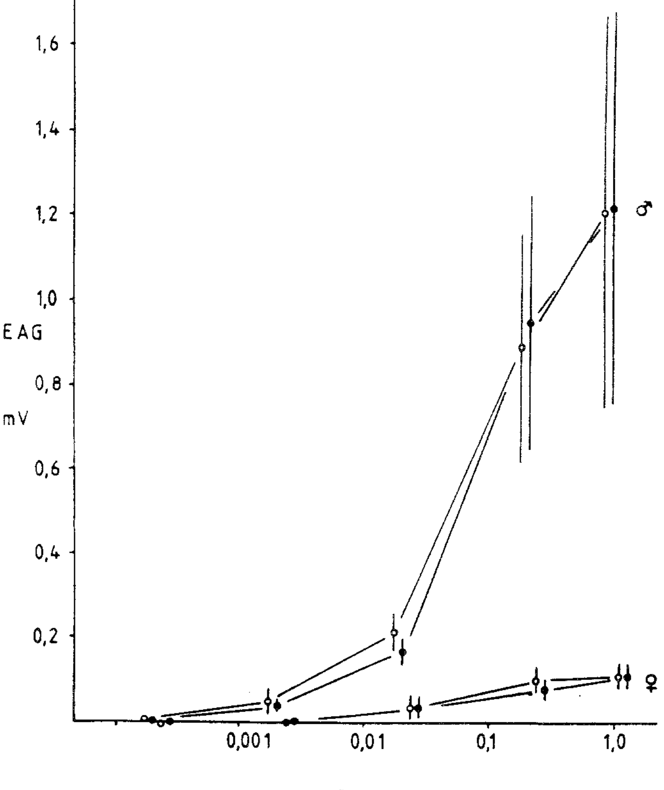

FIG. 5. Electroantennogram (EAG) response of *A. punctatum* to ovipositor extracts of *A. punctatum* (open circles) and *S. paniceum* (closed circles). ($\pm$ standard error, N = 6). Using analysis of variance, difference between male and female response was F = 13.5, $P < 0.001$; difference between extracts $F = 0.0$, NS.

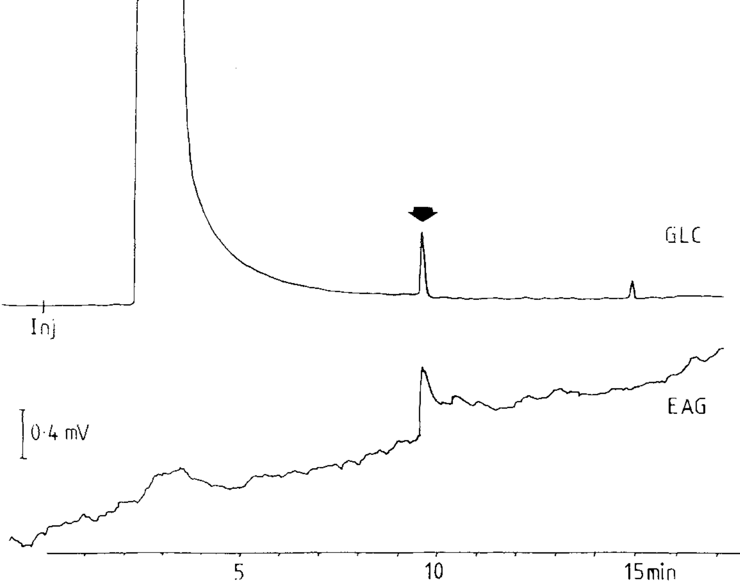

FIG. 6. Coupled GC-EAG response of male *A. punctatum* to conspecific ovipositor extract. GC oven intially at 150°C for 1 min, then programmed at 5°C/min to 230°C.

was no significant difference between the responses to the two extracts. Coupled GC-EAG traces for male *A. punctatum* (Figure 6) showed a single EAG response that was synchronous with elution of the single major component of the conspecific ovipositor extract. The EAG response to the female extract was therefore due to a response to the major component and not to any trace components.

Behavioral Assays. Results of the pitfall assays are presented in Table 1. Significantly more male *A. punctatum* were trapped by the conspecific female extract than the control at the concentration tested ($P < 0.001$), but there was no evidence of such a bias in females.

TABLE 1. ATTRACTION OF *A. punctatum* TO CONSPECIFIC OVIPOSITOR EXTRACT IN TWO CHOICE PITFALL ASSAY.[a]

	Test (0.2 FE)	Control (pentane)	No response	Total
Male	30	0	13	43
Females	0	2	29	31

[a] Difference between test and control: males $\chi^2_{(1)} = 30.0$, $P < 0.001$; females, NS.

A similar result was found in the wind-tunnel trials (data to be presented elsewhere). At least 20 of the 40 males tested responded by walking to the upwind edge of the platform, taking off and flying upwind, and landing on or within 2 cm of the source. Males flew to both *A. punctatum* and *S. paniceum* extracts. By comparison, no females flew in the wind-tunnel trials.

The response of males in the open arena assays (Figure 7) showed a significant effect of concentration ($P < 0.001$) with the time taken to reach the source decreasing with increasing dosage. Males responded to the odor by raising their antennae and then orienting in a series of zigzags to the source. Once at the source, males performed tight turning movements on the filter paper square. In contrast, when exposed to the solvent controls, males either remained stationary at the edge of the arena, or walked slowly around the perimeter. There was no difference, however, between the response of males to the two extracts. Female responses to the ovipositor extracts were not significantly different from responses to the solvent, even at the highest concentration tested (Figure 7).

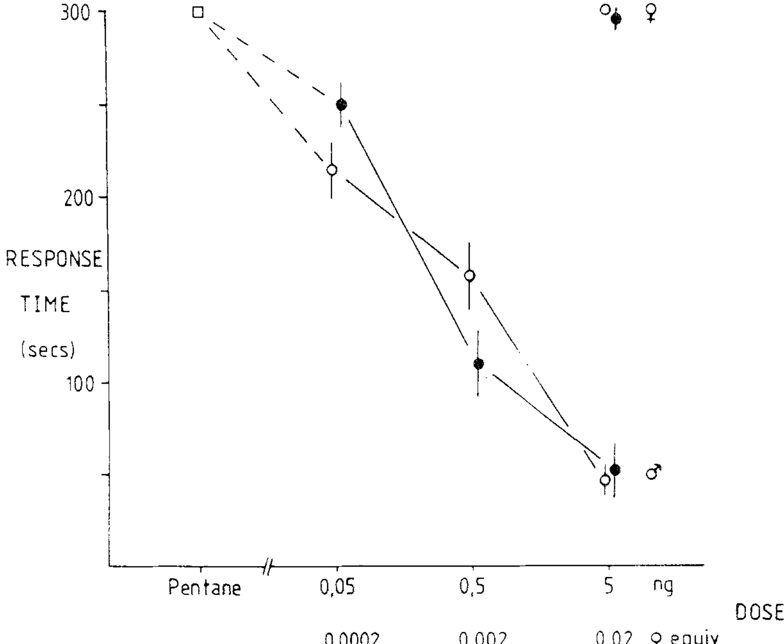

FIG. 7. Response of *A. punctatum* males to ovipositor extracts of *A. punctatum* (open circles) and *S. paniceum* (closed circles) in open arena behavioral assay. Response time gives mean time (± standard error, $N = 10$) taken to reach center of arena. Using analysis of variance, effect of dose $F = 40.6$, $P < 0.001$; difference between extracts $F = 0.1$, NS.

DISCUSSION

The female common furniture beetle, *A. punctatum*, was shown to release from the ovipositor a sex pheromone which attracts males. The GC-EAG results suggest that only one component from the ovipositor produces the response, and on the basis of mass spectra and retention times this was identified as stegobinone [2,3-dihydro-2,3,5-trimethyl-6-(1-methyl-2-oxobutyl)-4H-pyran-4-one]. This molecule possesses three chiral centers, giving eight possible stereoisomers. So far we have not been able to determine directly the configuration of the stegobinone extracted from *A. punctatum*, although the configuration of the sex pheromone of *S. paniceum* has been established by X-ray analysis as (2*S*,3*R*,7*R*)-stegobinone (Hoffmann et al., 1981). Since male furniture beetles responded identically to the extracts from *A. punctatum* and *S. paniceum* in both behavioral and electrophysiological assays, the sex pheromone of *A. punctatum* appears to have the same configuration. However, further chemical analysis is required to confirm this.

Males have a low threshold for this material, responding in the behavioral assay at doses below 0.05 ng (2×10^{-4} female equivalents) and in the EAG assay at 0.25 ng (10^{-3} FE), and attraction of males was further demonstrated in a flight tunnel. To our knowledge, this is the first instance where attraction of flying beetles to a pheromone source has been demonstrated in the laboratory. Choudhury and Kennedy (1980) reported this response in flying *Scolytus multistriatus*, but in uniform concentrations of pheromone.

Female common furniture beetles produce large amounts of the sex pheromone. The mean titer per female was 240 ng, and since female size varied widely (probably reflecting differences in the duration of the larval stage), some females are likely to contain considerably more than this. Kuwahara et al. (1975) found similar levels of pheromone in *S. paniceum* (50–200 ng per female). Furthermore, pheromone titer was found to rise following emergence in both *S. paniceum* (Kuwahara et al., 1975) and *Lasioderma serricorne* (Coffelt and Burkholder, 1972), reaching a plateau after five days. In this study female furniture beetles were extracted at 1 to 3 days following emergence, so they may not have reached a peak of pheromone content. This high pheromone content may result from strong selection acting on females to ensure that they are located by males, since the adult life-span is only about two weeks after a larval development that may last four years.

The results suggest that both *A. punctatum* and *S. paniceum* use the same sex pheromone. Although both species are placed in the subfamily Anobiinae, they are not generally positioned immediately adjacent to each other (White, 1971; Toskina, 1974). Crowson suggests (personal communication) that the two genera separated 40–50 million years ago in the Palaeocene, yet they appear to have retained the same sex pheromone. We intend to study other anobiid beetles to see if similar compounds are found.

Since male common furniture beetles respond equally well to the two extracts, it appears that they will be equally attracted to calling female drugstore beetles. We have yet to investigate the response of male drugstore beetles to determine whether they are able to discriminate between the two extracts, but at least in the case of *A. punctatum* there is the possibility of confusion if the species coexist. While other barriers to interspecific mating are likely to exist, selection should act to promote discrimination between species at the earliest possible stage, i.e., during location of the female, to avoid wasting time and energy following false trails (Linn et al., 1986; Cardé and Baker, 1984).

The two species appear to have been allopatric prior to association with human habitation; *A. punctatum* from the forests of northern Europe and Asia (Hickin, 1963), and *S. paniceum* from the Mediterranean or Middle East (Crowson, personal communication). They were further separated ecologically, since the former develops in wood, while the latter is found in bird nests (Woodroffe, 1953) and stores of organic material. However, *S. paniceum* has become a cosmopolitan pest of warehouses, stores, and houses (Mallis, 1960) since it can develop on almost any dried organic material (Pant and Fraenkel, 1954) and is now sympatric with *A. punctatum* over much of its range. Therefore, at least in houses, stores, and animal buildings, the two species may coexist. It will be interesting to determine whether confusion by males between the calling females does occur under such conditions, and if so, whether discriminating mechanisms develop.

Acknowledgments—We should like to thank: Mr. J. Grandidge for some assistance with bioassays; Mr. R.W. Berry, Building Research Establishment, Princes Risborough Laboratory, Bucks, U.K., for supplying insects and advice; Dr. R.T. Aplin, Oxford, and K. Rollins of V.G. Masslab, Altrincham, Cheshire, for assistance with GC-MS; Prof. F.R. Whatley, Department of Plant Sciences, Oxford, for use of GC-MS; Dr. R.A. Crowson, Department of Zoology, Glasgow, for helpful advice; and Prof. J.S. Kennedy for critical review of the manuscript.

(Received July 11, 1986; accepted October 20, 1986)

Abstract—The defensive secretion of *Tribolium brevicornis* contains 12 organic components, including quinones, hydroquinones, hydrocarbons, aromatic ketones, and aromatic esters. The two ketones, 2′-hydroxy-4′-methoxyacetophenone and 2′-hydroxy-4′-methoxypropiophenone, and the two esters, methyl 2,5-dihydroxy-6-methylbenzoate and methyl 2,5-dihydroxy-6-ethylbenzoate, represent ca. 0.25% of the biomass of the beetles. Mass spectral and NMR analyses were used to elucidate the structures of all components. The ketones are potent prostaglandin synthetase inhibitors (PSI), and the esters are suspected to be PSI.

Key Words—Biosynthesis, Coleoptera, Tenebrionidae, *Tribolium brevicornis*, prostaglandin, allomones, synthetase inhibitor, defensive secretion, 2′-hydroxy-4′-methoxyacetophenone, 2′-hydroxy-4′-methoxypropiophenone, methyl 2,5-dihydroxy-6-methylbenzoate, methyl 2,5-dihydroxy-6-ethylbenzoate.

INTRODUCTION

The defensive secretions of tenebrionid beetles often contain a diversity of natural products. The best known of these products are the ubiquitious quinones and olefins (Tschinkel, 1975a), but in addition compounds such as isocoumarins (Lloyd et al., 1978), terpenes (Gnanasunderam et al., 1981), aliphatic carbonyl

0098-0331/87/0700-1707$05.00/0 © 1987 Plenum Publishing Corporation

compounds (Tschinkel, 1975b; Gnanasunderam et al., 1982), salicylate esters (Gnanasunderam et al., 1984), and β-hydroxy aromatic ketones (Suzuki et al., 1975; Howard et al., 1986) have also been found. The physiological significance of most of the nonquinone and hydrocarbon components is unknown. We recently reported, however, that the red flour beetle, *Tribolium castaneum* (Herbst), contains microgram per beetle levels of 2′-hydroxy-4′-methoxyacetophenone (**1**) and 2′-hydroxy-4′-methoxypropiophenone (**2**) (Howard et al., 1986) and that these aromatic ketones are potent inhibitors of both insect and mammalian prostaglandin synthetases. We have subsequently found that similar aromatic prostaglandin synthetase inhibitors (PSI) are present in a diversity of other insect exocrine secretions (Jurenka et al., 1986).

As part of our continuing efforts to identify insect-derived PSI, we have reexamined (Markarian et al., 1978; Wirtz et al., 1978) the defensive secretion of the North American flour beetle *Tribolium brevicornis* LeC. We have found that this insect contains substantial quantities of ketones **1** and **2** as well as two previously undescribed β-hydroxy aromatic esters. We report here the structure determination of these compounds and discuss their possible physiological significance.

METHODS AND MATERIALS

Insects. Cultures of *T. brevicornis* were obtained from Dr. R. Strong, Department of Entomology, University of California, Riverside, California, and from Dr. W. Burkholder, USDA-ARS, Department of Entomology, Madison, Wisconsin. They have gone through approximately five generations in our laboratory and have been reared on whole wheat flour mixed with 3% brewer's yeast in constant darkness at 30 ± 1 °C, except for brief periods of examination in room light.

Isolation Methods. Beetles from each source population were chilled in an ice bath for ca. 10 min, causing many of the beetles to release their yellowish defensive secretion, which then solidified onto the cuticle. The solidified secretions were transferred with an insect pin to a 1-ml Reactivial,[3] diluted with diethyl ether, and examined by capillary gas chromatography–mass spectrometry (GC-MS). Other beetles were killed by freezing at −30°C, the entire insect extracted with diethyl ether, and then the extract was examined by GC-MS. Both methods with either population of beetles gave the same mixture of low-molecular-weight components in the same relative proportions. Therefore, all subsequent analyses utilized the whole-body extraction procedure.

Preparative Methods. Approximately 900 adult *T. brevicornis* (10.23 g)

[3]Mention of a proprietary product in this paper does not imply its approval by USDA to the exclusion of other products that may also be suitable.

were killed by freezing and then extracted 3× with 25-ml portions of diethyl ether. The combined extracts were concentrated in vacuo to yield 170 mg of a dark reddish yellow oil. This oil was chromatographed through a 2 × 20-cm column of BioSil A with 60-ml fractions of hexane, 1:9, 2:8, 4:6, 6:4, 8:2 ether–hexane, and 100% ether. Fractions were collected (7 ml) and monitored by GC-MS. Fractions containing aromatic components (10% ether and 20% ether) were concentrated in vacuo and further purified by thin-layer chromatography. Unactivated Kieselgel 60 F254 plates were predeveloped in $CHCl_3$, then streaked with CH_2Cl_2 solutions of fractions from the preparative column chromatography and redeveloped in $CHCl_3$, air dried, and examined under long-wavelength UV light. The β-hydroxy ketones, quinones, and esters all appeared as separate light-blue fluorescent bands. These bands were scraped from the plates and thoroughly extracted with CH_2Cl_2. The resulting CH_2Cl_2 solutions were concentrated in vacuo to yield the pure defensive secretion components. Individual components were stored in CH_2Cl_2 until used.

Quantitative Analysis of Individual Insects. Individual live beetles were placed in microvials constructed from Pasteur pipets and 50 μl of CH_3CN containing 0.5 μg vanillin/μl (as an internal standard) was then added. After 20 min, 1-μl aliquots of the CH_3CN solution were analyzed by capillary GC using a flame ionization detector. A comparison of peak areas of the internal standard to those of the quinones, ketones, and esters was used to calculate the abundance of these chemicals in individual beetles. Some of the beetles were subsequently crushed in the microvial and reanalyzed to assess how much of the defensive secretions was not recovered by the 20-min soaking.

Derivatization. A 10-μl portion of the ether solution from our preliminary isolation was treated with 100 μl Trisil® (Pierce Chemical Company, Rockford, Illinois), held at room temperature for 30 min, and then examined by GC-MS.

Instrumentation. GC-MS analyses were conducted on a Hewlett Packard model 5790A capillary GC (Hewlett Packard, Inc., Palo Alto, California) equipped with a 30-m × 0.2-mm DB-1 capillary column (J & W Scientific, Inc., Rancho Cordova, California), interfaced to a Hewlett Packard model 5970 mass selective detector operated at 70 eV, and a Hewlett Packard model 5730A gas chromatograph containing a 12.5-m × 0.2-mm HP cross-linked methyl silicone capillary column with a flame ionization detector. Nitrogen was the carrier gas, and injections utilized the splitless mode. Signals from the GC were stored and analyzed using a Hewlett Packard model 3380 Integrator. [^{1}H]NMR spectra were acquired on a Bruker WM-400 spectrometer (USA Bruker Instruments, Inc., Billerica, Massachusetts) using a 5 mm C/H probe, 32 K data points over a 6024-Hz spectral width, a 2.0-sec delay and, unless otherwise indicated, the spectra were processed with a 0.1-Hz line broadening. The samples were dissolved in "100%" $CDCl_3$ (Aldrich Chemical Co., Milwaukee, Wisconsin), and the chemical shifts were referenced to the protiochloroform peak taken as 7.26 ppm relative to tetramethylsilane (0 ppm). Specific reso-

nance homonuclear decouplings were done with 10L to 20L (low) settings using a 5-sec total delay time. All of the specific compound resonances reported integrated to the correct number of protons within ±10% when $C(O)CH_3$ or OCH_3 were taken as 3.0, except for the methyl protons of the 6-methyl compound **3**, which indicated approximately four hydrogens due to an overlapping signal from an unidentified impurity.

Sources of Chemicals. Reference compounds were either purchased from Aldrich Chemical Company, Milwaukee, Wisconsin, or were synthesized by R. Howard using standard synthetic procedures. Dr. Ronald Bentley, University of Pittsburgh, Pittsburgh, Pennsylvania, generously provided a series of aromatic esters as model compounds for our mass spectral studies.

RESULTS

Individual beetles contain substantial quantities of quinones, ketones, and esters in their defensive secretions (Table 1). A comparison of the amount extracted by simply soaking the intact beetle to that obtained by crushing the insect in the solvent indicates that soaking removes only about 20% of the actual amount present (Table 1). Since individual beetles weigh ca. 10 mg, their quinones and aromatic defensive secretion components together comprise ca. 2% of their biomass, with the ketones and esters representing ca. 0.25% of the insects biomass.

The acetophenone **1** and propiophenone **2**, which we isolated from *T. brevicornis*, were identical in all respects with the compounds previously isolated from *T. castaneum* (Howard et al., 1986). Our previous structure proofs relied on mass spectral and infrared spectral data coupled with total synthesis. In this paper we report 400-MHz [^{1}H]NMR data which further confirm the two reported structures (Figure 1A and 1B; Table 2). Compound **1** showed two methyl peaks, three aromatic protons, and a singlet far downfield at 12.716 ppm. The

TABLE 1. QUANTITIES OF QUINONES, AROMATIC KETONES, AND AROMATIC ESTERS EXTRACTED FROM WHOLE AND CRUSHED *Tribolium brevicornis* LeC.

Compound		Amount (μg per beetle, $\bar{X}$ ± SEM)	
		Whole (N = 18)	Crushed (N = 5)
2-Methylbenzoquinone		13.1 ± 3.1	51.9 ± 9.0
2-Ethylbenzoquinone		32.1 ± 7.2	122.9 ± 24.7
2′-Hydroxy-4′-methoxyacetophenone	**1**	0.4 ± 0.1	1.3 ± 0.2
2′-Hydroxy-4′-methoxypropiophenone	**2**	3.7 ± 0.8	20.6 ± 5.3
Methyl 2,5-dihydroxy-6-methylbenzoate	**3**	0.4 ± 0.1	3.8 ± 0.6
Methyl 2,5-dihydroxy-6-ethylbenzoate	**4**	0.4 ± 0.1	2.8 ± 0.4

most upfield of the aromatic resonances (Figure 1A) at 6.360 ppm was a doublet with a 2.4-Hz coupling constant, whereas the signal just downfield from it (6.390 ppm) was a doublet of doublets with 8.8- and 2.5-Hz coupling constants. The most downfield of the aromatic peaks (7.575 ppm) showed only the 8.8-Hz coupling. The observed coupling pattern strongly suggests ortho coupling between the 7.575 and 6.390 ppm resonances, combined with meta coupling between the 6.390 and 6.360 ppm protons, as expected for the trisubstituted aromatic ring of **1.** Table 2 compares the observed chemical shifts to those previously reported for **1** (Suzuki et al., 1975).

A confirmatory NMR analysis of the propiophenone **2** proved to be less straightforward. Its spectrum (Figure 1B) showed a singlet for the methoxy methyl resonance at 3.837 ppm, an upfield triplet and quartet indicative of an ethyl group, a complex set of peaks in the aromatic region, and a hydroxy proton signal at 12.845 ppm. Homonuclear decoupling of the 6.439 ppm resonance essentially collapsed the 7.664 ppm multiplet, indicating that the apparent complexity was due to second-order effects. Chemical shifts and coupling constants for the three aromatic protons were therefore obtained by simulation techniques using the Bruker PANIC program. The observed and calculated aromatic region spectra are compared in Figure 1B and C, and the calculated shifts and coupling constants for all protons are given in Table 2. These results confirm the 1,2,4-trisubstitution pattern of **2.**

The structures of the two esters **3** and **4** were established using mass spectral and NMR analyses in conjunction with selected derivatizations. The mass spectrum of **3** (Figure 2) showed a prominent molecular ion at *m/z* 182 which

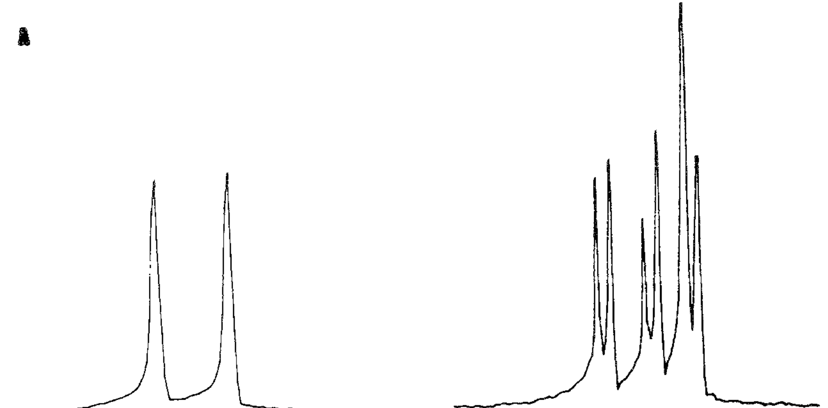

FIG. 1A. [^{1}H]NMR spectra at 400 MHz of the aromatic region of the ketones of *T. brevicornis* in $CDCl_3$. The spectra in A and B were processed with −0.25 Hz line broadening. (A) Compound **1,** 2′-hydroxy-4′-methoxyacetophenone.

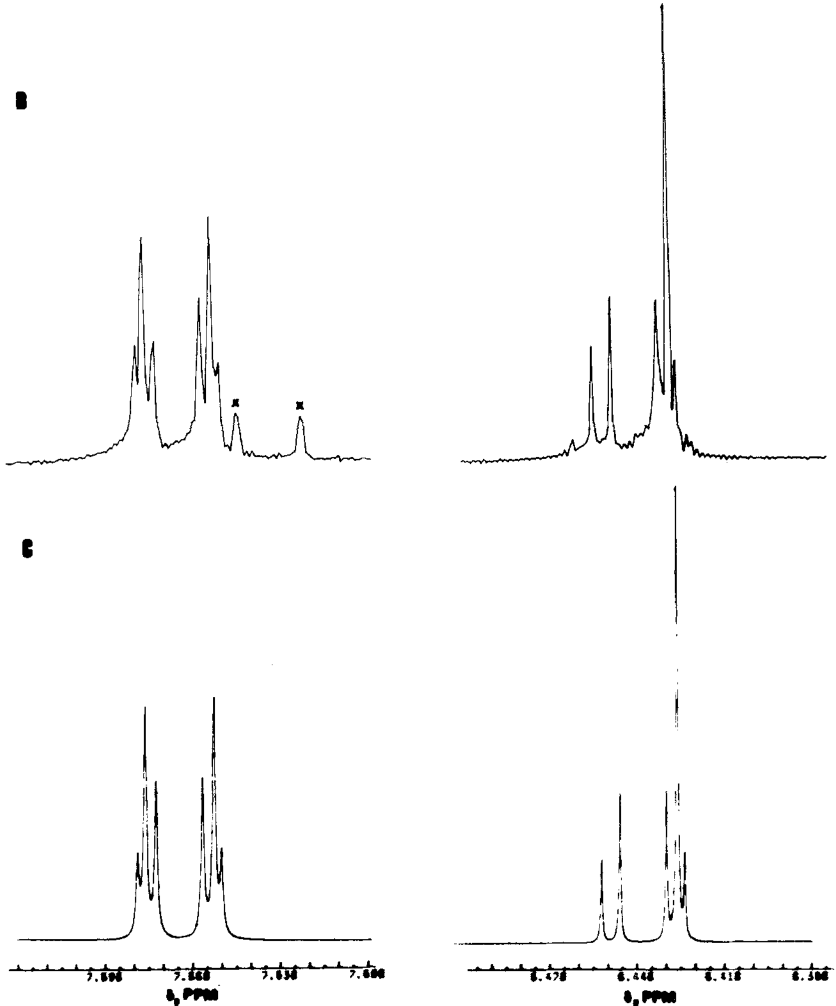

FIG. 1B, C. [^{1}H]NMR spectra at 400 MHz of the aromatic region of the ketones of *T. brevicornis* in $CDCl_3$. (B) compound **2**, 2′-hydroxy-4′-methoxypropiophenone; (C) simulated aromatic region spectrum of **2** using the Bruker PANIC program. In this spectrum the downfield set of peaks are displayed with a line width of 0.3 Hz and the upfield sets of peaks with a 0.5 Hz line width. The peaks marked × are from an unidentified contaminant.

fits a molecular formula of $C_9H_{10}O_4$. The base peak at *m/z* 150 (M-32) and the prominent ion at *m/z* 122 (M-32-28) strongly suggested that compound **3** was a substituted salicylate (Budzikiewicz et al., 1967). The two subsequent losses of mass 28 to give the ions at *m/z* 94 and *m/z* 66 indicated an aromatic molecule

[c] The aromatic proton δ and J values were obtained from simulated spectra (see Results).

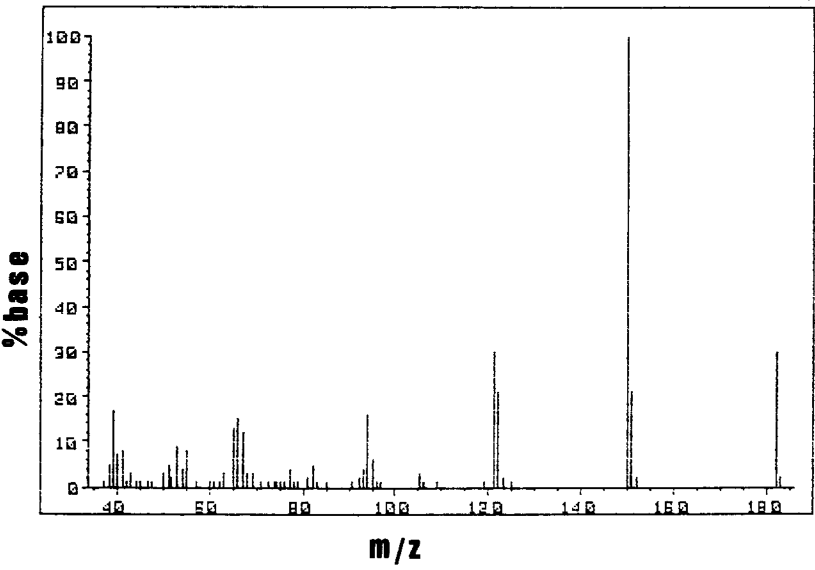

FIG. 2. EI mass spectrum of methyl 2,5-dihydroxy-6-methylbenzoate **3**.

with two ring hydroxyls, and by subtraction the remaining substituent on the ring had to be a methyl group. Derivatization of **3** with TMS yielded a product with a molecular ion (base peak) at *m/z* 268, corresponding to the addition of one methyl group and one trimethylsilyl residue to the starting ester. Other major fragment ions from this derivative occurred at *m/z* 253 (loss of methyl), *m/z* 237 (loss of -OCH_3), and *m/z* 73 (trimethylsilyl). These data thus confirmed our conclusion regarding the presence of two hydroxyl groups on the aromatic ring.

To this point the data argued for a trisubstituted methyl benzoate with one of the substituents being a hydroxy ortho to the carboxylate function. The placement of the methyl group could not be unequivocally determined from mass spectral data alone, although we suspected it to be at the other ortho position to the carboxylate functionality, from biosynthetic considerations and by analogy to the esters reported by Gnanasunderam et al. (1984). Similarly, the precise location of the second hydroxyl could not be determined solely from mass spectral evidence. It was possible, however, to exclude the second hydroxyl being at C-3 of the aromatic ring from the following considerations. Hydroquinones are known to undergo facile oxidation to the corresponding quinones in the hot injection ports of gas chromatographs, and indeed the production of such quinones was always observed in our analyses. Orthoquinones have very prominent $M + 2$ ions in their mass spectra which frequently are as intense as the M^+ ions (Zeller, 1974). The quinone derived from **3** has a prominent M^+

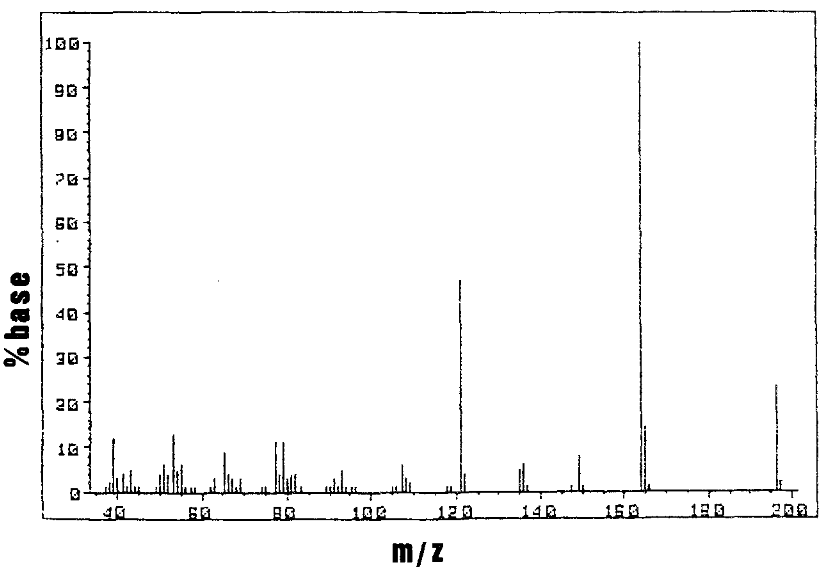

FIG. 3. EI mass spectrum of methyl 2,5-dihydroxy-6-ethylbenzoate **4**.

ion at *m/z* 180 and an M + 2^+ ion abundance of ca. 3% which clearly does not match known *o*-quinone behavior.

Inspection of the mass spectrum of compound **4** (Figure 3) suggested that it was probably an alkyl homolog of **3**. A prominent molecular ion at *m/z* 194 suggested a molecular formula of $C_{10}H_{12}O_4$, and the base peak again arose by a loss of methanol. The three subsequent successive losses of mass 28 producing ions at *m/z* 136, 108, and 80 again indicated a dihydroxy methyl benzoate with one of the hydroxyls ortho to the carboxylate group. The prominent ion at *m/z* 121 at first did not seem consistent with **4** being the ethyl homolog of methyl substituted **3**, and we considered the possibility that **4**, like **1** and **2**, contained a methoxy group. This possibility was tested by subjecting **4** to derivatization with the TMS reagent and examining the mass spectrum of the resulting derivative. That product had an M^+ at *m/z* 282 corresponding, as in **3**, to the addition of both CH_3 and trimethylsilyl to the starting ester, thus demanding that both ring oxygen functionalities be hydroxyls. As with ester **3**, the second hydroxyl was not at carbon 3 because of the low abundance of the M + 2 ion of the corresponding quinone. Therefore, other possible mechanisms that might lead to the ion at *m/z* 121 from the base peak at *m/z* 164 were considered. If the *m/z* 164 ion had a 6-ethyl substituent, it rationally could produce the *m/z* 121 ion by a loss of the methyl group from the ethyl side chain in conjunction with a ring expansion and 1,2-H shift to produce a keto tropylium ion, which in turn could lose carbon monoxide to produce a resonance stabilized

p-hydroxybenzene acylium ion of mass 121. Placement of an ethyl group elsewhere on the ring would not be expected to lead to a prominent *m/z* 121 ion nor would any dimethyl structure that we considered (Budzikiewicz et al., 1967). Our analysis to this point for compounds **3** and **4** strongly suggested that we were dealing with methyl 2,X-dihydroxy-6-alkylbenzoates.

From biosynthetic considerations it seemed likely that the second hydroxyl was at C-5. We accordingly synthesized methyl 2,5-dihydroxybenzoate **5** from the corresponding acid and used it as a standard for NMR comparisons. In Figure 4A, the [^{1}H]NMR spectrum of **5** is compared with that of ester **3** from *T. brevicornis* (Figure 4B). The natural product showed an additional 3H singlet resonance at 2.432 ppm due to the ring methyl. The chemical shift for the 6-methyl protons was in good agreement with the 2.48 ppm chemical shift reported for that group in methyl 2-hydroxy-6-methylbenzoate (Chan and Brownbridge, 1980). The 2.432 ppm singlet clearly is not a methoxy methyl since those chemical shifts are at 3.8 ppm or higher (Table 2). In addition, Chan and Brownbridge (1980) report the chemical shift of the C-4 methyl in methyl 2-hydroxy-4,6-dimethylbenzoate to be at 2.25 ppm.

In the aromatic region the alkylated benzoate **3** has only two resonances, 6.750 (d) and 6.933 ppm (d) compared to three for compound **5:** 6.872 (d), 7.010 (dd), and 7.273 ppm (d) (Figure 4A and B). That the missing proton at 7.273 ppm corresponded to the 6-position followed directly from the assignments of the ring hydrogens of **5.** Since the 7.010 ppm signal of **5** was a doublet of doublets with coupling constants of 8.9 and 3.1 Hz, that resonance corresponded to H-4, because 3.1 Hz would be unrealistically large for para coupling between H-3 and H-6 and therefore must have arisen from four-bond coupling between H-4 and H-6. The same coupling of 3.1 Hz was observed only at the 7.273 ppm resonance which identifies it as H-6.

Examination of the [^{1}H]NMR spectrum of ester **4** indicated it to be very similar to that of compound **3.** Differences include the absence of the 3H singlet at 2.432 ppm and the presence of a triplet at 1.191 ppm and a quartet at 2.917 ppm with identical coupling constants (J = 7.4 Hz), thus confirming the presence of an ethyl group in this compound. The shift of 2.917 ppm for the methylene protons excludes the possibility of an ethoxy derivative since in that case the shift would have been 4.0 ppm or greater (Jackman and Sternhell, 1969). The chemical shifts and coupling constants for compounds **3, 4,** and **5,** as well as literature (Gnanasunderam et al., 1984) values for methyl 6-methyl- and methyl 6-ethylsalicylate (**6** and **7,** respectively) are listed in Table 3.

The chemical shift values for the hydroxyl protons reported in Table 3 varied somewhat from sample to sample, apparently depending on the states of dryness of the sample. This variability is a well-known phenomenon for phenols, as evidenced by the range of chemical shift values reported for salicylates in the Sadtler Standard NMR Spectra (1970) (5 to ca. 13 ppm in $CDCl_3$). For compounds **3** and **4,** two OH peaks were observed near 12.75 and 10.5 ppm.

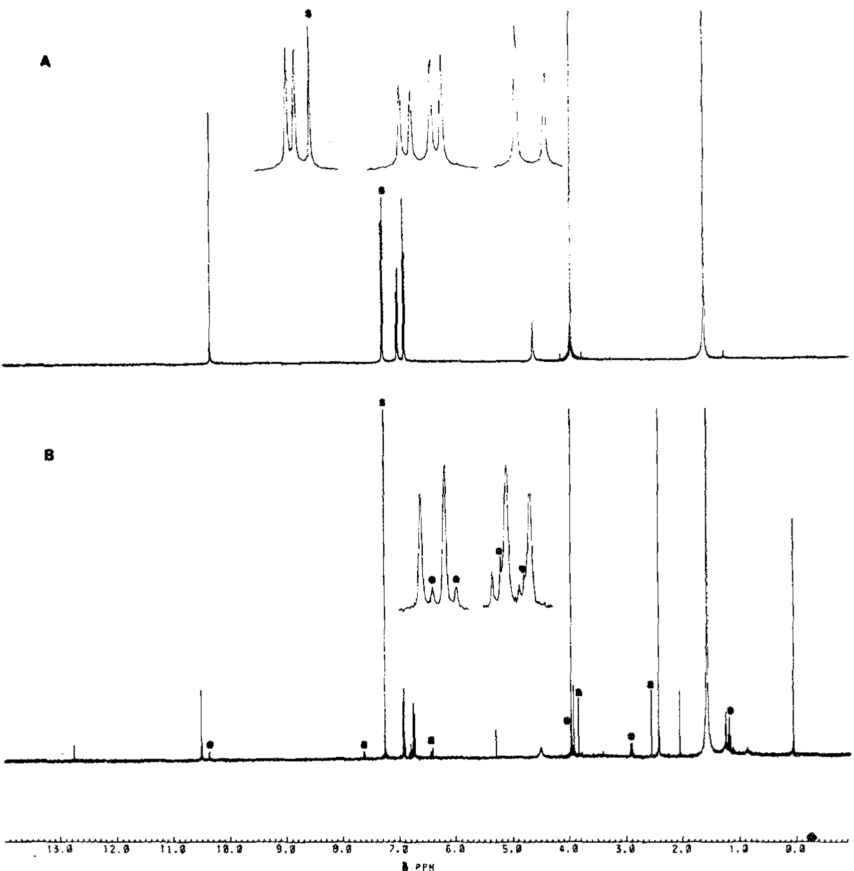

FIG. 4. [^{1}H]NMR spectra of the methyl benzoates at 400 MHz in $CDCl_3$. (A) Authentic methyl 2,5-dihydroxybenzoate. The expanded peaks are those between 6.8 and 7.3 ppm of the full spectrum with "s" denoting the protiochloroform peak. The large peak at ca. 1.5 ppm is an impurity from the isolation procedures, probably hexane. (B) Methyl 2,5-dihydroxy-6-methylbenzoate from *T. brevicornis*. The expanded peaks are those between 6.7 and 7.0 ppm of the full spectrum. The letter "e" above a peak denotes that it is from the corresponding 6-ethylbenzoate **4** and "a" indicates the acetophenone **1**. The other smaller peaks between 5.5 and 1.0 ppm, as well as the larger peaks at ca. 1.5 and 0 ppm, are contaminants from the extraction procedures.

Unfortunately, the spectrum of compound **5** (Figure 4A) gave only one signal in this region (10.4 ppm), but showed a broad feature in the water region at 5.5 ppm. The 2-O<u>H</u> chemical shifts in the β-hydroxy ketones **1** and **2** (Table 2) came at ca. 12.8 ppm, and the corresponding hydroxy signals for methyl 2-hydroxy-6-methyl benzoate **6** and methyl 2-hydroxy-4,6-dimethylbenzoate **8** are reported to occur at 11.03 and 11.00 ppm, respectively (Chan and Brownbridge,

[a] The chemical shifts, δ, are in ppm downfield from tetramethylsilane (0 ppm) as referenced to the solvent $CHCl_3$ peak taken as 7.26 ppm. The coupling constants, J, are in Hz.
[b] This difference is probably too large because the CO_2CH_3 shift of 3.72 ppm reported for 7 seems to be in error.
[c] Authentic methyl 2,5-dihydroxybenzoate (see Methods and Materials).
[d] Gnanasunderam et al. (1984), who used δ = 7.27 ppm for the $CHCl_3$ reference. Assignments of 3-H and 5-H for **6** and **7** are based on the current results for **3** and **4**.
[e] Peak obscured by $CHCl_3$.

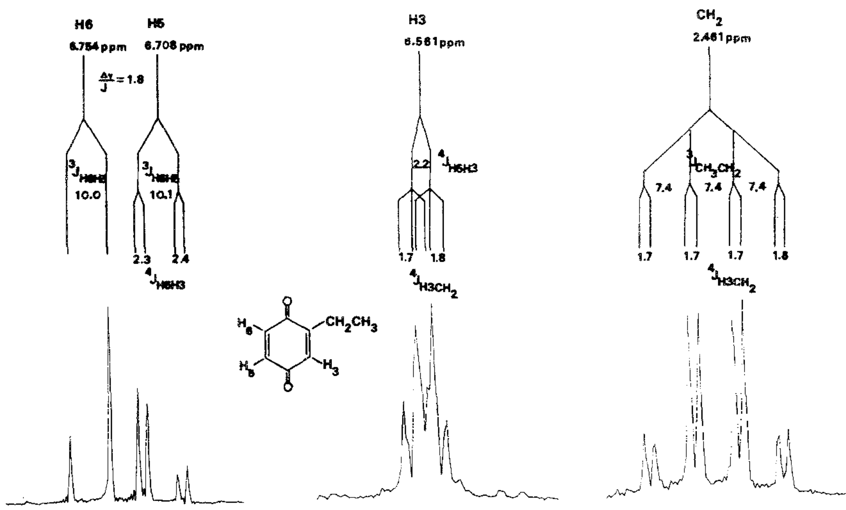

FIG. 5. [^{1}H]NMR multiplets of 2-ethylbenzoquinone from *T. brevicornis* at 400 MHz in $CDCl_3$. The triplet at 1.136 ppm for CH_2CH_3 did not show any long-range coupling and is not shown in this figure. The spectrum was processed with a −0.25 Hz line broadening. The coupling constants values shown are those obtained directly from the spectrum at each multiplet.

1980). Although we cannot unequivocally assign chemical shifts to the 2-O<u>H</u> and 5-O<u>H</u> resonances of **3** and **4**, we are tentatively assigning the most downfield resonance to the 2-O<u>H</u> hydrogen since it is involved in internal hydrogen bonding in $CDCl_3$ and matches most closely to the observed chemical shift for the β-hydroxy ketones of **1** and **2**. Thus considering all of the data, the structures of the *T. brevicornis* esters can be assigned as methyl 2,5-dihydroxy-6-methylbenzoate for **3** and methyl 2,5-dihydroxy-6-ethylbenzoate for **4**.

Although 2-methyl- and 2-ethylbenzoquinone are well-known defensive secretion products, we obtained a NMR spectrum of the ethyl derivative (Figure 5) in preparation for biosynthetic studies. Observation at 400 MHz of the long-range coupling between H-3 and the methylene protons of the 3-ethyl group rendered the proton assignments straightforward (Table 4). We note that even at 400 mHz, the aromatic protons still show slight second order effects.

DISCUSSION

The defensive secretion of *T. brevicornis* was previously reported by Markarian et al. (1978) and Wirtz et al. (1978) to contain 2-methylbenzoquinone, 2-ethylbenzoquinone, the corresponding hydroquinones, and 1-pentadecene. These are indeed the major components of this beetle's defensive secretion, but

[a] δ is in ppm downfield from tetramethylsilane (0 ppm) as referenced to $CHCl_3$ of the solvent (δ = 7.26 ppm).

we have also found substantial quantities of at least 10 other components, including six additional olefins (Howard, 1987), the two ketones, and the two esters which are the subject of this paper. Complex blends such as these are typical of insect defensive secretions. However, the functions of all components are not always so clear. Components such as the quinones and hydroquinones are presumably cytotoxicants or irritants, whereas the olefins most likely are serving as "biosolvents" to aid in the cuticular penetration of the toxicants (Blum, 1981) and the prostaglandin synthetase inhibitors.

Prostaglandins are local cell hormones which have been isolated from nearly every type of mammalian tissue (Bergstrom et al., 1968), from several nonmammalian vertebrates and marine invertebrates (Bundy, 1984), and from insects (Brady, 1983; Lange, 1984; Murtaugh and Denlinger, 1982; Wakayama et al., 1986). In vertebrates, prostaglandins have been shown to modulate adenylate cyclase activity and facilitate ion transport, nerve transmission, platelet aggregation, and gastrointestinal function (Samuelsson et al., 1978, 1980). In invertebrates, prostaglandins have been shown to mediate ion regulation in mollusks (Graves and Dietz, 1979; Freas and Grollman, 1980), to produce fevers in crayfish (Casterlin and Reynolds, 1978) and scorpions (Cabanac and Guelte, 1980), to regulate oviposition behavior in two species of crickets (Destephano et al., 1982; Loher et al., 1981) and a silkmoth (Yamaja Setty and Ramaiah 1980), and to be required for the normal emergence and flight capabilities of a mosquito (Dadd and Kleinjan, 1984). Future studies will undoubtedly show that prostaglandins play as important a role in invertebrate physiology as they do in mammals.

Given that prostaglandins do play such a vital role in the normal physiology of animals, it is not surprising that insects have evolved chemicals that would inhibit the biosynthesis of prostaglandins in their competitors, parasites, or predators. At least three orders of insects (Coleoptera, Hemiptera, and Hymenoptera) have been reported to possess exocrine secretions that contain aromatic compounds analogous to those that we have found in *T. brevicornis*

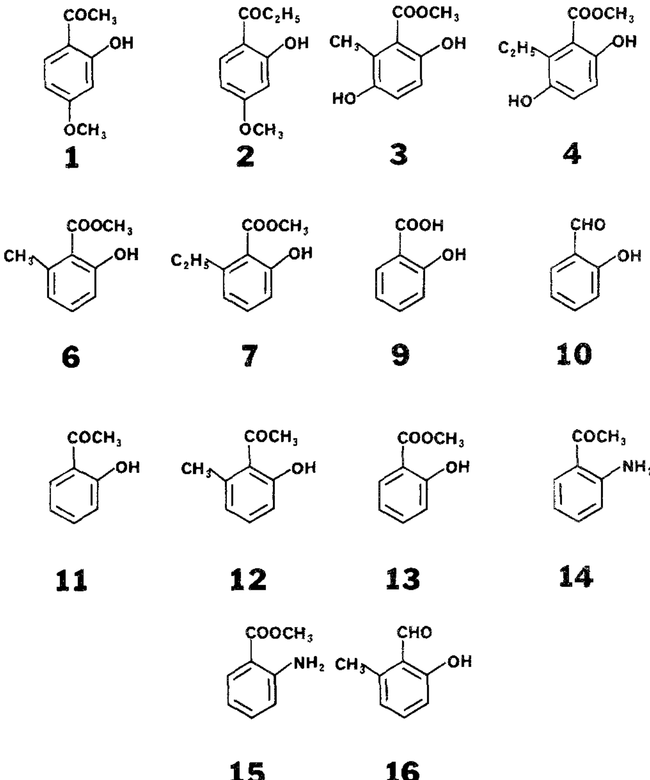

FIG. 6. Insect exocrine chemicals with known or suspected prostaglandin synthetase activity.

(Blum, 1981) (Figure 6). The common feature of all these compounds is the presence of the β-hydroxy or β-amino carbonyl moiety. Compounds **1, 2, 10, 13, 14,** and **15** (Figure 6) have been shown to be excellent prostaglandin synthetase inhibitors in both mammalian and insect systems (Howard et al., 1986; Jurenka et al., 1986). Although salicylic acid (**9,** Figure 6) has been reported to be only minimally active as a PSI, it has been shown to be converted in vivo to 2,5-dihydroxybenzoic acid, which is a very active PSI compound (Robinson and Vane, 1974). Such evolutionary "backfiring" of an organism's detoxification mechanism is of course well known to insecticide toxicologists (Matsumura, 1975). We consider it highly likely that the compounds in Figure 6, including the *T. brevicornis* esters **3** and **4,** which have not yet been tested for their PSI activity, will also prove to be excellent prostaglandin synthetase inhibitors, as will other compounds of a similar structure from other insects. Studies are now underway in our laboratories to identify such chemicals, to elucidate their ecological roles, and to further clarify the physiological roles of prostaglandins in insects.

Acknowledgments—We thank Colleen Hampton for assistance in rearing the insects and conducting initial chromatographic separations. We also thank Drs. Tappey Jones, Ronald Bentley, C.A. McDaniel, and Karl Kramer for their critical comments. This is contribution number 86-531-J from the Kansas Agricultural Experiment Station.

(Received July 28, 1986; accepted October 20, 1986)

Abstract—Attempted purification of synthetic racemic grandisal **1** by silica gel chromatography resulted in severe decomposition. The nature of this reaction was studied on silica gel and in an ether solution of *p*-toluenesulfonic acid. The same products resulted from both reaction systems, although in different ratios. Five racemic, rearrangement products were isolated by preparative GC and identified as follows: (1*RS*,3*SR*,6*RS*)-1-methyl-5-methylenebicyclo[4.2.0]octan-3-ol (**4**); (1*RS*,3*RS*,6*RS*)-1-methyl-5-methylenebicyclo[4.2.0]octan-3-ol (**5**); (1*RS*,3*RS*,6*RS*)-1,5-dimethylbicyclo[4.2.0]oct-4-en-3-ol (**6**); (1*RS*,3*SR*,6*RS*)-1,5-dimethylbicyclo[4.2.0]oct-4-en-3-ol (**7**); and 3-methyl-7-methylenecyclooct-3-en-1-ol (**8**). The stereochemical assignments are based on our proposed mechanism, which also accounts for all products observed. The racemic bicyclic enone (**3**) was a by-product of grandisol (**2**) oxidation.

Key Words—Grandisal, rearrangement, isomerization, acid catalysis, silica gel catalysis, *Pissodes* spp., Coleoptera, Curculionidae.

INTRODUCTION

Grandisal (*cis*-2-isopropenyl-1-methylcyclobutaneethanal) (**1**)[1] has been found in incubations of macerated boll weevil abdomens, *Anthonomus grandis* Boheman, but the compound was inactive (Hedin, 1977). This aldehyde, along with the corresponding alcohol, grandisol **2**, has been identified in the males of *Pissodes approximatus* and *Pissodes strobi* (Booth et al., 1983). These compounds, as racemates, are effective aggregation pheromone components for *P.*

[1] Structures are drawn as single enantiomers to represent relative stereochemistry; all compounds are racemic.

0098-0331/87/0700-1725$05.00/0 © 1987 Plenum Publishing Corporation

approximatus (Booth and Lanier, 1974; Booth, 1978), but their function in *P. strobi* is not clear.

During preparation of racemic grandisal **1** from grandisol **2** by pyridinium chlorochromate oxidation, we attempted purification by silica gel chromatography, in the course of which the sample decomposed. This extreme sensitivity led us to investigate the decomposition both on silica gel and in ether containing a catalytic amount of *p*-toluenesulfonic acid and to identify the products. We call attention to particular hazards of silica gel chromatography.

METHODS AND MATERIALS

GC isolations were carried out on a Varian-Aerograph model 1700 equipped with an effluent splitter and a thermal gradient collector (Brownlee and Silverstein, 1968). The following packed columns were used: column A was a 2.4-m × 7-mm-ID glass column packed with 10% Carbowax 20 M on Chromosorb W 60–80 mesh; column B was a 6.1-m × 4-mm-ID glass column packed with 4% Apiezon-L on Chromosorb G, 60–80 mesh. Column B was used isothermally to calculate Kovats' retention indices (Kovats, 1958). GC-MS was performed on a Finnigan GLC 9500 fitted with a 30-m × 0.2-mm-ID DB-1 capillary column (column C) interfacing a Finnigan 4000 mass spectrometer (ionizing voltage 70 eV). High-resolution mass spectra were obtained on an AEI-MS-902 instrument with 10,000 resolution. Infrared spectra were obtained on a Perkin-Elmer 1310; samples were run as neat films between NaCl plates. [^{1}H]NMR spectra were obtained on a Varian XL-100 (100 MHz) and a Bruker Widebore WM-360 (360 MHz) instrument. [^{13}C]NMR spectra were recorded on the Varian XL-100 instrument at 25.2 MHz. All NMR samples were run in $CDCl_3$ and are recorded as ppm from Me_4Si as internal reference. Elemental analyses were performed at Micro-Analysis, Inc., Wilmington, Delaware. Synthetic grandisol was obtained from Chemical Samples Company, Columbus, Ohio, and was judged to be about 92% pure by NMR and GC analysis.

cis-*2-Isopropenyl-1-methylcyclobutaneethanal (Racemic Grandisal) (1).* The procedure is essentially the one used by Corey and Suggs (1975). In a 100 ml, round-bottom flask fitted with a reflux condenser was suspended a mixture of 2.10 g (9.75 mmol) of pyridinium chlorochromate and 0.16 g (1.95 mmol) of sodium acetate in 10 ml of anhydrous methylene chloride. Racemic grandisol (**2**) (1.00 g, 6.5 mmol) in 5 ml of anhydrous methylene chloride was added in one portion to the magnetically stirred solution at room temperature. After 2 hr, the oxidation, monitored by GC, was judged complete. The black reaction mixture was diluted with five volumes of anhydrous ether and decanted from the black gum. The black solids were washed thoroughly with 3 × 10 ml of ether. The combined solution was passed through a short pad of Florisil. Pure grandisal was obtained in 68% yield by chromatography on column A (125°C

for 12 min, programmed to 150°C at 4°/min, N_2 60 ml/min): [^{1}H]NMR (Figure 1); MS *m/e* 53(13%), 55(15%), 56(4%), 57(8%), 67(60%), 68(100%), 69(18%), 79(4%), 81(8%), 83(5%), 93(7%), 95(4%), 96(5%), 97(5%), 107(2%), 108(37%), 109(22%), 123(1%); Kovats' index 1122.

(1RS,6RS)-*1,5-dimethylbicyclo*[*4.2.0*]*oct-4-en-3-one* (*3*).[2] Bicyclic enone **3** was the major by-product (5%) of grandisol (**2**) oxidation. After the initial fractionation on column A above, final purification was done with column B (isothermal at 150°C, N_2 60 ml/min): [^{1}H]NMR (Figure 2); [^{13}C]NMR δ21.7, 23.8, 27.7, 30.6, 37.2, 44.5, 46.6, 125.7, 162.0, 199.8; IR 1655, 1620, 1281, and 825 cm^{-1}; MS *m/e* 39(30%), 40(5%), 41(22%), 51(8%), 52(4%), 53(10%), 56(4%), 65(12%), 67(42%), 77(20%), 79(60%), 80(8%), 91(13%), 93(15%), 94(28%), 95(100%), 96(6%), 108(22%), 121(4%), 122(64%), 135(6%), 150(13%); Kovats' index 1242. Anal. calcd for $C_{10}H_{14}O$: C, 79.96; H, 9.39. Found: C, 80.03; H, 9.25.

Silica Gel-Catalyzed Rearrangement of Pure Grandisal (1). The silica gel (grade 923, 100–200 mesh, Aldrich) was activated at 130–140°C for 2 hr and cooled to room temperature under N_2. Two grams of this material was packed into a 20-cm × 1-cm-OD glass column as a pentane slurry under N_2. Grandisal (10 mg, 0.066 mmol) in 0.5 ml of pentane was added to the top of the column. The stopcock was opened, and the grandisal was allowed to drain into the gel bed. The column was closed at both ends and allowed to stand at room temperature for 14 hr. The column was eluted with diethyl ether. Removal of the solvent and short path distillation at 75°C (0.5 mm Hg) of the residual oil gave 8.5 mg of volatile components.

p-*Toluenesulfonic Acid-Catalyzed Rearrangement of Pure Grandisal (1).* To 10 mg (0.066 mmol) grandisal and 0.76 ml anhydrous ether in a 20-ml vial was added 0.24 ml (0.007 mmol) of a 5 mg/ml solution of *p*-toluenesulfonic acid monohydrate in anhydrous ether. The solution was held at room temperature for 12 hr. The reaction solution was shaken with dry sodium carbonate powder and then passed through 0.3 g of Florisil in a disposable pipet (17 cm × 7 mm OD). The solvent was removed, and vacuum distillation at 75°C (0.5 mm Hg) gave 8.7 mg of volatile material.

*Isolation of (1*RS,*3*SR,*6*RS*)-1-Methyl-5-methylenebicyclo*[*4.2.0*]*octan-3-ol (4j), (1*RS,*3*RS,*6*RS*)-1-Methyl-5-methylenebicyclo*[*4.2.0*]*octan-3-ol (5), (1-*RS,*3*RS,*6*RS*)-1,5-Dimethylbicyclo*[*4.2.0*]*oct-4-en-3-ol (6), (1*RS,*3*SR,*6*RS*)-1,5-Dimethylbicyclo*[*4.2.0*]*oct-4-en-3-ol (7), and 3-Methyl-7-methylenecyclooct-3-en-1-ol (8).* Since both rearrangement reactions gave the same products (although in different ratios, Table 1), the same procedure was used to isolate products from either system. Initial fractionation on column A (130°C for 12 min, programmed to 150°C at 4°/min, N_2 80 ml/min) gave four fractions, which

[2]In these racemic compounds, the relative configuration is shown by designating the first chiral center as *RS* and the others relative to it.

were collected separately. The first fraction contained a small amount of unreacted grandisal (**1**). The second fraction from column A was further fractionated on column B (150°C, N_2 60 ml/min) to give a pure compound identified as **4** with the stereochemistry tentatively assigned (see Discussion): [^{1}H]NMR (Figure 3); [^{13}C]NMR δ22.5, 30.2, 39.4, 40.2, 42.9, 46.5, 68.3, 111.8, 146.5; IR 3345, 1638, 1035, 880 cm^{-1}; MS *m/e* 39(58%), 40(12%), 41(100%), 43(28%), 44(6%), 51(12%), 52(6%), 53(29%), 55(30%), 56(15%), 57(20%), 65(15%), 67(49%), 68(71%), 69(51%), 77(27%), 79(47%), 81(52%), 82(8%), 83(9%), 84(12%), 85(7%), 91(49%), 92(12%), 93(36%), 95(36%), 96(31%), 97(38%), 105(14%), 106(50%), 108(97%), 109(41%), 110(7%), 119(23%), 123(8%), 124(26%), 134(12%), 137(21%), 152(4%); Kovats' index 1178. Anal. calcd for $C_{10}H_{16}O$: C, 78.88; H, 10.59. Found: C, 78.78; H, 10.57.

The third fraction from column A was fractionated on column B (150°C, N_2 60 ml/min). Two fractions were obtained. One fraction was shown to be a pure compound and has been identified as **5** with the stereochemistry tentatively assigned: [^{1}H]NMR (Figure 4); IR 3300, 1638, 1030, 880 cm^{-1}; MS *m/e* 39(53%), 40(13%), 41(100%), 43(28%), 44(67%), 51(10%), 53(31%), 55(46%), 56(14%), 57(21%), 65(15%), 67(52%), 68(68%), 69(49%), 77(26%), 79(42%), 81(41%), 82(6%), 83(77%), 84(8%), 85(77%), 91(40%), 92(11%), 93(32%), 95(28%), 96(30%), 97(26%), 105(14%), 106(40%), 108(79%), 119(22%), 121(5%), 123(7%), 124(20%), 134(7%), 137(15%), 152(4%); Kovats' index 1151. High-resolution mass spectrum; calculated for $C_{10}H_{16}O$, 152.1201; found, 152.1198.

The other fraction from column B was shown to be a mixture of two compounds on column C (80°C, programmed after 1 min to 130°C, 4°/min, 16 psi He). These compounds were identified as **6** and **7** (with the stereochemistry tentatively assigned) by comparing them to an authentic mixture of **6** and **7** produced by the reduction of **3**. Capillary GC-MS analysis of **6** gave *m/e* 39(20%), 41(25%), 43(14%), 51(6%), 53(10%), 55(11%), 65(7%), 67(9%), 69(10%), 77(16%), 79(19%), 81(11%), 91(27%), 93(22%), 95(16%), 97(63%), 105(6%), 106(12%), 107(12%), 108(28%), 109(100%), 110(10%),

119(5%), 123(20%), 124(7%), 137(24%), 152(6%); Kovats' index 1185. Mass spectral analysis of **7** gave *m/e* 39(22%), 41(26%), 43(15%), 51(5%), 53(11%), 55(11%), 65(6%), 67(10%), 69(10%), 77(13%), 79(18%), 81(12%), 91(26%), 93(16%), 95(19%), 97(48%), 105(6%), 106(11%), 107(11%), 108(22%), 109(100%), 110(9%), 123(23%), 137(18%), 152(6%); Kovats' index 1181.

The fourth fraction (essentially one compound) from column A was further purified on column B (150°C, N_2 60 ml/min). This compound was identified as **8**: [^{1}H]NMR (Figure 5); [^{13}C]NMR δ25.3, 26.6, 39.3, 39.5, 41.8, 70.8, 115.6, 125.2, 135.1, 146.1; IR 3350, 1636, 1032, 887, 823 cm^{-1}; MS *m/e* 39(49%), 40(129%), 41(67%), 43(19%), 44(7%), 51(7%), 53(32%), 55(33%), 56(16%), 65(8%), 67(42%), 68(31%), 69(72%), 77(16%), 79(32%), 81(31%), 83(14%), 84(21%), 91(26%), 93(62%), 95(18%), 97(19%), 105(9%), 106(7%), 108(100%), 109(28%), 119(16%), 124(5%), 134(8%), 137(5%), 152(3%); Kovats' index 1229.

Reduction of **3** *to a mixture of* **6** *and* **7**. A 1-ml tapered vial was flame dried and covered with a rubber septum. A solution of 2.7 mg (0.018 mmol) of **7** in 20 μl anhydrous THF was injected into the vial by a syringe. The vial was cooled to 0°C, and 44 μl (0.022 mmol) of a 0.5 M solution of 9-BBN (9-borabicyclo[3.3.1]nonane) in THF was injected into the reaction vial. The mixture was held at 0°C for 3 hr and shaken for another hour at 25°C. Methanol (1 μl) was added followed by 8.8 μl (0.026 mmol) of 3 N NaOH and 7.2 μl (0.06 mmol) of 30% H_2O_2 (exothermic reaction). This mixture was shaken for 0.5 hr at 60°C. The aqueous phase was saturated with anhydrous potassium carbonate and the organic phase was removed. The aqueous phase was extracted with two 50-μl portions of ether. The combined organic extract was washed twice with a 50-μl portion of water and dried ($MgSO_4$), and two compounds were collected from column A (150°C, N_2 80 ml/min). The identity of compounds **6** and **7** from treatment of grandisal and those from reduction of **3** was demonstrated by coinjection on column C and by capillary GC-MS.

RESULTS AND DISCUSSION

Identification of Compounds **4** *and* **5**. The mass spectra of these two compounds are nearly identical (M^+ 152). Combustion analyses and high-resolution mass spectrometry furnish the molecular formula $C_{10}H_{16}O$. Both compounds contain a hydroxyl group as evidenced by a strong broad peak at 3345 cm^{-1} for **4** and at 3300 cm^{-1} for **5** in their IR spectra (which are also nearly identical). The other prominent functional group in **4** and **5** is the vinylidene group (CH_2=). Absorptions from this group are prominent in both IR spectra (strong absorption at 880 cm^{-1}, medium at 1638 cm^{-1}). NMR (^1H and ^{13}C) analysis confirmed the presence of the vinylidene group. The two-proton absorption at δ4.83 for **4** and at δ4.73 for **5** is typical of a strongly coupled AB absorption. The [^{13}C]NMR of **4** (there was an insufficient amount of **5**) contains a peak at δ111.8 (typical for $=\underline{C}H_2$) and at δ148.5 (typical for $=\underline{C}R_2$). The methyl singlets in the [^1H]NMR spectra (δ1.19 for **4** and δ1.03 for **5**) and the lack of other double bonds (shown by the lack of other olefinic carbon absorptions in the [^{13}C]NMR) are strong evidence that the cyclobutane ring remained intact.

Since the molecular formula indicates three degrees of unsaturation, and since only two have been accounted for (one for the vinylidene group and one for the cyclobutane), the compound must contain another ring. That the rings are fused and four- and six-membered can be inferred from the starting structure and the proposed mechanism. Thus we have two diastereomers of 1-methyl-5-methylenebicyclo[4.2.0]octan-3-ol (**4** and **5**). The stereochemical assignments are discussed below.

Identification of **3**. Although enone **3** is not a direct product of grandisal rearrangement, its identification is included here for two reasons: first, it is the main by-product of grandisal oxidation with pyridinium chlorochromate, and second, because the identification of **6** and **7** hinges on structure **3**. Combustion analysis and a molecular ion peak at *m/e* 150 indicated a molecular formula of $C_{10}H_{14}O$. Evidence for a conjugated ketone group was obtained from the IR spectrum (strong absorption at 1655 cm^{-1} and medium absorption at 1281 cm^{-1}) and from the [^{13}C]NMR spectrum (a C=O peak at δ199.8). One double bond is present since two olefinic carbon peaks are found in the [^{13}C]NMR spectrum (δ125.7 and δ162.0). Since only a single olefinic proton can be found in the [^1H]NMR spectrum (δ5.95), the double bond must be trisubstituted. A three-proton singlet at δ1.28 and a three-proton doublet at δ1.87 ($J < 2$ Hz) represent methyl groups. Decoupling showed that the methyl at δ1.87 is allylic because

irradiation at δ5.95 collapsed the doublet to a sharp singlet. A two-proton apparent doublet at δ2.23 is actually a tightly coupled AB system representing a methylene group adjacent to the carbonyl. By the same reasoning as above for the number and sizes of the rings present, compound **3** is 1,5-dimethylbicyclo[4.2.0]oct-4-en-3-one.

Identification of 6 and 7. Compounds **6** and **7** could not be separated on the packed columns used, but separation on the capillary GC-MS system (column C) gave a mass spectrum for each compound that shows M^+ at *m/e* 152. Since the mass spectra of **6** and **7** are nearly identical to those of **3** and **4**, respectively, it is probable that **6** and **7** were merely endocyclic double bond isomers of **4** and **5**. Thus, enone **3**, obtained from grandisol oxidation, on reduction with 9-BBN (9-borabicyclo[3.3.1]nonane) (Krishnamurthy and Brown, 1977), gave a mixture of diastereomers, namely *endo-* and *exo-*1,5-dimethylbicyclo[4.2.0]oct-4-en-3-ol (**6** and **7**). Chromatographic and mass spectral analysis unequivocally showed that compounds **6** and **7** from isomerization of grandisal are identical to the reduction products. The stereochemistry is discussed below.

Identification of 8. High-resolution mass spectral analysis gave a molecular formula of $C_{10}H_{16}O$ (again, isomeric with grandisal). The IR spectrum suggested the presence of a hydroxyl group (strong absorption at 3350 cm^{-1} and a medium absorption at 1032 cm^{-1}). The [^{13}C]NMR clearly indicated the presence of two double bonds because there are four olefinic peaks (δ115.6, 125.9, 135.1, and 146.1). The upfield and downfield peaks (δ115.6 and 146.1, respectively) suggest a vinylidene group; the [^{1}H]NMR spectrum clearly supports this idea with a two-proton absorption at δ4.82. Since there is only one other olefinic proton in the [^{1}H]NMR, the other double bond must be trisubstituted. The three-proton doublet ($J < 2$ Hz) at δ1.76 represents a methyl group. The multiplet at δ2.19–2.37 consists of four methylene groups (eight protons). Decoupling provided the following information: irradiation at δ5.44 (one proton) collapsed the methyl doublet (allylic coupling) at δ1.76 to a sharp singlet, and it affected one of the methylene groups between δ2.19 and 2.33. Thus, the trisubstituted double bond is substituted by the methyl group, and the olefinic proton is adjacent to a methylene group. Irradiation at δ3.94 (the proton on the hydroxyl-bearing carbon) affected only the methylene groups (multiplet at δ2.19–2.33); thus, the hydroxyl carbon is attached only to methylene groups. Finally, since the compound must contain a ring (one degree of unsaturation remaining), the substitution pattern only allows for an eight-membered ring. Thus, component **8** is 3-methyl-7-methylenecyclooct-3-en-1-ol.

We have tentatively assigned the stereochemistry for compounds **4, 5, 6,** and **7,** on the basis of the following arguments. Figure 6 outlines a proposed mechanism (shown for a single enantiomer) to account for the products found in the grandisal rearrangement. We believe that the reaction is a concerted "ene"

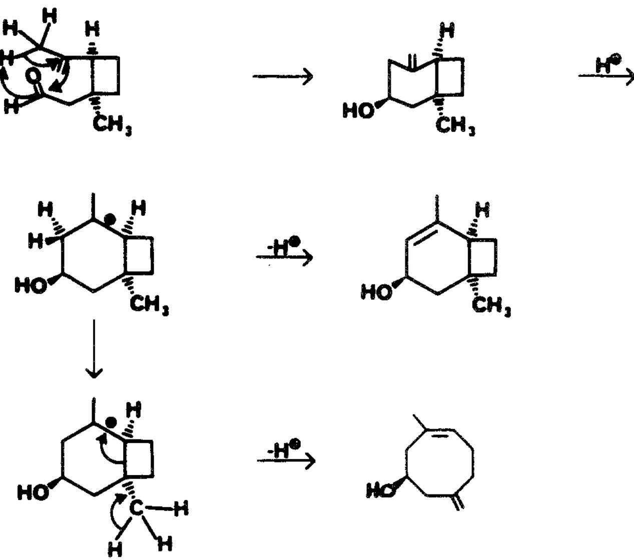

FIG. 6. Proposed mechanism to account for products and stereochemistry of grandisal rearrangement.

reaction (or nearly concerted) to account for the predominance of compounds **4** and **5** bearing the exocyclic double bond (Table 1). In this mechanism, attack of the aldehyde carbon (which probably has considerable cationic character due to the acid-catalyzed nature of the reaction) can occur from either side, but the backside (Figure 6) is relatively more accessible; attack from this side should occur more readily. Since attack from the front is not prohibited, both diastereomers should result. Acid-catalyzed isomerization of the double bond probably occurs at nearly the same rate with each diastereomer; thus, the ratio of **4** to **5** produced initially should be reflected in the ratio of **6** and **7**. Also, since *p*-tosic acid is a better protic acid than silica gel, the double-bond isomerization would be expected to proceed faster in the *p*-tosic acid reaction. The ratios recorded in Table 1 support these arguments. An external check on the stereochemistry can be made from the results of the reduction of enone **3**. Reduction of **3** would be expected to occur from the more accessible side of **3**, thus producing the *endo* alcohol. In other words, the ratio of **6** to **7** is expected to be similar in both cases, and this indeed was found to be the case.

Although the extensive isomerization of grandisal on silica gel, which is very weakly acidic, was quite unexpected, similar results under the weakly acidic conditions of pyridinium chlorochromate oxidation have been demonstrated (Corey and Boger, 1978). Grandisal contains the optimum features described by Corey for acid-catalyzed intramolecular attack by a double bond on

a carbonyl group: formation of a six-membered ring forming a fused-ring system.

Acknowledgments—This study was supported by a grant from the National Science Foundation. We thank Hazel Jennison and Alan Harvey of this college for routine mass spectral data and for the XL-100 NMR work, respectively. We also thank Dr. T. Wachs (Cornell University) for high-resolution mass spectral results and Dr. G. Levy (Syracuse University) for high-field NMR work.

(Received August 8, 1986; Accepted October 21, 1986)

Abstract—Allelopathic effects of entire shoot extract, plant part extracts, and shoot residue of parthenium (*Parthenium hysterophorus* L.) on corn (*Zea mays* L.), ryegrass (*Lolium multiflorum* Lam.), wheat (*Triticum aestivum* L.), velvetleaf (*Abutilon theophrasti* Medik.), and soybean [*Glycine max* (L) Merr.] growth were examined. Parthenium shoot contained water-soluble materials that were toxic to root growth of velvetleaf and wheat. At 4% (w/v) concentration, root growth of velvetleaf and wheat were reduced by 60 and 75%, respectively. The order of increasing sensitivity to parthenium was ryegrass, corn, wheat, and velvetleaf. There was a strong correlation between extract concentration and increased toxicity to test species. The toxicity of plant part extracts was also concentration dependent. At 1 and 2% (w/v), the inflorescence and leaves caused more root inhibition than stem extract. Parthenium shoot incorporated in soil at 1% (w/w) caused significantly more root inhibition of wheat than soybean, corn, and ryegrass. At 4% (w/w), root growth of all the test species was inhibited compared to the control. Toxicity of parthenium residue to wheat diminished with increasing periods of decomposition. Residue decomposed for four weeks was less toxic than the undecomposed residue.

Key Words—Allelopathy, parthenium, *Parthenium hysterophorus*, Compositae, corn, *Zea mays*, ryegrass, *Lolium multiflorum*, wheat, *Triticum aestivum*, velvetleaf, *Abutilon theophrasti*, soybean, *Glycine max*, inhibition.

INTRODUCTION

Parthenium is an annual, Compositae, weed native to the Americas. It is an aggressive weed of disturbed sites and commonly found in cultivated fields. The weed commonly forms huge pure stands and in such areas the vegetation seldom contains other plant species. Such a situation suggests competitive ability and a possible allelopathic mechanism being operative. Weeds like *Sorghum halepense, Salvia leucophylla*, and *Artemisia californica* form pure dense stands and are reported to exert allelopathic influence (Abdul-Wahab and Rice, 1967; Muller et al., 1964).

Discharge of allelochemicals into the environment occurs by exudation of volatile chemicals from living plant parts (Muller, 1965), by leaching of water-soluble toxins from above-ground parts in response to the action of rain (Grummer and Beyer, 1960; Tukey, 1966), by exudation of water-soluble toxins from below-ground parts (Fay and Duke, 1977; Guenzi and McCalla, 1962; Kozel and Tukey, 1968; Woods, 1960), by release of toxins from nonliving plant parts through leaching of toxins from litter decomposition (Guenzi et al., 1967; Patrick, 1971) or microbial by-products resulting from litter decomposition (Kaminsky, 1981; Kimber, 1973; Linderman, 1970).

Allelopathic plants may be used to control weeds or their inhibitory effect on crops could be avoided if several preconditions are met. Their selective toxicity to different plant species should be known. The plant parts with the most inhibitor should be identified and the relationship between inhibition and concentration must be understood. Despite the numerous reports on the allelopathic potentials of parthenium (Kanchan and Jayachandra, 1979a,b; Picman and Picman, 1984; Sarma et al., 1976), the above information is not documented for this important weed. This study was undertaken to fill the information gap.

The objectives of this investigation were to (1) determine the relative toxicity of parthenium water extracts and shoot residue to corn, ryegrass, wheat, and velvetleaf; (2) compare the toxicity of parthenium plant part extracts on root growth of wheat; and (3) evaluate the persistence of parthenium toxicity to wheat.

METHODS AND MATERIALS

Collection and Preparation of Parthenium Residues. Parthenium shoots with seeds were collected in November 1985 from fields near the Tropical Research and Education Center, Homestead, Florida. Plant samples were divided into two portions: plants sectioned into stems, leaves, and inflorescence, and whole shoots. Both plant portions were cut into 1- to 2-cm sections and oven dried at 40°C for a week. All experiments were repeated and the combined data were analyzed.

Plant Species Response to Parthenium Water Extract. Whole parthenium shoot sections were ground in a Wiley mill to pass a 1.27-mm^2 screen and stored in sample bottles at room temperature. Rates of 0, 0.5, 1.0, 2.0, and 4.0% (w/v) were prepared by mixing ground residues in distilled water at room temperature for 5 min with a magnetic stirrer in 250-ml Erlenmyer flasks. Extracts were filtered by vacuum filtration on a Buchner funnel with No. 2 Whatman filter paper. Osmotic potential of the different filtrates was determined by 5100 B Osmometer (Wescor Inc., Logan, Utah). Ten seeds of corn, wheat, ryegrass, and velvetleaf were placed in separate Petri dishes (10 cm diameter) with two No. 2 Whatman filter papers and 10 ml of each extract were added. The Petri dishes were kept in a dark incubator at 25°C and radicle lengths were measured after five days. Each treatment (extract) was replicated four times and the average root length of germinated seedlings per Petri dish was used for statistical analysis. Treatments were arranged in a randomized complete block design. The relationship between root growth and extract concentration for all test species was analyzed by linear regression.

Phytotoxicity of Parthenium Parts to Wheat. Dried sections of stem, leaves, and inflorescence (with seeds) were separately ground and stored in sample bottles at room temperature. Water extracts of each plant part were prepared at 0, 0.5, 1.0, 2.0, and 4.0% (w/v) as above. Ten seeds of wheat were placed in Petri dishes (10-cm diameter) with filter paper, and 10 ml of extract from each plant part were added. Wheat seedlings were grown as described above. Each treatment was replicated four times in a randomized complete block design with 3 (plant parts) × 5 (concentrations) factorial arrangement.

Rate Study with Parthenium Residues. Dried parthenium shoot sections were mixed at 0, 1, 2, and 4 g/100 g of sand and placed in plastic cups (16 oz) without any provision for drainage. Similar concentrations of sphagnum moss were added to controls to provide the same amount of soil organic matter (AlSaadawi and Rice, 1982; Schon and Einhellig, 1982). Ten seeds of wheat, corn, soybean, and ryegrass were planted in each cup at 0.5 cm below the soil surface. Cups were watered as necessary and 20 ml of 1% (w/v) of nutrileaf fertilizer (20-20-20 N,P,K) was added once every week. This fertilizer rate was found adequate to overcome the nutrient immobilization by microbes using sphagnum peat (Achhireddy and Singh, 1984). After 10 days, seedlings were thinned (uprooted) to three plants per cup. Four weeks after planting, plants were harvested and shoot and root lengths were measured. There were four cups per treatment, and cups were arranged in a randomized complete block design. The data were subjected to analysis of variance and least-significant differences of treatment means were determined.

Persistence of Inhibitors from Parthenium Residue. Oven-dried parthenium shoot sections were incorporated into sand at 0, 1, 2, and 4 g/100 g of sand and placed into 15-cm-diameter pots without any provision for drainage. Similar concentrations of sphagnum moss were also added to the sand and placed

in pots. This incorporation was done three times with two-week intervals to give 4, 2, and 0 weeks of decomposition before planting. The growing conditions were as described for the rate study. Each treatment was replicated four times in a randomized complete block design with 4 (residue rate) × 3 (decomposition period) factorial arrangement. After analysis, means for each decomposition time were calculated by averaging across residue rates.

RESULTS AND DISCUSSION

Plant Species Response to Parthenium Water Extracts. Extraction of parthenium shoot residue with water attempts to simulate the natural release of compounds that might be caused by rain acting on the standing or fallen plant material. The osmotic potential of the water extract was −1.8 bar for the highest concentration (4%) and pH was 6.5. Species differed in their response to parthenium water extracts (Figure 1). Ryegrass was the most tolerant while velvetleaf was the most sensitive. Corn and wheat were intermediate in their response. Root growth of the tolerant ryegrass was inhibited by 15%, whereas root length of velvetleaf was reduced by about 75% at the 4% concentration level. This demonstrates species-specific allelopathy. Overland (1966) found that the inhibitory action of barley (*Hordeum vulgare* L.) varied with test species. In general, chickweed [*Stellaria media* (L.) Cyp.] growth was strongly inhibited, shepherdspurse [*Capsella bursa-pastoris* (L.) Medik] and tobacco (*Nicotiana tabacum* L.) moderately inhibited, and wheat was not affected in the presence of living plants and dead roots of barley. The data (Figure 1) also showed that the allelopathic response of the two sensitive species, wheat and velvetleaf, was concentration dependent. Root inhibition increased with an in-

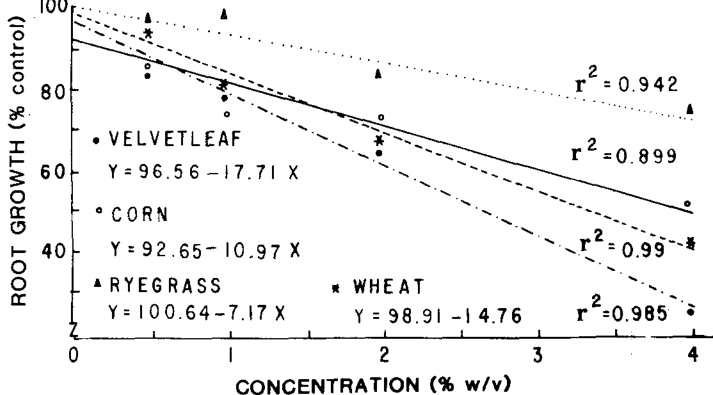

FIG. 1. The effect of various concentrations of parthenium extracts on root growth of corn, ryegrass, velvetleaf, and wheat.

crease in the concentration of the water extract. The relationship between root inhibition and extract concentration was similar for velvetleaf and wheat. However, the rate of root inhibition for the tolerant ryegrass was significantly lower ($P = 0.05$) than for the other species. Results are in agreement with previous investigations (Caussanel, 1979; Bhowmik and Doll, 1982) in that the activity of water extracts from allelopathic weeds was directly related to the extract concentrations. The results of these experiments demonstrated that water extracts of parthenium residue produced allelopathic inhibition, and the effects were dependent on extract concentration and test species.

Phytotoxicity of Parthenium Plant Part Extracts to Wheat. The effects of parthenium plant parts to wheat were also concentration dependent (Figure 2). At the lowest concentration (0.5%), the inflorescence extract significantly reduced wheat root growth compared to the leaf and stem extract. However, at 1 and 2%, the wheat root inhibition was similar for the inflorescence and leaves. At the highest extract concentration (4%), there was no significant difference among the plant parts. The differences observed at the lowest concentration of the inflorescence extract and the other plant parts, which were obtained from the same amounts of material, suggest that the inflorescence contains proportionally higher amounts of the allelopathic compounds than other plant parts. Kanchan and Jayachandra (1979a) also reported that soil from which parthenium plants were removed at the rosette and flowering stages caused greater inhibition of bean (*Phaseolus vulgaris* L.) nodulation and root and shoot growth than soil from which the weed was removed at the four-leaf stage.

Rate Study with Parthenium Residue. The incorporation of peat at all rates did not affect the shoot or root growth of corn, wheat, and soybean (Table 1).

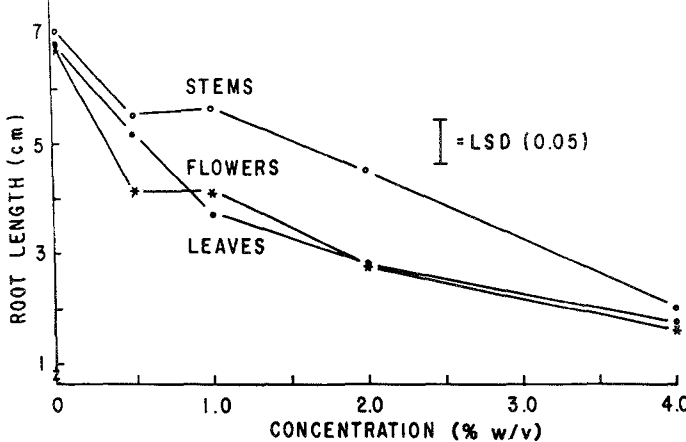

FIG. 2. Effects of water extracts of parthenium plant parts on the root lengths of wheat.

[a]Means ± SE.

In ryegrass, growth was significantly stimulated by peat compared to sand. This lack of root growth inhibition by peat even at 4% shows that any growth effect by parthenium shoot is not due to mere plant residue presence in the sand. Rather, it indicates a possible allelopathic effect by parthenium shoot on the test species.

The plant species differed in their response to the rate of parthenium residue in the growing medium. The data indicated that the root growth of corn and soybean was affected only by the highest rate (4%), whereas wheat was significantly inhibited by the lowest rate of parthenium. Root length of ryegrass in sand was lower than in all rates of peat as well as parthenium. However, root length of ryegrass in the highest rate of parthenium (4%) was significantly lower than the two lower rates (1 and 2%). The sensitivity of wheat observed in this experiment was in agreement with the results of the extract experiment (Figure 1). In both studies, wheat was more sensitive to parthenium than corn or ryegrass.

Allelochemicals from parthenium could be released through two possible mechanisms: either allelochemicals were produced by microorganisms during residue decomposition or they were leached directly from the residue. Residue extracts were toxic as evidenced in the laboratory experiments (Figure 1).

The allelochemicals released by the parthenium residue could have inhibited root growth by at least two mechanisms. The first possible target is cell division in roots (Bhowmik and Doll, 1982). Phenolics represent one of the largest groups of allelochemicals, and Avers and Goodwin (1956) have shown that various phenolic compounds inhibited cell division. It is also possible that cell elongation was affected by extracts of weed residues. Tomaszewski and Thimann (1966) found many allelochemicals inhibited gibberellin, and indoleacetic acid induced growth. These phenomena may account for the root inhibition of test species by the highest rate of parthenium residue.

Persistence of Inhibitors from Decaying Parthenium Residue. Wheat planted in the undecomposed parthenium had shorter root length than wheat in the residues decomposed for two and four weeks (Table 2). The means were averaged across four residue rates for each decomposition period. The statistical analyses also showed a significant interaction between decomposition period and root growth. Patrick et al. (1963) also reported decreased toxicity of barley, rye, and wheat residues to lettuce (*Lactuca sativa* L.) and spinich (*Spinacia oleracea* L.) seedlings with increasing periods of decomposition. Such diminished phytotoxicity with increasing decomposition period could be due to breakdown of inhibitors by microorganisms. The undecomposed parthenium residue also reduced shoot length of wheat more than residues decomposed for two and four weeks before planting (Table 2). However, shoot length means for two and four weeks were not significantly different as in the case of root length. This was similar to results obtained for residue rate study (Table 1) where roots were found to be more sensitive than shoots. In field studies, Patrick et al. (1963) found allelopathic injury to roots of lettuce and spinach seedlings was confined mainly to those parts in direct contact with or in the immediate vicinity of decomposing plant fragments in the soil.

TABLE 2. EFFECTS OF DIFFERENT LENGTHS OF DECOMPOSITION OF SOIL-INCORPORATED PARTHENIUM SHOOT ON ROOT AND SHOOT GROWTH OF WHEAT[a]

Decomposition time (weeks)	Root length (cm)	Shoot length (cm)
0	9.3c	20.4b
2	15.2b	31.8a
4	18.1a	32.7a

[a] Means within a column followed by the same letter are not significantly different at the 5% level according to Duncan's multiple-range test.

The results of this investigation demonstrated that the water extracts of parthenium shoot produced allelopathic inhibitors, and the effects were species-specific and concentration dependent. Furthermore, the study showed that the inflorescence contained proportionally higher amounts of inhibitors than the other above-ground parts. Toxicity from parthenium residue diminished with increased time of decomposition, indicating a breakdown of inhibitors within four weeks.

(Received July 30, 1986; accepted October 22, 1986)

Abstract—High concentrations of synthetic sex pheromone caused increased flight activity among mated female spruce budworm of all ages, a fact that may indicate an increase in dispersal. Flight activity also increased among older virgin females, but not among females one day old, the age at which they usually mate. Receptivity of young virgin females to courting males was not affected by pheromone-permeated air. Synthetic sex pheromone is therefore not likely to influence mating frequency through its effects on female activity.

Key Words—Spruce budworm *Choristoneura fumiferana*, Lepidoptera, Tortricidae, sex pheromone, female response, flight, copulation, dispersal.

INTRODUCTION

In the majority of Lepidoptera, male moths are "attracted" to the female moth by female-emitted sex pheromones. In a few species it has been shown that the female moths themselves are able to perceive the sex pheromone of their own species (Grant, 1970; Mitchell et al., 1972; Birch, 1977; Palaniswamy and Seabrook, 1978; Light and Birch, 1979).

The pheromone receptors of female spruce budworm [*Choristoneura fumiferana* (Clem.)] are on the antennae (Ross et al., 1979). Palaniswamy and Seabrook (1978) found that 3-day-old virgin female spruce budworm moths reacted to the synthetic pheromone of their own species by increased walking, increased flexing of the abdomen, and extension of the ovipositor. They also found that the number of moths responding was related to the dosage of the synthetic pheromone. Later Palaniswamy and Seabrook (1985) showed that a

0098-0331/87/0700-1749$05.00/0 © 1987 Plenum Publishing Corporation

higher proportion of females ''call'' (extrude the pheromone gland) in the presence of pheromone and that they start calling at least 2 hr earlier than in pheromone-free air. The implications of this behavior for population dynamics and control of spruce budworm could be profound. First, since moving female budworm do not call, high concentrations of pheromone that cause an increase in activity could result in a reduction in mating and hence a reduction in population density. Second, it could influence the dispersal of mated female moths, an important factor in the population dynamics of spruce budworm (Greenbank et al., 1980). The outcome of computer simulations of population dynamics is profoundly affected by whether or not dispersal is related to population density (Clark, 1979). The available evidence suggests that dispersal does not occur at low population densities (Greenbank et al., 1980). If this is so, then the question arises as to which factors trigger dispersal. One possibility is the high concentration of pheromone associated with high population density (Palaniswamy and Seabrook, 1978; Sanders, 1979a).

The experiments described here were carried out to determine if flight activity of female spruce budworm moths is increased, and if female spruce budworm are less receptive to the advances of male moths, in the presence of synthetic pheromone.

METHODS AND MATERIALS

All insects were from laboratory-reared stock, maintained at the Forest Pest Management Institute and the Great Lakes Forestry Centre, of the Canadian Forestry Service, Sault Ste. Marie, Ontario. The larvae were reared on synthetic diet (Grisdale 1970) and the insects were sexed as pupae, which were placed in separate cages for emergence. Conditions were maintained at 20°C and 70% relative humidity throughout.

Female Flight Activity. Flight activity was recorded by the technique described previously (Edwards, 1962; Sanders and Lucuik, 1975) of measuring the electrostatic disturbance caused by a moth flying inside a Faraday cage, 30 × 30 × 30 cm. There were four treatments: mated or virgin females with or without pheromone.

Freshly emerged female moths were collected between 0900 and 1200 hr the day before each experiment began. When mated females were required, the freshly picked-off females were placed in a screen cage with 1-day-old male moths. Mated pairs were removed from this cage every hour, placed in a separate cage, and left overnight. At 1200 hr the following day, 10 females were placed in the Faraday cage. Shoots of balsam fir, about 15 cm long, were placed in each of the four corners of the cage as resting and oviposition sites, and these were replaced with fresh shoots each morning. Electrostatic charges caused by moths flying in the cage were amplified and relayed to an event recorder. Each experiment was run continuously for three days.

For the experiments involving the pheromone, 14 pheromone dispensers were pinned to the outside of the cage, one at each of the eight corners, and one in the center of each side and the floor and roof. The dispensers were polyvinyl chloride pellets (Sanders, 1981) measuring 10 mm long × 4 mm diameter, containing 0.3% w/w of a 95 : 5 blend of (*E* : *Z*)-11-tetradecenal, the major components of the sex pheromone of the spruce budworm (Sanders and Weatherston, 1976; Silk et al., 1980). The pellets were aged 7–10 days before use, at which time the release rate of pheromone in moving air is estimated to be between 100 and 200 ng/hr (Sanders, 1981; Meighen et al., 1983).

The Faraday cage was housed inside a 0.12-m^3 (4-ft^3) controlled environment cabinet, maintained at 20°C with a light–dark cycle of 17 : 7. The air in the cabinet was recirculated and would therefore have been heavily laden with pheromone, although the concentration was not measured. In order to minimize the possibility of contamination by pheromone, treatments were run in the following sequence. Two treatments each of virgin and mated females in clean air were followed by one treatment each of virgin and mated females in pheromone-permeated air. An ultraviolet lamp was then placed in the environment cabinet for 10 days to hasten the degradation of the pheromone. The Faraday cage and the inside of the cabinets were then washed with soap and water and left for 60 days before the above sequence of treatments was repeated.

Female Copulation. The objective of this experiment was to determine the reaction of calling (i.e., sexually responsive) female moths to courting males in pheromone-laden air. The experiments were carried out in a glass wind tunnel 90 × 90 cm in cross-section, and 2 m long. A nylon screen was placed across the tunnel about 50 cm in from the downwind end. Attached to the screen were 16 circular "fences" made of aluminum screening 2 cm high and 12 cm in diameter. These were arranged at uniform spacing, and their purpose was to provide "roosting" niches for the female moths, to encourage them to remain on the screen and not to walk on the sides or roof of the tunnel.

Two hours before "lights-off," 1-day-old virgin female moths were placed on the screen and allowed to move around freely. After 1 hr the assays began. Two-day-old male moths in small wire cages were held, one at a time, downwind from each female moth that was on the screen. When a male responded by wing-fanning, the cover of the wire cage was removed and the male was allowed to fly upwind towards the female. As soon as the male touched the female, a stop watch was started. The reaction of the female on being touched by the male was recorded. If she moved more than 2.5 cm, she was recorded as having moved. The time was recorded until the pair copulated or until they lost contact. Assays were recorded only for those females that were on the screen, at least 2.5 cm from the edge, where males could approach and land on the screen without landing on the sides of the tunnel.

To minimize the risk of contamination, a new screen was used after each treatment, and a sequence of experiments began with a clean air treatment,

followed by treatments of successively more concentrated pheromone. After a full sequence of treatments, the tunnel was left for one week with a UV lamp inside it. It was then washed with soap and water. The complete sequence was repeated six times. The air in the tunnel was permeated with pheromone by pinning pieces of polyvinyl chloride impregnated with pheromone to a screen at the upwind end of the tunnel as previously described (Sanders, 1982). The screen was intersected by a 9 × 9 grid of 2.5-cm-wide masking tape, and a piece of PVC, 4 mm diam × 10 cm long, was pinned at each of the 81 intersecting points. The tape created turbulence which thoroughly mixed the air, as could be demonstrated by visualization of the airflow with smoke. At a point 30 cm downwind from the first screen, the air passed through a second screen which smoothed out the airflow as it passed into the observation area of the tunnel. PVC pellets containing three different concentrations of the pheromone were used: 0.0003, 0.003, and 0.03% synthetic pheromone w/w. On the basis of release-rate measurements (Sanders, 1981, Sanders and Meighen, in preparation) and an airflow of 25 cm/sec, concentrations of pheromone in the tunnel were estimated to be 10, 100, and 1000 p/m^3, respectively (Sanders, 1982.). The numbers of female moths used in a treatment varied, depending upon the supply; for any one treatment the maximum was 40, the minimum 10.

Numbers of moths responding in the different treatments were analyzed for differences by the G test (Sokal and Rohlf, 1981). The times from contact to copulation were transformed to logarithms and then subjected to analysis of variance.

RESULTS

Female Flight Activity. The flight activity of virgin female moths in clean air and pheromone-laden air is shown in Figure 1A, that of mated females in Figure 1B. For both virgin and mated females, the circadian pattern of activity was similar; it began early in the afternoon, peaked between 1600 and 2000 hr, and decreased to virtually zero by midnight. Flight activity was higher, by a factor of 10, among the mated females than the virgin females. Both virgin and mated females showed higher levels of activity in the presence of the pheromone. Among the virgin females, there was very little flight activity on the first day following emergence, in either clean or pheromone-laden air. On the second and third days, activity was still very low in clean air, reaching a peak of only 4 flights/hr. In the pheromone-laden air, activity increased to 17 flights/hr on the second day and to over 30 on the third day. Among the mated females, differences were most pronounced on the first two days, increasing from peaks of 10 in clean air to over 100 flights/hr in the pheromone-permeated air on the first day, from 46 to over 200 on the second day, but from 130 to only 195 on the third day.

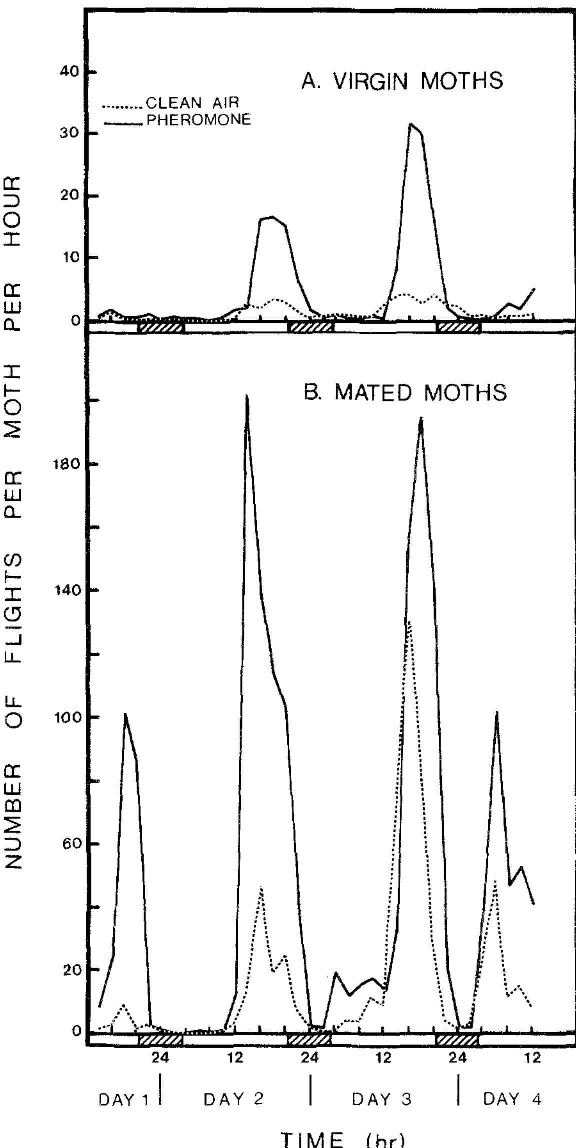

FIG. 1. Number of flights per hour per female spruce budworm moth recorded in an activity chamber in pheromone-permeated air (solid lines) and clean air (dotted lines). (A) Virgin female moths; (B) mated female moths. The day of emergence and mating is counted as day 0; recordings started when females were 24 hr old. In both A and B, the pheromone treatment = 2 replicates of 10 females each, the clean air = 5 replicates of 10 females each.

Female Copulation. No significant differences were recorded in the numbers of females that settled on the screen in the wind tunnel in the four different treatments. In clean air, 84 out of a total of 195 (43%) females settled on the screen; in the pheromone-laden air, in order of increasing concentrations, the figures were 70/179 (39%), 76/181 (42%) and 50/145 (34%).

In the clean air and in the lowest concentration of pheromone, males responded to the females by wing-fanning and flying upwind from a distance of 50 cm. However, at the two higher pheromone concentrations, males started wing-fanning as soon as they encountered the air flow in the tunnel; in order to have them "lock-on" to the pheromone plume from a female, they had to be held 10–20 cm from the females. Once the males were locked onto a female pheromone plume, their behavior was similar in all four treatments; they landed close to the female and ran around, fanning their wings until they contacted her. The first contact of a female by a male was usually with its antennae (confirmed in many instances by video recordings). After antennal contact, males began courting the female as described in Sanders (1979b). Occasionally the approaching male landed on top of the female, causing the female to fly immediately or drop from the screen. However, since this occurred in only 3% of the contacts, the effect on the overall results was negligible. On being contacted by the male, females were classified as remaining stationary or moving. To qualify for the latter category they had to move at least 2.5 cm before stopping.

The reactions of the females to the males in the four treatments, and the times between contact and copulation, are shown in Table 1. There were no significant differences among the four treatments. Fewer male–female contacts were obtained at the highest pheromone concentration. This was because the males had difficulty locating the females against the high background of pheromone, and not because of changes in female behavior. In 137 (62%) of the total of 222 contacts, the females remained stationary. None of these 137 females showed any visible reaction to the male, and in 121 (88%) of the encounters copulation followed in an average time of 3.3 sec from time of first contact. In the other 16 (12%) encounters, either the males lost their footing and departed before successfully copulating, or the females moved off after the males had made repeated but unsuccessful copulatory attempts.

In the remaining 79 encounters, the female moth walked away when contacted, and in 24 instances (28% of all those in which the female moved or flew), the male pursued and copulated with the female. This, of course, took longer than when the female remained stationary, the average duration from contact to copulation being 11.4 sec.

DISCUSSION

In the absence of pheromone, the levels of flight activity and the circadian patterns of flight activity of both virgin and mated females are very similar to

TABLE 1. RESPONSES OF VIRGIN FEMALE SPRUCE BUDWORM MOTHS AFTER BEING CONTACTED BY ATTRACTED MALE IN WIND TUNNEL IN CLEAN AIR AND PHEROMONE-PERMEATED AIR

those reported in previous experiments (Sanders and Lucuik, 1975). As in the previous experiment, mated moths were more active than virgin moths, particularly on days 2 and 3 (counting the day of emergence and mating as day 0. This is when dispersal probably begins, at least at higher population densities (Sanders and Lucuik, 1975; Greenbank et al., 1980). Flight activity peaked on day 3, the day on which female antennae show maximum response to pheromone (Ross et al., 1979).

The presence of the pheromone clearly increased flight activity levels of both virgin and mated females, although the virgin females remained inactive for a full 48 hr after emergence, even in the presence of the pheromone. On day 3, virgin females showed a marked increase in activity in the presence of the pheromone. This corresponds with observations of increased walking and oviposition in 3-day-old virgin spruce budworm in the presence of pheromone reported by Palaniswamy and Seabrook (1978). The same authors pointed out that mobile moths do not copulate, a factor that could contribute to the disruptive effect of pheromone on mating. However, the effects of pheromone on the activity of virgin females may not be of great significance in the field, since most females are mated in the first or second day after emergence when activity levels are low. Therefore, the evidence here suggests that the incidence of mating is not likely to be decreased because of increased activity of the virgin females in the presence of the pheromone

Among mated females, the largest increase in flight activity associated with pheromone occurred on day 2, the day of maximum oviposition and maximum dispersal activity (Sanders and Lucuik, 1975; Greenbank et al., 1980). However, levels of flight activity as measured in the activity cage must be interpreted with caution (Sanders et al., 1978). There is no way of differentiating between local flights associated with oviposition, long-range dispersal flight, or flight in response to the pheromone. The fact that peak activity in the cage corresponds to the time of peak dispersal suggests that much of the increased activity of mated females in the presence of pheromone is related to dispersal. This suggests that the incidence of dispersal is increased in the presence of high concentrations of pheromone. However, in field trials designed to determine the effects of synthetic pheromone on mating and dispersal behavior, no increase in dispersal activity has been observed from scaffold towers above the forest canopy (Sanders, 1979c; Sanders and Silk, 1982).

Results from the activity cage (Figure 1) indicate that female moths do not become habituated to the pheromone. Even though they were subjected to continuous high concentrations of pheromone for several days, increased flight activity occurred each day and persisted over several hours each day. Such behavior would be necessary for the pheromone to act as a dispersal cue.

The wind-tunnel bioassays (Table 1) indicate that the incidence of mating is not affected by changes in the receptivity of the female moth to courting males

in the presence of pheromone-laden air: there were no significant differences in any of the criteria of Table 1 attributable to the pheromone. It is possible that the tests were biased, because the bioassays were restricted to those females that had settled on the screen; any females that did not settle were removed from the sample. Palaniswamy and Seabrook (1985) have shown that a greater proportion of virgin female spruce budworm moths call and that they start calling earlier in the presence of pheromone; this would result in a higher proportion of receptive females and more settling on the screen in the presence of the pheromone in the present experiment. However, the fact that the proportions of females settling on the screen were not significantly different among the four treatments suggests that there was no bias.

Therefore, it is concluded that pheromone-permeated air does not affect the incidence of mating of spruce budworm moths by changing the activity levels of the virgin female moths, or by altering the receptivity of virgin females to courting males. This suggests that disruption of spruce budworm mating by synthetic sex pheromone is caused solely by the effects of the pheromone on the male moths. High concentrations of pheromone may result in more dispersal of mated female moths, since the activity level of mated females is markedly increased in pheromone-permeated air, but it is questionable if this would occur at the pheromone concentrations attained in field disruption trials.

These experiments were carried out with the two major components of the spruce budworm pheromone. It is possible that minor pheromone components (Silk et al., 1980; Sanders, 1984) could significantly affect female moth behavior.

Albany, California 94710

(Received June 9, 1986; accepted October 23, 1986)

Abstract—The indolizidine alkaloid, castanospermine (1,6,7,8-tetrahydroxy-octahydroindolizidine—a stereochemical mimic of glucose found in the Australian legume *Castanospermum australe*), differentially inhibited cellobiose, lactose, maltose, sucrose, and trehalose hydrolyzing enzymes from a broad taxonomic spectrum of insects (19 species from 12 different families). It was a potent inhibitor of cellobiase activity of all insects tested (50% inhibition at $\leq 3.2 \times 10^{-5}$ M castanospermine). With one exception, it also inhibited lactase activity of all insects examined. Only in the sap-feeding Homoptera did castanospermine inhibit all disaccharidase activities assayed. Trehalase activity of the Lepidoptera and Diptera was generally inhibited by castanospermine, whereas inhibition of trehalase activity of the Coleoptera by castanospermine was exiguous or not detectable. Castanospermine was a significant feeding deterrent towards pea aphids, *Acyrthosiphon pisum*, with an ED_{50} of 1×10^{-4} M in artificial diets. Two compounds stereochemically related to castanospermine, deoxynojirimycin and 6-epicastanospermine, were each slightly active at deterring the feeding of green peach aphids, *Myzus persicae*, ($ED_{50} = 2.5 \times 10^{-3}$ M) and greenbugs, *Schizaphis graminum* ($ED_{50} = 5 \times 10^{-3}$ M), respectively. Among the insects studied there was no distinct relationship between enzyme inhibition and adaptation to host plants containing castanospermine or other toxic alkaloids.

Key Words—Castanospermine, 6-epicastanospermine, deoxynojirimycin, cellobiase, lactase, maltase, sucrase, trehalase, endosymbiote, insect-plant interactions, allelochemicals, Homoptera, Coleoptera, Lepidoptera, Diptera.

INTRODUCTION

The indolizidine alkaloid, castanospermine (1,6,7,8-tetrahydroxyoctahydroindolizidine) (Figure 1A), occurs in the leguminous tree *Castanospermum australe* A. Cunn., the Moreton Bay chestnut or black bean, native to Queensland, Australia (Hohenschutz et al., 1981). The seeds of *Castanospermum* contain 0.3% castanospermine and are toxic to mammals (Elbein and Molyneux, 1986). A number of recent studies have shown that this alkaloid is either toxic or a feeding deterrent to insects. Studies by Nash et al. (1985) showed that larval development of the cow pea weevil, *Callosobruchus maculatus* F., was totally inhibited by 0.03% castanospermine incorporated into seed meal from the cow pea, *Vigna unguiculata* (L.) Walp. Fecundity of the confused flour beetle, *Tribolium confusum* du Val was reduced by 50% and 95% when castanospermine was incorporated into the diet at 0.01% and 0.1%, respectively. These same researchers found that castanospermine differentially inhibited feeding by two locusts. Whereas nymphs of *Locusta migratoria* (Reiche & Fairmaire) (the migratory locust) were deterred from feeding on sucrose by 0.02, 0.1, and 0.5% incorporation of castanospermine, nymphs of *Schistocerca gregaria* (Forskal) (the desert locust) were unaffected by the same concentrations. Dreyer et al. (1985) found that castanospermine was the most potent deterrent to feeding by the pea aphid, *Acyrthosiphon pisum* (Harris) of 11 pyrrolizidine, indolizidine, and quinolizidine alkaloids tested [50% of aphids were deterred from feeding on an artificial diet by only 0.002% (1×10^{-4} M) castanospermine].

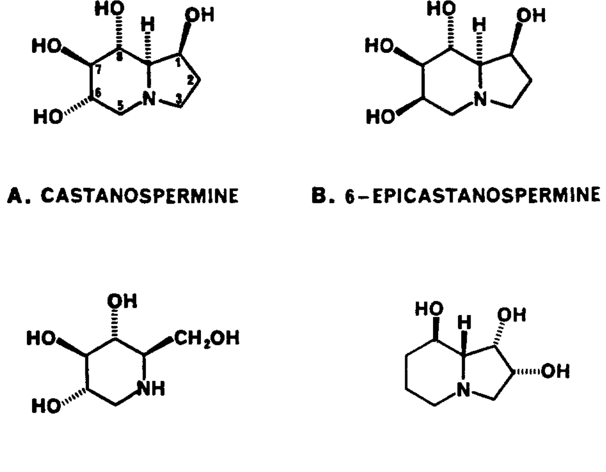

FIG. 1. Chemical structures of some polyhydroxy alkaloids known to inhibit the activity of certain glycosidases.

Castanospermine is a structural and stereochemical mimic of glucose and has been shown to be a potent inhibitor of various glycosidases from a number of sources. Scofield et al. (1986) found that castanospermine inhibited all mouse intestinal mucosal disaccharidase activities tested, including a number of α- and β-glucosidases and β-galactosidases. Castanospermine concentrations that resulted in 50% inhibition ranged from 1.7×10^{-5} M for β-glucosidase to 4.2×10^{-8} M for sucrase. However, castanospermine had differential inhibitory activity when screened against a variety of commercially available glycosidases (Saul et al., 1983). Castanospermine was most inhibitory to β-glucosidase of almond emulsin (50% inhibition at 5×10^{-5} M) and least inhibitory to β-xylosidase from *Aspergillus* (50% inhibition at 5×10^{-4} M). Additionally, castanospermine was a potent inhibitor (50% inhibition at $\leq 5 \times 10^{-5}$ M) of fibroblast β-glucocerebrosidase and lysosomal α-glucosidase. However, it was not inhibitory to a number of glycosidases from various sources including certain α-glucosidases, α- and β-galactosidases, α- and β-mannosidases, α- and β-fucosidases, β-glucuronidases, and β-*N*-acetylhexosaminidases. The β-glucosidase inhibition was not time-dependent and was seemingly of the mixed type.

Trugnan et al. (1986) found that castanospermine was a potent inhibitor of sucrase from a cell culture line of human colon cancer cells (Caco-2). They also determined that this inhibition was noncompetitive (interacting with the enzyme), and time- and dose-dependent. A preincubation period of 1 hr before assay resulted in castanospermine inhibiting sucrase activity by 50% at as low a concentration as 4×10^{-9} M, the most potent inhibition of sucrase known to date.

In view of the variable activity of castanospermine on inhibiting glycosidases from the above sources, we felt it would be of interest to examine the inhibitory activity of castanospermine on five disaccharidases known to occur in the midguts of a number of insect species (Treherne, 1967). We were particularly interested in the prospect of castanospermine as a selective inhibitor of insect trehalase. Also, we investigated the effect of castanospermine and two other structurally related polyhydroxy-imino alkaloids, 6-epicastanospermine (Figure 1B) and desoxynojirimycin (Figure 1C), on the feeding behavior of a legume-feeding aphid and two other species of aphids which do not naturally feed on legumes. In view of the stereochemical similarities of these alkaloids to hexose substrates, we hoped to determine if there was a connection between disaccharidase inhibition and effect on feeding behavior that would relate to insect–plant interactions. Next, we examined if a relationship occurred between disaccharidase inhibition by castanospermine and the taxonomic relatedness of the insects assayed. Finally, we investigated whether castanospermine might facilitate the biochemical characterization of certain insect glycosidases which are difficult to separate by traditional chromatographic or electrophoretic techniques.

METHODS AND MATERIALS

Castanospermine. Castanospermine was extracted from seeds of *C. australe* and purified according to procedures previously described (Hohenschutz et al., 1981).

Insects. All homogenates were made using live insects from colonies kept for ongoing research or collected from host plants in the field. Larvae of the fall armyworm, *Spodoptera frugiperda* (J.E. Smith), the pink bollworm, *Pectinophora gossypiella* (Saunders), the western spruce budworm, *Choristineura occidentalis* (Freemann), and the codling moth, *Cydia pomonella* L., were maintained from egg-hatch on standard artificial diets. Adults of the maize weevil, *Sitophilus zeamais* Motchulsky, and the rice weevil, *S. oryzae* (L.), and larvae of the Angoumois grain moth, *Sitotroga cerealella* (Olivier), were from colonies maintained on wheat grain (*Triticum aestivum* L. var. Scout 66). Adults of the Egyptian alfalfa weevil, *Hypera brunneipennis* (Boheman), were reared on alfalfa (*Medicago sativa* L. var. CUF-101). Spotted alfalfa aphids, *Therioaphis maculata* (Buckton), and pea aphids, *Acyrthosiphon pisum* (Harris), were from colonies maintained on alfalfa variety Caliverde. Larvae of the tobacco hornworm, *Manduca sexta* (Johannson), were reared on tomato plants (*Lycopersicon esculentum* Mill. var. Rutgers). Aphids of the greenbug, *Schizaphis graminum* (Rondani), were from a colony maintained on sorghum [*Sorghum bicolor* (L.) Moench. var. BOK-8]. Mealybugs, *Pseudococcus longispinus* (Targioni-Tozzetti), were from a colony maintained on Moreton Bay chestnut plants. Aphids of the green peach aphid, *Myzus persicae* (Sulzer), were from a colony maintained on mustard seedlings (*Brassica alba* Rabenh. var. Tendergreen). Larvae of the navel orangeworm, *Amyelois transitella* (Walker), were from a colony maintained on commercially purchased walnuts. All of the above insects are moderate to serious agricultural pests.

Seed beetles, *Acanthoscelides aureolus* (Horn), were collected in the field from locoweed, *Astragalus oxyphysus* Gray. Larvae of a tephritid were collected from pods of a wild lupin, *Lupinus* sp. These insects were included in the study because of their adaptation to poisonous range plants which contain quinolizidine or indolizidine alkaloids, some of which are known glycosidase inhibitors (Elbein and Molyneux, 1986). Lastly, the only predacious insect studied was the convergent ladybird beetle, *Hippodamia convergens* Guérin-Méneville, adults of which were purchased from Natural Pest Controls, Sacramento, California.

Enzyme Preparation and Assay. Insects were homogenized at 2% live wt/*v* in 0.2 M acetate buffer (pH 5.1), 0.01 M dithiothreitol (DTT), with 1.0% polyvinylpyrrolidone, using a glass tissue grinder (Ten Broeck). The homogenates were centrifuged at 15,000 rpm for 10 min, the supernatant recentrifuged and then "desalted" on Poly-Prep columns (Bio Rad, Richmond, California) packed with Bio Gel P-6, using the 0.2 M acetate −0.01 M DTT buffer as the

eluting solvent. The protein-containing fractions were recentrifuged at 15,000 rpm for 10 min and the supernatants used for the enzyme assays. All enzyme preparative procedures were performed at 4°C. The following disaccharides served as substrates: cellobiose (4-*O*-β-D-glucopyranosyl-D-glucose), lactose (4-*O*-β-D-galactopyranosyl-D-glucose), maltose (4-*O*-α-D-glucopyranosyl-D-glucose), sucrose (β-D-fructofuranosyl-α-D-glucopyranoside), and trehalose (α-D-glucopyranosyl-α-D-glucopyranoside) (Sigma Chemical Co., St. Louis, Missouri). Assays were performed by first adding 100 μl aliquots of 0.04 M solutions of substrates in 0.2 M acetate buffer (pH 5.1), containing diminishing concentrations of castanospermine (range = 5×10^{-4} M to 3×10^{-8} M castanospermine), to individual wells of microtiter plates (NUNC, Denmark). Next, 100 μl of enzyme preparation were added to the substrate making the final concentration of substrate 0.02 M. Each substrate–castanospermine concentration was replicated three times. The enzyme–substrate–castanospermine mixtures were incubated at 27°C on a shaker for 0.5 hr.

The reaction was terminated by addition of 100 μl of a 2.5% solution of Flozyme [a commercially prepared reagent for quantitation of glucose using a coupled-enzyme system of glucose oxidase and peroxidase as modified by Trinder (1969); Worthington Diagnostic Systems Inc., Freehold, New Jersey] with an additional 0.5 hr of incubation for chromophore development. Liberated glucose was quantitated by measuring the oxidized quinoneimine chromophore spectrophotometrically at 500 nm. The Flozyme reagent was not affected by even the highest concentration (2.5×10^{-4} M) of castanospermine. Trace quantities of free glucose in insect–enzyme preparations were considered in calculating background enzyme activity. No attempt was made to purify or separate any of the enzymes, and activities simply reflect the rate of hydrolysis of the substrates. Specific activities of the disaccharidases are expressed in katals per milligram protein; where 1 katal equals one mole of substrate hydrolyzed/sec. Quantitation of protein content in insect enzyme preparations was determined using the Bio-Rad Protein Assay (Bio-Rad, Richmond, California) as originally developed by Bradford (1976). Inhibition of enzyme activity is based upon the concentration of castanospermine that inhibited substrate hydrolysis by 50%. This concentration was determined using a computer-generated polynomial regression (Draper and Smith, 1966) of percent enzyme-activity inhibition (in comparison to controls) versus $\log_{10}$ concentration castanospermine. All polynomial regressions for calculating the 50% inhibition concentrations of all enzymes assayed had an $R^2 \geq 0.97$. Castanospermine was considered to be inactive for a given enzyme if concentrations of $>2.5 \times 10^{-4}$ M were required to achieve 50% inhibition. Because the enzymes were not purified, K_m and K_i values and type of enzyme inhibition could not be reliably determined.

Aphid Feeding Bioassays. Bioassays to test the feeding deterrency towards aphids of castanospermine, a related analog, 6-epicastanospermine (Figure 1B), and deoxynojirimycin (Figure 1C), a polyhydroxy alkaloid occurring naturally

in certain species of *Bacillus* and roots of mulberry (Nash et al., 1985), were performed as previously described (Dreyer et al., 1981). Deoxynojirimycin was obtained through the courtesy of E. Truscheit and D. Schmidt, Bayer A.G. Castanospermine and 6-epicastanospermine were isolated from *Castanospermum australe* seeds (Molyneux et al., 1986). These compounds were bioassayed against *A. pisum*, whose host plants consist of a wide range of legumes, and *S. graminum* and *M. persicae*, which do not feed on legumes. Results were expressed as the concentration of alkaloid that deters aphid feeding by 50% in comparison to aphids feeding on control diets (ED_{50}). These concentrations were calculated by a probit-analysis program to generate a dose–response curve (Schoofs and Willhite, 1984).

RESULTS

The specific activities of the disaccharidases studied for each species of insect and the effect of castanospermine on enzyme activity (as expressed by concentration required for 50% inhibition) are shown in Table 1. There are a number of conspicuous characteristics related to differential insect disaccharidase activities and their inhibition by castanospermine. Firstly, only in the case of the Homoptera [i.e., the aphids (*M. persicae, A. pisum, T. maculata, S. graminum*) and the mealybug (*P. longispinus*)] were all five disaccharidases inhibited by castanospermine. Moreover, inhibition of sucrase activity by castanospermine was only observed for this group of sap-feeding insects. Secondly, cellobiase and lactase activities were inhibited by castanospermine in every insect examined with the exception of the *Astragalus*-adapted seed beetle, *A. aureolus*. Concentrations required for 50% inhibition of cellobiase-activity ranged from 3.2×10^{-5} M for the rice weevil to 2.5×10^{-7} M for larvae of *H. zea*, the greatest degree of enzyme inhibition by castanospermine observed. Lactase inhibition ranged from 1.5×10^{-4} M castanospermine for *H. brunneipennis* to 3.6×10^{-6} M castanospermine for *C. pomonella*.

The results also indicated that, in general, trehalose-hydrolyzing enzymes in the Coleoptera are not inhibited by castanospermine. The one exception was the bruchid, *A. aureolus*, from *Astragalus*, the trehalase from which showed only a relatively slight degree of inhibition (1×10^{-4} M). Conversely, trehalase activities in the Homoptera and, in general, in the Lepidoptera are inhibited by castanospermine. With the exception of the Homoptera, insect sucrase activity is apparently unaffected by castanospermine. Similarly, maltase activity is generally unaffected by castanospermine with exception of the Homoptera and two Lepidoptera, *H. zea* and *M. sexta*. The only predatory insect examined, *H. convergens*, had a significantly higher specific trehalase activity in comparison to the other herbivorous insects (i.e., 1.4 nkatals compared to a mean of 0.4 nkatals for the other insects). The high trehalase activity of this insect, in ad-

dition to the relatively high maltase and sucrase activities, may reflect the comparatively high metabolism of an active, predatory insect.

The effects of the three polyhydroxylated alkaloids on aphid feeding behavior are presented in Table 2. Castanospermine was the most active compound in deterring 50% of feeding of *A. pisum* at only 1×10^{-4} M in artificial diets. However, it was inactive against *S. graminum* and *M. persicae*. 6-Epi-castanospermine was only slightly active against greenbugs, with an ED_{50} of 5×10^{-3} M, and was inactive against the pea aphid. Deoxynojirimycin was nominally active only against green peach aphids at an ED_{50} of 2.5×10^{-3} M.

DISCUSSION

The results show that castanospermine, on a selective basis, can inhibit various disaccharidases of insects, but this inhibition is highly dependent on insect taxa and particular disaccharide substrate. This variable inhibition of insect disaccharidases by castanospermine is in contrast to the inhibition of all disaccharidases of mouse gut epithelium (Scofield et al., 1986). Moreover, there is no distinct correlation with the degree of enzyme inhibition in the insects studied, and their relationship with or adaptation to plants containing either castanospermine or other toxic alkaloids. For example, the inhibition by castanospermine of disaccharidases from the mealybug, *P. longispinus*, living on *Castanospermum* plants is qualitatively and quantitatively similar to the other sap-feeding insects (all the aphids) studied. The survival of the mealybugs on *Castanospermum* is particularly puzzling in view of the fact that sucrase-activity is inhibited by castanospermine in the mealybugs. Sucrose is the chief constituent ingested from the phloem by sap-feeding insects, and its hydrolysis is an important digestive step preceding either absorption of glucose or its transglucosylation into glucans for osmotic regulation (Fisher et al., 1984). Castanospermine occurs in the honeydew of mealybugs feeding on *C. australe* and, therefore, is presumably ingested from the phloem. Furthermore, castanospermine is not active as a feeding deterrent against the mealybug (Dreyer et al., 1987). Perhaps, in the mealybug, sucrase is localized in such a way that it is not exposed to castanospermine.

However, castanospermine was a potent feeding inhibitor against the pea aphid but ineffective towards the other two aphids. Because of this potent feeding deterrency by castanospermine and its structural and stereochemical relationship to glucose, it was anticipated that the monocyclic analog, deoxynojirimycin, would be highly active as a toxicant or feeding deterrent. Deoxynojirimycin is a known trehalase inhibitor (Murao and Miyata, 1980) and, hence, was predicted to have a profound effect on the aphids. Such proved not to be the case, inasmuch as it possessed only weak activity against green peach aphids and no activity against the other aphids tested. Furthermore,

TABLE 1. SPECIFIC ACTIVITIES (SA, PKATALS/MG PROTEIN) AND CONCENTRATIONS OF CASTANOSPERMINE FOR 50% INHIBITION (I_{50} MOLAR) OF ENZYMATIC HYDROLYSIS OF DISACCHARIDE SUBSTRATES BY VARIOUS INSECTS[a]

change in the stereochemistry of castanospermine to 6-epicastanospermine, a mannose analog, also resulted in a loss of feeding-deterrent activity against pea aphids and a gain of ostensible deterrency against greenbugs. The potential role of these alkaloids in insect–plant interactions is therefore not readily apparent from the results.

The inhibition of trehalose hydrolysis by castanospermine occurred, generally, in the Homoptera and Lepidoptera and also in the one dipteran analyzed. Trehalase inhibition by castanospermine is of particular interest since trehalose is the chief metabolic source of energy in insect blood (Chefurka, 1965). Again, the pattern of inhibition of trehalose hydrolysis between the various insects showed no relationship to the degree of adaptiveness to plants containing glycosidase-inhibitory substances. Oddly, the seed beetle from *Astragalus* was the only beetle studied whose trehalase activity was inhibited by castanospermine. This insect and the pea aphid, whose trehalase activity was also inhibited, feed on *Astragalus* species which contain the α-mannosidase inhibitory indolizidine alkaloid, swainsonine (Figure 1D) (Molyneux and James, 1982).

Cellobiase was the only enzyme observed to be inhibited by castanospermine in all insects studied. Similarly, inhibition of lactase activity was observed in all insects with the intriguing exception of the seed beetle from *Astragalus*. Qualitatively, enzymes with cellobiase and lactase activities are widespread among insects and are believed to be the same enzyme (Morgan, 1975). Indeed, cellobiase and lactase are indistinguishable by discontinuous electrophoresis in the maize weevil (Campbell and Van Vleet, unpublished) and in larvae of a xylophagous cerambycid, *Rhagium inquisitor* L. (Chipoulet and Chararas, 1985). Our findings also show generally similar specific activities for hydrolysis of these substrates within the same species of insect. However, the inhibition of cellobiase by castanospermine and lack of inhibition of lactase activity in the seed beetle would indicate that in this insect there are two different enzymes responsible for hydrolysis of these substrates.

It is worth noting that insects belonging to the Rhyncophoridae, Curculionidae, Bruchidae, and Aphididae, known to possess endosymbiotes (Buchner, 1965), all had average cellobiase and lactase activities 14 and 8 times, respectively, higher than those insects studied which do not maintain endosymbiotes. The beetles and larvae of the Curculionidae, Rhynchophoridae, and Bruchidae generally bore into the interior of pods or seeds of their host plant while the Homoptera exhibit a specialized mode of feeding by using stylet-like mouth parts to reach the vascular bundle of the host plant (Pollard, 1973). Higher activities of cellobiase, for the ultimate breakdown of β-linked glucans (e.g., cellulose), and of lactase, for breakdown of β-linked galactans [e.g., the arabinogalactan side chains of pectic substances (Aspinall, 1981)], in these insects may reflect a broader spectrum of enzymes for the depolymerization of plant matrix polysaccharides. The relatively low cellobiase and lactase activities of the mealybug (which possesses endosymbiotes) may be a result of its feeding on *Castanospermum*. Castanospermine, continuously ingested by the mealybug while feeding from the phloem of *Castanospermum*, may have attenuated the activity of these enzymes, resulting in the lower specific activities observed in the homogenates. The lack of inhibition of lactase in the *Astragalus*-feeding seed beetle may represent some level of biochemical adaptation to indolizidine alkaloids.

Castanospermine appears to be a potent inhibitor of insect β-glucosidase and β-galactosidase activities and, on a more taxonomically limited basis, α-glucosidase activity. Recently, the imino sugars, 1,5-dideoxy-1,5-imino-D-mannitol (Evans et al., 1983) and 2,5-dihydroxymethyl-3,4-dihydroxypyrrolidine (Evans et al., 1985) were also shown to inhibit insect glycosidase activity at approximately the same concentration as castanospermine. These groups of compounds (and/or their analogs) may be promising candidates for the inhibition of insect digestive glycosidase activity which ultimately would disrupt normal insect carbohydrate metabolism.

CHEMICAL STIMULANTS AND DETERRENTS REGULATING ACCEPTANCE OR REJECTION OF CRUCIFERS BY CABBAGE BUTTERFLIES

J.A.A. RENWICK and CELIA D. RADKE

Boyce Thompson Institute
Ithaca, New York 14853

(Received July 15, 1986; accepted October 24, 1986

Abstract—Gravid *Pieris rapae* butterflies oviposit on many, but not all, crucifers. Rejection of *Erysimum cheiranthoides* and *Capsella bursa-pastoris* was initially explained by the presence of chemical deterrents in the plants. Analyses and bioassays of plant extracts indicated the absence of oviposition stimulants in *C. bursa-pastoris*, but similar chemical separation of *E. cheiranthoides* extracts revealed the presence of stimulants as well as deterrents. Choice tests illustrate how acceptance or rejection of a plant by an insect may depend on the balance of positive and negative chemical stimuli within the plant.

Key Words—Cabbage butterfly, *Pieris rapae*, Lepidoptera, Pieridae, oviposition, stimulants, deterrents, *Erysimum cheiranthoides*, *Capsella bursa-pastoris*.

INTRODUCTION

The host ranges of phytophagous insects are determined to a large extent by the presence or absence of specific chemicals in potential host plants (Thorsteinson, 1960; Städler, 1976). Discriminatory behavior has been linked to olfactory or contact chemoreception of attractants, repellents, stimulants, and deterrents (Dethier, 1947; Schoonhoven, 1968). The final response of an insect in accepting or rejecting a particular plant is thought to be mediated by a balance of sensory inputs from these positive and negative chemical stimuli in the plant (Dethier, 1982; Miller and Strickler, 1984). However, definitive proof of such a dynamic relationship has been difficult to obtain. One major problem is to determine whether a nonhost plant is avoided by a herbivore because of the presence of deterrents or a lack of stimulants.

The cabbage butterfly, *Pieris rapae* L., specializes on members of the Cruciferae (= Brassicaceae) and a few related plant families that contain mustard oil glycosides (Verschaffelt, 1911; Ma and Schoonhoven, 1973). Yet several crucifers are unacceptable to this insect (Feeny, 1977), and the chemical basis of such discriminatory behavior is not clear. Previous studies on *P. rapae* have shown that recognition of host plants by ovipositing butterflies depends on the presence of water-soluble chemical stimulants that are detected by tarsal contact with the plant (Traynier, 1979; Renwick and Radke, 1983), but host plants may also contain lipid-soluble deterrents (Renwick and Radke, 1985). Under natural conditions, these compounds apparently do not interfere with recognition of host plants, probably because their concentration on the surface of undamaged leaves is negligible. However, in nonhost plants, additional water-soluble deterrents are present, and these could be responsible for rejection by gravid butterflies (Renwick and Radke, 1985).

The crucifers that are unacceptable to *P. rapae* include *Erysimum cheiranthoides* L. and *Capsella bursa-pastoris* L. Both of these species contain water-soluble deterrents to oviposition (Renwick and Radke, 1985). The study reported here was designed to determine whether these deterrents alone can explain avoidance of the plants, or if the stimulants necessary for host recognition by cabbage butterflies are lacking.

METHODS AND MATERIALS

Insects and Plants. Butterflies used for behavioral assays were from a colony started from field-collected insects each summer and maintained on cabbage plants. Seeds of *E. cheiranthoides* and *C. bursa-pastoris* were collected in Vermont and Connecticut, respectively, by Dr. Frances S. Chew.

Extraction of Plant Materials. Plants were grown from seed under uniform conditions in the greenhouse. After three to four weeks, leaves were harvested and immediately dropped into boiling ethanol to minimize enzyme degradation of constituents. After cooling, the tissue was homogenized in a Waring blender and the resulting macerate filtered through glass wool. The ethanol extract was evaporated to dryness and the residue was sequentially washed with hexane and water. The water extract was filtered, evaporated to 150 ml, and extracted three times with *n*-butanol. Standard cabbage extracts were prepared using the same sequence of boiling ethanol, homogenization, filtration, evaporation, lipid removal, and water extraction.

Stimulant Bioassays. The presence of stimulant was detected using artificial plants consisting of 77 × 64-mm green index cards supported on wooden stems (Renwick and Radke, 1983). The cards were painted with 0.5 ml extract at a concentration of 5 g original fresh wt/ml to approximate the concentration of material present in a plant. Control cards were painted with solvent alone. Five pairs of butterflies were presented with one test card surrounded by three

control cards in a 60 × 60 × 60-cm cage in a greenhouse with supplemental lighting. Eggs laid on each card were counted after 24 hr. The stimulatory effect was measured by comparison with that of standard cabbage extract offered to the same butterflies on preceding and following days. Control cards were included to ensure that no eggs were laid on substrates that lacked stimulant.

Deterrent Bioassays. Deterrent activity was assayed using identical cages in the greenhouse. Five pairs of butterflies were offered a choice of two cabbage plants. One was sprayed with 3 g equivalents (original fresh weight) of test plant extract in 100% or 70% methanol (depending on solubility). The control plant was sprayed with methanol alone. The plants were left in the cage for 4 hr during the peak daily oviposition period before counting the eggs.

RESULTS

Fractionation of polar extracts of the test plants by partitioning between water and *n*-butanol resulted in transfer of the deterrent into the butanol (Figure 1). The butanol extracts of both *E. cheiranthoides* and *C. bursa-pastoris* were just as deterrent as the original water extract, whereas the activity was almost completely removed from the postbutanol aqueous layer (Figure 1).

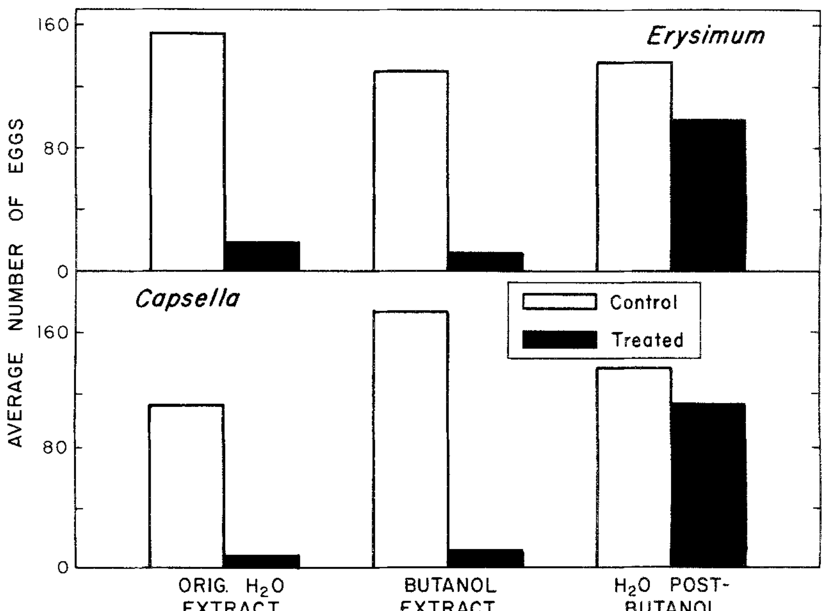

FIG. 1. Oviposition by *P. rapae* on cabbage plants treated with extracts of *Erysimum cheiranthoides* and *Capsella bursa-pastoris* or with solvent alone (controls) in choice assays.

TABLE 1. OVIPOSITION BY *P. rapae* ON CARDS TREATED WITH FRACTIONS OF EXTRACTS FROM *Erysimum cheiranthoides* AND *Capsella bursa-pastoris* COMPARED WITH STANDARD STIMULANT (H_2O EXTRACT OF CABBAGE)

Test material	No. of replications	Average No. eggs laid: Day 1 (cabbage standard)	Day 2 (test extract)	Day 3 (cabbage standard)	Relative stimulation (%)[a]
Erysimum cheiranthoides					
Orig. H_2O extract	7	92.7 (35.5)[b]	42.0 (51.8)	56.9 (27.7)	56
H_2O postbutanol	6	58.3 (28.3)	37.5 (40.2)	82.2 (28.8)	53
Butanol extract	9	76.5 (30.4)	27.0 (24.6)	68.1 (43.8)	37
Capsella bursa-pastoris					
Orig. H_2O extract	7	101.0 (38)	2.3 (3.5)	106 (23.5)	2.2
H_2O postbutanol	6	82.6 (17.1)	1.3 (2.8)	86.5 (27.6)	2.0
Butanol extract	5	137.6 (52.5)	0.6 (1.3)	154.2 (83)	0.4

[a]Relative stimulation (%) = No. eggs laid {day 2/[(day 1 + day 3)/2]} × 100, i.e., oviposition relative to mean oviposition on previous and following days in response to standard cabbage stimulant.
[b]Standard deviation is given in parentheses.

The same fractions from both plants were tested for stimulatory activity using artificial leaf bioassays. Activity was measured by comparison with standard cabbage extracts of known activity. The effect of possible changes in the butterflies' potential to lay eggs was eliminated by offering cabbage standard on days preceding and following the tests (Table 1). The results of these experiments clearly showed that the water-soluble fraction of *E. cheiranthoides* contains stimulant. Although less active than equivalent concentrations of cabbage extracts, this material was stimulatory before and after partitioning with butanol (Table 1). Some oviposition also occurred on cards treated with the butanol extract of *E. cheiranthoides* because of partial removal of the stimulant during the water–butanol partitioning.

Extracts of *C. bursa-pastoris* showed no significant stimulatory activity in any of the tests (Table 1).

DISCUSSION

The results indicate that the chemical explanation for avoidance of these two crucifers by cabbage butterflies is not the same. Since extracts of *C. bursa-pastoris* are not stimulatory, the presence of deterrent is not necessary for rejection of this plant. The lack of stimulant alone could account for unacceptability to landing butterflies. However, the presence of stimulant in *E. cheiran-*

thoides means that oviposition might be expected on this plant. Apparently the negative effect of the oviposition deterrent is sufficient to block the positive input from the stimulants. This result supports the suggestion of Jermy (1965) that the most potent stimuli inducing oviposition can be masked by inhibitory substances at an appropriate concentration.

Care is needed in interpretation of such laboratory results, especially when attempting to explain the factors that mediate oviposition in the field. Our green cards treated with standard cabbage extract are not as attractive as a host plant of comparable size. However, the concentrations of extracts used in these experiments were selected to represent levels of chemical stimuli comparable to those encountered by butterflies under natural conditions. Our efforts to mimic real plants are further complicated by the fact that little is known about the distribution of chemicals throughout the leaf. Since the ovipositional cues are contact stimuli, the active chemicals must be present at the leaf surface. Yet we have been unsuccessful in attempts to remove stimulant from cabbage leaves by solvent dipping (unpublished results). Despite these limitations in interpretation, we feel confident in concluding that we can readily determine whether stimulants are present in a plant. *P. rapae* does not lay eggs on blank green cards or cards that are treated with extracts of noncrucifer, nonhost plants (unpublished results).

The use of separate bioassay systems to detect oviposition stimulants and deterrents appears to be critical. The stimulant assay is particularly sensitive, and the use of three control cards in each cage emphasizes the ability of the butterflies to discriminate between low concentrations of active material or solvent alone (Renwick and Radke, 1983). Butanol extracts of *E. cheiranthoides*

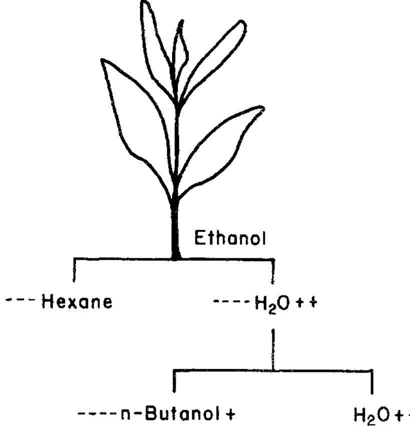

FIG. 2. Schematic representation of stimulant (+) and deterrent (−) activity of fractions from *Erysimum cheiranthoides* extracts affecting oviposition by *P. rapae*.

were slightly stimulatory when tested on green cards, even though most of the stimulant remained in the water fraction and despite the presence of deterrent (Table 1). When the same material was applied to cabbage plants, the deterrent effectively blocked the natural stimulant at the surface of the leaves (Figure 1). The reason for the lack of sensitivity to deterrent on the inert substrate provided by cards is not clear at this time. But the phenomenon does lend support to our conclusion that *Capsella* contains little or no stimulant since, even if other deterrents were present, they would probably have little effect.

The sequential extraction and the use of different bioassays for the study of *E. cheiranthoides* have effectively removed the mask from the stimulant which would not otherwise be detected (Figure 2). This may be the first demonstration that both oviposition stimulants and deterrents can actually occur in a plant that is rejected by an insect. The balance of such positive and negative signals within a plant is likely to play a major role in the acceptance or rejection of potential hosts by an insect.

Acknowledgments—We thank F.S. Chew for supplying seeds and for helpful discussions; and E. Städler, F. Gould, and F.J. Messina for critical comment.

(Z)-11-OCTADECENYL ACETATE, AN AGGREGATION PHEROMONE IN *Drosophila simulans*

ANGELA M. SCHANER, ROBERT J. BARTELT, and LARRY L. JACKSON

Department of Chemistry
Montana State University
Bozeman, Montana 59717

(Received August 1, 1986; accepted October 24, 1986)

Abstract—Existence of a male-produced pheromone, which attracts both males and females in a wind-tunnel olfactometer, has been demonstrated in *Drosophila simulans* (Sturtevant). A pheromone component was identified as (Z)-11-octadecenyl acetate (Z11-18:Ac), also known as *cis*-vaccenyl acetate. The pheromone is synergized by food volatiles. In bioassay ca. 1/1000 of a mature male equivalent of Z11-18:Ac is attractive and activity increases with increased amounts of Z11-18:Ac. Flies do not begin responding to Z11-18:Ac until after they have been away from food for at least 2 hr. Z11-18:Ac is transferred from the male to the female during mating, and the female emits the majority of the transferred Z11-18:Ac within 6 hr after mating.

Key Words—Diptera, Drosophilidae, *Drosophila simulans*, aggregation pheromone, (Z)-11-octadecenyl acetate, *cis*-vaccenyl acetate.

INTRODUCTION

Aggregation pheromones have previously been studied in seven *Drosophila* taxa: *D. virilis* (Bartelt and Jackson, 1984; Bartelt et al., 1985a); *D. a. americana, D. a. texana, D. novamexicana*, and *D. lummei* (Bartelt et al., 1986); *D. hydei* (Moats et al., 1987); and *D. melanogaster* (Bartelt et al., 1985b). In all these taxa, the pheromone component(s) are produced only by mature males and attract both males and females in a wind-tunnel olfactometer. This study was undertaken to determine whether an aggregation response could be demonstrated in *D. simulans* (Sturtevant), a close relative of *D. melanogaster*. In *D. melanogaster* a major aggregation pheromone component was identified as (Z)-

0098-0331/87/0700-1777$05.00/0 © 1987 Plenum Publishing Corporation

11-octadecenyl acetate (Z11-18:Ac) (Bartelt et al., 1985b). This pheromone, in combination with food, substantially increased the attractiveness of food odors. Z11-18:Ac has been reported in *D. melanogaster* to mediate close-range behavior as well, by discouraging males from courting other males or recently mated females (Jallon et al., 1981). Because of the dual role of Z11-18:Ac in *D. melanogaster* and because *D. simulans* also possesses Z11-18:Ac (Jallon, 1984), it was hoped that *D. simulans* would provide further information on the function of Z11-18:Ac. Starting with crude extracts of mature flies and using bioassay to guide purification, Z11-18:Ac was identified as a major component of the aggregation pheromone of *D. simulans*. Other experiments related to aggregation in *D. simulans* are also discussed.

METHODS AND MATERIALS

Flies. D. simulans (strain 14021-0251.0) was obtained from the National *Drosophila* Species Resource Center at Bowling Green, Ohio. It was originally collected at Kenscoff, Haiti. Flies were reared on Instant *Drosophila* Medium Formula 4-24 (Carolina Biological Supply Co. Burlington, N.C.) in 1-liter jars or in 3.5 × 10-cm vials under a light–dark cycle of 16:8 hr and ambient laboratory temperatures.

Extracts and Chromatography. Flies were separated by sex when 0–6 hr old and extracted at that time or at 6–7 days of age by soaking them in hexane at room temperature for 24 hr. The crude extracts were separated by polarity on open columns of silicic acid (Bartelt and Jackson, 1984). Elution solvents were hexane; 10% ether in hexane; 50% ether in hexane; and 10% methanol in methylene chloride. Further purification of the male 10% ether–hexane fraction was done by preparative GC. Preparative and analytical GC were conducted as described previously (Bartelt and Jackson, 1984).

Bioassay. Bioassays were conducted in a wind-tunnel olfactometer (Bartelt and Jackson, 1984). The bioassay was used to screen chromatographic fractions for activity and to compare various synthetic and fly-derived preparations. Approximately 1000 flies (0–2 days old) were placed into the olfactometer 2 hr before tests would begin. Tests lasted 3 min and were separated by 7–10 min. When an experiment included more than two treatments, they were tested in pairs, in all possible combinations (a balanced incomplete block design). Generally, each experiment included a high control [fly-derived or synthetic compound(s) that bioassayed well] and a low control (solvent) in addition to the preparation(s) being evaluated. The activity level of a treatment was usually expressed relative to the high and low controls because catches to any one treatment varied from day to day, but ratios between treatments remained fairly constant. Analysis of bioassay data was by the method of Yates (1940), paired

t tests, or simple linear regression. The data were transformed to the log (X + 1) scale before analysis to stabilize variance.

Once it was established that the flies responded to Z11–18 : Ac, three additional bioassay experiments were conducted involving this compound. First, the relationship between magnitude of response and dose of Z11–18 : Ac was investigated. Doses ranged from 0.1 ng to 10,000 ng, by factors of 10. Each bioassay experiment contained two consecutive doses and a control. All possible pairs of consecutive doses were tested, and results are expressed relative to the activity (= 100) for 1000 ng. Second, the relationship between response to Z11–18 : Ac and time away from food was studied by measuring the bioassay response, compared to controls, every 15 min throughout the day. To distinguish between time-of-day effects and those due to time away from food, four replications of the experiment were begun at 0800 hr, while four others began at 1100 hr. Third, synergism between Z11–18 : Ac and food odors (from rearing medium inoculated with yeast) was investigated, throughout the day (three replications) and at the time of "peak" activity.

Z11–18:Ac Transfer. An experiment was conducted to test for the transfer of Z11–18 : Ac from males to females and for the subsequent release of the ester from the females. Virgin females (6–7 days old) were mated with virgin males of the same age. Immediately after mating, females were either extracted or placed into an empty glass vial or vial with food medium for 6 hr and then extracted. The vials were then rinsed with hexane to recover any Z11–18 : Ac which had been released (Bartelt et al., 1985b). To recover the Z11–18 : Ac quantitively, it was necessary to rinse the food vials again with methylene chloride. The mated males were treated in a similar fashion. Each extract represented 10 fly equivalents. As controls, comparable sets of extracts were obtained from males and females which had not been allowed to mate. The Z11–18 : Ac in the extracts was quantitated by GC relative to an internal standard (Bartelt et al., 1985b). The rearing medium did not contain compounds with the same GC retention as Z11–18 : Ac.

RESULTS

Identification of Pheromone Component. The male crude extract was clearly active in bioassay against a control ($P < 0.001$). For example, the mean catches for male extract and control were 13.9 and 1.4, respectively ($n = 16$). Flies attracted to the male extract were 54% female. Both sexes responded similarly to all preparations discussed in this report.

After fractionation of the male extract on silicic acid, only the 10% ether–hexane fraction was substantially different from the control ($P < 0.001$) in bioassay (Table 1). By capillary GC, the male 10% ether–hexane fraction was

TABLE 1. ACTIVITY OF SILICIC ACID FRACTION AND EXTRACTS RELATIVE TO MALE CRUDE EXTRACT

Fraction or extract[a]	Relative response[b]	
	Male extract	Female extract
Hexane	6.4*[c] (4.5, 3.0, 26.5)[d]	−0.7 (0.8, 0.9, 14.5)
10% ether–hexane	85.0***(26.4, 5.5, 30.1)	26.0***(12.9, 5.8, 32.7)
50% ether–hexane[e]	0.8 (1.7, 1.6, 9.1)	3.0 (4.2, 3.4, 29.0)
10% methanol–methylene chloride	2.6 (2.1, 1.6, 21.1)	15.7 (3.9, 2.5, 11.4)
Crude extract	100.0***	63.0***(9.3, 1.4, 13.9)

[a] All extracts and fractions were used at one fly equivalent per test.
[b] Relative response = (fraction − control)/(male crude extract − control) × 100.
[c] *and*** denote significance of t tests vs. controls at the 0.05 and 0.001 levels, respectively.
[d] Even catches ($N = 8$) for test treatment, control, and male crude extract, respectively, shown in parentheses.
[e] Because 50% ether–hexane solvent was attractive to the flies, this fraction was taken almost to dryness under nitrogen and back up in hexane.

86% one compound. Previous work with *D. melanogaster* (Bartelt et al., 1985b) and *D. simulans* (Jallon, 1984) suggested this was probably Z11–18 : Ac. GC retention time of fly-derived and synthetic Z11–18 : Ac (Sigma Chemical Co., St. Louis, Missouri), mass spectra, and double-bond location by ozonolysis-GC confirmed this identity. Young males 0–6 hr old possessed only trace amounts of Z11–18 : Ac and virgin females of any age contained none.

The crude extract, 10% ether–hexane fraction, synthetic Z11-18 : Ac (99 + % pure) and fly-derived Z11–18 : Ac (obtained from the 10% ether–hexane fraction by preparative GC, 98 + % pure) were compared by bioassay (all at 640 ng Z11–18 : Ac/test, ca. 1 fly equivalent, Table 2). All were significantly greater than the control ($P < 0.001$). The synthetic and fly-derived Z11–18 : Ac treatments were not significantly different, and Z11–18 : Ac accounted for all the activity of the male 10% ether–hexane fraction and crude extract. In this study the 10% ether–hexane fraction, synthetic Z11–18 : Ac, and fly-derived Z11–18 : Ac were significantly greater than the crude extract ($P < 0.05$).

Other Studies with Z11–18 : Ac. Response to Z11–18 : Ac increased with dose (Figure 1, slope significant, $P < 0.005$, simple linear regression). A dose of 1 ng, comparable to ca. 1/1000 of a male equivalent was significantly greater than the control ($P < 0.01$), although 0.1 ng was not. The 1000 ng and 10,000 ng doses were not significantly different from each other ($P > 0.2$), suggesting further increases in dose would cause little, if any, increase in response.

TABLE 2. SOURCES OF Z11-18:Ac COMPARED IN BIOASSAY

Source[a]	Mean bioassay catch[b] (N = 32)
Control	4.7a
Synthetic Z11-18:Ac	24.8c
Fly-derived Z11-18:Ac	25.0c
Male 10% ether-hexane	28.5c
Male crude extract	19.1b

[a]Compared on an equal-weight basis for Z11-18:Ac (640 ng/test).
[b]Means followed by a different letter were significantly different at the 0.05 level (LSD).

The responsiveness of the flies to Z11-18:Ac increased with time away from the rearing jars (Figure 2), becoming significantly greater than the control (P = 0.01) after 2 hr. The onset of response was accompanied by a change in behavior. When first introduced into the olfactometer, the flies remained on the floor and moved about very little. Within a few hours, the flies became more

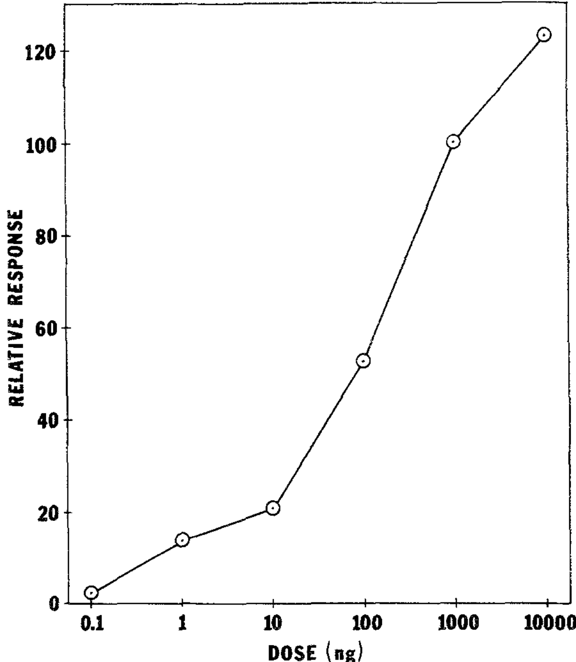

FIG. 1. Dose-response relationship for synthetic Z11-18:Ac. Relative responses are 100% for the 1000 ng dose and 0% for the controls. (See Table 1 for calculation of relative response.) Spacing along x axis is logarithmic.

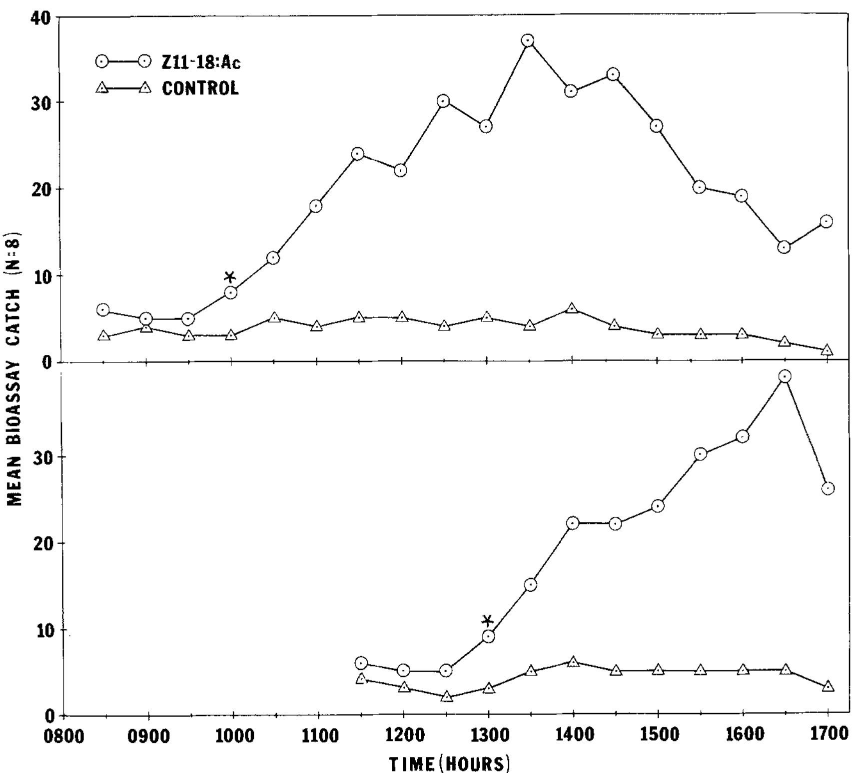

FIG. 2. Bioassay activity of Z11-18 : Ac vs. time after removing flies from food. Flies were placed in the olfactometer at 0800 hr (upper panel) or 1100 hr (lower panel). Synthetic Z11-18 : Ac was tested at 750 ng/test (ca. 1 fly equivalent). *Indicates when Z11-18 : Ac became significantly greater than the control ($P = 0.05$).

active and spent more time on the sides of the olfactometer and in flight. This response continued throughout the day, although the number caught per test decreased with time because fewer flies were left in the olfactometer. Bioassay behavior included flying upwind with a hovering, casting flight and descending into the vial or alighting on the vial and walking inside.

When a food source (Petri plate with rearing medium and yeast) was present in the downwind end of the olfactometer, the response to Z11-18 : Ac never commenced. After being tested for 6 hr, the mean catches for synthetic Z11-18 : Ac (750 ng/test) and control were 0.43 and 0.29, respectively ($N = 14$). Most of the flies spent the entire day at the food plate, moving or flying very little.

The onset of the responsiveness to Z11-18 : Ac appeared more related to time away from food than to time of day. The response to Z11-18 : Ac became

TABLE 3. SYNERGISM OF SYNTHETIC Z11-18:AC AND FERMENTED FOOD

Treatment	Mean bioassay catch[a] ($N = 18$)
Control	0.8a
Synthetic Z11-18:Ac[b]	10.6b
Food[c]	43.2c
Z11-18:Ac + food	103.6d

[a]Means followed by a different letter were significantly different in the log ($n + 1$) scale at the 0.001 level (LSD).
[b]Synthetic Z11-18:Ac used at 750 ng/test (ca. 1 fly equivalent).
[c]"Food" is 0.5 ml of *Drosophila* rearing medium inoculated with yeast 24 hr before bioassays began and placed in the bottom of a bioassay vial.

significantly greater than the control ($P = 0.01$) 2 hr after placing the flies into the olfactometer, regardless of whether this was done at 0800 or 1100 hr (Figure 2).

Although successful bioassays could be conducted with *D. simulans* in the absence of food, Z11-18:Ac was a potent synergist of the fermented rearing medium (Table 3). Z11-18:Ac increased the response to the food treatment by 60 flies per test, even though Z11-18:Ac alone caught only 10 flies per test. The treatment, Z11-18:Ac plus fermented food, was so attractive that flies responded to it above control levels within minutes of placing the flies into the olfactometer (Figure 3). Yet response to this treatment, as well as to the ester and fermented food alone, did increase strongly over time, consistent with earlier results (Figure 2). Catches for Z11-18:Ac alone were relatively few in this study, presumably due to the competition from the food-containing treatments. Nevertheless, Z11-18:Ac became significantly greater than the control 2 hr after tests began ($P = 0.05$), in agreement with earlier results.

Z11-18:Ac Transfer. Virgin females did not possess any Z11-18:Ac. However, males transferred approximately half of the Z11-18:Ac they possessed to the female during mating (Table 4). Within 6 hr after copulation, the female deposited the majority of the Z11-18:Ac transferred into a vial which contained rearing medium or even into an empty glass vial. The amount of Z11-18:Ac emitted by a recently mated female was ca. 10 times greater than that emitted by a virgin male. Few eggs were detected in the rearing medium vials after 6 hr, and none were in the empty vials.

Other Attractants. In bioassay, attraction to the female extract was significantly greater than the control (Table 1). Bioassay of all female silicic acid fractions indicated the 10% ether-hexane fraction was significantly above control levels ($P < 0.001$, Table 1), although not as active as the male-derived fraction. Thus a relatively nonpolar attractant in females of *D. simulans* is in-

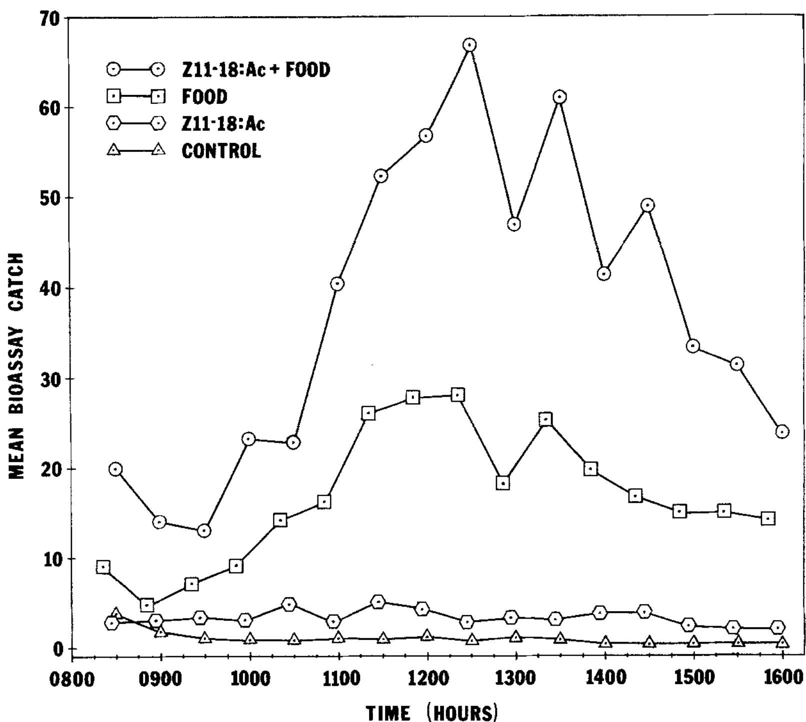

FIG. 3. Synergism of Z11–18 : Ac and fermented food over time. In each test, the treatment was bioassayed against a control. Except for controls, each point represents the mean of six catches (3 replications of experiment × 2 tests in each time interval). All control catches were combined to simplify the figure (N = 18); the means in any one time interval differed by no more than ±1 fly. Z11–18 : Ac was used at 750 ng/test (ca. 1 fly equivalent).

dicated (by GC no Z11–18 : Ac was detected). Identification of the attractant in this fraction is presently under investigation.

The male hexane fraction was also significantly greater than the control (P = 0.05) but accounted for only 6% of the activity of the male extract. The response was very subtle, and isolation of the active compound(s) under the present bioassay scheme would be very difficult.

The 10% methanol–methylene chloride fractions for both male and female were not significantly different from the control, although the extraction process for the crude extracts was geared toward the nonpolar attractants. A more thorough extraction may reveal active polar fractions, as observed in other *Drosophila* species (Bartelt et al., 1985a, 1986).

TABLE 4. MEAN AMOUNTS OF Z11-18:Ac EXTRACTED FROM MATED AND VIRGIN FLIES, AND FROM EMPTY VIALS OR FOOD VIALS WHICH THEY OCCUPIED FOR 6 HOURS

	Mean amount of Z11-18:Ac (ng/fly)			
Treatment	Mated male[a]	Mated female[a]	Virgin male	Virgin female
Flies immersed in hexane ($N = 4$)[b]				
Fly extract	386(±68)[c]	418(±112)	640(±137)	0
Flies in empty vial for 6 hr ($N = 2$ virgin, $N = 4$ mated)				
Fly extract	475(±65)	123(±81)	990(±438)	0
Vial rinse	30(±14)	158(±30)	0	0
Flies in food vial for 6 hr ($N = 2$ virgins, $N = 5$ mated)				
Fly extract	416(±89)	94(±38)	905(±78)	0
Vial rinse	48(±40)	188(±61)	15(±7)	0

[a] These flies either extracted or placed in vials for 6 hr immediately upon completion of mating.

[c] Standard deviation.

DISCUSSION

Males of *D. simulans*, like *D. melanogaster*, possess Z11-18:Ac as a major pheromone component which attracts males and females in a wind-tunnel olfactometer. In *D. melanogaster*, Z11-18:Ac is found in the ejaculatory bulb, transferred to the female during mating (Brieger and Butterworth, 1970; Butterworth, 1969), and deposited by the female onto the rearing medium within 6 hr after completion of mating (Bartelt et al., 1985b). *D. simulans* is similar to *D. melanogaster* in the transfer and release of Z11-18:Ac. In both species, the mature male emits Z11-18:Ac in small quantities and a recently mated female in larger amounts. *D. simulans* is also similar to *D. virilis* in that both species must be deprived of food in order to be attracted to their aggregation pheromone in the olfactometer (Bartelt and Jackson, 1984).

Food or food odors are not needed in combination with Z11-18:Ac for a successful bioassay with *D. simulans*, as is the case for *D. melanogaster* (Bartelt et al., 1985b). Therefore, *D. simulans* would be the more convenient species in which to investigate additional, minor pheromone components.

In nature, mating, feeding, and oviposition occur at the same site. It is accepted that flies are attracted to food sites by odors (Spieth, 1974). We believe attraction to a site is a complex phenomenon, involving both food odors and fly-derived compounds. *D. simulans* males produce an attractant, Z11-18:Ac, that is a powerful synergist of food odors. One nanogram of Z11-18:Ac was sig-

nificantly more attractive than a control in our bioassay, and over a 6-hr period, a mature male or recently mated female is capable of emitting well over this amount at a food site. Since 10 times more Z11–18:Ac is emitted by recently mated females than virgin males, mating sites would be particularly attractive. Interestingly, Spence et al. (1984) found that male *D. simulans* are preferentially attracted to cylinders which had contained recently mated females compared to those with males or virgin females. Thus, a fly without a food source, moving through an area, would tend to alight preferentially at a food source which was already occupied by others of the species, especially if mating had taken place. Once at a food site, the flies would tend to remain on or near the food (Spieth, 1974). Flies in the olfactometer did not respond to Z11–18:Ac when given a food source or until deprived of food for a few hours, which indicates that responsiveness to the aggregation pheromone diminishes upon feeding.

Announcement

The 1st International Conference on Classification, Phylogeny and Natural History of Scolytidae (Coleoptera)

To be held July 3–9, 1988, Vancouver, British Columbia, Canada, in conjunction with the XVIII International Congress of Entomology, will focus on current research relating to the morphology, systematics, phylogeny, zoogeography, ecology, physiology, and behavior of the Scolytidae. Potential participants and topics are now being solicited. Anyone interested in participating in the symposium is asked to notify one of the co-conveners listed below.

CYANOGENESIS—A GENERAL PHENOMENON IN THE LEPIDOPTERA?

KLAUS WITTHOHN and CLAS M. NAUMANN

Department of Animal Morphology and Systematics
Faculty of Biology, University of Bielefeld
POB 8640, D-4800 Bielefeld 1, Federal Republic of Germany

(Received May 27, 1986; accepted October 27, 1986)

Abstract—There are two different pathways known to be used for the detoxification of hydrocyanic acid in insects, viz., rhodanese and β-cyano-L-alanine synthase. We consider the latter to be indicative for cyanogenesis, while rhodanese might, in general, play a more important role in sulfur transfer for protein synthesis. This paper reports on the distribution of β-cyano-L-alanine (BCA) in the Lepidoptera. First reports of cyanogenesis are presented for the following families: Papilionidae, Pieridae, Lycaenidae, Hesperiidae, Lymantriidae, Arctiidae, Notodontidae, Megalopygidae, Limacodidae, Cymatophoridae, Noctuidae, Geometridae, and Yponomeutidae. New and old records for three other families, the Nymphalidae, Zygaenidae, and Heterogynidae, are included to complete the present state of knowledge. Special emphasis has been laid on the Nymphalidae, where BCA has been detected in eight subfamilies. Taxonomic, geographic, and seasonal variation has been found in a number of cases. In all cases observed so far, the source of cyanogenesis in the Lepidoptera is most probably the cyanoglucosides linamarin and lotaustralin, although cyanogenesis based on mustard oil glucosides and cyclopentenoid glucosides might occur as well. BCA has been found in both cryptic and aposematic species, including taxa such as the Pieridae, Danainae, Ithomiinae, and Arctiidae, where the defensive biology is believed to be linked with other compounds, like mustard oil glucosides, cardenolides, or pyrrolizidine alkaloids. The ecological interaction and significance of such secondary compounds is not yet understood.

Key Words—Lepidoptera, chemical defense, cyanogenesis, cyanoglucosides, β-cyano-L-alanine, rhodanese, phytophagous insects.

INTRODUCTION

According to recent records, cyanogenesis in animals is restricted to a few cases in the Arthropoda, where examples are known from the Myriapoda, the Diplo-

0098-0331/87/0800-1789$05.00/0 © Plenum Publishing Corporation

poda, and the orders Heteroptera, Coleoptera, and Lepidoptera in the Insecta (Davis and Nahrstedt, 1984). In the Myriapoda, Diplopoda, and Coleoptera (Cicindellinae and Chrysomelidae), HCN and benzaldehyde are produced by catabolic decomposition of mandelonitrile (benzaldehyde-α-hydroxynitrile) (Blum et al., 1981). In other insects, i.e., in *Acraea* and *Heliconius* butterflies (Nymphalidae) and in *Zygaena* moths (Zygaenidae), the source of cyanogenesis has been detected as the cyanoglucosides linamarin (2-β-D-glucopyranosyloxy-2-methylpropionitrile) and lotaustralin (2-β-D-glucopyranosyloxy-2-methyl-2*R*-butyronitrile) (Davis and Nahrstedt, 1979; Nahrstedt and Davis, 1983).

Most larval food plants of *Zygaena* moths and *Acraea* and *Heliconius* butterflies are themselves cyanogenic, but the source of cyanogenesis is different: in certain species of *Zygaena* the cyanoglucosides of the larval food plants (Fabaceae) and those of the insects are chemically identical, while the food plants of *Acraea* and *Heliconius* (Passifloraceae) usually contain cyanoglucosides with a cyclopentenoid aglycon (Davis and Nahrstedt, 1984). This indicates that larvae of *Zygaena*, *Heliconius*, and *Acraea* biosynthesize their cyanoglucosides independently from larval ingestion of cyanogenic food plants. In fact, Wray et al. (1983) have demonstrated that *Heliconius* and *Zygaena* use the same biosynthesis as plants that contain linamarin and lotaustralin. This synthesis starts from valine for linamarin and isoleucine for lotaustralin (Conn, 1979) (see Figure 1). The high amounts of cyanogenic compounds in these insects are generally thought to be linked with distastefulness to predators, which again is believed to be connected with the aposematic patterns of both the larvae and imagines.

Two different detoxification pathways for hydrocyanic acid have so far been demonstrated in insects (Figure 1).

1. The more commonly known, which had been favored especially in the older literature (Jones et al., 1962), is that found in vertebrates which produces thiocyanate (rhodanid) via the enzyme rhodanese (EC 2.8.1.1). The presence of this enzyme has been demonstrated by Beesley et al. (1985) to occur in a considerable number of phytophagous insects.

2. In other insects the catabolic reaction leads to β-cyano-L-alanine (BCA) via BCA synthase (EC 4.4.1.9). The presence of BCA in insects was first demonstrated by Duffey (1981) in larvae of *Heliothis zea* and *Spodoptera exigua* (Lepidoptera, Noctuidae) and in *Oncopeltus fasciatus* (Heteroptera, Lygaeidae). BCA has also been detected in the defensive secretion and tissues of *Zygaena* larvae, in *Zygaena* moths and in dried specimens of *Acraea* and *Heliconius* (Witthohn and Naumann, 1984a,b).

None of these detoxification systems is necessarily bound to the cyanoglucosides linamarin and lotaustralin; both could well be able to detoxify hydrocyanic acid released from any other cyanogenic precursor as well. It has also been argued that the role of rhodanese as a sulfur donor in protein synthesis

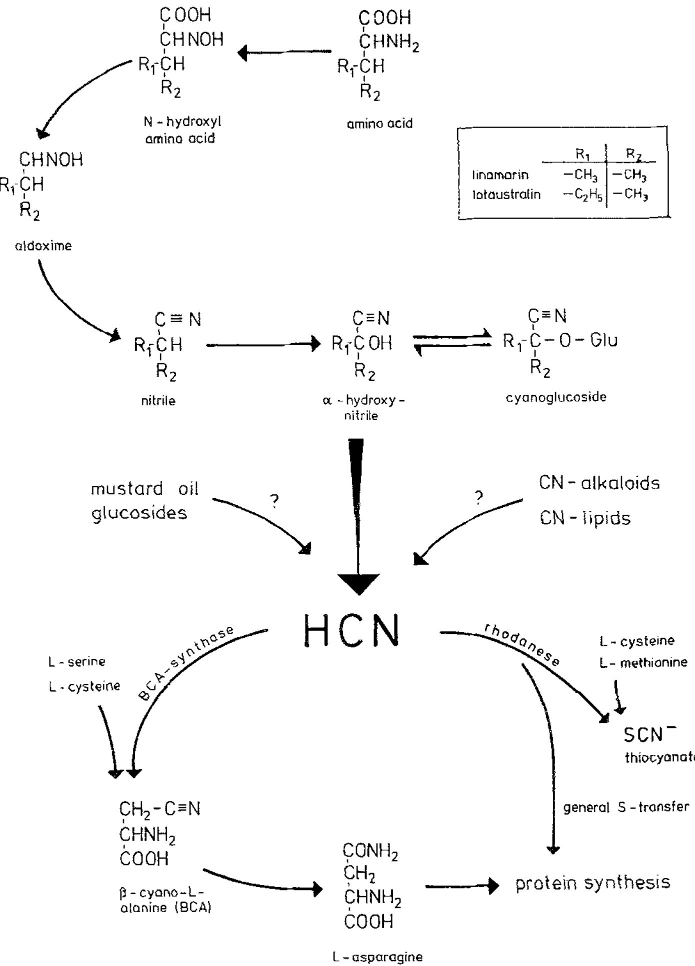

FIG. 1. Metabolic pathways for cyanoglucoside synthesis (modified, after Conn, 1979) and detoxification of hydrocyanic acid.

might be more important than its detoxifying properties (Volini and Alexander, 1981). If so, the presence of rhodanese does not necessarily imply that an organism is cyanogenic, but the evidence of BCA in animal tissues can generally be regarded as indicative for the presence of cyanogenic compounds. It is in this sense that we have used the test for BCA as an indicator for cyanogenesis in Lepidoptera in the present paper. Of course, the absence of BCA does not necessarily mean that the animal concerned is acyanogenic.

It has been shown that nonaposematic species of the Zygaenidae, especially those of the Zygaeninae, also contain the cyanoglucosides linamarin and lotaustralin (Davis and Nahrstedt, 1984; Witthohn and Naumann, 1984b), although like some aposematic species, they live on the same noncyanogenic food plants, the alkaloid-rich Celastraceae. Furthermore, we have previously demonstrated that cryptic species of the Zygaeninae detoxify hydrocyanic acid via BCA synthase, using the same method as their aposematic relatives. Similarly BCA has been demonstrated in some nymphalid genera unrelated to *Acraea* and *Heliconius* (viz., *Vanessa*, *Cynthia*, and *Maniola*). Of these, at least *Maniola* must be regarded as cryptic, although females of this species have been found to contain a histamine-like compound, leading to their rejection by a shama thrush (*Kittacincla malabaricus*) (Rothschild, 1985). Neither *Vanessa*, *Cynthia*, nor male *Maniola* butterflies have hitherto been thought to be chemically protected. Finally BCA has even been detected in the danaine butterfly *Danaus chrysippus*, a species which has been thought to be associated with cardioglucosides and pyrrolizidine alkaloids exclusively (Witthohn and Naumann, 1984b).

Following these results, we decided to investigate other families of butterflies for the presence of BCA and, having found it to be present in an astonishing number of cases, to extend the study to other lepidopterous families as well. The results of our research are presented in this paper.

METHODS AND MATERIALS

The tests were preferably carried out with fresh specimens which were either bred in captivity or caught in the wild. When such material was not available, specimens were either obtained from private collectors or from commercial dealers (Fa. Lörcher, Urach, F.R.G.). All tests on dried material reported here were done with specimens less than 5 years old, as we have found that BCA decomposes with time and its presence may be difficult to prove in older specimens, even of highly cyanogenic species. Thus, we could not demonstrate BCA in dried specimens of *Morpho* (Nymphalidae, Morphinae), while examples freshly emerged from imported pupae proved positive. The specimens were crushed and mixed with an aliquot solution of methanol–conc. aqueous ammonia (80:20), of which 10 μl were used for the tests. BCA was detected by two-dimensional thin-layer chromatography (TLC sheets 5 × 5 cm, Merck, silica gel 60, 0.2 mm), eluants: (1) chloroform, methanol, conc. aqueous ammonia (5:5:1); and (2) *n*-butanol, acetic acid, water (5:1:2). The sheet was sprayed with ninhydrin solution after drying. BCA could be identified by its characteristic blue color and its retention times: $R(F1) = 0.55$, $R(F2) = 0.19$. In a number of cases, the presence of the cyanoglucosides linamarin and lotaustralin was also examined by thin-layer chromatography with available lin-

amarin (Calbiochem) as reference; eluant ethylacetate–acetone–water (4 : 5 : 1), and spraying with anisaldehyde (Stahl and Kaltenbach, 1961).

Enzymatic activity, which must be responsible for the presence of BCA, was demonstrated following Henrickson and Conn (1969).

RESULTS

The results are given in Table 1. We have also provided information on the geographic origin of the specimens, the larval food-plant family, and whether cyanogenesis has been recorded in these food plants. These data have been taken from various literature sources.

According to the strength of the reaction, we have classified the concentration (c) of BCA into three groups: +: $c \leq 2$ μg/insect; ++: $2 \leq c \leq 20$ μg/insect; +++: $c \geq 20$ μg (175 nmol)/insect. The presence of the cyanoglucosides linamarin/lotaustralin has not been detected in all cases where BCA was found to be present, but they usually are present, when the reaction for BCA is strong (+++) and sometimes even when it is medium (++). Thus, the results are influenced by the fact that the test for the cyanoglucosides is less sensitive than that for BCA.

DISCUSSION

One might argue that the amounts of BCA detected in the different Lepidoptera could be due to postmortem microbial action and not to actual biosynthesis of the living insect. We have therefore compared the strength of the ninhydrin reaction for BCA in fresh and dried specimens of a number of species, including *Clossiana euphrosyne* (Nymphalidae), a number of *Zygaena* species and *Aglaope infausta* (Zygaenidae), and *Heterogynis penella* (Heterogynidae). There was no difference, and we therefore feel justified to presume that the amount of BCA contained in dried insects is, in fact, derived from the insect itself. We have furthermore demonstrated the presence of BCA synthase in *Clossiana euphrosyne* (Nymphalidae); *Pryeria sinica*, *Orna nebulosa*, *Zygaena trifolii*, *Rhagades pruni*, and *Aglaope infausta* (Zygaenidae); and *Heterogynis penella* (Heterogynidae). Of these, only *Zygaena trifolii* had been known to possess BCA synthase (Witthohn and Naumann, 1984a). These results suggest that BCA is actually biosynthesized by the insects themselves and is neither accumulated after larval or imaginal ingestion of food plants nor a result of microbial tissue decomposition.

Our data include the first records of cyanogenesis for another 14 lepidopterous families, i.e., the Papilionidae, Pieridae, Lycaenidae, Hesperiidae, Lymantriidae, Arctiidae, Notodontidae, Megalopygidae, Limacodidae, Cymato-

[a]Origin: 1 Afghanistan, 2 Algeria, 3 Austria, 4 Botswana, 5 Brasil, 6 Denmark, 7 Germany, 8 Hungary, 9 India, 10 Italy, 11 Japan, 12 Malaysia, 13 Mexico, 14 Morocco, 15 Nepal, 16 Peru, 17 South Africa, 18 Spain, 19 Turkey, 20 USA, 21 Yemen. dr = air-dried specimens; fr = fresh specimens, usually bred. BCA concentration: – not detected; +: $c < 2$ μg/insect, ++: $2 < c < 20$ μg/insect, +++: $c > 20$ μg (175 mmol)/insect. LIN/LOT (linamarin/lotaustralin) test: – not detected, + present.

[b]Cyanogenesis has been recorded for the following plant families: Apiaceae (1 sp.), Asclepidiaceae (2 sp.), Asteraceae, Caprifoliaceae, Crassulaceae, Brassicaceae, Ericaceae, Fabaceae, Poaceae, Passifloraceae, Rosaceae, Tiliaceae, Ulmaceae (Hegnauer, 1962–1973; Conn, 1981a,b).

[c]3–6 specimens examined for each population.

[d]Previously recorded in Witthohn and Naumann (1984b).

[e]Probably to be transferred to Zygaenoidea (Kyrki, personal communication).

phoridae, Lasiocampidae, Noctuidae, Geometridae, and Yponomeutidae. Hitherto, cyanogenesis had only been known to occur in three families, viz., the Nymphalidae, Zygaenidae, and Heterogynidae (Witthohn and Naumann, 1984b, and references therein). The specimens used in the Heliconiinae and Acraeinae (Nymphalidae) had obviously lost some of their original amounts of BCA, as could be seen from the generally poor representation of amino acids in TLC. We expect very strong reactions (+++) for all species when fresh specimens are available. This will presumably apply also to those species of the Heliconiinae and Acraeinae which were negative for BCA.

The cyanogenic species *Gymnogramma rufiventris* will be excluded from the Yponomeutidae in the near future. It might be placed in the cyanogenic Zygaenoidea, but not in the Zygaenidae proper (Kyrki, 1984, personal communication). Larvae of this highly cyanogenic species possess lateral abdominal glands which can be extruded and are probably used to store or compartmentalize toxic—possibly cyanogenic—compounds (Naumann, unpublished). A similar, but not homologous, larval defensive system has been found in the Zygaeninae (Povolny and Weyda, 1981; Franzl and Naumann, 1984, 1985).

The number of species actually detoxifying cyanide via BCA synthase might still be greater than our results show: firstly, because the greatest need to detoxify cyanide might occur in the larval instars, which might lead to a reduction of the amount of stored BCA in the imagines, and secondly because an insect might detoxify HCN via BCA synthase but might not store the product of the reaction.

Based on these results, cyanogenesis can no longer be considered a phenomenon restricted to some aposematic species, such as *Zygaena*, *Acraea*, *Heliconius*, and their close relatives. However, there is still a general trend for some groups to show stronger reactions than others. A rather singular case is found in the geometrid moth *Bapta temerata*, a cryptic and mainly night-active species. Since the larval food-plant spectrum includes some cyanogenic Rosaceae, there may exist a connection between cyanogenesis of the larval food plant and that of the moth itself.

The degree of cyanogenesis as evident from the amount of stored BCA varies in a number of respects:

Variation within Lepidoptera. While certain taxa such as the Zygaenidae, Acraeinae, and Heliconiinae must be considered as highly cyanogenic at the family or subfamily level, other taxa such as the Nymphalinae and most other butterfly families show considerable variation which seems to be only partially connected with cyanogenesis of larval food plants. Thus, in the Nymphalidae, the subfamily Satyrinae are confined to the Poaceae, which are known to be cyanogenic. The imagines of this subfamily are cyanogenic at a rather low level. In the Nymphalinae, those species which live on the Violaceae, a plant family not known to be cyanogenic, show comparatively high concentrations of BCA,

as judged from the strength of the ninhydrin reaction. *Clossiana euphrosyne*, a species where BCA synthase was proved in a separate experiment, belongs to these species which are bound to the noncyanogenic Violaceae. Species of the same subfamily living on the acyanogenic Urticaceae or Asteraceae only occasionally contain BCA. It cannot be excluded, of course, that the genera *Vanessa*, *Cynthia*, and *Polygonia* do in fact accumulate cyanogenics from their larval food plants, but at very low concentrations, so that the amount of BCA cannot be detected by the usual analytical technique.

Geographic Variation. Geographic variation in the amount of allelochemicals is certainly not new and was demonstrated for the pyrrolizidine alkoloids in the monarch butterfly, *Danaus plexippus* as early as 1972 (Brower et al., 1972). In the present study an additional geographic pattern is apparent in *Parnassius apollo*, *Aporia crataegi*, *Colias crocea*, *Vanessa atalanta*, *Cynthia cardui*, *Polygonia c-album*, *Melanargia galathea*, *Thymelicus sylvestris*, *Spilosoma lutea*, and *Noctua pronuba*: central European specimens of all these species do not contain BCA, while Mediterranean ones do. In most cases we have examined several specimens of each species. An explanation for such a general pattern is still lacking.

Seasonal Variation. In *Pieris brassicae* our data suggest seasonal variation: members of the spring generation contain BCA, which is absent in the summer generation.

These three different types of variation, which were just discernible in the present study, will necessitate further research on an individual, population, seasonal, and geographic basis, preferably with respect to the larval and imaginal food plants of the various individuals tested.

As discussed above the presence of the cyanoglucosides linamarin/lotaustralin could only be demonstrated in a limited number of cases, because the TLC anisaldehyde reaction is much less sensitive than the TLC ninhydrin reaction used as a test for BCA. Nevertheless, we believe it to be most likely that these cyanoglucosides are the source of cyanogenesis, at least in all cases of the Rhopalocera and Zygaenoidea tested so far. This is indicated by the data on Zygaenidae, Acraeinae, and Heliconiinae supplied by Davis and Nahrstedt (1984), and by the fact that in the present paper the cyanoglucosides have been detected in some cases of related but cryptic species also storing BCA. One might even suppose that in the Lepidoptera the two mentioned cyanoglucosides are usually detoxified as in plants, i.e., via BCA synthase.

At present we have no evidence of an insect that would make use of both detoxification pathways, rhodanese *and* BCA-synthase, to some biologically significant extent. On the contrary, the Zygaenidae seem to use the BCA pathway exclusively, since Beesley et al. (1985) found practically no rhodanese in this group. The same seems to apply to *Erynnis tages* (Hesperiidae). Conversely, rhodanese has been demonstrated in sufficient amounts in the blue but-

terfly *Polyommatus icarus* (Parsons and Rothschild, 1964; Beesley et al., 1985), while BCA is obviously not stored.

Jones (1979) has argued that there might be a general need for phytophagous insects to detoxify HCN, because small amounts of cyanoglucosides seem to be present in nearly all angiosperms. Larvae of the southern army worm, *Spodoptera eridiana*, even use hydrocyanic acid as a feeding stimulant (Brattsten et al., 1983). It has been shown that rhodanese occurs in a considerable range of insects, but often in very small amounts only (Beesley et al., 1985). We suggested that BCA might be used as a stored product for the biosynthesis of asparagine and other amino acids (Witthohn and Naumann, 1984a). Similarly Volini and Alexander (1981) have stressed the possible importance of rhodanese for the biosynthesis of sulfur-containing amino acids. If these assumptions prove correct, then the products will be reintroduced into the primary metabolic process in both reactions.

With regard to the role of the cyanoglucosides linamarin and lotaustralin in the ecology of *Zygaena*, it is important to note that the parasitoid braconid wasp *Apanteles zygaenarum*, which lives almost exclusively in *Zygaena* species, does not use BCA synthase to detoxify linamarin, which is obviously acquired from the host's tissues (Davis and Nahrstedt, 1984). The same applies to the parasitic fly *Zenillia*, which also lives in *Zygaena* species and uses the rhodanese pathway (Jones et al., 1962).

Recently Davis and Nahrstedt (1984) have stressed the importance of delimiting the distribution of the cyanoglucosides in the Nymphalidae and suggested that cyanogenesis might be a taxonomically important character for the Zygaenidae. The same was proposed by Naumann (1985). It is now clear that cyanogenesis is not restricted to the Nymphalidae but occurs in all families of butterflies, where it is always based on the two cyanoglucosides linamarin and lotaustralin. It will now be of great importance to delimit the amount of cyanogenics acquired or synthesized by butterflies with respect to their geographic origin, seasonality, and the cyanoglucoside content of their food plants. In the Zygaenoidea strong cyanogenesis extends far beyond the family level and has now been shown to occur in the Limacodidae and Megalopygidae which, at present, are believed to belong to the Cossoidea, but which have also been associated with the Zygaenoidea in the past (Brock, 1971). As the Cossidae themselves are good candidates for cyanogenesis (because they are cyanide-resistant as well), the use of this character for taxonomic and phylogenetic purposes diminishes. On the other hand, the larval storage system for cyanogenic secretion might provide a useful character to delimit at least one major monophyletic entity within the Zygaenidae (Naumann et al., in preparation).

Thus we conclude that cyanogenesis is a widespread phenomenon in the Lepidoptera. It seems to be based mainly or possibly exclusively on the cyanoglucosides linamarin and lotaustralin, and the main detoxification pathway of

the Lepidoptera seems to be BCA synthase. We suggest cyanogenesis to be a basic characteristic of the Lepidoptera, but at present it is impossible to say whether this could, at the same time, be a synapomorphy of the taxon. The use of BCA synthase to detoxify HCN originating from mandelonitrile in the Chrysomelidae (Coleoptera) has been proposed by Blum et al. (1981). It can thus be assumed that a wide distribution of BCA could be found in other phytophagous insect orders as well. The presence of BCA and BCA synthase has recently been demonstrated in the chrysomelid beetle *Paropsis atomaria*, which uses mandelonitrile and prunasin as sources for hydrocyanic acid (Nahrstedt and Davis, 1986).

Rothschild (1985) has recently listed allelochemicals that have been recorded from various British Macrolepidoptera. When compared with the list presented above, it becomes obvious how little is known at present about the cooccurrence of several allelochemicals in nonglandular tissues and their possible ecological interaction. Rothschild rightly points out that one of the major deficiencies of this branch of insect chemical ecology is the present concentration of research on one or two major compounds, mainly cardenolides and pyrrolizidine alkoloids (Boppré, 1986), while very little is known about the ecological importance of other compounds, which sometimes cooccur. Thus, Muhtasib and Evans (1987) have demonstrated synergism in the defensive properties of linamarin and histamine. As for the cyanoglucosides, we shall report elsewhere on the reaction of various predators to the cyanogenic compounds linamarin and β-cyanoalanine.

Acknowledgments—Dr. W. Dierl (Munich), Messers. A.J. and N.J. Duke (East London), Dr. H. Geertsema (Cape Town), Dr. Y. Johki (Kyoto), Mr. S. Oehmig (Leverkusen), Mr. U. Rammert (Bielefeld), Mr. K. Schurian (Sulzbach/Ts.), and Mr. H. Seipel (Büttelborn) have kindly provided specimens for this analysis. Mr. Th. Heinbockel (Stade) helped with the laboratory work, and Mr. W.G. Tremewan (London) kindly improved our English. The study was carried out within research project Na 90/3-2 supported by Deutsche Forschungsgemeinschaft, F.R.G.

NOVEL PYRAZINES FROM THE HEAD OF AUSTRALIAN PONERINE ANT *Rhytidoponera metallica*

BERHANE TECLE,[1] CHANG-MING SUN, JOSEPH J. BROPHY, and ROBERT F. TOIA

Department of Organic Chemistry
University of New South Wales
P.O. Box 1, Kensington
New South Wales 2033, Australia

(Received August 11, 1986; accepted October 27, 1986)

Abstract—The novel pyrazines, (*E*)- and (*Z*)-5-methyl-3-(2-methylbutyl)-2-(3-methylbut-1-enyl)pyrazine, (*E*)- and (*Z*)-5-methyl-3-isopentyl-2-(3-methylbut-1-enyl)pyrazine, (*E*)- and (*Z*)-5-methyl-3-(2-methylbutyl)-2-(3-methylpent-1-enyl)pyrazine, (*E*)- and (*Z*)-5-methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine, together with the known pyrazines, 2,5-dimethyl-3-(2-methylbutyl)pyrazine and 2,5-dimethyl-3-isopentylpyrazine, have been identified from the head of the Australian ponerine ant *Rhytidoponera metallica*. Alkanes and alkenes, in small amounts, were also detected.

Key Words—Ant, *Rhytidoponera metallica*, pyrazine, GC-MS, Hymenoptera, Formicidae, ponerine.

INTRODUCTION

Chemical investigations on ants of the subfamily Ponerinae (Formicidae) have been notable for the fact that pyrazines have been detected in the heads of the majority of species from various genera to date examined, e.g., *Anochetus*, *Odontomachus*, *Ponera*, *Hypoponera*, *Rhytidoponera*, *Brachyponera*, *Mesoponera*, and *Dinoponera* (Attygale and Morgan, 1984; Fales et al., 1984; Herman et al., 1984). In most of the species that did not contain pyrazines, sulfides have been detected (Casnati et al., 1967; Crew and Fletcher, 1974; Longhurst et al., 1979, 1980). Although pyrazines have been detected in other subfamilies of the Formicidae (Dolichoderinae, Myrmicinae, Myrmeciinae, and Formi-

[1] Present address: Pesticide Chemistry and Toxicology Laboratory, 210 Wellman Hall, University of California, Berkeley, California 94720.

cinae) (Attygale and Morgan, 1984; Brophy and Nelson, 1985), their occurrence is less common than in the Ponerinae.

Where activity tests have been carried out on the cephalic secretions (not only on the Ponerinae), alarm responses have been noted (Wheeler and Blum, 1973; Longhurst et al., 1978; Duffield et al., 1976; Howard et al., 1982; Brown and Moore, 1979). It is also of interest to note that an alarm pheromone is produced in the heads of doryline ants of the genera *Eciton*, *Nomamyrmex*, and *Labidus* and that in the case of *Eciton* and *Nomamyrmex*, the crushed worker heads emit a "meaty odor" assumed to be associated with the alarm substance (Brown, 1960). This observation is suggestive of the presence of pyrazines.

Ponerine ants of the genus *Rhytidoponera* have, to date, received relatively little attention. Two Australian species, *R. chalybaea* (at the time identified as *R. metallica*) (Brophy et al., 1981, 1984) and *R. aciculata* (Brophy et al., 1983), have been examined and both yielded 2,5-dimethyl-3-isopentylpyrazine (2) (the pyrazine most commonly detected in insects) and *R. chalybaea* also yielded 2,5-dimethyl-3-citronellylpyrazine. In each case the pyrazine(s) were isolated from the heads of the ants.

Study of *R. metallica* has been limited to an examination of the contents of its pygidial gland, which was shown to contain isogeraniol, *m*-hydroxybenzaldehyde, heptadecene, and heptadecadiene (Meinwald and Wiemer, 1983). We report here results of our investigations on secretions obtained from the heads of *R. metallica*.

METHODS AND MATERIALS

Identification of Ants. The ants used in this investigation were identified as *Rhytidoponera metallica* by Dr. R.F. Crozier, School of Zoology, University of New South Wales. Samples of the ants have been lodged with the Australian National Insect Collection, Canberra.

Extraction of R. metallica. The ants, which are approx. 8 mm in length and weighed approx. 5 mg, were collected in Centennial Park, Randwick, New South Wales. The heads of approx. 700 ants were removed and, after grinding with sodium sulfate, were extracted with dichloromethane (150 ml) in a Soxhlet apparatus for 10 hr. The extract was washed with sodium bicarbonate solution (2×20 ml) and water (2×20 ml) and dried over magnesium sulfate. Removal of the solvent yielded a pale yellow oil (51 mg) which was examined by combined gas chromatography–mass spectrometry (GC-MS).

Hydrogenation of Extract of R. metallica. A portion of the above extract of (20 mg) in ethanol (5 ml) was hydrogenated over Adams catalyst at room temperature and atmospheric pressure for 2 hr. Filtration through magnesium sulfate and removal of the ethanol gave a light yellow oil which was examined as above.

General Method for Synthesizing Alkenyl Pyrazines. The method generally follows that outlined by Wheeler et al. (1981). 2,5-Dimethyl-3-isopentylpyrazine and 2,5-dimethyl-3-(2-methylbutyl)pyrazine were prepared as previously described (Klein and Spoerri, 1951) in 19% and 10% yields, respectively by treatment of 2,5-dimethylpyrazine (Aldrich) with the appropriate alkyl lithium in petroleum ether (bp 40–60°C). The dimethylalkyl pyrazines (0.5 g, 0.03 mmol) so obtained were subsequently acylated with the desired ethyl ester at −78°C using lithium diisopropylamide as base, in 40–50% yields. Reduction of the pyrazyl ketones (0.1 g, 0.004 mmol) so formed with sodium borohydride in methanol at 40–50°C yielded the corresponding alcohols in 80–90% yields. The alcohols (0.08 g, 0.003 mmol) were treated with *p*-toluenesulfonyl chloride in the conventional manner to yield the tosyl esters which, without isolation, were refluxed in pyridine (15 hr) to yield the alkenyl pyrazines (70–80%) as pale yellow oils. In each case GC-MS examination of the synthetic pyrazines indicated that the ratio of *E* isomer to *Z* isomer was approx. 9 : 1.

[^{1}H]NMR (300 MHz) δ 0.86(d, J = 6 Hz, 3H); 0.91 (t, J = 7 Hz, 6H); 1.11 (d, J = 7 Hz, 3H); 1.19–1.48(m, 5H); 2.17–2.35(m, 1H); 2.49(s, 3H); 2.56–2.65(m, 1H); 2.82–2.90(m, 1H); 6.57(d, J = 16 Hz, 1H); 6.74(dd, J = 16, 8 Hz, 1H); 8.20(S, 1H).

E-5-Methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine (10): found 247.2155 (MH^+); calc. for $C_{16}H_{27}N_2$, 247.2174. [^{1}H]NMR (300 MHz) δ 0.91(t, J = 7 Hz, 3H); 0.96(d, J = 6 Hz, 6H); 1.11(d, J = 6 Hz, 3H); 1.40–1.59 (m, 4H); 1.62–1.70(m, 1H); 2.16–2.33(m, 1H); 2.48(s, 3H); 2.73–2.84(m, 2H); 6.54(d, J = 15 Hz, 1H); 6.73(dd, J = 15, 8 Hz, 1H); 8.19(s, 1H).

Hydrogenation of the synthetic pyrazines was carried out in the same manner as for the ant extract.

Interconversion of the synthetic *E* and *Z* isomers was achieved by irradiation of a deoxygenated dilute solution of the *E* pyrazine in pentane for 5 min at 300 nm.

Spectroscopy and Gas Chromatography. Mass spectra were obtained on an AEI MS12 mass spectrometer coupled to a Shimadzu GC6 AMP gas chromatograph. Separations were effected on SCOT columns, either (a) OV-1 (30 m × 0.5 mm) programmed from 90°C to 250°C at 5°C/min or (b) FFAP (85 m × 0.5 mm) programmed from 80°C to 225°C at 5°C/min, with helium as carrier gas. The mass spectrometer was operated at 8000 V and 70 eV ionizing voltage. Spectra were acquired and processed by a VG Digispec Display data system. Accurate mass measurements were obtained on an AEI MS902 mass spectrometer under chemical ionization conditions (isobutane reagent gas) using a chart timing method (Brophy et al., 1979). [^{1}H]NMR spectra were recorded in $CDCl_3$ solution on either a Varian EM 360 (60 MHz) or a Bruker CXP 300 (300 MHz) spectrometer.

RESULTS AND DISCUSSION

A GLC trace of the total extract of the heads of *R. metallica* is shown in Figure 1 and the assignments are given in Table 1. A chemical ionization mass spectrum of this crude extract was run using isobutane as reagent gas under conditions where all hydrocarbons fail to be protonated. This spectrum demonstrated the presence of components with molecular weights of 178, 232, 246, 264, and 278 and subsequent high-resolution mass spectrometry indicated that

TABLE 1. COMPOUNDS IDENTIFIED IN HEAD OF *Rhytidoponera metallica*

Number	Compound
1	2,5-Dimethyl-3-(2-methylbutyl)pyrazine
2	2,5-Dimethyl-3-isopentylpyrazine
3	Z-5-Methyl-3-(2-methylbutyl)-2-(3-methylbut-1-enyl)pyrazine
4	Z-5-Methyl-3-isopentyl-2-(3-methylbut-1-enyl)pyrazine
5	E-5-Methyl-3-(2-methylbutyl)-2-(3-methylbut-1-enyl)pyrazine
6	E-5-Methyl-3-isopentyl-2-(3-methylbut-1-enyl)pyrazine
7	Z-5-Methyl-3-(2-methylbutyl)-2-(3-methylpent-1-enyl)pyrazine
8	Z-5-Methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine
9	E-5-Methyl-3-(2-methylbutyl)-2-(3-methylpent-1-enyl)pyrazine
10	E-5-Methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine
11	Unknown, suspected mol wt 264
12	$C_{16}H_{28}N_2O$
13	$C_{16}H_{28}N_2O$
14	Unknown, suspected mol wt 264
15	Diisobutyl phthalate
16	Dibutyl phthalate

the formulas for these ions were *m/z* 178, $C_{11}H_{18}N_2$; *m/z* 232, $C_{15}H_{24}N_2$; *m/z* 246, $C_{16}H_{26}N_2$; *m/z* 264, $C_{16}H_{28}N_2O$; and *m/z* 278, $C_{16}H_{22}O_4$, respectively. Subsequent GC-MS analysis of the extract under electron inpact (EI) conditions indicated that there were two compounds of mol wt 178, four compounds of mol wt 232, and four compounds of mol wt 246. In addition, at least two compounds which did not show molecular ions but whose molecular weight was assumed to be 264 were present, as well as two phthalate esters which were assumed to be butyl phthalates.

Hydrogenation of the crude extract led to a more simple GLC pattern (Figure 2, Table 2). Whereas the compounds of mol wt 178 remained unaltered, two peaks whose mass spectra showed mol wt 234 appeared at the expense of the four isomers of mol wt 232. Similarily, two new peaks whose mass spectra showed mol wt 248 appeared at the expense of the four of mol wt 246. The peaks suspected to be of mol wt 264 remained unchanged, as did those for the phthalate esters.

The mass spectra of peaks (a) and (b) of mol wt 234 in the hydrogenation mixture (see Table 3) indicated that the compounds were probably trisubstituted pyrazines with side chains of one, five, and five carbon atoms, while the peaks (c) and (d) of mol wt 248 appeared to be trisubstituted pyrazines with side chains of one, five, and six carbon atoms. The orientation of these groups in the two sets of hydrogenated pyrazines was not known.

The two pyrazines (1) and (2) of mol wt 178 were identified as 2,5-di-

TABLE 2. COMPOUNDS IDENTIFIED IN HYDROGENATED EXTRACT FROM HEAD OF *Rhytidoponera metallica*

Number	Compound
1	2,5-Dimethyl-3-(2-methylbutyl)pyrazine
2	2,5-Dimethyl-3-isopentylpyrazine
a	5-Methyl-2-isobutyl-3-(2-methylbutyl)pyrazine
b	5-Methyl-2,3-diisobutylpyrazine
c	5-Methyl-2-(3-methylpentyl)-3-(2-methylbutyl)pyrazine
d	5-Methyl-2-(3-methylpentyl)-3-isopentylpyrazine
11	Unknown, suspected mol wt 264
12	$C_{16}H_{28}N_2O$
13	$C_{16}H_{28}N_2O$
14	Unknown, suspected mol wt 264
15	Diisobutylphthalate
16	Dibutylphthalate

methyl-3-(2-methylbutyl)pyrazine and 2,5-dimethyl-3-isopentylpyrazine, respectively, on the basis of their mass spectra. This was confirmed by coinjection with authentic compounds on a FFAP column, known to be able to separate the 2,3,5 isomer from the slower eluting 2,3,6-trisubstituted pyrazines (Wheeler and Blum, 1973).

Since the two pyrazines of mol wt 178 had the 2,3,5 substitution, it was thought likely that the four suspected pyrazines of mol wt 232 and the four of mol wt 246 also had the same substitution pattern and also that one of the substituents may have been either the 2-methylbutyl or isopentyl group, i.e., that these eight unknown pyrazines involved further elaboration on the already identified pyrazines of mol wt 178. Moreover, the results from the hydrogenation experiment suggested these compounds to be dialkyl alkenyl pyrazines.

As noted above, hydrogenation of each of the pyrazines of mol wt 232 and 246 cause the uptake of one molar equivalent of hydrogen, indicating one of the side chains contained an olefinic bond. That this double bond was in a five-carbon side chain in compounds (3)–(6) and in the six-carbon side chain in compounds (7)–(10) was also deduced from their mass spectra (Table 3). Thus ions at m/z 176 and 190 for compounds (3)–(6) and (7)–(10), respectively, arose from loss of C_4H_8 by McLafferty-type rearrangement of a C-5 saturated side chain in each case. There was no significant peak corresponding to the loss of C_5H_{10} in compounds (7)–(10). Such a peak would be expected to occur if the olefinic bond were in the C-5 chain in compounds (7)–(10).

The relative placement of the two large side chains in (3)–(10) could be determined by consideration of the results obtained in the structural elucidation of 5-methyl-3-*n*-propyl-2-(1-butenyl)pyrazine from the ant *Aphaenogaster rudis*

(Wheeler et al., 1982). It was observed that the occurrence of an alkenyl group adjacent to a large alkyl group (in this case *n*-propyl) diminished the intensity of the peak due to the McLafferty rearrangement. When the alkenyl group was adjacent to a methyl group or hydrogen, this rearrangement led to the base peak of the mass spectrum. It was also found that no matter what the substitution, the mass spectra of the *E* and *Z* alkenes differed quite considerably.

On the basis of these considerations candidate 2-alkenyl-3-alkyl-6-methyl- and 2-alkenyl-3-alkyl-5-methylpyrazines were synthesized for comparison with

the natural compounds. Full details of the compounds synthesized will be published elsewhere.

It was determined that compound (3) was (*Z*)-5-methyl-3-(2-methylbutyl)-2-(3-methylbut-1-enyl)pyrazine while peak (5) was (*E*)-5-methyl-3-(2-methylbutyl)-2-(3-methylbut-1-enyl)pyrazine. Compound (4) was (*Z*)-5-methyl-3-isopentyl-2-(3-methylbut-1-enyl)pyrazine and (6) was (*E*)-5-methyl-3-isopentyl-2-(3-methylbut-1-enyl)pyrazine. The *Z,E* relationship of these two pairs of compounds was shown by conversions of synthetic (5) into (3) and (6) into (4) by short irradiation of the *E* isomers. Similarly, the structure of compound (7) was shown to be (*Z*)-5-methyl-3-(2-methylbutyl)-2-(3-methylpent-1-enyl)pyrazine and (9) was (*E*)-5-methyl-3-(2-methylbutyl)-2-(3-methylpent-1-enyl)pyrazine, while (8) was (*Z*)-5-methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine and (10) was (*E*)-5-methyl-3-isopentyl-2-(3-methylpent-1-enyl)pyrazine. Once again the *E*, *Z* relationship of the pairs of isomers was shown by the photochemical conversion of the *E* into *Z* isomers. In every case mass spectra of the synthetic and natural compounds were identical, while the synthetic material enhanced the GLC peak of the natural material on a FFAP column.

The remaining compounds (11)–(14), of formula $C_{16}H_{28}N_2O$, whose mass spectra appear in Table 3 have so far eluded structural elucidation.

Also detected by GC-MS in the extract from the head were a series of *n*-alkanes and alkenes. These are indicated on Figure 1.

The mixture of 10 (possibly 14) pyrazines detected in the head of *R. metallica* represents the most complicated group of these compounds yet found; previously a series of five 2,6-dimethyl-3-*n*-alkylpyrazines had been found in the heads of an *Odontomarchus* species (Wheeler and Blum, 1973). Of the 10 compounds, 2,5-dimethyl-3-isopentylpyrazine (2) represents the pyrazine most commonly encountered in the Hymenoptera, having been identified from ants, bees, and wasps (Attygale and Morgan, 1984; Wheeler et al., 1982). 2,5-Dimethyl-3-(2-methylbutyl)pyrazine (1) has been detected once previously, from an Australian formicine ant of the genus *Calomyrmex* (Brown and Moore, 1979). In this ant it also cooccurs with 2,5-dimethyl-3-isopentylpyrazine.

Of the remaining eight pyrazines identified (3)–(10), no analogs as yet exist in nature. The presence of the more complex side chain in the 2 position so far has analogy only in 5-methyl-3-*n*-propyl-2-(1-butenyl)pyrazine, isolated from the heads of the myrmicine ant *Apaenogaster rudis* (Wheeler et al., 1982). The vagaries of the mass spectra of the various alkenyl pyrazines noted by Wheeler have been fully reflected in the mass spectra of the alkenyl pyrazines from *R. metallica*. It was not until the olefinic bond was hydrogenated that mass spectra more characteristic of alkyl pyrazines (Brophy and Cavill, 1980) were observed.

The only other olefinic pyrazines reported from the Hymenoptera have

been (*Z*)- and (*E*)-2,5-dimethyl-3-styrylpyrazines, isolated from the Argentine ant *Iridomyrmex humilis* (Cavill and Houghton, 1974). In this case it was shown, by extraction of the ants in the dark, that the $Z:E$ ratio was 1:3; extraction under ordinary laboratory conditions resulted in the detection of only the *Z* isomer. It was suggested that the natural compound in that ant was, in fact, the *E* isomer, with isomerization occurring during extraction and isolation.

With the olefinic pyrazines detected in *R. metallica*, the $Z:E$ isomer ratio was approx. 2:3, and this was reproducible over a number of extractions carried out under ordinary laboratory conditions. The synthetic *E* isomers could be converted to an approx. 1:1 mixture of *E* and *Z* isomers by irradiation at 300 nm for 5 min as noted above.

Of the two major remaining unidentified compounds, (12) and (13), the formulas of $C_{16}H_{28}N_2O$ and retention time on FFAP suggest an addition of the elements of methanol to the compounds (3)–(6). It is unlikely that these are artifacts since care had been taken to ensure that methanol did not come into contact with the extract. To date these compounds have eluded structural assignment.

The glandular origin of the pyrazines in the head of *R. metallica* has not been determined but, in light of previous reports, is assumed to be the mandibular gland. Behavioral tests have not been carried out.

The ubiquitous phthalate esters, (15) and (16), are considered to be artifacts, possibly having been acquired by the ant in the course of its food gathering, although contamination from solvents and glassware in the laboratory cannot be ruled out.

Acknowledgments—We thank Dr. R. F. Crozier of the University of New South Wales for identifying the ants, Mr. D. Nelson of the School of Chemistry for the chemical ionization and high-resolution mass spectra, and the Australian Government, through ADAB, for a scholarship to B.T. and through ARGS for support to C.M.S.

(Received June 30, 1986; accepted October 28, 1986)

Abstract—The compounds (*Z,Z,Z*)-3,6,9-nonadecatriene (I), (*Z,Z,Z,E*)- (II), and (*Z,Z,Z,Z*)-3,6,9,11-nonadecatetraene (III) have been implicated as components of the female sex pheromone of the fall cankerworm. Chromatographic determination of the proportions of these compounds in individual females of sympatric asexual and sexual reproductive forms of the species, with concurrent analysis of the electrophoretic profiles of the same females, showed that the I : II : III proportion of compounds was constant across electrophoretically differing asexual genotypes and between these and the sexual form. Life-history characters, in contrast, typically show great variation among these genetic groups. The results indicate that pheromonal constancy is maintained in a reproductive system that is theoretically vulnerable to selective pressures that would lead to heterogeneity in the species' pheromonal communication channel.

Key Words—Lepidoptera, Geometridae, *Alsophila pometaria*, fall cankerworm, sex pheromones, genetic variation, pseudogamy.

INTRODUCTION

Although differentiation in female sex pheromones is a common isolating mechanism in Lepidoptera (Roelofs and Brown, 1982; Struble and Byers, 1985), we have as yet little understanding of how such pheromone systems evolve (Cardé

0098-0331/87/0800-1823$05.00/0 © Plenum Publishing Corporation

and Baker, 1984). One unanswered question is the degree to which pheromone divergence results from selection, as imposed by factors such as overlapping signals from a related species, interception of the signal by predators, or physical characteristics of the habitat (Roelofs et al., 1982). Selection against deviant signals and receptors could be so strong as to prevent evolution of the pheromone channel except when gene frequencies are initially displaced by sampling error in founder populations (Wright, 1932; Templeton, 1981).

One gauge of the evolutionary plasticity of pheromone systems should be their intraspecific variability, but few relevant studies exist. Geographic variation in pheromone production or response has been reported for some species of Lepidoptera (Arn et al., 1982; Bailey et al., 1987; Klun and Cooperators, 1975; Klun and Maini, 1979), and intrapopulation variation has been examined in several others (Löfstedt et al., 1985; Miller and Roelofs, 1980). Single-locus polymorphism in pheromone isomeric composition was documented for the European corn borer (Klun and Maini, 1979), whereas quantitative heritability was demonstrated in the pink bollworm moth (Collins and Cardé, 1985).

Correlation of such intraspecific variation with inferred selective forces would provide evidence for the adaptive nature of pheromone differentiation, but it has rarely been sought. Character displacement of the pheromone composition has been suggested for a few species (Cardé et al., 1977; Greenfield and Karandinos, 1979). However, the only attempt to directly measure response to selection in the field was conducted by Haynes et al. (1984), who found no evidence of change in the pheromone system of the pink bolloworm moth after three to five years of field application of the species' pheromone as a mating suppressant.

We report a study of intraspecific variation of pheromone composition in the fall cankerworm (*Alsophila pometaria*), a geometrid moth that might be subject to continuous selection for novelty in the communication channel because of its unusual breeding system. The fall cankerworm has two female reproductive forms (Mitter and Futuyma, 1977). Eighty to ninety-nine percent of the individuals in most populations are pseudogamous asexual females, which must mate with conspecific males in order to reproduce but give rise to all-female progeny genetically identical to themselves, there being no paternal genetic contribution. The remaining 1–20% of these populations is composed of sexually reproducing males and females. The asexual females are genetically diverse due to repeated origin of asexual females from sexual progenitors (Harshman and Futuyma, 1985a), but one or a few widespread genotypes are typically dominant (Mitter and Futuyma, 1977; Harshman and Futuyma, 1985a,b; Mitter et al., 1987).

There are several reasons why selection in populations harboring pseudogamy might favor evolution of mating signals unique to the sexual form. Males make no genetic contribution to the offspring when they pair with asexual females. They should consequently face intense selection for discrimination

against asexual mates. Cankerworm females may also compete for the relatively scarce males (Harshman and Futuyma, 1985b), which make up only 1–10% of most fall cankerworm populations (Porter and Alden, 1924; Moore and Drooz, 1974; Mitter and Futuyma, 1977; Harshman and Futuyma, 1985b). Thus, any novel pheromone increasing the probability of male response might be strongly favored (West-Eberhard, 1984).

Evidence for mating discrimination favoring sexual females would also shed light on the puzzling dynamics of populations harboring pseudogamy. Under some conditions such discrimination could have the incidental effect of stabilizing the existence of these populations, which will tend to be driven to extinction by the superior reproductive potential of their all-female components (Kiester et al., 1981; Moore and McKay, 1971; Stenseth et al., 1985). Whether mating discrimination evolves may depend on such factors as the rate at which the dominant asexual genotypes can be replaced. If this turnover is rapid, there may be no divergence between the two reproductive forms for male discrimination to act on. Rare asexual variants might arise frequently in the fall cankerworm (Harshman and Futuyma 1985a), but how rapidly they could displace the dominant types is not clear.

We have sought to determine whether the fall cankerworm pheromone shows a pattern of variation suggestive of evolution under the pressure of pseudogamy. Such divergence could be manifest at several levels: as pheromonal difference between sexual and asexual forms; as variation among asexual genotypes, possibly reflecting the recency with which they have originated from the sexual form; or as geographic variation in the attractant blend resulting from independent evolution of the pheromone in different areas.

We therefore carried out a chromatographic analysis of the proportions of pheromone components in the glands of individual females of the sexual and asexual fractions of a fall cankerworm population near Beltsville, Maryland. We have also compared our findings with the pheromone composition determined for a fall cankerworm population at the opposite extreme of the species' range, near Saskatoon, Saskatchewan, Canada (Wong et al., 1984a). Wong et al. (1984a,b) indicated that the fall cankerworm pheromone is an approximately 25 : 60 : 15 mixture of *Z,Z,Z*-3,6,9-nonadecatriene (I), (*Z,Z,Z,E*)- (II), and (*Z,Z,Z,Z*)-3,6,9,11 nonadecatetraene (III). Components II and III, singly and in combination, attract males to traps. Compound II has greater attractiveness and was as attractive as any mixture of II and III. Component I is not attractive by itself, but is reported to synergize the effects of II and III (Wong et al., 1984a,b).

METHODS AND MATERIALS

Genetic Analysis. The moths analyzed in this study were laboratory-reared offspring of parents collected from three sites near Beltsville, Maryland. A con-

comitant survey of sex ratio, reproductive mode frequency, and genotypic composition at four electrophoretic loci (Mitter et al., 1987) showed the Beltsville population to be quite similar in breeding structure to intensively studied populations on Long Island, New York (Mitter et al., 1979; Harshman and Futuyma, 1985a,b). The proportion of females reproducing sexually was estimated from progeny testing to be 15–20%, while a sample of reared, wild-caught larvae contained 9% males. The asexual population was dominated by two very abundant genotypes (Table 1) (Mitter et al., 1987).

The individuals subjected to pheromone analysis were daughters of females collected in the winters of 1982–1983 and 1983–1984. The mode of reproduction of these females was determined from the sex ratios and electrophoretic profiles (at two polymorphic loci) of their progenies, following methods described by Mitter and Futuyma (1977) and Harshman and Futuyma (1985a).

Twelve sexually produced moths were assayed for pheromone composition, representing the offspring of eight different females. The 44 asexually produced females assayed represented 20 single-parent broods, and five different four-locus electrophoretic genotypes. The latter included the two abundant genotypes referred to above, plus three rare genotypes. Broods of asexual genotypes 1, 2, and 3 were assayed in a preliminary study in 1983. The larvae were mass-reared on cut foliage of *Prunus serotina* Ehrh. Additional broods of genotype 3, broods of genotypes 4 and 5, and sexual broods were assayed during more extensive progeny rearing in 1983, using "Fall Cankerworm Diet" supplied by Bioserv Inc. (Frenchtown, New Jersey), which follows the recipe of Fedde (1974).

Details of rearing procedures are given in Mitter et al. (1987). The virgin females used for pheromone analyses had eclosed an average of seven days earlier, with a range of 0–20 days. (Female fall cankerworms live 30 days or more at 4°C; unpublished observations.) After excision of the ovipositor for pheromone analysis, each female carcass was stored at −60°C until the specimen was subjected to electrophoresis. Electrophoretic methods and phenotype designations (as in Table 1) followed Mitter and Futuyma (1977) and Futuyma et al. (1981). Mothers and sibs of individuals subjected to pheromonal analysis were also electrophoresed to verify reproductive mode and genotype for each brood, as part of a larger genetic study (Mitter et al., 1987).

Chromatographic Analysis. Extracts of individual female pheromone glands were prepared by excising the ovipositor with fine dissecting scissors and soaking it for 3 min in 10 μl heptane contained in a conical microvial. The ovipositor was then removed from the solvent and 2–3 μl of the extract was injected onto a 60-m × 0.25-mm (ID) fused silica DB-1 open tubular capillary column (J&W Scientific Inc., Rancho Cordova, California) using the splitless injector (225°) of a Hewlett-Packard model 5840A gas chromatograph that was equipped with a flame ionization detector. Hydrogen, at a velocity of 50 cm/sec, was used as a carrier gas, and the column was temperature programmed:

120°C for 0.45 min after injection of a sample followed by heating to 175°C at 15°C/min.

The proportion of I, II, and III in each extract was calculated from the peak area recorded by the integrator of the gas chromatograph. Chromatographic peaks representing I, II, and III had 1867, 1903, and 1927 retention indices, respectively, on the DB-1 column. These retention indices were identical to samples of I, II, and III supplied by Dr. E.W. Underhill, National Research Council of Canada, Saskatoon, Saskatchewan, Canada. Combined gas chromatography-mass spectroscopy using the DB-1 column interfaced with a Finnigan model 6110 data system verified that the components at 1867, 1903, and 1927 retention indices in the combined extracts of four fall cankerworm ovipositors had mass fragmentation patterns identical to the authentic standards.

Statistical Analysis. Two aspects of pheromone composition were selected for statistical analysis. The proportion of the *Z,Z,Z,E* isomer (II) in the total of 3,6,9,11-nonadecatetraene (II + III) was examined because such isomeric ratios are of known behavioral importance in many other Lepidoptera. The proportion of the total pheromone made up by component I was also examined, because I is reported to have a qualitatively different behavioral effect from components II and III (Wong et al., 1984a, b).

Mean proportions among different genetic groups, consisting of the five asexual genotypes and the pooled sample of sexual females, were compared by analysis of variance, following arcsin square-root transformation.

RESULTS

Table 1 summarizes the chromatographic analyses of the ovipositor extracts of the Beltsville *A. pometaria* females. The data for 1983 and 1984 were combined because there was no statistical difference between years. Values are presented separately for the different electrophoretic classes of asexual females. The four-locus electrophoretic phenotype of each of those classes is also given, as is its frequency in samples of wild-collected larvae (Mitter et al., 1987).

The data of Table 1 indicate that the proportion of 3,6,9,11-nonadecatetraene comprised by the *Z,Z,Z,E* isomer (II) in the Beltsville samples does not vary significantly among the different genetic groups or between asexual females as a group and their sexual counterparts. The mean isomeric ratios for all genetic groups at Beltsville were also strikingly similar to the pooled value reported for the Saskatchewan population by Wong et al. (1984a).

The proportional amount of component I was also homogeneous across genetic groups at Beltsville. However, there was proportionally less of this component in Beltsville *A. pometaria* females than reported for Saskatchewan females (Wong et al., 1984a).

[a] I = (*Z,Z,Z,Z,E*)-3,6,9,11-C_{19}; II = (*Z,Z,Z,Z*)-3,6,9,11-C_{19}; III = (*Z,Z,Z*)-3,6,9-19_{19}. Values followed by the same letter are statistically indistinguishable at $\alpha = 0.05$. Genotype frequencies from Mitter et al. (1987).

[b] Compound III was not known to be a pheromonal component when these females were studied (1982–1983).

DISCUSSION

Our findings indicate that the proportion of the three known pheromonal components was essentially constant across a representative set of electrophoretically characterized sexual and asexual fall cankerworm genotypes at Beltsville. By contrast, asexual genotypes at Beltsville and elsewhere typically show marked differences in a wide range of other characters such as body size, phenology, host preference, and developmental response to crowding (Mitter et al., 1979, 1987; Schneider, 1980; Futuyma et al., 1981, 1984. Rare pheromonal variants may have been missed in our limited survey, and it is also possible that variation might exist in some as yet unknown component of the species' pheromone (Klun et al., 1979). Nonetheless, our findings suggest that the Beltsville fall cankerworm population is not undergoing continual evolution of the pheromone such as pseudogamy could theoretically produce. We find likewise no evidence of pheromone differences which could promote persistence of cankerworm populations by facilitating male preference for sexual females. Our observations are in general agreement with those of Harshman and Futuyma (1985b), who found a marginal indication of differential mating success among fall cankerworm genotypes in the wild, but no tendency for greater success by rare genotypes, which will presumably include the rare sexual individuals.

One explanation for these observations is that the rate of origin and turnover of asexual genotypes from the sexual population is sufficient to thwart the development of pheromonal divergence between the reproductive forms, despite the apparent persistence of the few widespread, dominant asexual genotypes (Harshman and Futuyma, 1985a; Mitter et al., 1979). The assumption that females compete for males might also be questioned, since mating frequency and longevity of males have not been studied in the field. Individual males have been observed to mate up to seven times in the laboratory (Moore and Drooz, 1974).

Another possibility is that episodes of pheromonal evolution driven by pseudogamy do occur but only sporadically, contingent on the appearance of appropriate pheromonal variants. Under this view, local fall cankerworm populations would most often show pheromonal constancy, but geographically separated populations might differ as a result of independent episodes of pheromonal evolution, which terminate when the asexual population gradually acquires the communication channel newly evolved by the sexual form. This is one of several explanations possible for the divergent proportions of 3,6,9-nonadecatriene observed in this study and by Wong et al. (1984a).

To summarize, the fall cankerworm population we studied, which is genetically diverse in reproductive mode and other characters, appears to be pheromonally constant despite the potential challenge of the pseudogamous breeding system. Our findings resemble those of Haynes et al. (1984), in indicating no pheromonal response to a presumed selection pressure.

Acknowledgments—We thank Dr. J.W. Neal, Jr., and Ms. K.M. Gott for providing much of the wild-caught material on which this study was based. The superb laboratory assistance of E. Silverfine was indispensable. We also thank Dr. B. Leonhardt, USDA, ARS, Beltsville, Maryland, for mass spectral verification of the fall cankerworm compounds; Dr. E.W. Underhill for the reference compounds; A. Wilson for much advice and assistance; and Dr. C. Reichelderfer for sharing his laboratory facilities. Drs. D. McCauley, J. McGlaughlin, and J.W. Neal, Jr., and two anonymous reviewers provided thorough criticisms of the manuscript but are not to blame for its remaining defects. This research is, in part, a contribution from the Maryland Agricultural Experiment Station, Scientific Article No. A-4475, Contribution No. 7468.

DISCRIMINATION OF OCCUPIED HOST FRUIT BY PLUM CURCULIO FEMALES (COLEOPTERA: CURCULIONIDAE)

SUSAN L. BUTKEWICH, RONALD J. PROKOPY, and THOMAS A. GREEN

Department of Entomology

Amherst, Massachusetts 01003

(Received June 25, 1986; accepted October 30, 1986)

Abstract—Larval survival of plum curculios (PCs), *Conotrachelus nenuphar* (Herbst), was found to decrease with increasing egg density per fruit. Subsequently, we assayed PCs for propensity to avoid egg-laying at sites (immature plums) already occupied by conspecific eggs. Laboratory choice tests showed PCs made an equal number of visits to and ovipositions in fruit with a single oviposition as in clean fruit. Although there was a trend toward more visits to fruit which contained four or eight oviposition wounds and eggs or eight artificial punctures than to clean fruit, PCs oviposited less frequently into these than clean fruit. Results suggest that wounding of fruit may enhance the ability of ovipositing PCs to locate fruit, but at the same time may furnish cues allowing some degree of discrimination against heavily infested fruit for oviposition.

Key Words—Plum curculio, *Conotrachelus nenuphar* (Herbst), Coleoptera, Curculionidae, oviposition, host discrimination, host location.

INTRODUCTION

Mechanisms which allow resource partitioning and subsequent avoidance of overcrowding and competition among individuals within a host of limited resource capacity are often of positive selective value (Prokopy et al., 1984). Prokopy (1981) reviewed the literature on an array of insects which respond to marking pheromones to avoid ovipositing at sites infested with their own progeny or progeny of conspecifics. Chemical cues emitted from a host likewise

0098-0331/87/0800-1833$05.00/0 © Plenum Publishing Corporation

may serve as signals of egg or larval occupancy (Rothschild and Schoonhoven, 1977; Renwick and Radke, 1981, 1985; Girolami et al., 1981; Saxena and Basit, 1982; Mitchell and Heath, 1985).

In recent years, we have been investigating partitioning of larval fruit resources by some of the major apple pests in northeastern North America. Thus far we have found that (1) the apple maggot fly, *Rhagoletis pomonella* (Walsh), lays down a pheromone after oviposition that deters conspecifics from laying additional eggs in the same host fruit (Prokopy, 1972); (2) ovipositing codling moths, *Cydia pomonella*, (L.) do not discriminate against occupied sites through chemical signals but may partition ovipositional resources via other mechanisms (Roitberg and Prokopy, 1982); and (3) the European apple sawfly, *Hoplocampa testudinea* (Klug), responds to wound exudates of host tissue in discriminating against apples already infested with conspecifics (Roitberg and Prokopy, 1984). To date, no quantitative work has been done to determine if a fourth major apple pest, the plum curculio (PC), *Conotrachelus nenuphar* (Herbst), assesses fruit for the presence of conspecifics.

PC adults overwinter in ground cover or soil in or near woods bordering host trees, yet little is known about how PCs locate and choose egg-laying sites upon spring emergence. We do know that within host trees, the majority of movement is by crawling on branches, stems, and petioles until a fruit is encountered (Owens et al., 1982).

Oviposition commences when a female first feeds under the skin of a fruit, forming a flap. She then reverses position and deposits an egg under the flap. After egg deposition, the female again reverses position and continues feeding, forming a large crescent of gouged tissue above the flap. This is thought to relieve pressure produced by proliferating cells of the growing fruit. PCs in nature have been observed ovipositing repeatedly into the same fruit (Quaintance and Jenne, 1912; Owens et al., 1982). This behavior suggests PCs may not discriminate strongly against fruit previously infested with conspecifics. On the other hand, Jacklin et al., (1968) found that PC larval crowding in apples reduced larval weight and rate of survival, hinting that a mechanism by which females could assess conspecific density within a host might be of selective advantage.

At least two other Curculionidae are known to partition resources by avoiding occupied hosts for oviposition. The boll weevil, *Anthomonus grandis grandis* (Boheman), has been shown to discriminate against cotton squares that contain one or more eggs (Stansly and Cate, 1984), and *Ceutorhynchus assimilis*, the cabbage seed weevil, lays down a marking pheromone after oviposition which acts as an oviposition deterrent (Kozlowski et al., 1984). Here we report evidence indicating that PCs can, in fact, recognize a high density of conspecifics within a host via cues emitted from oviposition and/or feeding puncture sites.

METHODS AND MATERIALS

Larval Survival. Studies were conducted in June 1982 in Amherst, Massachusetts, to determine to what degree larval density affected survival in fruit. Fruiting branches on unsprayed cultivated plum trees were bagged in spring prior to PC adult emergence to protect fruit from infestation. Upon spring migration, adults were collected from an unsprayed orchard by tapping limbs over a large white sheet onto which dislodged adults fell. PCs were placed in the bags and allowed to oviposit into fruit. Once fruit abscission began, all remaining fruit were picked because larvae in fruit that do not abscise prematurely usually do not survive (Levine and Hall, 1977). Fruit were sorted into groups with like number of oviposition scars (98% of the oviposition scars were found to contain a single egg). Egg density levels per fruit ranged from one to six. Fruit were placed in plastic 35-ml cups and held at 25°C, 50% relative humidity for 30 days. Once larvae emerged from the fruit, they were removed from the cups, and percent survival was recorded for each density level. Egg density and larval survival were compared using Spearman's rank correlation (Sokal and Rohlf, 1981).

Fruit Discrimination Study. Studies were conducted in June 1984 to determine the ability of PCs to discriminate against egg-occupied fruit. Tests were run under fluorescent light at 16:8 hr light-dark, 50–60% relative humidity, and at 24°C. Opaque dividers were placed between each cup or cage to visually isolate each PC. Mirrors were placed on the wall behind a row of cups or cages so that PCs could be viewed from all sides. Because PCs frequently feign death when disturbed, a white curtain was hung just below eye level of the observer to hide the observer's movements from PCs.

Females were pretested to standardize their physiological state of readiness for oviposition. An immature plum (ca. 17 mm diam.) was hung in the center of a 35-ml transparent plastic cup, and a single PC was introduced. Each PC was allowed one oviposition per fruit over a total of three fruit. After a PC completed oviposition, the fruit was replaced with a clean one. All pretests took place within 5 hr of testing. We maintain the importance of standardizing through pretests the physiological state of PCs for subsequent assay, yet also recognize that, in so doing, PCs could conceivably learn to accept fruit of a particular type, e.g., clean fruit.

Once pretested, a female was placed gently into a 5-dram vial on a test cage floor and allowed to remain undisturbed for 15 min before the vial was opened. Test cages were placed on a wooden platform constructed so that cages could be removed from below. Test cages were transparent cylindrical plastic tubes 11 cm high by 8.5 cm diam. (Figure 1). At the center of each cage was a wooden stand in which a stem and crosspieces made from plum twigs were mounted. Two clean fruit and two other fruit of like treatment (with one, four,

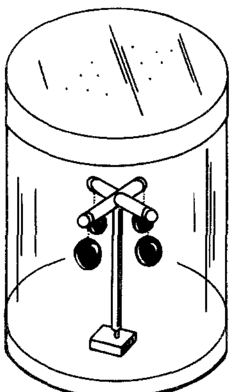

FIG. 1. Cage for PC fruit discrimination choice tests.

or eight ovipositions or eight artificial punctures) were hung at the ends of the crosspieces in an alternating fashion. Fruit were of the same size and type as in the pretest. Treatment fruit were prepared on the day of testing. Each of those to be infested was placed with one or two PCs in a 35-ml cup until the desired number of oviposition scars was observed. Artificial punctures were made with a scalpel to resemble natural oviposition scars in size and shape. Therefore, this treatment offered fruit in what appeared to us as being the same state as fruit which had received oviposition scars naturally except that all insect visitation previous to testing was eliminated.

We designated tests as beginning when a PC started crawling up the stem of the crosspiece and ending when the first oviposition was completed. We recorded the fruit type visited first by a PC (i.e., first visits), the total number of visits to each fruit type, and the fruit type in which oviposition occurred. If a PC fed on a fruit without ovipositing, the fruit was replaced with a new one of the same treatment. If a PC did not oviposit within 3 hr, it was removed and replaced with a new pretested individual. If a PC failed to oviposit, it was not included in the analysis of data. Test cages were rotated 45° after each test was completed to randomize treatment placement.

RESULTS

Larval survivorship was greatest, 36%, at a density of one egg per fruit (Table 1). With increasing egg density per fruit, larval survivorship progressively declined, reaching a low of 9% at six eggs per fruit.

PCs made an equal number of first visits, total visits, and ovipositions on clean fruit and fruit with one previous oviposition (Table 2). Every visit to a

[a]Values within the same column within the same treatment comparison followed by the same letter are not significantly different at the 5% level according to a G test.

fruit in this choice test resulted in an oviposition. Thus, PCs did not discriminate in favor of or against infested fruit at a level of one egg per fruit. In all other choice tests, however, there was a greater number of first and total visits to insect- or artificially punctured fruit than to clean fruit. However, differences were significant only in the case of total visits to fruit with eight ovipositions vs. clean fruit, according to a *G* test for goodness of fit (Sokal and Rohlf, 1981). These results suggest that fruit wounded with four or eight ovipositions or eight artificial punctures had a positive effect on a female's propensity to visit that fruit. PCs had less propensity to oviposit in fruit with four or eight ovipositional punctures or eight artificial punctures than in clean fruit. There was a significant difference in the number of total visits which resulted in oviposition only in tests of eight oviposition wounds or artificial punctures vs clean fruit, according to a *G* test of independence (Sokal and Rohlf, 1981). The fact that ovipositional propensity was similar for fruit with eight ovipositional punctures as for fruit with eight artificial punctures suggests the stimulus leading to rejection of such punctured fruit for oviposition was of fruit and not insect origin.

DISCUSSION

The mechanism by which PCs locate and choose feeding and oviposition sites is not well understood. Preliminary olfactometer tests (Groden, Drummond, and Prokopy, unpublished) showed that female PCs crawled upwind more often toward chambers which contained apples than toward chambers containing moist cotton. This suggests that, at short range, PCs may respond positively to fruit volatiles to aid in fruit finding.

Physiological changes occur when a plant is wounded that may alter the nature or enhance the quantity of volatiles released. It is also known that volatile chemicals released from insect-damaged plant tissue can increase the attractiveness of damaged plants to some insects (Finch, 1980). Perhaps fruit volatiles which appear to aid PCs in host finding are modified in nature or enhanced in quantity in wounded tissue, leading to increased PC visitation to such fruit. It appears that volatiles from fruit with a single ovipositional puncture are not modified in quantity or quality so as to have a detectable effect on PC visitation, but volatiles released from fruit with four or more punctures do produce such an effect.

Prior to visiting fruit wounded with four or more punctures, several PCs appeared excited, crawling quickly up the main stem and then to the end of a crosspiece where fruit was hanging. However, PCs would sometimes stop before reaching the end of a crosspiece, display antennal waving, and then either continue on or change direction. Many insects align their body in the direction of an odor source upon detection of a gradient of odor molecules (Shorey, 1973; Kennedy, 1978). Conceivably, antennal waving could aid a PC in locating the

direction of wounded fruit by comparing the concentration of odor on each side of its body. Owens et al. (1982) noted PCs in nature making short pauses between bouts of crawling, accompanied by antennal waving and sometimes reorientation. Miller (1979) proposed that a stop-go pattern of walking, as observed in phorid flies, may serve a visual and/or chemosensory function, aiding in orientation to host resources. However, we believe that PCs' use of vision to locate fruit within a tree is limited.

PCs often crawled onto wounded fruit, fed in wounds, and then left without ovipositing. During several replicates, PCs also were seen feeding on the tips of freshly cut fruit petioles, suggesting that wounded tissue may stimulate feeding behavior. Owens et al. (1982) reported PCs feeding at petiole abscission scars and on ooze exuding from damaged fruit tissue.

Why did PCs leave without ovipositing after feeding on wounded fruit? Several hypotheses are possible. First, wounded fruit tissue may release compounds which deter oviposition. Second, perhaps only feeding behavior, not oviposition behavior, is stimulated by wounded fruit. Third, the complete oviposition sequence may somehow be interrupted after sensing nearby wounded tissue, causing a female to enter a feeding mode rather than continue in an oviposition mode. PCs may partition time spent exploring or feeding at potential oviposition sites according to their physiological state or previous host-searching experience. If the appropriate oviposition cues are not received within a particular window of time, PCs may leave in search of a more suitable fruit.

A mechanism for discrimination against occupied hosts may exist in PCs, but in our tests it was not as strongly manifested as in most other herbivorous insects exhibiting discrimination. Perhaps this is because PCs' ability to move within a tree is rather limited. When a PC locates a fruit, it may tend to oviposit regardless of the fruit's condition and regardless of the lower probability of progeny survival with increasing egg density, as a PC may not encounter another fruit very readily. In other words, PCs appear to have a comparatively limited ability to sample a wide range of fruit within a tree, leading to comparatively greater propensity to accept discovered fruit despite possible harmful consequences to progeny. Low larval survival, even at one egg per fruit, may be due to inadequate nutrients and/or presence of toxic secondary plant compounds within the host. PCs' expansion from wild plum to cultivated plum (within the past 150 years) may not yet have allowed sufficient time for high larval survival.

Since plant-insect interactions often involve three trophic levels (plant-herbivore-enemies) (Price et al., 1980), one must also consider ways in which utilization of chemical cues may aid PCs in predator avoidance. Faeth (1985) found that leafminers chose significantly more intact leaves for oviposition sites than damaged ones. Damaged leaves received more parasitism than intact ones. Such parasitism may have constituted selection pressure giving rise to individual leafminers which avoided leaves occupied by conspecifics. Perhaps the ovi-

positional response of PCs to damaged fruit may have been shaped, at least in part, by a similar sort of parasitoid or predator selection pressure.

In conclusion, resource partitioning via response to chemical cues from occupied sites is not always a "tight" system. When the dispersal power of ovipositing females is weak, avoidance of overcrowding of resources and attendant effects on progeny competition may not be under strong selection. It appears that ovipositing PCs do possess some ability to discriminate against egg-occupied fruit on the basis of high levels of fruit-originating stimuli emitted from wounds, but that behavioral traits coupled with ecological conditions do not favor pronounced expression of this ability.

PRESENCE OF PTERIN PIGMENTS IN WINGS OF LIBYTHEIDAE BUTTERFLIES

OAKLEY SHIELDS[1]

4890 Old Highway
Mariposa, California 95338

Abstract—A few pterin pigments were discovered in the wings of six of eight libytheid species tested, using thin-layer chromatography with 1% HCl in butanol as a solvent. A 10X sample of *Libytheana bachmanii larvata* (Strecker) produced xanthopterin, isoxanthopterin, erythropterin, and leucopterin. Leucopterin was absent in the other libytheids tested. Morphology and pterin pigment data from wings suggest a Pieridae ancestry for the Libytheidae from the region of the northern Neotropical realm (including the Greater Antilles).

Key Words—Pterin pigments, *Libythea, Libytheana*, Libytheidae, Lepidoptera, thin-layer chromatography.

INTRODUCTION

The isolated family Libytheidae (two genera: *Libythea*, Old World; *Libytheana*, New World) shows a morphological relationship to both the Nymphalidae (adults) and the Pieridae (immatures) but not to Riodinidae (Jordan, 1925; Kristensen, 1976; Shields, 1974). It was decided to test for the presence of pterin pigments in libytheid wing scales, since these pigments are universally distributed in pierid wings but have been shown to be lacking in the wings of all other butterfly families except erythropterin in the nymphalid *Heliconius* (Heliconiinae) and isoxanthopterin in Nymphalidae, some Lycaenidae, one Riodinidae, and one Papilionidae (Ford, 1947a,b; Baust, 1967; Rawson, 1968; Robinson, 1971). If Libytheidae is a phylogenetically transitional family between Pieridae (primitive) and Nymphalidae (advanced), as its morphology indicates, it might still contain an array of pterins, at least in trace amounts.

In Pieridae wings, pterins are deposited on the canal walls in the scales during the pupal and teneral adult stages and give the white, yellow, and red coloration to the wings (Wigglesworth, 1939; Ziegler-Gunder, 1956). Since pterins are chemically related to uric acid, they are probably excretory products transported by the hemolymph (Ford, 1947a; Ziegler-Gunder, 1956). Small amounts of uric acid and other nitrogenous breakdown products also occur in Pieridae wings (Gates, 1947; Harmsen, 1966). Pieridae differs dramatically in the origin and structure of its wing-scale pigments from the other butterfly families (Ford, 1947a).

In insects, pterins are reported in the bodies of various Rhopalocera and Geometridae, *Ascalaphus* (Neuroptera), *Gaema* (Cicadidae), *Tettigonia* (jassid), various Hemiptera, *Vespa* (Hymenoptera), some Diptera, and *Bombyx* (Bombycidae) (Bartel et al., 1958; Rawson, 1968). Thus, within the Pterygota, pterins are present in some of the advanced infraclasses of Paraneoptera (hemipteroids) and Oligoneoptera (Coleoptera, Neuroptera, Lepidoptera, etc.) but are lacking in the more primitive infraclasses of Paleoptera (Ephemerida and Odonata) and Polyneoptera (orthopteroids) (see Fox and Fox, 1964, pp. 337–339).

METHODS AND MATERIALS

An attempt to identify pterins from eight of the 12 species of libytheids was made by removing both wings from one side of an individual specimen of each and macerating them in 1% HCl. The mixture was centrifuged twice at 5000 rpm for 7 min. The decanted supernatent was air-dried in test tubes, redissolved in 1% HCl, and 13–33 μl spotted on a Baker-Flex thin layer cellulose plate. The solvent of 1-butanol–acetic acid–water (4 : 1 : 1) follows Watt (1964) and Pfeiler (1970). Two wings of *Eurema nicippe* (Cramer) were similarly extracted and 10 μl spotted as above, as the control on the same plate. The TLC plate was allowed to equilibrate against the butanol solvent vapor for 1 hr. Then the butanol solvent was added and allowed to migrate up the plate for 3–4½ hr in a chromatography tank. The 1% HCl in butanol was found to yield a far greater number of pterins than when 1% NH_4OH in butanol was used.

Spots from the libytheid species were matched to the control in color and R_f values under UV light after drying. R_f values and colors under UV follow Harmsen (1966) and Pfeiler (1970). The pterin spots were located under short wavelength UV light (2000 Å) for xanthopterin and under long wavelength UV light (ca. 4000 Å) for the other pterins.

Because unusual amounts of xanthopterin occur in *Libytheana bachmanii larvata* Strecker from Ciudad Victoria, Mexico, it was decided to further isolate the pterins from this population by removing the wings from five specimens (22.1 mg), or approximately ten times the sample size of the other species

tested. The same procedures were used (93 μl spotted), with *Pieris rapae* (Linnaeus) as a control using the R_f values for its pterins in Pfeiler (1970), except this time propanol solvent (1-propanol–1% aqueous ammonia, 2:1) was run in one direction while the butanol solvent was run at 90° on the same plate. Finally, the spots isolated under UV were scraped off and run separately on another TLC plate in the butanol solvent only.

RESULTS

Pterins were entirely absent in the western Old World species *Libythea labdaca* Westwood (Uganda), *L. laius* Trimen (South Africa), and *L. celtis celtis* Fuessly (Spain). However, xanthopterin was present in *Libythea narina rohini* Marshall (Thailand), which lacked other pterins, and in *Libytheana bachmanii bachmanii, Libythea myrrha*, and *L. geoffroy*. Erythropterin was faintly present in *Libythea geoffroy orientalis* Godman & Salvin (Guadalcanal) but appeared fairly prominently in *L. celtis formosana* Fruhstorfer (Taiwan), *L. myrrha sanguinalis* Fruhstorfer (Thailand), *Libytheana carinenta* Cramer (Brazil), and *L. b. bachmanii* Kirtland (Tennessee). Leucopterin was not detected in any of the libytheids, and isoxanthopterin was absent in all except *L. celtis formosana* for this sample size.

The larger sample of *Libytheana bachmanii larvata* (three males, two females) collected in August 1937 at Ciudad Victoria, Mexico, contained a very prominent amount of xanthopterin (yellow green under UV of 2000 Å, R_f = 0.42) which decomposed to uric acid after several weeks, prominent leucopterin (pale blue, R_f = 0.06–0.08, 2000 Å), and a faint spot of isoxanthopterin (blue under UV of ca. 4000 Å, R_f = 0.27). Erythropterin (R_f = 0.05) was also present but sepiapterin was absent. Xanthopterin and sepiapterin have identical R_f values in butanol but not in propanol. The Ciudad Victoria *L. b. larvata* wings had brown mottling on a whitish background on the undersurface, while *L. b. bachmanii*'s underside contained much less white and more brown, also reflected in the pterin results.

DISCUSSION

Pterin pigments present in the wings of most libytheids strengthen a possible tie with Pieridae that is also suggested on morphological grounds. This ancestral type may have had a yellow (prominent), white, and red wing pattern judging by the pterin results for *L. b. larvata*.

The Cuban *Libytheana motya* Hubner (not tested here) is likely the most primitive libytheid because of its extensive white coloration; it appears related to nearby *L. bachmanii* and *L. terena* Godart, but not to *L. carinenta*. The next

least advanced libytheids are probably the worldwide brown forms (*L. bachmanii, L. terena, L. carinenta, L. fulvescens* Lathy, *L. laius, L. celtis, L. myrrha*) with *L. labdaca, L. narina*, and *L. geoffroy* the most advanced black (and iridescent) forms. This scheme is substantiated by the pterin pigment results presented here and the phylogeny of their *Celtis* host plants (Shields, 1986). Thus *L. motya* is the most pierid-like libytheid with its white coloration, while at the opposite end of the spectrum *L. geoffroy* is the most nymphalid-like. This trend from primitive to advanced also included a corresponding shortening of their elongated labial palpi. New World *Libytheana* genitalia are closest to pierids, while Old World *Libythea* genitalia are closer to nymphalids (Shields, 1985, 1986). It is noteworthy that African *Mylothris*, one of the pierids probably close to libytheids in relationship, contains a very prominent amount of xanthopterin (Harmsen, 1970), as did *L. b. larvata*. Another is *Melete* (Neotropical, 13 species) which approaches *Libytheana* in genitalia and palpi. Both *Mylothris* and *Melete* use Loranthaceae as larval food plants, a family occasionally parasitic on *Celtis* (Celtidaceae), the food plant of libytheids. Earliest *Celtis* fossils date from the uppermost Cenomanian 92–94 million years ago (lower Upper Cretaceous time) (Shields, 1986).

CONCLUSION

Six of eight Libytheidae species tested by TLC contained pterin pigments in their wings: xanthopterin (four species), erythropterin (five species), and isoxanthopterin (one species). Few or no pterins were found in the most advanced species. A 10-fold sample of *Libytheana bachmanii larvata* wings from northeastern Mexico contained large amounts of xanthopterin and leucopterin, lesser amounts of erythropterin and isoxanthopterin, and no sepiapterin. Only the butterfly family Pieridae is known so far to contain such an array of pterin pigments in their wings. The findings help to strengthen the ties between the Pieridae and Libytheidae that had been suggested on morphological and behavioral grounds. The Libytheidae, a transitional family between the Pieridae and Nymphalidae, probably arose from Pieridae (e.g., *Melete*) in the northern Neotropical realm no earlier than lower Upper Cretaceous times, the earliest age of its *Celtis* host-plant fossils.

Acknowledgments—Dr. C.L. Judson (University of California, Davis) kindly provided laboratory equipment, research facilities, and helpful advice. J.P. Donahue (Los Angeles County Museum) donated six of the species used in these experiments. I also wish to thank Drs. A.M. Shapiro and S.R. Sims for lively discussions, Dr. J.A. Scott and the two reviewers for criticisms of the manuscript, and J. Lackner for laboratory assistance.

Heliothis subflexa (GN.) (LEPIDOPTERA: NOCTUIDAE): DEMONSTRATION OF OVIPOSITION STIMULANT FROM GROUNDCHERRY USING NOVEL BIOASSAY[1]

EVERETT R. MITCHELL and ROBERT R. HEATH

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Gainesville, Florida 32604

(Received August 15, 1986; accepted November 3, 1986)

Abstract—Methanol extracts of homogenized groundcherry, *Physalis angulata*, leaves increased egg deposition by *Heliothis subflexa* (Gn.) (HS) on treated tobacco plants (a nonhost) 8.5-fold over untreated controls. In dose-response tests using whole-leaf washes of groundcherry leaves, the threshold of positive response vs. no response to the chemical stimulant was within one log dose unit when compared to the controls. This response was consistent whether the chemical was evaluated on plants in greenhouse-cage tests or in an olfactometer using pieces of broadcloth as the oviposition substrate. The olfactometer used allows year-round study of the behavioral effects of plant allelochemics on insect oviposition behavior in a controlled environment.

Key Words—Groundcherry, *Physalis angulata*, *Heliothis subflexa*, Lepidoptera, Noctuidae, oviposition stimulant.

INTRODUCTION

Heliothis subflexa (Gn.) (HS) is an innocuous noctuid moth that feeds exclusively on groundcherry (*Physalis* spp.) (Brazzel et al., 1953). Although not a pest, it recently has become the subject of numerous hybridization studies between it and the tobacco budworm, *H. virescens* (F.), a broadly sympatric sibling species of great economic importance (Laster, 1972). The basis of these control studies lies in the production of sterile male and fertile female hybrids and back-cross progeny which, when released into a natural *H. virescens* (HV) population, should reduce the numbers of HV via the induction of male sterility.

Although the role of sex pheromones has been documented in *H. subflexa* (Teal et al., 1981; Klun et al., 1982), virtually nothing is known as to how this and, indeed, most phytophagous insect species locate their host plants or the mechanisms (chemical or mechanical) responsible for inducing oviposition once the host is found. The reasons for the lack of fundamental information on such important behaviors can be attributed to many factors, not the least of which is the ever changing biochemistry of plants, especially annuals, as they pass through their life cycle from seed germination and plant emergence to maturity and senescence. Such rapid changes in the biochemistry of the plant have made the development of reliable indoor bioassays for oviposition stimulants especially difficult. Jackson et al. (1984) found that whole-leaf cuticular washes from NC 2326 tobacco leaves will stimulate HV oviposition on TI 1112, a resistant tobacco strain. The major components in the NC 2326 methanol–water soluble fraction of the whole-leaf wash that stimulated HV oviposition were the α- and β-4,8,13-duvatriene-1,3-diols. It is significant that this process of identification and verification of activity had to be carried out over several seasons in small field plots and screen cages in the greenhouse using potted plant material because of the lack of a bioassay system that would permit monitoring of progress in the identification procedure indoors under controlled environmental conditions.

The present study was designed to develop a bioassay system that would be applicable to chemicals affecting oviposition behavior in a variety of insects. We selected HS as the test subject because of its limited host range (groundcherry) (Brazzel et al., 1953) and also because of implications in the host-plant selection process, which might be exhibited as a result of hybridization between HS and its sibling species, HV (Laster, 1972).

METHODS AND MATERIALS

Groundcherry Extracts Using Different Solvents. The response of *H. subflexa* to extracts of groundcherry leaves and fruit (in bracts) was determined by homogenizing 100 g of fresh-weight material in a Waring® blender in 500 ml of distilled water, methanol, ethanol, acetone, or methylene chloride. Large particles were removed by filtering the extract through a white Viva® paper towel. All extracts, except the distilled water, were concentrated to near dryness in a rotary evaporator and brought back to 1-g equivalents per 1 ml of 3:1 acetone–distilled water for spraying onto potted tobacco plants (a nonhost). The test plants were ca. 40 cm in height, and they were stripped to four leaves, each about equal in size.

Each test was conducted in a natural-color Saran® field cage (round) 2.9 m in diameter and 1.2 m high with one vertical zipper. The bottom of the cage also was made of Saran screening. A test consisted of four treated plants placed

alternatively with four control plants (ca. 85 cm between plants) in a circular pattern inside each cage (four replications per night per cage). A compressed-air spray brush (Badger®, model 250) was used to apply the treatments (20 g equivalent test material in 20 ml of 3:1 acetone–distilled water per plant) in a fine mist at ca. 1500 hr. Control plants were sprayed with 20 ml of the solvent only. Test plants were sprayed on both the upper and lower sides of the leaves outside the cage and moved inside after drying. Two paper cups containing a cotton ball saturated with 10% honey–water solution were placed in the cage center along with ca. 50 pairs of 3- to 4-day-old moths, which had been held together in small cages indoors since emergence for mating. All moths were from a stock colony of HS reared in the laboratory on artificial diet. The number of eggs deposited on each plant was recorded the following morning, and the plants then were removed from the cage and destroyed. Additional moths were added as needed to maintain the test population at ca. 50 pairs. Each treatment was replicated 8–24 times, and means were separated using the unpaired t test (Steel and Torrie, 1960).

Evaluation of Extraction Methods. One-hundred grams of fresh ground-cherry leaves were homogenized in methanol in a Waring blender for 30 sec or washed for 10 or 30 sec in 500 ml of methanol. The liquid was filtered through a white Viva paper towel, concentrated to near dryness in a rotary evaporator, and brought back to 20-g equivalents in 20 ml of a 3:1 acetone–distilled water solution.

Potted cotton plants (ca. 40 cm high, a nonhost) were sprayed with 20 ml of the test material using a Badger air brush. The plants were stripped to six leaves about equal in size before spraying. Both upper and lower surfaces were sprayed. Control plants were sprayed with 20 ml of the acetone–distilled water solution only. The treated and control plants were placed in opposite corners of a 100-cm^2 × 70-cm-high screenwire cage with ca. 70 cm between plants. Twenty to 30 pairs of 3- to 4-day-old HS moths reared in the laboratory on artificial diet were released in each cage. Fresh insects were added daily to keep the moth population at the desired level. Each cage was equipped with two paper cups filled with cotton balls saturated with 10% honey–water solution as a food source for the moths.

All tests were carried out in the greenhouse under natural light at ca. 23°C at night, 27°C during the day, and ambient relative humidity of ca. 50–60%. The plants were sprayed at 1600 hr, allowed to dry, and immediately placed in the test cages. The cages then were draped with black polyethylene that covered the top and all four sides to the greenhouse floor. The polyethylene cover prevented influences from street lights in the test area vicinity and also prevented air movement through the cages. Thus, the plants were in an essentially static air environment for the test duration (ca. 16 hr). The number of eggs deposited on the treated and control plants were counted the following morning. The plants

were used only once, and each test was replicated eight to nine times. For statistical analysis, the data were transformed to arcsin $\sqrt{\text{percentage}}$; differences between treatment means were separated using the paired t test (Steel and Torrie, 1960).

Dose Response. The response of HS to different dosages of the oviposition stimulant was conducted under two different sets of conditions: first, in screen-wire cages in the greenhouse as described above for evaluating the leaf-extraction techniques [homogenized vs. whole-leaf wash (WLW)]; and second, in an olfactometer designed specifically for use in a controlled environmental chamber. Dosages evaluated in the greenhouse setting were 0.01-, 0.1-, 1.0-, 5.0-, 20-g equivalents in methanol WLW sprayed onto cotton plants in 20 ml of a 3:1 acetone–distilled water solution. Control plants were sprayed only with the solvent. Methods for handling plants and insects, the environmental conditions in the greenhouse, recording the number of eggs deposited on treatment and control plants, and transformation of the data were as described above. The data then were evaluated (6–13 replicates/dosage level) using regression analysis and the paired t test (Steel and Torrie, 1960).

An olfactometer was developed and tested for bioassaying the response of HS to the oviposition stimulant obtained from WLW of groundcherry (Figure 1). The olfactometer was constructed of 0.64-cm Plexiglas and consisted of a removable top plate, the insect holding chamber, and a base that connected the

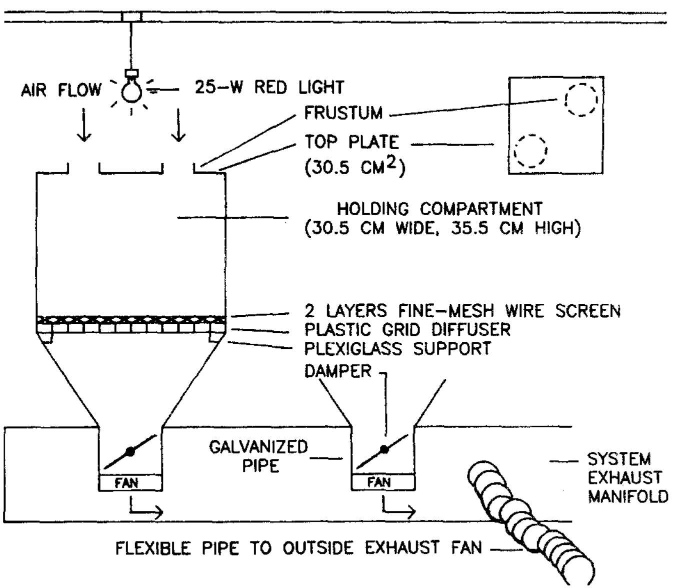

FIG. 1. Schematic of Plexiglas olfactometer (not to scale) for bioassaying oviposition stimulant (see text for dimensions and materials).

holding chamber to an exhaust manifold. The top plate (30.5 cm^2) had two 9.6-cm-diam. holes centered on a diagonal line equidistant from each other and the corners. A frustum (collar, 10.0-cm OD bottom, 9.2-cm OD top, 6.5 cm high) was glued to each hole. The frustums were made by cutting out the bottoms of clear plastic containers (Tri-State Molded Plastics, Inc., round container model T40C), and gluing the top edge of the containers to the Plexiglas top.

The square insect-holding compartment was 30.5 cm wide by 35.5 cm high and had 2.54 × 0.64-cm Plexiglas strips glued to the inside of the base to support a plastic grid cut from fluorescent light diffuser material (1.2 cm high with 1.4-cm^2 openings). The plastic grid was overlaid with two pieces of fine-mesh screen wire. The base of the holding chamber was connected to the exhaust manifold via a trapezoidal-shaped duct (34-cm high), which measured 30.5 cm at the top and narrowed to 20.5 cm at its base. The bottom plate of the duct had a 14.5-cm-diam. hole to which was connected a short length of galvanized stove pipe that was equipped with a damper that exited into the system manifold. The manifold was connected via a flexible plastic pipe to an exhaust fan that pulled air through the chamber from top to bottom and exhausted outside the holding room. An intake vent located in the wall (opposite wall from the exhaust vent) of the holding room allowed a continuous flow of fresh, unfiltered air into the room from the outside. Air flow through the oviposition chamber was adjusted with the damper and maintained at 0.24 m/sec when measured at the top of the frustum. The air exchange rate through the chamber was approximately once every 12 sec.

Eight of the oviposition chambers were fitted side by side on a wooden frame equipped with casters (Figure 2). Each chamber had a 25-W red light (GE®) suspended directly over its center ca. 12 cm from the Plexiglas top to provide a light source during the scotophase period (1100–2100 hr). The sides of the test chambers were covered with black construction paper to eliminate light reflections from the white walls of the test room through the Plexiglas holding chambers and from another bank of cages (there were two banks of eight cages each in the test room).

The bioassay chambers were located in an environmentally controlled room 3 m long, 2.6 m wide, and 2.1 m high. The room was equipped with an electric timer to turn the overhead fluorescent lights (two banks of two bulbs, 40 W each) on and off; a separate timer was used to turn the red lights over the oviposition chambers on and off. A heat pump/air-conditioner installed in one wall controlled the temperature in the room at ca. 28.6°C. A room humidifier maintained the relative humidity at ca. 50%.

Dosages of oviposition stimulant evaluated in the olfactometer were 0.001-, 0.01-, 0.1-, 1.0-, and 10.0-g equivalents of WLW in 1 ml methanol. The test material was dissolved in 1 ml methanol and pipetted in a circular pattern onto the center of a piece of white broadcloth (ca. 20 cm^2), the oviposition substrate. After drying, the broadcloth was fitted over the open end (ca.

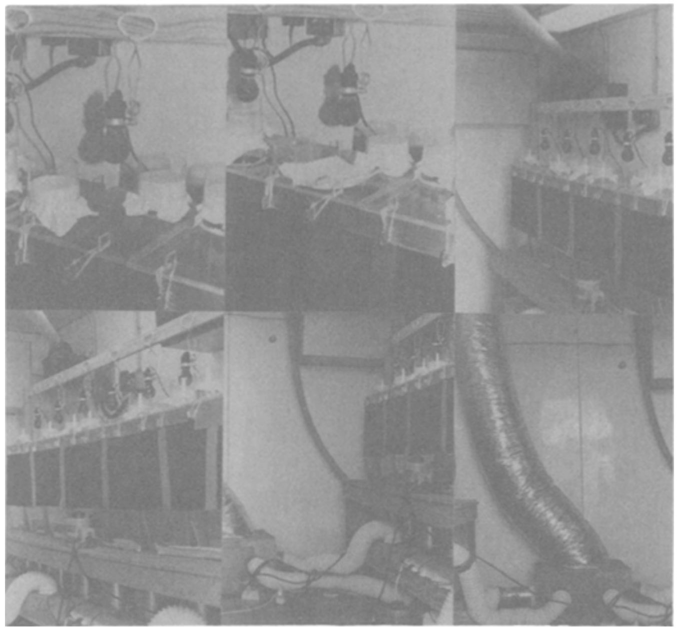

FIG. 2. Olfactometer system for testing oviposition stimulant chemical(s) for *Heliothis subflexa* extracted from groundcherry plants. Top left: individual chamber with oviposition substrates (two pieces of broadcloth) held in place with O-rings; top center: chamber with open (left) and covered port (right); top right: bank of eight bioassay chambers (five shown) with red lights and black construction paper on sides of chambers; bottom left: bank of bioassay chambers (six shown), with fresh air intake (upper left) and two exhaust pipes exiting from manifold (bottom); bottom center: exhaust manifold pipes entering collection chamber (lower left) for exhausting air outside of bioassay room; bottom right: air collection box with attached pipes from manifolds of bioassay chambers (two systems of eight compartments each); large flexible pipe leads to fan mounted outside of room, small flexible pipe (right side) is part of vacuum system used to remove moths from chambers when cleaning.

9.2 cm) of one of the frustums and secured into position with a plastic O-ring. A control cloth treated with 1 ml of methanol was fitted over the second frustum. A cotton ball soaked with 10 ml water was then placed on the top of each cloth and covered with a paper cup.

Each test cage contained 10 laboratory-reared female HS that were confined with eight males for two days for mating before being placed in the test chamber. The females were preconditioned through one complete light–dark cycle in the test chambers before being exposed to the test materials; thus, the females were 3 days old when first subjected to the treatments. The same moths

were subjected to different treatments (i.e., dosage levels) on days 4 and 5 before being replaced with new moths. The moths were supplied daily with fresh food (10% honey-water solution on a saturated cotton ball in a paper cup).

Treatment and control clothes (oviposition substrates) were replaced and repositioned twice daily at 1100 and 1500 hr. Treatments placed in position at 1500 hr were removed during the daylight phase the following morning (lights on at 2100 hr). The number of eggs deposited on each cloth (treatment and controls) was recorded and converted to percentages of the total number of eggs deposited in each chamber during each time period (11–21 replicates/dosage level). The data then were transformed to arcsin $\sqrt{\text{percentage}}$ and subjected to regression analysis and the paired t test (Steel and Torrie, 1960).

RESULTS AND DISCUSSION

Homogenate extracts of fresh groundcherry leaves in methanol increased egg deposition by HS on treated tobacco plants (a nonhost) in field cages 8.5 × over untreated controls; other solvent systems that showed significant oviposition stimulant activity from homogenized leaves included distilled water, ethanol, and methylene chloride (Table 1). By contrast, the highest levels of HS oviposition obtained from homogenates of groundcherry fruit was with dis-

tilled water (4.1×) and methanol (0.6×). None of the other solvent systems used to extract groundcherry fruit showed any significant increase in oviposition activity on treated plants vs. the controls.

Homogenate extracts of fresh groundcherry leaves were quite effective in stimulating HS oviposition (Table 1). However, a 30-sec WLW of fresh groundcherry leaves in methanol produced increased oviposition activity comparable to the homogenate leaf extract (Table 2). Although washing groundcherry leaves for 10 sec produced somewhat less activity than washing the leaves for 30 sec, the difference in increased oviposition activity was not significant (unpaired t test, 16 df, t = 1.1193). Nevertheless, the 30-sec WLW procedure was used routinely throughout the remainder of the tests and for preparation of materials used in the isolation and identification of chemical(s) (now in progress) responsible for the observed increases in oviposition. The WLW extract was virtually free of any foreign material except sand particles from the leaf-surface, which subsequently were removed via filtration through paper towels. We have stored the crude WLW extract (methanol) for more than 1 year in a freezer at 0°C without significant loss in oviposition stimulant activity.

In the dose–response tests (Figure 3), there was no significant relationship (regression analysis) between dose and the percentage of eggs deposited on treated cotton plants in cages or on broadcloth oviposition sheets in the olfactometer. In both tests, however, a significantly higher percentage of the total eggs deposited were recorded on treated plants or broadcloth vs. corresponding controls except at the lowest dosage levels (paired t test). The overall percentage of increase in oviposition was somewhat higher on treated cotton plants in the greenhouse test than in the olfactometer, although HS females typically

[a] Fresh leaves (100 g) were homogenized in methanol using a Waring blender for 30 sec or washed for 10 or 30 sec in 500 ml methanol. The liquid was filtered through a white Viva paper towel, concentrated to near dryness and then brought back to 20-g equivalents in 20 ml of a 3 : 1 acetone–distilled water solution that way sprayed on the test plant (cotton, a nonhost), with a compressed air sprayer. The controls were sprayed with 20 ml of the acetone–distilled water solution.
[b] Increased oviposition = (eggs on treatment − eggs on control)/eggs on control.
[c] **Significant at $P < 0.01$, paired t test.

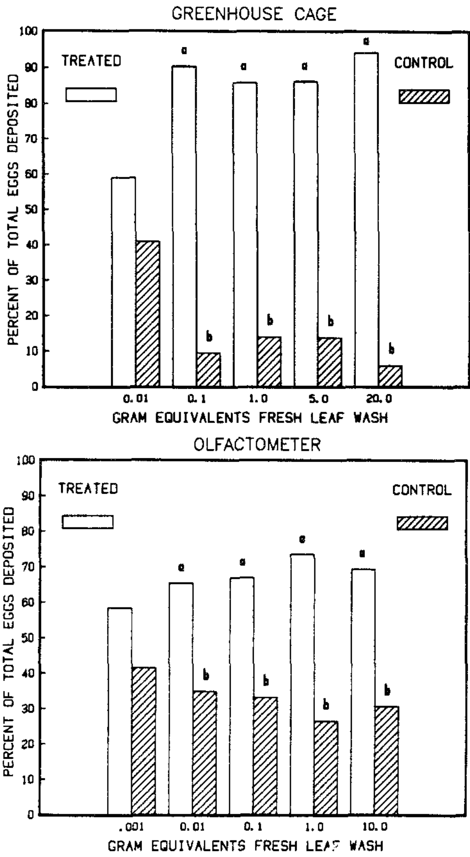

FIG. 3. Response of *Heliothis subflexa* females to different dosages of ovipositional stimulant extracted via whole-leaf washes in methanol in two different bioassay systems (greenhouse cage, top; olfactometer, bottom). Means within each dosage level followed by different letters are significantly different ($P < 0.01$), paired t test; absence of letters indicates no significant difference between means.

responded to a lower threshold dosage in the olfactometer (0.01-g equivalents) than in the greenhouse cage (0.1-g equivalent). Reasons for the difference in the two bioassay systems are unknown. Air movement, or the lack of it, possibly could explain some of the variation observed. The greenhouse tests were conducted in virtually static air (cages were covered with polyethylene), whereas the air in each chamber of the olfactometer was exchanged ca. every 12 sec.

The olfactometer described here offers the opportunity to study the behavioral effects of plant allelochemics on insect oviposition behavior in a controlled environment without the need for a constant supply of live plant material as oviposition substrate. Such an apparatus should speed the identification of these

chemicals, as it permits virtually year-round operation and is not dependent upon live plant materials, which are so costly to provide in time and funds.

(Received April 29, 1986; accepted November 3, 1986)

Abstract—Stegobinone, (2*S*,3*R*,1′*R*)-2,3,-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-oxobutyl)-4H-pyran-4-one, the sex pheromone of drugstore beetles (*Stegobium paniceum* L.), elicited the pheromonal response from the males of the species in our bioassay system; however, the synthesized diastereomeric mixture of this compound was actually inactive to the males. Although the stegobinone isolated from the beetles of this species had significant activity, its enantiomeric [(±)-2*S*,3*R*,1′*S*-] and diatereomeric [(±)-2*S*,3*S*,1′*RS*-] isomers were inactive. Adding the (±)-2*S*,3*R*,1′*S* isomer to stegobinone significantly reduced the male response. Furthermore, the activity of stegobinone vanished on keeping it at room temperature for two weeks. In such a stored stegobinone sample, the presence of 2*S*,3*R*,1′*S* isomer, the inhibitory component, was confirmed. This isomer might be produced by C-1′ epimerization during storage.

Key Words—Sex pheromone, drugstore beetle, Coleoptera, Anobiidae, *Stegobium paniceum* L., stegobinone, diastereoisomer inhibition, pheromonal activity.

INTRODUCTION

The drugstore beetle, *Stegobium paniceum* L., is a devastating pest of stored food and crops. The structure of its sex pheromone has been established as stegobinone, 2,3-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-oxobutyl)-4H-pyran-4-one (Kuwahara et al., 1975, 1978), whose absolute configuration at C-2, C-3, and C-1′ has been assigned 2*S*,3*R*,1′*R* on the basis of several stereoselective

FIG. 1. Eight possible structures of stegobinone and diastereoisomers.

syntheses and its CD spectrum (Hoffmann et al., 1981). The amount of stegobinone was estimated at about 10^{-1} μg/female (Kuwahara et al., 1975). As stegobinone has three chiral centers at C-2, C-3, and C-1′, there are eight possible stereoisomers shown in Figure 1, in which the isomer in the upper row, such as (2*S*,3*R*,1′*R*) and the corresponding ones in the lower row, such as (2*R*,3*S*,1′*S*) are enantiomerically paired. Many synthetic approaches have been reported. Recently, Mori and Ebata (1986) accomplished the stereoselective synthesis of this compound. In early work, Ansell et al. (1979) synthesized two diastereomeric racemates, (±)-(2*S*,3*R*,1′*RS*)-stegobinone. The pheromonal activity of this diastereomeric mixture was at least 10^3 lower than that of the natural pheromone. This result suggested, among other possibilities, that one or more of the stereoisomers was inhibiting the response of male beetles to the active component.

Here, we report on an inhibition by one of the stegobinone isomers to the pheromonal activity of stegobinone.

METHODS AND MATERIALS

The insects were reared on a mouse diet at 28 ± 1°C and 60 ± 10% relative humidity. Males for bioassay were collected from cultures as papae and selected by observance of the posterior end of pupae (Azab, 1954). Selected male pupae were transferred to a separate room from that used for culturing and kept in a female-free incubator under the above conditions until bioassay, two to three days after adult emergence.

Instruments. Gas chromatography (GC) was performed using a Shimadzu 7A instrument equipped with FI detector and a 50-m × 0.2-mm-ID fused silica column coated with Carbowax 20 M. The column temperature was programmed

from 100 to 210°C at the rate of 2°C/min. Proton NMR spectra were obtained with a Bruker AM 500. GC mass spectra (GC-MS) were obtained on a Hitachi M 80 instrument equipped with the same column as above. High-performance liquid chromatography (HPLC) was performed with a Hitachi 655 constant flow pump, equipped with UVILOG-5A (Oyo-bunko kiki Co., Ltd., Tokyo) UV detector.

Stegobinone. Adult (150,000) drugstore beetles of mixed sex were extracted twice with hexane (1 liter × 2). After removing the solvent under reduced pressure at 40°C, 2.7 g of an oily residue was obtained. The extract was then charged on a silica gel column (3 cm ID × 27 cm) and fractionated with hexane–ether. Stegobinone (10 mg) was isolated from 30% ether–hexane effluent by HPLC (μ-Porsil, hexane–THF–MeOH, 6000:100:1). Although the obtained stegobinone (99.9% pure by G C) did not crystallize, all spectral data were identical with those reported previously (Kuwahare et al., 1978).

Diasstereoisomers. Diastereoisomers of stegobinone were synthesized by the method of Ono et al. (1983). Materials obtained consisted of eight diastereoisomers whose gas chromatogram is shown in Figure 2. The molar proportions of *SRR*, *SRS*, and *SSRS* were 3:4:4. The racemic mixtures and diastereoisomers used are designated herein as *SSR*, *SRS*, and *SSRS* which indicate enantiomeric mixtures of 2*S*,3*R*,1′*R* and 2*R*,3*S*,1′*S* isomers, 2*S*,3*R*,1′*S* and 2*R*,3*S*,1′*R* isomers, and 2*S*,3*S*,1′*RS* and 2*R*,3*R*,1′*RS* isomers, respectively.

SRR, SRS, *and* SSRS. Synthetic mixture of eight diastereoisomers of stegobinone, obtained by the method of Ono (1983), were separated by HPLC into three fractions (Figure 3). The first isomer eluted was *SSRS*, the second *SRS*, and the last *SRR*, whose relative configurations were established by comparing ^{1}H- and ^{13}CNMR spectra to those previously reported (Hoffmann et al., 1981). The purity of each group, determined by GC, was more than 99.9%.

Bioassay. The bioassay procedure utilized for another species of Anobiidae, the tobacco beetle, *Lasioderma serricorne* F., (Mori et al., 1985) was employed with several modifications. Large-size (90-mm-ID) plastic Petri dishes were used to avoid saturation with the test samples during the bioassay. A 90-mm-ID filter paper was tightly fitted on the floor of the Pertri dish. Ten virgin males were allowed to acclimate in each dish 3–4 hr prior to testing, and those individuals came to rest during that period. One microliter of hexane solution of test samples were dispensed onto a filter paper (5 × 25 mm, folded in W letter shape) by using disposable 5 μl pipets. After allowing the solvent to evaporate for ca. 10 sec, the sample-impregnated filter paper was immediately placed at the center of the Petri dish.

In the bioassay, the following three parameters were scored for 10 min: (1) attractiveness, total number of the males attracted on the sample-impregnated filter paper; (2) sex stimulation, total number of attempted couplings; (3) aggregation, maximum number of males that climbed on the sample-impregnated filter paper at the same time.

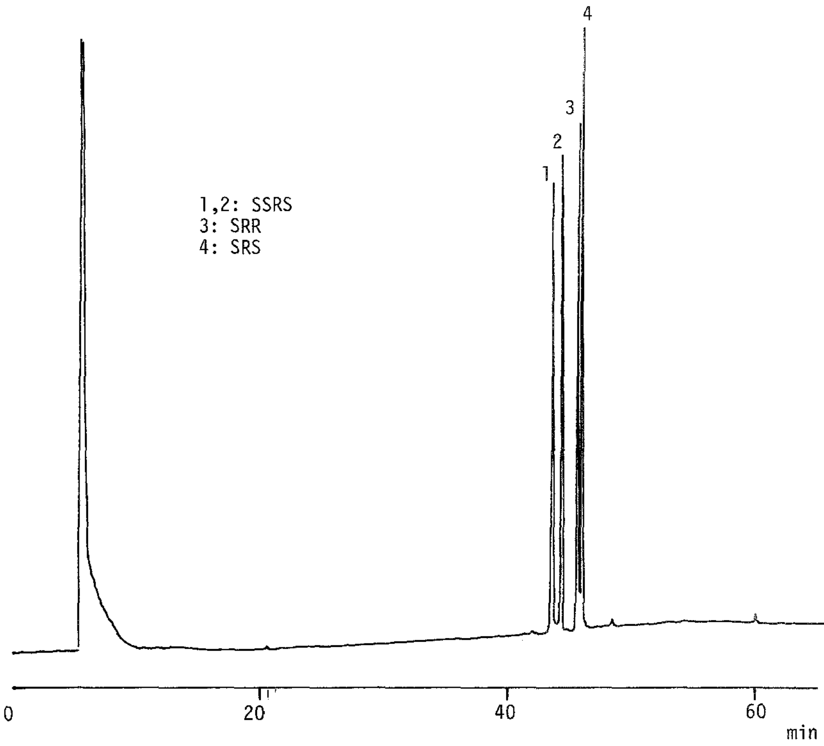

FIG. 2. Gas chromatogram of diasstereoisomers of stegobinone. conditions: column, 50 m × 0.2 mm ID fused silica coated with Carbowax 20 M; column temperature, 100–210°C (2°C/min); carrier gas, nitrogen at a flow rate of 1.1 ml/min; flame ionization detector.

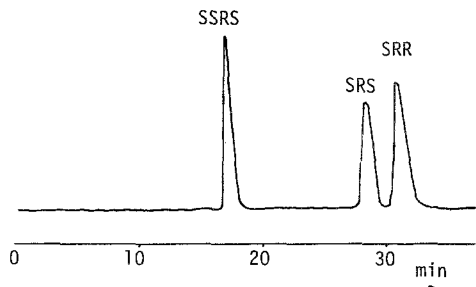

FIG. 3. HPLC of diastereomers of stegobinone. conditions: column, μ-Porasil (3.9 mm ID × 30 cm); mobile phase, hexane–THF–MeOH 6000 : 100 : 1; flow rate, 2.5 ml/min; detected by UV absorption at 281 nm.

A minimum of three and a maximum of nine replicates were run. Each male was used only once for the bioassay. The test room for the bioassay was illuminated by cool white fluorescent lighting. All bioassays were conducted at $28 \pm 1°C$ and $60 \pm 10\%$ relative humidity.

RESULTS AND DISCUSSION

Behavioral Aspects of Male Response to Stegobinone in Bioassay. Previous reports showed that stegobinone elicited precopulatory searching behavior. In our bioassay, not only searching but also the following behavior could be observed. The first response to stegobinone in the bioassay consisted of alerting followed by rapid movement around the stegobinone-impregnated filter paper with occasional arrest, during which antennal elevation and extension of the forelegs were observed. After this searching behavior, the males were attracted to the stegobinone-impregnated filter paper and climbed on it. When a male palpated another male, he mounted the other and extruded his aedeagus.

Male Response to Synthetic Stegobinone and Diastereoisomers. Responses of male drugstore beetles to stegobinone and diastereoisomers are shown in Table 1. In the replicated bioassay at 10^5–10 μg of tested sample, males showed a threshold (minimum dose per assay to elicit a pheromonal response) at 10^{-2} μg of stegobinone. Male beetles showed no response to the diastereoisomers. The most likely explanation for the lack of activity of the diastereoisomers seemed to be inhibition of the activity by one or more of the possible isomers in the diastereoisomers.

Male Response to SRR, SRS, *and* SSRS. As the diastereoisomers failed to elicit the pheromonal response from the males, activities of chromatographically separated *SRR*, *SRS*, and *SSRS* were examined. The results were summarized in Table 2. In the bioassay, 10^{-2} μg of *SRR* induced a positive response to the males, whereas *SRS* and *SSRS* failed to elicit the response from the males. The pheromonal activity of *SRR* suggested that its component enantiomer, *1R,2S,1'S* isomer, was not an inhibitor. Although the diastereomer separated by preparative TLC from synthetic stegobinone has been reported to have some pheromonal activity (Ansell et al., 1979), behavioral activity of *SRS*, or *SSRS* could not be observed.

Inhibition by SRS. Since *SRS* and *SSRS* were inactive, the effect of these isomers to the stegobinone was examined independently. Stegobinone was mixed individually with these isomers in 1000 : 1, 100 : 1, 10 : 1, and 1 : 1 ratios in which the amount of stegobinone was held constant at 0.1 μg. The results are summarized in Table 3. No apparent effect was observed for the mixture of *SSRS* and stegobinone, but *SRS* showed significant reduction of male response. As little as 10^{-3} μg of *SRS* was required to reduce the activity with every three

[a] Differs significantly from natural at the 5% level, Student's t test.

parameters. Considerably less than an equal amount of *SRS* entirely eliminated the pheromonal activity. This mixture did not induce rapid movement or antennal elevation on the males tested.

Inhibition by Epimerized Stegobinone. After stegobinone was kept for two weeks at room temperature, its activity was entirely lost. GC and GC-MS analysis showed the 10% presence of a stegobinone isomer, whose retention time on GC was identical with that of *SRS*. The amount of the isomer is 10% of the stegobinone. Samples of 10^{-5}, 10^{-3}, 10^{-2}, 10^{-1}, 1 and 10 μg of this partially epimerized stegobinone were bioassayed. The results are summarized in Table 4. Athough the amount of partially epimerized stegobinone was increased, behavioral activity could not be observed in 10–10^{-1} μg, and little activity could be observed in the assay of 10^{-2}–10^{-3} μg. The inhibitory activity of the isomer, whose amount was 10% of the stegobinone, might be below threshold in these bioassays. In the stegobinone molecule, the C-1′ position which is the α position to the C-2′ carbonyl group is easily epimerized. Therefore, the absolute configuration of this inhibitor was assumed to be 2*S*,3*R*,1′*S*.

The mating behavior of male drugstore beetles has been reported in detail (Ward, 1981). In our bioassay, it is shown that stegobinone significantly contributed to mating behavior, eliciting not only searching but also copulating. Several pheromones that contain asymmetric carbons have been identified, and in most cases only one enantiomer elicits a pheromonal response; all the other isomers were inactive. Furthermore, a certain enantiomer or isomer inhibited pheromonal activity in several cases; Tumlinson et al. (1977) reported that the attraction of male Japanese beetles (*Popillia japonica*) by the pheromone, (*R*,*Z*)-5-(1-decenyl)-dihydro-2(3H)-furanone, was inhibited by its enantiomer. Recently Mori et al. (1985) reported that the serricornin isomer inhibited the male response of cigarette beetles. In most cases, such isomers do not occur in nature, whereas the epimerization of stegobinone to its inhibitor took place naturally.

(Received April 29, 1986; accepted November 10, 1986)

Abstract—New sex pheromone component of female *Stegobium paniceum* L. was isolated and identified as 2,3-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-hydroxybutyl)-4H-pyran-4-one, stegobiol, by spectral data and chemical conversion from stegobinone. Relative configuration at C-2, C-3, and C-1′ was determined as 2*S*,3*R*,1′*S* by the conversion from (2*S*,3*R*,1′*R*)-stegobinone. This new sex pheromone elicits the pheromonal response from the species.

Key Words—Sex pheromone, drugstore beetle, *Stegobium paniceum* L., Coleoptera, Anobiidae, stegobiol.

INTRODUCTION

The drugstore beetle, *Stegobium paniceum* L., is a devastating pest of stored grain. The structure of the sex pheromone has been established as 2,3-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-oxobutyl)-4H-pyran-4-one, **2** in Fig. 1, stegobinone (Kuwahara et al., 1975, 1978), and subsequent, study determined the absolute configuration at C-2, C-3, and C-1′ to be 2*S*,3*R*,1′*R* (Hoffmann et al., 1981). Stegobinone elicits precopulatory searching behavior from the males of the species (Kuwahara et al., 1975). Recently, we reported that stegobinone elicited not only searching but also mating behavior, and its pheromonal activity was inhibited by its 1′-epimer (Kodama et al., 1987). In the course of our study, we confirmed the presence of another sex pheromone component which we named stegobiol according to its structural similarity to stegobinone.

0098-0331/87/0800-1871$05.00/0 © Plenum Publishing Corporation

Here, we report the isolation and structural determination of this new sex pheromone.

METHODS AND MATERIALS

The insects were reared on mouse diet at 28 ± 1°C and 60 ± 10% relative humidity. Male pupae were removed from cultures and isolated from females by observance of the characteristics described by Azab (1954). Selected male pupae were transferred into a separate room from that used for culturing and placed in a female-free incubator at 28 ± 1°C and 60 ± 10% relative humidity. The isolated insects were kept in the incubator until tested when 8–10 days old.

Instrumentation. Analytical gas chromatography (analytical GC) was performed using a Shimadzu 7A equipped with FI detector and a 50-m × 0.2-mm-ID fused silica column coated with Carbowax 20 M. The column temperature was programmed at 2°C/min from 100 to 210°C. High-performance liquid chromatography (HPLC) was performed with a Hitachi 655 constant flow pump, and for monitoring the column's effluent a UVILOG-5A UV detector (Oyo-Bunko Kiki Co., Ltd., Tokyo) was used. Mass and IR spectra were measured on a Hitachi M-80 and Nicolet 60SX instruments, respectively. Proton and ^{13}C NMR spectra were obtained with a Bruker AM 500 NMR spectrometers. The chemical shifts are expressed as ppm downfield from Me_4Si as an internal standard. Two-dimensional NMR experiments were performed on a Bruker AM 500 NMR spectrometer using available 2D software. The data size of the time domain of the correlated spectrum (COSY) was a 512 × 2048 matrix. To improve the spectral resolution, these data were multiplied in both directions with a sine bell function. Fourier transformation was performed with zero filling in *t*1 direction. Heteronuclear-shift-correlated 2D NMR was processed in a similar way. The data size of the time domains was 256 × 2K.

Isolation of Pheromone. Drugstore beetles of both sexes (150,000 adults) were extracted twice with hexane (1 liter, each). After removing the solvent

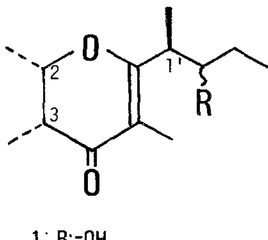

FIG. 1. The structure of the pheromones (**1**: stegobiol, **2**: stegobinone).

under reduced pressure at 40°C, 2.7 g of oily residue was obtained. The extracts were then charged on a silica gel column (3 cm ID × 27 cm) and fractionated with hexane, 10, 20, 30, 50, and 100% ether–hexane (250 ml each). Two substances eluted by 30% ether–hexane and ether elicited the pheromonal response from the males. Subsequent fractionation of the former by HPLC (μ-Porasil, 3.9 mm ID × 30 cm; mobile phase, hexane–THF–MeOH 6000:100:1; flow rate, 2.5 ml/min; detected by UV absorption at 281 nm) resulted in the isolation of stegobinone (10 mg). Although stegobinone obtained did not crystallize, all spectral data were identical with those reported previously (Kuwahara et al., 1978). The latter was successively fractionated by HPLC as shown in Figure 2. Active component (9.7 mg) was obtained from peak A and identified as 2,3-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-hydroxybutyl)-4H-pyran-4-one (stegobiol) **1**. $[\alpha]_D^{23} = -98.3°$ (c = 0.06, $CHCl_3$). HR-MS $C_{13}H_{22}O_3$ [found 226.1535, calc. 226.1567]. EI-MS (70 eV) m/z (%): 226(8, M^+), 168(88), 141(20), 139(17), 124(15), 113(70), 112(100), 109(27), 101(17), 85(17), 84(15), 83(87), 70(16), 59(49), 57(33), 56(37), 55(45), 43(41). IR ν_{max}: 1597 and 1652 (C=C—C=O), 3427 (OH) cm^{-1}. Proton NMR spectra are described in Table 1. ^{13}CNMR (125 MHz, $CDCl_3$): δ 197.1(C-4), 172.2(C-6), 109.5(C-5), 76.6((C-2), 75.5(C-2′), 43.8(C-3), 40.9(C-1′), 28.3(C-3′), 15.9(C-7), 14.8(C-10), 10.1(C-4), 9.4(C-8), 9.3(C-9).

Bioassay. Bioassay was performed by the procedure described before (Kodama et al., 1987).

Reduction of Stegobinone. A racemic mixture of stegobinone (22.6 g, 0.1 mol) synthesized by the method of Ono et al., (1983) was dissolved in ether (100 ml). Sodium borohydride ($NaBH_4$, 3.8 g, 0.1 mol) and zinc chloride

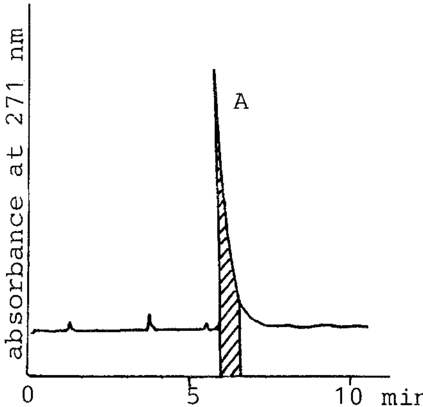

FIG. 2. High-performance liquid chromatogram of 100% ether fraction. Column, μ-Porasil (3.9 mm ID × 30 cm); mobile phase, 85% hexane–ether; flow rate, 3.0 ml/min; detected by UV absorption at 271 nm.

TABLE 1. [^{1}H] NMR ASSIGNMENTS FOR STEGOBIOL (500 MHz)

	Chemical shifts (ppm)	Coupling constants (Hz)
H-2	4.49 (dq)	$J_{2,3} = 3.4$, $J_{2,7} = 6.6$
H-3	2.38 (dq)	$J_{3,8} = 7.3$
Me-7	1.33 (d)	
Me-8	1.04 (d)	
Me-9	1.75 (s)

Me-4′	1.00 (t)	

($ZnCl_2$, 10.1 g, 0.1 mol) were added to this solution and subsequently stirred for 3 hr at room temperature. This suspended solution was then filtered and evaporated to give a diastereoisomeric mixture of stegobiol **1** (22 g). The starting materials, a racemic mixture of stegobinone, could not be detected in these products by GC and GC-MS. The diastereoisomeric mixture (5 g) was then charged on a silica gel column (4 cm ID × 30 cm) and fractionated with hexane, 10, 20, 30, 50, and 100% ether–hexane (500 ml each).

RESULTS

*Spectroscopic Analysis of **1**.* The most striking feature of the EI mass spectrum (EI-MS) of **1** is quite similar to that of stegobinone except for the M^+ peak at *m/z* 226. On the basis of an analysis of the high-resolution mass spectrum (HR-MS), the molecular formula of **1** was assigned as $C_{13}H_{22}O_3$. The IR spectrum showed the absorption of enone and hydroxy group. These data suggested the structure of **1** to be C-2′ hydroxy derivative of stegobinone. The assignment of the signals in ^{1}H- and ^{13}CNMR spectra gave the precise structure of **1**. The proton NMR spectrum of **1** at 500 MHz (Figure 3A) showed the clear separation of the resonance due to each proton. The lowest frequency doublet of quartet at δ 4.90 could be assigned to the proton H-2 which was bonded to oxygen atom. The position of the resonances due to H-3, Me-7, and Me-8 are clearly revealed by the contour plot (Figure 3B) from COSY experiment. Off-diagonal peaks correlate the H-2 resonance with the H-3 and Me-7 resonances which appear as a doublet of quartets at δ 2.38 and a doublet at δ 1.33 in Figure 3A, respectively, and H-3 resonance with Me-8 resonance, which

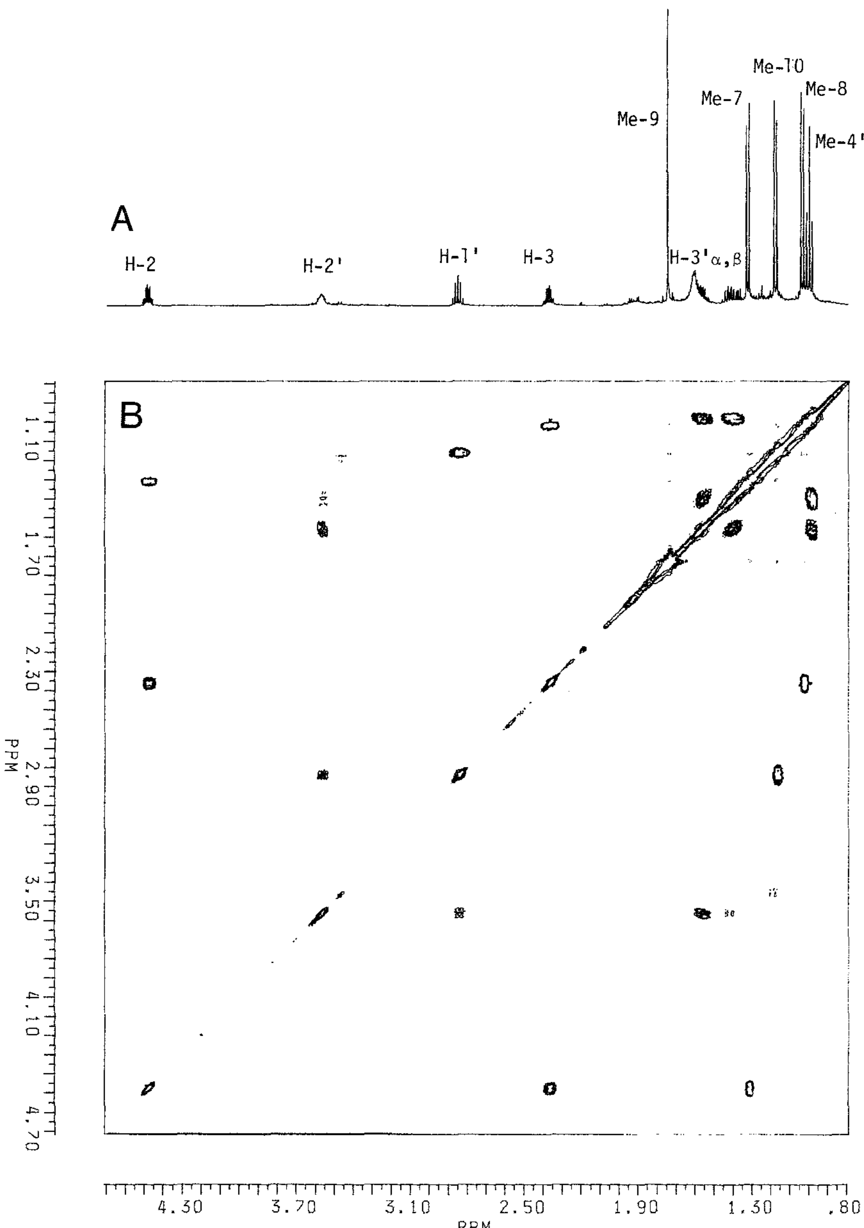

FIG. 3. (A) 500-MHz [¹H]NMR spectrum of **1** (in $CDCl_3$); (B) Two-dimensional [¹H]COSY NMR spectrum of **1**.

appears as doublet at δ 1.04 in Figure 3A. Also the position of the resonances due to Me-10, H-1′–H-3′α and β, and Me-4′ are clearly revealed. The highest frequency triplet at δ 1.00 can be assigned to Me-4′. Off-diagonal peaks correlated this resonance with the H-3′α and 3′β which appear as multiplet and doublet of doublet of quartet at δ 1.42 and δ 1.60, respectively. These resonances were correlated with the H-2′ resonance, which appears as a doublet of doublets at δ 3.58 in Figure 3A. An off-diagonal peak correlates the H-2′ resonance with H-1′ resonance which appears as a doublet of quartets at δ 2.86 and correlates with the Me-10 resonance appearing as a doublet at δ 1.18.

The carbon signals of **1** were assigned as follows. Resonances due to CH, CH_2, or CH_3 groups were identified from the spectra obtained using the DEPT pulse sequence. The assignment of resonances corresponding to carbon atoms was made by a heteronuclear correlation experiment. The assignments of the carbon signals, except for C-4, 5, and 6, were made by direct correlation with the resonances of the corresponding proton signals previously assigned. These spectra confirm the structure of **1** to be 2,3-dihydro-2,3,5-trimethyl-6-(1′-methyl-2′-hydroxybutyl)-4H-pyran-4-one.

Elucidation of Structure 1 by Chemical Conversion. Chemical reduction by the synthesized stegobinone afforded a diastereoisomeric mixture of **1**. Eight possible racemates in the diastereoisomeric mixture showed the corresponding eight peaks as shown in Figure 4. The mixture was further separated by silica-gel column chromatography as described above. The isomer eluted by 100% ether showed a single peak on the analytical gas chromatogram, which corresponded to peak 5 in Figure 4. Proton-, ^{13}C NMR and EI mass spectra of the isomer were identical with those of **1**.

Relative Configuration of 1. A resolution-enhanced one-dimensional proton-NMR spectrum showed the interproton coupling between H-2 and H-3. The $J_{2,3}$ (3.4Hz) value indicated the relative configuration between Me-7 and Me-8 to be *cis*. The relative stereochemistry at C-1′ was determined by the chemical conversion from 2,3-*cis*-stegobinone. Chromatographically separated (±)-2*S*,3*R*,1′*R*- and (±)-2*S*,3*R*,1′*S*-stegobinone were independently reduced by the manner described above to give (±)-2*S*,3*R*,1′*S*,2′*RS*- and (±)-2*S*,3*R*,1′*R*,2′*RS*-stegobiol, respectively. On the analytical gas chromatogram, the former showed two peaks corresponding to peaks 5 and 8, and the latter to peaks 3 and 7. The retention time of **1** on the gas chromatogram was identical with one of those of the former (peak 5). From the above observation, the relative configuration at C-2, C-3, and C-1′ was determined to be 2*S**,3*R*,1′*S*.

Biological Activity of Stegobiol. Responses of male drugstore beetles to stegobiol are summarized in Figure 5. In a replicated bioassay at 10^{-5}–10 μg dose, stegobiol showed the same level of biological activity as that of stegobinone, and the threshold of its activity was 10^{-3} μg. Although the parameters scored were almost the same between two pheromones, a small difference in

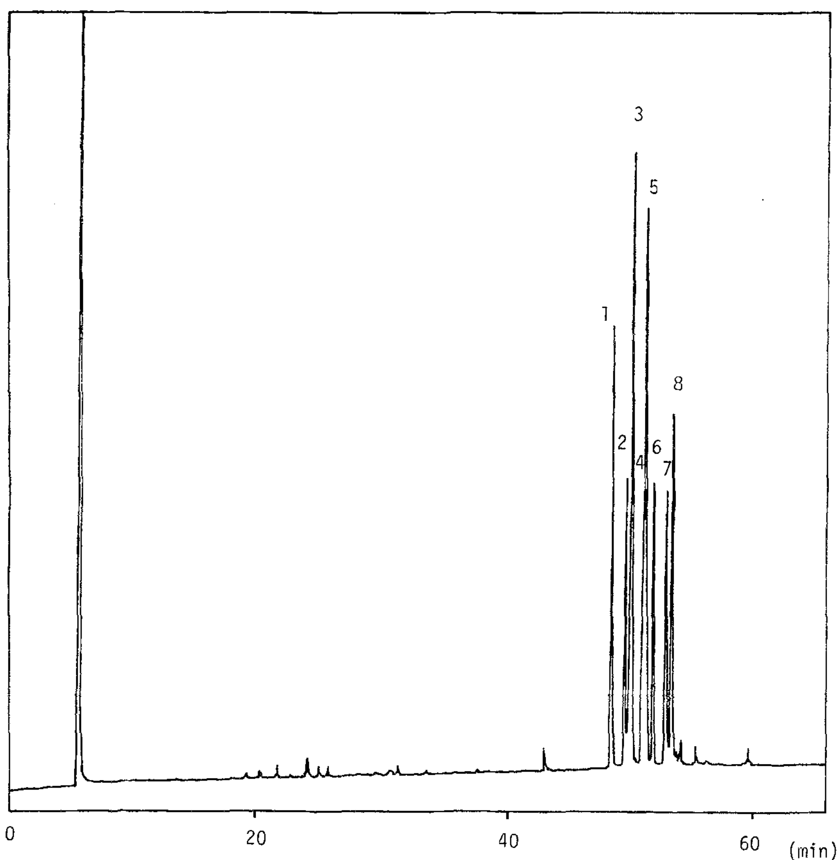

FIG. 4. Analytical gas chromatogram of the diastereoisomeric mixutre of **1**. Retention time and assignment: peak 1, 48.3 min, 2,3-*trans*; peak 2, 49.4 min, 2,3-*trans*; peak 3, 49.8 min, (+)-2*S*,3*R*,1′*R*; peak 4, 50.7 min, 2,3-*trans*; peak 5, 50.9 min, (+)-2*S*,3*R*,1′*S*; peak 6, 51.5 min, 2,3-*trans*; peak 7, 52.5 min, (+)-2*S*,3*R*,1′*R*; peak 8, 53.0 min, (+)-2*S*,3*R*,1′*S*. Peak 5 corresponded to that of stegobiol obtained from the male.

behavioral response was observed. In the bioassay of stegobiol, a few minutes passed before the males awakened, whereas stegobinone elicited immediate awakening. Once the males awakened, no difference of the response was observed between them. Pheromonal activity of synthetic stegobiol was also examined. Although a diastereoisomeric mixture showed no pheromonal activity, the column-chromatographically separated isomer corresponding to peak 5 on the analytical gas chromatogram elicited the pheromonal response from the males.

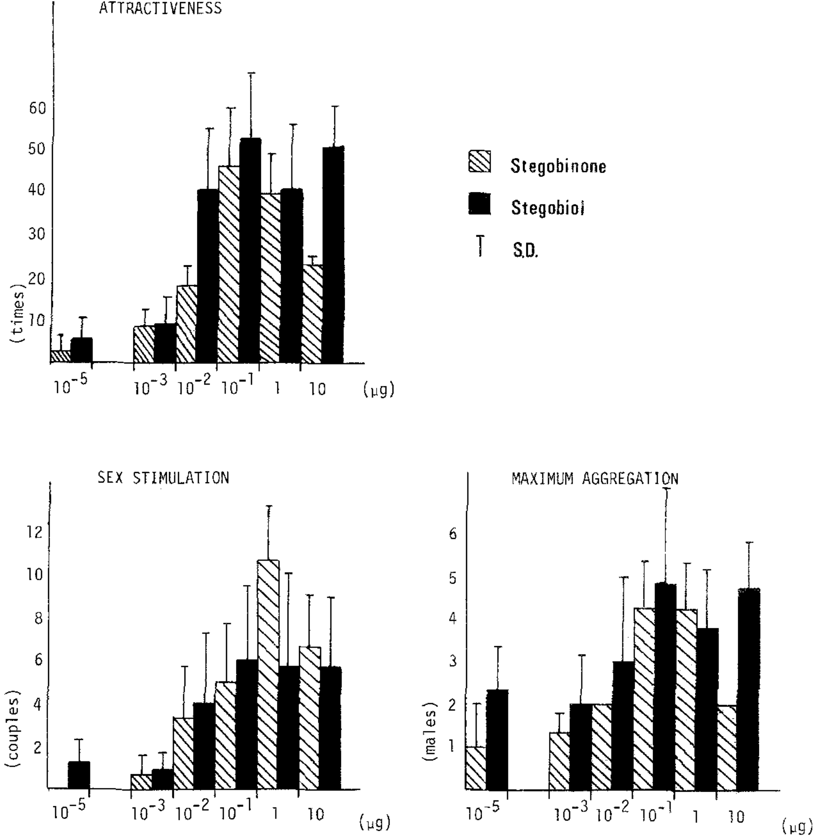

FIG. 5. The pheromonal activity of stegobiol and its diastereoisomeric mixture. The assay data for stegobinone are from a previous paper (Kodama et al., 1987).

DISCUSSION

We previously reported the mating behavior induced by stegobinone (Kodama et al., 1987). The newly identified pheromone, stegobiol, elicited the same response as stegobinone. Although the absolute configuration is still unknown, the structure of stegobiol is closely related to that of stegobinone in regard to relative stereochemistry at C-2, C-3, and C-1′. The stereochemistry at C-2, C-3, and C-1′ was thought to be necessary to elicit the pheromonal response.

We also reported that stegobinone is easy to epimerize to the C-1′ epimer that is the inhibitor, whereas stegobiol is stable and no epimerization could be observed under the same conditions. The diastereoisomeric mixture of stegobiol

elicited no response from the males. An isomer, which possessed the same relative chemistry as that of the stegobinone inhibitor, is also thought to inhibit the pheromonal activity. The volatility of two pheromones is thought to be considerably different because of the nature of C-2′ substituents. In the stegobiol molecule, the hydroxy substituent at C-2′ should depress its volatility. The difference of the response between two pheromones observed in the bioassay, the lag time before awakening, may be attributed to their volatility. These two pheromones may have independent roles in eliciting pheromonal activity, i.e., perhaps stegobiol and stegobinone and short-range and long-range sex attractants, respectively.

The absolute configuration of stegobiol, including the stereochemistry at C-2′, should be confirmed by synthesis.

Acknowledgments—We would like to thank Prof. K. Mori and Dr. T. Ebata of Tokyo University for their valuable suggestions.

(Received August 18, 1986; accepted November 6, 1986)

Abstract—The germination rates of cotton and wheat seeds were significantly affected by various extracts of wheat mulch and soils collected from the wheat field. This toxicity was even more pronounced against seedling growth. Five allelochemics: ferulic, *p*-coumaric, *p*-OH benzoic, syringic, and vanillic acids, were identified from the wheat mulch and its associated soil. Quantitatively, ferulic acid was found at higher concentrations than *p*-coumaric acid in the soil. Various concentrations of ferulic and *p*-coumaric acids were toxic to the growth of radish in a bioassay. The functional aspects of allelochemic transfer from decaying residue to soil and the subsequent microbial degradation within agroecosystems are discussed, particularly as they relate to wheat crop rotation, with wheat and cotton, in Pakistan.

Key Words—Allelopathy, ferulic acid, *p*-coumaric acid, *p*-OH benzoic acid, syringic acid, vanillic acid, *Triticum vulgare*, *Gossypisium hirsutum*.

INTRODUCTION

Rice (1984) reported that inhibitory effects (allelopathy) of crop plants on other crop plants have been reported as far back as 300 B.C. by Theophrastus. Unfortunately, research in allelopathy did not develop successionally, and only a few historical reports are found prior to the beginning of the twentieth century. Schreiner and Reed (1907) reported that the roots of wheat, oats, and other crop plants exude chemicals inhibitory to their own seedlings. Eveneri (1949) demonstrated the presence of seed germination inhibitors in several crop plants.

In the late 1940s, McCalla and his associates in Nebraska started their

0098-0331/87/0800-1881$05.00/0 © Plenum Publishing Corporation

systematic studies with crop versus crop allelopathy. They isolated and quantified many allelochemics from the crop residues and their associated soils. Guenzi and McCalla (1962) tested various hot- and cold-water extracts of oats, corn, wheat, sorghum, sweetclover, and soybean and reported a wide range of inhibition of germination, shoot growth, and root growth of wheat. Subsequently, Guenzi and McCalla (1966a,b) isolated various allelochemics from crop residues and their associated soils. Wang et al. (1967) isolated five different phenolic acids from sugarcane-associated soils. The concentration of inhibitors found in many soils was sufficient to decrease the growth of wheat, corn, and soybean when applied to plants growing in nutrient culture solutions. Chou and Lin (1976) and Chou et al. (1981) reported that the decreases in rice productivity of crops following the first was due mainly to the allelopathic effects of decaying rice residues. Shilling et al. (1985) reported allelochemic activities in rye and wheat and alluded to their possible significance in no-till weed control.

It is clear that allelochemic interactions exist and play a major role in crop plants. Crop residue can be used to decrease and/or eliminate weeds from cropping areas, but they may also lower the productivity of subsequent crops of the same kind or of different crops used as rotational crops (Putnam and Duke, 1978; Chou et al., 1981; Lodhi, 1981; Rice, 1984; Putnam, 1985). In Pakistan, wheat crops are rotated in various combinations: wheat–fallow–wheat, wheat–cotton–fallow–wheat, rice–wheat–rice, wheat–green manuring–wheat, sugarcane–wheat–fallow–wheat, and wheat–legume–wheat. All rotations are based on region and season at the starting point of the rotation scheme; however, no data were found to show the effects of crop residue and their associated soils or crop–crop interaction of the various crop species. With this in mind, a project was initiated to establish systematic studies of the allelochemic behavior of crop species. This report deals mainly with wheat–cotton and wheat–wheat interactions.

METHODS AND MATERIALS

Location and Description of Study Area. A research plot was established at the Field Research Sites of the Nuclear Institute for Agriculture and Biology (NIAB) in Faisalabad, Pakistan. Six randomly located soil samples, 0–30 cm in depth, and six standing wheat mulch samples, from the same locations, were collected. All samples were air-dried to a constant weight at room temperature. Three composite samples were made by mixing two samples each of soil and wheat mulch. Test crop plants used in all experiments were the same as cultivated locally: *Triticum vulgare* Punjab 81 (wheat) and *Gossypium hirsutum* Niab 78 (cotton).

Effects of Wheat Mulch. Aqueous extracts were prepared with cold (20°C)

and hot (75 °C) water and treated separately for experimentation. Extracts were prepared by immersing the leaf mulch in water at the appropriate temperature for 10 min, grinding it in a blender for 5 min, and removing the particulate matter by centrifugation. Experimental dilutions were made at 1:10 and 1:20, leaf mulch–water, respectively. Twenty-five seeds each of the wheat and cotton were placed in each of three dishes containing filter paper saturated with 10 ml of distilled water (control), 10 ml of 1:10 extract solution or 10 ml of 1:20 extract solution. Seeds were allowed to germinate in the dark at room temperature. The percent germination index was calculated based on the formula $4(1g + 2g + 3g)$, where g represents the total germination each day.

To determine the allelopathic effects of wheat on wheat and cotton seedlings, plants were grown in a sand–vermiculite mixture for two weeks in Hoagland's nutrient solution (Hoagland and Arnon, 1950). Seedlings were then transferred to plastic vials containing one of the following solutions: 100% Hoagland's solution (control) or 1:10, 1:20, or 1:40, (test) mulch–Hoagland's solution, respectively. All extracts were prepared in Hoagland's solution to maintain the nutrient balance. Seedlings were allowed to grow in these solutions for five additional days, harvested, oven dried, and weighed.

Effects of Field Soil. Soil aqueous extracts were prepared with cold (20 °C) and hot (75 °C) water and treated separately for experimentation. Extracts were prepared by immersing soil samples in water at the selected temperature and magnetically stirring them for approximately 12 h. The soil was then removed by centrifugation. Experimental dilutions were made at 1:10 and 1:20, soil–water, respectively. To determine the percent germination index, experiments were conducted following the procedure described above.

Identification and Quantification of Phytotoxins. The procedures used to isolate the compounds were the same as used previously by Lodhi (1975a). Air-dried ground wheat or soil were separately hydrolyzed with 2 N NaOH in an autoclave for 45 min. The extracts were centrifuged and acidified to a pH 2.0 with HCl, then extracted with three half volumes of diethyl ether. The ether fractions were shaken with two half volumes of 5% $NaHCO_3$ and the ether fractions discarded. The alkaline portions were acidified again to pH 2.0 and reextracted with two half volumes of diethyl ether. The ether portions were evaporated to dryness and the residue taken up in 5 ml of 95% ethanol. The soil and mulch fractions were chromatographed in two dimensions using *n*-butanol–acetic acid–water (63:10:27 v/v/v, BAW), followed by 6% aqueous acetic acid (6% AA). The chromatograms were inspected under short and long UV. Compounds were marked under UV light and subsequently eluted with 95% ethanol and chromatographed in one dimension using several different solvent systems: BAW, 6% AA, upper phase of benzene–acetic acid–water (6:7:3 v/v/v, B_zAW), and sodium formate–formic acid–water (10:1:200 v/v/v, NaFW). The chromatograms were dipped in various reagents and maximum

absorption peaks in 95% ethanol determined with a spectrophotometer before and after the addition of two drops of 2 N NaOH to the cuvette.

Quantitative analysis of phytotoxins was done according to the procedure described by Lodhi (1975b). Known amounts of soil extracts were spotted on chromatography paper and developed as described above. Eluates of identified compounds were taken in known amounts of 95% ethanol and concentrations determined from the standard curves of known compounds. The standard curves were determined by spotting known concentrations of authentic samples on chromatography paper following the same procedure as used with the soil extracts. All standard curves were determined at the maximum absorption peaks of the authentic reagents.

Biological Activity of Quantified Phytotoxins. It was considered necessary to determine the biological activity of the compounds quantified from soil samples. Solutions of various concentrations of ferulic and *p*-coumaric acids in various concentrations were prepared with phosphate buffer, pH 5.65, to determine their biological activity against seed germination and radicle growth of the radish, a good indicator species (Lodhi, 1979). Known amounts of test buffer solutions were added to Petri plates containing 25 radish seeds on filter paper. Controls were treated in the same manner, except seeds were watered with toxin-free buffer solutions. After three days, germination was determined and each plate thinned, leaving only the 10 longest radicles per dish. Radicles were allowed to grow for two additional days, after which radicle growth was measured.

RESULTS

The germination rates of cotton and wheat seeds, as expressed by the percent germination index, were suppressed by the wheat mulch and soils taken from the wheat field (Table 1). Cold extracts inhibited the cotton germination rate more effectively than the hot extracts, whereas hot extracts (1 : 20) inhibited the wheat germination rate more effectively than the cold extracts. The two test concentrations, among themselves, were signifcantly different in a few cases in their effectiveness in inhibiting the germination rates (Table 1). Cold and hot soil extract effectiveness against cotton was significantly different between the two test concentrations. On the other hand, the wheat germination rate was significantly different between the two test concentrations using cold plant extracts (Table 1).

The toxicity of wheat was even more pronounced against seedling growth than germination (Table 2). Most seedlings in 1 : 10 mulch–Hoagland's solution died and were excluded from the data. Wheat and cotton seedling growth was significantly reduced in the remaining test concentrations (Table 2).

Allelochemics identified from mulch and associated soils were ferulic, *p*-

TABLE 1. EFFECTS OF VARIOUS EXTRACTS OF WHEAT MULCH AND ASSOCIATED SOIL ON GERMINATION INDEX (% GI) OF WHEAT AND COTTON ($N = 3$, MEAN ± SD)

Extract	Control % GI	Test % GI	
		1:20	1:10
Cotton			
Cold plant	324 ± 59.7	121 ± 12.0[a]	168 ± 43.3[a]
Hot plant	324 ± 59.7	250 ± 67.1	203 ± 26.6[a]
Cold soil	324 ± 59.7	117 ± 40.5[a,b]	237 ± 22.0
Hot soil	324 ± 59.7	320 ± 59.7[b]	124 ± 10.6[a]

coumaric, *p*-OH benzoic, syringic, and vanillic acids (Table 3). The amount of ferulic acid isolated was calculated as 941 kg/ha; *p*-coumaric acid was 684 kg/ha. Para-OH benzoic, syringic, and vanillic acids were not measured after initial analysis due to their smaller amounts as compared to ferulic and *p*-coumaric acids (Figure 1). Other compounds were also isolated in soil and plant fractions, but no attempts were made to identify all compounds. Concentrations of ferulic and *p*-coumaric acids significantly reduced the germination and radicle growth of radish (Figure 1). Further, radicle growth was significantly different between test concentrations (Figure 1).

DISCUSSION

Experimental data clearly support the allelopathic impact of wheat on cotton and wheat autotoxicity, since competition was not a factor. Dilution of wheat mulch and soil extracts in buffered and nutrient-rich solutions inhibited the germination rates and seedling growth of wheat and cotton, and this clearly indicated the presence of allelochemics (Tables 1 and 2). In Punjab province, a wheat crop rotated with cotton and wheat (after fallow) would probably have an adverse effect on crop productivity.

There is growing evidence that many crop plants produce phytotoxic substances (Borner, 1960; Garb, 1961; McCalla and Haskins, 1964; Guenzi et al., 1967; Wang, et al., 1967; Putnam and Duke, 1978; Lodhi, 1981; Schumacher et al., 1983; Rice, 1984; Pope et al., 1985; Panasiuk et al., 1986). Kimber (1973) pointed out that subsequent low crop yields are generally attributed to nitrogen immobilization. His carefully designed experiments demonstrated that various combinations of wheat residues and nitrogen affect the yield of wheat

crops cultivated in the presence of straw residues. Further partitioning of experiments showed that the soil-surface straw very effectively depressed germination. Additionally, nitrogen immobilization affected yield the most when straw was mixed in the soil and adding more nitrogen did not minimize residue phytotoxicity. This supports our data, which showed reduced germination that occurred at a slower rate. Rapid germination rates play an important role in reducing the loss of seeds due to decay in soil and in providing more vigorous seedlings because of an early start.

The toxicity level was much more pronounced against seedling growth in cotton and wheat. A ratio of 1:10 (mulch) was too toxic and killed the test seedlings, whereas the same ratio only significantly reduced the germination rates of both test species (Tables 1 and 2). A concentration of 1:40 (mulch) was still strongly inhibitory ($P \leq 0.001$) to test seedling growth. This is an important point, which answers a frequently asked question about the retention time of allelochemics in the agro-, or natural, ecosystems. The various concentrations (1:10, 1:20, 1:40) used, represented possible toxicity retained during the course of mulch decay. Guenzi et al. (1967) reported changes in the phytotoxicity of decomposing wheat, and several other crops, after harvest. Phytotoxic levels in decomposing residue varied from crop to crop, but remained significant for several weeks. Loss of allelopathy from the mulch is simply (at least in part because some may decompose) a transfer of allelochemics to the associated soils. The process is not any different than the transfer of any other organic matter from crop/natural litter to soils in a natural or agroecosystem. Therefore, the presence of allelochemics in soils is as important as their presence in the crop litter (Lodhi 1975b, 1978).

Ferulic, *p*-coumaric, *p*-OH benzoic, syringic, and vanillic acids were identified in wheat residue and associated soil samples (Table 3). All five compounds are known to be allelopathic in natural and agroecosystems (Rice, 1984; Mandava, 1985). Ferulic and *p*-coumaric acids found in soil were in larger concentrations than *p*-OH benzoic, syringic, and vanillic acids. Further, the amount of ferulic acid was larger (941 kg/ha) than the amount of *p*-coumaric acid (684 kg/ha). These amounts seem to be higher than reported previously by Guenzi and McCalla (1966a); however, they reported higher amounts of ferulic and *p*-coumaric acids in the mulched plot than in the plowed plot. Lodhi (1975b, 1978) reported the cycling and larger amounts of many phenolics in soil systems throughout the year in forest communities. Furthermore, in a partially unharvested corn field, the amounts of ferulic and *p*-coumaric acids remained consistently high, comparable to the amounts reported in the current study (Lodhi, 1981); however, the amounts of phenolic compounds can vary due to cultivation or because of geographic, environmental, or ecological reasons. Additionally, the differences in phenolic profiles and concentrations can be due to eco-evolutionary reasons (Levin, 1971).

The mechanisms by which phytotoxins inhibit growth are not well understood. Allelochemics can target one or more physiological systems to block growth processes; therefore, a mixture of several allelochemics can be more detrimental than one inhibitor at the same concentration. Rasmussen and Einhellig (1977) reported that an equimolar mixture of ferulic and *p*-coumaric acids reduced sorghum germination and various growth factors of the seedlings more than either compound alone. In their systematic studies, Einhellig and Rasmussen (1978) reported on the synergistic action of vanillic and *p*-OH benzoic acids on sorghum growth at an equimolar concentration of 5×10^{-4}, which approximately resulted from a 10^{-3} M concentration of either phenol.

The dynamic nature of phenolics in soil is very complex. Phenolics can originate from microbial metabolism, lignin degradation, humate breakdown, etc. Paracoumaric acid can be oxidized by soil microbes into *p*-OH benzoic acid. Similarly, vanillic acid can be an oxidized product of ferulic acid (Wang et al., 1967; Turner and Rice, 1975). One should keep in mind that quantitative analysis of soil phenolics only represents the allelochemic functional status; ecologically speaking, the presence of the same phenolics in plants would be essential as an original source. Losses in the amounts of ferulic and *p*-coumaric acids do not necessarily represent a lessening in toxicity. Lowered amounts of ferulic and *p*-coumaric acids, combined with their oxidized products, vanillic and *p*-OH benzoic acids, collectively remained allelopathically active (Lodhi, 1978). Furthermore, the original syringic and *p*-OH benzoic acids constantly released from the residue into the soil will unquestionably accentuate the toxic nature of wheat mulch allelochemics.

It is clear that the involvement of biochemicals in an agroecosystem is a phenomenon that cannot be ignored, because these phytotoxins play a multipurpose role. Allelochemics can lower the yield of subsequent crops if proper rotation is not determined; yet they can also be used to minimize weed invasion and competition in crop fields (Lodhi, 1981). Such manipulations may assist in determining an effective (high yield) rotation of crops in mixed cropping. Thus it seems necessary to determine and exploit the primary roles of these secondary compounds classified as allelochemics.

OLFACTORY RESPONSES OF A SPECIALIST AND A GENERALIST GRASSHOPPER TO VOLATILES OF *Artemisia ludoviciana* NUTT. (ASTERACEAE)

M.H. BLUST[1] and T.L. HOPKINS[2]

Department of Entomology
Kansas State University
Manhattan, Kansas 66506

(Received July 7, 1986; accepted November 7, 1986)

Abstract—*Hypochlora alba* is a specialist grasshopper that lives and feeds almost exclusively on *Artemisia ludoviciana*, a plant that produces large amounts of allelochemics including a variety of monoterpenes. This plant is not a host for generalist grasshoppers such as *Melanoplus sanguinipes*. The role of olfaction in the grasshopper–plant relationship was investigated by comparing electroantennograms (EAGs) of males and females of both species generated by solvent-extracted volatiles from plant leaves and by major individual components. Volatiles of *A. ludoviciana* were identified by gas chromatography–mass spectrometry. The major components were 1,8-cineole, camphor, camphene, and borneol, while minor identified compounds were α- and β-pinene, α-thujene, myrcene, *p*-cymene, Artemisia ketone, α-thujone, and bornyl acetate. The EAGs (mV) of *H. alba* males to a range of concentrations of individual volatiles or the total plant extract were nearly double those of conspecific females or both sexes of *M. sanguinipes*. However, both sexes of *M. sanguinipes* were more sensitive than either sex of *H. alba* to geraniol, a monoterpene that commonly occurs in many plant species but is absent or is present in only trace amounts in *A. ludoviciana*. The increased sensitivity of *H. alba* males to the odor components of their host plant appears to be related to the greater number of certain olfactory chemoreceptors on male versus female antennae. The significance of this phenomenon is discussed.

Key Words—*Hypochlora alba*, *Melanoplus sanguinipes*, Orthoptera, Acrididae, *Artemisia ludoviciana*, electroantennogram, specialist insect, generalist insect, plant volatiles, grasshopper, monoterpenes.

INTRODUCTION

Phytophagous insects have evolved different strategies for obtaining food. Generalists feed on a wide variety of plants, while specialists use only a single species or group of related species. The mechanisms of host plant location and nonhost avoidance involve many behavioral and sensory adaptations (Ahmad, 1983). Olfactory specializations of receptors in the peripheral nervous system have been found in several specialist species (reviewed by Mustaparta, 1984; May and Ahmad, 1983; Visser, 1983, 1986). A number of insects such as the Colorado potato beetle *Leptinotarsa decemlineata* (Visser, 1979), the carrot fly *Psila rosae* (Guerin and Visser, 1980), the oak flea weevil *Rhynchaenus quercus* (Kozlowski and Visser, 1981), the chrysomelid beetle *Trihabda bacharides* (Dickens and Boldt, 1985), the cereal aphid *Sitobion avenae* (Yan and Visser, 1982), and the boll weevil *Anthonomus grandis* (Dickens, 1984) have been found to be sensitive to certain volatiles typical of their host plants and to general green plant volatiles (Visser, 1979).

Hypochlora alba (Dodge) is a highly specialized grasshopper which feeds almost exclusively on Louisiana sagewort, *Artemisia ludoviciana* Nutt. (Knutson, 1982). This plant appears to be protected by both glandular and nonglandular trichomes and is fed upon very little by generalist grasshoppers such as the related *Melanoplus sanguinipes* (Fabr.) (Mulkern et al., 1969). This model system has been the subject of several previous studies emphasizing the physical defenses of the plant and adaptations of the specialist grasshopper to these defenses (Knutson, 1982; Smith and Grodowitz, 1983; Smith and Kreitner, 1983).

This study examines the role of olfaction in the adaptation of the specialist grasshopper, *H. alba*, to its host plant and, by use of the electroantennogram (EAG) technique (Schneider, 1957), the possibility of sensory specialization to volatiles of the host plant. This was done by comparing EAGs of specialist and generalist grasshoppers generated by volatiles from *A. ludoviciana* extract and by individual monoterpenes that are major components of the plant's odor.

METHODS AND MATERIALS

Analysis of Plant Volatiles. Two methods were used to collect the volatiles from *A. ludoviciana*. In the first, air was swept through a flask containing overdried (55°C), ground-up leaves and then through a glass U-tube (0.5 cm ID) immersed in liquid nitrogen. After trapping for 30 min, the tube was rinsed with 1 ml of dichloromethane. After separation of the water and solvent, the latter was drawn off, concentrated under nitrogen, and stored at −20°C for analysis. In the second method, specimens of *A. ludoviciana* were cut at the stem base and care was taken not to damage the leaves. These specimens were placed in a closed glass container which was purged with nitrogen at a rate of

1 liter/min through a trap containing 2 ml of Tenax. Volatiles were trapped for 6 hr before rinsing the Tenax with 4 ml of diethyl ether and concentrating to 0.5 ml under nitrogen. Volatiles were analyzed by capillary column gas chromatography (GC), and certain components were tentatively identified using retention times of standards. A Tracor 540 capillary GC with a 25-m BP-1 (SE-30 equivalent) vitreous silica 0.33-mm-ID column was used for analysis. Conditions were 50°C for 5 min, to 250°C for 5 min at a rate of 10°C/min. Helium was used as the carrier gas at a head pressure of 6 psi. Confirmation of structural identity of certain monoterpene components from the headspace volatiles was obtained by capillary gas chromatography–mass spectrometry (GC-MS) using a Hewlett Packard 5790A GC and 5790 MS detector.

Experimental Insects. Two species of grasshoppers were used in this investigation. The specialist, *H. alba,* was collected from a pasture 5 miles west of Brookville, Kansas. They were maintained in a rearing room and fed on freshly cut host plants until tested. The generalist, *M. sanguinipes* was from a nondiapausing laboratory colony that was reared in a greenhouse and fed seedling rye grass and ground Purina guinea-pig pellets.

Electroantennogram Techniques. Using adult insects, EAGs (in millivolts) were recorded from excised antennae of males and females of *H. alba* and *M. sanguinipes*. The distal tips (one segment or less) of the antennae were removed, and the antennae were severed from the head. Each antenna was placed between the tips of two Pasteur pipets containing cockroach saline II (Oakley and Schafer, 1978). Ag–AgCl wires were inserted into the saline from the other end of the pipet and connected to a Grass P-18 DC amplifier. The amplifier output was read on a Tektronix 564B storage oscilloscope.

Five test volatiles and a standard were used. The test volatiles were the monoterpenes found to be 5% or more of either of the two volatile collections. These were camphene (99%), camphor (97%), borneol (98%), (Aldrich Chemical Company), and 1,8-cineole (ca. 99%) provided by Dr. T. Mabry, University of Texas. The fifth test substance was a dichloromethane extract of *A. ludoviciana* leaves. The standard was the monoterpene geraniol (98%), also provided by Dr. Mabry. Each of these test volatiles was applied to a 1-cm^2 piece of filter paper at rates of 2, 20, and 200 ng in 20 μl of dichloromethane. The standard was used at the 200-ng rate. The filter paper was placed in the wide end of a Pasteur pipet. After the solvent evaporated, a 0.3-m length of Tygon tubing was attached. The pipets were positioned 1 cm from the antenna, and a syringe was attached to the other end of the tubing and used to blow a 0.5-ml puff over the antennae. A minimum of 30 sec was allowed between test readings.

The test pipets were coded by number so the identity of the substances was not known during the test. Only the identity of the standard was known, and this was used at the beginning of each series of 15 samples (five volatiles at three levels each) and after every fifth sample. Each of the five test responses

(millivolts) recorded between two standard responses was divided by an average of the latter to obtain readings relative to the standard. This procedure was used to compensate for decline in antennal response with time. These ratios were then multiplied by the initial response of the standard to obtain the final results in mV. Conversion to mV was necessary for comparisons between sexes and species. The series of 15 test odors was performed twice for every antenna, and the results were averaged. The data were evaluated by analysis of variance. Comparisons between the four test groups, and comparisons at the 200-ng level of the responses within a test group, were made using Duncan's multiple-range test.

RESULTS

Composition of Plant Volatiles. Capillary gas chromatograms of headspace volatiles collected from oven dried and whole fresh sage plants showed similarities in the compounds collected and their relative amounts (Figure 1). This indicates that most of the volatile terpenoids found in the sage are being released from undamaged plants. Table 1 shows compound identifications by GC-MS, and those identifications which have been confirmed by correspondence with retention times of monoterpene standards. In addition, the table contains the normalized peak area percentages of the compounds collected by the two methods. 1,8-Cineole was the major component, accounting for one third to one half of the volatiles. Other compounds constituting more than 5% of the volatiles collected by either of the two methods were camphor, camphene, borneol, and two unidentified compounds. Other monoterpenes identified in lesser amounts included α-pinene, p-cymene, myrcene, and bornyl acetate.

Electroantennograms Generated by Plant Volatiles. EAGs ranged from 0.06 to 1.26 mV for test substances while the response to an odorless air puff was ca. 0.07 mV (Table 2). No significant differences were found between the EAGs of male and female *M. sanguinipes* generated by any of the individual volatiles or the plant extract. Because of the similarity in responses between sexes of *M. sanguinipes*, interspecific comparisons were made by pooling the data from males and females of this species.

H. alba showed a sexual difference in its response to the host-plant volatiles (Table 2). Males had a significantly higher response to most of the volatiles except no significant difference was evident for any level of camphene, the lowest level of the extract of *A. ludoviciana*, and the control, geraniol. The strength of the EAGs of female *H. alba* was very similar to the responses of *M. sanguinipes*. Female *H. alba* had a significantly lower response only to the control, geraniol. Male *H. alba* showed statistically greater responses than *M.*

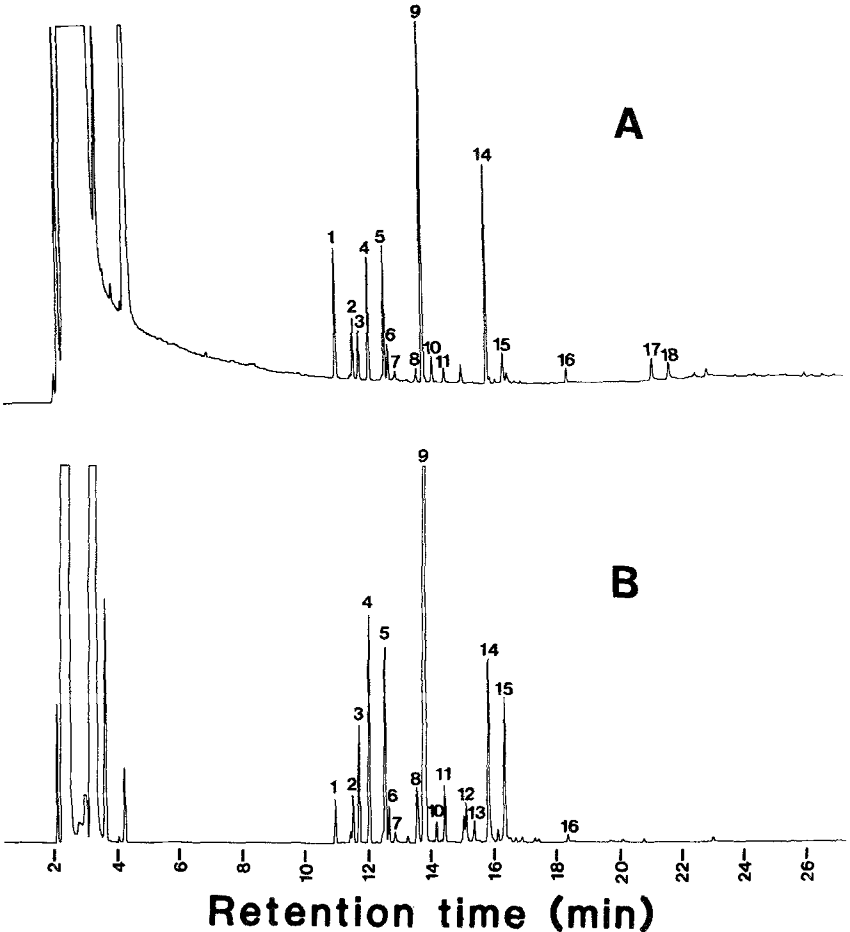

FIG. 1. Comparison of volatiles from (A) whole fresh plants and (B) oven dried foliage of *Artemisia ludoviciana* by capillary gas chromatography. Compounds assigned peak numbers are listed in Table 1. See Methods and Materials for details of analysis.

sanguinipes at all levels of camphor, 1,8-cineole, borneol, and extract, but no significant difference at any level of camphene.

Using the pooled data for *M. sanguinipes*, camphene, 1,8-cineole, and camphor gave the lowest responses. They were followed in increasing order by borneol, *A. ludoviciana* extract, and geraniol. This same pattern was followed closely by both male and female *H. alba* with geraniol as the major exception. This monoterpene gave a much more intense response in the generalist than in the specialist grasshopper (Table 2).

DISCUSSION

The monoterpenes identified in this study as major volatiles from *A. ludoviciana* match closely those identified by Stangl and Greger (1980). They list camphor and 1,8-cineole as occurring in relatively high concentrations, with lesser amounts of camphene, borneol, α- and β-pinene, and myrcene. They do not list α-thujone or *Artemisia* ketone as being found in this species. The authors state that cineole, thujane, and camphane derivatives are characteristic of sections *Artemisia* and *Abrotanum*. *A. ludoviciana* is placed in either of these two groups by various systematic schemes.

H. alba has evolved a monophagous relationship with its host plant *A. ludoviciana* and has adapted to its host in many ways. It is a brachypterous species with highly cryptic coloration and form while on its host. From the evidence presented here, it appears that only the male of this species has evolved significant changes in the peripheral olfactory system that result in increased

[b] Values (200 ng) within a column followed by the same letters are not significantly different ($P < 0.05$) by Duncan's multiple-range test. Data are means from 10 male and 8 female antennae of *H. alba*, and 6 male and 5 female antennae of *M. sanguinipes*.
[c] X represents statistical difference ($P < 0.05$) by Duncan's multiple-range test.

sensitivity to the plant odor. However, it is possible that differences in individual receptors may exist which would not be apparent in EAG measurements since EAGs are a summation of the response of all receptors on the antennae. EAGs from female *H. alba* showed no differences from the responses of the nonadapted generalist *M. sanguinipes*. In addition, the generalist showed no sexual differences in its sensitivity to the plant volatiles tested. Male *H. alba*, however, showed significantly greater responses than conspecific females and both sexes of *M. sanguinipes*.

The sexual difference in EAGs is correlated with a difference in the number of certain antennal olfactory sensilla (Bland, 1982). Male *H. alba* have 50–80% more sensilla basiconica types I–III than females. Sensilla basiconica type IV, sensilla trichodea, and sensilla coeloconica are present in more equal numbers between sexes. Thus it appears that the sensilla basiconica types I–III may be involved in the reception of host-plant volatiles for this species. The sensilla basiconica have been shown to respond to host odors in other insects such as

the white pine weevil (Mustaparta, 1975) and the Colorado potato beetle (Ma and Visser, 1978).

Few EAG studies have examined sexual differences in responses to host-plant volatiles (Den Otter et al., 1978; Dickens, 1984; Guerin and Visser, 1980; Kozlowski and Visser, 1981; Visser, 1979). In the species studied, sexual differences in EAGs usually occur when the female needs to locate a host plant for oviposition. In species where the adults feed on the host, sexual differences in olfactory sensitivity are minimal. Chapman (1982) states that differences in numbers of antennal olfactory sensilla between sexes usually occur in species where the feeding habits of the sexes differ or when males are attracted to females by pheromones. He also summarizes data on numbers of olfactory receptors on other Acrididae, including *M. sanguinipes*, and shows no sexual differences except in *Truxalis nasuta*, an African species whose biology is still largely unknown. Thus, it appears that *H. alba* is relatively unique in having adults with similar feeding habits, yet having more antennal sensilla sensitive to host volatiles on the males than on the females.

One possible explanation is that females sequester the host volatiles for use as sex pheromones. This seems unlikely since the volatiles from surrounding host plants would probably mask such a pheromone. Another explanation for sexual differences in sensilla numbers may also relate to male behavior in locating females. The host plant propagates primarily by rhizomes, resulting in a patchy distribution. Eggs are laid in the soil within these patches and females need not leave a patch during their lifetimes. Males, however, may travel between patches in search of receptive females. Dispersion between host patches would also have genetic advantages by decreasing inbreeding. The increased sensitivity of males to host-plant volatiles would aid in location of other patches. This hypothesis is supported by the darker green, less camouflaged coloration of the males. The greenish-white color of the females makes excellent camouflage while on the host but would be more conspicuous for males traveling the darker vegetation between patches of sage. This type of behavior pattern has been found in the milkweed beetle *Tetraopes tetraophthalmus*. Studying the movement patterns of adult beetles, McCauley et al. (1981) found the males to be more vagile than the females. The host plant of this species also spreads by rhizomes and has a patchy distribution.

The extract from sage leaves containing a mixture of monoterpenes generally gave significantly greater responses in both grasshopper species than did the major monoterpenes tested individually. These data suggest that a mixture of volatiles making up the plant odor is more stimulatory than any of the individual components, as has been demonstrated with other species (Visser, 1986). Minor components not tested may also be highly stimulatory as was shown with the carrot fly, *Psila rosae* (Guerin et al., 1983). Borneol tended to be the most stimulatory of the individual components tested.

The response to geraniol in relation to the other volatiles showed a large difference between the generalist and specialist grasshoppers. Geraniol elicited a much stronger response in *M. sanguinipes* than did the other monoterpenes or the sage extract. Conversely, geraniol elicited a medium response in *H. alba* and was the only monoterpene that showed no sexual difference in the EAGs. Therefore, the greater olfactory sensitivity of male *H. alba* appears to be specific to its host volatiles, while the generalist grasshopper is more sensitive to geraniol, a widespread monoterpene in plants (Loomis and Croteau, 1980), as a possible host location stimulus.

Acknowledgments—The authors thank Dr. Harry Young, DSIR, Auckland, New Zealand, and Dr. Ralph Howard, U.S. Grain Marketing Research Laboratory, USDA-ARS, Manhattan, Kansas, for their assistance in obtaining the mass spectra of the head-space volatiles from *A. ludoviciana*; and Dr. Tom Mabry, University of Texas, Austin, Texas, for certain monoterpene standards. The assistance of Georgia Grodowitz in rearing and collecting grasshoppers is also appreciated. Supported in part by NSF grant DEB 7905482 and Kansas Agricultural Experiment Station Project 548. Contribution 86-415-J from the Kansas Agricultural Experiment Station.

(Received August 28, 1986; accepted November 14, 1986)

Abstract—Soybean plant volatiles, extracted as steam distillates, significantly affected the behavior and biology of the cabbage looper, *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae). Distillates from the susceptible Davis variety attracted *T. ni* larvae and female adults, whereas those from resistant PI 227687 plants repelled them. When mixed in an artificial diet, steam distillates from PI 227687 plants caused mortality of first-instar larvae. Adults emerging from pupae topically treated with 5 μg of such PI 227687 extractable showed developmental abnormalities. Larval feeding was significantly less on Davis leaves treated with PI 227687 volatiles as compared to solvent (acetone) or such Davis extractables. However, Davis volatiles on PI 227687 leaves did not increase larval feeding. HPLC analyses of steam distillates from susceptible Davis versus resistant PI 227687 indicated differences.

Key Words—Allelochemicals, cabbage looper, *Glycine max*, Lepidoptera, Noctuidae, plant resistance, plant volatiles, soybeans, steam distillates, *Trichoplusia ni*.

INTRODUCTION

Among soybean [*Glycine max* (L.) Merr.] genotypes which bear resistance to insects and to cabbage looper [*Trichoplusia ni* (Hübner)] in particular, plant

0098-0331/87/0800-1903$05.00/0 © Plenum Publishing Corporation

introduction (PI) 227687 is one of the more resistant (Luedders and Dickerson, 1977). *T. ni* thrives on numerous commercial varieties such as Davis, but feeds less, grows more slowly, and shows poorer survival on resistant PI 227687 plants (Khan et al., 1986a, b).

Chemical parameters contributing to PI 227687 resistance to insects may include plant volatiles. Such compounds contribute to rice resistance to a leafhopper, *Nephotettix virescens* (Distant) (Khan and Saxena, 1985). When steam distillates from a resistant rice cultivar were applied to a susceptible cultivar, *N. virescens* feeding behavior was disrupted. Steam distillates from resistant versus susceptible rice cultivars also had differing effects on the biology and behavior of *Nilaparvata lugens* (Stål) and *Sogatella furcifera* (Horváth) planthopper pests (Saxena and Okech, 1985; Khan and Saxena, 1986).

In the present study, plant volatiles, extracted as steam distillates from resistant PI 227687 versus susceptible Davis plants, were investigated for differential effects on behavioral and physiological responses by *T. ni*.

METHODS AND MATERIALS

Plants and Insects. Seeds of resistant soybean PI 227687 were obtained from Dr. Curtis Williams, Jacob Hartz Seed Co., Stuttgart, Arkansas. The commerical cultivar Davis was used as an insect-susceptible control. Soybean plants were grown in insect-proof, nylon-screen cages in a greenhouse at the University of Wisconsin at Madison.

Seeds were treated with Thiram (Science Products Company, Inc., Chicago, Illinois) and were germinated in moistened, sterilized vermiculite in flats. Germinated seedlings were transplanted at the first-leaf (V1) stage into 20-cm-diam. autoclaved earthen pots (two plants per pot) containing a sterilized potting mixture (field soil, sand, vermiculite, 2 : 1 : 1). To supplement the natural light, plants were kept under a 16-hr photophase using Metalarc high-intensity (1000-W), full-spectrum metal halide lighting (Duke et al., 1974). The plants were uniformly watered twice a day and were maintained at 27 ± 5°C and 60 ± 10% relative humidity.

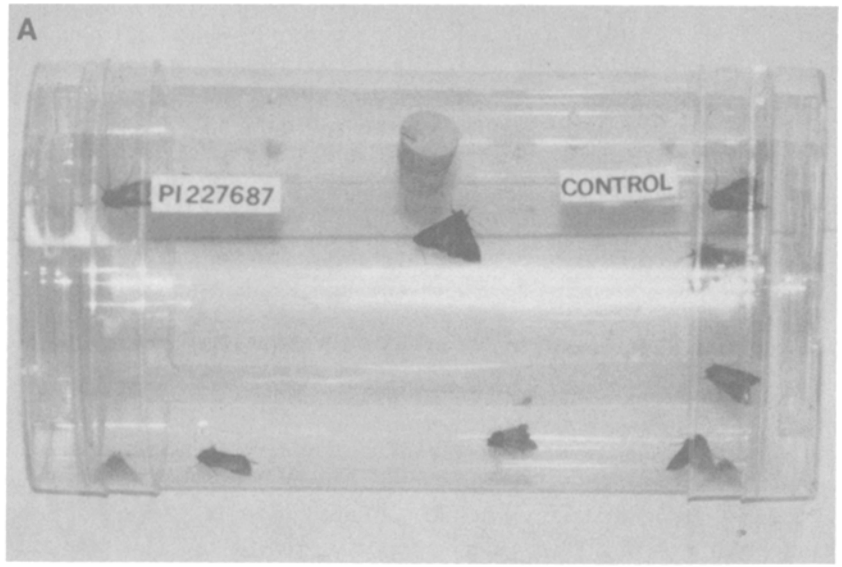
The colony of *T. ni* was maintained in the laboratory on a pinto bean-based artificial diet (Shorey and Hale, 1965) at 27 ± 2°C and 50 ± 10% relative humidity with a photoperiod of 14 : 10 hr light–dark.

Steam Distillation and Extraction of Plant Tissues. Leaves of 10-week-old soybean plants of resistant PI 227687 or susceptible Davis were harvested and ground without added solvent in an electric grinder (Waring Products Corporation, New York, New York). Each resultant 200-g sample was steam distilled for 3 hr according to Saxena and Okech (1985) and yielded approximately 900 ml of distillates. Distillates were extracted with diethyl ether (300 ml distillate–100 ml diethyl ether) by shaking the mixture in a 1000-ml separatory funnel for

5 min. Essential oils and other volatiles were absorbed by the diethyl ether. The aqueous layer was discarded. Ether extractables were pooled from several samples in a 500-ml beaker and dried with 100 g anhydrous sodium sulfate. Excess ether was removed from the resultant mixture in a fume hood to yield a final volume of approximately 25 ml. This final volume was covered with aluminum foil and held overnight to allow the sodium sulfate to absorb further traces of water from the extractables. Each sample was next reduced by evaporation to 10 ml and decanted into a preweighed glass vial. The vial was covered with perforated aluminum foil and the ether was evaporated under vacuum in a desiccator to yield a yellow oily residue. The sample vial was then reweighed, sealed under nitrogen, and kept at −30°C.

Orientation of Female Adults. Orientational responses of *T. ni* adult females to odors extracted from resistant and susceptible soybean plants were assayed in horizontal, cylindrical Mylar plastic (21-cm-long, 14-cm-diam.) chambers closed at each end with nylon net (Figure 1A) (adapted from Khan and Saxena, 1986). Treatment chemicals (4000 ppm in 0.25 ml paraffin oil) were sprayed on a 9-cm-diam. filter-paper assay disc using a spray atomizer (Sigma Chemical Company, St. Louis, Missouri). Control filter-paper discs were sprayed only with 0.25 ml paraffin oil. An extract- or solvent- (control) treated filter-paper disc was attached singly to the center of a 14-cm-diam. Petri-dish lid. Each dish lid had four 2-cm-diam. "air" holes positioned equidistantly on a circle 3 cm away from the center of the lid. A lid bearing a treated disc covered one end of each assay chamber, and one bearing a control (solvent) disc covered the opposite end. Ten 1-day-old *T. ni* females were introduced into the middle of each test chamber, and insect responses were observed for 30 min. Females thus could perceive odors, but could not contact the "source" filter-paper disc due to an intervening nylon-net wall. Percentages of arrivals of *T. ni* adult females on the nylon-net wall adjacent to the extract-treated filter paper disc were calculated as $100A/(A + B)$, where A is the number of arrivals on the wall facing the extract-treated filter-paper disc; and B is the number of arrivals on the wall facing the control filter-paper disc (Saxena et al., 1974; Obata et al., 1983).

Orientation of Larvae. Orientational responses of *T. ni* larvae to odors from resistant PI 227687 and susceptible Davis soybean plants were measured in a horizontal 15-cm-long, 3-cm-diam. cylindrical glass chamber enclosed by nylon-net ends (Figure 1B). Treatment chemicals (4000 ppm in 100 μl paraffin oil) were applied to a 2.5 cm-diam. filter-paper disc using a microsyringe. Control treatment for each assay was 100 μl paraffin oil. Each extract- or solvent- (control) treated filter-paper disc was attached singly to the center of the inside bottom of a plastic cup (4 cm high, 3.5 cm diam.) having four 0.5-cm-diam. airflow holes arranged equidistantly in a circle both on the bottom and the side. One plastic cup, with either an attached extract- or solvent- (control) treated filter-paper disc, was snug-fitted over each end of the assay chamber. Ten third-



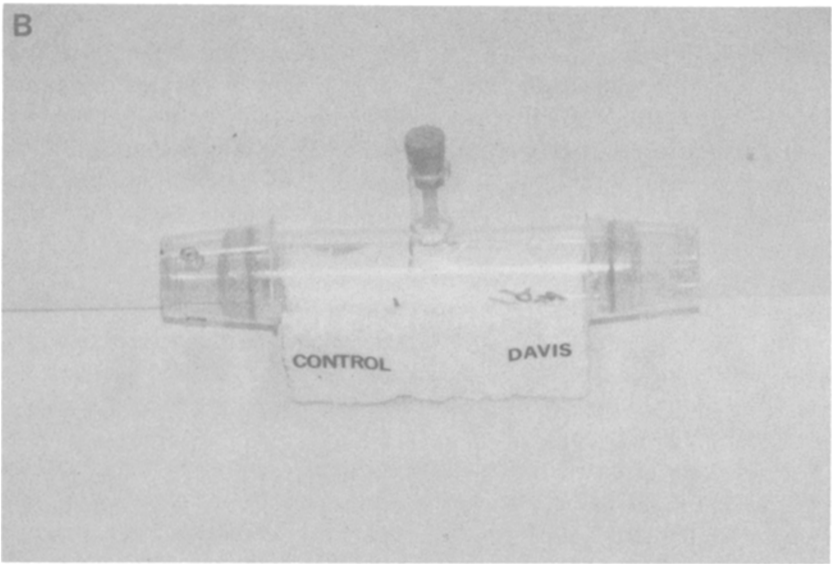


FIG. 1. Chambers for testing orientational responses of *T. ni* female adults (A) and larvae (B).

instar *T. ni* larvae were introduced at the midpoint in the assay chamber, and insect responses were observed for 2 hr. Percentages of arrivals of *T. ni* larvae on the nylon-net end adjacent to the extract-treated filter-paper disc were calculated using the same formula as with adult females.

Toxicity of Steam Distillates to First-Instar Larvae. Toxicities of steam distillates from resistant versus susceptible soybean plants were determined by incorporating diethyl ether extractables from PI 227687 or Davis tissues into a standardized artificial diet (Shorey and Hale, 1965). Twenty-five grams of the artificial diet, containing 25 μl of 1000, 2000, or 4000 ppm extractables from PI 227687 or Davis dissolved in acetone or just acetone (control) (HPLC grade, Aldrich Chemical Co., Milwaukee, Wisconsin), were placed in a plastic cup (4-cm-high, 3.5-cm-diam.). Acetone was evaporated from such diets by placing it in plastic cups under vacuum for 24 hr. Ten first-instar *T. ni* larvae were released in each cup, and it was enclosed with a perforated lid. Cups were maintained at 27 ± 2°C and 60 ± 5% relative humidity. Larval mortality was observed at 24-hr intervals for seven days.

Effects of Steam Distillates on Larval Development and Adult Emergence. Diethyl ether extractables from steam distillates from resistant PI 227687 or susceptible Davis soybean plants were diluted with acetone (HPLC grade, Aldrich Chemical Co.) to yield a 5 μg extractable/1 μl solution. Third-instar larvae and pupae of *T. ni* were individually treated topically, using a microsyringe, with 1 μl extractables on the dorsum of their first thoracic segment. Insects were similarly treated with 1 μl acetone (control solvent). Test larvae were maintained on the standardized artificial diet in a randomized complete block design at 27 ± 2°C and 65 ± 5% relative humidity until they pupated. Pupae were maintained similarly until emergence of adults.

Feeding Assays with Steam Distillates. Cabbage looper feeding was assayed with 18-mm-diam. leaf discs of susceptible Davis or resistant PI 227687 plants as the substrate. Discs were presented in a choice test in a 9-cm-diam. Petri-dish arena (Khan et al., 1986a, b). Five leaf discs from Davis or PI 227687 plants were positioned equidistantly in a circle with their abaxial side up. Four of the five discs randomly received 20 μl of 500, 1000, 2000, or 4000 ppm diethyl ether extractables from steam distillates from Davis or PI 227687 plants on their abaxial surface and were air dried for 5 min before being placed into a bioassay. The fifth leaf disc was treated only with 20 μl acetone (solvent control). Before exposing to *T. ni* larvae for feeding, the area of each leaf disc was measured in square centimeters using an automatic area meter (model LI-3100, LI-COR, Inc., Lincoln, Nebraska). Ten, 2-hr starved but water-satiated, third-instar *T. ni* larvae were placed in each five-treatment-choice assay arena. Bioassays were run for 20 hr at 27 ± 2°C and 65 ± 5% relative humidity. After termination of each experiment, the leaf area was again measured, and the area of feeding by *T. ni* larvae on each leaf disc was determined as the square centimeter difference.

High-Performance Liquid Chromatography of Soybean Plant Volatiles. Qualitative analysis of steam distillates was conducted by high-performance liquid chromatography (HPLC) using a prepacked silica column (25-cm-long, 4.6-mm-diam., packed with 5-μm-diam. silica particles) (Ultrasphere, Beckman Inc., Berkeley, California) and a variable UV spectrophotometer detector (model 100-40, Hitachi, Tokyo, Japan). The steam distillate from each variety was dissolved in hexane:2-propanol (95:5) (HPLC grade, Aldrich Chemical Co.) to a concentration of 10 mg/ml or 10,000 ppm. Twenty microliters of the solution were then injected per HPLC analysis. Operating conditions were: temperature, ambient; mobile phase, hexane:2-propanol at 96:4 for 1 min and then 95:5 for 9 min; flow rate, 1 ml/min; column pressure, 420 psi. The resolved peaks were not identified but were numbered according to order of elution. Steam distillates from each variety were analyzed at least five times.

Diethyl ether extractables from the steam distillates from resistant PI 227687 or susceptible Davis plants were collected as three HPLC fractions (peaks 1–5, fraction 1; peaks 6–12, fraction 2; peak 13, fraction 3). Each fraction was concentrated by evaporating the solvent under nitrogen, weighed, and diluted with paraffin oil to a concentration of 4000 ppm. Such fractions were tested individually, and in all combinations, for attractancy or repellency against *T. ni* adult females, as described above.

Statistical Analysis of Data. All experiments were replicated 5–10 times in a randomized complete-block design, and data were analyzed using the statistical procedures indicated in the footnotes of each table.

RESULTS

Orientation of T. ni *Adults and Larvae.* Diethyl ether extractables from the steam distillates from the susceptible Davis soybean cultivar attracted significantly more ($P < 0.01$, t test) *T. ni* female adults and third-instar larvae as compared to solvent (paraffin oil) control, whereas such odors from resistant PI 227687 plants repelled these insects (Table 1).

Toxicity of Steam Distillates to First-Instar Larvae. Steam distillates from PI 227687 plants, when incorporated in an artificial diet, were more toxic [$P < 0.05$, Duncan's multiple-range test (DMRT)] to first-instar larvae than such extractables from susceptible Davis plants (Table 2, Figure 2A). Larval mortality on Davis extractables-treated artificial diet was low, but significantly ($P < 0.05$, DMRT) more than that on solvent-treated (control) diet. Percentage of *T. ni* larval mortality on PI 227687 extractables-treated diet increased through 72-hr exposure.

Effects of Steam Distillates on Larval Development and Adult Emergence. All third-instar larvae that received a topical application of 5 μg extractables from PI 227687 or Davis plants completed their life cycle. However, adults

Insect stage	Odor source[b]	Arrivals (%) on nylon-net wall facing filter-paper discs		Difference (A − B)
		Distillates-treated (A)	Paraffin oil-treated (B)	
Adult	PI 227687	26 ± 9.7	74 ± 9.7	−48**[c]
	Davis	70 ± 11.5	30 ± 11.5	40**
Larva	PI 227687	25 ± 8.5	75 ± 8.5	−50**
	Davis	73 ± 11.6	27 ± 11.6	46**

[a] Data are averages of 10 replications; in each replication 10 female adults or third-instar larvae were used.
[b] Odor source for female adults was a 9-cm-diam. filter-paper disc treated with 0.25 ml of 4000 ppm distillates; and for third-instar larvae, was a 2.5-cm-diam. filter-paper disc treated with 100 μl of 4000 ppm distillates.
[c] Differences between means followed by double asterisks are significantly different at $P = 0.01$ level (t test).

TABLE 2. MORTALITY OF FIRST-INSTAR *T. ni* LARVAE IN ARTIFICIAL DIET SUPPLEMENTED WITH DIFFERENT CONCENTRATIONS OF STEAM DISTILLATES FROM RESISTANT PI 227687 OR SUSCEPTIBLE DAVIS PLANTS[a]

Plant	Distillate conc. (μg/25 g diet)	Mortality (%) hours after release (HAR)[b]		
		24 HAR	48 HAR	72 HAR
PI 227687	100	64 ± 12.6 A	98 ± 4.2 A	100 ± 00 A
	50	25 ± 6.2 B	37 ± 10.1 B	59 ± 11.5 B
	25	13 ± 2.7 C	31 ± 9.9 B	35 ± 9.3 C
Davis	100	13 ± 3.6 C	14 ± 2.9 C	14 ± 2.9 D
	50	16 ± 2.3 C	16 ± 2.3 C	16 ± 2.3 D
	25	14 ± 2.7 C	14 ± 2.7 C	14 ± 2.7 D
Solvent (control)	0	00 ± 00 D	00 ± 00 D	00 ± 00 E

[a] Data are averages of 10 replications; in each replication 10 newly emerged first-instar larvae were used.
[b] Observations were recorded for seven days after release, but there was no increase in mortality after 72 hr.
[c] In a column, means followed by a common letter are not significantly different by Duncan's multiple range test at $P = 0.05$ level.

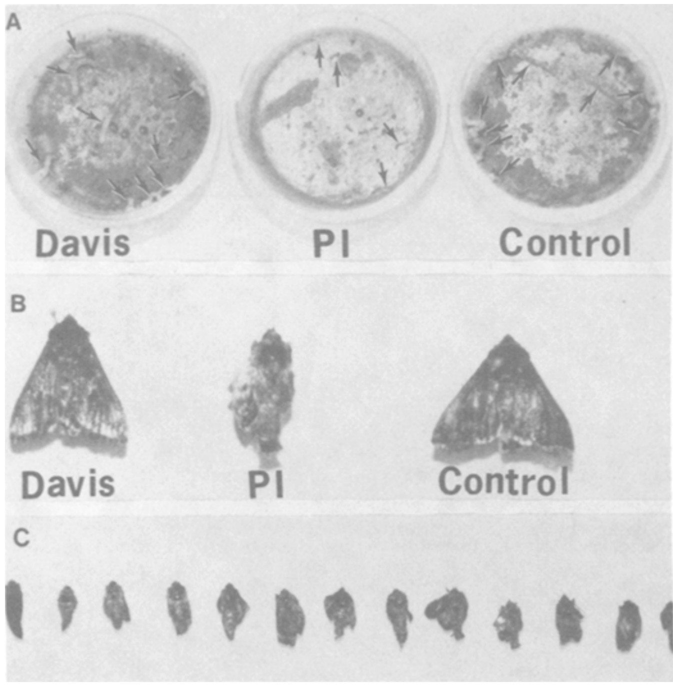

FIG. 2. (A) Surviving (see arrows) *T. ni* larvae on an artificial diet treated with 100 μg steam distillates from susceptible Davis or resistant PI 227687 plants, as compared to control. (B) Adult with deformed wings that emerged from pupa that received 5 μg steam distillates from PI 227687 plants, whereas those that emerged from pupae that received such distillates from Davis plants or acetone (control) were normal. (C) Various forms of wing deformaties in adults that emerged from pupae that received 5 μg of steam distillates from PI 227687 plants.

emerging from pupae that received 5 μg extractables from PI 227687 showed varying degrees of wing deformaties. Such wings were reduced in size and crumpled (Figure 2B,C). Application of 5 μg susceptible Davis extractables did not cause such abnormalities.

Feeding Assays with Steam Distillates. Application of 20 μl of 500, 1000, 2000, or 4000 ppm diethyl ether extractables from the steam distillates from PI 227687 plants to Davis leaf discs significantly reduced ($P < 0.05$, DMRT) feeding by third-instar larvae as compared to that on discs treated with acetone (solvent control) or Davis extractables (Table 3, Figure 3A,C). Such applications of Davis extractables on resistant PI 227687 leaf discs did not increase, or decrease, insect feeding as compared to that on controls (Figure 3B).

TABLE 3. COMPARATIVE FEEDING OF THIRD-INSTAR *T. ni* LARVAE ON LEAF DISCS FROM SUSCEPTIBLE DAVIS OR RESISTANT PI 227687 PLANTS, TREATED WITH DIFFERENT CONCENTRATIONS OF STEAM DISTILLATES FROM PI 227687 OR DAVIS SOYBEAN LEAVES IN CHOICE TEST[a]

	Feeding area (cm^2)[c]		
Extract conc. (ppm)[b]	Davis leaf disc treated with PI 227687 distillates	Davis leaf disc treated with Davis distillates	PI 227687 leaf disc treated with Davis distillates
500	1.52 ± 0.28 B	1.90 ± 0.15 A	0.28 ± 0.06 A
1000	1.16 ± 0.21 C	1.99 ± 0.16 A	0.30 ± 0.09 A
2000	0.44 ± 0.08 D	1.95 ± 0.10 A	0.27 ± 0.07 A
4000	0.22 ± 0.04 D	1.86 ± 0.04 A	0.24 ± 0.04 A
0[d]	2.22 ± 0.13 A	1.93 ± 0.12 A	0.33 ± 0.05 A

[a] Data are averages of five replications.
[b] All concentrations were prepared in acetone.
[c] In a column, means followed by a common letter are not significantly different by Duncan's multiple range test at the $P = 0.05$ level.
[d] Control was the solvent, acetone.

High-Performance Liquid Chromatography. Thirteen HPLC peaks were resolved in the diethyl ether extractables from the steam distillates of both PI 227687 and Davis plants (Figure 4). Three especially prominent peaks in both samples had similar retention times (*RT*), peak 2 ($RT = 3.4$ min), peak 4 ($RT = 4$ min), and peak 13 ($RT = 8$ min). Other peaks also showed similar retention times in both samples, e.g., peaks 1, 3, 5, 6, 7. Peaks 1, 3, and 13 were especially more prominent in PI 227687 than in Davis plants.

Bioassay results with the individual HPLC fractions 1, 2, and 3 from PI 227687 or Davis steam distillates showed that repellent activity was absent in the single fractions (Table 4). All paired combinations of the three Davis fractions (1 + 2, 1 + 3, and 2 + 3) significantly ($P < 0.01$, *t* test) attracted *T. ni* adult females. With PI 227687 steam distillates, one paired combination (1 + 3) of the three HPLC fractions was repellent to *T. ni* adult females.

DISCUSSION

Insects possess many intimate and subtle relationships with plants (Khan and Saxena, 1986). Their distinction between nonhost and host species may be based on several parameters (Norris and Kogan, 1980; Chiang and Norris, 1985). However, minor changes in physical or chemical characteristics among individuals within a host-plant species can cause significant differences in their

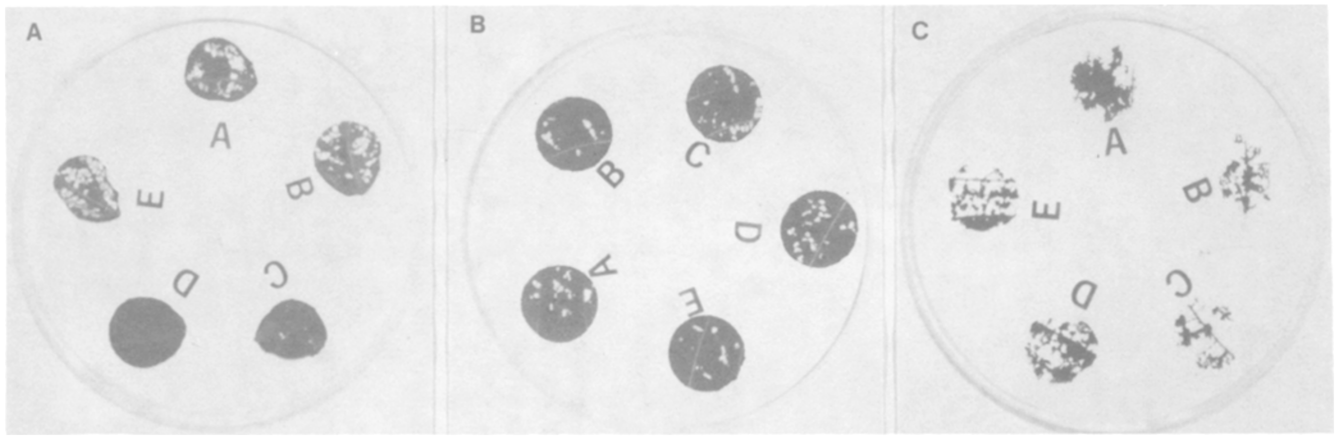

FIG. 3. *T. ni* larval feeding on (A) Davis leaf discs treated with PI 227687 distillates, (B) PI 227687 leaf discs treated with Davis distillates, and (C) Davis leaf discs treated with Davis distillates. Leaf discs were treated with 20 μl of 500 ppm (a), 1000 ppm (b), 2000 ppm (c), or 4000 ppm (d) distillates from PI 227687 or Davis plants, or acetone as control (e).

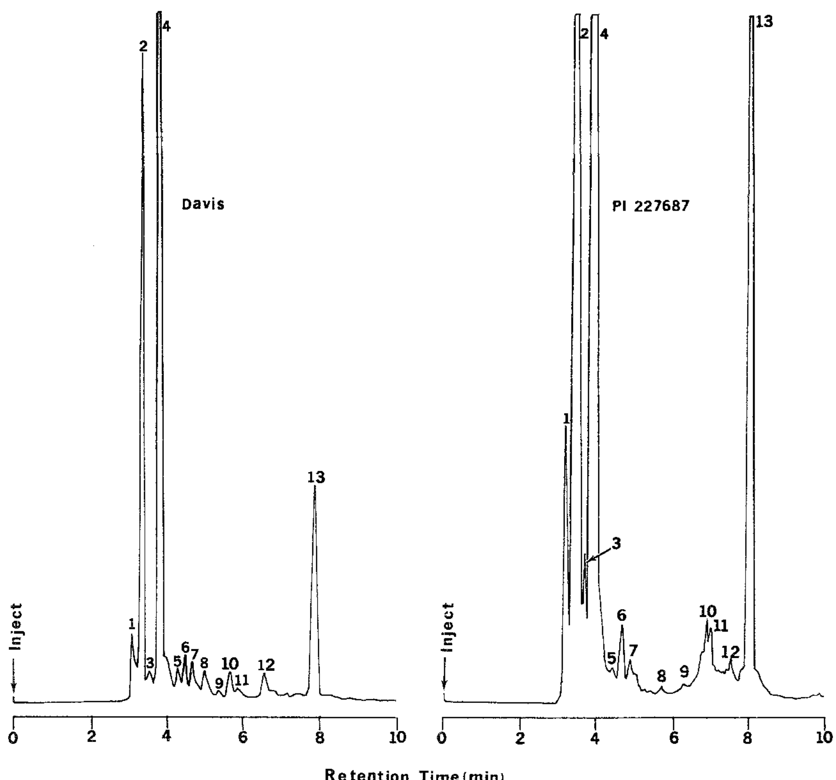

FIG. 4. High-performance liquid chromatograms of steam distillates from susceptible Davis and resistant PI 227687 plants.

relative acceptabilities to an insect species or biotype. Our results in this paper demonstrate specifically how limited chemical differences in soybean plants can alter their relative acceptabilities to *T. ni*.

Recently, we demonstrated significant roles for leaf trichomes (Khan et al., 1986b) and ethyl acetate- and hexane-extractable compounds (Khan et al., 1986a) in making the soybean line, PI 227687, less acceptable than the Davis cultivar for *T. ni* larval feeding. But the primary decisions regarding host plants are usually made by adult female *T. ni* moths in conjunction with selecting ovipositional sites. Because these moths initially approach potential host plants while flying, volatile repellent chemicals emanating from PI 227687 plants might serve a more primary role than leaf trichomes or relatively nonvolatile anti-feedant molecules in the insect's primary rejection of such soybeans as hosts. Diethyl ether extractables from steam distillates from PI 227687 did cause such a repulsion of moths in our currently reported studies. More than one volatile compound is involved in this PI 227687 repellency of *T. ni* adults because a

positive (repulsive) response was only obtained when two (i.e., fractions 1 and 3) HPLC fractions were combined in the assay.

Our results with Davis plants indicate that *T. ni* moth decisions between two or more soybean cultivars regarding an ovipositional site may involve attractants in addition to repellents. Whereas, the combination of volatile fractions 1 and 3 from PI 227687 repelled the moths, all paired combinations of the three HPLC fractions of comparable volatiles from Davis attracted the moths. In summary, plant volatiles apparently are the first chemical cues which *T. ni* adults contact in making decisions about host preferences among soybean cultivars, and repellent compounds apparently are the dominant volatile chemical messengers in such insect decisions, but attractants may be involved with relatively acceptable soybeans.

The diverse other allelochemical activities of the ether extractables from PI 227687 steam distillates included (1) reduced *T. ni* larval feeding when applied to the surface of otherwise-preferred Davis leaves; (2) mortality of first-instar larvae when added to a standard artificial diet; and (3) abnormal wings in adult *T. ni* emerging from pupae treated topically. Similar morphogenetic effects were reported on the rice stem borer, *Chilo suppressalis* (Walker), for steam distillates from a resistant rice variety (Saxena, 1978).

The range of allelochemical effects revealed now for certain volatiles from soybeans on the various stages of *T. ni* indicates some of the multiple-component chemical defense of this plant species against even an insect that has already adapted to use it as a host.

TRANSFER OF PYRROLIZIDINE AND QUINOLIZIDINE ALKALOIDS TO *Castilleja* (SCROPHULARIACEAE) HEMIPARASITES FROM COMPOSITE AND LEGUME HOST PLANTS

FRANK R. STERMITZ and GUY H. HARRIS

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

(Received September 24, 1986; accepted November 14, 1986)

Abstract—*Castilleja* (Scrophulariaceae) species of the western United States contain pyrrolizidine and quinolizidine alkaloids. The *Castilleja* obtain the alkaloids by root parasitism on host plants, with *Senecio atratus* and *S. triangularis* (Asteraceae) furnishing the pyrrolizidines, and quinolizidines being obtained from *Lupinus* species and *Thermopsis montana* (Leguminosae). Individual plants within a given *Castilleja* species population may be devoid of alkaloids while others have high alkaloid content. No populations have been found which are made up of both pyrrolizidine- and quinolizidine-containing individuals. These results have important implications for *Castilleja* ecology, for the study of insect herbivores which are *Castilleja* specialists, and in the development of systems for the investigation of the role of alkaloids as plant defenses.

Key Words—*Castilleja*, Scrophulariaceae, *Senecio*, Asteraceae, *Lupinus*, Leguminosae, hemiparasites, alkaloids, plant–insect interactions.

INTRODUCTION

Castilleja (Scrophulariaceae; subfamily Rhinanthoideae) is a large, complex plant genus of about 200 species concentrated in western North America and is difficult from an evolutionary and taxonomic viewpoint (Heckard, 1968). Species and population variations have been ascribed (Heckard and Chuang, 1977) to a high degree of polyploidism and a lack of cross-breeding barriers among

[1] Paper 10 in the series "Chemistry of the Scrophulariaceae." Paper 9: D.R. Gardner, J. Narum, D. Zook, and F.R. Stermitz. *J. Nat. Prod.* **50:** In press.

SCHEME 1.

some species. *Castilleja*, like some members of its subfamily, are hemiparasites, are hosted by a wide range of angiosperms (Heckard, 1962), and in turn are hosts to a number of specialist insects, including checkerspot butterflies [*Euphydryas* and *Chlosyne* (*Thessalia*)] (Ehrlich and Murphy, 1981; Singer, 1983) and plume moths (*Amblyptilia and Platyptilia*) (Lange, 1950).

To elucidate the roles of secondary plant metabolites in the biochemical systematics and plant-insect interactions of *Castilleja*, we undertook plant alkaloid analyses and reported (Roby and Stermitz, 1984a) isolation of unsaturated pyrrolizidine alkaloid senecionine (**1**) from *Castilleja rhexifolia*, ammondendrine and quinolizidine alkaloids from *C. miniata* (McCoy and Stermitz, 1983) and the saturated pyrrolizidines sarracine (**2**) and 7- and 9-angelylplatynecines (**3**, **4**) from an unnamed taxon (Roby and Stermitz, 1984a) variously described as *C. rhexifolia* aff. *miniata* or *C. miniata* aff. *rhexifolia* (Heckard and Chuang, 1977) (Scheme 1). More recently (Stermitz et al., 1986), we found populations of the latter two taxa with the quinolizidine *N*-methylcytisine (**5**) as a major alkaloid and, importantly, found populations of *C. sulphurea* which had no alkaloids, only saturated pyrrolizidines, only unsaturated pyrrolizidines, or only quinolizidines. Although we have not yet studied all species and populations where alkaloids were encountered, the results reported here establish alkaloid uptake from a host plant as the cause of the variable *Castilleja* alkaloid content. Most of the *Castilleja* taxa also contain pyridine monoterpene alkaloids, but these iridoid-derived alkaloids are inherent to the *Castilleja*.

METHODS AND MATERIALS

Plant collections are listed in Table 1 and exact locations given on the voucher specimens. D. Wilken (Colorado State University), L. Heckard (University of California, Berkeley), and D. Dunn (University of Missouri) assisted with species determinations.

Alkaloid isolation and other general procedures were as previously given (Roby and Stermitz, 1984a; McCoy and Stermitz, 1983; Stermitz et al., 1986). Briefly, above-ground plant material was wetted with dilute $NaHCO_3$ solution, extracted with 1 : 1 butanol–toluene, and this solution extracted with 1 M H_2SO_4. The acidic solution was made basic to pH 9 and extracted with $CHCl_3$. The $CHCl_3$ layers were evaporated to yield a purified total alkaloid mixture which could be analyzed by TLC, [^{1}H]NMR, and/or NH_3 CI-MS (McCoy et al., 1983). Individual alkaloids were then separated and purified by chromatogra-

phy. Identifications were by TLC, high-field (270- or 360-MHz) [^{1}H]NMR, and mass spectra in comparison with compounds we had previously reported, with obtained standards, or with literature values.

RESULTS

Key preliminary results came from qualitative alkaloid analysis of plants within alkaloid-containing populations. Individual plants were encountered that did not contain alkaloids and were hosted by plant species that also contained no alkaloids. In a given population, individual *Castilleja* plants that contained alkaloids had the same qualitative spectrum of alkaloids as did a host plant. Finally, entire alkaloid-free populations of each *Castilleja* taxon were found.

For example, thin-layer chromatography (Figure 1) showed that *C. linariifolia*, hosted in eastern Gunnison County, near Taylor Reservoir by sage-

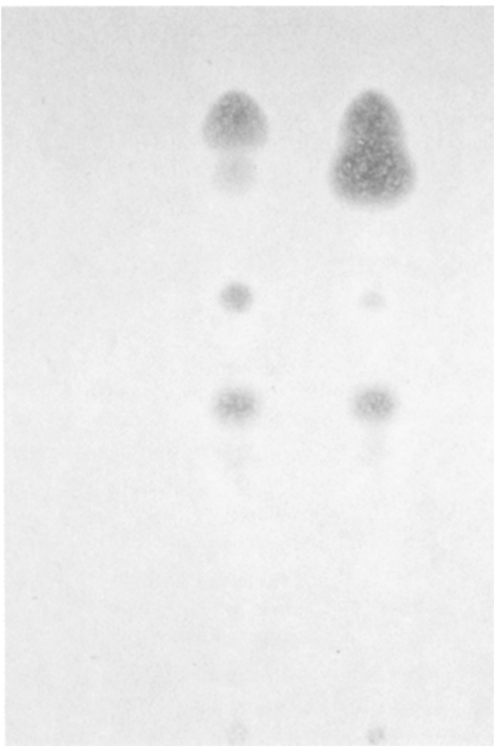

FIG. 1. TLC of total alkaloid isolate from: (A) *Castilleja linariifolia* on *Artemisia* and (B) *C. linariifolia* on *Lupinus bakeri* subsp. *amplus*; (C) *L. bakeri* subsp. *amplus*. (silica gel; 7:3 cyclohexane–diethylamine; iodoplatinate visualization).

brush (*Artemisia* sp.), was devoid of alkaloids, while *C. linariifolia* hosted by *Lupinus bakeri* subsp. *amplus* and the *Lupinus* host plant itself contained the same five quinolizidine alkaloids, although in different concentration ratios. Similarly, a central Colorado *C. miniata* population (Michigan Hill) growing with *Thermopsis montana* contained exactly the same five quinolizidine alkaloids (*N*-methylcytisine major) as did the host plant. These two parasite–host pairs have only been qualitatively studied so far, but represent clear-cut cases of a complex spectrum of alkaloids being identical in the host and parasite. Several parasite-host pairs were studied in more detail as described in the following.

C. rhexifolia *aff.* miniata *and* C. sulphurea *on* Senecio. Throughout Colorado, the *C. rhexifolia* aff. *miniata* taxon occurs mainly in the 2900 to 3200-m altitude region. Its host plant has been found to be *Senecio atratus*, which is considered (Pesman, 1959) to be an indicator of the same subalpine region. Both taxa are most often found in disturbed areas such as sandy roadbanks. Sarracine, 7- and 9-angelylplatynecines and their *N*-oxides were previously reported (Roby and Stermitz, 1984a) from the *Castilleja*. From one population (Cameron Pass), *S. atratus* (a previously uninvestigated species) was analyzed and found to contain the same sarracine and angelylpatynecine derivatives. Although sarracine has been reported from other *Senecio* species, the angelylplatynecines are only known from *C. rhexifolia* aff. *miniata*, and they are now shown to also be in *S. atratus*.

Individual *Castilleja* plants were found which did not contain alkaloids. For example, several were growing in association with *Antennaria anaphaloides* (Asteraceae), and neither these *Castilleja* nor the host plant contained alkaloids. Hemiparasites in the Rhinanthoideae of the Scrophulariaceae, such as *Castilleja*, produce specialized root structures, haustoria, which form the connection between parasite and host plant (Kuijt, 1969; Riopel and Musselman, 1979; Heckard, 1962). We found haustoria on the *Castilleja* root connections to *S. atratus*. Other *C. rhexifolia* aff. *miniata* populations on *S. atratus* were found at Winfield and Monarch Pass, with qualitative alkaloid TLC analyses confirming the parasite–host relationship.

C. sulphurea is also hosted by *S. atratus* (Winfield and Emerald Lake populations) as indicated by comparative alkaloid TLC analyses. In the latter population, the *C. sulphurea* is growing intermixed with *C. miniata*. The *C. miniata* from this location contained only quinolizidine alkaloids (α-isolupanine, 5,6-dehydro-α-isolupanine, and thermopsine) and no pyrrolizidines, but *C. sulphurea* did not contain quinolizidines. A lupine species (unflowered and unidentified) also grows within these populations and is likely to be the source of the quinolizidines in *C. miniata*.

C. sulphurea *on* Lupinus argenteus *subsp.* rubricaulis. Alkaloid isolation from a *C. sulphurea* population in eastern Jackson County near Gould yielded several quinolizidine alkaloids of which the major one ($C_{15}H_{22}N_2O_3$ by high-

resolution mass spectrometry) is new. Its structure will be described elsewhere. The alkaloid content was very low in the total *Castilleja* population sample, but high or completely absent in individual plants. The alkaloid-containing plants were in close association with *L. argenteus* and haustorial attachments could be identified. The alkaloid content of the *Lupinus* was essentially identical with that of the *C. sulphurea* which it hosted.

C. rhexifolia *and* C. sulphurea *on* S. triangularis. *C. rhexifolia* generally occurs at higher altitudes (3200–3500 m) than *C. miniata* or *C. rhexifolia* aff. *miniata*, although its range occasionally overlaps with these. It can be found with *C. sulphurea* and close to *C. occidentalis* at the upper altitude range. Four populations of *C. rhexifolia* (Cameron Pass, Kite Lake, Cumberland Pass, Schofield Pass) were found to be dominated in alkaloid content by senecionine and its *N*-oxide. No populations contained quinolizidine alkaloids or sarracine, and one population (Monarch Pass Campground) contained no alkaloids. Some populations close to Cameron Pass contain virtually no alkaloids as well. Absolute identification of a host plant has been difficult since the *Castilleja* roots in the swampy habitat are entwined with those of many other plants in a heavy, wet root ball. Nevertheless, the common denominator of all populations appears to be *S. triangularis*, with which the *Castilleja* is growing in close proximity wherever it contains alkaloids. Analysis of *S. triangularis* indeed showed it to have a high level of senecionine, as was previously reported (Roitman, 1983) from a California collection.[2] At Cameron Pass, *C. sulphurea* populations also occur and individual plants are occasionally found in close proximity to *C. rhexifolia*. We previously (Stermitz, et al., 1986) reported high levels of senecionine in these *C. sulphurea*. Close examination of the populations has now shown that these, too, are growing with *S. triangularis*. Table 2 summarizes the *Castillegia*-hostplant-alkaloid relationships found.

TABLE 2. *Castilleja* TAXA, HOST PLANTS, AND ALKALOIDS TRANSFERRED

Castilleja sp	Host plant(s)	Alkaloid(s)
rhexifolia	*Senecio triagularis*	senecionine, **1**
rhexifolia aff. *miniata*	*S. atratus*	sarracine **2**, platynecines **3** and **4**
linariifolia	*Lupinus bakeri*	quinolizidines
miniata	*Thermopsis montana*	N-methylcytisine **5** (and other quinolizidines)
sulphurea	*S. triagularis*	senecionine, **1**
sulphurea	*S. atratus*	sarracine **2**, platynecine **3**, **4**
sulphurea	*Lupinus argenteus*	quniolizidines

[2]Rueger and Benn (1983) failed to find senecionine in a Canadian collection.

DISCUSSION

There is now little doubt that the high variability in alkaloid content previously observed among *Castilleja* taxa has its genesis in variability of host plant use by this hemiparasitic genus. Although alkaloid transfer from host plant into obligate, chlorophyll-lacking parasites such as *Orobanche*, *Cuscuta*, and species in the mistletoe (Loranthaceae) family have been demonstrated (Wink et al., 1981; references in Atsatt, 1977; Kuijt, 1969), this appears to be the first unequivocal demonstration of such transfer into a hemiparasite. Some reviews quote the finding (Ubaev, et al., 1963) of two alkaloids typical of *Plantago* in *Pedicularis* as evidence for such a transfer. However, these were pyridine monoterpene alkaloids common to many Scrophulariaceae, and there was no evidence for transfer. The same workers, however, reported the presence of *N*-methylcytisine in *P. olgae*. This alkaloid is typical of *Lupinus* and does suggest that alkaloid transfer from *Lupinus* to *Pedicularis* has occurred.

The implications of these results for our studies on *Castilleja* ecology are far reaching and can only be adumbrated here until such time as detailed testing of new hypotheses can be accomplished. Several specific observations can, however, be made.

The particularly high alkaloid variability of *C. sulphurea* as compared to the other *Castilleja* taxa (Stermitz et al., 1986) is now explicable since *C. sulphurea* is far less restricted in habitat than the other taxa and can be found where it has exploited each of the three plant hosts containing either unsaturated pyrrolizidines (senecionine-type), saturated pyrrolizidines (sarracine-type), or quinolizidines. Are the *c. rhexifolia* and *C. rhexifolia* aff. *miniata* more restricted in habitat because their preferred alkaloid-containing hosts are also restricted to those habitats? This seems less likely since populations and individuals that are hosted by plant species which do not contain alkaloids seem to be sustainable.

The question of specificity in host-plant choice is a particularly difficult one to answer at this time. In a short and clearly incomplete listing of *Castilleja* host plants, 10 separate genera from six families were noted (Heckard, 1962). There seems to be no reason why the list could not approach that of *Pedicularis*, also of the Scrophulariaceae, where 80 species from 35 families were identified as hosts for *P. canadensis* (Piehl, 1963). It has been suggested (Kuijt, 1969) that all hemiparasites are nonspecific. Yet some specificity must occur since we found no cases where populations of a single taxon contain both pyrrolizidine- and quinolizidine alkaloids. In several habitats there is clear opportunity for populations to choose among several different alkaloid-containing host-plant species yet only one appears to be utilized. Particularly striking were the results near Emerald Lake where *C. sulphurea* and *C. miniata* grow intermixed. The former contains only sarracine and platynecines, while the latter contains only quinolizidines. The presumed host plants, *S. atratus* and a *Lupinus* species are

part of the same habitat as are *Delphinium* and other alkaloid-containing genera of the Ranunculaceae and Boraginaceae whose particular types of alkaloid structures have not as yet been encountered in *Castilleja*. Whether or not this specificity can be due to recognition of an individual alkaloid, perhaps as an inducer of haustoria formation (Steffens et al., 1982), is yet to be determined.

A seminal paper (Atsatt, 1977) proposed parallelisms in ecological and evolutionary patterns between herbivorous insects on the one hand and parasitic seed plants on the other. Many of the concepts and terminologies of herbivory theory were suggested to be applicable to the parasitic seed plant system and a number of suggestions were made for specific exploitation of these ideas. Of particular importance was a discussion of "secondary utilization of host defensive compounds," focusing on the possible chemical differences among *Orthocarpus* and *Plantago* hosts for the checkerspot butterfly *Euphydryas editha*, depending upon the inclination for *Orthocarpus* to be parasitic on *Plantago*. Clearly, if alkaloids are important as plant defensive substances (Wink, 1985), their presence or absence in individual plants of a given *Castilleja* population which is hosting an insect herbivore should profoundly affect individual plant choice and utilization. We are currently investigating this hypothesis in the cases of *Euphydryas*, *Chlosyne* (*Thessalia*), and *Amblyptilia* hosted by *Castilleja*. In addition to an exploration of the effect of alkaloid presence on insect utilization in natural populations, one can also now design field experiments for the study of alkaloids *per se* as defensive substances. Identification of alkaloid-containing and alkaloid-free individual plants in an otherwise uniform species population would allow for relatively natural control and test samples for comparative growth and survival studies.

(Received September 3, 1986; accepted November 14, 1986)

Abstract—A general method for synthesis of insect pheromones having alkyl branched carbon skeletons is demonstrated with the preparation of a diastereomeric mixture of 8-methyl-2-decanol, whose propionate is an attractant of some *Diabrotica* species. The procedure involves reaction of a ketone with lithium acetylide ethylenediamine complex to afford a propargylic alcohol containing the branch of the target molecule. Copper (1) mediated alkylation of the derived propargylic acetate with a primary alkyl halide yields a trisubstituted allene having the desired chain length, and isomerization with an alkali metal amide of either ethylenediamine or 1,3-diaminopropane, affords the alkyl branched terminal acetylene. The triple bond is converted to the methyl ketone and reduced to the methyl carbinol. The reactions proceed in good yield, and can be conveniently carried out on large scale. The method should prove useful for production of pheromone components in cases where diastereomeric mixtures can be employed.

Key Words—Alkyl branched, pheromone, triple bond, alkyne, allene, isomerization, 8-methyl-2-decanol, 8-methyl-1-decyne.

INTRODUCTION

The sex pheromone of the western corn rootworm, *Diabrotica virgifera virgifera* LeConte has been identified as the propionate of 8-methyl-2-decanol, and the synthetic racemic mixture is reported to attract western corn rootworms at all concentrations tested (Guss et al., 1982). Males of the Mexican corn rootworm, *D. virgifera zeae* Krysan and Smith, and *D. porracea* Harold are also attracted by the racemic mixture (Guss et al., 1984). Males of the northern corn

[1] Issued as NRCC No. 27519.

0098-0331/87/0800-1927$05.00/0 © Plenum Publishing Corporation

rootworm, *D. barberi* Smith and Lawrence, are attracted to the racemic mixture in low doses, but at higher doses the 2*S*,8*R* and 2*S*,8*S* isomers inhibit attraction (Guss et al., 1985). Syntheses of both the racemic mixture (Guss et al., 1982) and the four stereoisomers of 8-methyl-2-decanol have recently been published (Sonnet and Heath, 1982; Sonnet et al., 1985; Mori and Watanabe, 1984).

Many other insect pheromones have been found to have alkyl branched carbon skeletons (Rossi, 1978). In some cases the racemic mixtures have been found to be biologically active. Among these is the pheromone of the southern corn rootworm, *Diabrotica undecimpunctata howardi* Barber, which has been identified as 10-methyl-2-tridecanone; the *R* enantiomer has been found to be active while the *S* enantiomer is inactive and not inhibitory (Guss et al., 1983). The sex pheromone of the peach leafminer moth, *Lyonetia clerkella* Linne, 14-methyl-1-octadecene has been shown to have the *S* configuration; the *R* enantiomer was found to be inactive (Manabe et al., 1985). The terminal alcohol, aldehyde, and ester of 14-methyl-8-hexadecenyl skeleton, with both *cis* and *trans* double bonds have all been identified as pheromones (Rossi, 1978). Synthesis and testing of the optically active forms of (Z)-14-methylhexadec-8-enal, the pheromone of the female dermestid beetle, *Trogoderma inclusum* LeConte revealed that the (*R*)-(−)-enantiomer was the active compound, and the *S* isomer was biologically inactive (Mori et al., 1978).

We have developed a general synthesis of this class of alkyl branched insect pheromones based upon an extension of our modifications (Abrams and Shaw, 1986; Abrams, 1982) to known acetylene isomerization chemistry (Brown and Yamashita, 1975). The method is illustrated with the preparation of 8-methyl-2-decanol, an intermediate in the synthesis of the western corn rootworm pheromone. The advantages of the present synthesis over those in the literature are that the procedure is brief and the starting materials are readily available. The yields are good, and the process should be amenable to production of large quantities of pheromone.

METHODS AND MATERIALS

The reactions that required dry conditions were performed in oven-dried (110°C for more than 2 hr) glassware, under a positive pressure of argon. 1,3-Diaminopropane was distilled from barium oxide and stored over activated 4A sieves.

[^{1}H]NMR spectra were recorded on a Bruker AM-360-WB (360 MHz) spectrometer, employing $CDCl_3$ as solvent with $CHCl_3$ as reference. IR spectra were obtained with a Perkin Elmer 237B instrument. Gas chromatographic separations were carried out with a Varian 3700 instrument equipped with a DB-5 capillary column (J and W Scientific, 30 m) and a flame ionization detector. GC-MS spectra were obtained by using a DB-5 column (60 m) in a Finnigan

4000 E instrument in the electron impact mode with an Incos 2300 data system. Mass spectra are reported in mass to charge units (m/z) with the relative intensities as percentages of the base peak given in parentheses.

3-Methyl-3,4-decadiene. To a suspension of CuI (10.47 g, 55.0 mmol) in (1964), to 3-methyl-1-pentyn-3-ol (Aldrich, 98 g, 1.00 mmol) was added a solution of H_3PO_4 (1.5 g) in acetic anhydride (122.5 g, 1.20 mol) at such a rate that the internal temperature did not exceed 60°C. The reaction mixture was allowed to stand overnight at ambient temperature and then was poured into ice water and extracted with ether (3×). The combined ethereal extracts were washed with saturated Na_2CO_3 solution until the aqueous phase was basic, and then further washed with water (1×) and NaCl solution (1×), then dried over Na_2SO_4, filtered, and distilled to afford 3-acetoxy-3-methyl-1-pentyne (126 g, 90%) which had bp 46–49°C at 11 mm Hg, and which gave N_D^{25} 1.4232 [lit. N_D^{25} 1.4212, Julia et al., (1964)].

3-Methyl-3,4-decadiene. To a suspension of CuI (10.47 g, 55.0 mmol) in diethyl ether (anhydrous, 100 ml) at −78°C, was added a solution of pentyl magnesium bromide in ether [prepared from bromopentane (18.12 g, 120 mmol), magnesium turnings (2.92 g, 120 mmol), and ether (90 mL)] at such a rate that the internal temperature was maintained at approximately −45°C. After stirring for 10 min, a solution of 3-acetoxy-3-methyl-1-pentyne (7.5 g, 50 mmol) in ether (50 ml) was added dropwise with the internal temperature again maintained at −45°C. After continued cooling for 1 hr, the temperature of the mixture was allowed to rise to ambient, was stirred for a further 2 hr, and then was poured into saturated NH_4Cl solution. The organic phase was separated and washed with H_2O (3×) and then with saturated NaCl solution (1×), and dried briefly over Na_2SO_4. Distillation afforded 3-methyl-3,4-decadiene (bp 62–68°C at 10 mm Hg, 5.0 g, 33 mmol, 66%) contaminated with decane (2.4 g, estimated by [^{1}H]NMR).

From another run the allene was obtained in pure form by careful distillation (bp 100°C at 90 mm Hg) and gave [^{1}H]NMR ($CDCl_3$, 360 MHz, rel. to TMS) δ: 5.02 (m, 10 lines, C=C=CH, 1H), 1.9 (m, $H_2CC{=}C{=}C$, 4H), 1.66 (d, J = 2.8 Hz, $H_3CC{=}C{=}C$, 3H), 1.2–1.4 (m, CH_2, 6H), 0.97 (t, J = 7.4 Hz, $\underline{H_3}CCH_2C{=}C{=}C$, 3H), and 0.88 (t, J = 7 Hz, $\underline{H_3}CCH_2CH_2$, 3H); IR (film) ν_{max} 1960 cm^{-1} (w); MS (CI) 153 (13, $M^+ + 1$), 151 (42), 96 (51), 95 (53), and 83 (100); MS (EI) 152 (M^+, absent), 96 (57), and 81 (100).

8-Methyl-2-decanol. To the isomerization reagent (prepared from lithium (420 mg, 60 mmol), 1,3-diaminopropane (20 ml, dry, previously distilled from BaO and stored over 4A sieves) and potassium *t*-butoxide (4.95 g, 45 mmol), according to Abrams and Shaw (1986), at room temperature was added a solution of 3-methyl-3,4-decadiene (1.3 g, 8.6 mmol) in 1,3-diaminopropane (5 ml). The mixture was stirred for 1.5 hr, then poured into ice water and extracted with pentane (4× 50 ml). The pooled pentane extracts were washed succes-

sively with water, 10% HCl solution, and saturated NaCl solution, then dried over Na_2SO_4, and filtered; the solvent was evaporated at atmospheric pressure.

To the residue was added water (0.9 ml, 50 mmol), ethanol (10 ml), and mercuric-ion-impregnated ion-exchange resin (500 mg; Olah and Meidar, 1978). The mixture was stirred for 6.5 hr, then was filtered through a fine sintered glass funnel, and the catalyst was washed with ethanol (50 ml). $NaBH_4$ (1.14 g, 30 mmol) was added to the filtrate, and the mixture was stirred for 0.75 hr, then diluted with water, and extracted with hexane (3×). The combined organic extracts were dried over Na_2SO_4, and the solvent was removed at reduced pressure. The product was purified by silica gel chromatography eluting first with hexane to remove nonpolar impurities, and then with 50% ether–50% hexane to obtain the chromatographically pure product 8-methyl-2-decanol [570 mg, 3.3 mmol, 38% from the allene which gave NMR and IR data identical with those reported by Mori and Watanabe (1984)].

RESULTS AND DISCUSSION

The principle upon which the synthesis was based is outlined in Figure 1. The alkyl branch is constructed first by the well-known reaction of a ketone with lithium acetylide ethylenediamine complex (for example, Schmidt, 1976) affording the propargylic alcohol. The carbon skeleton is completed by alkylation of the derived propargylic acetate with a Grignard or organolithium reagent of a straight chain primary halide in the presence of cuprous salts. This reaction is known to proceed cleanly and in good yield to give trisubstituted allenes (Rona and Crabbe, 1969).

FIG. 1. General synthesis of alkyl branched pheromone components.

The key step of the synthesis is the isomerization of the allene to the triple bond at the terminus of the chain. The rearrangement of triple bonds of hydrocarbons (Brown and Yamashita, 1975) and alkynols (Abrams and Shaw, 1986) mediated by the very strongly basic isomerization reagents, alkali metal amides of ethylenediamine or 1,3-diaminopropane, has been employed to prepare terminal alkynes in high yields. Disubstituted allenes have been observed as intermediates in such rearrangements (Abrams and Shaw, 1985). Allenes, particularly trisubstituted ones, have not before been used as starting materials.

The terminal acetylene thus produced is a versatile intermediate that can be transformed as desired using well-established chemical procedures. Thus, either carbon can be oxygenated or the triple bond alkylated affording the disubstituted alkyne, or *cis* or *trans* olefin.

Based upon this scheme, the synthesis of 8-methyl-2-decanol has been undertaken (Figure 2), employing as the starting material commercially available 3-methyl-1-pentyn-3-ol, the product of reaction of butanone and lithium acetylide ethylenediamine complex. The acetate of 3-methyl-1-pentyn-3-ol was constructed according to the method of Julia et al. (1964) in 90% yield. The desired carbon skeleton was prepared by alkylation of the acetate with pentyl magnesium bromide and cuprous iodide in either to afford the allene, 3-methyl-3,4-decadiene. In our hands the Grignard reagent gave slightly higher yields than the corresponding alkyllithium reagent. A by-product of the reaction, decane, due to coupling of the Grignard reagent with itself, codistilled with the allene, but did not interfere with subsequent steps and was removed at the end of the sequence. The yield of the allene after distillation was determined to be 66% by [^{1}H]NMR.

Remote functionalization of the hydrocarbon chain and manipulation of the triple bond to the secondary alcohol was carried out in a three-step sequence

FIG. 2. Synthesis of 8-methyl-2-decanol.

that required no purification of intermediates. The allene, on being subjected to the strongly basic reagent, the mixed lithium–potassium salt of 1,3-diaminopropane, gave the terminal alkyne, 8-methyl-1-decyne, contaminated with decane and approximately 10% of by-products that appeared by NMR to be mainly isomeric conjugated dienes. These by-products were not investigated further as they did not interfere with the subsequent steps and could be removed in the final chromatography.

The isomerization reaction has also been carried out with ethylenediamine, and the same distribution of products was observed. In general, the yields in such rearrangement reactions have been observed to be slightly higher with 1,3-diaminopropane, but the lower cost of ethylenediamine may make it more attractive in some applications.

The crude isomerization product was conveniently hydrated to the methyl ketone in ethanol employing an ion-exchange resin to which mercuric ion was bound (Olah and Meidar, 1978). Other standard hydration techniques were also effective (Abrams, 1981). Filtration of the catalyst and reduction of the product with sodium borohydride gave the alcohol. The 8-methyl-2-decanol was purified by chromatography to separate the hydrocarbon by-products from the more polar alcohol. The yield of pure 8-methyl-2-decanol obtained from 3-methyl-3,4-decadiene was 39%.

The short sequence demonstrates the general method for building up alkyl branched hydrocarbons using triple-bond isomerization chemistry. The procedure is limited to the synthesis of racemic mixtures. Other work in our laboratory (Abrams and Shaw, submitted for publication) has shown that stereochemistry at the alkyl branch is lost on subjection of allenes and alkynes to the isomerization conditions.

It is hoped that the procedure described here will find use in syntheses of other alkyl branched insect sex pheromones.

(Received August 11, 1986; accepted November 17, 1986)

Abstract—Antialgal, antibacterial, and allelopathic properties of the submersed, aquatic, dicotyledonous water shield, *Brasenia schreberi* Gmelin (Cabombaceae), were examined. Extracts of *B. schreberi* were found to inhibit the eukaryotic alga, *Chlorella pyrenoidosa*, and the prokaryotic alga, *Anabena flosaqua*, as well as nine different bacteria. Lettuce seedling bioassay showed *B. schreberi* to be allelopathic. These phytotoxic properties probably contribute to the observed dominance of *B. schreberi* in aquatic environments and also make it a promising candidate for allelopathic plant management of aquatic weeds.

Key Words—Phytotoxicity, allelopathy, *Brasenia schreberi*, Cabombaceae, water shield, antibiosis, bacteria, algae.

INTRODUCTION

Brasenia schreberi Gmelin (Cabombaceae), common name water shield, is a submersed, aquatic dicotyledonous plant widely, sporadically distributed in North and Central America, West Indies, East Asia, and Australia. Although the plant was first described in 1789, studies of this unique species have been largely restricted to anatomy, morphology, and systematics. Submersed organs of *B. schreberi* are remarkable in that they are covered by a thick, clear mucilagenous substance. This mucilage originates from secreting glands which project into the air spaces of organs (Schrenk, 1888). Interest in this mucilage has led to its characterization as a polysaccharide with an extremely complicated structure (Misaki and Smith, 1962; Kakuta and Misaki, 1979a,b).

Brasenia schreberi is not an exotic or imported plant species, yet its pop-

0098-0331/87/0900-1935$05.00/0 © 1987 Plenum Publishing Corporation

ulations appear to be the sole occupants within any area in which they occur in large numbers. Occasionally very dense populations impair boat travel (Burkhalter, 1978). Once *B. schreberi* is established in an area, growth of other plants may well be inhibited by shading effects of its densely packed floating leaves. Observations of sequences of events over a three-year period within dense populations of fragrant white waterlilies (*Nymphaea odorata* Ait.) indicate that once a single water shield propagule is established within the area, the species rapidly becomes dominant, leading to the exclusion of other species. The small size of the *B. schreberi* leaves relative to the waterlilies suggests that shading is not the principle competitive factor involved in water shield's rapid dominance. Both species are perennials, exhibit partial leaf retention throughout the winter, and resume spring growth at about the same time. Other factors must be involved; this paper examines some possible factors for the observed dominance of *B. schreberi*.

METHODS AND MATERIALS

Plant Collection and Processing. Brasenia schreberi was collected during the late spring and throughout the summer from a population along US 98, a highway five miles west of Hattiesburg, Mississippi, in Lake Serene. The plants were washed free of debris, dried at 55°C, coarsely ground in a commercial meat grinder, and stored at room temperature in plastic bags until used.

Extraction Solvents. Reagent grade solvents were glass distilled in our laboratory prior to use.

Extraction and Fractionation. A 20-g portion of the dried plant material was extracted with 400 ml of methanol for 24 h in a Soxhlet apparatus. The extract was concentrated under reduced pressure, and the concentrate was subjected to antialgal and antibacterial bioassay. The concentrate was fractionated according to the following scheme, and each fraction (A–E) was subjected to the same antialgal and antibacterial bioassays as the unfractionated concentrate. The concentrate was extracted with 5% aqueous HCl. The acid-insoluble portion was taken up in chloroform and filtered to give a chloroform-insoluble fraction (C) and a chloroform-soluble fraction which was concentrated and partitioned between 90% CH_3OH and hexane to give, after concentration, fractions A and B, respectively. The acid-soluble fraction was neutralized to pH 7 with sodium hydroxide, and the now neutral fraction was extracted with three portions of ethyl ether. The combined ether extracts were concentrated and labeled fraction D. The neutral fraction remaining was made strongly basic with sodium hydroxide and reextracted with ether. This ether extract was concentrated and labeled fraction E.

A second portion of dried plant material was successively extracted for four days each with petroleum ether, ethyl ether, acetone, and methanol in a

Soxhlet apparatus with about 1000 ml solvent per 250 g dried plant material used. After concentration, the petroleum ether, ethyl ether, and acetone extracts were subjected to lettuce seedling bioassay.

Antialgal Bioassay. Axenic cultures of *Anabena flosaqua* UTEX 1444 and *Chlorella pyrenoidosa* UTEX 26 were obtained from Dr. Richard Star, University of Texas algae collection, kept in culture in Bold's modification of Bristol's medium (Bold, 1949), and subcultured onto slants of this same medium solidified with agar. For assays, 9-cm Petri dishes containing Bold's basic agar were inoculated either with 0.1–0.2 ml of settled cells removed from the liquid culture after turning off the aerator or with a portion of an inoculum prepared by vortex mixing of that number of algal cells which could be removed from the agar slants with a sterile loop with a 0.3-ml to 1.0-ml portion of sterile water. The sample being tested was dissolved in an appropriate solvent, and a small sterile filter paper disk was saturated in the solution. The solvent was allowed to evaporate, and the sample paper disk was placed on the algal inoculated test plate. Control dishes included plain paper disks and disks which had been saturated in the solvent(s) used to dissolve samples and allowed to evaporate for an equivalent period of time. The test was read when a control plate (no sample or control disks) first showed good growth. Tests were scored as $-$ (no inhibition) and $+$, $++$, or $+++$ for degrees of inhibition. Since neither the algal concentration nor the sample concentration is known, the results are qualitative.

Antibacterial Bioassay. Antibacterial activity was determined by a modified procedure of the Bauer-Kirby single disk method (Bauer et al, 1966). Standard bacterial cultures of *Staphylococcus aureus*, *Bacillus subtilis*, *Escherichia coli*, *Salmonella gallinarium*, *Klebsiella pneumoniae*, and *Mycobacterium smegmatis* were obtained from the University of Southern Mississippi Biological Sciences Department. Three bacterial strains were cultured from water taken from Lake Serene where the *B. schreberi* was collected but from an area where it was not growing. One of these latter three was subsequently identified as *Chromobacterium violacens*, a gram-negative bacterium. The other two remain unidentified. The bacteria were kept in culture on nutrient agar slants. For assays, a sterile loop was used to remove cells which were mixed with 10 ml of water; 9-cm Petri dishes containing nutrient agar were inoculated with 0.1 ml of this mixture. Sample-saturated paper disks were prepared in the same manner as for antialgal bioassay; the plates were scored in a similar manner.

Lettuce Seedling Growth Bioassay. Radical growth inhibition assay of lettuce (black-seeded Simpson) was carried out as previously reported (Elakovich and Stevens, 1985).

Data Analyses. The results of the lettuce seedling growth bioassay were analyzed separately using a Honeywell DPS-8 mainframe computer and a Statistical Package for the Social Sciences, version 9 (Hull and Nie, 1981). Statis-

tical analyses included one-way analysis of variance and the Duncan multiple-range test for differences among all treatment means.

RESULTS

Antialgal Bioassays. The methanol extract of dried, ground *B. schreberi* inhibited the growth of the eukaryotic alga, *Chlorella pyrenoidosa*, and, to a lesser extent, also inhibited the prokaryotic alga, *Anabena flosaqua* (Table 1). All fractions (A–E) obtained from *B. schreberi* also inhibited *C. pyrenoidosa*. Only fractions C and D inhibited the growth of *A. flosaqua*; C was the more active fraction.

Antibacterial Bioassays. The methanol whole-plant extract as well as all fractions (A–E) were tested against a standard culture of *Salmonella gallinarium* and against the three bacteria cultured from the lake where *B. schreberi* was collected. All fractions were inhibitory except for fraction C, which was inactive toward *S. gallinarium* and whose activity toward the unknown gram-negative bacterium was in question (Table 2). Fractions A–E were also tested against five additional bacterial strains, *Bacillus subtilis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Mycobacterium smegmatis*, and *Staphylococcus aureus*. Activity was least toward *K. pneumoniae* and greatest toward *S. aureus* and *M. smegmatis*. Both gram-negative and gram-positive bacteria were inhibited, but no pattern of inhibition related to Gram stain characteristic could be detected.

Lettuce Seedling Growth Bioassay. The three Soxhlet extracts tested, Skelly F, ethyl ether, and acetone, all caused reduction in lettuce seedling root growth (Table 3). The Skelly F extract was only slightly water soluble and oiled out of the aqueous agar solution in concentrations higher than 375 ppm. At this concentration, it reduced lettuce radical growth by 24% as compared to the control, a result which was not significantly different from the 28% reduction shown by

the 100-ppm sample level. This would suggest that 25% is close to the maximum inhibition level achievable by the Skelly F extract. At 100 ppm, the ethyl ether extract reduced radical growth by 14%, but this reduction was not significantly different from the control. At 500 ppm, this extract reduced radical growth by 65%. The acetone extract was the most active, reducing radical growth by 39% at 100 ppm and by a dramatic 78% at 500 ppm. Neither the

ethyl ether nor the acetone extract were tested at concentrations greater than 500 ppm. It is possible both extracts would have demonstrated even greater radical growth inhibition at higher concentrations.

DISCUSSION

Integrated approaches to aquatic plant management are increasingly considering use of allelopathic plant species. A search of the literature shows that most aquatic plants thus far reported to have allelopathic potential are *not* deep water plants. Thus *B. schreberi* with its antibacterial activity, its antialgal activity, and its ability to inhibit lettuce seedling radical growth is a promising candidate for allelopathic plant management of aquatic weeds. The ability of *B. schreberi* to inhibit the three bacterial strains cultured from lake water where the plant was collected, but not growing, suggest that its antibacterial activity may contribute to its rapid dominance. Growth inhibition of the six additional standard bacterial strains suggests the antibacterial activity of *B. schreberi* is broad-based rather than focused. This is underscored by the fact that both gram-negative and gram-positive bacteria and both eukaryotic and prokaryotic algae were inhibited. The fact that inhibitory activity is displayed by the different fractions A–E and by the Skelly F, ether, and acetone Soxhlet extracts suggests that *B. schreberi* produces a series of allelochemicals. Studies are curently underway to determine the chemical nature of the allelochemicals of *B. schreberi*.

VARIATIONS IN MOUSE (*Mus musculus*) URINARY VOLATILES DURING DIFFERENT PERIODS OF PREGNANCY AND LACTATION

BOZENA JEMIOLO, FRANCA ANDREOLINI, DONALD WIESLER, and MILOS NOVOTNY

Department of Chemistry
Indiana University
Bloomington, Indiana 47405

(Received August 15, 1986; accepted November 17, 1986)

Abstract—Mouse urine samples from different pregnancy and lactation periods were examined by capillary gas chromatography to assess variations in the volatile signals that may affect the endocrine function of other females. Statistically significant changes in the excretion of certain urinary volatiles were observed; from 26 readily quantifiable constituents, 14 appear to be under the endocrine control. These selected components, positively identified through mass spectrometry and retention data, and the synthetic standards are ketones, unsaturated alcohols, esters, and cyclic vinyl ethers.

Key Words—Female mouse urine, pregnancy, lactation, urinary volatiles, mouse, *Mus musculus*.

INTRODUCTION

In the house mouse (*Mus musculus*), there are at least three female urinary chemosignals that can affect the reproduction status of other females: (1) the delay of puberty occasioned by treatment with urine from grouped females (Drickamer, 1974, 1977, 1983a); (2) the acceleration of puberty by the urine from estrus females (Drickamer 1982a); and, (3) the acceleration of puberty (Drickamer and Hoover, 1979) and prolongation of the estrous period (Hoover and Drickamer, 1979) through exposure to the urine from pregnant and lactating females. It has been suggested (Drickamer, 1982b) that some chemical substances in the urine of females may act as the general signals to other conspecifics regarding the adequacy of social and environmental conditions which are important for successful reproduction.

0098-0331/87/0900-1941$05.00/0 © 1987 Plenum Publishing Corporation

Urine samples collected at different time periods during pregnancy and lactation are differentially effective in terms of the acceleration of the first estrus relative to control females treated with water (Drickamer, 1983b, 1984). The chemosignals from pregnant/lactating females seem to be present in the urine only during the last two thirds of pregnancy or lactation (Drickamer, 1983b). In addition, Cowley and Wise (1972) reported that the urine from pseudopregnant females applied to the nasal region of neonatal females has an accelerating effect of their growth, while the application of urine from females in late pregnancy is associated with a slow rate of growth. It is not yet known what set of hormonal and related physiological conditions within the female mice may reflect these changes in the chemical signals released by donor females.

Since no chemical investigations on these signals have been conducted to date, their nature remains a subject of speculation. Earlier study by Drickamer and Hoover (1979) has shown that the urine from pregnant or lactating females, either applied daily on the external nares of the young animals or provided to them in a plastic (inaccessible) capsule, can accelerate their sexual maturation. In addition, the urine from pregnant or lactating females that is exposed to the ambient air remains effective for only one to three days (Drickamer, 1986). These findings suggest that the pregnancy/lactation chemosignal(s) is either an air-sensitive or a volatile substance.

The chemosignals from pregnancy urine and that of lactating animals may or may not contain similar substances. Both chemical characterization and biological experiments are needed to elucidate this problem.

Our previous successful uses of a headspace sampling technique (Novotny et al., 1974) and capillary gas chromatography–mass spectrometry to identify the male chemosignals responsible for aggression (Novotny et al., 1985), estrus synchronization (Jemiolo et al., 1986a), and the female signals causing the delay of puberty (Novotny et al., 1986) have prompted us to apply similar techniques to the identification of additional female chemosignals in this study. As the initial approach to this complex problem, the urinary profiles of volatile substances were quantitatively followed throughout the pregnancy and lactation periods. Statistically significant alterations in quantities of certain volatile components are reported here and correlated with the animals' endocrine status. The structures of these components were verified through their mass spectra and chromatographic behavior of authentic substances.

METHODS AND MATERIALS

All mice used as urine donors were from a randomly bred, closed colony of ICR/Alb (*Mus musculus*) purchased from Ward's Natural Science Establishment, Inc., Rochester, New York. Females were housed in plastic cages (12 × 28 × 27 cm), maintained at 21°C ± 0.2°C, 50–70% humidity, and a 12-

hr light–12-hr dark daily regime. Unlimited amounts of Purina Mouse Chow (Ralston Purina Corp., St. Louis, Missouri) and water were supplied throughout the whole experimental period. Bedding was changed weekly.

For use as urine donors, 120 virgin and 120 multiparous females, in total, were bred with fertile males. The occurrence of pregnancy was established by a daily examination for vaginal plugs (day 0). After insemination, each female was caged alone over the whole period of pregnancy. The urine from pregnant females was collected from days 2 to 7 (period 1), 8 to 12 (period 2), 13 to 15 (period 3), and from day 16 postplug to the last day before parturition (period 4). An additional 120 multiparous pregnant female mice were isolated into individual cages and checked daily for newborns. On the day of delivery, the litters were counted and reduced to 10 pups. Collection of urine from lactating females was done at the same periods as during pregnancy: days 2–7 (period 1), 8–12 (period 2), 13–15 (period 3), and from day 16 postpartum until the young were 21 days old.

All females used as urine donors were 80–130 days of age. Fresh urine was collected by holding a mouse over a glass vial and gently squeezing the abdomen and flanks. Immediately after collection, samples were stored at −20°C and analyzed within two to four days. All types of urine were analyzed three to six times by using each time a 1-ml sample obtained from different collections within the same experimental period. For each sample, the urine was collected and pooled from 8 to 10 pregnant or lactating females. As a standard sample, we used urine collected from virgin, nonreproducing females at 90–120 days of age, that were housed singly. Collection of the urine was carried out throughout all stages of the estrous cycle.

The urinary volatiles were analyzed using the headspace technique, employing Tenax GC (a porous polymer) as the adsorption medium (Novotny et al., 1974). The volatiles were sparged from 1-ml urinary samples at room temperature with purified helium gas at a flow rate of 100 ml/min and adsorbed onto a precolumn packed with 4 mg of Tenax GC. The sample was subsequently desorbed in the heated injection port (220–240°C) of a gas chromatograph (Perkin-Elmer, 3920 instrument, Norwalk, Connecticut) equipped with a flame ionization detector, and retrapped into a cooled section of a glass capillary column. The analytical column was a glass capillary (60 m × 0.25 mm, ID) of a soda-lime type, coated statically with UCON 50-HB-2000 (Schwende et al., 1984a,b).

While quantitative comparisons were obtained through peak integration routines (Sigma 10, Perkin-Elmer), identification of the individual profile constituents was established through a combined GC-MS (Hewlett-Packard, 5981 dodecapole mass spectrometer, Palo Alto, California) using electron impact ionization at 70 eV. Wherever feasible, authentic samples were either purchased or synthesized in the laboratory to verify agreement of spectral information and gas-chromatographic retention time.

Statistical Calculations. Statistical comparisons of the levels of excreted volatiles were made using one-way analysis of the variance (ANOVA) with Duncan's new multiple-range test (Zar, 1974). The probability level for statistical significance was set at $P < 0.05$.

RESULTS AND DISCUSSIONS

The complexity of mouse urinary volatile profiles has been demonstrated in our previous studies (Novotny et al., 1980, 1984, 1986; Schwende et al., 1984a,b, 1986; Jemiolo et al., 1986a,b); genetic background, sex, endocrine status, etc., all seem to influence the quantitative proportions of various urinary constituents. The capillary chromatogram shown in Figure 1 is representative of a profile obtained from pregnant female ICR/Alb mice. From a large number of components, 26 substances are numbered; most have been positively identified by combined capillary gas chromatography–mass spectrometry and the retention measurements of authentic compounds (Table 1).

Through careful visual inspection of the profiles obtained from different stages of pregnancy and lactation, as well as from nonreproducing females, we first established that 14 constituents showed obvious variations in their chro-

[a] Presumed isomeric cyclic vinyl ethers unique to the mouse (Schwende et al., 1986); dehydration products of known 5,5-dimethyl-2-ethyltetrahydrofuran-2-ol.
[b] Concentration of the compound dependent on a period of pregnancy or lactation.
[c] Concentration of the compound does not seem dependent on a period of pregnancy or lactation.

matographic peak areas (Table 1, see peaks numbered in bold type). The remaining substances listed in this table demonstrated relatively constant concentrations throughout all periods of pregnancy and lactation. The additional peaks in the chromatogram (Figure 1) have not been quantified for two reasons: (1) their small peak areas would not permit reliable measurements; and (2) for the early eluting constituents (substances with high volatility), peak areas are greatly affected by the sampiing procedure.

TABLE 2. MEAN VALUE (±SEM) OF PEAK AREAS (ARBITRARY UNITS) FOR VOLATILE COMPOUNDS FOUND IN URINE OF PREGNANT PRIMIPAROUS (A), MULTIPAROUS (B); AND LACTATING (C) FEMALES DURING DIFFERENT PERIODS OF PREGNANCY AND LACTATION[a]

[a] N = 3–6 runs for each average peak area value; 1 ml of urine collected from 8–10 females was used in one run. Those means not connected by the same vertical lines are significantly different at the 0.05 level. Those means in rows not marked by the same superscript letter (a, b, c) are significantly different at the 0.05 level. If there are no superscript letters in a row, there are no significant differences among the means.

The 14 components exhibiting some dependence on the animals' endocrine status can be readily classified into one of four structurally distinct categories: ketones, esters, alcohols, and dihydrofurans (cyclic vinyl ethers). The components selected for a careful quantitative evaluation in the urine of pregnant primiparous (A), pregnant multiparous (B), and lactating (C) females are listed in Table 2. A majority of the investigated urinary components tended to be more concentrated in pregnant primiparous than in either pregnant multiparous or lactating females. This trend was observed for all distinct periods; however, only in a few cases (Table 2) are the differences between the pregnant primiparous and pregnant multiparous animals statistically significant. On the other hand, statistical significance ($P < 0.05$) is obvious when comparing the levels of ketones, esters, alcohols, and dihydrofurans of lactating females with the pregnant animals. Substantial decreases were generally observed.

The levels of the 14 investigated compounds changed clearly during the different periods of pregnancy and lactation. Most of these appeared at a higher average level during the first period of pregnancy or lactation than in the second. Some of the ketones and esters that decreased in concentration at the second period of pregnancy have shown a tendency toward elevation in their levels during the consecutive periods (Table 2). In the urine of lactating females, most ketones and all esters also decreased initially during the second period, but maintained the same levels throughout the rest of the experiment. The concentrations of alcohols in female urine have a tendency to increase during the last periods of pregnancy. Yet, the same substances drop after the first period of lactation and remain at low levels until parturition.

In order to provide "reference levels" of the investigated urinary volatile constituents, samples from singly caged, nonreproducing females were analyzed under identical experimental conditions (Table 3). The average levels of the 14 volatile compounds found in the urine of pregnant and lactating females were then tabulated and compared to the same 14 peaks from urine of the nonreproducing females (control data). The percentage of the difference in the peak area of ketones, esters, alcohols, and dihydrofurans is shown in Figures 2–7. On the basis of our earlier work (Novotny et al., 1986), we have learned that the urine of group-caged females contains a similar set of volatile compounds, but the concentrations of such compounds were clearly different as compared to singly caged, nonreproducing animals. The data reflecting these percentage differences have been placed at the right side of each figure (Figures 2–7) to provide an additional point of comparison. Seven ketones (peaks 6, 8, 10, 15, 16, 20, and 21 of Figure 1) varied in concentration in the urine of pregnant primiparous females (Figure 2). 2-Hexanone (6), 4-heptanone (8), and 2-heptanone (10) exhibited concentrations that were significantly ($P < 0.05$) higher, as compared to those in nonreproducing animals, throughout all distinct periods.

TABLE 3. MEAN VALUE (±SEM) OF PEAK AREAS (ARBITRARY UNITS) FOR SELECTED VOLATILE COMPOUNDS FOUND IN URINE OF SINGLY CAGED, NONREPRODUCING FEMALES[a]

Peak designation	Structure	Average levels
1	mol wt 126	43.2 ± 2.7
6	2-hexanone	2.5 ± 0.4
7	mol wt 126	12.7 ± 0.8
8	4-heptanone	1.3 ± 0.1
10	2-heptanone	52.1 ± 4.3
11	*n*-pentyl acetate	4.1 ± 0.6
14	*cis*-2-penten-1-yl acetate	4.9 ± 0.5
15	*trans*-5-hepten-2-one	4.8 ± 0.3
16	*trans*-4-hepten-2-one	18.3 ± 1.2
17	4-penten-1-ol	1.5 ± 0.3
18	mol wt 142 ester	3.0 ± 0.2
20	6-methyl-6-hepten-3-one	12.3 ± 0.7
21	6-methyl-5-hepten-3-one	7.5 ± 0.5
26	1-octen-3-ol	1.4 ± 0.7

[a] N = 13–17 runs for each peak area value; 1 ml of urine collected from 10–20 females was used in one run.

The remaining ketones, *trans*-5-hepten-2-one (15), *trans*-4-hepten-2-one (16), 6-methyl-6-hepten-3-one (20), and 6-methyl-5-hepten-3-one (21) exhibited either an increase or decrease in concentration compared to nonreproducing females, but the range of changes was not significant.

In the urine of group-caged females, the concentrations of 2-hexanone (6) and 4-heptanone (8) were similar to those appearing in nonreproducing animals. However, this type of urine contained additional ketones, such as 2-heptanone (10), *trans*-5-hepten-2-one (15), and *trans*-4-hepten-2-one (16) in higher concentration than did the urine from nonreproducing females (Figure 2).

The increases observed for ketones in the urine of pregnant multiparous animals were less than in pregnant primiparous females. However, a trend toward more elevated levels of 2-hexanone (6), 4-heptanone (8), and 2-heptanone (10) as compared to the control group of females was still noticeable (Figure 3). Two compounds, 6-methyl-6-hepten-3-one (20) and 6-methyl-5-hepten-3-one (21), have become significantly suppressed in the pregnant multiparous animals as compared to nonreproducing females (Figure 3).

For all the ketones, the most dramatic changes were seen in the urine of the lactating females (Figure 4). There was a clear suppression of these compounds, from 45–95%, compared to nonreproducing females. That suppression

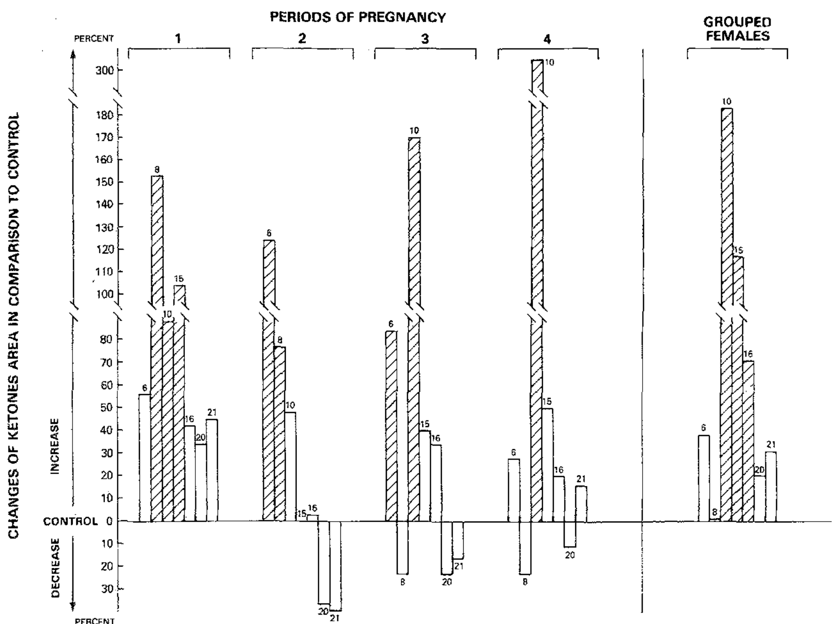

FIG. 2. Percentage difference in the peak areas of urinary ketones between pregnant primiparous and nonreproducing (control) females of ICR/Alb strain. Diagonally striped bars represent significant increases of ketones in pregnant and grouped females as compared to controls.

was observed throughout all lactation periods. Two exceptions were noted: for 2-heptanone during the first period, and for 4-heptanone during the second period. The latter substance attained a level never noted before with any urine sample.

The levels of esters are dealt with in Figure 5; *n*-pentyl acetate (11), 2-penten-1-yl acetate (14), and an unidentified ester (18) showed both increases and decreases in urines of pregnant, lactating, and group-caged females as compared with the control. Here, the concentration of esters is variable and dependent on a type of urine and period of collection. Grouped and pregnant females produced these compounds in very high concentrations only during the first and last periods of pregnancy. In the mid-pregnancy intervals, these esters were found at a low level (similar to the control group). The urine collected at the first period of lactation (up to seven days) contained 80% more 2-pentyl acetate (11) than did the urine from nonreproducing females. During the next three periods, the concentration of esters in the urine of females dropped significantly (Figure 5).

The same type of comparison used for ketones and esters was also em-

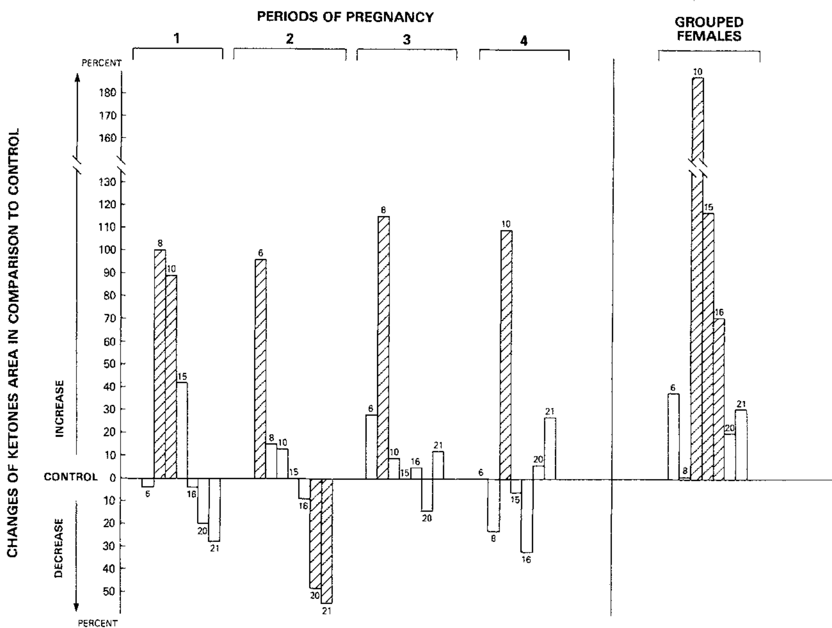

FIG. 3. Percentage difference in the peak areas of urinary ketones between pregnant multiparous and nonreproducing (control) females of ICR/Alb strain. Diagonally striped bars represent significant increases and decreases of ketones in pregnant and grouped females as compared to controls.

ployed for alcohols and dihydrofurans (see Figures 6 and 7). Extremely high levels of alcohols were found in the urine of pregnant females, both primiparous and multiparous (Figure 6). In both types of urine, an elevation of 4-penten-1-ol (17) and 1-octen-3-ol (26) appeared during the last period of pregnancy rather than at the beginning. The urine of grouped females also contained alcohols in very high concentration. Only the urine from lactating females showed no changes in the concentration of alcohols, as compared to controls, during the last periods. However, in the first period of lactation, the levels of alcohols were significantly different from those of control females (Figure 6).

The last group of investigated compounds, the dihydrofurans of molecular weight 126, were structurally postulated in a previous publication (Schwende et al., 1986). For these "mouse-specific" compounds, significant variations were found as well (Figure 7). Concentration of the dihydrofurans was decreased 20–45% in the urine of pregnant primiparous females, while the samples from pregnant multiparous and lactating animals exhibited levels 35–80% lower.

Although a wealth of statistically significant data has been acquired here

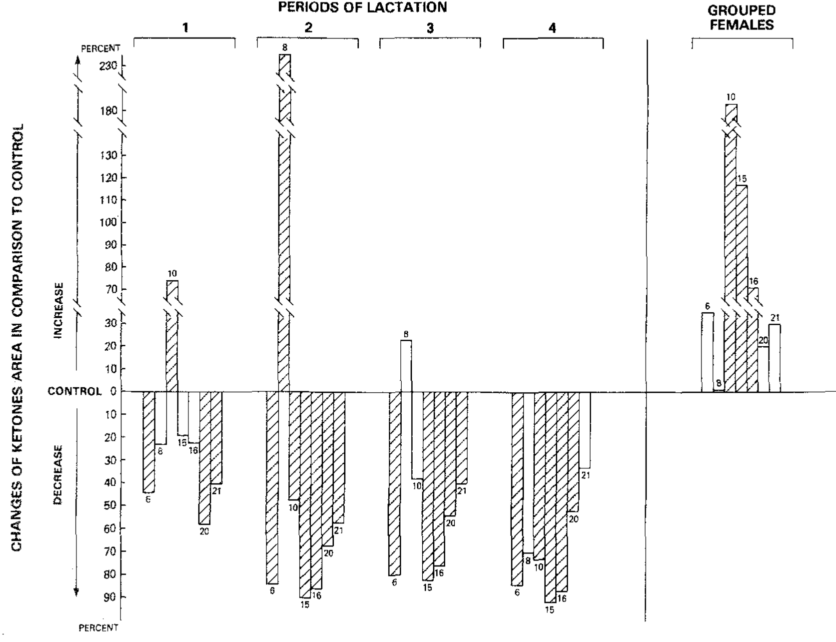

FIG. 4. Percentage difference in the peak areas of urinary ketones between lactating and nonreproducing (control) females of the ICR/Alb strain. Diagonally striped bars represent significant increases and decreases of ketones in lactating and grouped females as compared to controls.

regarding the occurrence and levels of structurally interesting compounds in different stages of pregnancy and lactation, the ultimate interpretation of their roles in the previously observed biological phenomena remains distant. The volatile substance profiles from urines collected at various reproductive stages of females appear to be distinguished more by the differences in their relative proportions than by a presence or absence of a specific substance. Interestingly, all four investigated classes of compounds are biochemically related to each other.

Comparison of these profiles provides a basis for the following general conclusions regarding the urinary chemosignals from pregnant and lactating females: (1) there are obvious differences in the concentration of urinary volatiles between pregnancy (both cases) and lactation; (2) production of urinary volatiles in lactating females is at a considerably lower level in comparison to either pregnant or singly caged, nonreproducing females. On the other hand, Drickamer (1983b, 1984, 1986) has clearly demonstrated that the urine from both sources has the same biological activity. The urine of both pregnant and lactating females accelerates the sexual development of young mice (Drickamer and

Hoover, 1979). Possibly, the acceleratory chemosignals from pregnant/lactating urines have not formed specifically as a communication signal but may be secondary metabolic products of physiological processes within the female. Only under specific social and environmental conditions could their total levels or quantitative proportions trigger biological activity of the whole urine.

According to Drickamer (1984), the unidentified urinary factors that accelerate maturation in young females are present in pregnancy or lactation urines regardless of the sample collection time during the day. However, the substance(s) is present only during the last two thirds of pregnancy or lactation (Drickamer, 1983b). Our observations here indicate a different quantitative composition for the urinary ketones in the second part of pregnancy and lactation periods as compared to the initial period. The urinary esters, which had previously been implicated as puberty-delaying factors (Novotny et al., 1986), were found in mid-pregnancy and lactation at levels comparable to nonreproducing, singly caged females, but significantly lower than in grouped females. 2,5-Dimethylpyrazine, another puberty-delaying substance (Novotny et al., 1986), was found at a trace, constant level during the entire pregnancy and lactation period.

It remains unclear whether a single volatile substance or a set of volatiles act in concert in the puberty-acceleration phenomenon. It is even conceivable that a lack of puberty-delaying factors in sufficient amounts could be a contributory factor. Chemical syntheses are currently underway in our laboratory to enable us to test the 14 substances separately or in groups for any possible puberty acceleration effects.

It is known that, under environmental conditions adequate for successful reproduction, pregnant and lactating females release the puberty-acceleration factor throughout the year (Drickamer, 1986). It is possible that some reduction of the urinary volatiles will be observed when pregnant or lactating females are housed under conditions of shortened photoperiods, limited food supply, or high densities.

(Received September 19, 1986; accepted November 17, 1986)

Abstract—Chemoreception in the adults of the freshwater prawn *Macrobrachium rosenbergii* was investigated under controlled laboratory conditions, using behavioral assays. Tests were carried out on groups, as well as on individuals, all at their intermolt stages of the molt cycle, and prestarved for three to four days. Of 28 different substances tested, the amino acids taurine, glycine, arginine, and betaine, as well as trimethylamine, elicited a positive behavioral response in at least 50% of the test animals when applied at a threshold concentration of 10^{-5}–10^{-8} M. A positive response comprises enhanced antennular flicking and food search motion. Of the various nucleotides tested for chemoattraction, only adenosine monophosphate elicited a response similar to that of the above amino acids, although at a concentration of 10^{-4} M, whereas adenosine diphosphate required a dosage of 10^{-1} M.

Key Words—*Macrobrachium rosenbergii*, Crustacea, chemoreception, taurine, glycine, trimethylamine, adenosine monophosphate, feeding stimulants.

INTRODUCTION

Chemoreception is an important mechanism governing the process of food searching in many aquatic animals. Earlier work on the attraction of *Macrobrachium rosenbergii* to foodstuffs has shown that while larvae of this prawn do not seem to respond to waterborne stimuli, postlarvae actively swim towards the apparent source of chemical attractants (Moller, 1978). Moller's work,

0098-0331/87/0900-1957$05.00/0 © 1987 Plenum Publishing Corporation

however, was of a preliminary and qualitative nature, performed mainly in Petri dishes on crude materials, and did not include the adult stage.

In a recent preliminary study by Holland (1985), in which *M. rosenbergii* prawns were individually tested, a fish extract and some chemically defined materials were identified as inducing two grades of reaction: food detection and search. A similar characterization of the behavioral response pattern of the prawn has been observed by Harpaz et al. (1987), who also demonstrated the importance of the prawn's stage in the molt cycle during chemotactic examinations.

The present work reports the results of quantitative studies on a number of chemically identified crustacean attractants, including certain nucleotides. The latter were included because they serve as potent attractants for some marine decapods (Carr and Thompson, 1983; Derby et al., 1984).

METHODS AND MATERIALS

The effects of chemoattractants on *M. rosenbergii* were tested on groups of prawns and on individuals. Tests on groups served only as a preliminary screening of various chemicals. Those found attractive were then tried on individuals to obtain dose–response data.

Animals were kept in glass aquaria at a constant temperature of $27 \pm 2°C$. They were fed commercial pelleted fish feed containing 25% protein supplemented occasionally with 1-g pieces of frozen fish and fresh leaves (see Harpaz and Schmalbach, 1986).

Prior to every test, the animals were starved for three to four days. The weight range of both sexes of adult prawns employed in the tests was 6–20 g, although within each test group prawns were selected for more uniform weight.

M. rosenbergii are nocturnal, thus the tests were conducted under dimmed light conditions; when necessary, only red light illumination (brightness of 0.9 lamberts) was used, since crustaceans are not sensitive to it (Kennedy and Bruno, 1961). These conditions minimized the interfering effects of shyness due to the presence and movements of the human experimenter.

The test attractants were introduced into the aquaria by means of a 10-ml pipet containing 7 ml of the stimulant, with an enlarged tip aperture. The pH of aquarium water fluctuated between 6.5 and 7.5 and, when necessary, the stimulant's pH was adjusted accordingly. A similar pipet, containing aquarium water only, was introduced simultaneously at another corner of the aquarium in order to distinguish between chemical, as opposed to visual and/or mechanical response. For this particular purpose, water circulation (see below) had to be stopped, and time allowed for the animals to readjust. Under such almost still conditions, diffusion of the attractants from the pipet would be very slow were it not for the differences between the level of liquid in the pipet and that of the water in the aquarium. This provided an initial hydrostatic pressure for pushing

the solution out of the pipet so as to elicit a response within 60 sec. The respective concentration reaching the prawn's chemoreceptors might be up to 1000-fold lower depending on the position of the prawn and the slight water turbulence caused by the gill bailers, as well as prawn's movements. In dye simulation, the cloud covered close to half the aquarium volume within 1 min. In the solitary aquaria the attractant was introduced at a point most distant from the prawn's head. All test chemicals were purchased from Sigma Chemical Company, St. Louis, Missouri.

A response was considered positive only when a specific sequence of events relating to feeding behavior took place. These include increased antennular flicking as described by Schmitt and Ache (1979), followed by food searching motions carried out by the first pereiopods. The latter search the substratum in front of the animal in a sweeping movement with their chelae, frequently bringing them towards the mouthparts. This sequence usually ends with the animal's eventual arrival at the stimulant release point. For a detailed description, see Harpaz et al. (1987).

In a given assay, each prawn was scored only once unless stated otherwise. Each stimulant was tested at a minimum of five concentrations with at least 10 replicates per concentration. A total of 50 prawns took part in these experiments.

Where appropriate, the significance of differences between compounds was analyzed using ANOVA followed by the Student-Newman-Keuls test (Sokal and Rohlf, 1969), as well as by log probit analysis according to Daum (1970) for determination of ED_{50}.

Tests on Groups. Ten groups of six adult prawns each were kept in 50 liters of water contained in glass aquaria measuring 50 × 40 × 30 cm. A 5-cm layer of gravel, placed at the bottom of each aquarium, served as a biological filter, from which water was constantly circulated through the entire volume of the aquarium by an electrical air pump. Sections of plastic tubing (5 cm diameter, 10 cm long) were placed on the gravel layer as hiding sites to reduce cannibalism.

The group trials served as a first approximation in which the same concentration (0.1 M) was applied for every one of the 23 test chemicals. Attractiveness was expressed in terms of the time required for 50% of the group to respond positively. A ceiling limit of 6 min was set for a positive response, any later arrivals at the target were considered as accidental and nonsignificant under these experimental conditions.

When cannibalism occurred (rare and normally following molting), the whole group was disqualified.

Tests on Individuals. The individual tests were carried out only with prawns that were at responding stages of the molt cycle. Prawns at the nonfeeding stages (D_3 and A) were not tested. Designation of the different stages of the molt cycle was according to Peebles (1977). This was based on the recognized

phenomenon that many crustaceans, including *M. rosenbergii*, do not feed during the periods immediately before and after ecdysis. Moreover, during these particular nonfeeding stages of the molt cycle, the animals do not respond in the typical manner to chemical attractants (Harpaz et al., 1987).

The aquaria for individual prawns measured 30 × 15 × 20 cm and contained 7 liters of water each. A 300-ml cup filled with gravel and placed on the bottom of the aquarium was used as above for constant water filtration. Each of these aquaria was optically insulated from its neighbor to avoid visual-response interference arising from prawns learning and memorizing as reported by Singer et al. (1979). The molt cycle was recorded for each individual in this type of aquarium. The light–dark regime in these aquaria was 12L:12D to simulate the conditions of this prawn's tropical origin.

Based on preliminary tests, the time limit in this series for reaching the target in a positive response had to be raised to 10 min. In the control assays (pipets containing aquarium water only) included in each chemoattractant test, no more than 2% of the animals actually reached the pipet tip. However, practically all these "positive" responses should be regarded as chance arrivals since very rarely did any of these prawns go through the entire repertoire constituting a complete positive response. On the other hand, at very low concentrations (varying according to the attractants), the animal performed the behavioral repertoire, but finally failed to reach the target. Nevertheless, such cases were still recorded as positive response.

RESULTS

Test on Groups. Table 1 lists the chemicals eliciting a positive response in *M. rosenbergii* at an initial concentration of 0.1 M at the point of introduction.

TABLE 1. MEAN TIME REQUIRED FOR 50% OF GROUP-TESTED PRAWNS TO DETECT AND RESPOND TO 10^{-1} M CONCENTRATION OF VARIOUS CHEMOATTRACTANTS ($N = 10$ GROUPS FOR EACH ATTRACTANT)

Attractant	Time (sec, $X \pm$ SD)
Glycine	125.5 ± 36.3a[a]
L-Arginine	135.0 ± 41.9a
Trimethylamine (TMA)	142.2 ± 41.9a
Casein hydrolysate	143.5 ± 38.4a
Betaine	193.0 ± 75.2
L-Isoleucine	206.0 ± 79.0b
L-Proline	245.0 ± 84.2b

[a] Figures with the same letter do not differ significantly ($P > 0.05$).

Results are presented in terms of the time (in seconds) required for 50% of the prawns to detect and perform the food searching behavioral pattern while approaching the attractant source. The following chemicals either did not elicit any response, or the reaction was nonsignificantly positive at this relatively high concentration: adenosine, adenosine 5′-triphosphate (ATP), alanine, aspartic acid, cysteine, glutamic acid, glutathione, histidine, leucine, lysine, methionine, phenylalanine, serine, threonine, tryptophan, tyrosine. All amino acids were L forms.

Tests on Individuals. Except for casein hydrolysate and proline, the attractants eliciting a positive response in the group tests are indicated in Table 2, where the minimum molar concentrations required for these chemicals to attract at least 50% of the test prawns are presented. Taurine and nucleotides, which have been reported as powerful chemoattractants to other decapods (Case, 1964; Ache, 1972; Shepheard, 1974; Fuzessery et al., 1978; Heinen, 1980; Carr and Thompson, 1983; Derby et al., 1984), were tested as well. Among the amino acids, the most attractive were taurine, glycine, and isoleucine.

Table 3 presents the percentages of prawns positively responding to various nucleotides at ascending log concentrations. The most potent was AMP. However, at concentrations higher than 10^{-2} M, the response to this nucleotide decreased, indicating an inhibitory effect of AMP at higher concentrations. As shown in Table 3 (for 10^{-1} M), the potencies of GMP, ADP, and IMP were low and decreased in the indicated order. ATP and adenosine were inactive even at the highest concentration tested.

The results obtained with individual prawns actually confirmed the conclu-

TABLE 2. ED_{50}[a] VALUES OF VARIOUS CHEMOSTIMULANTS ELICITING POSITIVE BEHAVIORAL RESPONSES IN INDIVIDUALLY TESTED *Macrobrachium rosenbergii* PRAWNS

Test chemical	ED_{50}	Slope ± SE
TMA	3.03×10^{-8}	0.204 ± 0.032
taurine	4.55×10^{-8}	0.273 ± 0.040
glycine	2.78×10^{-7}	0.246 ± 0.031
L-isoleucine	2.34×10^{-6}	0.281 ± 0.033
betaine	4.98×10^{-6}	0.274 ± 0.042
L-arginine	1.14×10^{-5}	0.268 ± 0.041
AMP	3.29×10^{-4}	0.337 ± 0.057

[a] ED_{50} = mean molar concentration required for eliciting a positive response in 50% of the tested prawns, calculated from log probit regression according to Daum (1970). Statistical differences exist only between concentrations which are one log step apart. Saturation levels are similar except for AMP (see text).

TABLE 3. RESPONSE[a] OF INDIVIDUALLY TESTED *Macrobrachium rosenbergii* TO 10^{-1} M CONCENTRATIONS OF VARIOUS NUCLEOTIDES

Nucleotide	Rating
GMP	+++
ADP	++
IMP	+
ATP	no response
Adenosine	no response

[a] Since the response did not exceed 50%, rating was according to the following scale: +++ ≤ 50%; ++ ≤ 40%; + ≤ 30%.

sions drawn from the group trials in the case of glycine, arginine, TMA, betaine, and isoleucine. Also, the pattern of behavior towards the attractant's release point was observed to be identical in the two series of trials. At a high concentration of attractant, the entire sequence of events, as mentioned above, is performed with remarkable intensity and, upon reaching the target area, the prawns vigorously shake the pipet with their chelae. As the concentration decreases, the intensity of food searching movements diminishes, and the prawn at times gives up the search before reaching the target area, thus indicating that the mechanism involved is much more complex than a mere "all-or-none" response.

DISCUSSION

In this study, chemoattractants for *M. rosenbergii* were identified and their dose–response relations determined through the use of behavioral methods commonly employed in such studies: tests on prawn groups and individuals.

Many studies on feeding behavior of decapod crustaceans have been carried out on groups rather than individual animals (Carr, 1978; Deshimaru and Yone, 1978; Carr and Thompson, 1983; Carr et al., 1984). This is because, besides experimental convenience, results of group trials can at times be better related to field conditions, thereby making them more directly applicable to aquaculture. However, group experiments have some potential disadvantages; one of them is that all prawns are often not at the same stage of the molt cycle (see Methods and Materials). Another drawback is that at the beginning of each experiment animals are not equally distant from the pipet tip, so that the concentration gradient between the tip of the pipet and the site of the animal about to respond can influence the results. Furthermore, one cannot rule out the possibility of a responding animal stimulating other members of the group into

motion. Another source for possible error is the prawn's territorial behavior. This is displayed by its tendency, upon discovering a food site, to deter other prawns from approaching the site (Harpaz, 1986). Tests carried out on individuals offer a better chance of controlling experimental conditions, validating group test results, and avoiding most of their drawbacks.

Most of the chemicals tested in the present study have been reported as stimulants with various degrees of potency for other crustaceans (Case, 1964; Ache, 1972; Shepheard, 1974; Carr and Gurin, 1975; Carr, 1978; Fuzessery et al., 1978; Johnson and Ache, 1978; Heinen, 1980; Derby and Atema, 1982; Carr and Thompson, 1983; Santos-Filho, 1983; Derby et al., 1984). Some of these chemicals were also tested on *M. rosenbergii*, although only preliminarily (Holland, 1985). It is difficult to compare results obtained in different studies since the methods, experimental set-ups, and criteria used are not the same. Nevertheless, as regards *M. rosenbergii*, the ranking of the different chemoattractants is similar. The most potent were TMA, glycine, and taurine. In addition, we have found that betaine and, to a lesser extent, nucleotides are also active. The most potent nucleotide was AMP followed by GMP, ADP, and IMP in the listed order, while ATP and adenosine were not active. These results are similar to those reported by Carr and Thompson (1983) for *Palaemonetes pugio*, and by Derby et al. (1984) for the spiny lobster *Panulirus argus*. Yet, even the most potent nucleotide AMP was two to three orders of magnitude less effective than the amino acids for *M. rosenbergii*. For other arthropods, e.g., hematophagous insects, the trend of nucleotide potency ranking was found to be reversed (Galun et al., 1985).

In the present study, no attempt was made to discriminate between chemoreceptors associated with the senses of smell and taste. Following antennular removal, *M. rosenbergii*, like *Procambarus clarkii* (Ameyaw-Akumfi, 1977), regains (after a short recovery period) its ability to home in on several attractants. This points toward the possibility that other parts of the body (presumably the first pereiopods and maxillipeds) possess chemoreceptors which are able to substitute for those located on the antennules (Harpaz, unpublished). It seems that some of the amino acids and nucleotides, identified as chemoattractants for *M. rosenbergii*, have a dual function. All the amino acids eliciting a powerful response in *M. rosenbergii* stimulated (with varying degrees of activity) the chemoreceptors of the walking legs of the lobster *H. americanus* (Derby and Atema, 1982). Since, in Crustacea, leg and mouthparts contain the sensory structures involved in the sense of "taste" (gustation) (Atema, 1980), it seems that these amino acids may be powerful phagostimulants. Thus, incorporation of trimethylamine hydrochloride to a low-grade feed of adult *M. rosenbergii* brought about a 30–38% increase in food consumption (Costa-Pierce and Laws, 1985). In an attempt to improve the nutritional value of commercial pellets fed to adult *M. rosenbergii*, Farmanfarmaian and Lauterio (1979) supplemented

these pellets with various amino acids reported as essential for Crustacea. Among these amino acids, arginine appreciably stimulated growth. This beneficial effect may have been contributed also by the powerful attractancy of arginine to *M. rosenbergii* as shown in the present study.

BEHAVIORAL EVIDENCE FOR MULTICOMPONENT TRAIL PHEROMONE IN THE TERMITE, *Reticulitermes flavipes* (KOLLAR) (ISOPTERA: RHINOTERMITIDAE)

CHRISTINA D. RUNCIE

Department of Zoology
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina 27514

(Received May 19, 1986; accepted November 20, 1986)

Abstract—Evidence is presented for a multicomponent trail pheromone in the eastern subterranean termite *Reticulitermes flavipes* (Kollar). Choice tests were used to compare strength and persistency of trails made by termites in glass tubes. Tubes connected to termite nests for 24 hr were marked by termites with an extremely long-lasting chemical that persisted for at least one year, and a highly volatile substance that decayed in 15 min. Individual termites varied the trail they deposited under different circumstances. When removed from the nest and placed in a clean tube, they deposited a highly volatile substance. They left stronger and more persistent trails when exploring clean tubes attached to the nest. When they discovered a new food source, they left trails that were more attractive and far more persistent than trails made by exploring or displaced termites. A food trail made by 15 workers was still effective after 24 hr, whereas a trail made by 50 displaced workers, walking one after another through a tube, lasted only 5 min.

Key Words—*Reticulitermes flavipes*, Isoptera, Rhinotermitidae, termite, trail pheromone, chemical communication.

INTRODUCTION

Chemical trails are important orientation cues for subterranean termite species, but also appear to function in recruitment communication. For example, in *Zootermopsis nevadensis*, workers lay trails to recruit nestmates for defense (Stuart, 1963, 1967). In *Nasutitermes costalis*, soldiers lay trails to recruit nestmates for exploration, defense, and food-harvesting (Traniello, 1981; Traniello and Busher, 1985). Trail pheromones are also used for recruitment to food by workers of *Trinervitermes bettonianus* (Oloo and Leuthold, 1979). These find-

0098-0331/87/0900-1967$05.00/0 © 1987 Plenum Publishing Corporation

ings suggest that individual termites can regulate the amount and/or composition of trail pheromone deposited under different circumstances, but this has been clearly demonstrated in only one study. Oloo and Leuthold (1979) demonstrated that single workers returning to the nest from a new food-find laid trails that were far more attractive to nestmates, but shorter-lived, than trails laid by exploring workers before the discovery of food.

Although the principal component of trail pheromone has been identified for several termite species (reviewed in Prestwich, 1983), the high degree of species specificity in trails of closely related species has led several researchers to suggest the presence of secondary components in termite trail pheromones (Moore, 1974; Howard et al., 1976, 1982; Kaib et al., 1982; McDowell and Oloo 1984). These secondary components may be important for species or colony identification, but they could also function in the organization of colony activity. For example, Traniello (1982) and Traniello and Busher (1985) found that sternal gland extract of *N. costalis* contains both a highly volatile chemical that acts as an attractant, and a long-lasting component that functions as an orientation cue.

In this study, a behavioral bioassay has been used to compare the strength and volatility of trails deposited in different contexts by workers of *Reticulitermes flavipes* (Kollar).

METHODS AND MATERIALS

Reticulitermes flavipes is a subterranean termite species common throughout most of the eastern United States. It nests in the soil and feeds on wood. Termites for my experiments were collected in Chapel Hill, North Carolina in April 1981. Ten laboratory nests were set up in closed, quart-sized plastic canisters containing moist white play sand and blocks of partially decayed sweetgum wood. Each nest was started with 1500 workers (undifferentiated individuals beyond the third instar, see Esenther, 1969) and 30 soldiers collected from the same source colony. The nests were maintained at room temperature (19–23°C), in the laboratory, for two years. They remained healthy during this period and developed supplementary reproductives, young, and nymphal forms.

A glass tube (10 cm × 5 mm OD) was attached to a hole in the base of each nest canister where it was accessible to the termites in the nest at all times. The tubes were sealed at the far end with tight-fitting plastic caps and became, in effect, extensions of the nest galleries. A regular flow of traffic in and out of the tubes was present during most observation periods. These nest tubes facilitated observation of termites and made it possible to remove termites and to attach additional tubing or bait dishes with a minimum of disturbance to termites in the interior of the nest.

A bioassay chamber was used to examine trails laid by termites in glass

tubes. This chamber was a Lucite disk, 1 cm thick and 5 cm in diameter, which contained a Y-shaped tunnel (arms separated by 120°). Glass tubes containing termite trails were fitted into the two tunnels that formed the arms of the Y, and a termite was placed in the third tunnel which formed the stem of the Y. It would walk to the junction and was then faced with a choice between the two glass tubes. The arms of the Y-tunnel were approximately 5.1 mm in diameter, which was just large enough to accommodate 5-mm-OD glass tubes. The stem tunnel was 3 mm in diameter, which matched the inside diameter of the tubes used, so that a termite in the chamber could enter either glass tube without having to step up or down. The chamber was used to test for preferences between two trails laid in different contexts, or between an aged trail and an unused tube.

At the start of each testing session, several workers were removed from a nest tube and placed together in a small petri dish. For each trial, the glass tubes to be tested were first slipped into the two arms of the test chamber, and then a single termite was lifted out of the dish with a paint brush and placed in the chamber entrance. It would then walk to the junction and would enter one of the tubes presented. If the trails were similar, a termite would often poke its head and antennae into first one tube and then the other, but a choice was not recorded until it had fully entered (at least one body length) one of the two tubes. Usually it then continued down to the end of the tube and was removed along with the tubes being tested.

Because of the possibility of trail reinforcement by test termites, each trail-containing or control tube was used for only a single choice test. Tubes were then cleaned by soaking in dichromic acid for 24 hr and rinsing thoroughly with both tap and distilled water before being reused. A different set of tubes as well as a different test termite were used for every trial. Termites from several different nests were used to generate and test trails for each experiment, although termites used to test a particular trail were always from the same colony as those used to generate the trail. Because of the length of time required to generate some of the trails, experiments often required several days for completion.

Statistical analysis of trail-choice experiments was based on the binomial distribution (Hays, 1973). A probability of less than 0.05 was considered to be a significant result. If termites chose randomly between two glass tubes, they were presumed to contain trails of equal strength or attractiveness. For cases in which the control trail was a clean, unused glass tube, a random choice indicated that the trail offered had faded to the point where it was no longer perceptible to test termites. If the termites showed a statistically significant preference for one trail over another, then the preferred trail was considered to be stronger or to contain a more attractive component than the other trail.

Two groups of experiments were carried out. In the first group, trails along well-used passageways connected to the nest were examined for persistence and rate of decay. In the second group, trails laid by single termites (or small num-

bers of termites) in three different situations were examined for persistence and compared to each other in terms of termite preference.

Trail Markers in Well-Used Passageways Connected to Nest

Trail Persistence. Several short (5 cm) glass tubes were fitted tightly together by plastic "sleeves" to form longer tubes, and then these were attached to nest tubes. The ends of the long tubes were sealed with plastic caps. Termites were given 24 hr to explore and travel in the tubes. The tubes were then disconnected, and any termites that were in them were shaken out. Choice tests were made between these tubes and unused tubes. Some tubes were tested immediately while others were set aside (in an open glass jar) and tested at one of five elapsed times (10 min, 24 hr, 8 days, 3 months, 1 year).

Rate of Decay. Choice tests were performed between pairs of trails that differed in how recently they had been in use. Two short (5 cm) tubes were connected to a nest tube in series and were left in place for 24 hr. The outer tube was removed first and both ends quickly covered with plastic caps to minimize the loss of volatile chemicals. After waiting for different periods of time (from 10 min to two days), the second tube was removed and both tubes placed in the test chamber. Test termites chose between an older and a more recently used trail. Eight combinations, shown in Table 2, were tested.

Trails of Single Workers

Displaced from the Nest. To determine the presence of trail marker, a worker was removed from the nest tube, placed in one end of a clean 5-cm glass tube, allowed to walk to the other end, and then shaken out. This tube and an unused tube were immediately placed in the testing chamber and a different worker was allowed to choose between the two.

To determine the persistence of the single worker trail, single worker trails were tested 2, 4, 5, 6, and 10 min after they were laid in choice tests with unused tubes.

To determine the additive nature of trails, 10 workers were placed one after another in one end of a clean 5-cm glass tube and then shaken out as soon as they reached the other end. This procedure took less than 2 min since each termite takes only 5–6 sec to walk through the tube. Choice tests were run between 10 superimposed trails and a single worker trail.

To determine the persistence of superimposed trails, 10 workers were quickly placed one after the other in the end of a glass tube and then shaken out when they reached the other end. After 6 min (the expected duration of a

single trail) the trail was compared to an unused tube in the test chamber. This was repeated with 50 workers.

Starting from the Nest: Exploration Trail. A clean glass tube (terminus closed by a plastic cap) was attached to the end of a nest tube. After waiting for a single termite to enter this clean tube and walk to the far end, the termite was shaken out before it could turn around and retrace its steps. Although several termites invariably would have investigated the entrance to the clean tube, the far end of the tube contained only a single one-way trail. This was the end that was tested. This tube was compared in the testing chamber to a single displaced worker trail (as above).

To determine persistence, exploration trails were tested 10 min and 15 min after being laid in choice tests with unused tubes.

Starting from the Nest: Food-Find Trail. I was unable to obtain a single food-find trail for comparison with a single exploration trail because it is made by a termite on the return trip to the nest. Instead the following system was devised. A clean 2.5-cm tube was attached to a nest tube and a food dish containing damp sand and a wood block was connected to its terminus. A single termite was allowed to traverse the clean tube, antennate the wood block, and then return to the nest. This tube now contained an outbound exploration trail and a return trail from the food find. This tube was immediately removed and a second clean 2.5 cm tube was attached in its place. The second tube was sealed with a plastic cap at its terminus (i.e., no food present). Again, a single worker was allowed to traverse the full length of the tube and return to the nest. The second tube now contained a two-way (outbound and return) exploration trail. Test termites were given a choice in the chamber, between a "food-find" trail (with underlying exploration trail) and a two-way exploration trail (no food present).

To determine persistence, food-find trails were tested 60 min after being laid in choice tests with unused tubes.

As a control for tube contact with wood blocks, unused glass tubes were placed in direct contact with wood blocks for 30 min and then tested in choice tests with other clean tubes.

Multiple Food-Find Trails. For comparison with a well-used nest tube, a clean 5-cm tube was attached to a nest with a food dish at its far end and 15 workers were allowed to reach the food and return to the test. Choice tests were run between this tube and a nest tube (from a different part of the nest) that had been in use for a month and had presumably been traveled by hundreds of termites.

To determine persistence of superimposed food-find trails, tubes containing 15 superimposed food-find trails were tested 24 hr after being laid in choice tests with unused tubes.

RESULTS

Trail Markers in Nest Tubes

Tubes that had been connected to the nest for 24 hr were preferred to unused tubes at all ages tested (Table 1). A chemical marker was perceptible to workers even after one year, although not a single termite had entered the tubes during that time.

Fresh trails (used by termites within 30 sec of the test) were significantly preferred to trail tubes removed from the nest 15 min earlier (see Table 2). This indicates the presence of a volatile chemical that fades appreciably (to workers) in 15 min. Over the next 5 hr, the trail marker showed no significant further decay. Trails disconnected from the nest 15 min before being tested were not significantly different from trails that had been disconnected for 30 min, 2 hr, or even for 5 hr. They were, however, significantly preferred to trails that had been unused for 24 hr, indicating that the trail continues to fade over the 24-hr period, but does so at a much slower rate than during the first 15 min. Trails unused for 24 hr were equal in strength to trails unused for 48 hr, which indicates that the rate of decay becomes even slower after the first 24 hr.

Trails of Single Workers

Displaced from the Nest. Termites removed from the nest, and made to walk through clean glass tubes, left chemical markers clearly perceptible to other termites; tubes traversed by a single worker (in one direction only) were significantly preferred to unused tubes (21:9, $P < 0.02$).

The results in Table 3 show that the trail of a displaced worker lasts between 5 and 6 min; it was significantly preferred to an unused tube 5 min after it was deposited but was no longer preferred when tested after 6 min.

TABLE 1. SINGLE WORKER CHOICES IN TESTING CHAMBER BETWEEN TUBES CONNECTED TO NEST FOR 24 HOURS AND UNUSED TUBES

Elapsed time since tube disconnected	No. of tubes tested	Worker choices, used–unused	Binomial probability
1 h	16	14:2	0.002
1 day	16	15:1	0.0002
8 days	16	14:2	0.002
3 months	16	13:3	0.01
1 year	16	12:4	0.03

TABLE 2. SINGLE WORKER CHOICES IN TESTING CHAMBER BETWEEN OLDER AND MORE RECENTLY USED TRAILS

Elapsed time since trails last used		No. of trails tested	Worker choices, trail A–trail B	Binomial probability
Trail A	Trail B			
<30 sec	10 min	18	12:6	0.07
<30 sec	15 min	18	14:4	0.02
<30 sec	30 min	18	15:3	0.01
15 min	30 min	18	10:8	0.17
15 min	2 hr	18	9:9	0.19
15 min	5 hr	18	10:8	0.17
15 min	24 hr	18	15:3	0.01
24 hr	48 hr	18	9:9	0.19

Ten superimposed worker trails were significantly preferred to a single worker trail when tested immediately (14:4, $P < 0.02$). When these trails were tested 6 min after being made, in choice tests with clean tubes, no preference was found (10:8, $P < 0.17$). Similarly, 50 superimposed worker trails, when tested 6 min after being laid, were not significantly preferred by workers to unused tubes (10:8, $P < 0.17$).

Exploration Trail. The trail of a single worker exploring a clean tube attached to the nest was significantly preferred to the trail of a single displaced worker (15:3, $P < 0.01$). This "exploration" trail was preferred to an unused tube when tested 10 min after being laid (14:4, $P < 0.02$), but was no longer detectable by workers when tested after 15 min (12:6, $P < 0.08$), and so appears to last between 10 and 15 min.

Food-Find Trail. Food-find trails (which contained an underlying explo-

TABLE 3. SINGLE WORKER CHOICES IN TESTING CHAMBER BETWEEN TUBES TRAVERSED ONCE BY SINGLE DISPLACED WORKER AND UNUSED TUBES

Elapsed time before tubes were tested (min)	No. of tubes tested	Worker choices, used–unused	Binomial probability
2	18	13:5	0.04
4	18	13:5	0.04
5	18	14:4	0.02
6	18	7:11	0.12
10	18	9:9	0.19

ration trail) were significantly preferred to two-way exploration trails (14:4, $P < 0.02$) even though they were always older (4–25 min) than the exploration trails to which they were compared (since food trails were laid first).

Food-find trails were significantly preferred to unused tubes when tested 60 min after being laid (16:2, $P < 0.0006$). The two-way exploration trail decayed in 15 min after being laid (12:6, $P < 0.08$). This was consistent with the results for the one-way exploration trail (see above) which also lasted for only 10–15 min.

Workers chose randomly between clean tubes that had touched wood blocks for 30 min and other clean tubes (8:7, $P < 0.2$), indicating that tubes were not contaminated through contact with the food source.

Multiple Food-Find Trails. Test termites chose randomly between 15 superimposed food-find trails and nest tubes (15:9, $P < 0.08$). When tubes containing 15 superimposed food-find trails were tested 24 hr after being laid, they were significantly preferred to unused tubes (17:1, $P < 0.0001$), indicating the presence of a long-lasting component in the recruitment trail that persists for at least 24 hr.

DISCUSSION

This study was designed to examine the possibility that individual *R. flavipes* workers vary the amount or the composition of the trail marker deposited under different circumstances. The bioassay used, in which single termites were given choices between different trails (in glass tubes), in a Y-shaped intersection, enabled trails to be compared in terms of worker preference. In this bioassay, a statistical preference for one trail over another indicates that the preferred trail is either stronger or contains a more attractive component than the other trail. It should be noted that termite responses may be affected by the conditions of the bioassay (as test termites were removed from the nest). Nevertheless, the fact that termites prefer one trail over another clearly indicates that they can perceive a difference between the two trails. Choice tests between trail tubes and unused tubes allowed the longevity of different trails to be assessed. The lifetime of a given trail was considered to be the length of time until termites were no longer able to distinguish it from a clean tube.

Glass tubes used as passageways by *R. flavipes* colonies contain a chemical marker clearly perceptible to workers in choice tests with clean tubes. Although this chemical marker may be primarily a trail pheromone actively deposited from the sternal gland, it probably also contains salivary secretions, excrement, and substances passively rubbed off from the cuticle. Some component, or components, of this trail marker appears to be extremely persistent as it was still perceptible (to termites) after a year without reinforcement. It should be noted that the aging of trails under natural conditions may be very different from that

found for trails in glass tubes. It is possible that trail tubes may have picked up chemicals from the lab, as they were stored with ends uncapped, but this would be unlikely to account for the striking preference seen even in the 1-year-old tubes, especially as control tubes were also stored uncapped (although for a shorter time).

Traniello (1982) similarly found evidence for an extremely long-lasting component in passageways used by *Nasutitermes costalis*; an effective trail was produced from extracts of 4-year-old shelter-tube flooring. Tschinkel and Close (1973) found that extracts of trails laid on paper by *Trinervitermes trinervoides* produced trail-following for up to 7.5 hr. As suggested by Traniello (1982), persistent trails are probably found in termite species because these insects feed for extended periods on long-lasting food resources, and because, being blind, they rely heavily on chemical cues for orientation. In a temperate species such as *R. flavipes*, colonies appear to abandon chambers and foraging sites near the soil surface in winter and migrate to chambers below the frostline (Esenther, 1969). For these species, persistent trails may enable foragers to return to profitable foraging sites the following spring.

Comparison of older and more recently used trails revealed a rapid decline in trail attractiveness during the first 15 min of nonuse and a much more gradual decay after that time, a result which suggests that trails contain a volatile component. Some of the volatile material was probably dissipated in the time it took to disconnect and cover the tube ends, and plastic tube caps may have slowed, but would not prevent, their dispersion. These results must therefore be taken as an approximation of the natural decay curve.

A volatile trail pheromone has been reported in two other termite species. Oloo and Leuthold (1979) found that workers of *Trinervitermes bettonianus* laid highly volatile (15 min) recruitment trails following food discovery. Traniello (1982) found a volatile excitatory component in sternal gland extracts of *N. costalis* that produced a mass outpouring of workers from the nest. In these two species the volatile trail component is presumed to function as an excitatory pheromone that stimulates nestmates to forage and is therefore used primarily in recruitment communication. In the present study, a volatile pheromone was present in tubes that had never led to food sources (they were closed with tube caps) and that had been in use for 24 hr. It is therefore very unlikely that this component was related to recruitment effects. Instead, termites may reinforce all trails as they walk, and the volatile fraction may serve to distinguish trails currently in use from those that have been abandoned.

The presence of two or more components in the trail marker of *R. flavipes* is similar to the findings of Traniello (1982) for sternal gland extracts of *N. costalis*, which contain both a volatile recruitment component and a long-lasting orientation component although, in the present case, the functions of the two components have not been identified. The possibility of a multicomponent pheromone is consistent with sternal gland structure in *Reticulitermes*. Smythe and

Coppel (1966), in their histological study of the sternal gland of *R. flavipes*, first suggested that this species has some control over the amount and nature of trail substances emitted. Quennedey (1978), using electron microscopy, identified four different types of secretory cells in the sternal gland of *R. santonensis*, each containing a unique chemical secretion. The sternal cuticle forms a dome over the central region of the gland and encloses an extracellular space in which the secretion products of two cell types accumulate. Other secretion products are conducted through canals that pierce the dome and so reach the surface of the gland directly.

Comparison of trail markers left by single termites in three different situations revealed differences in both trail strength and volatility. Termites removed from the nest and placed in clean tubes left a marker that was clearly recognizable by other termites but that persisted for only 5 min. This highly volatile substance may function as a lifeline, to aid termites in maintaining contact with the colony, or it may be an alarm pheromone (pheromones which are characteristically short-lived; Wilson, 1971), as termites were undoubtedly agitated by their removal from the nest and by the lack of familiar odors in the clean tubes.

A worker exploring a clean tube attached to the nest left a trail that was intermediate in strength and persistence between that of a displaced worker and that of a food recruiter. It lasted for 10–15 min compared to 5 min for the trail of a displaced worker, and more than 1 hr for a food-find trail. However, when the tube remained attached to the nest for 24 hr, so that numerous termites traveled up and down its length, it came to contain a trail that persisted for a year. Therefore, although the initial worker laid a trail that lasted only 10–15 min, at some point during the 24-hr period, the extremely long-lasting component was deposited. Perhaps each exploring termite deposits only a small amount of the durable trail component because the stimulus is less exciting than, for example, a block of wood. Even so, with sufficient traffic, enough termite trails would accumulate so that the pathway would become permanently marked.

Although trails left by food-finders were stronger and much more long-lasting than exploration trails, this difference may be only quantitative. This is supported by the fact that termites chose randomly between 15 recruitment trails and a well-used nest tube. If the recruitment trail were qualitatively different, one would have expected even a very new recruitment trail to be chosen over a well-traveled pathway that did not lead to food. On the other hand, test termites were displaced from the nest and in this context might not be as attracted by a food recruitment trail as they might be otherwise. The bioassay used in this study did not distinguish between attraction and orientation, as trails were presented to single termites rather than to groups and because termite response was limited to movement within a tube. Therefore the results do not exclude the possibility that the food-find trail contains a volatile attractant or other components not present in other trails.

There does appear to be a qualitative difference between the trails of displaced workers and those of workers returning from a food find. Whereas a trail made by 15 food-finders lasted for 24 hr, the superimposed trails of 50 displaced workers lasted for only 5 min. The long-lasting component appears to be entirely absent in the trails of displaced workers.

These results clearly demonstrate the ability of individual workers to vary the amount or composition of trail marker deposited under different circumstances. Stuart (1964) first suggested, for *Zootermopsis nevadensis*, that termites may be able to regulate the amount of pheromone that is released from the extracellular reservoir by varying the amount of pressure exerted by the abdomen against the substrate. The cuticular dome of the sternal gland is studded with campaniform sensillae which provide proprioceptive information about the degree of compression of the dome. One may speculate that in *R. flavipes*, the secretions that accumulate in the extracellular space constitute the long-lasting component of the trail. Termites could vary the amount of persistent component that is deposited in relation to the nature of the stimulus, as in exploration and food-recruitment trails, by varying the pressure of the abdomen against the substrate. Volatile components may be conducted directly to the surface of the gland, and so be passively emitted at all times. This explanation would be consistent with the presence of a volatile component in well-used passageways, with the ability of workers to deposit a volatile component by itself and with their ability to vary the amount of long-lasting component that is deposited.

Directions for future work include identifying the separate components of the trail pheromone and assessing their functions in the organization of colony activity.

Acknowledgments—I am grateful to Dr. G. Happ for his instruction and consultation time and for generously providing lab space and equipment at the University of Vermont where much of this work was done. I thank Dr. E.A. McMahan, Dr. D. Richards, and Dr. J.F.A. Traniello for helpful comments on the manuscript. Above all, I thank my advisor Dr. E.A. McMahan for guidance and support. Financial support came from a Biomedical Research Assistantship from the University of North Carolina and from two grants-in-aid of research given by Sigma Xi, the American Research Society.

(Received May 30, 1986; accepted November 20, 1986)

Abstract—A male-produced sex pheromone of the papaya fruit fly, *Toxotrypana curvicauda* Gerstaecker, was isolated from volatiles collected from air passed over calling males and was identified as 2-methyl-6-vinylpyrazine by comparative gas-liquid chromatographic and spectroscopic evidence. Synthetic 2-methyl-6-vinylpyrazine elicited typical pheromonal responses from unmated mature female flies such as walking, running, and flying in an arena bioassay; flying upwind with a zigzag flight pattern; and hovering in the pheromone plume in a wind-tunnel bioassay. These responses were similar quantitatively and qualitatively to responses to naturally occurring pheromone from calling male papaya fruit flies.

Key Words—*Toxotrypana curvicauda*, Diptera, Tephritidae, papaya fruit fly, male sex pheromone, pheromone, 2-methyl-6-vinylpyrazine.

INTRODUCTION

The papaya fruit fly, *Toxotrypana curvicauda* Gerstaecker, is a major obligate pest of papaya fruit in south Florida, Central and South America, and the Caribbean. The behavior of this insect is of particular interest because, unlike other tropical frugivorous tephritids, it is very limited in its selection of hosts; the larvae usually infest only the fruit of papaya (Wolfenbarger and Walker, 1974).

This tephritid, unlike many other fruit fly species, is not known to be attracted to or feed on yeast hydrolysate paste (Landolt, 1984) and is not attracted to aqueous solutions of brown or refined sucrose or to trimedlure, methyl eugenol, cue-lure, or vinegar (Sharp and Landolt, 1984). Thus there are no attractants or trapping materials available to monitor papaya fruit fly populations.

Landolt et al. (1985) reported the presence of a male-produced sex pheromone in *T. curvicauda* that elicited excitatory behavior in females such as walking, running, and flying in an arena bioassay and attraction in a wind-tunnel bioassay. The need for an attractant to monitor this pest insect and the potential of a female attractant for pest control led us to investigate the chemical nature of the sex pheromone produced by male papaya fruit flies.

This paper reports the isolation, identification, and synthesis of a male-produced sex pheromone of the papaya fruit fly that elicits both short- and long-range behavioral responses by unmated, mature females that are similar to responses from calling males in laboratory tests.

METHODS AND MATERIALS

Papaya fruit fly larvae were collected from field-infested papaya fruit from Dade County, Florida, and from fruit infested in the laboratory by field-collected flies. Larvae emerging from fruit were placed in wax-coated paper cartons filled with damp, heat-sterilized potting soil or vermiculite into which they burrowed and pupated. Emerging adults were sorted daily by sex and were held in aluminum screen cages supplied with sugar cubes and wet cotton dental wicks. All insects were held at 26 ± 1°C, 50 ± 5% relative humidity, and on a 12L : 12D photoperiod with lights on from 7:00 AM to 7:00 PM. Females used in bioassays were unmated and were reproductively mature (6–9 days old). They were kept in a room separated from males in 30 × 30-cm aluminum screen cages with sugar and water.

Arena and Wind-Tunnel Bioassays

Arena bioassays were conducted using single females in 500-ml clear plastic cups turned upside down, as described by Landolt et al. (1985). Doses of a candidate chemical or fraction on filter paper were introduced into the cups and the activities of the flies observed for a 2-min time period. The number of females responding by walking, running, and flying was recorded. The bioassays were conducted between 11:30 AM and 1:00 PM.

A preliminary test of gas–liquid chromatography fractions of volatiles collected from males (see later) was conducted with this arena bioassay. One male-hour-equivalent of each of three fractions was pipetted onto filter paper, and the behavior of the flies was observed and recorded. A dose–response test was con-

ducted using this bioassay at 0, 0.01, 0.1, 1, 10, and 100 μg of synthetic pheromone and its isomer with five flies tested per dose. This test was replicated three times.

Wind-tunnel bioassays were conducted in a tubular Plexiglas wind tunnel (0.44 m diam × 2.44 m long) with 22 cm/sec wind speed (measured in the center of the tunnel at the male release point) at 24–25°C under fluorescent lighting. Rubber septa (A.H. Thomas Co. 8753-D22, Philadelphia, Pennsylvania, 5 × 9 mm extracted with methylene chloride for 24 hr) were impregnated with the synthetic pheromone or its isomer in 100 μl of hexane. These septa were air dried in a fume hood for 24 hr after loading with the chemicals and then used only once. This pheromone source was suspended in the center of the upwind end of the tunnel by a clip hung on a steel stand. A female was placed at the downwind end of the tunnel in an upright 35-ml plastic vial and observed for 2 min. All behavior observed was recorded, particularly the time it took to leave the vial (activation time), the number of flights during 2 min, the upwind distance attained, plume tracking (upwind anemotaxis within the plume with casting or zigzagging), hovering (a stalled casting or circling flight pattern within 15 cm of the source), and landing at the pheromone source (septum or end of stand holding septum). Bioassays were conducted from 11:00 AM to 12:30 PM. Doses tested were 0, 1, 10, 100 μg, and 1 and 10 mg per septum. On each of nine days, five mature unmated females were tested per dose, beginning at the lowest dose of the series. Treatment means were separated with Duncan's new multiple-range test.

Comparison of Behavioral Responses to Synthetic and Natural Pheromones

A comparison was made of the responses of mature, unmated female papaya fruit flies (6–8 days old) to calling males and to synthetic sex pheromone in a flight-tunnel bioassay. Four males were held in a 3.8-liter glass jar through which air was pumped into the upwind end of the tunnel. Incoming air was passed through a charcoal filter and regulated with a flowmeter at 1 liter/min. Outgoing air was vented into the tunnel via 4-mm-diam steel tubing, with the vented air directed downwind from near the center of the upwind end of the tunnel. Synthetic pheromone was introduced into the tunnel using the same system and was dispensed from a 25-μl glass disposable micro-sampling pipet (Corning), sealed on one end, to provide a release rate of about 300 ng/hr. Release-rate determinations for pheromone from capillaries were made as described for rubber septa (see later). Batches of 10 female papaya fruit flies were tested alternately for responses to male-produced and synthetic pheromone. Each female was observed for 2 min following its introduction into the downwind end of the tunnel. Females were scored for plume tracking and for hovering in the plume near the pipe vent. A total of 20 females (two sets of 10) was tested per treatment.

Collection of Volatiles

Volatile sex pheromone produced by males was collected on Porapak N by the method of Landolt et al. (1985) for subsequent purification and spectroscopic analysis. Pheromone was collected by passing prefiltered (Porapak N) air over calling papaya fruit fly males held in glass jars and then through another Porapak N filter (pheromone trap). The collection system was operated 6–7.5 hr after the onset of the photophase, with 50, 3- to 8-day-old male papaya fruit flies placed in each jar. Each Porapak air filter and pheromone trap was extracted with 10 ml of hexane and then baked in an oven at 95°C for 2 hr before use. After volatile collection, pheromone traps were extracted with 10 ml of hexane and the extract was stored in a freezer. Similar volatile collections were made from mature, unmated female papaya fruit flies.

Male volatiles were also collected on charcoal filter traps with an apparatus similar to the one described by Tumlinson et al. (1982) for direct capillary GLC analysis. Compressed air, purified by passing it through two in-line charcoal filters, entered a glass chamber (4.2 cm OD × 4 cm long) where the insects were held. The upwind end of the collecting chamber was fitted with a glass frit to disperse the air and induce laminar flow. Air flow through the chamber was maintained at 1 liter/min. About 80% of the air entering the system and passing over the males was pulled by vacuum through a small charcoal (Aktivkohle für Gaschromat. nach Dr. Grob, 0.05–0.1 mm, Bender & Hobein AG, Zürich) filter trap similar to the one described by Grob and Zürcher (1976). Approximately 20% of the flow, measured by a flowmeter, was vented to maintain a slight positive pressure within the chamber.

Volatiles from a single mature (3- to 5-day-old) male papaya fruit fly were collected from 5 to 7 hr after the beginning of the photophase. Collection from a single male was replicated 20 times. Additionally, volatiles were collected from a group of five mature male flies in the same manner. Volatiles were extracted from the charcoal filter trap with 80 μl of dichloromethane (20 μl × 4). After adding *n*-nonane as an internal standard, the extract was concentrated slowly with a stream of N_2 to about 1 or 2 μl. Then 2 or 3 μl of hexane was added to the concentrate and the hexane solution was analyzed by capillary GLC.

Release rates of the synthetic pheromone from rubber septa were measured by collection of the volatiles released and analysis by GLC. Septa loaded with 100 μg and 1 mg of pheromone were placed in a 15 mm (ID) × 20 mm (long) stainless-steel tube, purified air was passed over them at 1 liter/min, and the volatiles were trapped on a charcoal filter. Each septum was loaded 24 hr prior to measuring the release rate and aired at room temperature until release rate measurements began.

Pheromone Purification

Crude pheromone extracted from Porapak N filters with hexane was concentrated to a small volume by a stream of nitrogen, and the concentrated material was subjected to micropreparative gas–liquid chromatography (GLC). Micropreparative GLC for purification of the pheromone was performed on a Varian model 1400 gas chromatograph equipped with a flame ionization detector. The glass column (2.3 mm ID × 2 m) was packed with 10% OV-101 on 60/80 mesh Chromosorb W. Temperatures of inlet, detector, and transfer line were 230, 250, and 80°C, respectively. Column temperature was maintained at 80°C. Carrier gas (N_2) flow rate through the column was 20 ml/min. The chromatograph was modified to accommodate a 95:5 effluent splitter and external outlet for collection (Brownlee and Silverstein, 1968). The effluent from the transfer line after the splitter was collected in 1.5-mm-ID × 305-mm-long U-shaped capillary glass tubes connected to the external outlet and cooled directly by an acetone–Dry-Ice bath to minimize the loss of the highly volatile pheromone.

Synthesized materials were purified by preparative high-performance liquid chromatography (HPLC) on a 1.25-cm-OD × 25-cm-long stainless-steel column packed with Lichrosorb 5 μm silica. A Lab Data Control Constametric II G pump delivered the hexane–ethyl acetate (75:25) mobile phase at 2.0 ml/min, and eluting components were detected with a Waters model 401 differential refractometer.

Pheromone Analysis and Identification

Naturally occurring pheromone and the synthesized chemicals were analyzed on 50-m × 0.25-mm-ID fused silica capillary columns as follows: an OV-101 column was maintained at 60°C for 1 min after injection, programmed at 5°C/min to 200°C, and then operated isothermally; a CPS-1 column was maintained at 60°C for 1 min after injection, programmed at 10°C/min to 180°C and then operated isothermally. A Carbowax-20M column was maintained at 60°C for 2 min after injection, programmed at 5°C/min to 210°C then operated isothermally. All columns were operated in the splitless–split mode (splitless delay 30 sec) with He carrier gas flow of 19 cm/sec in a Varian model 3700 gas chromatograph.

Mass spectral data were obtained with a Nermag R10-10C mass spectrometer equipped with a chemical ionization (CI)–electron impact (EI) source. A Varian Vista model 6000 gas chromatograph equipped with split-splitless injection system and 0.25-mm-ID fused silica capillary columns served to introduce samples to the ion source. For CI mass measurement, methane was em-

ployed as reagent gas. Helium was used as the GLC carrier gas in the EI and CI mass measurements. Data acquisition and reduction were accomplished with a Digital PDP 11/23 computer interfaced to the mass spectrometer.

Proton magnetic resonance spectra were obtained with a Nicolet 300-MHz Fourier transform NMR spectrometer interfaced to a Nicolet 1280 data system. All data were measured in benzene-d_6 solution using 16K data points and a 6-μsec pulse. The NMR spectrum of the natural pheromone was obtained from 10,000 scans on ca. 4 μg/20 μl benzene-d_6 solution in a 2-mm-OD NMR tube (Wilmad Glass Co., catalog No. 507 with WGS-5BL stem).

Synthesis of Pheromone

2-Methyl-6-dimethylaminoethylpyrazine. A mixture of 2,6-dimethylpyrazine (Pyrazine Specialties, Inc., Atlanta, Georgia, containing 2%, 2,5-isomer) (15.5 g) and dimethylamine hydrochloride (13.0 g) was heated until it began refluxing, and then formaldehyde (22.5 g as 38% aqueous solution) was added over a 30-min period. The resulting solution was refluxed for 2 hr. The solution was cooled to room temperature and diluted with water, made basic by the addition of 10% aqueous solution of sodium hydroxide, and extracted with chloroform. After removing the solvent, distillation of the residue gave 7.8 g of 2-methyl-6-dimethylaminoethylpyrazine with 5% of the 2,5-isomer (33% yield), 120–126°C/12 mm Hg: IR (cm^{-1}, CCl_4 solution); 3045 (m), 2980 (s), 2955 (s), 2870 (s), 2830 (s), 2770 (s), 1538 (s), 1465 (s), 1380 (m), 1270 (m), 1200 (s), 1180 (s), 1165 (s), 1080 (m), 1045 (m), 1020 (m), 880 (m), PMR (C_6D_6); 8.29 (1H, s), 8.14 (1H, s), 2.80 (1H, m), 2.65 (1H, m), 2.23 (3H, s), 2.12 (6H, s).

6-Methylpyrazylethyl-trimethylammonium iodide. Methyl iodide (6.4 g) was added to a stirring solution of 2-methyl-6-dimethylaminoethylpyrazine (4.6 g) in 20 ml of anhydrous ether under argon atmosphere. The mixture was allowed to stand overnight at room temperature. A yellow solid formed was filtered and washed with a small amount of ether to give 6.0 g of the quarternary iodide salt (70% yield). This hygroscopic compound was subjected to the next step without further purification.

2-Methyl-6-vinylpyrazine. The quarternary ammonium iodide (6.0 g) was dissolved in 40 ml of water. Then, 1.7 g of sodium hydroxide was added and the mixture was refluxed for 1 hr. The resulting solution was cooled to room temperature and extracted with chloroform. The chloroform solution was dried over Na_2SO_4 and evaporated carefully at atmospheric pressure. Microdistillation at 12 mm Hg gave 2.4 g of 2-methyl-6-vinylpyrazine (74% yield) with 5% of the 2,5-isomer. Pure 2-methyl-6-vinylpyrazine (100% purity) for bioassay was obtained by HPLC purification on the Lichrosorb column. Capacity factors (k') (Schram, 1980) of 2-methyl-6-vinylpyrazine and its 2,5-isomer were 2.0

and 3.2, respectively, under the conditions described in the experimental section). MS (m/z); 37 (43), 52 (72), 54 (26), 94 (26), 120 (M^+, 100).

IR (cm^{-1}, CCl_4 solution); 3105 (m), 3045 (m), 2940 (m), 1545 (s), 1456 (m), 1422 (s), 1395 (s), 1380 (m), 1275 (s), 1260 (s), 1228 (s), 1178 (s), 1160 (s), 1020 (s), 986 (s), 940 (s), 930 (s), 880 (s), PMR (C_6D_6); 8.16 (1H, s), 7.98 (1H, s), 6.50 (1H, dd, J = 17.4 Hz, 10.5 Hz), 6.33 (1H, dd, J = 17.4 Hz, 1.6 Hz), 5.22 (1H, dd, J = 10.5 Hz, 1.6 Hz), 2.08 (3H, S).

2-Methyl-5-vinylpyrazine. In the same manner, 2-methyl-5-vinylpyrazine was synthesized from 2,5-dimethylpyrazine (Pyrazine Specialties), containing 7% of the 2,6-isomer. Pure 2-methyl-5-vinylpyrazine (99.8% purity) for bioassay was obtained by HPLC purification as described in the experimental section. MS (m/z); 37 (52), 52 (79), 64 (29), 94 (26), 120 (M^+, 100).

IR (cm^{-1}, CCl_4 solution); 3080 (m), 3015 (m), 2930 (m), 1485 (s), 1410 (m), 1380 (m), 1320 (s), 1170 (s), 1032 (s), 985 (s), 940 (s), 925 (s), 905 (s), 880 (m), PMR C_6D_6); 8.20 (1H, s), 8.03 (1H, s), 6.54 (1H, dd, J = 17.4 Hz, 10.5 Hz), 6.31 (1H, dd, J = 17.4 Hz, 1.6 Hz) 5.21 (1H, dd, J = 10.5 Hz, 1.6 Hz), 2.09 (3H, s).

RESULTS AND DISCUSSION

Isolation and Identification

The capillary GLC analysis of the calling male papaya fruit fly volatiles collected on the charcoal filter indicated the existence of a single major peak (Figure 1), which did not appear in the analyses of volatiles from females. In an arena bioassay, only the GLC fraction that contained the major peak elicited the typical pheromone-stimulated responses by females (Landolt et al., 1985). The release rate of this compound, determined by GLC analysis of the volatiles collected from individual calling males, was 63.2 $\pm$ 33.2 ng/male-hr. The release rate from a group of five males was about 80 ng/male-hr.

Hexane extracts of the Porapak N filters were concentrated and subjected to micropreparative GLC purification as described in the experimental section to obtain sufficient material for PMR analysis. The purity of the isolated biologically active component of the volatiles was estimated to be 99.9% by capillary GLC analysis in which three different types of columns were used.

Structural Elucidation

The methane CI mass spectrum of the pure isolated major component established that the molecular weight was 120, with diagnostic peaks at m/z 121 (M+1), 149 (M+29), and 161 (M+41). In the EI mass spectrum (Figure 2), the presence of a strong parent peak at m/z 120 (M) and characteristic even

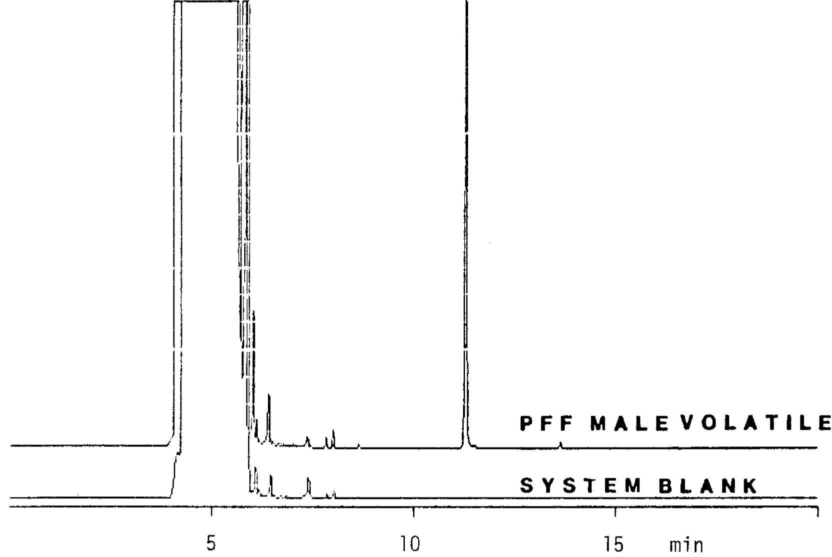

FIG. 1. Gas chromatogram of the volatiles from calling male PFF. Column: 50 m, capillary fused silica OV-101. Temp. program: 60°C for 1 min, 5°C/min to 200°C. Injection mode: splitless/split, split delay 30 sec.

fragment ions at *m/z* 52, 54, and 94 suggested that the pheromone has a heterocyclic structure involving two nitrogen atoms.

The 300-MHz [^{1}H]NMR spectrum of the pheromone (Figure 3) strongly supported the presence of a heterocyclic system in the structure. Two single-proton signals at 8.26 (s) and 8.08 (s) were attributable to the ring protons, the chemical shifts of which were consistent with those of a disubstituted pyrazine. A three-proton signal at 2.18 (s) and three one-proton signals at 6.59 (dd, J = 17.4 Hz, 10.5 Hz), 6.45 (dd, J = 17.4 Hz, 1.7 Hz), and 5.31 (dd, J = 10.5 Hz, 1.7 Hz), which appeared to be ABX systems, were attributable to a methyl and vinyl group, respectively, attached to the pyrazine ring. The presence of unsplit signals at 8.26 and 8.08 indicated that the substitution system should be 2,6 or 2,5. Due to slight downfield chemical shifts caused by the solvent dilution effect, exact assignments could not be made.

Both 2-methyl-6-vinylpyrazine (2,6-MVP) and 2-methyl-5-vinylpyrazine (2,5-MVP) were synthesized from 2,6-dimethylpyrazine and 2,5-dimethylpyrazine, respectively, employing a Hoffman exhaustive methylation procedure and modifications described by Kamal et al. (1962) (Figure 4).

The structure of the pheromone was deduced conclusively from the comparison of the 300 MHz [^{1}H]NMR spectra and the retention times on three different capillary GLC columns of the natural pheromone and synthetic 2,6-

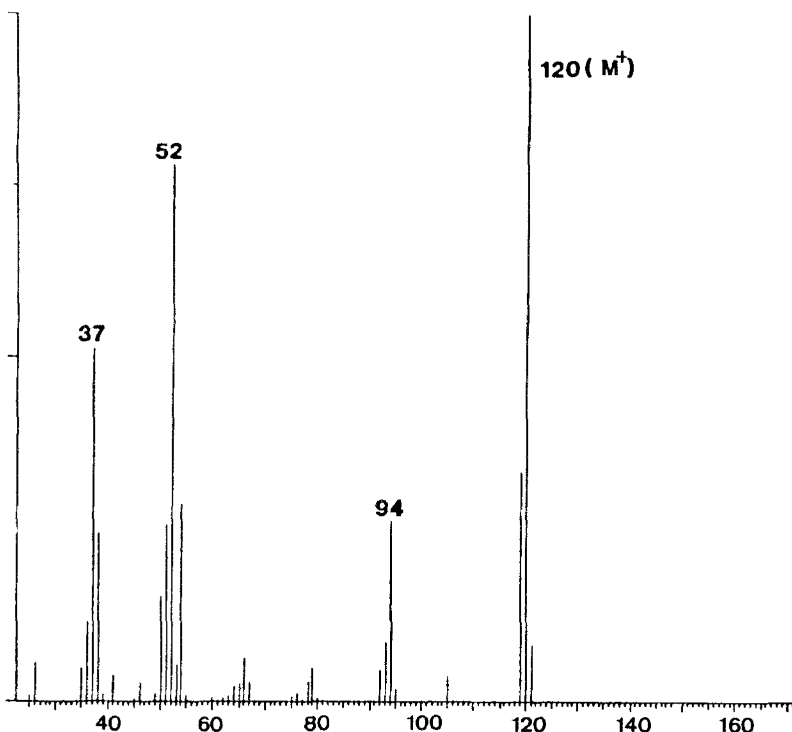

FIG. 2. Electron impact mass spectrum of the sex pheromone.

MVP and 2,5-MVP. The retention indices (Kovats, 1965) of 2,6-MVP and 2,5-MVP, respectively, on the three columns were: OV-101, 995 and 1000; Carbowax 20 M, 1455 and 1499; CPS-1, 1327 and 1355. The mass spectral data and GLC retention times of the natural pheromone were identical to those of 2,6-MVP, and thus the structure of the sex pheromone isolated from volatiles of the male papaya fruit fly was determined to be 2-methyl-6-vinylpyrazine.

Arena and Wind-Tunnel Bioassays

Synthetic 2,6-MVP was tested in the arena and wind-tunnel bioassays to compare its pheromonal activity to that of natural pheromone. Results of the arena bioassay, summarized in Table 1, indicated that synthetic 2,6-MVP elicited running and flying as did calling males and volatiles from calling males in a previous experiment (Landolt et al., 1985). Optimum response rates in the arena bioassay were obtained at 0.1- and 1-μg doses.

In the wind-tunnel dose–response experiment, summarized in Table 2, the

TABLE 1. PERCENTAGE OF FEMALE PAPAYA FRUIT FLIES RESPONDING TO DOSES OF SYNTHETIC 2,6-MVP IN ARENA BIOASSAY ($N = 15$)

Dosage (μg)	Walking (%)	Running (%)	Flying (%)
0.0	80	0	20
0.01	90	50	30
0.1	100	100	90
1.0	100	90	100
10.0	100	70	70
100.0	100	100	80

first significant responses were attained at the 10 μg dose, with a sharp reduction in the activation time and an increase in the number of females tracking the plume and hovering in the plume near the septum. The peak response was attained with the 1-mg dose, which gave a 53% response rate for close-range hovering and 33% for landing. The 100-μg dose elicited 29% close hovering and 22% landing.

Release rate data from septa loaded with 100 μg and 1 mg of 2,6-MVP were obtained at 0.5-hr intervals over a 2-hr period that commenced 24 hr after loading. These data were subjected to linear regression analysis. A linear curve fit of the data for the 1-mg load resulted in the equation: release rate (ng/hr) = 602 − 2.5X (where X = time in minutes after commencing release rate measurement). Similarly, the equation for the 100-μg load was: release rate (ng/hr)

TABLE 2. MEAN TIME TO TAKE FLIGHT FROM RELEASE VIAL AND PERCENTAGES OF FEMALE PAPAYA FRUIT FLIES RESPONDING TO SYNTHETIC 2,6-MVP ON RUBBER SEPTA IN WIND-TUNNEL BIOASSAY ($N = 45$)[a]

Dosage (μg)	Time to flight (sec)	Plume tracking (%)	Close hovering (%)	Landing (%)
0	64.0c	0.0a	0.0a	0.0a
1	49.1c	0.0a	0.0a	0.0a
10	24.6b	26.7b	22.2b	11.1ab
100	12.9ab	40.0bc	28.9b	22.2bc
1000	13.4ab	60.0c	53.3c	33.3c
10000	5.1a	42.2bc	40.0bc	13.3ab

[a] Means in the same column followed by the same letter are not significantly different by Duncan's new multiple-range test ($P = 0.05$).

$= 93.6 - 4.5X$. While this release rate curve indicates a fairly rapid decrease in the rate of release over the 1- to 2-hr period during which the response of females to a septum was being tested, the release rate of 2,6-MVP from a 100-μg loaded septum is approximately the same as that from a calling male PFF.

To obtain a more accurate quantitative comparison of female responses to calling males with that to synthetic pheromone, neat 2,6-MVP was dispensed from glass capillary pipets to give a constant release rate of 300 ng/hr, approximately the same as the release rate, from four calling males (about 63 ng/hr per male). The responses of the females in the wind tunnel to both pheromone sources were similar. Sixty percent of the females entered zigzagging upwind flight and 40% hovered near the pipe vent in response to synthetic 2,6-MVP, vs. 55% and 20% for the same responses to pheromone from four calling males.

The response of male papaya fruit flies was also tested in the wind-tunnel bioassay using the 1-mg dosage. No response was evident in testing the males ($N = 10$), either as a general increase in activity, upwind movement, or orientation. Additionally, synthetic 2,5-MVP did not elicit pheromone responses from mature unmated females in a dose–response test conducted in the arena bioassay or the wind tunnel.

We conclude from the results of these bioassays that 2,6-MVP is a sex pheromone of the papaya fruit fly and is attractive to mature unmated females at a distance. Response rates were similar to those observed to natural material

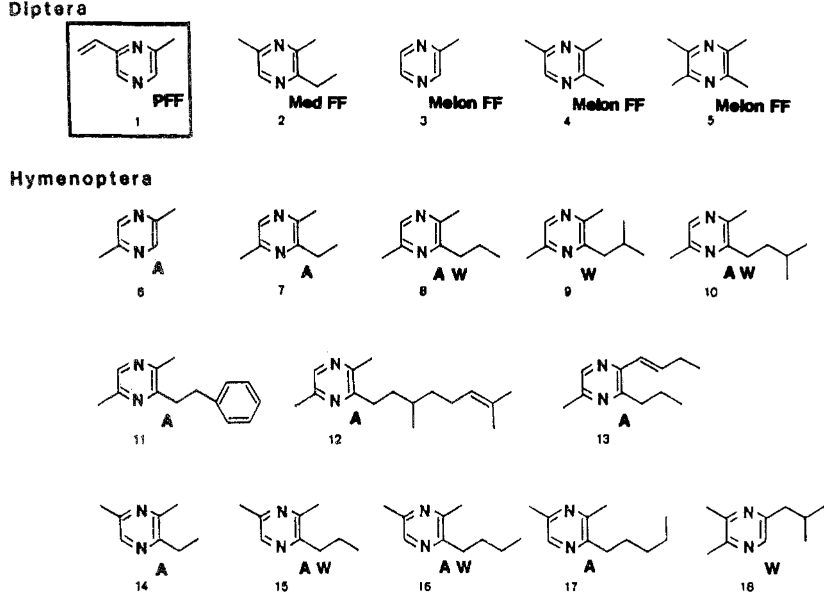

FIG. 5. Pyrazines from insects; FF = fruit flies, W = wasps, A = ants.

vented from calling males and thus the presence of other components is not indicated.

Previously, various alkylpyrazines (Figure 5) have been reported as mandibular and poison gland secretions from ants and wasps (Figure 5, 7–18) (Wheeler et al., 1982), and as trail pheromones of ants (6 and 7) (Attygalle and Morgan, 1984). Although pyrazines have been reported in the volatile components from male *Ceratitis capitata* (Wied.), the Mediterranean fruit fly (2) (Baker et al., 1985), and as rectal gland secretions of male *Dacus cucurbitae* Coquillett, the melon fruit fly (3–5) (Baker et al., 1982), the biological roles of these pyrazines were not determined. Also, 2-methyl-6-vinylpyrazine was reported as a flavor component of coffee (Bondarovich et al., 1967; Goldman et al., 1967) and roasted filberts (Kinlin et al., 1972). We present the first evidence that 2-methyl-6-vinylpyrazine is used in an insect communication system as a sex pheromone, which appears to function as a long-distance attractant.

CUTICULAR HYDROCARBONS REGULATE MATE RECOGNITION, MALE AGGRESSION, AND FEMALE CHOICE OF THE ROVE BEETLE, *Aleochara curtula*

K. PESCHKE

Zoologisches Institut III der Universität Würzburg
Röntgenring 10, D-8700 Würzburg, F.R.G.

(Received April 1, 1986; accepted November 24, 1986)

Abstract—Immature, starved, or multiply mated males of the staphylinid beetle, *Aleochara curtula*, mimic their females chemically. The titer of the female sex pheromone components (Z)-7-heneicosene and (Z)-7-tricosene was quantified for various physiological types and both sexes by gas chromatography and correlated with the sexual response of males towards the cuticular hydrocarbon fractions. Modulation of intermale aggression by production of the female pheromone was shown by (1) reduction of the alkene titer of females kept at elevated temperatures, (2) treating live males with the synthetic female pheromone mixture, and (3) gradual amputation of male antennal segments. *A. curtula* males do not fight against members of other *Aleochara* species with a different hydrocarbon pattern. Contamination of *A. peschkei* males with the hydrocarbon fraction of *A. curtula* males, however, provoked the release of aggression. Choosy females reject mating attempts of males bearing the female sex pheromone.

Key Words—*Aleochara curtula*, Coleoptera, Staphylinidae, female sex pheromone, cuticular hydrocarbons, chemical mimicry, male aggression, female choice.

INTRODUCTION

In many insect species particular components of the cuticular hydrocarbons are used as female sex pheromones (for review see Howard and Blomquist, 1982; Jallon, 1984). Other communicative functions of surface hydrocarbons like caste recognition in social insects are mediated by the complex pattern of many compounds that vary in chain length, methyl branching, or unsaturation (Lok et al., 1975; Howard et al., 1978, 1982a; Clement and Lange, 1984). Deceptive in-

0098-0331/87/1000-1993$05.00/0 © 1987 Plenum Publishing Corporation

formation is emitted by termitophilous or myrmecophilous beetles, mimicking the pattern of their hosts' cuticular hydrocarbons (Howard et al., 1980, 1982b; Vander Meer and Wojcik, 1982).

Chemical female mimicry by hydrocarbon pheromones has been demonstrated for males of the carrion-inhabiting rove beetle, *Aleochara curtula* (Goeze) (Peschke, 1985, 1987). (Z)-7-Heneicosene and (Z)-7-tricosene were identified as main components of the female sex pheromone (Peschke and Metzler, 1986). As measured only in a bioassay (Peschke, 1985, 1987), various physiological types of *A. curtula* males also elicit homosexual responses of other males by means of aphrodisiacs, and such behavior correlates with the avoidance of severe intermale aggression, which may lead to mechanical injuries, contamination with the toxic defensive secretion (Peschke and Metzler, 1982), and expulsion from the carcass. By female mimicry, however, the males get access to the carrion as a feeding and mating site (Peschke et al., 1987). The chemical identity of male releasers of homosexual responses with the female sex pheromone has so far only been demonstrated for immature beetles (Peschke, 1985). In the present paper, we report the chemical quantification of the alkene pheromone titer for other *A. curtula* individuals of various sex and physiological status, such as age, nutrition, previous copulations, and body size.

The evident positive correlation of the release of male homosexual responses by producing the female sex pheromone with the reduction of intermale aggression was confirmed by three sets of experiments: (1) The chemical information output of the females was affected by reducing their alkene pheromone content by keeping the beetles at elevated temperatures. (2) The chemical information output of the males was modified by contamination with the synthetic female pheromone mixture. (3) The sensory input of males was manipulated by gradual amputation of antennal segments.

Although the modulation of male contest by the female sex pheromone is fairly well understood, the essential releasers of aggression are unknown. Therefore, experiments on the role of the species-specific hydrocarbon composition in the recognition of male competitors have been conducted. We investigated the behavioral responses of *A. curtula* males towards other *Aleochara* species with different hydrocarbon patterns and the effect of their chemical manipulation.

While males releasing homosexual responses are protected from assaults of other males, females repulse mating attempts of these mimicking males. In this way they choose physiologically competent, nonmimicking males, which are capable of withstanding the aggressive interactions at the mating site and of transferring a large spermatophore (Peschke, 1985, 1987). In order to prove the hypothesis that female sex pheromone components also act as releasers of female repulsion behavior, we manipulated the chemical information output of males by contamination with the synthetic pheromone mixture.

METHODS AND MATERIALS

Field Collections and Laboratory Cultures

A. curtula (Goeze) and *Philonthus politus* (L.) were collected at rabbit carcasses in deciduous forests near Ochsenfurt, Bavaria (Peschke et al., 1987). *Aleochara (Euryodma) brevipennis* (Grav.) originates from the "Zeubelrieder Moor" (Ochsenfurt) and the Bodensee (fish bait). The species co-occurs with *A. curtula* on carcasses in middle Europe (Peschke and Fuldner, 1977). *A. peschkei* (Likovsky, 1983) was collected from fish carcasses from the banks of the river Comoe (Ivory Coast, West Africa).

These *Aleochara* species were continuously reared in the laboratory according to Fuldner (1968) and Peschke (1978, 1987) with puparia of *Calliphora erythrocephala* (Meig.) or *Lucilia sericata* (Meig.) serving as hosts for the parasitoid larvae (Peschke and Fuldner, 1977). Small beetles were obtained by using small puparia as hosts. Males were kept in groups of 10 in plastic boxes of 10 × 10 × 7 cm. Individual beetles and single pairs were kept in boxes of 5.5 × 3.5 × 1.5 cm. Three times a week, the beetles were transferred to freshly prepared boxes with moist filter paper and cut third-instar *Calliphora* maggots as food. Sexually isolated and well-fed beetles of both sexes at an age of 3 weeks were termed "standard laboratory beetles." The normal temperature and light regime were 22°C and 16:8 hr light–dark. Starved males were kept individually in order to avoid cannibalism.

Chemical Methods

Extracts were prepared according to Peschke and Metzler (1986). Thirty to 100 beetles were killed by freezing and extracted in 200 ml methylene chloride in a Soxhlet apparatus for 24 hr. The hydrocarbon fraction was purified on a silica gel column.

Gas chromatography was also conducted according to Peschke and Metzler (1986) on a Varian 3700 instrument with a 30-m DB-1701 capillary column (split 1:10, 1 ml He/min, 60°C to 300°C at 3°C/min, flame ionization detector). Quantitative measurements were carried out with a Kontron-Anacomp 220 computer system. The concentrations of the two pheromone alkenes were determined by using the corresponding *n*-alkanes as internal standards of constant titer and then related to the pheromone content of standard laboratory females [1 female equivalent (FE) (Z)-7-heneicosene = 2 μg, 1 FE (Z)-7-tricosene = 12 μg; Peschke and Metzler, 1986]. Both alkenes were synthesized according to Peschke and Metzler (1986). Some samples were also obtained from Dr. L.L. Jackson (Bozeman, Montana). For comparison of hydrocarbon patterns, we calculated the equivalent chain length for methyl-branched alkanes and plot-

ted the cumulative distribution functions of compounds versus increasing chain length (Hadley, 1977; Toolson and Hadley, 1977).

Behavioral Responses

At a distance of about 2.2 mm from the female, the male bends his mobile abdomen over his head and protrudes the genitalia with the tong-shaped parameres (grasping response; Peschke, 1978). Male aggression is characterized by pushing the opponent with head and mandibles and by drumming with the mobile abdomen on the other individual. Females that repulse the male grasping response do so by oscillating their mobile abdomen thereby avoiding the fixation of the male genitalia. In neutral encounters of two individuals, no conspicuous behavior could be observed (Peschke, 1987).

Bioassays

The sexual response of *A. curtula* males to the purified hydrocarbon fractions of beetles of various physiological status was tested in the model bioassay (Peschke, 1978). Soxhlet-extracted odorless beetles were glued to the tips of glass needles and treated with *n*-pentane solutions of 0.01 ml containing one beetle equivalent. The number of standard tester males responding to the model with the grasping response was specified in percentiles and statistically evaluated by the χ^2 test or the exact test of Fisher (Sachs, 1984). Confidence limits were calculated for the 95% level.

Beetles of both sexes and various physiological status were observed as single pairs in plastic boxes of 5.5 × 3.5 × 1.5 cm for a period of 30 min. The individuals were marked by dots of enamel paint on pronotum and both elytra. We recorded whether a certain behavioral response was seen at least once during the observation period, or we registered all encounters of beetles and specified the percentage in which a certain behavior was shown. Living beetles were treated with extracts or synthetic chemicals: 0.01 ml pentane solutions with one beetle equivalent concentration were applied to the pronotum of a chilled individual (6°C). As a control, beetles were treated with the pure solvent. One hour after contamination, the beetles were brought together and the pair was observed for 30 min as usual.

Antennal segments or palps of males 7 days old were cut off using pincers which were sharpened like scissors. Scapus and pedicellus were counted as segments 1 and 2, the flagellar segments as 3–11. After a further week, males of normal agility were observed individually together with single females (30 min).

For observation of interspecific reactions of beetles under natural conditions, we used an arena of 50 × 50 cm, in the center of which a small piece of carrion was placed (beef liver with *Calliphora* maggots, covered by a dish of

red glass; for details see Peschke, 1987). Individually marked *A. curtula* males and females (five each) were put together with five males and five females of another species (*A. brevipennis*, *A. peschkei*, and *Philonthus politus*). The beetles were observed at the carcass with a red-sensitive camera in a natural rhythm of white and dark red light (18:6 hr light–dark). The behavioral events at the carcass were recorded for 3 min every 60 min at normal speed over a period of 24 hr. For each encounter of two beetles, we recorded whether aggression, grasping, or neutral behavior was exhibited by *A. curtula* males.

RESULTS

Sex Pheromone Content in Beetles of Various Sex and Physiological Status

In former investigations (Peschke, 1985, 1987), all bioassays for testing pheromone contents had been conducted with entire beetles freshly killed by freezing. In the present experiments, sexual responses were also elicited by the purified total hydrocarbon fraction from extracts of females and males of various physiological status (model bioassay; Figure 1).

The cuticular hydrocarbon fraction from females collected in the field released the male sexual response at the same high rate as did extracts from standard laboratory females, from females just after copulation, and from those of small body size (Figure 1). Freshly emerged females yielded a somewhat lower grasping rate. The grasping response rate was drastically reduced by exposing the females to elevated temperatures (14 days at 27°C).

High behavioral release rates were also obtained with extracts from males captured in the field. The hydrocarbon fraction from young, starved, or multiply mated laboratory males also elicited homosexual grasping responses (Figure 1). On the other hand, hydrocarbons from sexually isolated, well-fed males reared in the laboratory did not trigger homosexual grasping responses, regardless of temperature (22°C or 27°C) and body size (large standard beetles: breadth of pronotum 2.0 $\pm$ 0.02 mm, small beetles: 1.4 $\pm$ 0.03 mm).

The quantitative determination of components of the hydrocarbon fractions used in the former bioassay gave a good correlation of grasping rates with the contents of (*Z*)-7-tricosene (Figure 1). Parallel to the determination of amounts (in micrograms), we preferred the scaling in terms of female equivalents in order to obtain a more lucid comparison of pheromone contents of mimicking individuals with that of standard laboratory females (defined as 1 FE). Females of various physiological status, apart from young beetles, had a constantly high tricosene content. In females kept at elevated temperatures, only trace amounts of this compound could be detected. Standard laboratory males had a concentration of 10^{-3} FE tricosene irrespective of their body size and the temperature at which they had been reared. Young, starved, and multiply mated males, however, yielded tricosene contents ranging from 0.08 to 1 FE.

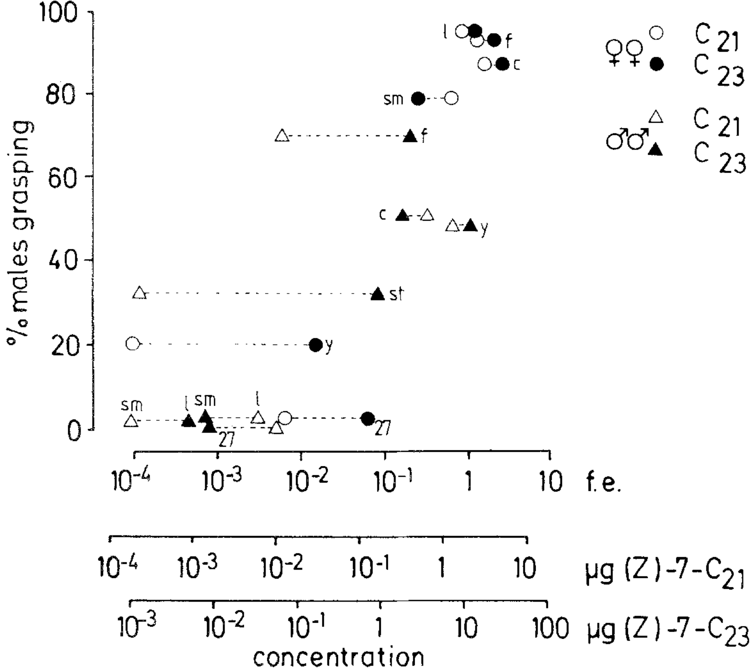

FIG. 1. Grasping response of *A. curtula* males towards models contaminated with one beetle equivalent of the total cuticular hydrocarbon fraction from extracts of males (triangles) and females (circles) of various physiological conditions: l: laboratory standard females (sexually isolated, well fed, 22°C); f: field-collected beetles; y: freshly emerged beetles; st: mature beetles starved for a period of 10 days; c: one copulation at the day of extraction; 27: beetles kept at elevated temperatures (27°C); sm: beetles reared on a small host. Thirty to 100 beetles were used per extraction; at least 100 males were tested for grasping in five replicates per sample. The grasping rate is plotted against the concentrations of the two pheromone compounds (Z)-7-heneicosene (open symbols) and (Z)-tricosene (solid symbols) in the hydrocarbon fraction as determined by quantitative gas chromatography. The concentration is scaled in terms of female equivalents as related to the content of laboratory standard females (= 1 FE). Because the combined action of compounds was tested in the bioassay, one value of grasping rate refers to two values of concentration of both pheromone compounds, which are linked by a dotted line.

The grasping rate is correlated with the concentration of (Z)-7-heneicosene in a similar way (Figure 1), except in the cases of field-collected or starved males and of young females, which release male sexual responses but have a low or even undetectable titer of the C_{21}-alkene. In these cases, the tricosene alone seems to be responsible for the release of the homosexual grasping response. Heneicosene could also not be detected in small males and males kept at 27°C.

Modulation of Male Aggression by Female Sex Pheromone

In the experiments described above, we demonstrated a correlation of homosexual responses with the production of female sex pheromone components by males. In the following experiments, the sex-specific chemical information was manipulated in order to investigate the correlation of female pheromone production with the release of male aggressive behavior.

Temperature Experiment. Males and females kept at 22°C or 27°C were observed as single pairs in various combinations (Table 1). As in the experiments with extracts, females kept at 27°C did not release male grasping at any encounter. On the other hand, the reduction of pheromone titer in females kept at elevated temperatures provoked a high aggression rate of males towards these females. The behavioral sequence was not different from that observed in intermale combats.

Contamination of Males with Synthetic Female Pheromone Mixture. A reduction of the release of aggression was demonstrated in observations (30 min) of pairs of males, to one of which the hydrocarbon fraction of a female surface washing had been applied; to the other, the pure solvent (Table 2). The male bearing the female pheromone attacked the other male in a high percentage of encounters, whereas the male without the pheromone only occasionally behaved aggressively towards the treated male. The treated male, however, released a high rate of homosexual graspings.

The same tendencies were observed when one male was contaminated with 1 FE of the synthetic female sex pheromone (Table 2). The rate of aggression is drastically reduced towards the treated male; however, more neutral encounters than homosexual grasping responses were observed in comparison to experiments with the total female hydrocarbon fraction.

Amputation of Male Antennal Segments. Males with their antennae amputated to various degrees were observed together with females during a 30-min period. The number of males exhibiting the grasping response towards

females was not reduced as long as four antennal segments were left (Figure 2). The next step of amputation (three segments left), however, gave a significant decrease of the grasping rate, which was continued with removal of further antennal segments or palps. Coincidentally with the stepwise decrease of sexual responses, the percentage of males behaving aggressively towards females increased, with a peak rate obtained when only the scapus was exempted from amputation. The rate of aggression was then decreased with further steps of removal of antennal segments and palps.

Releasers of Aggression

Sexual behavior as well as male aggression can be manipulated by the female sex pheromone titer. However, the simple absence of the female sex pheromone may be a signal for males to fight against another individual, or species-specific signals that may be other cuticular hydrocarbons may release male aggression. While in the former experiments the concentration of pheromone alkenes has been shown to vary considerably between the sexes, the saturated hydrocarbons have a very constant distribution (Peschke, 1985; Peschke and Metzler, 1986). The cumulative frequency function of the equivalent chain length of saturated hydrocarbon components also shows a very similar pattern for both sexes of *A. curtula* (Figure 3). In contrast, cuticular hydrocarbons of male *A. brevipennis* or *A. peschkei* have a distribution very different from that

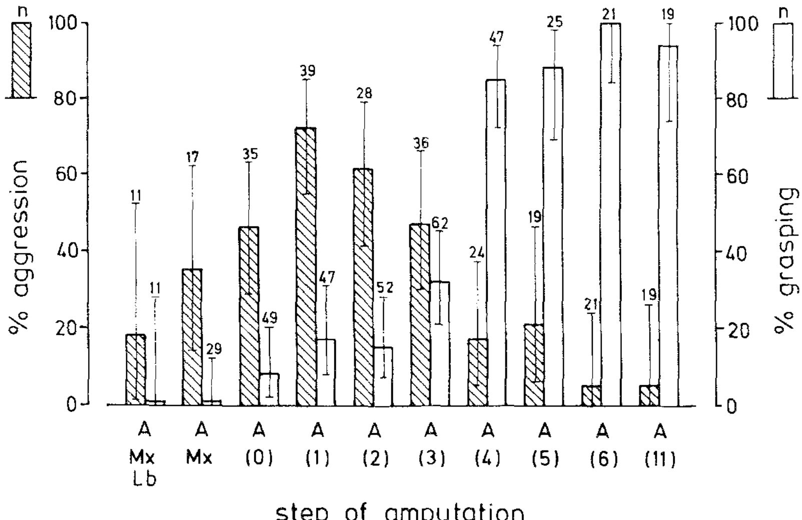

FIG. 2. Behavioral responses (grasping, aggression) of *A. curtula* males (various steps of symmetrical amputation of antennal segments and palps) to standard females during a 30-min observation (percent pairs showing the response at least once). Steps of amputation: A: antenna (in parentheses number of segments exempted from amputation, A11: control), Mx: maxillar palps; Lb: labial palps. Vertical bars: 95% confidence limits; n: number of pairs).

of *A. curtula*. Most noteworthy is the shift to higher carbon numbers and the total absence of C_{21} and C_{23} hydrocarbons. The identification of components of *A. brevipennis* and *A. peschkei* by mass spectrometry with the original gas chromatograms will be published elsewhere (Peschke and Metzler, in preparation).

A. curtula males and females were put together with individuals of other species in the video observation setup. *A. brevipennis* released a few grasping responses of *A. curtula* males (Table 3) which might be due to unsaturated C_{27} hydrocarbons. Aggression of *A. curtula* males against *A. brevipennis* individuals of both sexes was observed at an intermediate level. *A. peschkei* did not release interspecific grasping or aggressive responses of *A. curtula* males. Individuals of both sexes of *Philonthus politus*, a distantly related species from another subfamily of rove beetles (Staphylininae instead of Aleocharinae), also failed to provoke either aggression or sexual responses of *A. curtula* males (Table 3).

In conclusion, male aggression of *A. curtula* seems to be released by species-specific chemical cues, probably involving the saturated hydrocarbons of the cuticle. This hypothesis is supported by experiments with *A. peschkei* males contaminated with the hydrocarbon fraction of male *A. curtula* extracts (Table

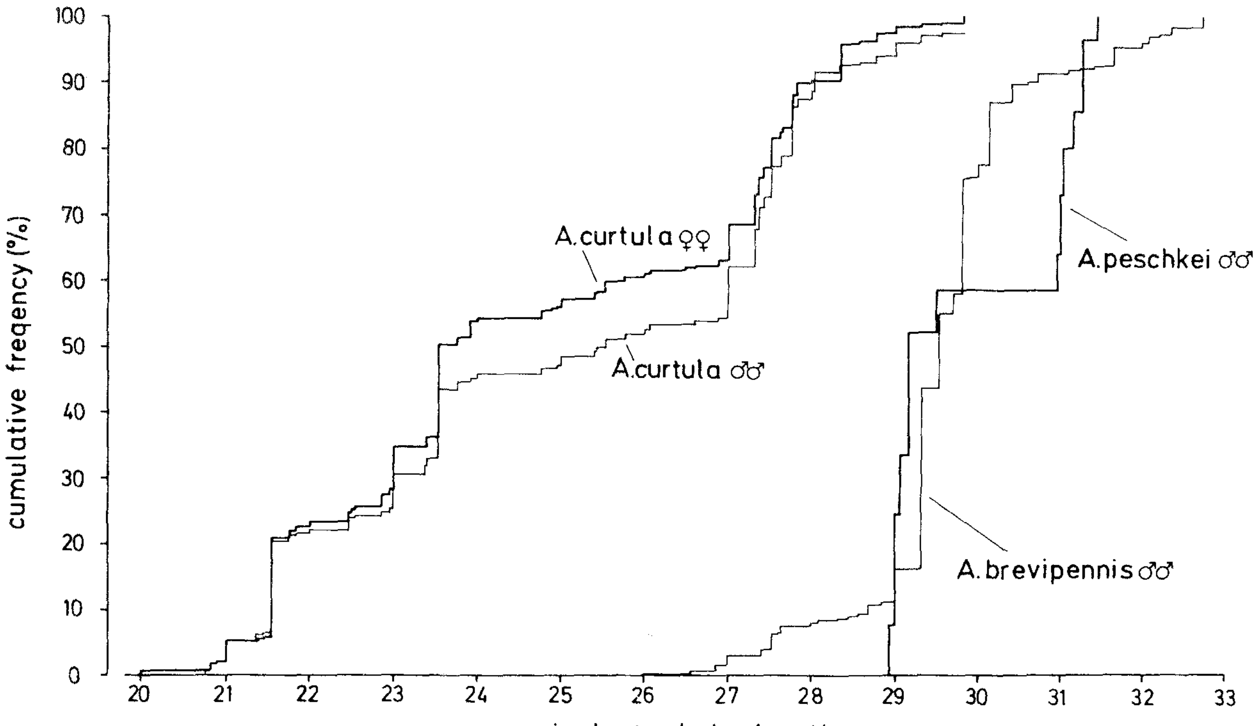

FIG. 3. Cumulative distribution functions of cuticular hydrocarbons of various equivalent chain lengths of carrion-inhabiting *Aleochara* species (*A. curtula* males and females; males of *A. brevipennis* and *A. peschkei*).

males, they are more often repulsed by the female, who drums with her abdomen and thus avoids the fixation of male genitalia (Peschke, 1987). In order to investigate the releasers of female repulsion behavior, males were contaminated with 1 FE of the synthetic mixture of the female pheromone (Table 5). The treated males did not show an alteration in their own sexual response to females as measured by the grasping response rate during a 30-min observation period. On the other hand, the repulsion behavior of females towards such treated males is significantly increased.

DISCUSSION

Female mimicry in vertebrates using chemical (Mason and Crews, 1985) or behavioral and morphological cues (for review see Weldon and Burghardt, 1984) has been described for many species. Stealing sneaky copulations, avoidance of intermale aggression, and access to other males' territories are discussed as the main benefits of mimicking males. Behavioral transvestism in insects has only been described for scorpion flies where males behave like females in order to steal the nuptial gifts of other males (Thornhill, 1979).

Certain physiological types of males of the rove beetle, *Aleochara curtula*, mimic their females chemically in order to avoid intermale aggression. In this way they get access to a carcass and are able to feed on blow fly maggots in order to replenish their energy reserves for a forthcoming reproductive cycle (Peschke, 1987). On the other hand, females prefer males without the female pheromone. The adaptive significance of female coyness towards mimicking males seems to be the choice of an optimal mate: immature, starved, or multiply mating males, which all produce the female sex pheromone, need access to the

food resource; they transfer only small spermatophores and fertilize less eggs. On the other hand, physiologically competent males without the female sex pheromone have succeeded in numerous aggressive interactions with other males (Peschke, 1987).

(Z)-Heneicosene and (Z)-7-tricosene have previously been isolated and identified from mature *A. curtula* females as the main sex pheromone components (Peschke and Metzler, 1986). The pheromone molecules are components of the epicuticular waxes and are spread over the entire surface of the beetles (Peschke, 1978, 1986). Male antagonistic pheromones, which might be involved in the regulation of sex specificity of the pheromone information, could not be detected (Peschke, 1986). In the present work the pheromone alkenes were also found in the cuticular hydrocarbons of those males which release homosexual responses, e.g., young, starved, or multiply mated beetles. All these physiological types of males are mixed up in field collections (Peschke et al., 1987), where they also bear the female sex pheromones. Small males, which perform an alternative mating tactic as satellites in the surroundings of carrion (Peschke, in preparation), do not produce the female sex pheromone for protection.

The contents of the two pheromone components in various physiological types and both sexes of *A. curtula* range over three powers of 10 and are correlated with the release of male sexual responses. In most samples, both compounds contribute to the releasing effect of the total hydrocarbon fraction. In some cases, tricosene alone seems to be responsible for the release of sexual responses. In tests of individual synthetic substances, tricosene had its optimum at about 0.1 FE, whereas heneicosene released more sexual responses at the higher concentration of 1 FE (Peschke and Metzler, 1986). It is therefore difficult to quantify the contribution of the individual pheromone component to the releasing efficiency of the total hydrocarbon mixture of each physiological type. The combination of both compounds had no synergistic, only an additive, effect; the admixture of (Z)-9-heneicosene or (Z)-9-tricosene, which are produced together with the respective 7-isomers but have only little releasing efficiency (Peschke and Metzler, 1986), did not produce an antagonistic action (Peschke, in preparation).

Differences in the release of grasping rates towards synthetic compounds or towards the total hydrocarbon fraction containing the same amounts of pheromone components may be due to retardation of evaporation by the accompanying saturated hydrocarbons in the latter case (Peschke, 1986). This effect may also be responsible for different responses towards contaminated living males. Homosexual grasping is released at a lower rate after contamination with the synthetic pheromone mixture in comparison to males treated with the total hydrocarbon fraction of females. However, the aggression rate is reduced to the same extent in both cases. Individual (Z)-7-heneicosene and (Z)-7-tricosene

both contribute to the reduction of intermale aggression (Peschke, in preparation).

The modulatory effect of the female sex pheromone on the release of male aggression was also demonstrated by manipulation of the chemical information output of the female. Females which have been exposed to elevated temperatures show a significantly reduced content of cuticular alkenes in comparison to that of saturated compounds. This may be due to differential evaporation of saturated and unsaturated compounds. However, it cannot be excluded that the beetles actively alter the pattern of hydrocarbon synthesis at different temperatures (see Hadley, 1977; Toolson and Hadley, 1977). Males behave aggressively towards these females in the same way as towards other males.

A further indication of the modulatory effect of pheromone alkenes is the gradual increase of aggression accompanied by a decrease of sexual recognition with successive amputation of male antennal segments. In a preliminary investigation of the antennal morphology of *A. curtula* (Ungelenk and Altner, unpublished), no sex specific sensilla or striking quantitative difference in the distribution and number of various types could be found. The pattern of densely packed sensilla seems to be repeated in segments 5–11, whereas scapus, pedicellus, and the two proximal flagellar segments bear only a few sensilla. It seems likely that the sex pheromone information is perceived by numerous receptor organs sequentially distributed on the distal antennal segments. Removal of them gradually diminishes the input of sex pheromone information, whereas information on aggression-releasing chemicals, probably the saturated hydrocarbons, still can be perceived. Further steps of amputation reduce this input too. However, electrophysiological investigations of pheromone perception in *A. curtula* are urgently needed.

Females of *A. curtula* are apparently able to perceive the female sex pheromone too. However, the female behavioral response elicited by these chemicals, the release of aggressive repulsion of male mating attempts, is the reverse of the male reaction where aggression is reduced.

The releasers of intermale aggression of *A. curtula* may comprise components of the saturated hydrocarbon mixture that are present in both sexes. The shift to longer carbon chains in related species reduces aggression of *A. curtula* males; on the other hand, contamination of males of the other species with hydrocarbons of *A. curtula* males, which do not contain female pheromones, provoked intermale combats. At present, synthetic methyl-branched alkanes are not available, and therefore it is not possible to determine yet whether individual *n*-alkanes, methyl-branched alkanes, or the complex pattern of compounds of variable chain lengths serve as the releasers of male aggression. Saturated hydrocarbons modulate the information of alkenes acting as female sex pheromones in several muscid flies (e.g., Rogoff et al., 1980; Sonnet et al., 1975, 1977; Uebel et al., 1975a, b, 1976), or represent the major female pher-

omones, for example, in tsetse flies (e.g., Carlson et al., 1978; Huyton et al., 1980a, b) or butterflies (Grula et al., 1980).

Acknowledgments—I am very grateful to Mrs. C. Gantert for technical assistance. Thanks are due to Prof. Dr. L.L. Jackson and Prof. Dr. M. Metzler for synthetic pheromone compounds. I wish to thank Dr. A.E. Jürss for reading the English manuscript. This work was supported by the Deutsche Forschungsgemeinschaft (Pe 231/3 and 4).

INTERACTIONS OF ALKALOIDS WITH GALEAL CHEMOSENSORY CELLS OF COLORADO POTATO BEETLE

B.K. MITCHELL

Department of Entomology
University of Alberta
Edmonton, Alberta, Canada T6G 2E3

Abstract—The galeal chemosensory system of the adult Colorado potato beetle was used as a model to study the effects of alkaloids on insect gustation. Nine alkaloids, representing a wide range of structural types, were used. Their ability to stimulate chemosensory cells when presented in isolation and their ability to interfere with normal chemosensory processes were emphasized. None of the alkaloids stimulated chemosensory cells in a dose-dependent manner, although a few stimulated low-level activity from some cells. There was no evidence for a general "deterrent receptor" in these beetles. Some of the alkaloids had a marked inhibitory effect on normal chemosensory responses. Tomatine, solanine, papaverine, and sparteine significantly inhibited responses to amino acids (represented by GABA) while quinine and papaverine inhibited responses to sucrose. An attempt was made to correlate neurophysiological action of some alkaloids with their effects on feeding behavior. It was clear from this correlation that even a dramatic inhibition of sensory input by an alkaloid does not necessarily lead to measurable effects on behavior. The results are discussed in the context of current theories on the mode of action of alkaloids and other secondary plant compounds which may be involved in host recognition by phytophagous insects.

Key Words—*Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, Colorado potato beetle, deterrent receptor, feeding deterrents, alkaloids, sugar receptor, amino acid receptor, chemoreception, steroidal alkaloids, antifeedants.

INTRODUCTION

Alkaloids represent one class of plant compounds that have come to be considered secondary because of the difficulty encountered in discovering a role for them in primary plant metabolism. The idea that secondary plant compounds

0098-0331/87/1000-2009$05.00/0 © 1987 Plenum Publishing Corporation

might be important in protecting plants against natural enemies has generated a working hypothesis which suggests that insect herbivores will not feed on most plant species because of the presence of secondary compounds which inhibit feeding. One of the earliest and most comprehensive statements of this hypothesis came from Jermy (1961, 1966). More recently, several review papers have been published in which the relationships among secondary compounds, feeding deterrency, and chemoreception are discussed (Dethier, 1980, 1982; Jermy, 1983; Schoonhoven, 1982).

While it is clear from these papers that we now realize chemical messages signaling acceptance and nonacceptance are complex, the ideas of "specific deterrent receptors" (Schoonhoven, 1982); generalist receptors for deterrents, with the central nervous system responsible for decoding a complex message (Dethier, 1980); and an "inhibitory biochemical profile" for recognition of nonhost plants (Jermy, 1983) are given prominence. Implicit in each of the above hypotheses is the existence of receptors (in the pharmacological sense) evolved to interact with secondary plant compounds. These receptors may be found primarily on a cell which sends a negative message to the central nervous system (the so-called deterrent receptor) or they may be found spread variously over the membranes of a number of sensory cells requiring the central nervous system to decode the complex message. These ideas are largely based on data obtained from larvae of a number of lepidopteran species.

An additional hypothesis, which appears to better fit existing data on chrysomelid beetles, puts more emphasis on the general bioactive nature of many plant secondary compounds. Mitchell and Sutcliffe (1984) suggest that these compounds may not normally require a particular receptor type (specific or general) in order to have an effect. Instead, they may only need to be "capable of interfering with processes that are generally found in excitable membranes." These processes include receptors (in the pharmacological sense) for feeding stimulants as well as basic membrane properties associated with maintenance of a resting potential and production of a generator potential or an action potential.

The Colorado potato beetle, *Leptinotarsa decemlineata* (Say) has been important in the development of ideas concerning the role of plant secondary compounds as feeding deterrents. Considerable effort has so far failed to reveal specific feeding stimulants which could account for the clear recognition of several solanaceous species as host plants by this insect (Ritter, 1967; Hsiao, 1968). On the other hand, the steroidal glycoalkaloids of the Solanaceae are well known, and the concept of host-plant selection by avoidance of deterrents has been associated with the Colorado potato beetle for some time. Because the suggested influence of alkaloids on plant avoidance by this beetle is generally accepted, its chemoreceptors provide an excellent system on which to test the various hypotheses discussed above.

In an earlier study (Mitchell and Harrison, 1985), we attempted to determine if the galeal chemosensory system of the adult Colorado potato beetle had cells sensitive to steroidal glycoalkaloids which could be interpreted as deterrent cells. Such cells were not found in this sensory field, instead the alkaloids elicited nonspecific responses from many cells, and caused at least short-term loss of sensitivity. The effect was similar to that caused by other surfactant chemicals such as saponins, and no differences were observed among effects of tomatine, solanine, and chaconine. In this paper, the possibility of alkaloid interactions with the stimulants sucrose and α-amino butyric acid (GABA) is addressed, together with an extension of the search for specific responses to alkaloids in this chemosensory system. In addition, an attempt is made to relate observed effects of some of these compounds on chemosensilla to their influence on feeding behavior in a complex sensory environment.

METHODS AND MATERIALS

Adult insects of both sexes were used for sensillar recording. To keep variability to a minimum, recordings were always made from adults which had emerged within 24 hr of the time of the experiment. Beetles were from a laboratory colony that is continuously maintained on fresh cut leaves of *Solanum tuberosum*. Wild *L. decemlineata* are collected each summer in the Edmonton area and added to this culture. Details of the rearing technique are provided in Mitchell and Harrison (1984) and in Harrison (1985).

Only the apical chemosensitive pegs on the galea of the maxilla were considered. This chemosensory field consists of 11–15 peg-like sensilla, usually with four chemosensory cells per peg (Sen and Mitchell, 1987). One of the sensilla in this field was termed the α-sensillum by Mitchell and Harrison (1984) because its sensitivity to amino acids was much greater than that of other galeal sensilla. Because of this sensitivity difference, the study of alkaloid interaction with GABA was conducted using the α-sensillum exclusively. All galeal chemosensilla have equal sensitivity to sucrose (Mitchell and Harrison, 1984). The tip-recording method originally described by Hodgson et al. (1955) was used throughout. The galeal sensilla studied have a very low sensitivity to NaCl and KCl, with concentrations as high as 150 mM stimulating very little activity. This feature allows a wide choice of saline concentrations for the carrier solution in the stimulating–recording electrode. In this study 50 mM NaCl was used. This concentration of salt rarely stimulates any activity from galeal chemosensilla in this insect. Alkaloids were dissolved in 50 mM NaCl made up in deionized water (pH approx. 6.7). When necessary (e.g., solanine and tomatine) solvent pH was lowered to 2 in order to dissolve the alkaloid, following which the pH was raised to 5 before testing. No effect related to pH alone in the range

5–7 has been observed (unpublished observations and Mitchell and Harrison, 1985).

Cell injury is always a possibility when working with alkaloids at the concentration used in this study (1 mM). Consequently, no more than three alkaloids were tested on any particular sensillum. In addition, regular applications of 10 mM GABA or sucrose were used to confirm that at least one of the cells in the sensillum was functioning normally during the entire experiment. Deterioration in response or signal-to-noise ratio terminated experiments on a preparation. In tests of alkaloid effect on responses to GABA or to sucrose, paired stimuli (e.g., GABA followed by GABA + alkaloid) were used to keep variability to a minimum. Responses were recorded on magnetic tape using a TEAC four-channel recorder and a Vetter FM recording adapter. Segments of each response were digitized using an Apple II computer fitted with an analog to digital card, and plotted on a Hewlett-Packard digital plotter for analysis and presentation. This system is described in Mitchell and McIntyre (1986).

Adult feeding on water-infused and alkaloid-infused potato leaves was measured using an assay described in Harrison (1985). Briefly, this method uses video analysis of prefeeding behavior and aspects of first meal consumption of individual, newly emerged adult beetles of both sexes. Care was taken to ensure that leaves maintained turgor pressure and other visible characteristics of good health during infiltration and during the feeding test. Analysis of the video data produced a number of measures related to plant acceptance and feeding (Harrison, 1985). For this study the following four were chosen: (1) time (seconds) spent in prefeed maceration activity, this is the first behavior that brings the plant sap into contact with mouthpart sensilla, probably the epipharyngeal sensilla in the upper part of the buccal cavity; (2) percent of beetles which rejected the leaf after some time spent in prefeed maceration behavior; (3) area of leaf consumed during first meal (mm^2, measured with a leaf-area meter), end of a meal was defined as more than 3 mm without feeding following some period of feeding; and (4) feeding rate (area/feeding time). Ten beetles were used in each experiment.

RESULTS

Stimulation with Alkaloids Alone. All the alkaloids shown in Figure 1 were tested at 1 mM for their effects on galeal sensilla. They were each applied to several sensilla on six preparations (four for atropine) using short (1–3 sec) application times. In no cases were there responses resembling the phasic–tonic responses normally obtained from insect chemoreceptors. In some cases a more or less regular, low-level response was elicited from a single cell. This was most consistent for strychnine (six of six animals) and occurred in three of six cases with arecoline, sparteine, and quinine. Atropine, papaverine, caffeine,

tomatine, and solanine did not stimulate any cell in this manner. Irregular, bursting patterns of firing from one or more cells during short applications was seldom observed (four of 52 cases).

Because of the single-cell response in some preparations to 1 mM strychnine, arecoline, sparteine, and quinine, a limited dose–response study was con-

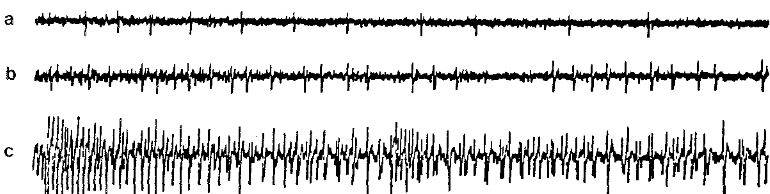

FIG. 2. (a, b) Response to sparteine sulfate (10 mM) from two sensilla on the same preparation. First second of response is shown. (c) burst of multicell activity after 4 sec of stimulation with 5 mM strychnine nitrate. Time bar = 100 msec.

ducted with these compounds. There was no increase in the low-level response over several concentrations between 1 and 10 mM for any of the compounds. Figure 2a and b shows a typical response to 10 mM sparteine sulfate from two preparations. The same four alkaloids were tested in long-term applications (approximately 30 sec). Strychnine and quinine, at 5 mM and 10 mM, elicited bursting activity after several seconds of application (Figure 2c). This activity is reminiscent of the delayed responses caused in this system by 1 mM concentrations of steroidal glycoalkaloids and saponins (Mitchell and Harrison, 1985). The high concentrations necessary to obtain this response with strychnine and quinine make it unlikely that the effect is behaviorally significant.

[b] $P < 0.05$ Mann-Whitney U test. This survey was conducted using 18 adult *L. decemlineata*. Two to three alkaloids were tested per preparation. Multiple amino acid stimulations were distributed throughout the test period and each response to a mixture of GABA and alkaloid was compared to the preceding response to GABA alone.

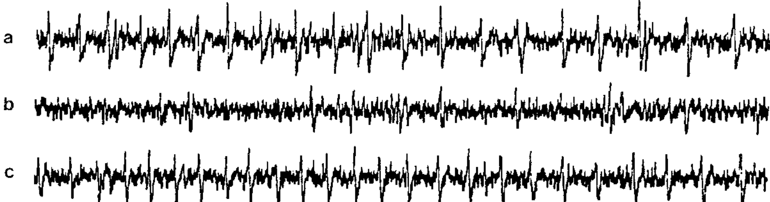

FIG. 3. Response of an α-sensillum to three sequential stimulus applications. (a, c) 10 mM GABA; (b) 10 mM GABA + 1 mM tomatine. Records show responses from 250 to 750 msec following stimulus application. Time bar = 100 msec.

tion of nine alkaloids when applied to the α-sensillum (Mitchell and Harrison, 1984) in the presence of 10 mM GABA. This sensillum contains a cell which is particularly sensitive to GABA and L-alanine, and Mitchell (1985) presents evidence that the same receptor is activated by both of these amino acids. Four of the alkaloids, when present at 1 mM, significantly reduced the response to 10 mM GABA. Tomatine was especially effective, reducing the response nearly fourfold (Table 1 and Figure 3).

The same cell in the α-sensillum responds to sucrose (Mitchell and Harrison, 1984), presumably involving a different receptor site (see Discussion). Most of the alkaloids tested at 1 mM had no significant effect on the response to sucrose, but quinine and papaverine were strong inhibitors (Table 2).

Stimulation of Additional Cells. The ability of these alkaloids to stimulate

cells when presented alone may not necessarily predict their action on additional cells when one cell in the sensillum is already active. Therefore, the ability of alkaloids to stimulate additional cells when the amino acid-sensitive cell was already active was tested using mixtures of 10 mM GABA and 1 mM alkaloid. In some preparations, some alkaloids markedly stimulated additional cells when the amino acid-sensitive cell was active. This type of response was quite variable, but it occurred often enough and was of sufficient intensity when it occurred to warrant quantification. The data are presented in two ways: (1) average activity in non-amino acid-sensitive cell(s) during stimulation with GABA and GABA plus alkaloid are compared (Table 3); and (2) responses from preparations which showed a marked effect of alkaloid on non-amino acid-sensitive cell(s) under these conditions are presented alone (Table 4).

A marked effect was defined as a firing rate >20 impulses/sec from the non-amino acid-sensitive cell(s). During stimulation with GABA alone, spikes from cells other than the amino acid-sensitive cell were sometimes seen. These usually occurred at low frequencies ranging from one to five impulses in the 500-msec sample period (Table 3). Paired applications of 10 mM GABA and 10 mM GABA + 1 mM alkaloid on the same sensillum were used to keep variability to a minimum. Several alkaloids, notably atropine, did stimulate considerable activity in a second cell under these experimental conditions. Ref-

Arecoline	1/4	11
Quinine	1/6	10

[a] A sensitive preparation is defined as one where the non-amino acid-sensitive cell(s) fired at a rate greater than 20 impulses/sec. during stimulation with the GABA–alkaloid mixture.
[b] Impulses counted between 250 and 750 msec of response and expressed as impulses per 0.5 sec.

erence to Table 4, however, shows that most of this additional activity, with atropine present, was produced in the α-sensilla of three of seven preparations. In these three animals, the response of the second cell averaged 26 impulses/sec. Figure 4 shows an example of this type of response. Two of the six preparations also had this kind of sensitivity to strychnine.

Behavioral Response to Alkaloid-Treated Food. Adult beetles, offered healthy leaves infiltrated with one of five different alkaloids, showed a variety of responses. The video bioassay used measured a number of parameters (Harrison and Mitchell, 1988), four of which are given in Table 5. Only atropine and papaverine had significant effects, with atropine being the most potent. Forty percent of adults refused the atropine-treated leaves after a significantly prolonged prefeed maceration time. The 60% which fed did not differ from controls in amount consumed or in feeding rate. Papaverine caused only a re-

duction in amount consumed; other parameters remained indistinguishable from control beetles.

DISCUSSION

Deterrent Receptors. This study and a previous one on steroidal alkaloids and saponins (Mitchell and Harrison, 1984) provide no evidence for a receptor cell, which is sensitive to a wide range of potentially distasteful secondary plant compounds, in the galeal chemosensory field of the Colorado potato beetle. The idea of a deterrent-sensitive cell comes from work on several caterpillar species (Schoonhoven, 1982), and the best evidence for such a cell comes from *Bombyx mori* (Ishikawa, 1966) and *Pieris brassicae* (Ma, 1972; Blom, 1978). A variety of compounds stimulates these cells at concentrations in the micromolar range, and there is some evidence for a positive dose–response relationship. These two features strongly support the idea of high sensitivity to a number of structurally different secondary compounds in at least some lepidopterous species, but detailed studies are lacking on all but two species. Dethier (1980) questions the idea of a generalized deterrent receptor in lepidopterous larvae, stressing instead the fact that secondary compounds stimulate several cells in 59% of the cases he has studied.

The actions of repellents on mosquito antennal sensilla provide an interesting parallel to the situation in phytophagous insects. Davis (1985) reviewed the mosquito work and presented a list of possible actions of repellents which is remarkably similar to the one proposed by Schoonhoven (1982) for plant feeders. With the evidence to date in both systems, it is not possible to identify

any single mechanism that explains the effects of repellents or feeding deterrents. Given the vast array of chemical structures represented by these compounds, and the large number of potential molecular sites of action in a chemoreceptive system, each situation will require detailed study.

Comparative Aspects of Alkaloid Action. When the effects of a number of compounds on the same system are compared, some preliminary conclusions regarding mechanisms of action can be drawn. The evidence to date strongly suggests that sucrose, GABA, and L-alanine stimulate the same cell in the α-sensillum of the Colorado potato beetle (Mitchell and Harrison, 1984). Because of the difference in molecular structure of the amino acids and sucrose, and because of the high specificity of the amino acid response (Mitchell, 1985), there are probably at least two receptor sites on the same cell, one for the amino acids and one for sucrose.

The actions of the nine alkaloids given in Tables 1 and 2 can be interpreted against this background. Interestingly, except for papaverine, the compounds which significantly inhibit the response to GABA do not affect the response to sucrose. This suggests that tomatine, solanine, and sparteine have their effect on some site related to the amino acid receptor which is separate from the sucrose-receptor site. This observation also supports the hypothesis that the amino acid and sucrose receptors are separate entities. The fact that papavarine inhibits both responses does not exclude the possibility that it interacts with both receptor sites, but it is also possible that this alkaloid acts at sites other than the receptor site causing the entire cell or even all cells in the sensillum to be less sensitive. It is possible that the mode of action of papaverine, at the molecular level, is quite different from that of tomatine, solanine and sparteine. The data do not provide any information on the possible differences between the actions of the latter three compounds. It should be noted that the effect of tomatine and solanine described here is distinctly different from the long-term effects of these compounds which involve all cells in the sensillum (Mitchell and Harrison, 1985).

There are very few data on other phytophagous insect species with which to compare these results. Dethier (1982) emphasized the importance of peripheral integration in the context of host-plant recognition. He cited unpublished data from work on several lepidoptereous larvae which showed that tannic acid, quinine, piperidine, and caffeine inhibit electrophysiological responses to sugars. Apparently there is some variation in effects of these compounds across lepidopterous species. Frazier (personal communication) finds that caffeine excites a candidate ''deterrent'' cell in *Manduca sexta* confirming a similar result reported by Schoonhoven (1972). Caffeine was ineffective in all experiments reported here. Such differences in activity across orders may reflect differences in receptor mechanisms, and it should be possible to gain additional insight into the role of these compounds and the mechanisms underlying their action by

using a comparative approach. Interestingly, quinine has so far proven to be an effective inhibitor of sucrose stimulation in Diptera (Morita, 1959), Lepidoptera (Dethier, 1982), and Coleoptera (Mitchell and Sutcliffe, 1984, and present study). The fact that quinine inhibits the response to sucrose in the Colorado potato beetle, while leaving the response of the same cell to GABA unaffected, suggests that this alkaloid acts at a site specifically involved with sugar reception.

Correlation of Sensory Physiology and Behavior. The adult bioassay was limited to five alkaloids, because the results suggest that little is to be gained by looking at the remaining alkaloids which were studied electrophysiologically. It is assumed that the alkaloids introduced into the potato leaf remained intact for the duration of the test and that they were accessible to the beetle's chemosensory system. Only papaverine and atropine caused significant reduction of any of the feeding parameters measured (Table 5). Papaverine strongly inhibited responses to GABA and to sucrose, suggesting these effects may be causally related to its effect on feeding. It would be interesting to test papaverine more thoroughly. Solanine, tomatine, and quinine, although clearly effective at the cellular level, did not significantly disrupt consumption when presented in the whole-leaf context.

The lack of clear correlations between physiological and behavioral results in these, admittedly limited, data, is not altogether surprising. First, only the galeal sensilla are represented in the physiological study. Epipharyngeal sensilla are present in adult beetles (unpublished data) and probably in larvae as well. These sensilla may, in fact, contact leaf sap before the galeal sensilla, and their input is probably important in regulating feeding behavior as it is in lepidopterous larvae (de Boer et al., 1977). Unfortunately these sensilla are technically difficult to record from, making their inclusion in a general survey such as this a daunting task. Second, we still know very little about the nature of sensory codes in sensilla which mediate host-plant recognition. In a pioneering study, Dethier and Crnjar (1982) suggested a number of possible types of codes whereby lepidopterous larvae may recognize different hosts and nonhost plants. Their data did not allow firm conclusions, but they did indicate that detailed analyses of complex interactions at the chemosensory level will be required to make progress in this area. The results presented here lead to the same conclusion.

An interesting study by Derby et al. (1984) on *Homarus americanus* illustrates the generality and the complexity of the action of secondary compounds on sensory systems and their influence on behavior. They demonstrated that a number of chemosensilla on antennules and walking legs were sensitive to several of 14 secondary plant compounds tested. They also had difficulty in correlating the sensory effect with behavioral results. For example, ferulic acid stimulated a large response from leg and antennular sensilla but had no effect

on behavior, while tannic acid reduced food intake while only stimulating antennular sensilla.

It seems clear that future progress in this area will require in-depth study of a few well-chosen model systems. Prerequisites will be a good understanding of the basic responses of the chemosensory system in each preparation, an easily interpretable behavioral bioassay, and a thorough study of interactions of a few ecologically relevant secondary compounds with the sensory system in question. Success in correlating sensory and behavioral data will likely be enhanced if comparisons are made on an individual plant (defined substrate) and an individual insect basis.

EFFECTS OF DOUBLE-BOND CONFIGURATION ON INTERACTION BETWEEN A MOTH SEX PHEROMONE COMPONENT AND ITS RECEPTOR:
A Receptor–Interaction Model Based on Molecular Mechanics

(Received August 15, 1986; accepted December 3, 1986)

Abstract—The dependence of the electrophysiological activity on the change of double-bond configuration of (Z)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, and a dienic analog, (*E*)-2,(Z)-5-decadienyl acetate, have been investigated by single-cell measurements and molecular mechanics calculations (MM2). A previously reported model for the interaction between a moth sex pheromone component and its receptor has been refined. This new model gives an essentially quantitative correlation between the measured activities and the calculated conformational energies for a biologically active conformation defined by the model. Previously obtained structure–activity results for chain-elongated analogs of (Z)-5-decenyl acetate are significantly improved by the refined model. The effect of a change of the double-bond configuration on the substrate–receptor interaction is not additive but depends on the conformational properties of the entire molecule.

Key Words—Structure–activity, conformational energy, molecular mechanics, double-bond configuration, *Agrotis segetum*, Lepidoptera, Noctuidae, sex pheromone, single-cell recordings, receptor interaction.

INTRODUCTION

Straight chain monoolefinic acetates with a (Z) double bond constitute by far the largest class of known pheromone components of noctuid moths (Scheme 1) (Steck et al., 1982).

SCHEME 1.

Field trapping experiments and electrophysiological measurements on the response of male moth antennae (EAG) or single olfactory receptor cells have revealed that the (*E*) isomer of a pheromone component is significantly less active than the natural (*Z*) isomer. In an EAG screening of a large number of noctuid species, Priesner et al. (1975) reported that the (*E*) isomer is 1.8–5.6 times less active than the (*Z*) isomer. Single-cell measurements, which are better suited for this kind of comparison, show up to 10-fold less activity for the (*E*) isomer in noctuid species (Priesner, 1979). In tortricid species, this difference is usually about 100-fold (Priesner, 1979, 1980, 1983).

However, of all analogs of natural (*Z*) pheromone components so far tested in various studies, the corresponding (*E*) isomer is nevertheless among the most active. For instance, its activity corresponds to, or exceeds, the activity of analogs chain elongated or chain shortened by one methylene unit, which are geometrically more modest perturbations of the natural compound than the (*Z*) to (*E*) configurational change.

Previous structure–activity studies on moth pheromone components strongly indicate that the spatial relationships between the acetate group, the double bond, and the terminal methyl group are crucial for the biological activity (Kafka and Neuwirth, 1975; Kikuchi, 1975; Bestmann and Vostrowsky, 1982; Liljefors et al., 1985). Considering that the three-dimensional shapes of the thermodynamically preferred conformers of the (*Z*)- and (*E*) isomers are significantly different, the relatively high activity of the (*E*) isomer is surprising. However, straight-chain monoolefinic acetates are very flexible molecules. Rotations about single bonds of the (*E*) isomer may make it possible for this isomer to approach the three-dimensional shape of the corresponding (*Z*) isomer. This has previously been suggested by Kafka and Neuwirth (1975) in connection with the development of a receptor interaction model for pheromone components, but no attempts were made to fit (*E*) isomers to this model (Kafka and Neuwirth, 1975; Neuwirth, 1973).

Recently, we reported a new model for the interactions between a monoolefinic pheromone component and its receptor, employing structures and conformational energies calculated by the molecular mechanics method (Liljefors et al., 1985). This model was successfully used to rationalize the effects of chain elongation on observed electrophysiological single-cell activities of homologs of (*Z*)-5-decenyl acetate (**1**), a pheromone component of the turnip moth, *Agrotis segetum* (Bestmann et al., 1978; Arn et al., 1980; Löfstedt et al., 1982). In the present work, we report an extension of this model to include

the effects of a change of the double-bond configuration as well. This extension made necessary a refinement of the previously reported receptor interaction model (Liljefors et al., 1985). As will be described below, this refinement also significantly improves the quantitative aspects of the previously obtained results for chain-elongated analogs.

In connection with structure–activity studies on dienic analogs of (Z)-5-decenyl acetate (Bengtsson et al., 1987), we surprisingly observed that changing the configuration from (Z) to (*E*) at position 5 of (*E*)-2,(Z)-5-decadienyl acetate (compounds **4** and **5,** respectively) did not produce any significant change in the electrophysiological activity, in contrast to the effect of the corresponding configurational change in (Z)-5-decenyl acetate (see above). These observations provide a good test of the performance of the refined receptor interaction model.

We report electrophysiological single-cell measurements and conformational analysis of the compounds shown in Figure 1. Olfactory receptor cells specifically tuned to (Z)-5-decenyl acetate (**1**) are present in antennal sensilla type SW1 of the turnip moth, *Agrotis segetum*, and are readily accessible for single-cell recordings (Hallberg, 1981; Löfstedt et al., 1982; van der Pers and Löfstedt, 1983).

METHODS AND MATERIALS

Chemicals. The synthesis of (Z)-5-decenyl acetate (Figure 1, **1**), (*E*)-5-decenyl acetate (**2**), and the chain-elongated analogs (**6**)–(**12**) have previously been reported (Olsson et al., 1983; Liljefors et al., 1985). (*E*)-5-Dodecenyl acetate (**3**) was purchased from the Institute for Pesticide Research, Wageningen, The Netherlands. The synthesis of (*E*)-2,(Z)-5-decadienyl acetate (**4**) will be reported elsewhere (Bengtsson et al., 1987).

(E)-*2,*(E)-*5-Decadienyl Acetate (5).* This was prepared according to the method of Ando et al. (1982) from zirconocene monohydride (2.2 g, 9 mmol) (Schwartz's reagent), 3-(2-tetrahydropyranyloxy)-1-propyne (1.2 g, 9 mmol), 1-bromo-2-heptene (1.5 g, 9 mmol) and $Pd(PPh_3)_4$ (0.26 g) to yield 1.6 g (91%) of crude (**5**). δ_H(300 MHz; $CDCl_3$) 0.89 (3H, t, Me), 1.28–1.36 (4H, m, CH_2CH_2), 1.98–2.04 (2H, m, $CH_2C{=}$), 2.06 (3H, s, MeC=O), 2.72–2.78 (2H, m, $={CCH_2C}=$), 4.52 (2H, dd, OCH_2), 5.33–5.51 (2H, m, J_{AB} = 15.2 Hz, CH=CH), 5.51–5.62 (1H, m, J_{AB} = 15.2 Hz, C$\underline{H}$=CH), 5.72–5.83 (1H, m, J_{AB} = 15.2 Hz, CH=C$\underline{H}$), δ_C(15.03 MHz; $CDCl_3$) 14.0, 21.0, 22.2, 31.6, 32.2, 35.2, 65.1, 124.1, 126.9, 132.3, 134.9, 170.9, *m/e*: 136 (M^+-60; 5%), 107 (1), 93 (7), 79 (32), 67 (10), 55 (11), 43 (100).

The compounds were purified by argentation liquid chromatography (Houx et al., 1974) and by preparative GLC (column OV-351, 6 m). All compounds were at least 98.5% isomerically pure as determined by capillary GLC (column Supelcowax 10, 30 m). The double-bond configurations were confirmed by ^1H

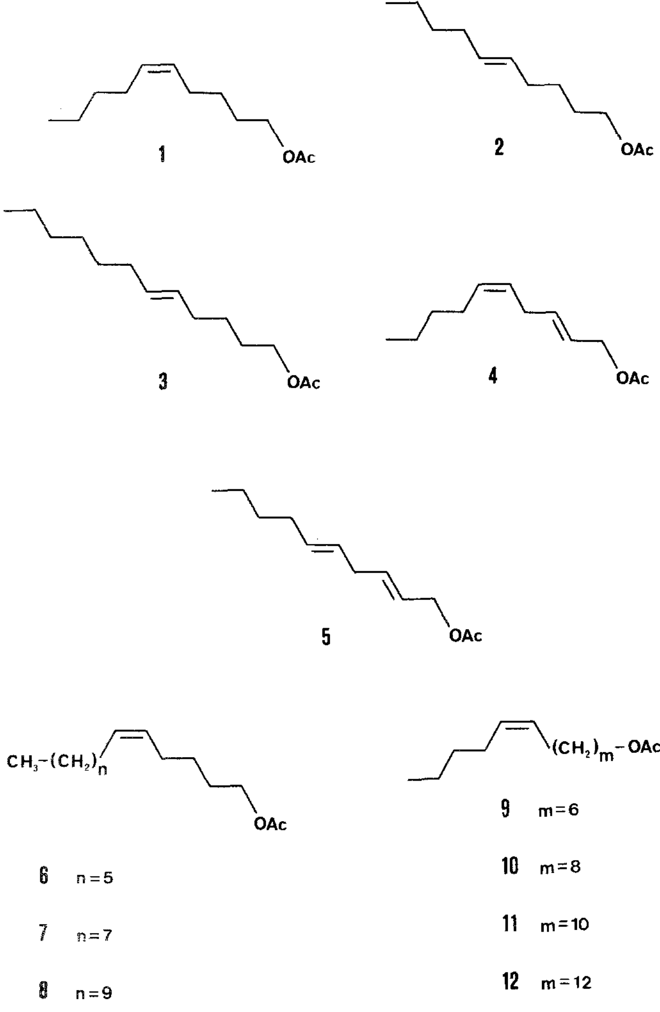

FIG. 1. Compounds studied.

and ^{13}C NMR spectroscopy using a Varian XL-300 or a Nicolet 360 WB spectrometer. Mass spectra were recorded on a Finnigan 4021 mass spectrometer.

Calculations. Energy-minimized geometries and conformational energies were calculated using the molecular mechanics program MM2 developed by Allinger and coworkers (Allinger and Yuh, 1980; Burkert and Allinger, 1982). Starting structures for the energy-minimization program were constructed by the molecular modeling system MIMIC (Liljefors, 1983; von der Lieth et al., 1984). This system was also used in the molecular superimposition studies and in the calculation and plotting of conformational energy maps.

Electrophysiology. The biological activities of the different compounds were established by measuring the electrical responses of receptors selective for (*Z*)-5-decenyl acetate (**1**) on the male *Agrotis segetum* antenna.

The measuring procedure was essentially the same as that described by van der Pers and den Otter (1978). A freshly excised antenna from a 2-day-old moth was placed with the base in a capillary electrode filled with Beadle-Ephrussi Ringer solution and connected to earth by an Ag–AgCl wire. The tip of an olfactory sensillum was cut off by a glass knife, and the recording electrode was placed in contact with the cut surface of the sensillum. The recording electrode was then connected to a high-impedance amplifier by an Ag–AgCl wire.

The stimulus was loaded onto a piece of filter paper and put into a plastic syringe. The amounts used ranged from 10^{-3} to 10^{2} μg. Two milliliters of the gaseous content of the syringe was injected into an airstream flushing the antenna continuously at a linear flow of 0.5 m/sec. Ten replicates were recorded with each different stimulus.

The response of the receptor cell was defined as the number of action potentials (nerve spikes) generated during 1 sec, starting from the onset of the stimulation. Dose–response curves using five different concentrations were made for all compounds tested.

The relative electrophysiological activities of the tested compounds were calculated from the dose-response curves, and expressed as the reciprocal of the relative quantities required to elicit the same response of the receptor cell.

Corrections for differences in vapor pressure were calculated as previously described (Liljefors et al., 1985), using data from Olsson et al. (1983).

Refined Substrate–Receptor Interaction Model

The new features of the refined model are: (1) the use of the entire pheromone component molecule **1** in the construction of the model instead of using only part of the molecule; (2) the use of the complete structure of the analogs in the calculations of conformational energies; and (3) addition of flexibility to the model with respect to the required location of the double bond (see Computational Procedure section below). As in our previously described model, the natural pheromone component **1** is used to define spatial relationships in the cavity of the receptor active site between positions of molecular parts crucial for full biological activity (Liljefors et al., 1985). The corresponding molecular parts in the studied analogs (**2–12**) may, through conformational rearrangements of their alkyl chains, be positioned in these space locations. The conformational energy required for such a rearrangement may then be related to the biological (electrophysiological) activity of the analog. A high conformational energy should correspond to a low biological activity and vice versa. As before, we assume receptor sites complementary to the acetate group, the double bond, and the terminal methyl group (Liljefors et al., 1985).

At the present stage of development our model is only applicable to com-

pounds analogous to the natural pheromone component and which have the ability to position the crucial molecular parts, as defined above, in the required positions. Thus, compounds such as chain-shortened analogs cannot be fitted directly to the model and its assumed interaction sites. It must also be borne in mind that the details of the transduction process are still largely unknown and that the process may be a complex multistep one (Kaissling, 1974, 1976, 1977). Our model is to be understood as a model for an "activated complex" related to the efficacy (intrinsic activity) rather than as model for the initial binding of the substrate.

In our previous model only those parts of the molecules which were changed in the test series were included in the calculations. This simplification facilitated the calculations for the chain-elongated analogs **6–12** in the structure–activity analysis previously reported (Liljefors et al., 1985) but is less satisfactory in the general case. In the present work the complete molecules are used in the calculations. This, however, introduces a complication since we now have to take the conformational properties of the natural pheromone component **1** into account.

Conformational Analysis of Compound 1. Compound **1** is a very flexible molecule with a large number of conformers within 1 kcal/mol of the energy of the thermodynamically most stable one. However, a study of conformationally restricted dienic analogs of compound **1** strongly indicates that the alkyl chains of **1** should have an all-*anti* conformation in the biologically active state (Bengtsson et al., 1987). This reduces the problem to the conformation with respect to the C=C—C—C fragment. It is then implicitly assumed that one of the stable conformers in this respect corresponds to the biologically relevant structure of compound **1**.

A calculated conformational energy map for the rotation about the vinylic bonds in (Z)-4-octene, used as a model for the olefinic part of a monoolefinic pheromone component, is shown in Figure 2. It shows a degenerate double-minimum for the *cisoid* conformation (Figure 3) and a single minimum for the *transoid* one with an energy difference of 0.11 kcal/mol, favoring the *transoid* conformation. The populations of the two types of conformations are thus very similar, in agreement with experimental data on other (Z)-olefins. An electron diffraction study on (Z)-3-hexene indicates the presence of both types of conformations with comparable populations (van Hemelrijk et al., 1981). This has also been concluded from infrared data on liquid (Z)-3-hexene (Shimanouchi et al., 1971). Raman spectra of crystals of (Z)-monoolefinic fatty acids show the molecules to have either the *cisoid* or the *transoid* conformation depending on the crystalline modification (Koyama and Ikeda, 1980).

The energy barrier between the two *cisoid* conformers in (Z)-4-octene is calculated to be very low, 0.12 kcal/mol. The interconversion between the two *cisoid* forms may thus be described as a large amplitude torsional motion. The energy barrier for the *cisoid* to *transoid* interconversion is calculated to be 0.84

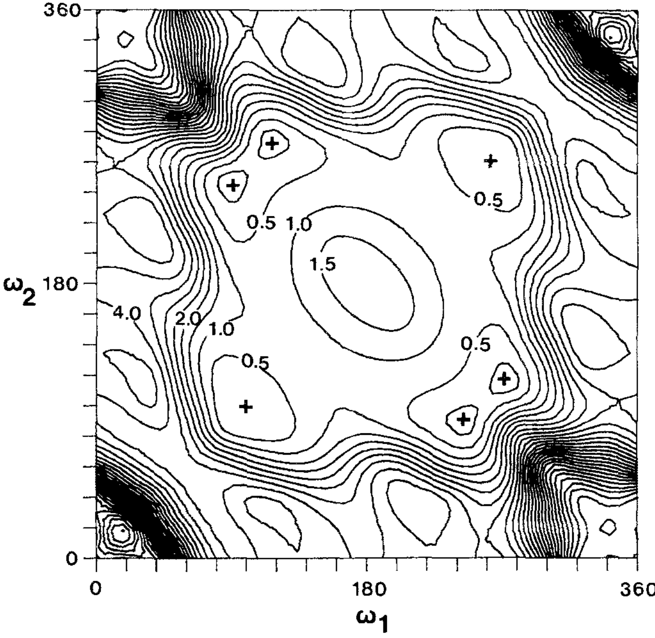

FIG. 2. Conformational energy map for the rotation about the vinylic bonds of (*Z*)-4-octene. ω_1 and ω_2 are C=C—C—C dihedral angles in degrees. Local minima are denoted by +. Isoenergy contours are shown with an energy difference of 0.5 kcal/mol. At the degenerate minima at ω_1, ω_2 = 90,240 and 120,270 (and the symmetry related pair) the 0.2 kcal/mol level also is shown.

kcal/mol, in good agreement with the experimental value 0.60 ± 0.06 kcal/mol for the analogous barrier in (Z)-2-pentene (van Eijk, 1981). The above analysis of (Z)-4-octene implies that there are three conformers of the natural pheromone component **1** which are candidates for the biologically active structure within the context of our model.

The energy-minimized geometries of these conformers are shown in Figure 4. The *cisoid 1* and *cisoid 2* conformers differ mainly in the torsional angles about the (C=C)-(C—C) bonds. In the *cisoid 1* structure the C=C—C—C dihedral angles are calculated to be 116.1 and −87.2 degrees for the *n* and *m* chains, respectively. The corresponding values for the *cisoid 2* conformer are 88.4 and −114.9 degrees. The difference in calculated conformational energy

between the three conformers is less than 0.06 kcal/mol. As there are presently no data from which it is a priori possible to choose which of these conformers to use as a model for the biologically active conformation of **1**, all three were used in turn and all calculations were done for each of the three models. These models will, in the following, be denoted *cisoid 1, cisoid 2,* and *transoid* according to Figure 4. The use of all three models in the calculations gives a good check of the sensitivity of the calculated results to the precise geometry of the substrate–receptor interaction model.

Computational Procedure. As in our previous model, the pheromone component analogs studied were assumed to interact with the receptor with the terminal methyl group and the acetate group in the relative positions in space defined by the natural pheromone component. Computationally this is accomplished by restricting the encircled atoms in Figure 5 to these fixed positions during the energy-minimization procedure. In our previous model the double bond and the vinylic carbons were also restricted to fixed positions. However, the results obtained indicated that these constraints are too severe in the general case (Liljefors et al., 1985). To add more flexibility to the model, the double bond and the vinylic carbon atoms were allowed to move during the energy minimization process in the plane defined by the C—C=C—C fragment in the reference molecule **1**. The restriction to a common plane ensures that the pi orbitals have the same direction in all molecules studied, and thus may interact with the corresponding binding site in a similar way. Before energy-minimization, the double bond in the studied analog was placed in a position as close to the double bond in the reference molecule **1** as possible.

With these restrictions, the molecules were energy-minimized with respect to all remaining degrees of freedom. A large number of starting structures was employed, and the lowest energy one after energy-minimization was used in the further analysis. The construction of trial structures for the chain-elongated analogs, employing a diamond lattice, has previously been described (Liljefors et al., 1985). Next, the unconstrained global energy minimum for each molecule was calculated. The conformational energies required by the molecules to acquire their "biologically active conformations" could then be evaluated by

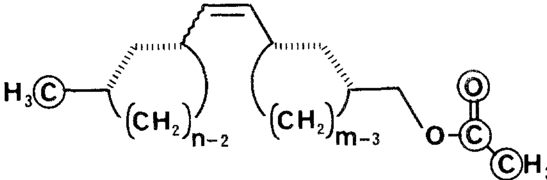

FIG. 5. Encircled atoms are held in fixed positions in the calculations of structures and energies for biologically active conformations. The dashed lines indicate the alkyl chains in the natural pheromone component **1**. For constraints on the double bond, see text.

taking the difference in calculated energy between the lowest energy conformationally rearranged structure that fits the requirements of the receptor–interaction model and the unconstrained global energy minimum. These energies are then compared to the observed electrophysiological activities relative to the reference compound **1**.

Note that in the context of our model the interaction energies between the terminal methyl group, the double bond, and the acetate group and their receptor counterparts are the same or at least very similar for all molecules included in the present study. This is due to the requirement that the three receptor-interacting parts of the substrate molecule are at fixed positions in space or, in the case of the double bond, only allowed a very limited freedom of motion. However, the conformational energy required to attain the biologically active structure is different and depends on the structure of the molecule. Thus, the differences in total receptor–interaction energies along the series of molecules are, according to our model, determined by the different conformational energies. The calculated conformational energies correspond to enthalpies. The entropy terms have not been explicitly considered in the present work, but differences in the conformational entropy contributions for the molecules in the series investigated should largely be compensated by differences in hydrophobic binding (Liljefors et al., 1985).

RESULTS AND DISCUSSION

Chain-Elongated Analogs. The new model described above was first used to recalculate the conformational energies required for the previously studied chain-elongated analogs **6–12** to acquire their "biologically active conformations". For details of the results obtained previously, see Liljefors et al. (1985). The purpose of this recalculation was to study the performance of the refined model in relation to the old one and to investigate if the calculated results are dependent on the choice of biologically relevant conformer for the natural compound **1** (*cisoid 1, cisoid 2* or *transoid*, see Figure 4).

The results are shown in Figure 6. The calculated energies are clearly not very dependent on the conformer assumed to be the biologically active one for the natural pheromone component **1**. The observed minima in activity for compounds **7** and **10** correspond to calculated conformational energy maxima in all three cases, and the results are qualitatively similar to those previously obtained (Liljefors et al., 1985). However, very satisfactorily, the refined model now makes it possible to put the results for chain elongation on either side of the double bond on the same energy scale. Our previous model clearly exaggerated the conformational energies required for the analogs chain-elongated between the double bond and the acetate group, by as much as 8–10 kcal/mol (Liljefors et al., 1985). This was due to the overly severe constraints imposed on the molecule in the previous model.

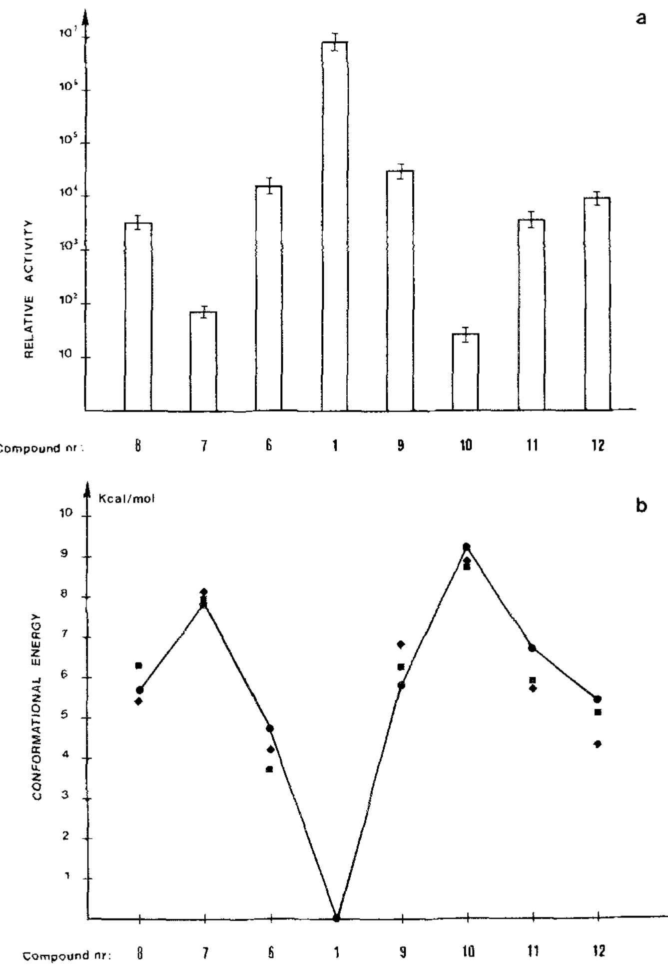

FIG. 6. (a) Experimental single-cell activities (from Liljefors et al., 1985 and (b) calculated conformational energies for the biologically active conformations of chain-elongated analogs of **1**. ♦ *cisoid 1;* ● *cisoid 2;* ■ *transoid* model. The calculated energies for the *cisoid* 2 model are connected by a solid line.

From the results in Figure 6 it is possible to calculate the conformational energy corresponding to a decrease of the biological activity by a factor of 10. On average this becomes 1.7, 1.7, and 1.6 kcal/mol for the *cisoid 1, cisoid 2,* and *transoid models*, respectively. For all three models and for all seven analogs the maximum calculated deviation from these numbers is 0.5 kcal/mol. The refined model thus significantly improves the results for the chain-elongated analogs **6–12,** and gives an essentially quantitative relationship between calculated conformational energy and observed biological activity. The similar re-

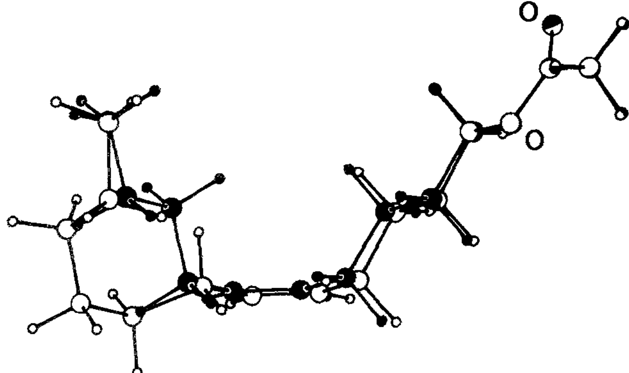

FIG. 7. Superimposition of the *cisoid* 2 conformer of **1** (filled atoms) and the calculated biologically active conformation of compound **6**.

sults obtained with this series of compounds for the three different models precludes the possibility of selecting one of them as the most probable biologically active structure of the natural pheromone component **1**.

As an example of the structure of a calculated biologically active conformation, a superimposition of the calculated "active structure" of compound **6** and the natural pheromone component **1** in its *cisoid* 2 conformation is shown in Figure 7. To fit the geometrical requirements of the receptor–interaction model, **6** is forced to adopt *gauche* conformations about two adjacent bonds. The difference in double bond positions of **1** and **6** is quite small. The distance between the midpoints of the double bonds in **1** and **6** in the superimposition shown is 0.6 Å. The calculated conformational energy of **6** in this "biologically active" conformation relative to the lowest energy one is 4.7 kcal/mol, which may be compared to the corresponding value using our previous model, 5.8 kcal/mol. For compounds **9–12**, the difference between the calculated energies using the old and new models is even larger, as much as 5–10 kcal/mol. This implies that a substantial reduction of the conformational energy may be achieved with a modest adjustment of the double-bond position in the cavity of the receptor "active site." It should be noted that the calculated biologically active conformations of **6–12** do not correspond to local energy minima of the unconstrained "free" molecules.

Double-Bond Configurational Isomers. The measured electrophysiological single-cell activities for compounds **2–5** relative to the natural pheromone component **1** are shown in Figure 8a. The (*E*) isomer **2** is less active by a factor of 100 than the corresponding natural (*Z*) isomer **1**. Chain elongation by two methylene units (compound **3**) further lowers the activity by about a factor of 100 (including corrections for differences in vapor pressure). This may be compared

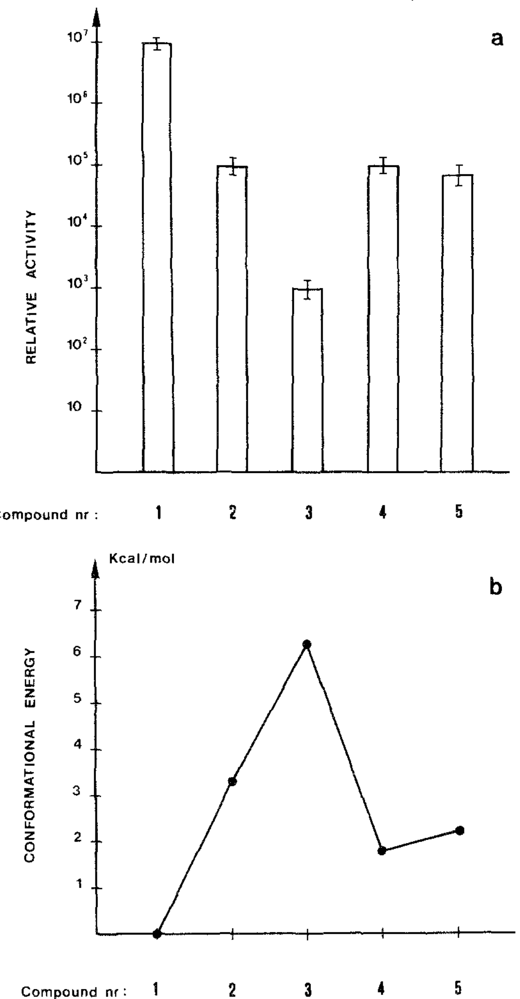

FIG 8. (a) Experimental single-cell activities for compounds **1–5**. (b) Calculated conformational energies for the biologically active conformations (*cisoid* 2 model) of compounds **1–5**.

to the relative activity for **6** with respect to **1**, which is ca. 1000 (Figure 6). The loss of activity due to chain-elongation is thus somewhat less in the (*E*) series than in the corresponding (*Z*) series.

Introduction of an (*E*) double bond in the 2 position of the natural pheromone component (compound **4**) has approximately the same effect as the *Z*/*E* configurational change (Figure 8a); the observed activity is reduced by a factor of ca. 100. Surprisingly, no further significant change in the activity was ob-

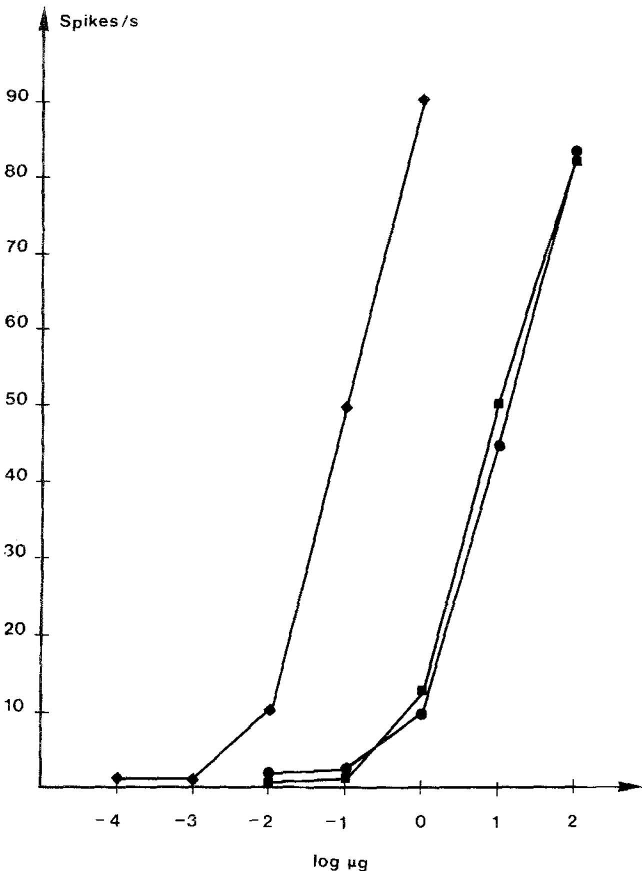

FIG. 9. Dose–response curves for compounds **1**, ♦; **4**, ■; and **5**, ●; obtained by electrophysiologic single-cell recordings.

served for the (*E*)-5 isomer **5** of this diene. The close similarity of the electrophysiological response of the two compounds is demonstrated in Figure 9, which shows the dose–response curves for the natural pheromone component **1** and the two diene analogs **4** and **5**. The effect of configurational change is thus not additive, but depends on the properties of the entire molecule.

The conformational energies required for compounds **2–5** to acquire their biologically active conformations, according to the receptor–interaction model described above was calculated, and the results are shown in Figure 8b. (The results for the *cisoid 2* model according to Figure 4 are shown. The results for the other two models in this series are also very similar).

The calculated conformational energies clearly have a very close correla-

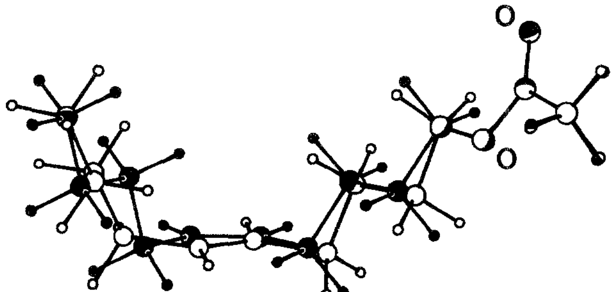

FIG. 10. Superimposition of the *cisoid 2* conformer of **1** (filled atoms) and the calculated biologically active conformation of compound **2.**

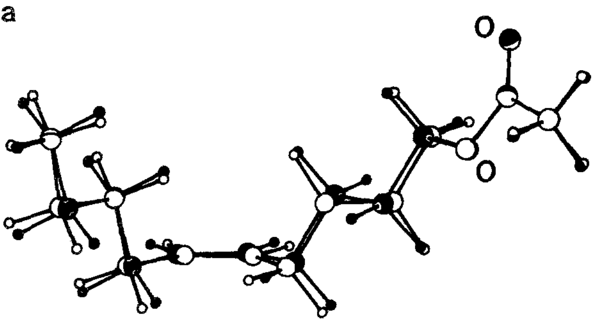
tion to the measured electrophysiological activities. The calculated conformational energy for compound **2** is 3.3 kcal/mol, which corresponds to 1.65 kcal/mol for each power of 10 of decrease in activity compared to **1.** This is identical to the number obtained for the chain-elongated analogs. A superimposition of compound **2** in its calculated "biologically active conformation" and compound **1** is shown in Figure 10. The (*E*) isomer is forced to adopt a *gauche-anti* conformation of the alkyl chain connecting the double bond and the methyl group. The position of the (*E*) double bond in **2** is sufficiently close to that of the (Z) double bond in **1** to assure similar interactions with the binding site.

The chain-elongated (*E*) isomer **3** is calculated to have a conformational energy requirement of 6.3 kcal/mol to reach its "biologically active conformation." Using the value 1.65 kcal/mol for a 10-fold decrease in activity as obtained above, this should give a reduction of the activity by a factor of ca. 100 compared to that of **2,** which is also observed (Figure 8a). Furthermore, comparing compounds **2** and **3,** the conformational energy for reaching the biologically active conformation is increased by 3.0 kcal/mol due to chain-elongation by two methylene groups in the (*E*) series. This may be compared to the corresponding value of 4.7 kcal/mol in the (Z) series (Figure 6, compound **6**). The calculations thus also reproduce the observation that chain elongation in the (*E*) series leads to a smaller decrease of the activity than in the (Z) series.

Gratifyingly, the unexpected similarity of the activities of compounds **4** and **5** is also well calculated. After conformational rearrangements which increase the energy by 1.8 kcal/mol (Figure 8) the (*E*)-2, (Z)-5 diene **4** becomes an extremely good "mimic" of the natural pheromone component **1,** as is demonstrated by the superimposition of the two molecular structures in Figure 11a. The (*E*) double bond in **4** closely mimics the *anti*-conformation of the corresponding saturated fragment in **1.** The (*E*)-2, (*E*)-5 diene **5** requires a conformational energy of 2.2 kcal/mol, only slightly higher than that for **4,** to mimic the molecular shape of **1,** as can be seen in Figure 11b.



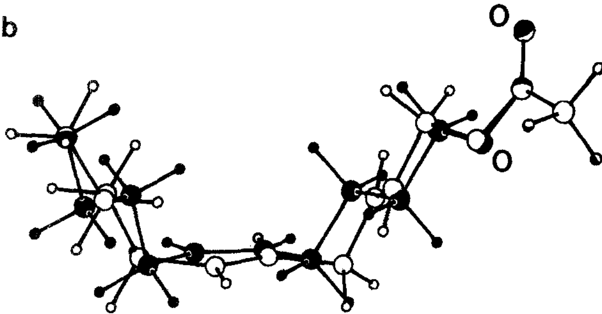


FIG. 11. Superimpositions of the *cisoid 2* conformer of **1** (filled atoms) and the calculated biologically active conformations of (a) compound **4** and (b) compound **5.**

CONCLUSIONS

The model for the interaction between a pheromone component and its receptor presented in this work gives an essentially quantitative correlation between the measured electrophysiological single-cell activities and conformational energies calculated by molecular mechanics. The calculated conformational energies correspond to the energies required for the molecules to acquire a biologically active conformation as defined by the model. It should be noted that the resulting conformations for the analogs of the natural pheromone component are not local energy minima for the "free" molecules.

The effect of a change of double-bond configuration on the biological (electrophysiological) activity is not additive, but depends on the conformational properties of the entire molecule.

(Received September 23, 1986; accepted December 3, 1986)

Abstract—Larvae of the small ermine moth *Yponomeuta mahalebellus* were reared on foliage of *Prunus mahaleb*, a plant known to contain coumarins. Thin-layer chromatography and gas chromatography showed that coumarin, umbelliferone, and herniarin were present in leaves of *P. mahaleb* and in pupae and adults of *Y. mahalebellus*. Overall concentrations of simple coumarins in the plant and insect were, respectively, 0.54% and 0.003–0.004% (dry weight). The possible role of coumarins in the chemical defense of both the plant and insect is discussed.

Key Words—*Prunus mahaleb*, Rosaceae, *Yponomeuta mahalebellus*, Lepidoptera, Yponomeutideae, coumarin, umbelliferone, herniarin, plant–insect interaction, chemical defense.

INTRODUCTION

In preliminary feeding trials, small ermine moths appeared to be unpalatable to birds (unpublished observations). This has prompted us to search for distateful chemicals in these insects (Fung et al., in preparation). In our screening, we found that extracts of pupae of *Yponomeuta mahalebellus* (Lepidoptera: Yponomeutideae) contained fluorescent compounds when inspected in UV light. Larvae of this small ermine moth feed on leaves of *Prunus mahaleb* (Rosaceae), a plant known to accumulate simple benzo-α-pyrones like coumarin and the hydroxycoumarins umbelliferone and herniarin (Figure 1) (Hegnauer, 1964–1973; Murray et al., 1982). As some coumarins are strongly fluorescing compounds, we decided to examine *Y. mahalebellus* and its host plant for the presence of simple coumarins.

Several classes of chemicals are known to occur in arthropods, i.e., alkaloids, cardiac glycosides, phenols, and cyanogenic glycosides (Rothschild,

1973; Harborne, 1982). These secondary metabolites are often sequestered from the food plant, and they may offer the insect protection against predators on account of their toxicity and/or bitterness. To our knowledge, there has been no earlier report on the presence of coumarins in insects. The occurrence of coumarins in *P. mahaleb* and *Y. mahalebellus* will be discussed in view of their possible ecological function.

METHODS AND MATERIALS

Insect and Plant. P. mahaleb and *Y. mahalebellus* are not indigenous to The Netherlands, but occasionally *P. mahaleb*, presumably originated from cultivated plants in parks, is present among the natural vegetation. *Y. mahalebellus*, offspring of a strain originally collected from Reims, France, was reared on its host plant *P. mahaleb* found in the dunes of Meijendel, The Netherlands. In May 1986, fourth-instar larvae were collected from this shrub and reared further in the laboratory on the same foliage at 20°C. Adult moths were killed 24 hr after emergence. Leaves, pupae, and adults were freeze-dried and stored in a desiccator until chemical analyses were performed.

Extraction and Purification. Leaf powder (0.5 g) and insect material (0.7–0.8 g) were extracted with 15 ml 50% methanol (40–50°C; 1 hr). After filtration, the residue was rinsed with 3× 5 ml 50% methanol. The combined aqueous methanol solutions were extracted with 3× 25 ml chloroform. The organic layers were combined and concentrated under reduced pressure. Plant extracts were then ready for analyses, whereas insect extracts had to be further purified in order to remove interfering fatty substances. Insect extracts were cleaned by preparative thin-layer chromatography on silica gel plates (60 F_{254}, 1 mm layer thickness; Merck, Darmstadt, Germany). After development of the plates in toluene–ether (1 : 1) saturated with 10% acetic acid solution, bands with coumarin (R_f = 0.68), umbelliferone (R_f = 0.42), and herniarin (R_f = 0.60), detected in UV light at 254 nm and 365 nm, were scraped off and powdered. The

combined powder was washed with 200 ml ethanol, and the filtered alcoholic solution was concentrated under reduced pressure.

Thin-Layer Chromatography (TLC). Analyses of plant extracts, dissolved in 400 μl methanol, and purified insect extracts, redissolved in 200 μl methanol, were carried out on silica gel plates (60 F_{254}, 0.25 mm layer thickness; Merck). The solutions (4–12 μl) were applied and the plates were developed in toluene–ether (1 : 1) saturated with 10% acetic acid solution (Wagner et al., 1983). Coumarins were detected in UV light at 254 nm and 365 nm, before and after spraying with 5% potassium hydroxide in ethanol (Wagner et al., 1983).

Gas Chromatography (GC). After TLC analyses, extracts were dried and silylated with 300 μl *N,O*-bis(trimethyl)-acetamide and 100 μl dimethylformamide. Sensitivity of umbelliferone in GC analyses was enhanced after silylation. After heating at 50°C for 15 min, the solutions were ready for injection. The presence of coumarin, umbelliferone, and herniarin in the extracts was confirmed by coinjection with commercially available reference compounds. Coumarins were also assessed in a semiquantitative way by comparing peak areas of the extracts with peak areas of known concentrations of reference compounds.

Analyses were carried out on a Perkin-Elmer 3920 B gas chromatograph equipped with a FID detector and a capillary WCOT SE 52 fused silica column (0.32 mm ID × 25 m; Chrompack, Middelburg, The Netherlands). On-column injection was performed. Nitrogen was used as carrier gas at a rate of 1 ml/min. A temperature program was applied: 4 min isotherm at 130°C, consequently 16°C/min until 230°C, isotherm at 230°C. Temperature of the injection block and FID interface was kept at 250°C.

RESULTS AND DISCUSSION

Coumarins are secondary metabolites that are widespread in the plant kingdom. There are several types of coumarins, differing in the substitution pattern of the benzo-α-pyrone nucleus. Simple coumarins which lack additional fused ring systems are the most common representatives of this group (Hegnauer, 1964–1973).

It has been suggested that under the selective pressure of herbivory, the production of novel types of coumarins in plants was stimulated. New paths in biosynthesis led to the formation of more complicated coumarins, i.e., linear furanocoumarins and angular furanocoumarins, which are more toxic to insects than the simple coumarins (Berenbaum, 1983). For example, larvae of the southern armyworm *Spodoptera eridania* grew normally on a diet containing umbelliferone, while larval development was inhibited when the linear furanocoumarin xanthotoxin was incorporated in the diet (Berenbaum, 1978). Still, simple coumarins are not harmless to phytophagous insects. Coumarin in high

dose generally inhibits feeding of a number of insects. At a concentration of 0.2%, coumarin was an antifeedant to caterpillars of the gypsy moth *Porthetria dispar* (Meisner and Skatulla, 1977). At a level of 1.5% in an artificial diet, coumarin inhibited feeding of larvae of the cotton leafworm *Spodoptera littoralis*; at lower concentrations food intake was decreased and pupal weight was reduced as the efficiency of assimilated food conversion was inhibited (Mansour, 1981). Coumarin inhibited completely larval development of *S. littoralis* at higher concentrations and affected greatly growth and adult fertility at lower dosages (Mansour, 1982). When broad-bean plants were treated with 0.01% and 0.02% coumarin and offered as food to *Aphis craccivora*, the natality and natality rate of this aphid decreased significantly (Mansour et al., 1982). As for small ermine moths, coumarin was toxic to larvae of *Y. padellus* and *Y. rorellus* (van Drongelen and van Loon, unpublished results).

Our analyses showed that high concentrations of coumarin and herniarin, and a trace of umbelliferone, were present in leaves of *P. mahaleb* (Figure 2). The amount of coumarin was 0.27% dry weight. Since coumarin at this level is known to be a feeding deterrent to a number of insects, the presence of simple coumarins in *P. mahaleb* must confer some chemical protection against herbivory. It is interesting to note that *P. mahaleb* is poisonous to *Y. malinellus* and *Y. padellus*: larvae of these species died after being fed with this plant (Gerrits-Heybroek et al., 1978; Gerrits-Heybroek and Ulenberg, unpublished results).

Obviously *Y. mahalebellus* has overcome this toxic barrier as their larvae are specialist feeders on *P. mahaleb*. The tested pupae of this small ermine moth contained umbelliferone along with some coumarin and herniarin; these three coumarins were also present in the adults (Figure 2). Overall concentration of simple coumarins in *Y. mahalebellus* was low: 0.003–0.004%. Variations in coumarin contents in the plant and insect remain unknown, since lack of insect material prevented us from carrying out replicate analyses. Coumarins in *Y. mahalebellus* are most likely derived from the plant as they are absent in larvae of *Y. evonymellus*, *Y. malinellus*, and *Y. rorellus*, which feed on plants lacking coumarins.

At this stage it is not clear whether such small amounts of simple coumarins can protect *Y. mahalebellus* against predation. In the literature injurious effects of coumarins were reported at higher dosages. Coumarin and hydroxycoumarin exert toxic actions to several organisms (Murray et al., 1982). Coumarin produced liver damage in rats and dogs; for rats it was toxic at a 0.25% dietary level (Hazleton et al., 1956). Several workers suggest that some secondary substances, i.e., aristolochic acids and cardiac glycosides, are sequestered in insects because they are protective agents against microbes and parasites (Urzúa et al., 1983; Smith, 1978). Tests have shown that umbelliferone and its derivatives inhibit fungal and bacterial growth at 0.05% level and that herniarin is a more potent antimicrobial agent than umbelliferone (Jurd et al., 1971). Antimicrobial activity declines substantially with decreasing concentra-

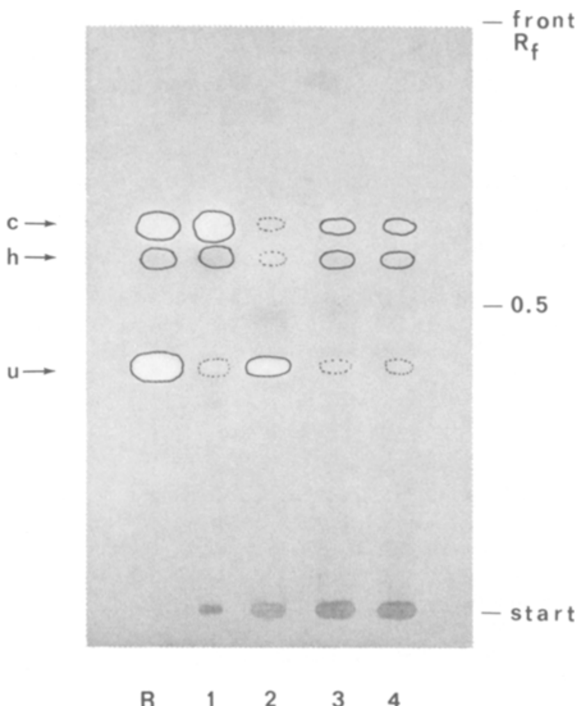

FIG. 2. TLC of simple coumarins in *P. mahaleb* and *Y. mahalebellus*. For TLC conditions see Methods and Materials. The plate was photographed in UV light, 365 nm. tions of hydroxycoumarins, so it is uncertain whether they are still active at 0.003–0.004%, the levels found in *Y. mahalebellus*.

Recently high concentrations of carotenoids were recorded for *Y. mahalebellus* (Rothschild et al., 1986). It was suggested that carotenoids, which have antioxidant properties as they are effective quenchers of singlet oxygen, might function as photoprotective agents for this small ermine moth against the harmful effects of coumarin in its body (Rothschild et al., 1986). Coumarins in *Y. mahalebellus* and its host are simple coumarins, and simple coumarins are much less photoreactive towards nucleic acids than furanocoumarins (Marciani et al., 1971). Since only a small amount of simple coumarins is detected in pupae and adults of *Y. mahalebellus*, it seems unlikely that in these stages a protective function against coumarins can be attributed to the high levels of carotenoids found in this moth.

In summary, we conclude that some coumarins are present in *Y. mahalebellus* but that it is doubtful whether they play a significant role in the chemical defense of the insect. It seems that when the larvae feed on leaves of *P. mahaleb*, some coumarins pass through the gut and are not totally eliminated from the insect's body. For cocaine, it was demonstrated that most of the ingested alkaloid was excreted by larvae of the lymantriid moth *Eloria noyesi*, while some unchanged base was retained in the body during metamorphic development to adults (Blum et al., 1981). The significance of low levels of cocaine in these moths is also unknown.

Acknowledgments—We thank H. J. Dijkerman and R. E. Kooi for providing the plant and insect material. Thanks are also due to Prof. R. Hegnauer for his valuable comments on this manuscript.

Book Review

Social Odours in Mammals, Volumes 1 and 2. Richard E. Brown and David W. Macdonald (eds.). Oxford and New York: Clarendon Press, Oxford University Press, 1985. $60 (£55) and $45 (£35), 882 pp. illustrated.

Richard Brown and David Macdonald have brought together a uniquely valuable and most timely zoological compendium, illustrated with line drawings and nearly 70 photographic plates, which demands a place on the shelf of anyone with an interest in the interdisciplinary study of chemical signalling in mammals.

No one scanning this encyclopedic two-volume work of 20 independent chapters, each with its own detailed bibliography, can doubt the pervasive importance of chemical cues in the lives of mammals. Brown and Macdonald have rendered future students a very great service indeed by gathering together a veritable mine of information which will be worked and reworked by many in this emerging field of study.

Their work is a catalog par excellence, with all the strengths and weaknesses of such a text. It is an encyclopedic work of reference, encompassing a vast amount of information, but without uniting this information very satisfactorily. Although aspiring to be interdisciplinary, it is also very much a zoologist's book.

The field has been divided by taxon, the 13 authors confining themselves to giving detailed accounts of what is known of the role of scent in the lives of specific groups of mammals, and while this subdivision has its merits, it has not encouraged a unified discussion of broader issues. Only in the introduction and in the competent first chapter by Peter Flood on the anatomical sources of significant mammal scents is the presentation free to range widely. Integration is helped a little by general indices of author, species, and odor source (principally the names of various glands) repeated at the end of each volume.

The text is particularly strong in cataloging the occurrence and structure of scent glands and other scent sources across the whole of the Mammalia, including orders which have not figured widely in such discussion previously. The social functions of odors in the lives of mammals, including scent-marking patterns and behavioral responses, are also documented, and in some chapters the anatomic organization of the olfactory organs is detailed.

Other facets of the subject are dealt with less well. Thus, a consideration

0098-0331/87/1000-2049$05.00/0 © 1987 Plenum Publishing Corporation

of the molecular aspects of the subject is largely absent or is dealt with peripherally and inadequately, even for those relatively few species which have been studied in some depth chemically. The molecular dimension is one in which the authors seem not to be confident, one mentioning the possibility of volatile peptides for example. Even so, this work will provide an invaluable source of background zoological information for molecular scientists and others entering this interdisciplinary field. A notable exception to the absence of chemistry is provided by the chapter by Gisela Epple and Amos Smith in which they bring together their findings on the chemistry and biology of communication in the saddle-backed tamarin, *Saguinus fuscicollis*.

In addition to the chapters already mentioned, there are useful chapters on the monotremes and marsupials by Eleanor Russell, on the insectivores (including the tree shrews and the elephant shrews) with a separate chapter as a specific case study on *Tupaia belangeri* by Dietrich Holst, and on the bats by Uwe Schmidt. Richard Brown has provided a chapter on primer effects under the heading of rodents, as well as further chapters on myomorph rodents; on the primitive ungulates (elephants, hyraxes, and the aardvark); on armadillos, sloths, anteaters, and pangolins; and on marine mammals. David Macdonald has written on the hystricomorph rodents and on the carnivores. Zuleyma Halpin has provided a chapter on the sciuromorph rodents, Diana Bell on rabbits and hares, Patricia Moehlman on the Perrisodactyla, Morris Gosling on the Artiodactyla, Gisela Epple on the primates, and the work is concluded by a chapter by Richard Doty on man.

Valuable as the work is, I did feel that the presentation was noticeably uneven even for a multiauthor work, and that, perhaps with more ruthless editorial direction, it could have been condensed into a more balanced and more manageable single volume. Some authors have given concise summaries of whole orders, while others have dealt with single species, and others still have presented their own primary research findings as they might in a journal, and quite often a sharper, crisper presentation could have been achieved. I also noticed one or two places where I felt the text to be in error, but slips cannot be avoided in such a work.

But the merit of this text easily survives such criticisms. As the editors write:

> The literature on social odours lies widely scattered in the vaults of several disciplines. A profusion of loose ends juts out from the literature to overwhelm the reader; by considering all the mammalian families within these two volumes, we hope that some of these loose ends will be knotted together, while the remainder will be considerably untangled.''

While the text may not have fully lived up to this utopian aspiration of

interdisciplinary synthesis, it has none the less provided a most important zoological contribution to that end.

Book Review

The Science of Allelopathy. A.R. Putnam and C.-S. Tang (eds.). New York: Wiley Intersciences Publication, John Wiley & Sons, 1986. $52.50, xi + 317 pp., illustrated.

This book consists of 17 chapters comprising the contributions of 21 of the participants in a symposium on allelopathy convened by the two editors at the International Congress of Pacific Basin Societies, held in Hawaii in December 1984. The initial chapter, by A.R. Putnam and C.-S. Tang, is devoted to an overview of the science. This is a stimulating introduction to the subject based upon early and recent history, the present state of knowledge and techniques, and the editors' views on the needs and the probable future of the science. The very strong emphasis on agriculture, industrial interests, and interdisciplinary requirements of the subject are predictable from the editors' interests, but they are probably well earned by the events in the discipline. It did seem to me, however, that if such a major part of basic allelopathic research as its implication in ecology was to be omitted from this chapter on the basis of its having been reviewed in E.L. Rice's second edition of *Allelopathy*, several other entire chapters might have been omitted from the book on the grounds that their entire subject matter was recently published in the *Journal of Chemical Ecology*. I am, of course, opposed to either or both omissions. On balance, this initial chapter is a valuable introduction to the subject of allelopathy for the advanced student or researcher.

The remaining 16 chapters are divided into groups constituting three parts of the volume. Part 1, comprising Chapters 2 through 6, is entitled "Field Observations of Allelopathy and Autotoxicity" and actually contains much more.

In Chapter 2, E.L. Rice gives a thorough review of the literature on "Allelopathetic Growth Stimulation" to which he appends a brief but convincing research report establishing a grotesque stimulation of growth by unidentified allelochemical compounds. Mature leaves of ground-ivy decaying in soil stimulated the growth of radish shoots by as much as 1064% and downy brome shoots by as much as 770%.

In Chapter 3, A.R. Putnam and L.A. Weston review "Adverse Impacts of Allelopathy in Agricultural Systems" in limited detail. With most of the weeds listed in tabular form, the subject is still massive.

0098-0331/87/1000-2053$05.00/0 © 1987 Plenum Publishing Corporation

"The Role of Allelopathy in Subtropical Agroecosystems in Taiwan," by C.-H. Chou, constitutes Chapter 4. The great preponderance of allelopathic studies issued from Chou's laboratory, but some have been the work of two other groups, especially that of T.S.C. Wang. At the end of his review Chou offers a brief proposal of a theory of the origins of allelopathy and autotoxicity, their evolution, natural selection, and value to the species in which they occur. His proposal fell far short of its mark.

In Chapter 5, J.V. Lovett discusses "Allelopathy: The Australian Experience" in a well-balanced and comprehensive presentation. Australia has, at least in its drier districts, some landscapes richly dappled with "halo" patterns associated with shrubs and trees long suspected of allelopathic complicity. Yet, the studies of species interactions have concentrated upon weed impacts on pastures and various field crops and, among native species, crop residues, forest tree inhibition, etc., a strong bias toward economically important questions. Although some neglect of basic science necessarily resulted, it is remarkable how readily the investigators recognized fundamental questions and contributed to their solutions. The rhizosphere, the intricate dynamics of weed–pasture interactions, and the allelopathic peculiarities of insect frass incidental to *Eucalyptus* defoliation are better known than the widely visible "halo" patterns in coastal health vegetation of southern Australia.

C.-C. Young presents "Autointoxication of *Asparagus officinalis* L." in Chapter 6. The literature is reviewed and the first steps in an analysis of an allelopathic hypothesis are presented, while identification and modes of action of phytotoxins are projected.

Part 2, entitled "Techniques for Studies of Allelochemicals and Their Modes of Action" comprises Chapters 7 through 11.

C.S. Tang describes in detail "Continuous Trapping Techniques for the Study of Allelopathy in Higher Plants" in Chapter 7. The trapping action is based on the passage of excess or cycling aqueous medium through columns of Amberlite XAD-4 resin and the eventual elution of adsorbed chemical compounds from the resin by suitable organic solvents. This method is precise when rigorously applied, but it lacks the flexibility required in most allelopathic studies. Aside from root exudation, it is difficult to envision any natural process in plant interaction to which it would be applicable without relaxation of the rigorous conditions of isolation for the sake of purity.

G.R. Leather and F.A. Einhellig offer "Bioassays in the Study of Allelopathy" in Chapter 8. They introduce the subject with a strong argument for standardization of bioassays. While extreme care ensuring uniformity within a bioassay is doubtlessly mandatory, requiring that standardized bioassays be employed whenever, wherever, and whoever investigates biochemical interactions of whatever plant species can only stifle experimental innovation. I hope that was not the intent. However, under "Seed Germination" the authors complain that "Even reports originating from the same laboratory differ in the conduct

of the assay." This is an excellent way to put an end to experimental originality. Although the authors recognize the fact that some allelopathic studies employed both seed germination and seedling growth bioassays, they apparently did not recognize that several of the studies they listed under "seed germination" in their table 8.1 employed only seedling growth and offered no seed germination data at all. Their descriptions of assays utilizing aquatic, cryptogamic, and miscellaneous other receiver plants include evidence that they, too, have practiced some innovative experimental design. The chapter is very useful.

H.G. Cutler writes on "Isolating, Characterizing, and Screening Mycotoxins for Herbicidal Activity" in Chapter 9. He offers a stimulating and highly instructive introduction to the subject which is intriguing to the broadly interested biologist and should be invaluable to the novice in this specialty.

F.A. Einhellig reviews "Mechanisms and Modes of Action of Allelochemicals" in Chapter 10. This is an excellent review of a complex and very incompletely known facet of allelopathy. The great variety of allelochemicals and the diversity inherent in their modes of release, movement, and accumulation, playing upon differential susceptibilities of multiple processes constituting growth in divers receiver plants almost defy definition. However, what little is known is shown to relate very likely to membrane perturbation, hormone and enzyme disruptions, and a long list of absorptive, retentive, and metabolic processes issuing from these disruptions. Just enough is known about these effects of certain phenolic and terpenoid allelochemicals to suggest a multitude of future research projects for plant physiologists for much longer than their interest will likely persist.

In Chapter 11, "Allelochemical Mechanisms in the Inhibition of Herbs by Chaparral Shrubs" is treated by the late W.H. Muller.[1] The physiologic mechanisms described are based almost entirely upon his own work and that of collaborators under his leadership. The field-directed research involved collaboration with others and established the environmental elements here treated. In the effects of *Salvia* monoterpenoids (especially cineole) on growth of a series of seedling species, a mechanism involving membrane perturbation and disruption of respiration and absorptive control is as nearly fully established as any allelopathic mechanism yet proposed.

Part 3 treats "Chemistry and Potential Uses of Allelopathy" in Chapters 12 through 17.

"The Function of Mono- and Sesquiterpenes as Plant Germination and Growth Regulators" by N.H. Fischer occupies Chapter 12. It is a rather detailed review of the literature with particular attention given to relations between structural qualities of regulatory molecules and their specific biologic activities. The treatment should remain of general value long after its coverage has been outdated by the passage of time.

[1] Professor Walter H. Muller died on May 28, 1986.

''Polyacetylenes as Allelochemicals,'' by K.L. Stevens, constitutes Chapter 13. This is an instance of the chemistry of a group of compounds being far ahead of the corresponding ecology, partly because of the ephemeral nature of the compounds. Their biotic activity has been repeatedly demonstrated in vitro and plants that produce them appear to be allelopathic, but these extremely toxic compounds are too dynamic for the application of anything approaching Koch's postulates. The plants may be telling us things never dreamed of by Koch.

''Qualitative and Quantitative Determination of the Allelochemical Sphere of Germinating Mung Bean'' is treated in Chapter 14 by C.S. Tang and B. Zhang. The authors used the continuous trapping method with Amberlite XAD-4 to quantify the exudation of allelochemicals by germinating mung beans. On the basis of this quantity, the size of a mung bean, and the degree of toxicity revealed by bioassays of exudates, they calculated the thickness of allelochemical spheres of germinating mung beans. Considering the several highly variable factors in the environment of the germination process, this might be highly approximate. The authors conclude, among other things, ''Based on the data obtained, we introduced and established the concept of allelochemical spheres.'' I once thought that concept originated in my work, but then I encountered an older writer as follows: ''For they say that the vine scents the cabbage and is infected by it. Wherefore the vine-shoot, whenever it comes near this plant, turns back and looks away as though the smell were hostile to it'' (Theophrastus, ''Enquiry into Plants'', IV, xvi, 6.). Modern terminology, identification, allelochemicals, and experimental methodology we can claim for our own generation (or that of our grandfathers), but we have no monopoly on ideas.

In Chapter 15, ''Caffeine Autotoxicity in *Coffea arabica* L.'' is treated by G.R. Waller, D. Kumari, J. Friedman, N. Friedman, and C.-H. Chou. This is a summary treatment of a program embracing studies of allelochemicals of *Coffea arabica* (of which caffeine is the principal one), biologic activity, metabolism, source, incidence in the environment, absorption and translocation in *Coffea* seedlings, isolation of susceptible tissues from toxins, and autotoxic deterioration of old plantations from work in Waller's laboratory and from the recent literature.

In Chapter 16, ''Allelopathic Activity of Rye (*Secale cereale* L.)'' is presented by J.P. Barnes, A.R. Putnam, and B.A. Burke. This also is a summary statement based upon extensive literature, a significant part of which issued from Putnam's laboratory. The most powerful toxicity was exhibited by the benzoxazines which, although they accounted for a small proportion of rye toxicity, occurred in small quantities and therefore must have been extremely potent.

In Chapter 17, ''Microbially Produced Phytotoxins as Herbicides—A Perspective'' is offered by S.O. Duke. This is an impressive subject, comprising much evidence of the implication of microbial species in what appears at first

examination to be a simple case of higher plant allelopathy. The prospect of significant herbicides from this source seems very promising.

The usual weaknesses of symposium volumes are a bit more serious in this book than they are in most of the genre. The style, quality, significance, and inclusiveness of the several chapters are far from uniform. One gathers from the Preface that publication was an afterthought or at least that it was not assured before the gorup was assembled, thus limiting the opportunity of the editors to integrate the volume. These complaints are minor, however, compared to the positive qualities of the book. Its avowed purpose of reviewing the science of allelopathy, assessing its state and its future, and supporting the concept of interdisciplinary research is well met by the several writers. There remains, however, ample room for alternative opinion. I am particularly pleased to see in some of the powerful ephemeral phytotoxins evidence supporting the theory of A.G. Winter,[2] that some cases of allelopathy may involve fleetingly present toxins that one can never hope to find accumulated in the environment. Winter theorized that plant roots had equal chance with decomposition microorganisms to absorb ephemeral inhibitors. First proposed in 1942 and repeatedly supported by its author for almost 20 years, Winter's very logical proposal finds strong support in some of the chemical advances issuing from the new ambience of team research so strongly emphasized in this volume. If the book did nothing else than lead to an accommodation of modern allelopathic thinking to the subtle logic of one of the best theorists of the preceding generation, it would be proven a success.

INHIBITION OF FEEDING BY A GENERALIST INSECT DUE TO INCREASED VOLATILE LEAF TERPENES UNDER NITRATE-LIMITING CONDITIONS

CHARLES A. MIHALIAK, DENIS COUVET,[1] and DAVID E. LINCOLN

Department of Biology, University of South Carolina Columbia, South Carolina 29208

(Received July 28, 1986; accepted December 4, 1986)

Abstract—Nitrogen-limited plants of *Heterotheca subaxillaris* accumulate greater quantities of leaf volatile terpenes than do nitrogen-rich plants. A series of feeding trials were performed to determine if such nitrate-limited plants are better defended against generalist-feeding insect herbivores. Soybean looper (*Pseudoplusia includens*) larvae were fed leaves from *H. subaxillaris* rosettes grown under high and low nitrate supply regimes. Larval consumption, growth, and survival declined as the leaf volatile terpene content increased. Larval consumption and growth were enhanced by higher plant nitrate supply and with increasing leaf age. The results suggest that the higher quantity of volatile terpenes in the leaves of nitrate-limited plants may better defend these leaves against generalist-feeding insects.

Key Words—*Heterotheca subaxillaris*, Asteraceae, *Pseudoplusia includens*, Lepidoptera, Noctuidae, volatile terpenes, nitrogen, herbivory.

INTRODUCTION

Plants growing under nitrogen-limiting conditions generally have a slower growth rate than those growing under nitrogen-rich conditions (Chapin, 1980). Comparable loss of leaf nitrogen to herbivores by nitrate-limited and nitrate-rich plants presumably has a greater impact on the growth of nitrogen-limited plants. Carbon supply does not limit plant growth under low nitrate conditions, and consequently, increased quantities of carbon-based defenses should be selected for as nitrate availability decreases (Janzen, 1974; McKey et al., 1978; Bryant et al., 1983; Coley et al., 1985; Mihaliak and Lincoln, 1985).

Leaf mono- and sesquiterpenes are known to function as carbon-based chemical defenses against herbivores (Eisner, 1964; Rice et al., 1978; Mabry and Gill, 1979; Langenheim and Hall, 1983). Increased quantities of leaf mono- and sesquiterpenes occur as plant nitrate availability decreases (Mihaliak and Lincoln, 1985) and may provide greater defense against insect herbivores. The quantity of leaf volatiles is also known to decline with leaf age (Crankshaw and Langenheim, 1981; Mihaliak and Lincoln, 1985). This decrease coincides with the lower productivity and nitrogen content of older leaves (Mooney, 1972; Mihaliak and Lincoln, 1985). The high volatile terpene content of young leaves under nitrate-limiting conditions (Mihaliak and Lincoln, 1985) suggests a pattern of increased carbon allocation to the defense of those leaves which represent the largest relative proportion of the potential photosynthetic capacity of a plant. Plant allocation to defense should reflect leaf value (Rhoades, 1979), assuming that leaf value is measured by its relative contribution to future plant productivity and the cost of replacement (Mooney and Gulmon, 1982).

The objective of this study was to determine if the increased quantity of leaf mono- and sesquiterpenes under nitrate-limiting conditions better defends plants against a generalist insect herbivore. A further goal was to investigate whether patterns of insect consumption and growth are consistent with the prediction that a leaf which represents a high relative proportion of the photosynthetic capacity of a plant is better defended than a leaf which will contribute less to future plant productivity. Despite an often observed increase in herbivore consumption on leaves with a relatively low concentration of nitrogen (Mattson, 1980; Scriber and Slansky, 1981; Lincoln et al., 1982, 1986), we predict that insect consumption rates should decline as leaf terpene levels increase under nitrate-limiting conditions. Further, since the potential contribution of a leaf to plant productivity is greatest when a leaf is young, and decreases with leaf age, (Mooney and Gulmon, 1982), we expect that consumption and growth of herbivores will be less on these young leaves than on older, less defended leaves.

To test these predictions, we have performed feeding trials using the generalist lepidopteran *Pseudoplusia includens* (soybean looper) and young and mature leaves from *Heterotheca subaxillaris* rosettes grown under high and low nitrate supply regimes. *Pseudoplusia includens* is recognized as a polyphagous species (Kogan and Cope, 1974) and has been observed feeding on *H. subaxillaris* (personal observation).

METHODS AND MATERIALS

The plant species used in this experiment, *Heterotheca subaxillaris* (Lam. Britton and Rusby) (Asteraceae) (camphorweed), is a herbaceous annual/biennial (Awang and Monaco, 1978) which occurs in old fields, disturbed sites, and open sandy areas of the southeastern United States. Forty-one mono- and ses-

quiterpenes have been identified from the leaves of *H. subaxillaris* (Lincoln and Lawrence, 1984). *Pseudoplusia includens* (Walker) larvae used in the feeding trials were obtained from a laboratory colony which was maintained on a pinto bean–soy protein–wheat germ diet (Greene et al., 1976) in an environmental incubator under a thermophotoperiod of 14 hr light–10 hr dark (26°C–20°C).

The plants were grown in a greenhouse using seed germinated on filter paper in Petri dishes. Seedlings were transferred into a potting medium of perlite, vermiculite, and sand (1 : 1 : 1) within one week of germination and maintained under a photoperiod of 14 hr day–10 hr night using 1000-W coated metal halide and high-pressure sodium lamps as supplemental light (690 μmol/m^2/sec). The plants were watered on alternate days with either tap water or a nutrient solution. The nutrient solution contained either 0.5 mM or 5.0 mM nitrate and provided the nitrate-limited and nitrate-rich treatments, respectively. These solutions consisted of equimolar concentrations of KNO_3 and $Ca(NO_3)_2$. $CaCl_2$ and KCl were added to the nitrate-limited solution to maintain equal Ca^{2+} and K^+ concentrations. Both nutrient solutions contained 1.65 mM K_2HPO_4, 1.35 mM KH_2PO_4, 2.0 mM $MgSO_4$, micronutrients, and chelated iron.

Feeding trials were performed by removing leaves from individual 12-week-old *H. subaxillaris* rosettes, enclosing the petiole in a folded moistened tissue, and then placing the larvae and leaf into a plastic Petri dish. All leaves and insects were kept in the environmental incubator throughout the feeding trial under the thermophotoperiod described above. A second matched leaf was removed from each plant and used to determine the leaf volatile terpene content, the leaf nitrogen content, and the leaf water content. No perceivable changes in the leaf volatile terpene or nitrogen content occur when leaves are detached from the plant.

Larvae were fed either an immature (1-week-old) or fully expanded (4-week-old) leaf from a *H. subaxillaris* plant grown under either the 0.5 mM or the 5.0 mM nitrate treatment. For comparison, feeding trials were also performed using 1-week-old leaves from soybean plants (*Glycine max* L. Merr. cv. Ransom) grown under the 5.0 mM nitrate treatment. Leaf age was determined by placing small rings over the petiole of newly emerging leaves. All of the feeding trials began with larvae which had recently molted to the fourth instar and had not begun to feed. The larvae were kept with the leaf until they either molted to the fifth instar or died. Seventy feeding trials were performed on *H. subaxillaris* leaves, and ten were performed using soybean leaves.

The initial fresh weight of each larva and leaf used in the feeding trials was recorded. At the end of the feeding trial, the leaf was dried and weighed, and larva was frozen and then dried to determine the final dry weight. The initial dry weight of the larvae was computed using a fresh weight–dry weight conversion calculated from matched larvae not used in the experiment. The initial dry weight of the leaves was calculated from a regression analysis of the fresh and dry weights of the matched leaves which were also used to determine leaf

terpene, nitrogen, and water content. The relative growth rate (RGR), relative consumption rate (RCR), and efficiency of conversion of ingested food (ECI) (Waldbauer, 1968) were computed on a dry weight basis over the entire fourth-instar feeding period.

Leaf volatile terpene content was determined for the matched leaves using gas chromatography by adding a known amount of an internal standard (*n*-tetradecane) to a pentane extract of each leaf. After extraction, the sample was centrifuged to remove all leaf material and then concentrated to a volume of approximately 100 μl under a stream of nitrogen. Analyses were performed using a gas chromatograph equipped with a SP-1000 fused silica capillary column (0.25 mm $\times$ 30 m), a flame-ionization detector, and a digital integrator (temperature program from 50 to 175°C at a rate of 3°C/min with a 5-min initial and 15-min final isothermal period). Leaf volatile terpene contents were calculated without response factors for individual compounds.

The nitrogen content of the residual leaf material collected after pentane extraction was measured using a Hewlett-Packard Carbon-Hydrogen-Nitrogen Analyzer and a digital integrator. The nitrogen content of each sample was computed using a response curve generated with cystine (U.S. Department of Commerce, Bureau of Standards). Measured leaf nitrogen contents were not corrected for the materials extracted with pentane.

All statistical analyses were performed using the Statistical Analysis System, SAS Institute Inc.

RESULTS

The leaf volatile terpene content was higher under nitrogen-limiting conditions ($\bar{X} = 4.73$ mg/g, SD = 1.39) than under nitrogen-rich conditions ($\bar{X} =$ 3.73 mg/g, SD = 2.38; $F = 7.87$, $P < 0.01$), and the leaf nitrogen content was reduced when plant nitrate availability was limited (Table 1; $\bar{X} = 24.4$ mg/g at high nitrate, $\bar{X} = 18.5$ mg/g at low nitrate; $F = 19.6$, $P < 0.001$). As leaves aged, reduced quantities of leaf volatile terpenes ($F = 21.7$, $P < 0.001$) and leaf nitrogen ($F = 4.22$, $P < 0.05$) occurred (Table 1). The volatile leaf terpene content changed less with leaf age under nitrate-rich conditions than under nitrate-limiting conditions ($F = 5.61$, $P < 0.05$ for nitrogen treatment by leaf age interaction). Under nitrate-limiting conditions, leaf nitrogen content was near the level suggested as the minimum necessary for larval growth (Fox and McCauley, 1977).

Larval consumption (RCR), growth (RGR), and survival were lower on the leaves of nitrate-limited plants (Table 1; nitrate treatment effect: RCR, $F =$ 31.5, $P < 0.001$; RGR, $F = 55.97$, $P < 0.001$; survival, $\chi^2 = 16.6$, $P <$ 0.01). These leaves of nitrate-limited plants contain more volatile terpenes and

TABLE 1. CHARACTERISTICS OF LEAVES OF *Heterotheca subaxillaris* AND SOYBEAN, AND PERFORMANCE OF *Pseudoplusia includens* LARVAE OVER ENTIRE FOURTH INSTAR[a]

	0.5 mM Nitrate		5.0 mM Nitrate		
	Immature	Mature	Immature	Mature	Soybean
Leaf nitrogen content (mg N/g leaf)	20.5[ab]	16.6[a]	24.8[c]	23.5[bc]	34.8[d]

[a] Larvae were offered either immature (1-week-old) or mature (4-week-old) leaves from plants grown using nutrient solutions which contained either 0.5 mM or 5.0 mM nitrate. *Pseudoplusia includens* performance on 1-week-old leaves of soybean plants grown using 5.0 mM nitrate is given. Means in each row followed by the same letter are not significantly different (Tukey's studentized range test, $P < 0.05$, * arcsin square root transform).

less nitrogen than comparable leaves of nitrate-rich plants. The negative mean growth rate for larvae which fed on leaves of nitrate-limited plants is due to weight loss of some larvae prior to their death during the feeding trial. The RGR of the surviving larvae which were offered leaves from the 0.5 mM plants averaged 0.50 mg/mg larva over the fourth instar. Consumption and growth were reduced on immature leaves and increased on older leaves (leaf age effect: RCR, $F = 7.61$, $P < 0.01$; RGR, $F = 6.72$, $P < 0.01$).

Leaf volatile terpene content has a negative effect on the growth and consumption rate of *P. includens*, while larval growth was positively related to leaf nitrogen content (Table 2). The absence of a relationship between consumption and leaf nitrogen contrasts with the often observed compensatory feeding response of herbivores which encounter nitrogen-poor leaves (Mattson, 1980; Scriber and Slansky, 1981; Lincoln et al., 1982, 1986).

Leaf water content, measured as percent of leaf fresh weight, increased significantly under nitrate-rich conditions (for 0.5 mM plants, $\bar{X} = 75.3\%$, SD $= 3.2\%$; for 5.0 mM plants, $\bar{X} = 78.1\%$, SD $= 1.8\%$; $F = 11.6$, $P < 0.005$).

TABLE 2. EFFECT OF LEAF VOLATILE TERPENE CONTENT AND LEAF NITROGEN CONTENT ON RELATIVE GROWTH RATE AND RELATIVE CONSUMPTION RATE OF *P. includens* LARVAE OVER ENTIRE FOURTH INSTAR[a]

	Leaf nitrogen content		Leaf volatile content	
	Slope	P	Slope	P
Relative growth rate	0.03	<0.05	−0.09	<0.01
Relative consumption rate	0.33	<0.19	−2.00	<0.006

[a]Multiple regression analysis, $df = 2, 67$.

However, when added to a multiple-regression analysis with leaf volatile terpene and leaf nitrogen content, leaf water content did not significantly influence either RCR ($P < 0.44$) or RGR ($P < 0.56$) of the larvae.

The total amount of leaf tissue consumed by larvae was lowest on leaves from nitrate-limited plants (Table 1; $F = 31.5$, $P < 0.001$). Increased larval consumption on leaves from nitrate-rich plants resulted in both a greater absolute amount of leaf tissue being eaten and a larger proportion of each nitrate-rich leaf being consumed by the herbivores. Further, more leaf tissue was consumed by larvae feeding on mature leaves than on immature leaves.

The conversion efficiency (ECI) of larvae was significantly lower when offered leaves of nitrogen-limited plants than when offered nitrogen-rich leaves ($F = 5.03$, $P < 0.05$). Further, ECI was lower when larvae fed on *H. subaxillaris* leaves than on soybean leaves (Table 1). The growth rate of *P. includens* larvae on soybean leaves was not different from their growth rate on *H. subaxillaris* leaves grown under nitrate-rich conditions. However, a significant increase in consumption occurred when feeding on the *H. subaxillaris* leaves.

DISCUSSION

The higher leaf volatile terpene content combined with the reduced leaf nitrogen content of nitrate-limited plants resulted in decreased performance by a generalist herbivore. These results suggest that leaves of nitrate-limited plants may be better defended from generalist-feeding insect herbivores than leaves of nitrate-rich plants and that young leaves are better protected than older leaves.

The concentration of leaf nitrogen is usually considered to be a major determinant of insect herbivore feeding and nutrition (Mattson, 1980; Scriber and Slansky, 1981; Lincoln et al., 1982; Scriber, 1984). However, the results of this study and of previous investigations of the interactions between leaf nitrogen and carbon-based chemical defenses suggest that both nitrogen and allelochemicals are important factors in determining the nutritional quality of

plant tissue for herbivores (Lincoln et al., 1982; Redak and Cates, 1984; Lincoln, 1985; see, however, Morrow and Fox, 1980).

In the current study, leaf water content was lower under nitrate-limited conditions but failed to explain the variance in either RCR or RGR. Low leaf water content (ca. 60%) can suppress larval growth and nitrogen utilization efficiency (Scriber, 1977; Scriber and Slansky, 1981). However, slower larval growth due to variation in water content is not likely to occur on leaves from herbaceous plants (Scriber, 1977; Slansky and Feeny, 1977).

An abundance of leaf nonstructural carbohydrates appears to increase production and/or decrease turnover of volatile terpenes (Croteau et al., 1972; Croteau, 1984). Higher concentrations of nonstructural carbohydrates accumulate in leaves as plant nitrate availability declines (Chapin, 1980; Fritsch and Jung, 1984). Thus, the ecological hypothesis regarding increased carbon allocation to defense under nitrate-limiting conditions (Rundel, 1982; Coley et al., 1985; Mihaliak and Lincoln, 1985) and the current results are consistent with the hypothesized physiologic controls on plant terpene biosynthesis (i.e., increased availability of carbon for the production of volatile terpenes under nitrate-limiting conditions).

The results agree with the predictions of the leaf value hypothesis (Rhoades, 1979). Nitrogen-limited plants commonly have a slower growth rate than nitrogen-rich plants. Loss of leaf material by a nitrogen-limited plant should have a greater impact on growth than a comparable loss of leaf tissue by a nitrogen-rich plant. In the current study, less consumption occurred on the leaves of nitrate-limited plants than on leaves of nitrate-rich plants, and the quantity of leaf volatiles was highest under nitrate-limiting conditions. Thus, leaves which potentially contribute a high relative proportion to total plant productivity appear to be better defended. Similarly, the potential contribution to productivity is greatest in immature leaves and declines with leaf age. Young leaves contained higher levels of volatile terpenes, and consumption was reduced on these leaves.

The high leaf terpene content in leaves with a relatively low nitrogen content (i.e., those of nitrate-limited plants) increases the quantity of terpenes per unit nitrogen an insect must consume when feeding on these leaves. If leaf volatile terpenes are toxic, herbivores may be able to consume only small quantities of the immature leaves of nitrate-limited plants or, if the terpenes were repellent, the herbivore would move in search of another food source. In either case, the increased allocation to carbon-based defense by the slower growing, resource-limited plant (Coley et al., 1985; Mihaliak and Lincoln, 1985) would be successful in retaining leaf nitrogen.

Acknowledgments—We thank R. Sox and the greenhouse staff at the University of South Carolina for assistance in maintaining the plants and J.C. Morse for identification of *P. includens*. Support for this study was provided by NSF grant DEB82-07116 to DEL.

(Received August 11, 1986; accepted December 4, 1986)

Abstract—*Drosophila mettleri* is a soil-breeding, cactophilic drosophilid which lives in the Sonoran Desert. Several chemical constituents of cacti in this region have been identified as having major roles in insect-host plant relationships involving *Drosophila*. For example, isoquinoline alkaloids, which are present in senita cactus, have been shown to be toxic to seven of the nine species tested. The two tolerant species are *D. pachea*, the normal resident, and *D. mettleri*. Necroses of senita cacti are often used as feeding substrates by *D. mettleri* adults, but this species has never been reared from senita rots. Soil, which have been soaked by juice from saguaro and cardón rots, are the typical breeding substrates of this species. The tissues of both of these cacti also contain alkaloids, chemically related to those in senita, but at much lower concentrations. Alkaloid concentration in saguaro-soaked soil was found to be 1.4–27 times the average concentration in fresh tissue. Alkaloids were extracted from saguaro tissue and used in tests of larva-to-adult viability, developmental rate, and adult longevity. Elevated concentrations of saguaro alkaloids had no significant effect on the longevity of *D. mettleri*, but significantly reduced the longevity of *D. nigrospiracula* and *D. mojavensis*, two nonsoil breeding cactophilic species. Viability and developmental rates of all three species were affected, but the effect on *D. nigrospiracula* was comparatively greater. It is argued that the adaptations that allow *D. mettleri* to utilize the saguaro soil niche also convey tolerance to alkaloids present in senita tissue. The ability to utilize senita necroses as feeding substrates represents an ecological advantage to *D. mettleri*, in that the density of potential feeding sites is increased as compared to species which are more specific in their host-plant relationships.

Key Words—*Drosophila*, *D. mojavensis*, *D. nigrospiracula*, *D. mettleri*, Diptera, Drosophilidae, cactus, alkaloids, viability, development, longevity, host-plant relationships.

INTRODUCTION

The study of the chemical ecology of the four cactophilic *Drosophila* species that live in the Sonoran Desert of North America has led to a reasonably complete picture of the chemistry involved in host-plant utilization (Fogleman and Heed, 1987, and references therein). These drosophilids feed and breed in the necroses of columnar cacti and are highly host-plant specific. Briefly, the primary *Drosophila*-cactus relationships are: *D. mojavensis*-*Stenocereus gummosus* (agria) or *S. thurberi* (organ pipe); *D. pachea*-*Lophocereus schottii* (senita); *D. nigrospiracula*-*Carnegiea gigantea* (saguaro) or *Pachycereus pringlei* (cardón); and *D. mettleri*-soils which have been soaked by saguaro or cardón (Heed, 1978).

The latter species, *D. mettleri*, exhibits a novel behavioral characteristic, i.e, ovipositing in soils which have been soaked by cactus rot exudate. The only other reported example of soil-breeding *Drosophila* involves a Hawaiian species, *D. heedii*, which oviposits in soil that has been inundated by tree drippings (Kaneshiro et al., 1973).

Drosophila mettleri is also the only one of the four species that is not limited in its substrate utilization by host-plant chemistry (Fogleman and Heed, 1987). The chemical constituents of cacti that have been shown to have toxic effects on adults and larvae of nonresident *Drosophila* species include medium-chain fatty acids (C_8 to C_{12}) and dihydroxy sterols in agria and organ pipe cacti and high concentrations (3–15% dry weight) of alkaloids in senita cactus (Kircher, 1969, 1982). These fatty acids and sterol diols are toxic to *D. nigrospiracula* (Fogleman et al., 1986; Fogleman and Kircher, 1986), and senita alkaloids are toxic to both *D. nigrospiracula* and *D. mojavensis* (Kircher et al., 1967). Although larval viability is significantly reduced in some cases, laboratory experiments have demonstrated that *D. mettleri* can successfully complete larval development in necrotic tissues of all five cactus species mentioned above (Fogleman, 1984).

Despite its chemical tolerance, *D. mettleri* appears to be behaviorally restricted to soil-breeding, but not necessarily to soils soaked by a particular species of cactus. Adults have been reared from naturally occurring organ pipe-soaked soil (Fogleman et al., 1981) and from artificially produced senita-soaked soil in the field (Fogleman et al., 1982). It probably also uses agria-soaked soil, but no rearing records are available for this substrate. Cardón- and saguaro-soaked soils, however, are more commonly used because, being much larger cacti than the others, rots in these species are more likely to produce an adequate substrate. In essence, *D. mettleri* is an opportunistic generalist.

The ability of *D. mettleri* to use all of the cactus species as feeding substrates represents an obvious ecological advantage over the other, more restricted cactophilic *Drosophila*. Since several of the columnar cactus species are present in any given area of the Sonoran Desert, the density of feeding substrates for *D. mettleri* is greater. Its penchant for opportunistically using any soaked soil is also of ecological value in the stringent environment of the desert. The question of current interest is how *D. mettleri* became tolerant to the alkaloids present in necrotic tissue of senita cactus in light of the fact that other cactophilic *Drosophila* (i.e., *D. nigrospiracula* and *D. mojavensis*) have remained intolerant and that the evolutionary history of *D. mettleri* does not support the idea that it evolved its tolerance in the same manner as the resident species, *D. pachea*.

The cacti which produce soaked soils more commonly used by *D. mettleri*, saguaro and cardón, also contain alkaloids (Gibson, 1982). Brown et al. (1972) reported that 95% of the alkaloids in saguaro are the isoquinolines, carnegine (1,2-dimethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline) and gigantine (1,2-dimethyl-5-hydroxy-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline). The remaining 5% are trace β-phenylethylamine and isoquinolines (Ordaz et al., 1983). The chemical structures of the major saguaro alkaloids are depicted in Figure 1. The senita alkaloids, lophocereine (1-isobutyl-2-methyl-6-methoxy-7-hydroxy-1,2,3,4-tetrahydroisoquinoline), pilocereine, and piloceredine (two lophocereine trimers), were first isolated and identified by Djerassi et al. (1958, 1962). The majority of the alkaloid fraction of senita exists as the trimers which are more stable than the monomer, lophocereine (Kircher et al., 1967). The structures of lophocereine and pilocereine are also shown in Figure 1. The fitness measurements made by Kircher et al. (1967) demonstrate that the toxicity of senita alkaloids is mainly due to pilocereine since lophocereine (at 1% dry weight of the medium) has essentially no effect on adult longevity and a comparatively minor effect on larval viability. A subsequent study of the effect of senita alkaloids on *D. mettleri* showed that this species was less affected with respect to adult longevity and larval viability than *D. pachea* at concentrations which are fatal to other desert *Drosophila* (Fogleman et al., 1982). This same study reported that, in collections of adults feeding on rotting senita in nature, *D. mettleri* can be present in significant proportions, sometimes outnumbering *D. pachea*.

In contrast to senita, the alkaloids in saguaro are only present at 1–1.7% of the dry weight of the tissue (Brown et al., 1972) and, at these concentrations, are apparently not toxic to the larvae of any of the desert *Drosophila* (Fellows and Heed, 1972). However, the actual breeding site of *D. mettleri* represents a situation where the alkaloids may be much more concentrated. As rot juice continually drips on the soil, water evaporates—producing a substrate in which all solutes become more concentrated than in the tissue itself. Therefore, the alkaloids in saguaro- and cardón-soaked soils could be in sufficiently high con-

FIG. 1. Chemical structures of saguaro and senita alkaloids: (A) carnegine, (B) gigantine, (C) lophocereine, (D) pilocereine.

centration that the adaptations which accompanied the evolutionary invasion of *D. mettleri* into the soaked-soil niche convey tolerance to similar compounds in other substrates, e.g., necrotic senita tissue. This was suggested by Fogleman et al. (1982) as a possible explanation of *D. mettleri*'s ability to tolerate senita alkaloids. The similarity in chemical structure of saguaro alkaloids and lophocereine can be clearly seen in Figure 1.

This paper reports the results of experiments designed to test the following questions: (1) is the concentration of alkaloids in samples of saguaro-soaked soil greater than that of the tissue? and (2) do elevated concentrations of saguaro alkaloids have any effect on fitness parameters of cactophilic *Drosophila*? Fitness was estimated through the standard parameters of adult longevity and larval viability and developmental rate. *Drosophila nigrospiracula* and *D. mojavensis*

were also tested as controls since their response to senita alkaloids is known and neither species is capable of utilizing soaked soils as larval substrates.

METHODS AND MATERIALS

Strain Derivation. Strains of all three *Drosophila* species were multifemale lines initiated by rearing adults from natural substrates. Cultures had been maintained in the lab on Carolina Instant *Drosophila* Medium (Formula 4-24) for approximately two years. All experiments were carried out under ambient laboratory temperature (ca. 25°C) and humidity. Although these parameters varied during the experimental period, all replicates were subject to identical conditions.

Alkaloid Extraction. Fresh saguaro tissue (ca. 30 kg) was extracted first with methanol and then with a 2 : 1 chloroform–methanol solution in a continuous Soxhlet extractor. The evaporated extracts were added to a 5% HCl solution and extracted several times with ether. The aqueous phase was made alkaline with NH_4OH and extracted with ether. The ether was evaporated and the crude alkaloids were purified through another ether–HCl–NH_4OH–ether sequence followed by evaporation. A total of 38.51 g (0.9% of the dry weight of the plant) of purified alkaloids was obtained in this manner. Since soaked soil and cactus tissue differ greatly with respect to percent dry weight, alkaloid concentration is expressed as milligrams of alkaloids per milliliter of water (total weight minus dry weight) so that direct comparisons can be made between substrate types. The concentration of alkaloids in the fresh tissue was determined to be 1.50 mg/ml.

Alkaloid solutions were made up by dissolving the purified alkaloids in slightly acidic water (pH 6.0 via phosphoric acid). These solutions had alkaloid concentrations of 5, 10, and 15 times the concentration of fresh tissue based on the following parameters: dry weight = 14.27%; alkaloid concentration = 1.0% dry weight (1.67 mg/ml). The 5×, 10× and 15× concentrations represent 8.35, 16.7, and 25.04 mg/ml respectively. A control solution was composed of the acidic water without alkaloids.

Three soaked-soil samples weighing approximately 1337, 344, and 593 g respectively, were collected from beneath rotting saguaros in the vicinity of Tucson, Arizona. Only the top 2.5 cm of soil was taken, and all three samples contained *D. mettleri* larvae. Alkaloids were extracted and their concentrations in the soil samples were determined in the manner described above.

Adult Longevity Experiments. Three replicate sets of four vials (10 × 6 cm) were set up for both sexes of *D. mettleri*, *D. nigrospiracula*, and *D. mojavensis*. The vials contained a total volume of 10 ml of *Drosophila* medium consisting of 5 cc of dry *Drosophila* medium (Carolina Formula 4-24) and 5 ml of one of the solutions (0, 5×, 10×, or 15×). Approximately 10 grains of

bakers' dry yeast were added to each vial. Thirty-three adult flies (5–10 days old, sexes separate) were placed in each vial, and the number of dead flies in each vial was recorderd daily. Twice a week, the flies were transferred to vials containing fresh food. The experiments were terminated after 30 days or when half the flies had died (LT_{50}), whichever period was longer.

Larval Viability and Developmental Rate Experiments. First-instar larvae were obtained by allowing adults of the three species to oviposit in water–agar Petri dishes which contained a 2.5 cm patch of a paste made from dry saguaro powder and water. The flies were transferred to new plates daily. Plates containing eggs were stored for 24 h until the first-instar larvae hatched. Larvae were transferred to experimental media with a small probe.

Three replicate sets of four Petri dishes (60 × 15 mm) were set up for *D. mettleri*, *D. nigrospiracula*, and *D. mojavensis* larvae. Each dish contained 10 cc of dry *Drosophila* medium, 10 ml of one of the alkaloid solutions (0, 5×, 10×, or 15×), several grains of bakers' dry yeast, and 50 first-instar larvae. The number of eclosing adults was recorded daily until eclosion ceased. These data represent the viabilities of the larvae in media containing different alkaloid concentrations. Arcsine transformation was performed on the data before statistical analysis. Developmental rate was calculated as the average number of days required for eclosion for all flies eclosing from each concentration.

RESULTS AND DISCUSSION

Table 1 contains the data on alkaloid concentration in senita and saguaro tissue that have been reported in the literature and our determination of the average concentration present in field samples of saguaro-soaked soil. The concentration in soaked soils ranged from about 1.4 to 27 times the typical alkaloid concentration in fresh saguaro tissue (1% dry weight or 1.67 mg/ml). One of the three soil samples (concentration = 45.4 mg/ml) is probably close to an upper limit in alkaloid concentration since this sample was very tarry and contained only one *D. mettleri* larva. These results support the hypothesis that the

TABLE 1. ALKALOID CONCENTRATIONS (IN mg/ml OF AVAILABLE WATER) IN *Drosophila* SUBSTRATES

Substrate type	*N*	Average	Range	Reference
Senita tissue (mature stems)	12	10.7	6.5–20.5	Kircher (1969)
Senita tissue (young stems)	10	12.7	1.8–36.8	Kircher (1969)
Saguaro tissue (mature stems)	not reported		1.4–2.4	Kircher (1982)
Saguaro-soaked soils	3	17.8	2.4–45.4	

plant solutes are more concentrated in the soaked-soil substrate than in the plant itself. Furthermore, the range of alkaloid concentrations measured in saguaro soil is greater than and includes the entire range of values reported for senita.

The results of adult longevity experiments are given in Table 2. The parameter, LT_{50}, was obtained by averaging the three replicate vials for each alkaloid concentration. Although average longevity of both sexes of all three species decreased with increased alkaloid concentration in the medium, this trend was much more pronounced (and statistically significant) for *D. nigrospiracula* and *D. mojavensis*. The percent reduction in longevity (averaged over sex) for *D. nigrospiracula* and *D. mojavensis* with the 5× treatment was 56.7 and 48.9, respectively, as compared to only 91.4 for *D. mettleri*. *Drosophila nigrospiracula* was also the only species in which there was a difference in longevity between sexes. Males consistently exhibited greater longevity than females. In two-way analyses of variance for all three species, no significant interactions were detected for either sex by alkaloid concentration or species by alkaloid concentration. The ability of adults to tolerate saguaro alkaloids may be summarized by: *D. mettleri* > *D. mojavensis* > *D. nigrospiracula*.

The results presented above may be compared with those obtained by Kircher et al., (1967) and Fogleman et al. (1982) in their investigations of the effect of senita alkaloids on adult mortality. Kircher demonstrated that *D. mojavensis* and *D. nigrospiracula* were intolerant of senita alkaloids (or purified pilocereine) at 1% of the dry weight of the medium, while Fogleman and his co-workers revealed that *D. mettleri* was less affected than the resident species, *D. pachea*, by alkaloid concentrations up to 10% dry weight. Although these studies and the present investigation may be considered parallel and both saguaro and senita cacti contain isoquinoline alkaloids, it should be emphasized that senita's alkaloid composition is much more complex. The majority of the alkaloid fraction of senita is composed of the trimers, pilocereine and piloceredine, which are more toxic than the monomer (Kircher et al., 1967). The toxicity of lophocereine at levels above 1% dry weight is not known, but it is reasonable to expect that it would be directly comparable to that of the simple saguaro alkaloids.

The results of the investigation of the effect of saguaro alkaloids on larval viability are shown in Table 3. The statistical analyses indicate that, unlike adult longevity, larval viability of all three species is significantly affected by increasing concentrations of alkaloids in the medium. *Drosophila nigrospiracula* was, by far, the most affected since no adults eclosed from media containing alkaloid concentrations of 10× and 15×.

For *D. mettleri* and *D. mojavensis*, it is of interest to determine the alkaloid concentration at which they first suffered a significant reduction in viability. A Student-Newman-Keuls procedure, which is a multiple comparison test for differences between means (Sokal and Rohlf, 1969), showed that *D. mettleri* ex-

D. mojavensis	3	50.7 ± 9.7	52.0 ± 11.7	34.7 ± 7.7	6.0 ± 3.1	7.641[c]

[a] Results of one-way ANOVA (F_s) on arcsine transformed data are also given.
[b] Times the concentration in fresh tissue (1.67 mg/ml).
[c] $P < 0.01$.
[d] $P < 0.001$.

perienced the viability decrease at the 5× concentration since all means were significantly different. The larval viability of *D. mojavensis* was only decreased in the 15× medium since the average viabilities in the 0, 5×, and 10× media were not significantly different.

The ability of *D. mojavensis* larvae to tolerate high concentrations of alkaloids was unexpected because this species does not utilize senita rots or saguaro-soaked soil, and its occasional utilization of saguaro rots would not expose it to alkaloid concentrations much greater than 1.67 mg/ml. The fact that the normal host plants of *D. mojavensis* contain toxic compounds, i.e., dihydroxy sterols and medium-chain fatty acids, provides a possible explanation of this phenomenon. Whatever mechanism, detoxification or exclusion, is responsible for the tolerance of *D. mojavensis* larvae to these compounds may also convey tolerance to the chemically simple saguaro alkaloids.

In previous studies on the toxicity of senita alkaloids to *Drosophila* larvae, the F_1 and F_2 generations of *D. mojavensis* were drastically reduced compared to controls when either senita cactus or medium containing 1% dry weight pilocereine was used (Kircher et al., 1967). Still, *D. mojavensis* produced more F_2 progeny under these conditions than most of the other eight species tested. Therefore, some tolerance to senita alkaloids has been demonstrated, but *D. mojavensis* larvae appear to be more tolerant of saguaro alkaloids than of senita alkaloids. Senita alkaloids in fly medium at 5% dry weight reduced the egg-to-adult viability of *D. nigrospiracula* to one third of the percent viability in control medium without alkaloids, while 10% alkaloids reduced the viability to zero (Fogleman et al., 1982). The viabilities of *D. mettleri* and *D. pachea* were not significantly reduced even in medium containing 10% senita alkaloids. Senita and saguaro alkaloids, then, have a similar effect on the larval viability of *D. nigrospiracula*. On the other hand, *D. mettleri* appears to be less affected by the alkaloids present in senita than by those in saguaro-soaked soils since the 5× treatment (Table 3) caused a significant reduction in larval viability.

TABLE 4. EFFECT OF SAGUARO ALKALOID CONCENTRATION ON LARVAL DEVELOPMENT TIME (AVERAGE NUMBER OF DAYS TO ECLOSION ± SE)[a]

[d] $P < 0.001$.

The average number of days to eclosion for each species in the different alkaloid concentration media are reported in Table 4. The data for *D. nigrospiracula* were not statistically analyzed due to the low number of flies that eclosed. Both *D. mettleri* and *D. mojavensis* showed a significant increase in development time with increasing concentration of alkaloids in the medium. Although the increase in development time for both species was approximately two days, the value of the F statistic for *D. mojavensis* was much greater than that for *D. mettleri*. This is probably due to the greater number of *D. mojavensis* adults which eclosed. The significance of the change in development time may be magnified as a consequence of the larger sample size. In comparison, a significant increase in the developmental rate of *D. mettleri* was not observed in response to senita alkaloids (Fogleman et al., 1982). The effect of senita alkaloids on the developmental rate of *D. nigrospiracula* was minor compared to the loss of larval viability, and their effect on *D. mojavensis* has not been tested.

In summary, the results show that saguaro alkaloids are, in fact, significantly more concentrated in samples of soaked soil than in the cactus tissue. The negative effect of elevated alkaloid concentration on fitness parameters of cactophilic *Drosophila* has also been demonstrated. The intolerance of *D. nigrospiracula* to elevated alkaloid concentration partly explains the inability of this species to utilize saguaro-soaked soil. Both *D. mettleri* and *D. mojavensis* are much more tolerant of high saguaro alkaloid concentration than *D. nigrospiracula*. The primary difference between *D. mettleri* and *D. mojavensis* with respect to saguaro alkaloids is the greater tolerance of *D. mettleri* adults. The viability of *D. mojavensis* larvae in saguaro-soaked soil has not been tested, but adults have never been reared from this substrate in nature. Other factors, such

as soil abrasiveness, tolerance to desiccation, or absence of chemicals associated with adult attraction, may also be involved in the exclusion of *D. mojavensis* from saguaro-soaked soil (Fogleman and Heed, 1987).

Little is known about the action of dietary alkaloids on insects (Fogleman et al., 1982). Suggestions on this subject include the idea that alkaloids may block steroid metabolism or phytosterol assimilation (Schreiber, 1958; Harley and Thorsteinson, 1967). The physiologic mechanism exhibited by *D. mettleri* and *D. mojavensis* which conveys tolerance to the toxic compounds in cacti is also unknown. However, a group of enzymes, collectively called mixed-function oxidases (MFOs), have well-established roles in the metabolism of insecticides and the protection of insect herbivores against chemical stress from secondary plant substances (Agosin and Perry, 1974; Brattsten et al., 1977). MFO activity in the midgut of southern armyworm moth larvae was induced to 270% that of control larvae when the *N*-heterocyclic compound, quinoline, was added to the diet at 0.1% (Brattsten et al., 1977). Other secondary plant compounds also induced MFO activity in this insect, but quinoline has the same chemical skeleton as both saguaro and senita alkaloids. A considerable amount of research has been recently reported on MFO activity in *Drosophila melanogaster*. In general, these reports demonstrate that MFO activity is induced by a variety of insecticides and mutagenic chemicals, most of which are nitrogen-containing compounds (Baars et al., 1980; Hällström et al., 1981; Hällström and Grafström, 1981; Zijlstra et al., 1984). MFO activity in this species of *Drosophila* may be genetically related to chemical resistance in that resistant strains have higher MFO activity than susceptible strains (Morton and Holwerda, 1985). In one study, the gene responsible for the MFO activity pattern in an insecticide-resistant strain of *D. melanogaster* was mapped near to, and thought to be identical with, a gene known to impart insecticide resistance (Hällström et al., 1982).

It is likely, therefore, that MFO enzymes are also involved in the ability of certain cactophilic *Drosophila* to tolerate the toxic compounds present in cacti. At present, our hypothesis is that *D. mettleri* and *D. mojavensis* have either a higher basal level of MFO activity than *D. nigrospiracula* or that MFO activity can be induced to higher levels in these species. Our results also lead us to expect a difference in MFO activity level between adults of *D. mettleri* and *D. mojavensis*.

The evolutionary history of the cactophilic *Drosophila* was recently reviewed by Heed and Mangan (1986). *Drosophila mettleri* is now thought to be a marginal isolate of a once widespread species. Many of the present-day adaptations of the four species associated with the Sonoran Desert probably were initiated along with the ecological shift of the region from thorn forest to existing desert conditions (Heed and Mangan, 1986). Unfortunately, it is not possible to determine when, in evolutionary time, *D. mettleri* developed the adaptations necessary to colonize soaked soil as a breeding substrate. The results

reported herein suggest that one adaptation that is necessary in order to utilize the saguaro-soil niche is the ability to tolerate toxic alkaloids. Given the chemical relatedness of saguaro and senita alkaloids, tolerance to the latter is probably derived from the same mechanism as tolerance to the former. The ecological significance of alkaloid tolerance, as previously mentioned, is that *D. mettleri* adults can and do use senita rots as alternate feeding substrates. This gives *D. mettleri* an ecological advantage over other, more restricted species. The observational rarity of senita-soaked soil in nature is an additional indication that the major advantage of the tolerance of *D. mettleri* to senita alkaloids is to the adult rather than the larval stage of the life cycle.

Acknowledgments—This research was supported by NSF grant (BSR-8207056) and NIH grant (GM34820) to J.C.F. and a grant from the University of Denver undergraduate honors program to J.M.M. We wish to thank Drs. W.T. Starmer and W.B. Heed for their helpful comments and critical review of the manuscript.

(Received August 13, 1986; accepted December 5, 1986)

Abstract—Agroecosystems in Tlaxcala, Mexico, are surrounded by trees and water channels and have a great variety of cultivated and noncultivated plants. The main results of a study carried out on a traditional agroecosystem in Santa Inés, Tlaxcala are presented. Some ecological aspects of polycultures, plant covers (dry leaves of *Alnus firmifolia*, *Berula erecta*, and *Juncus* sp.), and the allelopathic potential of crops and noncultivated plants (fresh and dry material) were analyzed. The main plants (trees, shrubs, and herbs) present in the agroecosystem were identified. The total number of weeds in plots where plant covers were added was reduced. The number of nodules of *Rhizobium phaseoli* and the production of bean and squash increased with plant covers. Corn, beans, and squash showed a clear allelopathic effect, as well as *Chenopodium murale, Tradescantia crassifolia, Melilotus indicus,* and *Amaranthus hybridus*, among other weeds. The contribution of allelopathy in studies of traditional agroecosystems is of great importance for the management of species in space and time. Allelopathy can be the basis of biological control of pests and weeds and of the discovery of new useful substances.

Key Words—Allelopathy, traditional agroecosystems, corn, bean, squash, *Alnus firmifolia, Berula erecta,* green manures, *Rhizobium phaseoli*, agroecology, Tlaxcala, "camellones."

INTRODUCTION

The need for an holistic view of the ecology of agroecosystems, especially of the traditional ones, is greater than ever, because the damage to natural re-

0098-0331/87/1100-2083$05.00 © 1987 Plenum Publishing Corporation

sources and the demographic explosion endanger the future survival of humanity. The study of the traditional management of the land offers new alternatives to understand the structure and function of the ecological systems managed by man and to find appropriate technologies to get a sustainable production with minimum deterioration of the environment. The study of allelopathy, within this context, mainly contributes to the general management of the species in time and space, since it can be the basis for the biologic control of pests and weeds, and for the discovery of new drugs, herbicides, pesticides, and growth regulators (Farnsworth, 1977; Rice, 1984; Waller, 1982).

In Mexico (Figure 1), we find a traditional use of land in the deserts in the north; the "chinampas," "terrazas," and "camellones" in the center; and the corn fields and home gardens of the Mayas in the southeast. There exists much information related in some way to allelopathy, which should be carefully studied and applied to benefit the production of food, wood, and other raw materials.

In parts of Mexico, peasants deliberately permit the growth of some weeds in the crop fields. These are named "buen monte" in the southeast, as opposed to the bad weeds ("mal monte") that are commonly eliminated (Chacon and Gliessman, 1982). In certain shaded coffee plantations in Xalapa, Veracruz, some species of Commelinaceae from the herbaceous stratum are favored, cultivated, and managed by peasants together with the coffee crop, to protect the soil, to produce organic matter, to retain humidity, and to eliminate other weeds (Anaya et al., 1982; Ramos et al., 1983). In the chinampas of the Valley of Mexico, peasants use water hyacinth to improve the soil, because it can prevent the growth of some weeds, stop salt deposition by evaporation on the soil surface, and increase the organic matter content (Anaya et al., 1987).

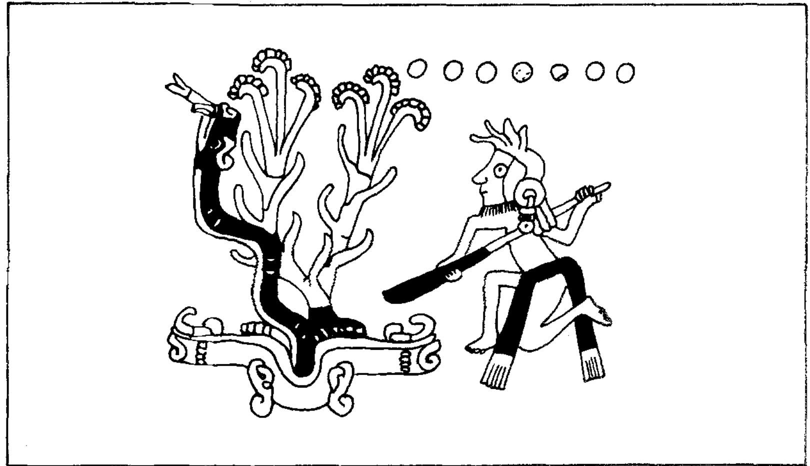

FIG. 1. Antique Nahua illustration representing the traditional cultivation of corn.

The traditional agroecosystems (camellones) in Tlaxcala, Mexico, include the management of trees, shrubs, and herbs that are useful in many ways for the local people. Fields are surrounded by water and trees, mainly *Alnus firmifolia* (Figure 2), and these constitute the main components in the agricultural landscape. Peasants cultivate a great variety of corn, bean, squash, oat, onion, lettuce, radish, barley, garlic, different spice herbs, lucerne and other forage plants; and fruit trees such as apple, appricot, peach, avocado, capulin, and tejocote (sloelike fruit), using different intercropping and rotation practices. They also use different plant and animal manures: for example, leaves of maguey, capulin, sabine, and alder or the decomposing organic matter from the leaves of plants accumulated in the water channels that surround some of the fields (González-Jácome, 1984, 1985).

Importantly, from an agricultural point of view, Tlaxcala is the most efficient and autosufficient state, as the consumption of fertilizers, pesticides, and herbicides is the lowest in Mexico (Dr. José Nieto de Pascual, personal communication).

In recent years, there have been studies of mixed-crop systems with the specific intention of looking for the effects of allelopathic compounds actively being added to the environment by the different members of the mixture (Ama-

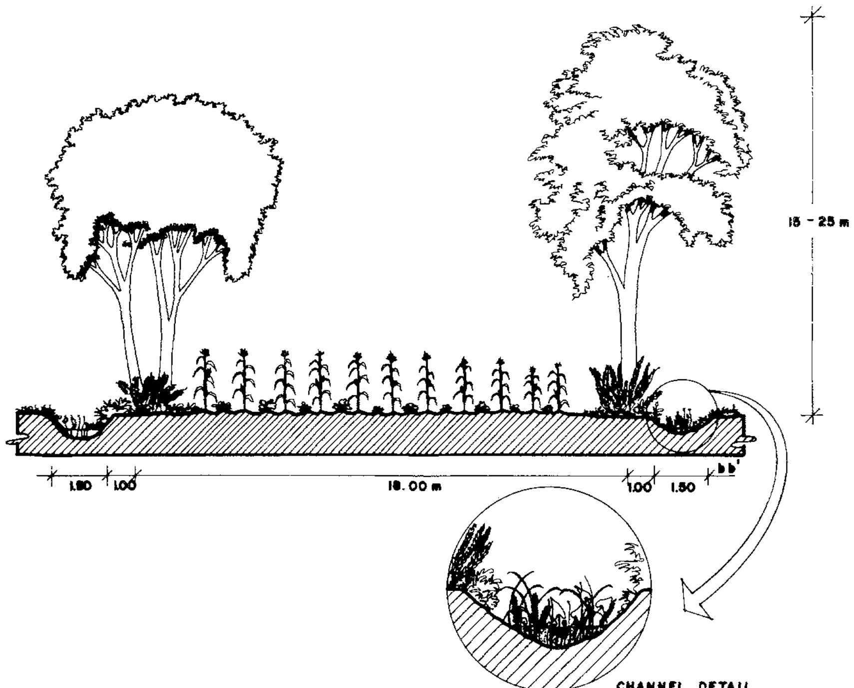

FIG. 2. Transverse view of a camellón in Santa Inés Tecoexcomac, Tlaxcala, México.

dor and Gliessman, 1982; Jiménez-Osornio et al., 1983; Dzyubenko and Petrenko, 1971). In order to better understand the way in which cultivated and wild plants in a traditional agroecosystem (camellón) of Tlaxcala interact with their neighbors, this study analyzes the use of some of the cultural practices of peasants in this zone, like the use of native selected seeds, the combination of different crops and varieties, the different purposes of the use of wild and cultivated trees and shrubs along the border of the camellones, the use of water deposits where aquatic plants and organic matter are accumulated, the rotation of crops, the control of weeds, the use of natural manures, the use of noncrop plants as fodder, food, or medicines. In relation to the use of green manures or plant covers, we studied the use of two different kinds: leaves of *Alnus firmifolia*, *Berula erecta* and *Juncus* sp. and their effect on the growth of weeds, and *Rhizobium* sp. inoculations. We studied also the results of different bioassays designed to detect the allelopathic potential of crops and noncultivated plants.

METHODS AND MATERIALS

Field Experiment. A field experiment was carried out in Santa Inés Tecoexcomac, Tlaxcala, Mexico, during 1985. This place is located in a valley between the Atoyac and the Zahuapan rivers, with a temperate, subhumid climate. Rainfall is concentrated during the period from May to October, with an annual average of 1000 mm, and into an irrigated agricultural zone, where the traditional cultivation plots are called camellones. These are strips of land surrounded on two or three sides by water channels, similar to the chinampas.

A typical camellón of 273 × 18 m, cultivated for the last three years with three varieties of corn, was selected. Some years before it had been cultivated in rotation with different kinds of beans, lucerne, and squash. The three varieties of native corn usually sowed in here are: spotted corn, red corn, and blue corn. The former is the most productive and the "slowest" of these, as it matures one or more months later than blue or red corn and it is used commonly to make tortillas. Red corn is used to make atole (hot drink made with milled dried corn and milk) and tamales (cooked corn dough with meat or fruit inside a dry corn leaf) because it is very sweet. Blue corn is also used to make tortillas, and its special flavor is appreciated by all the people.

Soil samples were collected at 0–40 cm for chemical and physical analysis. Plowing and sowing were accomplished in the traditional way with animal traction and manual work. The following crops were placed in a complete randomized block design: (1) native spotted corn in monoculture, (2) native spotted corn plus "canary" beans, (3) native spotted corn plus Italian squash.

Corn was sowed on April 30 by making a hole every 90 cm along the furrow with a shovel and putting four seeds in it. Beans and squash were sowed on May 15 in the same way, next to the furrows of corn. Three treatments with

four replications were applied to each culture: (1) control (without plant cover), (2) cover with *Alnus* leaves, and (3) cover with *Berula erecta* and *Juncus* sp. leaves.

Each plot was 3 × 21 m in size and had three longitudinal furrows, where 50 kg of leaves were spread during the first week of June and 50 kg more during the first week of July. The weeds in the different plots were identified and quantified on June 30, August 31, and September 30. The plots were weeded the last week of July. Squash was harvested in August and beans in September. Corn was cut in the last days of September and left drying in the field until October, when it was harvested. The total number of weeds was analyzed as a split–split plot design. Corn, bean, and squash production data were analyzed as a randomized complete block design.

Experiment with Rhizobium *in the field.* A plot 18 × 30 m was selected and corn was interplanted with canary bean. Before sowing, beans were divided into two groups: one group was inoculated with a mixture of three strains of *Rhizobium phaseoli* (C MexI, C MexII, and C Mex 22); the other group was not inoculated.

Following a randomized complete block design, four treatments with three replications were applied to each group: (1) cover with *Alnus* leaves; (2) cover with *Berula* and *Juncus* leaves; (3) without cover, weeding the plot; and (4) without cover, without weeding.

Each plot was 3 × 4 m in size. Corn was sowed on April 30, and beans were sowed every 50 cm next to the furrows of corn on June 15. The treatments were applied twice, on July 1 and August 5, spreading 30 kg of leaves uniformly along the furrows of corn and bean in each plot.

To quantify the number of nodules of *Rhizobium* in the roots, in each treatment two samples of bean plants were collected 30 and 60 days after sowing. The results were analyzed by analysis of variance with two factors.

Laboratory Bioassays. Four kinds of bioassays were carried out to detect the allelopathic potential of crops and weeds, testing leachates of fresh leaves, roots, and dry leaves as shown in Table 1. Aqueous leachates of 10 g of aerial parts and roots of fresh plants and 1 g of dry leaves were used, with the osmotic pressure being measured and controlled. Ten milliliters of each leachate were mixed with 10 ml of agar (2%) in Petri dishes where seeds were sowed. Controls were made with agar (1%). Petri dishes were placed in the dark at 25°C. All experiments included three replications. At the end of each experiment, the radicle length of the seedlings was measured. All the results were analyzed as a complete randomized block design.

Seeds of the following species were tested: cultivated seeds—native spotted corn, Italian squash, and canary bean; weed seeds—*Amaranthus hybridus, Plantago major, Hordeum vulgare, Echinochloa crusgalli, Portulaca oleracea, Amaranthus leucocarpus*, and *Brassica campestris*.

RESULTS AND DISCUSSION

Field Experiments. Soil analysis showed that the plot is characterized by a slimy sand soil with an alkaline pH (8.3) and a low electrical conductivity (0.57 mmho/cm), without salinity problems. The plot is fertilized with small quantities of cow manure once a year, before sowing the crops, so it is fairly rich in organic matter (2.3%), nitrogen (0.15%), and phosphorus (14 kg/hectare); this soil has a TICC[1] of 19.5 meq[2]/100 g. Ca^{2+}, Mg^{2+}, and K^+ are the most abundant cations, characteristic of calcareous soils.

Table 2 lists the main species and families of weeds found in the plots. The Compositae was the most abundant family; the species *Bidens aurea, Melampodium perforatum, Galinsoga parviflora,* and *Simsia amplexicaulis* were very conspicuous in all the plots. These shared their dominance mainly with Chenopodiaceae (*Chenopodium album* and *Ch. murale*), Amaranthaceae

TABLE 2. LIST OF FAMILIES AND WEEDS IN THE PLOTS

Compositae	*Bidens aurea, Melampodium perforatum, Simsia amplexicaulis,* and seven more species
Amaranthaceae	*Amaranthus hybridus*
Chenopodiaceae	*Chenopodium album, Ch. murale*
Convolvulaceae	*Ipomea* sp.
Cucurbitaceae	*Sicyos deppei*
Leguminosae	*Melilotus indicus, Medicago lenticulata, Dalea leporina*
Polygonaceae	*Polygonum aviculare*
Commelinaceae	*Tradescantia crassifolia, Commelina erecta*
Oxalidaceae	*Oxalis* sp.
Solanaceae	*Physalis* sp., *Solanum nigrum*
Labiatae	*Salvia tiliaefolia, Marrubium* sp.
Onagraceae	*Lopezia racemosa*
Cruciferae	*Brassica camperstris, Raphanus raphanistrum, Lepidium* sp.
Portulacaceae	*Portulaca oleracea*
Cyperaceae	*Cyperus* sp.

[1]TICC = total interchange cations capacity.
[2]meq = milliequivalent.

(*Amaranthus hybridus*), Commelinaceae (*Tradescantia crassifolia*), Cucurbitaceae (*Sicyos deppei*), Convolvulaceae (*Ipomea* sp.), Leguminosae (*Melilotus indicus* and *M. lenticulata*), and Solanaceae (*Physalis* sp. and *Solanum nigrum*).

On the border of camellones under the shade of the trees, the herb stratum was dominated by Gramineae and the shrub stratum by *Baccharis glutinosa* (jarilla) (Figure 3). The latter is cut in winter and used by peasants as firewood. In the water channels, the most abundant aquatic plant is *Berula erecta* (Umbelliferae) and various species of *Juncus, Lemna minor, Hydrocotile* sp., and *Typha* sp., among others.

The total numbers of weeds in the plots when they were quantified on June 30, August 31, and September 30 (hereinafter termed "times") were significantly different between times (Table 3), since the entire parcel was hand weeded at the end of July (Figure 4). However, the interaction between times and managements (treatments) was significantly different (Table 3). In June, August, and September, the number of weeds in the plots with *Alnus* and *Berula* and *Juncus* was significantly reduced compared with the number of weeds in plots without cover. Also, the total number of weeds in plots with *Berula* and *Juncus* cover was significantly smaller than with *Alnus* cover. This suggests that the decomposition of both kinds of cover (especially *Berula* and *Juncus*) may release some allelopathic compounds that contribute to the control of weeds.

The total number of weeds in the corn–squash plots was significantly smaller than in the corn–bean and monoculture corn plots (Figure 4). This is due probably to the allelopathic potential of squash observed in many kinds of agroecosystems (Chacon and Gliessman, 1982).

The interaction between crops and managements (Table 4) was also significant; the total number of weeds in the three crops with plant cover was lower than in the plots without cover. *Alnus* and especially *Berula* and *Juncus* contributed to reduce the growth of weeds in all plots.

The production of corn was similar in the three treatments whether in monoculture or in polyculture (Table 5). The production of beans was significantly higher in the plots with both covers and that of squash was higher only in the *Berula* and *Juncus* treatment. It is observed that this kind of cover had the most inhibitory effect on the growth of weeds, but, on the other hand, it was the only one that improved squash production. Finally, squash seemed to be the only crop with an inhibitory effect on weed growth in this field experiment.

It is necessary to conduct more studies during the annual cycles to determine which are the soil properties that change with the incorporation of plant covers and improve bean and squash production, and to detect if there are some stimulating compounds released into the soil through the decomposition of plant covers. On the other hand, it is a fact that peasants receive many benefits using polyculture, because they obtain a diversified production in the same time and space.

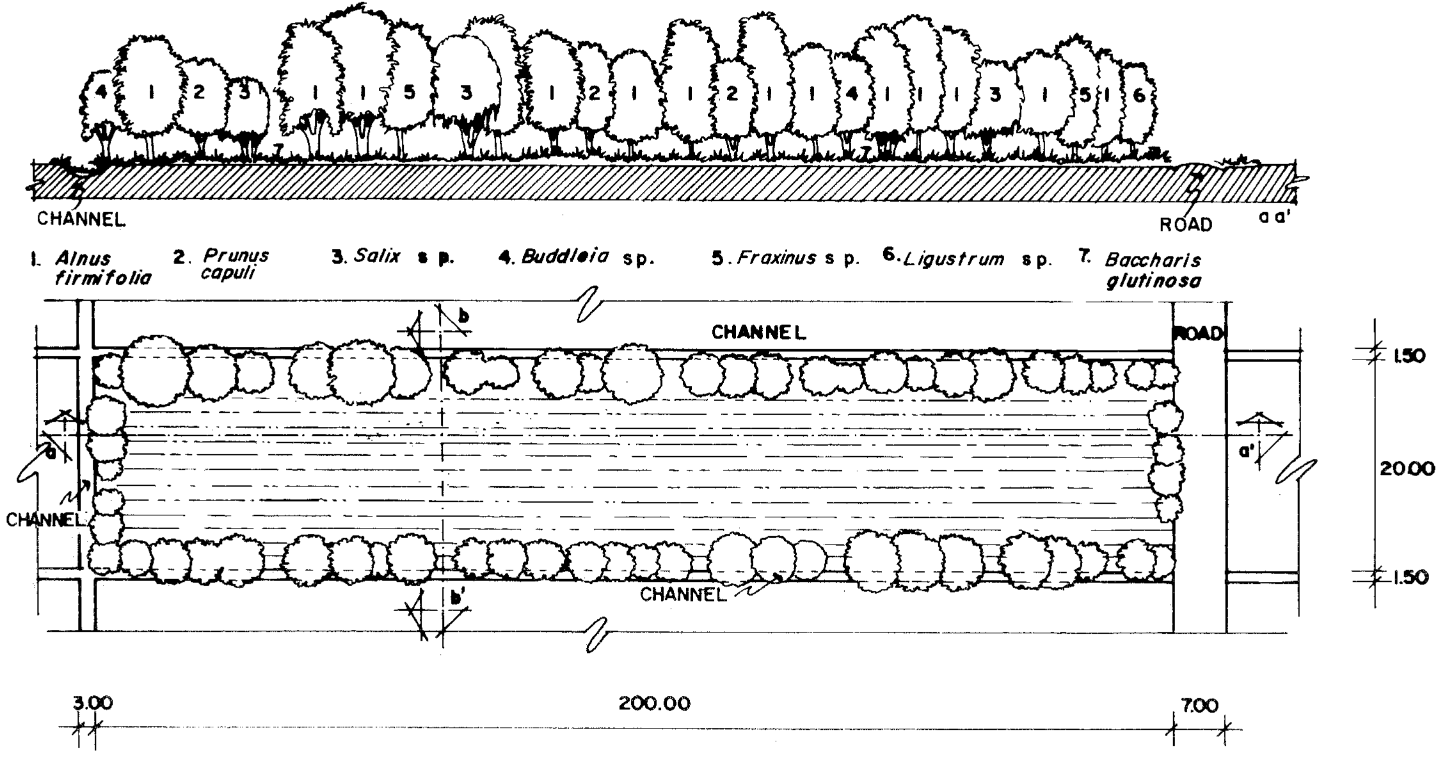

FIG. 3. Profile and scheme of the camellón, showing the main species in the border.

Experiment with Rhizobium. The numbers of nodules on the roots of beans were significantly different between inoculated and noninoculated beans at 60 days after they were sowed (Table 6). There is also a significant difference within each management. Both covers (*Alnus* and *Berula*) caused an increase of the number of nodules, especially *Berula* and *Juncus*. In the plots without weeding, the number of nodules in inoculated beans was also increased. Pena-Cabriales and Alexander (1983), suggested that appreciable *Rhizobium* growth in unamended soil occurs only in the presence of germinating seeds, growing roots, and decomposing nodules. In this case, it is possible that the presence of a great variety of compounds in the rich rhizosphere of these plots can be a factor that increases the development of *Rhizobium*. It is also possible that these compounds are inhibitory to other microorganisms or even green plants, because the effects are different depending on the receptor organism. This is a general rule in allelopathy.

Nevertheless, in the case of camellones, there exist various nitrogen-fixing microorganisms in the different species of cultivated and noncultivated plants whose dynamics are determined to a great degree by the special management the peasants give to the agroecosystems. Winter crops are preferentially legumes such as lucerne and broad bean. Several nitrogen-supplying species of noncultivated plants exist in the fields of Tlaxcala where *Alnus* is one of the most important ones. Through its root nodules, it releases significant amounts of nitrogen to the soil. This fact has been mentioned by many researchers on other species of *Alnus* (Atkinson and Hamilton, 1978; Berg and Doerksen, 1975). For this reason *Alnus* is an important element in the agroecosystem, but it is also a tree of increasing value for its wood products. Moreover, in the summer, *Macrodactylus* sp. (frailecillo), one of the main insect pests of corn and other cultivars, is trapped by the leaves of *Alnus* and of *Baccharis glutinosa* (jarilla), located at the borders of the plots, preventing its attack on the crops. Farrell et al. (1987) mentioned the same beneficial role of other "trap plants,"

such as *Lupinus* spp. and *Brassica campestris*. *Alnus*, on the other hand, is a soil builder, because its litter production constantly adds organic matter to soils; the soil can be covered in some periods of the year, especially in winter, with a great amount of leaves of this tree. This fact is important for good development of *Rhizobium* (Table 6) and also for the control of some weeds such as *Brassica*, *Amaranthus*, *Echinochloa*, and *Portulaca* (Tables 3 and 7). This fact points out again the various responses of the receptor organisms to the allelochemicals. Some isoflavonoids, well known as phytoalexins, do not have inhibitory effects on *Rhizobium phaseoli*, as shown by Pankhurst and Biggs (1980).

Laboratory Bioassays. The detection of the allelopathic potential of leachates carried out for almost all the weeds present in the plots. Because of the great number of bioassays and results, we include only those where the results were significant (*F* test at the 1% level). The leachates of fresh and dry leaves and roots of *Alnus* and the leaves of *Berula* and *Juncus* did not have any significant effect on the growth of corn, squash, and bean, as is shown in Table 7. The roots of *Alnus* stimulated one of the crops, squash, and inhibited weed growth. Dried leaves were more inhibitory than fresh ones.

Table 8 shows the effects of the leachates of fresh weeds on the radicle growth of corn, bean, and squash. *Bidens aurea, Melilotus indicus, Simsia amplexicaulis, Chenopodium murale, Ipomea* sp., *Melampodium perforatum, Cyperus* sp., and *Portulaca oleracea* produced high inhibition of radicle growth of test species. Leachates from dried weeds produced the greatest radicle growth inhibition, not only on the crop species but also upon other weeds (Table 9). *Chenopodium murale, Ipomea* sp., *Sicyos deppei, Lopezia racemosa, Simsia amplexicaulis, Physalis* sp., *Melilotus indicus, Amaranthus hybridus, Brassica campestris*, and *Portulaca oleracea*, among others, produced more than 50% inhibition. Beans and squash were highly affected by the leachates. *Sicyos deppei*, which is considered by peasants as one of the worst weeds, was one of the most inhibiting species to corn (73%), followed by *Lopezia racemosa* (74%). *Chenopodium album* and *Melilotus indicus* also markedly inhibited the growth of corn (65% and 68%).

The weed species most affected by leachates from dry material were: *Brassica campestris, Portulaca oleracea, Echinochloa crusgalli,* and *Amaranthus hybridus*. Only *Brassica campestris, Tradescantia crassifolia, Chenopodium murale*, and *Oxalis* sp. inhibited *Hordeum*. It is important to note that the most abundant weeds in the plots were the ones which produced the greatest inhibitions. *Sicyos deppei* and *Physalis* sp. (green tomato) greatly inhibited bean and squash. *Physalis* sp. is a cultivated species, but in the crop field it was found in its wild state. Probably *Physalis* sp. cannot be interplanted with bean, squash, and corn because of its allelopathic effect on these three crops.

[a] All numbers are significant at 1% level (F test). NS, nonsignificant effect.

Some of the weeds present in the plots and tested for their allelopathic potential had already been reported as allelopathic: *Ambrosia cumanensis, Portulaca oleracea, Chenopodium album, Cyperus* sp., *Amaranthus* sp., *Brassica campestris, Melilotus indicus,* and *Medicago* sp. (Anaya and del Amo, 1978; Rice, 1984).

The leachates of fresh leaves of cultivated plants had no inhibitory effect on the growth of corn; however, the root of beans stimulated its growth 31% (Table 10). All the leachates of dry leaves caused an inhibitory effect, not only on corn but also on bean and squash. Leachates of dried crops (Table 10) produced a stronger inhibitory effect on weed growth than leachates from fresh leaves. In general, *P. oleracea* and *E. crusgalli* were the species most affected by the leachates of crops. *Hordeum vulgare* was the only species not affected by the leachates of crops, either fresh or dry.

In nature, the allelopathic interaction between crops and weeds is carried out as a dynamic active liberation process by aerial parts or roots and by decomposition, especially of dead leaves. The allelopathic substances can inhibit and stimulate other organisms in the environment, and the specific knowledge of their effects could allow us to interplant some wild plants with crops, to use a particular plant cover, to fertilize the soil with dried weeds or crops, and to mix two or more crops, among other managements. Pronin and Yakovlev reported in 1970 (stated by Gliessman, 1985) that yields of corn and fodder beans increased in mixed plantations and that this is associated with a favorable increase of root excretions of each plant on the other, rather than merely an improvement of nitrogen nutrition by the legume. Gliessman (1983) reported the use of *Stizolobium deeringeanum* planted in rotation with corn in Tabasco, Mexico, to control weed growth. The interplanting of squash (*Cucurbita pepo*) in corn–bean polycultures by peasants in southeastern Mexico helps to control weeds due to the combined effects of shade and phytotoxins (Amador and Gliessman, 1982).

In another study, Jiménez-Osornio and Schultz (1981) found that corn in monoculture in unweeded plots produced 20% less than corn interplanted with bottle gourd also in unweeded plots. This suggests that the allelopathic potential of this member of the Cucurbitaceae can interfere with weeds and permit a better growth of corn. The biomass and density of *Polygonum* sp., one of the main weeds of the zone of this study, was significantly reduced in the plots where bottle gourd was planted. They demonstrated the important influence that cultivated plants have on weeds, especially corn. Dzyubenko and Petrenko (1971) demonstrated that root excretions of maize inhibit the growth of some weeds such as *Amaranthus retroflexus*. Jiménez-Osornio et al. (1983) found that corn pollen severely affects the growth of some weeds.

If we gain knowledge about the ecological and cultural fundamentals of the traditional management of the land, we can make sure that a sustainable

agriculture suitable to the needs and particular resources of the people of any locality will be available. Also we can improve this management by combining appropriately new technologies with the old ones, introducing more varieties of crops, and increasing the use of the noncrop plants as organic matter producers, nitrogen or soil fixers, insect or weed controllers, food or drug producers, etc. All these activities open new alternatives to improve the quality of life of peasants and country people, and help to conserve the germplasm of our different geographic areas.

Acknowledgments—This work was sponsored by CONACyT. We thank Dr. Alba González-Jácome for introducing us to the study area; Dr. José Nieto de Pascual for his statistical assistance; Dr. Ronald Ferrera Serrato for providing us the strains of *Rhizobium*; Mr. Francisco Ramos and Mr. Rafael Hernández from the Instituto de Biología, UNAM, for their help in the identification of plants; Juan José Jiménez-Osornio, MS, for help in the field work; Mr. Juan Carlos Esparza for his beautiful drawings.

ANALYSIS OF PEACH BARK VOLATILES AND THEIR ELECTROANTENNOGRAM ACTIVITY WITH LESSER PEACHTREE BORER, *Synanthedon pictipes* (GROTE AND ROBINSON)[1,2]

J.F. ANDERSEN,[3] K.L. MIKOLAJCZAK, and D.K. REED[4]

Northern Regional Research Center, Agriculture Research Service
U.S. Department of Agriculture, Peoria, Illinois 61604

(Received August 14, 1986; accepted December 5, 1986)

Abstract—Bark volatiles from two peach cultivars (Bisco and Redskin) were obtained by vacuum steam distillation and fractionated by preparative gas chromatography. The fractions were then assayed with the electroantennogram (EAG) method on antennae of female lesser peachtree borer [*Synanthedon pictipes* (Grote and Robinson)]. With both cultivars, two fractions elicited the largest responses. Analysis of this material by GC-MS revealed a complex mixture made up of aromatic alcohols, esters, ketones, and acids, as well as phenols, aliphatic aldehydes, and aliphatic acids. EAG responses to pure samples of all identified components were recorded, and many of these compounds were found to be quite active. Among the most stimulatory were guaiacol, methyl benzoate, and 1-phenyl-1,2-propanedione. Also tested were six-carbon aliphatic aldehydes and alcohols which are components of the foliar tissue of most plants. Of these, 1-hexanol showed moderate activity, while the aldehydes and unsaturated alcohols were only weakly active.

Key Words—*Synanthedon pictipes*, Lepidoptera, Sesiidae, host volatiles, electroantennogram, olfaction, oviposition, benzaldehyde, methyl benzoate, guaiacol, phenol.

INTRODUCTION

The lesser peachtree borer, *Synanthedon pictipes* (Grote and Robinson) feeds as a larva under the bark on the limbs and trunk of its host. This predation

causes severe damage, which may result in the girdling and death of the limb. Numerous studies have dealt with the female-produced pheromones and associated male behavior of this and related sesiids (Tumlinson et al., 1974). However, few of the details of the postmating ovipositional behavior of females are known.

Female *S. pictipes* oviposit in crevices in the bark, particularly around wounds and cankers. Investigations with the congeneric peachtree borer [*S. exitosa* (Say)] indicate that nonvolatile substances found in peach bark promote oviposition after arrival at a potential site (Gentry and Wells, 1982). In an early study (Snapp and Swingle, 1929), several volatile materials, including a steam distillate of peach bark, were found to attract *S. pictipes* (sex not specified) to field traps. In the present study, the composition of the peach bark volatile mixture is determined and the influence of certain constituent compounds on the olfactory system of female *S. pictipes* is evaluated.

METHODS AND MATERIALS

Steam Distillation of Bark. Bark was removed from the Bisco and Redskin cultivars of peach and ground to a powder in a Wiley mill. The ground bark was added (300 g/distillation) to a 5.0-liter flask containing 3.0 liter of distilled water. A slight flow of nitrogen was bled into the flask during the course of the distillation. The mixture was distilled under reduced pressure at 40–50°C until ca. 1.6 liter of distillate was collected in a cooled 2.0-liter flask. A dry ice-cooled trap was placed in the system to prevent any volatile material from escaping the distillate. The aqueous distillate and cold-trap contents were combined and extracted with diethyl ether for 16 hr in a continuous liquid–liquid extractor.

The ether extracts were then passed through anhydrous sodium sulfate and concentrated to a volume of 20 ml by distillation through a Vigreux column. Samples were further concentrated to a volume of 1.0 ml under a gentle stream of nitrogen.

Fractionation and Electroantennography. All samples of steam distillate were fractionated by preparative GC on a 1.8-m × 4.0-mm ID glass column packed with 3% OV-17 on Gas-Chrom Q (60/80). A glass-lined splitter directed 10% of the effluent to a hydrogen flame-ionization detector, while the remaining 90% was directed to a thermal gradient fraction collector cooled by a Dry Ice–methanol bath (Brownlee and Silverstein, 1968). The column temperature was programmed from 40 to 200°C at 8°C/min with a 1-min hold at 40°C, and fractions were collected in 305-mm capillary tubes which could be flame sealed after collection or immediately rinsed out with a small volume of diethyl ether. The carrier gas (helium) flow rate at 40°C was 20 ml/min, and the injector and detector temperatures were 230°C.

Electroantennogram (EAG) signals were amplified 100-fold with a Grass P-18 DC preamplifier and recorded on a Fisher Recordall chart recorder (Andersen and Wilkin, 1986). The insects used were laboratory reared by the method of Reed and Tromley (1985), and females could be stored for up to five days in a refrigerator in Petri dishes lined with moist filter paper. A female antenna was prepared by removal of the distal few segments, followed by excision of the antenna at its base. It could then be mounted between two glass capillary tubes containing 0.7% aqueous NaCl. Silver–silver chloride wires were inserted into each capillary and connected to the active or ground inputs of the preamplifier. The active electrode was shielded with aluminum foil as described by Roelofs (1977). Fractions were assayed by breaking the ends of a sealed capillary and injecting 0.4 ml of air through the tube and into a filtered airstream (100 ml/min) which flowed over the antenna (Roelofs, 1977).

GC-MS and Verification of Structure. Electron impact mass spectrometry (70 eV) was carried out on a Kratos MS-30 instrument coupled with a gas chromatograph. Fused silica capillary columns (J & W Scientific, Inc.) coated with DB-1701 (25 m × 0.32 mm) and DB-Wax (30 m × 0.32 mm) were used for analysis. When necessary, proton NMR data were obtained from isolated compounds in $CDCl_3$ by means of a Bruker WM-300 spectrometer.

Identifications were made by comparison of sample mass spectra with authentic reference spectra and structural verification was accomplished by comparing GLC retention data of unknowns with those of authentic standards on the columns described above. The temperature program for the DB-1701 column consisted of a 5-min hold at 40°C followed by an increase of 6°C/min to a temperature of 200°C. For DB-Wax, an initial hold at 40°C for 1 min was followed by an increase of 6°C/min to 200°C. In both cases, the carrier gas was helium and the injector and detector temperatures were held at 230°C. Splitless injection was used to introduce all samples to the columns.

All standards obtained from commercial sources were found to be at least 95% pure by GC analysis. *p*-Cymene-8-ol was obtained from R. Bos, Groningen, The Netherlands, and was 95% pure. *p*-Vinylphenol was prepared from *p*-coumaric acid by the method of Hashimoto et al. (1976) and was purified to 90% by recrystallization from hexane. Retention indices were calculated from the homologous *n*-alkane series (Van den Dool and Kratz, 1963).

Electroantennography of Synthetic Compounds. Numerous synthetic compounds, including those identified in the peach volatile mixture, were screened individually for activity at the 100-μg dosage level. Test substances in 10 μl of ether solution were placed on small filter paper triangles. After evaporation of the solvent, the triangles were placed in disposable Pasteur pipets which were closed at the large end with rubber septa (Arthur Thomas Co.). Stimuli were delivered to female *S. pictipes* antennae as described above, except that 1.0-ml quantities of air were pumped through the pipet and into the airstream. Since the magnitudes of the responses decreased over time, the response to each test

compound is expressed as a proportion of the response to a standard compound (Visser, 1979; Dickens, 1984). The standard (10 μg of guaiacol) was presented approximately 30 sec prior to and following each test stimulus. The values of the two responses were averaged and then divided into the response value for the intervening test stimulus. In most instances, each test compound was presented to three female antennae. However, due to a shortage of insects, some compounds were tested on only two antennae. Where appropriate, responses were compared statistically by a *t* test for two means.

Selected compounds were also tested in dosage-dependence studies. In this case, 1, 10, 100, and 1000 μg of each test substance were applied to filter paper and presented in the same manner as above, and 10 μg of guaicol was used as a standard. Dosage–response data were obtained on two female antennae.

RESULTS AND DISCUSSION

Analysis and EAG of Peach Bark Steam Distillates. Capillary GC analysis of the steam distillates showed that the volatile mixture released by ground peach bark was dominated by a few components (Figure 1). One in particular was very prominent, comprising 78.5% of the Bisco steam distillate, and 84.8%

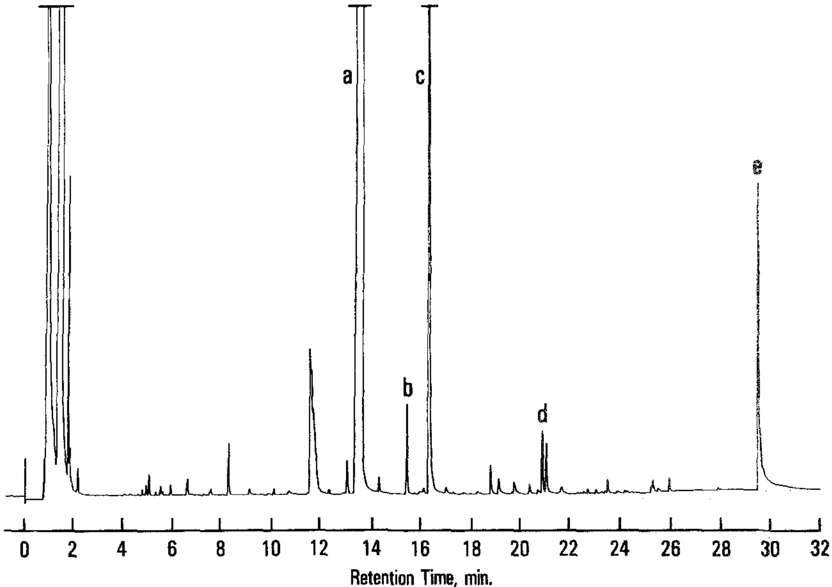

FIG. 1. Gas chromatogram of the steam distillate from Bisco peach bark on DB-Wax capillary: (a) benzaldehyde; (b) methyl benzoate; (c) 2-methylbutanoic acid plus ethyl benzoate; (d) 2-phenylethanol; (e) benzoic acid.

of the Redskin mixture. This was identified by GC-MS as benzaldehyde. Two other components, 2-methylbutanoic acid and benzoic acid, together with benzaldehyde, constituted over 90% of the steam distillates of both cultivars. 2-Methylbutanoic acid was present in larger quantities in the Bisco cultivar (ca. 10%), and benzoic acid occurred at approximately 3% in both. At these levels, benzoic acid is likely to be an artifact formed by the oxidation of benzaldehyde during sample preparation.

The steam distillate mixtures from both cultivars were fractionated by GLC on 3% OV-17 and the fractions tested in EAG assays to determine the antennal sensitivity of *S. pictipes*. EAG activity was found to be distributed over a number of fractions (Table 1), but two fractions eluting at 10–14 min gave consistantly stronger responses than all others with both cultivars. Examination of the GC recordings showed that a very small proportion (<2%) of the volatile material was associated with these fractions, suggesting that highly active compounds were present. Benzaldehyde, the dominant mixture component, was not eluted in this temperature range but was largely contained in the 8 to 10-min fraction (Table 1).

A larger quantity of the active 10 to 14-min Bisco material was collected as one fraction, concentrated 50-fold over the original steam distillate, and analyzed by GC-MS. The pertinent spectral and chromatographic data are given in Table 2. Identified components in the concentrated active material constituted 97% of the peak area measured from the DB-Wax column. pounds identified, 15 were aromatics, and the remainder were divided between aliphatic aldehydes, aliphatic acids, and monoterpene alcohols. Eleven components comprised over 1% each of the 10 to 14-min mixture, of which four constituted at least 10% each (Table 2). Together, the latter made up ca. 75% of the active fraction (Table 2).

Benzaldehyde and 2-methylbutanoic acid were largely eluted prior to 10 min. The quantities of these two components in the active fraction are due to peak tailing and represent only a small fraction of the quantities found in the whole steam distillate.

Most major components of the Redskin 10 to 14-min fraction could be identified by their gas chromatographic retention times on DB-Wax. The components determined in this manner made up over 80% of the fraction peak area (Table 2). One major component could not be accounted for by chromatographic comparison with the Bisco mixture and was consequently identified as phenol by GC-MS (Table 2). While the composition of Redskin was generally similar to Bisco, the relative quantities of many major components were drastically reduced (Table 2). Methyl benzoate comprised less than 4% of the Redskin mixture, while neither 2-phenylethanol nor 2-methylbutanoic acid were detected. These facts may explain the slightly smaller responses to the 10 to 12- and 12 to 14-min Redskin fractions in EAG tests when compared to the Bisco results (Table 1).

EAG Activity of Identified Components. Since the active fractions proved to be complex mixtures, individual components were screened for EAG activity at the 100-μg dosage level. Selected compounds were also tested at various dosages in order to give an indication of maximum responses and response threshold levels. Differences in volatility between compounds make it difficult to directly compare EAG responses of structurally dissimilar stimuli. However, large differences in response to structurally similar compounds were taken to indicate inequalities in the number of stimulated antennal receptors. Guaiacol was found to be quite active in preliminary experiments, so it was chosen as a standard that was presented to the antennae at the 10 μg level. Responses to all other test compounds are reported as proportions of the response to guaiacol.

Table 3 illustrates that all compounds tested produced measurable EAG responses. However, large variations in response magnitude were observed. Aromatic alcohols varied substantially in the magnitude of responses elicited. Those with secondary or tertiary hydroxyl groups, such as *p*-cymene-8-ol and 1-phenylethanol were significantly more active than the primary aromatic alcohols, benzyl alcohol and 2-phenylethanol ($P < 0.02$, Table 3). This difference was also apparent in dosage–response studies (Figure 2) where secondary and tertiary alcohols showed a larger increase in response than primary alcohols at dosages between 1 and 100 μg.

Two nonaromatic cyclic alcohols were also tested; α-terpineol proved to

[a]Responses are a proportion of the response to 10 μg guaiacol (relative response).
[b]Compounds tested on antennae from two females.

be highly active, but carveol was not. The former bears similarity to *p*-cymene-8-ol in that an isopropanol substituent is attached to the six-membered ring, while in the latter a secondary hydroxyl group is situated directly on the cyclohexane ring. Since none of the chiral alcohols tested in this study (1-phenylethanol, α-terpineol, and carveol) were optically pure, the effect of chirality on the responses to alcohols is not known.

Like the alcohols, phenolic compounds showed variation in activity. Phenol elicited only very small responses, while responses to guaiacol (*o*-methoxyphenol) were significantly larger ($P < 0.01$) than those to phenol and 4-ethylphenol. Dosage–response curves for phenol and *p*-ethylphenol (Figure 2) reveal similar maximum responses. However, *p*-ethylphenol appears to saturate the receptor near 100 μg while phenol elicits a lower response at 100 μg and shows a continued increase between 100 and 1000 μg. The dosage–response curve for guaiacol had a completely different appearance than those for other phenolics, with both a lower threshold value and a larger maximum response magnitude (Figure 2).

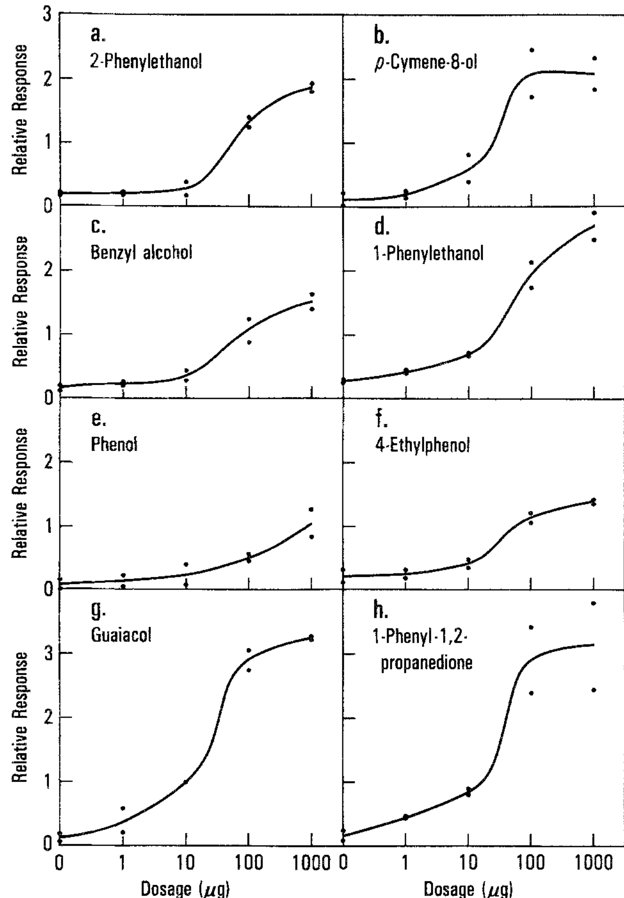

FIG. 2. Dosage–response curves for various peach bark volatile compounds; each point represents the relative response of a single female at a particular dosage.

Several aliphatic acids were major constituents of the volatile mixture. With the linear forms, maximum response magnitudes were seen at six carbons, and the responses decreased with increasing chain length. Neither of the two branched five-carbon acids, 2-methylbutanoic and senecioic, produced large responses, and the aromatic benzoic acid elicited the lowest responses of any compound (Table 3).

Responses to aliphatic aldehydes were all quite strong, but benzaldehyde was substantially less active than the aliphatic compounds (Table 3). Recall that the latter was the dominant component of the steam distillates, comprising over 75% of both mixtures.

The three identified aromatic esters showed strong activity, with methyl

benzoate being one of the most active compounds tested. Ethyl benzoate was significantly less stimulatory than methyl benzoate ($P < 0.05$), and methyl salicylate was even less active (Table 3).

The only ketone found in the peach volatile mixture was 1-phenyl-1,2-propanedione. This compound occurred in small quantities in the volatile mixture, but it elicited the largest responses of any compound in the 100-μg experiment (Table 3) and was also quite active at 1 μg (Figure 2).

The data discussed above indicate that *S. pictipes* female antennae are responsive to the volatile components of peach bark and that they are sensitive to relatively minor differences in structure. To further test the selectivity of the *S. pictipes* olfactory system, a numbr of six-carbon aliphatic alcohols and aldehydes were examined by EAG. These are widely distributed components of the foliar tissue of higher plants, and many leaf-associated insect species have been found to respond strongly to them in EAG tests (Visser, 1979; Guerin and Visser, 1980; Dickens, 1984; Dickens and Boldt, 1985). Being a wood-feeding insect, *S. pictipes* does not associate with foliar tissue and may be expected to respond to a different complex of volatiles than leaf feeders.

Of the six-carbon compounds tested, only 1-hexanol showed activity comparable to the more active of the peach volatile compounds (Table 4). Responses to hexanal and (*E*)-2-hexenal are much smaller than those to 1-hexanol, and substantially smaller than many of the peach volatile compounds (Table 3 and 4). It is interesting to note that the nine- and ten-carbon aldehydes found in the peach bark mixture elicited somewhat larger responses than their six-carbon counterparts (Table 3 and 4). Previous studies have indicated that receptors sensitive to the six-carbon green leaf volatiles are the most abundant receptor types on the antennae of many leaf-feeding insect species (Visser, 1979; Guerin and Visser, 1980; Kozlowski and Visser, 1981).

The Colorado potato beetle, *Leptinotarsa decimlineata*, and the oak flea weevil, *Rhynchaenus quercus*, are most responsive to saturated and unsaturated six-carbon alcohols (Visser, 1979; Kozlowski and Visser, 1981) while the carrot fly is most responsive to hexanol and (*E*)-2-hexenal. With the chrysomelid

TABLE 4. EAG RESPONSES TO SIX-CARBON ALDEHYDES AND ALCOHOLS[a]

Compound	Relative response ± SE
Hexanol	0.82 ± 0.08
(*E*)-2-Hexenal	1.21 ± 0.01
1-Hexanol	2.28 ± 0.29
(*E*)-2-Hexen-1-ol	1.65 ± 0.18
(*Z*)-3-Hexen-1-ol	1.44 ± 0.02

[a]Responses are expressed as a proportion of the response to 10 μg guaiacol. 100 μg dosage level.

beetle *Trirhabda bacharides*, 1-pentanol and 1-hexanol were both quite active, while heptanal, octanal, and nonanal were all more active than hexanal (Dickens and Boldt, 1985). However, (*E*)-2-hexenal gave the largest responses of any compound tested with this species (Dickens and Boldt, 1985). A similar situation exists with antennae of the boll weevil, *Anthronomus grandis*, which are very responsive to saturated and unsaturated six-carbon alcohols (Dickens, 1984). Boll weevil response to saturated aldehydes is maximal at seven carbons, but again (*E*)-2-hexenal is highly active.

The reduced sensitivity of *S. pictipes* to six-carbon "green leaf volatiles" in comparison to many of the peach bark volatile compounds appears to be unusual among phytophagous insects. This may represent an adaptation by this species to the complex of compounds characteristic of its host plant.

CONCLUSIONS

The volatile mixture obtained from ground peach bark is dominated by a single component identified as benzaldehyde. The olfactory system of *S. pictipes*, however, does not respond maximally to the benzaldehyde-containing fraction, but rather to a fraction containing less than 2% of the total mixture. This fraction contained numerous simple aromatic compounds as well as volatile aliphatic acids and aldehydes. Female *S. pictipes* antennae were responsive to many of these compounds but showed some selectivity. For example, aromatic esters generally elicited larger responses than simple phenols. Also, the six-carbon "green leaf volatiles" showed low activity in comparison to many of the peach volatile compounds (e.g., aromatic esters and ketones).

Only one published study exists concerning the responsiveness of *S. pictipes* to plant-derived volatiles and it contains only descriptive results (Snapp and Swingle, 1929). However, of 122 materials tested in field trapping experiments, only the steam distillates of green peaches, and peach bark as well as ethyl benzoate, phenol, salicylaldehyde, malate plus acetaldehyde and sodium bisulfite were found to be "slightly attractive" (Snapp and Swingle, 1929). It is interesting to note that two peach volatile compounds ethyl benzoate and phenol, were mentioned as being attractive and that several bark volatile constituents are structurally similar to the reported attractants. These include methyl benzoate, methyl salicylate, *p*-ethylphenol, *p*-vinylphenol, guaiacol, and benzaldehyde. It is notable that the compounds mentioned above elicit EAG responses of variable magnitude. The relationship of EAG response with behavioral activity for plant volatiles is not well understood, and only further behavioral testing will fully determine the role of bark volatiles in the location of oviposition sites by *S. pictipes*.

Acknowledgments—The authors thank R.E. England for the GC-MS analysis and N.J. Tromley for the supply of *S. pictipes*.

(Received August 14, 1986; accepted December 12, 1986)

Abstract—Measurements were made of the quantity and composition of the steam-volatile essential oils in gastrointestinal tract contents of greater gliders fed *Eucalyptus radiata* foliage and brushtail possums fed *E. melliodora* foliage. In both species, there was less oil in the stomach contents than in an equivalent mass of foliage. Only minor losses of leaf oils occurred during mastication by greater gliders, and absorption from the stomach appeared to be the major reason for the difference in the oil content of ingested leaves and of stomach contents. The apparent digestibility of oils over the whole gut was 96–97%, although oils from the cecum and feces of both species contained compounds not present in the original leaf oils. Absorption of oils before they reach the hindgut should reduce the severity of antimicrobial effects but may involve a metabolic cost to the animal in detoxification and excretion.

Key Words—Folivores, marsupials, allelochemicals, transformation, detoxification.

INTRODUCTION

The greater glider (*Petauroides volans*) and the brushtail possum (*Trichosurus vulpecula*) are folivorous marsupials. Greater gliders feed almost exclusively

on eucalypt leaf (Marples, 1973). Although the leaves of eucalypts form an important part of the diet of the brushtail possum in southeastern Australia, they are usually supplemented with foliage from other species of trees and shrubs, fruits, flowers, and herbage (Kerle, 1984). The importance of noneucalypt foods in the diet of the brushtail possum has led several authors (e.g., Freeland and Winter, 1975) to speculate that the consumption of eucalypt foliage is limited by the presence of "toxic" allelochemicals such as essential oils.

Although there has long been speculation about the effects that essential oils of *Eucalyptus* spp. might have on phytophagous animals (Pratt, 1937; Fleay, 1937; Betts, 1978), recent studies have failed to find relationships between the level and/or composition of leaf oils and the feeding perferences of some mammals (e.g., koala: Southwell, 1978; and insects (*Paropsis*): Morrow and Fox, 1980).

Irrespective of the effects of oils on gross food preference, their ingestion results in a metabolic cost for detoxification (Cleland, 1946; Hinks and Bollinger, 1957a, b), and their biological actions have the potential to affect populations of microbes in the digestive tracts of animals (Freeland and Janzen, 1974). Several studies have demonstrated a deleterious effect of mono- and sesquiterpenes on ruminal fermentation (Nagy et al., 1964; Nagy and Tengerdy, 1968; Oh et al., 1967, 1968). However, all these studies were performed in vitro, consequently no allowance was made for absorption of the oils, and in some cases the concentrations of oils used were unrealistically high. In contrast to ruminants, essential oils in hindgut fermenters may be absorbed and detoxified before they reach the site of microbial activity.

This paper describes the pattern of absorption of essential oils from the gut of the greater glider and brushtail possum. Volatile material extracted from digesta at five points along the gut was separated into its component compounds by gas–liquid chromatography. Also, the hypothesis that leaf oils may be lost during mastication was tested in greater gliders.

METHODS AND MATERIALS

Animals. Greater gliders were caught by hand during logging operations in a forest dominated by New England blackbutt (*E. andrewsii* ssp. *campanulata*) (Forest Type 161: Forestry Commission of New South Wales, 1965) in northern New South Wales. Brushtail possums were caught in wire cage traps in eucalypt woodland dominated by *E. melliodora*, *E. blakelyi*, *E. viminalis*, and *E. caliginosa* near Armidale, NSW. Both species were housed in metabolism cages in an air-conditioned room (20 ± 3°C) on a 12 : 12 light–dark regime for at least three weeks prior to each experiment. The greater gliders were fed *E. radiata* foliage and the brushtail possums fed *E. melliodora* foliage which was collected fresh each week and stored in plastic bags with the stems in water

at 8°C. Further details of these procedures and those used in the sampling of foliage and the collection of feces and urine are given by Foley and Hume (1987).

Experiment 1: Digestion of Essential Oils. Six greater gliders (one male, five females) were fed foliage from one *E. radiata* tree and three male brushtail possums foliage from one *E. melliodora* tree for 14 days. Samples of the leaves offered and feces collected for the last five days were stored in plastic bags at −15°C. These samples were steam distilled and the distillates analyzed by gas–liquid chromatography (GLC) and mass spectrometry (GLC-MS) as described below.

Experiment 2: Sites of Oil Absorption. Three female greater gliders were fed foliage from one *E. radiata* tree, and three male brushtail possums were fed foliage from one *E. melliodora* tree for 10 days. Samples of the diet and feces were collected for the last five days. The animals were then killed by an overdose of sodium pentabarbitone at 1200 hr, five hours after foliage was last available. The digestive tract was quickly excised, and the contents of the stomach, small intestine, cecum, proximal colon, distal colon, and rectum were removed, bulked within each species, frozen in liquid nitrogen, and stored at −15°C. These samples were steam distilled, and the distillate was analyzed by GLC as described below.

No marker substance was used in this experiment since in preliminary experiments only traces of oil could be recovered from gut contents of greater gliders that had received the marker Cr-EDTA in the drinking water (0.28 mg/ml). The oil appeared to be polymerized and oxidized and would not pass through the GLC column. The chelated chromium may have catalyzed the autoxidation of essential oil components (Garnier and Gaiffe, 1967).

Experiment 3: Oil Losses during Mastication. The amount of terpene lost during mastication of leaf by greater gliders was measured after conversion of the respirometers described by Foley (1984) to an open-flow system. Expired air was bubbled through two flasks containing cyclohexane which had been shown in a preliminary experiment to trap expired terpenes. At 0600 hr on day 1, leaves from one *E. radiata* tree were placed in the chamber and the pump started. At 1800 hr, a greater glider was placed in the chamber and allowed to feed normally. Fresh cyclohexane was placed in the traps. At 0600 hr on day 2, uneaten leaves, feces, and urine were removed from the chamber, fresh cyclohexane was placed in the traps, and the animal was left until 1800 hr when the experiment was terminated. This procedure was replicated three times with different animals. Samples for the two controls (leaf only, animal only) and the experimental treatment were bulked over the three replicates. Two runs in which a known volume of *E. radiata* essential oil was evaporated in the chamber were conducted to estimate recoveries. The cyclohexane was removed from each sample by fractional distillation on a series of Vigreaux and packed columns.

The remaining material was analyzed by GLC-MS after addition of *n*-dodecane as an internal standard.

Analytical. Essential oils were extracted from wet leaves, feces, and gut contents by steam distillation with cohobation in an all-glass apparatus (Hughes, 1970). Eucalypt leaves were distilled for 8–12 hr; gut samples were distilled for 12–24 hr. All oil samples were stored in air-tight glass bottles over sodium sulfate at −20°C.

Analytical GLC was carried out on a Perkin-Elmer 900 instrument using a quartz-silica SCOT column (50 m × 0.5 mm ID) coated with FFAP (free fatty acid phase polyethylene glycol reacted with nitroterephthalic acid) and with helium as the carrier gas. A Hewlett Packard 3370A Integrator was used to determine peak areas.

Combined GLC–mass spectrometry (GLC-MS) was performed on a Shimadzu GC6-AMP instrument with a SCOT column (70 m × 0.5 mm) coated with FFAP and programmed from 80°C to 225°C at 3°C/min. This system was connected to an AEI MS12 mass spectrometer via an all-glass straight split. Mass spectra were recorded at 70 eV ionization voltage with an ion source temperature of 150°C. Spectra were recorded every 6 sec on a VG Digispec Display data system which produced standard bar graphs for direct comparison with published spectra. Chemical ionization mass spectrometry was performed on an AEI MS902 mass spectrometer fitted with a Chemspect source. Ammonia was used as reagent gas at a pressure of 0.5 torr. High-resolution mass spectrometry was performed on this instrument under the same conditions using perfluorokerosene as reference and a peak timing method (Brophy et al., 1979). Identification of compounds was based on comparison of mass spectra with those of known compounds and coinjection with authentic compounds.

The oil distilled from the feces of greater gliders (20 mg in 1 ml methanol) was added to 4 ml of 1 M aqueous sodium hydroxide, and the mixture was heated at reflux for 4 hr. The basic solution was extracted with pentane (3 × 2 ml), the aqueous layer acidified with conc. hydrochloric acid and then reextracted with methylene chloride (3 × 2 ml). Both solutions were dried over sodium sulfate and the solvent removed under a stream of nitrogen. The residue resulting from the methylene chloride solution was taken up in 1 ml ether and treated with diazomethane.

RESULTS

The yield of steam-volatile oils from foliage, gut contents, and feces in all experiments is given in Table 1. The percentage composition of the major components of the oils from *E. radiata* leaves and the corresponding greater glider feces and from *E. melliodora* leaves and brushtail possum feces is given in Tables 2 and 3. GLC traces of the oil from leaf and feces of each species are shown in Figure 1.

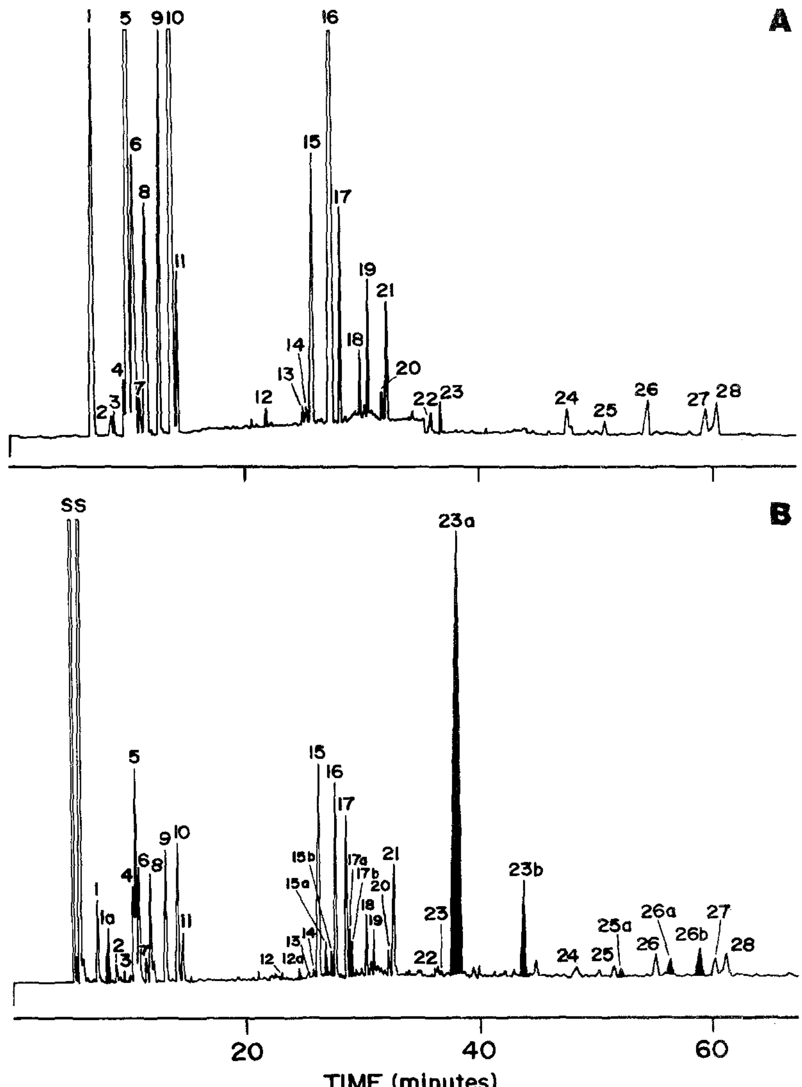

FIG. 1. GLC trace of steam-volatile essential oils from (A) *E. radiata* foliage, (B) feces from greater gliders fed *E. radiata* foliage, (C) *E. melliodora* foliage, and (D) feces from brushtail possums fed *E. melliodora* foliage. Shaded peaks represent feces oil components not present in leaf oils. Peaks not identified in Tables 2 and 3 are as follows: *E. radiata*/greater glider: 2, β-pinene; 3, sabinene; 4, myrcene; 7, limonene; 12, $C_{10}H_{18}O$; 12a, menthone; 13, linalool; 14, unknown; 15a, menthyl acetate; 15b, unknown; 17a, menthol, 17b, alloaromadendrene; 23a, an octane diol dibutyrate; 23b, globulol; 25, $C_{15}H_{26}O$; 25a, $C_{15}H_{24}O$; 26a, $C_{15}H_{28}O$; 26b, thymol. *E. melliodora*/brushtail possum: 4, myrcene; 7, γ-terpinene; 10, terpinen-4-ol; 11, caryophyllene; 11a, b, unknown; 12, pinocarveol; 14, bicyclogermacrene; 15, *cis*-mentha-1(7),8-dien-2-ol; 16, *trans*-mentha-1(7),8-dien-2-ol; 16a, an octane diol dibutyrate; 16b, unknown; 16c, 17, 18, 19a, $C_{15}H_{26}O$; 20, $C_{15}H_{24}O$. "S" represents solvent.

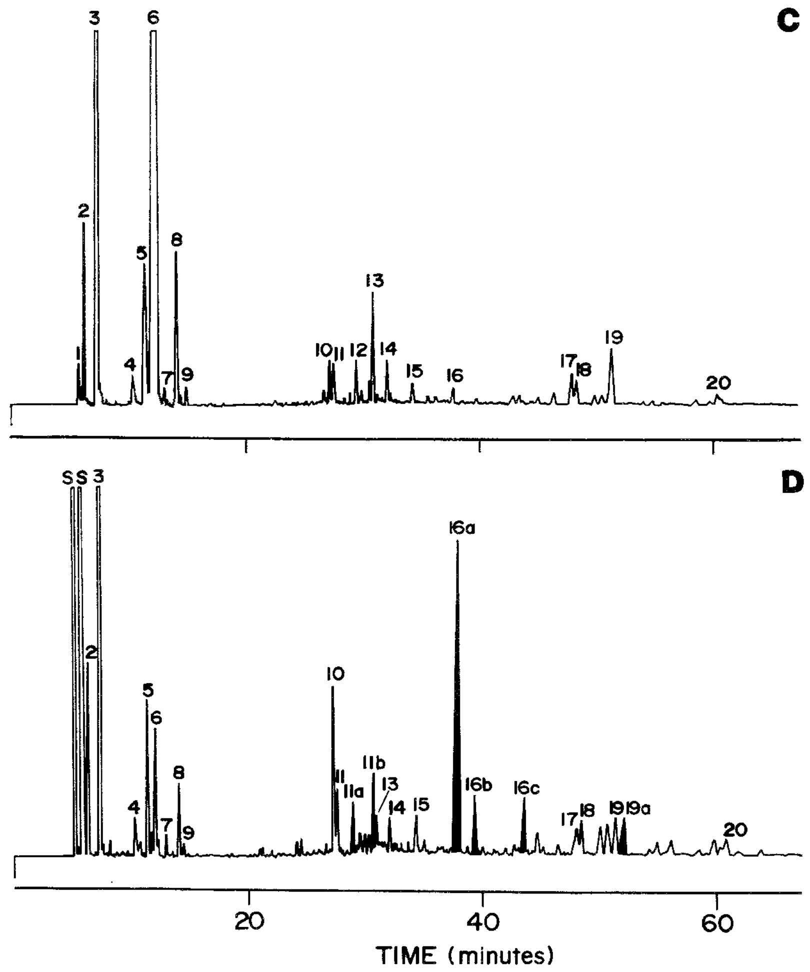

FIG. 1. Continued.

Experiment 1. E. radiata oil was complex, consisting primarily of terpinen-4-ol (20%), *p*-cymene (11%), α-phellandrene (9%) and γ-terpinene (8%). *E. melliodora* oil was much simpler, being dominated by 1,8-cineole (63%) with smaller amounts of α-pinene (7%), and limonene (4%). Both oils contained only small amounts of sesquiterpenes (3–5%).

Only minor amounts of oil were recovered from the feces of both species. However, these oils were more complex than those from the corresponding leaves. The oil from the brushtail possum feces was notable for the almost complete absence of 1,8-cineole (3% vs. 63% in the leaf). In the oil from the feces of the greater glider, the peaks representing terpinen-4-ol, *p*-cymene, α-

pinene, and α-phellandrene were greatly reduced, and no oil component passed through the gut without some apparent digestion.

In both species, some peaks appeared in the oil from the feces but did not occur in the oil from the leaves. While many of these were minor (e.g., Figure 1B, peaks 12a, 15a, 17a), peak 23a was the largest component (21%) of the oil from the greater glider feces. The same component appeared in the oil of the brushtail possum feces (Figure 1D, peak 16a) as 14% of the total oil. Infrared spectra of the two feces oils showed large absorptions at 1740 cm^{-1} and 1160 cm^{-1}, characteristic of an ester function. The strength of these bands, absent in the leaf oils, suggested that they belonged to the large extra peaks in the GLC traces of both feces oils. The mass spectra of these GLC peaks indicated that the highest mass ion was at m/z 243; however, chemical ionization mass spectrometry showed a (MH^+) ion at m/z 287, and accurate mass measurement of this ion resulted in a mass of 287.2236, indicating a formula of $C_{16}H_{31}O_4$ (287.2220) for the (MH^+) ion.

Alkaline hydrolysis of a sample of the oil from the greater glider feces resulted in the elimination of this significant extra GLC peak, lending support to the suggestion that it was an ester. From the base-soluble fraction, after acidification, solvent extraction, and methylation, a GLC trace was obtained which contained a peak, the mass spectrum of which is suggestive of an octane diol, which fits the solubility characteristics of the compound. The mass spectrum was similar (but not identical) to that of 2-ethylhexane-1,3-diol. A small amount of methyl butyrate was also detected in this fraction.

It appears from these results that the unknown peak in the feces oil from both folivores is a dibutyrate ester of an octane diol. In fact, the mass spectrum of 2-ethylhexane-1,3-dibutyrate was similar (but not identical) to that of the natural material. The natural material had a shorter retention time (on FFAP) than either 2-ethylhexane-1,3-dibutyrate or diisobutyrate, suggesting greater branching in the natural material.

Experiment 2. Details of the yield and percentage composition of the major components of the steam-volatile oils recovered from different parts of the digestive tracts of the two species are given in Tables 1–3. Although the yields of oils from the leaves were notably higher in this experiment than in experiment 1, the yield of oil from the feces was similar. On the other hand, while the percentage composition of the oils from leaves was similar to that in experiment 1, those isolated from the feces were different. For example, the octane diol dibutyrate found in experiment 1, although present in this sample, comprised only 9% of the oil from greater glider feces and 3% of that from brushtail possum feces.

Experiment 3. The essential oil peaks on the GLC trace of cyclohexane-soluble material from expired air of greater gliders in preliminary experiments were identified by their mass spectra. This also indicated that some of the other

peaks represented aliphatic straight-chain hydrocarbons resulting from impurities in the cyclohexane solvent.

No peaks representing essential oils were apparent in the GLC traces of the air samples from the leaf alone in the chamber, from greater gliders feeding on the leaf in the chamber, or from the greater gliders alone in the chamber. Recoveries of evaporated terpenes in the two runs with *E. radiata* essential oils were 28% and 35%.

DISCUSSION

Some workers (e.g., Von Rudloff, 1975) have criticized steam distillation as a means of extracting essential oils because of the possibility of inducing artifactual rearrangements of components of the oils. This was unlikely to have been a serious problem in the present study. Lassak (unpublished) has shown that the steam-volatile essential oil of the leaves of *E. dives*, a close relative of *E. radiata* (Ladiges et al., 1983) is chromatographically identical to that extracted from individual oil glands with a fine capillary needle.

Using the mean intake and dry-matter digestibility figures for greater gliders and brushtail possums fed *E. radiata* and *E. melliodora*, respectively (44 g/kg body mass$^{0.75}$/day and 58% in greater gliders and 36 g and 51% in brushtail possums; Foley, 1984), it can be calculated that greater gliders apparently digested 97% of the essential oils of *E. radiata* while brushtail possums apparently digested 96% of *E. melliodora* essential oils. Using similar techniques, Eberhard et al. (1975) found that koalas apparently digested 70–97% of the essential oils of the leaves of *E. punctata*. Similarly, Southwell et al. (1980) found only traces of essential oil in the feces of brushtail possums dosed with 5 ml of purified oil components (*p*-cymene and 1,8-cineole) daily for five days. Igimi et al. (1974) detected only 10% of the ^{14}C label in the feces of rabbits fed [^{14}C]*d*-limonene. That components of these essential oils are readily absorbed is not surprising in view of their low molecular weight and high lipid solubility. The important question is where are they absorbed?

The apparent interaction between Cr-EDTA and essential oils in the gut, discovered in preliminary experiments, meant that the site of absorption could not be accurately ascertained. However, analysis of oils from different parts of the gut showed that the quantity of oil in the stomach contents was only 49% of what would be expected, on the basis of digesta mass, in brushtail possums and 59% in greater gliders. Similar discrepancies have recently been observed in the rumen contents of mule deer (*Odocoileus hemionus*) (Cluff et al., 1982) and stomach ingesta of pygmy rabbits (*Brachylagus idahoensis*) (White et al., 1982). There are two possible explanations for this. First, lipid-soluble material such as essential oils could be rapidly absorbed across the mucosa of the stomach of both ruminants and hindgut fermenters (Cook et al., 1952, Alexander

and Chowdhury, 1958). Igimi et al. (1974) have shown that there is rapid disappearance of [^{14}C]*d*-limonene from the rat stomach after dosing by stomach tube. Similarly, Narjisse (1981) was unable to detect monoterpenes in the rumen contents of goats 3 hr after direct infusions.

Alternatively, volatile oils may be lost during mastication of the leaf. If this is the case, it is surprising that the percentage loss from stomach contents was greater in the brushtail possum than in the greater glider, since mastication in the greater glider produces finer particles (Gipps, 1980; Foley, 1984). However, the coarse grinding action of brushtail possum teeth may be more effective in disrupting oil glands than the fine cutting action of greater gliders (Gipps, 1980).

The results of experiments designed to measure losses of essential oils during mastication by greater gliders suggested that this was of only minor importance. Although preliminary qualitative experiments had detected terpenes arising from expired breath, no traces of oils were detected in the quantitative experiment. This was unexpected since several steps were taken to maximize the recovery of oil components. This involved decreasing the rate of air flow through the chamber, bulking samples from three animals, and distilling the cyclohexane through longer packed columns. Although recoveries of standards evaporated in the chamber averaged only 32%, the losses measured during mastication cannot explain the low concentration of oil in the stomach contents of the greater gliders relative to that ingested.

Using a similar collection system (but with diethyl ether), White et al. (1982) found that twice as much monoterpene was trapped when *Artemisia tridentata* foliage was in a chamber with pygmy rabbits compared with *Artemisia* alone. Nevertheless, this represented only a minor proportion (0.5%) of the total fraction "missing" from the stomach contents. No measurements of the efficiency of the collecting apparatus were made in the experiments of White et al. (1982), but even assuming that this was only 10%, losses during mastication of *Artemisia* would still account for only 5% of the volume of oil missing from the stomach. It would seem that in both the White et al. (1982) and the present study, although losses through mastication can occur, they are of minor quantitative importance, and absorption from the stomach must be the principal avenue of loss.

Further absorption must take place in the small intestine, since the amount of terpene reaching the hindgut was of the order of only 1% of that ingested by both greater gliders and brushtail possums. There would thus seem to be little chance of major interaction with the microbial ecosystem in the hindgut. On the other hand, it is interesting that a major unknown feces peak was found in both the greater glider and brushtail possum. No examination was made of the feces of animals fed noneucalypt diets in the present experiments, but Southwell et al. (1980) did not detect any similar metabolite in the feces of brushtail pos-

sums fed a diet of fruit or fruit supplemented with 1,8-cineole, *p*-cymene, or α-pinene.

The fact that the major unknown feces peak was detected only in or distal to the cecum suggests that it is a product of microbial metabolism. Although the unknown compound was nonterpenoid and most likely a dibutyryl ester of an octane diol, it may have resulted from microbial fermentation of terpenes. For example, Joglekar and Dhavalikar (1969) isolated the 10-carbon compound 3,7-dimethyl-1,7-octane-diol from the fermentation of citral by a soil pseudomonad. Similarly, Bhattacharyya and Dhavalikar (1965) isolated the nonterpenoid anhydride of 2-nonene-2,3-dicarboxylic acid from the *Aspergillus niger* fermentation of a number of different terpenes such as camphene, β-santalene, longifolene, caryophyllene, and δ-cadinene. They suggested that the anhydride was formed by a metabolic shift in which the normal oxidative process in the mold would have been impaired to such a degree that excess pyruvate and acetate were channeled into the formation of the anhydride.

New feces peaks could also arise by absorption and subsequent biliary excretion. Eberhard et al. (1975) suggested that biliary excretion would be important, together with urinary excretion, in dealing with those compounds greater than mol wt 150 (i.e., monoterpenoids and sesquiterpenoids). The amount of digesta in the small intestine of both species was too small to recover any oil, and the gallbladders of both species contained only a minor amount of bile. Igimi et al. (1974) found that 25% of ^{14}C from ingested [^{14}C] *d*-limonene in rats was excreted in the bile within 14 hr. However, since only 5% of the dose was eventually excreted in the feces, much of the biliary excretion must have been fermented or reabsorbed lower in the gut and excreted in the urine. In the present study, it is likely that the majority of oil ingested by both species was absorbed, detoxified, and excreted in the urine. Southwell et al. (1980) found several novel products in the urine of brushtail possums fed fruit and isolated terpenes. Future studies using labeled terpenes would be necessary to identify the pathways of detoxification and to quantify the routes of excretion of ingested essential oils.

The possibility that dietary essential oils could have deleterious effects on gut microorganisms has been raised by several authors (e.g., Freeland and Janzen, 1974; Bryant and Kuropat, 1980). This possibility is based on the work of Nagy et al. (1964), Nagy and Tengerdy (1968), and Oh et al. (1967, 1968), who found that some sagebrush *Artemisia* and Douglas fir terpenes could inhibit fermentation in the rumen of deer. However, this work has been challenged (Welch et al., 1981, 1982; Welch and McArthur, 1979) on the ground that the volumes of oil used to demonstrate microbial inhibition were unrealistically high in relation to the amounts normally expected to be ingested. Also, the in vitro systems did not allow for absorption of the oil. Oh et al. (1967) found that microbial inhibition occurred at an essential oil concentration of 1.2% of

deer rumen fluid. This is about 20 times greater than the concentration of oil found in the hindgut of the greater glider and the brushtail possum in this study.

On the other hand, Sadler (1983) found that pure compounds and ether dilutions down to 10^{-4} of 1,8-cineole, *d*-limonene, terpinen-4-ol, and α-terpineol inhibited the growth of cellulolytic bacteria which had been previously cultured on *Eucalyptus viminalis* leaf in vitro. Similarly, while ether extracts of *E. viminalis* and *E. blakelyi* inhibited both "adapted" and "nonadapted" cellulolytic bacteria, extracts of *E. radiata* did not differ from controls even though these leaves (from the same batch as those used in experiment 3) contained substantial proportions of terpinen-4-ol and α-terpineol. Thus antimicrobial effects of essential oils may be due to synergistic effects of particular components (see also Akimov et al., 1977). Andrews et al. (1980) suggested that the antimicrobial action of terpenes results from disruption of cytoplasmic membranes and that gram-negative organisms are more resistant than gram-positive microbes. Nothing is known of the occurence of each of these groups in the hindgut of greater gliders and brushtail possums, although London (1981) found the cecal flora of the koala to be predominantly gram-positive.

The results from the present study indicate that in both the greater glider and the brushtail possum the microbial population in the hindgut is largely, although not completely, protected from the deleterious effects of *Eucalyptus* essential oils by their absorption mainly from the stomach and small intestine. However, the metabolic cost of detoxifying absorbed oils in the liver may limit the range of eucalypt species that these folivorous marsupials can utilize as a sole source of nutrients. It is suggested that future studies of leaf choice by arboreal folivores should take account of the levels of primary nutrients as well as allelochemicals in selected and rejected plant species.

Acknowledgments—We thank Dr. I.D. Hume for assistance in the collection of samples in experiment 2 and in the preparation of the manuscript, Dr. K. Rübsamen for help in constructing the respirometers used in experiment 3, and Dr. I.A. Southwell for his comments on an earlier draft of this manuscript. W.J.F. was supported by a University of New England Postgraduate Research Award.

1,8-CINEOLE (EUCALYPTOL), A MOSQUITO FEEDING AND OVIPOSITIONAL REPELLENT FROM VOLATILE OIL OF *Hemizonia fitchii* (ASTERACEAE)[1]

JAMES A. KLOCKE, MARK V. DARLINGTON, and MANUEL F. BALANDRIN

NPI, University of Utah Research Park
417 Wakara Way, Salt Lake City, Utah 84108

(Received July 25, 1986; accepted December 18, 1986)

Abstract—The mosquito feeding and ovipositional repellency of the major monoterpenoid present in the volatile oil of *Hemizonia fitchii* (Asteraceae), i.e., 1,8-cineole, was investigated. Although 1,8-cineole did not exhibit any significant mosquito larvicidal activity, it was moderately effective as a feeding repellent and highly effective as an ovipositional repellent against adult *Aedes aegypti* (yellow fever mosquito). The ovipositional repellency of 1,8-cineole, coupled with the presence of several *Hemizonia* chromenes previously shown to possess mosquito larvicidal activity, may therefore account in large part for the observed suppression of local mosquito populations which was associated with *H. fitchii* plants in northern California.

Key Words—*Hemizonia fitchii*, Asteraceae, Compositae, 1,8-cineole, eucalyptol, mosquito repellent, *Aedes aegypti*, Diptera, Culicidae.

INTRODUCTION

In a systematic search for naturally occurring compounds that may be useful as sources and/or models of new insect control agents, we have been screening extracts from over 800 species of xeric higher plants, from the arid and semiarid regions of the western United States, for activity against several species of economically important pest insects. Xerophytes represent an important resource in the search for potentially useful bioactive compounds because such plants

are native to stressful environments where biochemical interactions among organisms via their secondary metabolites (antibiosis, allelopathy, etc.) may play a key role in survival, coevolution, and the maintenance of ecological balances (Harborne, 1982; Rodriguez, 1983; Myers, 1984). For example, we have isolated and identified insecticidal linear furanocoumarins from *Thamnosma montana* Torr. & Frem. (Rutaceae) (Klocke and Balandrin, 1984), insect growth-inhibiting polyphenolics (hydrolyzable tannins) from a variety of semiarid land plants (Klocke et al., 1986), and mosquito larvicidal chromenes from *Hemizonia fitchii* A. Gray (Asteraceae) (Klocke et al., 1985).

Our interest in *H. fitchii* (Fitch's spikeweed, tarweed) stems from field observations made in Butte County near Oroville, California, that this plant species was associated with reduced populations of the mosquito *Aedes melanimon* Dyar. Previous work (Klocke et al., 1985) established that these plants accumulate a series of volatile bioactive chromenes (Proksch and Rodriguez, 1983) that possess moderate larvicidal activity against *Culex pipiens* L. (the common house mosquito) and *Oncopeltus fasciatus* (Dallas) (the large milkweed bug). However, other constituents of the steam-distilled volatile oil of *H. fitchii*, including several volatile fatty acids and 1,8-cineole, were found to be essentially devoid of larvicidal activity against *C. pipiens* (Klocke et al., 1985).

In this communication, we have extended our investigation of the biologically active chemical constituents of *H. fitchii* to include the major monoterpenoid present in its volatile oil, i.e., 1,8-cineole, as a feeding and ovipositional repellent against the yellow fever mosquito, *Aedes aegypti* (L.).

METHODS AND MATERIALS

Collection and Extraction of Plant Material. Whole aerial parts of *H. fitchii* were collected in August, 1981, in Butte County near Oroville, California, by Mr. Elmer J. Kingsford (formerly with the Butte County Mosquito Abatement District, Oroville, California). A voucher specimen representing this collection has been deposited in the herbarium of NPI in Salt Lake City, Utah. Samples of the volatile oil of *H. fitchii* were prepared as described previously (Klocke et al., 1985) by subjecting the plant parts to steam distillation for 24 hr using a modified Clevenger-type circulatory steam-distillation apparatus (von Rudloff, 1969). Steam distillates were collected into diethyl ether, concentrated under a stream of nitrogen, and stored in tightly capped glass vials at −20°C.

Thin-Layer Chromatography (TLC) of Volatile Oil. Analytical and preparative silica gel TLC was carried out as described previously (Klocke et al., 1985). However, an additional method of visualization, involving spraying the TLC plates with 50% v/v aqueous sulfuric acid spray reagent followed by oven heating (15 min), was utilized.

Direct Insertion Probe Mass Spectrometry (MS). Electron impact mass spectral (EI-MS) data of the major constituents isolated from the volatile oil of *H. fitchii* were acquired using a Varian MAT (Florham Park, New Jersey) 112S double-focusing mass spectrometer operating at an ionization voltage of 70 eV.

For comparative purposes, an authentic sample of 1,8-cineole (eucalyptol) was purchased from Sigma Chemical Co. (St. Louis, Missouri) and was analyzed by TLC, GC, and GC-MS (Klocke et al., 1985).

Rearing of Aedes aegypti *Mosquitoes.* A colony of *Aedes aegypti* (L.) (Culicidae) Rockefeller strain was started using eggs supplied by Dr. George B. Craig, Jr., from the Vector Biology Laboratories of the University of Notre Dame, Notre Dame, Indiana. All stages of *A. aegypti* were reared at approximately 26°C in ambient humidity and photoperiod. Larvae were fed ground dried dog food. Adults were fed fresh orange slices and, after mating, the females took blood meals from anesthetized gerbils. Eggs were oviposited just above the water line on moist paper towels lining plastic 1-qt bowls filled with tap water. Eggs were collected, slowly dried, and used as needed (Smith, 1962).

Mosquito Antifeeding/Repellency Bioassay. To test the antifeeding/repellency properties of 1,8-cineole against adult female mosquitoes, two gerbils (in each of three replicate trials) were anesthetized [Vetalar (ketamine HCl, Parke, Davis & Co., Detroit, Michigan), 35–45 mg/kg intramuscular] and placed inside a piece of tubular stockinette, leaving only the hind legs and tail of each gerbil exposed. One gram of Vaseline (Chesebrough, New York, New York) was applied topically over the exposed areas of each control gerbil. One hundred milligrams of 1,8-cineole were incorporated into 1 g of Vaseline (i.e., 10% w/w), and this preparation was applied topically over the exposed areas of each experimental gerbil. Each gerbil was proffered to 1000–2000 starved (72 hr) adult mosquitoes of both sexes (from the same cohort) inside a BioQuip (Santa Monica, California) (18″ × 18″ × 18″) cage. The gerbils were removed after 25–30 min, and the number of engorged females in each cage was counted.

Mosquito Ovipositional Bioassays. To test the ovipositional repellency properties of 1,8-cineole against gravid female mosquitoes, both "choice" and "no-choice" ovipositional bioassays were conducted. The "choice" bioassay provided the gravid female mosquitoes with a choice of ovipositing on paper toweling lining glass crystallizing dishes (70 × 50 mm) containing either 1,8-cineole in tap water (at a concentration of 0.8, 0.4, or 0.2% w/v) or tap water only. The numbers of eggs laid during the course of the bioassay (9–11 hr) were counted in the dishes containing 0.8% and 0.4% w/v 1,8-cineole. The numbers of eggs laid in the dishes containing either 0.2% w/v 1,8-cineole or tap water only were too numerous to be counted and were therefore estimated gravimetrically (dry weight).

In the "no-choice" bioassay, the gravid females in each BioQuip cage were presented with a glass crystallizing dish containing either 1% w/v 1,8-

cineole in tap water or tap water only. The 1,8-cineole mixture and water were replaced with fresh 1,8-cineole mixture or water, respectively, every 9–11 hr until the conclusion of the experiment (approximately three to five days).

Egg Viability Assay. The viability of eggs oviposited in dishes containing 1% w/v 1,8-cineole in tap water was determined. The 1,8-cineole mixture was replaced daily with fresh 1% w/v 1,8-cineole in tap water during the period of egg laying, and for three days after the dishes had been removed from the cages, to ensure embryonation of all eggs. Groups of 100–150 eggs were then transferred to dishes containing tap water only, and the extent of hatching was recorded. Eggs oviposited in dishes containing tap water only served as the controls. The development of mosquitoes hatching from the 1,8-cineole-treated eggs and the control eggs was monitored throughout all stages of their life cycle.

RESULTS

Mosquito Antifeeding/Repellency Bioassay. The results of the antifeeding/repellency bioassay indicated that in all three trials, two to three times as many adult female mosquitoes fed upon the control gerbils (Vaseline only) as did those that were presented with the experimental gerbils (10% w/w 1,8-cineole in Vaseline) (Table 1). Female mosquitoes that landed on the control gerbils began probing the exposed areas with their proboscises within 2 min after the gerbils were presented to them, whereas the female mosquitoes alighting on the treated gerbils were repelled for approximately 16 min. After this time, the female mosquitoes began to feed upon the experimental gerbils, but they were observed to keep their heads as far from the gerbils as possible while feeding.

Mosquito Ovipositional Bioassays. The results of the "choice" ovipositional bioassay indicated that the gravid females were deterred from ovipositing in dishes containing 0.2% w/v or greater amounts of 1,8-cineole (Table 2). The numbers of eggs laid in the experimental dishes decreased with increasing concentrations of 1,8-cineole (Table 2). In all trials at the highest concentration of 1,8-cineole tested (i.e., 0.8% w/v), the gravid females laid very few eggs (an

Experimental	0.2	10.1 mg[a]	22.9 mg	37.4 mg
Control	—	23.7 mg	58.0 mg	84.4 mg

[a] Eggs laid were too numerous to count. Therefore, results were determined gravimetrically (dry weight).

average of 30), whereas they consistently laid more than 1500 eggs in the control dishes (Table 2). At the lowest concentration of 1,8-cineole tested (i.e., 0.2% w/v), oviposition was still notably deterred. On average, 24 mg of eggs were oviposited in the experimental dishes containing 0.2% w/v 1,8-cineole compared to an average of 55 mg in the control dishes (Table 2).

In the "no-choice" ovipositional bioassay, oviposition by the gravid females was completely inhibited by 1% w/v 1,8-cineole in tap water and was delayed for as long as 24–36 hr compared to controls. After this delay, only a small number of eggs were laid in the experimental dishes. The eggs that were laid in the presence of 1,8-cineole were generally oviposited on the paper toweling along the outer rim of the experimental dishes, i.e., the point farthest from the main concentration of 1,8-cineole. This differed from the control eggs, which were typically laid just above the water line in the control dishes. However, normal oviposition resumed shortly after the dishes containing 1% w/v 1,8-cineole were replaced with dishes filled with tap water only.

Egg Viability Assay. There was no significant difference between the numbers of control and 1,8-cineole-treated eggs that hatched. Furthermore, the mosquitoes that hatched from the 1,8-cineole-treated eggs developed normally throughout all stages of their life cycle.

DISCUSSION

In our previous work (Klocke et al., 1985), we reported that compounds produced by *H. fitchii* plants appeared to suppress local mosquito populations in Butte County, in northern California. The three major chromenes produced and accumulated by *H. fitchii* were isolated and were shown by bioassay to be moderately toxic to *C. pipiens* (common house mosquito) larvae (Klocke et al.,

1985). The other major volatile constituents of *H. fitchii*, namely, the three volatile fatty acids (isobutyric, isovaleric, and 2-methylbutyric acids) and 1,8-cineole were found to be inactive as mosquito larvicides. However, we postulated that some of these volatile compounds might act as ovipositional repellents to mosquito adults (Klocke et al., 1985). In the present report, we provide evidence that 1,8-cineole, the major monoterpenoid in the volatile oil of *H. fitchii*, acts both as a feeding repellent and as an ovipositional repellent against *A. aegypti*.

Our results (Tables 1 and 2) show that 1,8-cineole is a stronger deterrent of oviposition than of feeding for female *A. aegypti*. The topically applied preparation of 10% w/w 1,8-cineole in Vaseline provided some measure of protection to the treated gerbils against female mosquitoes seeking a blood meal (Table 1). However, the feeding repellency afforded by 1,8-cineole lasted for only approximately 16 min. On the other hand, lower concentrations of 1,8-cineole (i.e., 0.2–0.8% w/v) resulted in a more pronounced and much longer lasting effect (9–11 hr) as an ovipositional repellent (Table 2).

The decreasing effectiveness of 1,8-cineole as a feeding repellent over time, and its concentration dependency as an ovipositional repellent (Table 2), may be due to losses incurred because of the volatility of the compound. The amount of 1,8-cineole vapor present in any given area naturally decreases over the time course of the experiment and in a concentration gradient over distance (space), perhaps to a point below a threshold level that deters female mosquitoes from feeding and ovipositing. For example, in the "no-choice" ovipositional bioassay, the female mosquitoes generally oviposited their eggs along the outer rim of the experimental dishes (i.e., the point farthest from the main concentration of 1,8-cineole), whereas the control eggs were typically oviposited just above the water line.

1,8-Cineole has previously been reported to repel American cockroaches (Verma and Meloan, 1981; Maugh, 1982; Scriven and Meloan, 1984) and Colorado potato beetles (Schearer, 1984; J.A. Klocke, K.J. Brown, and M.F. Balandrin, unpublished results). Against the leafhopper *Amrasca devastans* (Distant), 1,8-cineole was found to inhibit mating (Saxena and Kumar, 1984), but not oviposition (Saxena and Basit, 1982). Other insects are attracted by 1,8-cineole. For example, 1,8-cineole, as a constituent of many floral scents, may serve as a pollinator (and sex) attractant for certain male euglossine bees (Rodriguez and Levin, 1976; Harborne, 1982; Janzen et al., 1982; Romero and Nelson, 1986).

1,8-Cineole is present in certain essential oils isolated from plants in the families Asteraceae (Compositae), Magnoliaceae, and Rutaceae, and in certain arthropod defense secretions, all of which have been shown to be effective insect repellents (Rodriguez and Levin, 1976; Moore and Brown, 1981; Olagbemiro and Staddon, 1983; Schearer, 1984). In addition, other plant parts and

extracts containing significant amounts of 1,8-cineole have previously been reported to repel insects. For example, the Tasmanian blue gum tree (*Eucalyptus globulus* Labill., a native of Australasia) produces a pharmaceutical grade volatile oil (eucalyptus oil) that contains at least 70–85% 1,8-cineole (eucalyptol) (Swinyard and Lowenthal, 1975; Leung, 1980; Tyler et al., 1981). Eucalyptus oil enjoys a wide reputation as an insect repellent and insecticide in Australia and elsewhere (Cribb and Cribb, 1983). It has also been reported to be useful in insect (especially mosquito) repellent formulations (Jacobson, 1966; Der Marderosian, 1975; APhA, 1979), and it is reportedly effective as a mosquito repellent on human skin (Wilen and Wilen, 1984). *Eucalyptus* (i.e., *E. globulus*) leaves have been reported to repel fleas and other insects (Lust, 1974) and to possess insecticidal properties (Cribb and Cribb, 1983). Similarly, the leaves of the sweet bay laurel tree (*Laurus nobilis* L.), which contain an essential oil consisting of 30–50% 1,8-cineole (Leung, 1980), have been reported to be effective general insect repellents, with specific activity against moths, fleas (Lust, 1974), and cockroaches (Verma and Meloan, 1981; Maugh, 1982; Scriven and Meloan, 1984). Laurel leaves and berries, and their volatile oils, are also reportedly useful as weak insecticides (Stuart, 1982). Other notable sources of 1,8-cineole include cajeput (or cajuput) oil (50–65% 1,8-cineole), spike lavender oil (40–60% 1,8-cineole and camphor), and rosemary oil (ca. 47% 1,8-cineole) (Grieve, 1971; Leung, 1980; Tyler et al., 1981; Stuart, 1982; Duke, 1985). Cajeput oil and leaves exhibit mosquito and general insect repellent properties (e.g., against fleas and lice) (Jacobson, 1966; Stuart, 1982; Duke, 1985), and lavender and rosemary oils are sometimes used as moth repellents and externally as insect repellents (Morton, 1976; Leung, 1980; Stuart, 1982; Duke, 1985).

1,8-Cineole has a camphoraceous (camphor-like) odor, and volatile oils containing large quantities of this compound (e.g., eucalyptus oil, cajeput oil) have been used externally as ectoparasiticides and antiseptics (Swinyard and Lowenthal, 1975; Windholz et al., 1976, 1983; Leung, 1980; Tyler et al., 1981). The general insect repellent activity of 1,8-cineole may be mediated by a mechanism of action similar to that of camphor, a widely used moth repellent. Wright (1975) has theorized that mosquito repellents act by blocking, "plugging up," or "jamming" the olfactory receptors on the mosquitoes' antennae [see Dethier (1956) and Rodriguez and Levin (1976) for brief discussions of this topic]. If this is the case, then a number of volatile terpenoids that exhibit a camphoraceous odor and vapor may possess an insect repellent activity similar to that of 1,8-cineole and camphor. The similarities in chemical structure and physicochemical properties between 1,8-cineole and camphor are illustrated in Figure 1.

It is noteworthy that Australian/Tasmanian *Eucalyptus* trees have long been reported to be useful in the elimination of mosquito breeding places. In the past,

FIG. 1. Comparison of the stereostructure and physicochemical properties of 1,8-cineole (eucalyptol) with those of the widely used moth repellent, camphor.

Tasmanian blue gum trees were introduced into the coastal and wet regions of southern and western Europe (especially in the Mediterranean regions of Italy and Spain), Africa, the Middle East, India, and many other parts of the world that serve as breeding places for malarial mosquitoes. These very large and rapidly growing trees, which have large water requirements, have been found to be extremely useful in draining marshy areas and in reclaiming swampy lands, making them mosquito- and malaria-free areas within a few years. In Spain and elsewhere, where *E. globulus* has been associated with malaria reduction, it is known as the "fever tree." In the past, widely publicized successes in malaria-ridden areas have been attributed almost exclusively to the soil drainage effects caused by the large water requirements of the *Eucalyptus* trees (Grieve, 1971; Stuart, 1982; Cribb and Cribb, 1983; Bianchini et al., 1985). The ability of these trees to dry up wet lands is indisputable.

In light of our new findings, the successes achieved in destroying mosquito breeding places with the planting of *Eucalyptus* trees may also be at least partly attributable to the effects of 1,8-cineole and related (camphor-like) volatile terpenoids. Local saturation of water, air, and possibly soil particles with 1,8-cineole might have a significant ecological effect in reducing mosquito populations by virtue of the effectiveness of the compound as an ovipositional mosquito repellent. It has previously been shown that ecologically significant concentrations of 1,8-cineole are produced under natural conditions by certain aromatic plants (including *Eucalyptus* spp.) in California and elsewhere. Eco-

logically significant concentrations of 1,8-cineole are present in the atmosphere surrounding these plants and adsorbed onto colloidal soil particles in their immediate surroundings (Harborne, 1982). In the case of *H. fitchii*, it is possible that the nearby pond water and local atmosphere (where these plants were found growing) were saturated with 1,8-cineole. Thus, the ovipositional repellency of 1,8-cineole, coupled with the larvicidal activity of the *Hemizonia* chromenes (Klocke et al., 1985), may explain in large part the observed suppression of local mosquito populations which was associated with *H. fitchii* in northern California.

1,8-Cineole (eucalyptol) has been widely used (either as a pure compound or as the major constituent of eucalyptus oil) as an antiseptic, external analgesic, inhalational expectorant and antitussive, and as a nasal and bronchial decongestant in well-known over-the-counter proprietary pharmaceutical formulations, and as a flavoring agent in foods and toothpastes (Swinyard and Lowenthal, 1975; Windholz et al., 1976, 1983; APhA, 1979; Leung, 1980; Tyler et al., 1981). Since 1,8-cineole is approved and is currently being used commercially in products for inhalational, oral, and external use, the compound may be safe for use in insect repellency products (e.g., as a mosquito feeding repellent for humans and as a flea repellent for pet cats and dogs) and/or as an ovipositional repellent in potential mosquito breeding places. However, before widespread commercial use of the insect repellent properties of 1,8-cineole can be realized, certain questions concerning its safety and effectiveness need to be addressed, particularly its potential attractiveness to stinging insects, its potential for excessive percutaneous skin absorption, its extreme volatility, and its potential toxicity towards nontarget organisms. Careful product formulation may help to overcome such difficulties.

Acknowledgments—We are grateful to Mr. Elmer J. Kingsford for collection and identification of the plant material and for helpful discussions concerning the field observations of the ecological effects of *H. fitchii*. We thank Dr. George B. Craig, Jr. (University of Notre Dame, Notre Dame, Indiana) for providing the *Aedes aegypti* eggs essential for colony establishment and for helpful discussions concerning the rearing of mosquitoes. Ms. Kathleen J. Brown extracted the *H. fitchii* volatile oil, prepared the voucher specimen, and performed the repellency bioassays involving Colorado potato beetles. We are grateful to Dr. Mark A. Barnby for reviewing this manuscript and for helpful discussions and suggestions.

Abstract—The relationships between catch of *D. brevicomis* LeC. at sources of the synergistic pheromone components, *exo*-brevicomin (E) and frontalin (F), and increasing distance of separation of sources were investigated in the forest. The two components were each released with the host monoterpene, myrcene (M), in trap pairs. The traps of each pair were spaced apart at various distances (0–16 m) in either horizontal or vertical lines that were perpendicular to the mean wind direction. Both sexes were most strongly attracted when the two components were released from the same source, and increasing distance of separation between components caused exponential decreases in trap catch for all trap configurations. Males were significantly more attracted to traps with E, M alone than to corresponding traps with F, M alone, while females exhibited a preference for F, M. The theoretical relationships and properties of two coalescing plumes of individual components and their intersecting "active space" are presented and discussed. It is proposed that "confusion" or "communication disruption" techniques for insect control may be more successful if components are released individually from many points rather than released similarly in blends.

Key Words—*Dendroctonus brevicomis*, Coleoptera, Scolytidae, pheromone, synergism, plumes, *exo*-brevicomin, frontalin, myrcene.

[1] *Dendroctonus brevicomis* LeC. (Coleoptera: Scolytidae).

INTRODUCTION

To date there has been very little research on the theoretical and biological consequences of physically separating the release points of individual pheromone components that normally would be released together. There are several reasons why research on the interactions of pheromone component odor plumes is of interest to chemical ecologists. From a practical standpoint, it may be that "confusion methods," which disrupt pheromone communication, are more effective if synergistic components are released separately in disjointed blends than if full blends are released. From a field test design standpoint, it is of importance to understand how far apart traps of different component blends must be placed in order to minimize interactions and yet take advantage of "homogeneous" populations levels found in a particular area. Finally, it is of basic interest to determine the physical dimensions of synergistic component interaction for various species and their sexes.

There are two major ways that a semiochemical treatment in a trap can interfere with the catches of insects in nearby traps containing different treatments. In the first way, semiochemicals can affect the responses of insects at distances from the source that include the adjacent traps. For instance, traps releasing high concentrations of attractants may cause high numbers of insects to enter the vicinity and some could be caught incidentally on nearby traps and thus artificially increase their catches. Schlyter et al. (1987a) found that high-releasing pheromone traps did increase the catch of the bark beetle *Ips typographus* on nearby blank traps as well as lower-releasing traps, presumably by attracting large numbers of beetles into the area. They also found that the catch on the adjacent traps became increasingly greater as the distances between traps were decreased. The second way that semiochemical treatments can affect the catches on adjacent traps is by synergistic component odor plume interactions. This has not been studied with insects in the field and is the focus of this paper.

The Western pine beetle *Dendroctonus brevicomis* LeConte (Coleoptera: Scolytidae), provides an appropriate system for investigations into the interactions of pheromone component odor plumes because of its sex-specifically-produced synergistic components. The female begins the colonization of ponderosa pine (*Pinus ponderosa* Doug. ex. Laws.) when she bores through the outer bark and excavates a gallery in the phloem layer. She produces a pheromone synergist, *exo*-brevicomin (E), which accumulates in her hindgut upon feeding (Pitman et al., 1969; Hughes and Renwick, 1977; Byers et al., 1984) and is released with the fecal pellets in the frass (Silverstein et al., 1968). Although Libbey et al. (1974) found that females in glass tubes could release small amounts of E without feeding, it appears most E is released during feeding. A male attracted to the entrance tunnel soon releases frontalin (F) (Kinzer et al., 1969; Libbey et al., 1974; Browne et al., 1979), and it appears he is capable

of doing so immediately upon defecation (Byers et al., 1984). F, together with E, synergistically enhances the attraction of both sexes, with a small further increase due to the host resin monoterpene, myrcene (M) (Wood et al., 1976; Bedard et al., 1980). This synergism results in a dramatic increase in beetle visitation and cooperative "mass attack" which functions to overcome the resinous defense mechanisms of the host tree (Wood, 1982).

In several earlier reports, the female-produced E was found to attract primarily males, while the male-produced F attracted mostly females (Bedard et al., 1969; Vité and Pitman, 1969a, b; Pitman and Vité, 1971; Hughes and Pitman, 1970). However, it must be understood that release of F alone probably does not occur in nature because males always join females in their galleries. On the other hand, it is possible for males to release F upon landing on the tree as large quantities are present in their hindguts (Byers et al., 1984). Vité et al. (1972) proposed that *D. brevicomis* could release pheromone upon landing with a "contact pheromone" as opposed to the feeding-dependent pheromone components of many *Ips* species ("frass pheromone"). Wood et al. (1976) determined that only the (+)-E and the (−)-F enantiomers were bioactive. Furthermore, the presence of inactive enantiomers in the racemic mixtures did not cause inhibition or inactivation.

The objectives investigated here are: (1) What are the relationships between the distance of separation, either horizontal or vertical, of release points of the synergists, E and F, and the attraction of each sex to these sources? (2) What are the theoretical mathematical relationships among the ratios of the pheromone component concentrations at various places in the intersecting odor plumes for varying degrees of intersection?

METHODS AND MATERIALS

Interacting Exo-*brevicomin (E) and Frontalin (F) Odor Plumes.* All experiments were conducted at two sites (A and B) in the Sierra National Forest near Bass Lake, Madera County, California, at about 1000 m elevation. In September 1978, a test was conducted at site A with pairs of tubular sticky traps (19 cm diam. × 30.5 cm high, 6.3-mm wire mesh coated with Stickem Special), each supported on a pipe standard 1.2 m above the ground. One trap of a pair contained a release device (Byers and Wood, 1980) that had a glass tube (52 mm × 3.5 mm ID) with E (>95% and no F by GLC) and another with myrcene (M) (>97%), while the other trap contained M and a glass tube (62 mm × 2.2 mm ID) with F (>95% with no E by GLC). The chemicals from Chem. Samples Co., Cleveland, Ohio, were each released at about 2 mg/day under field conditions (Browne, 1978) or somewhat less at about 1.5 mg/day according to Tilden and Bedard (1985). Eleven 1-day-long, replicates were ob-

tained on each of five trap pairs horizontally spaced apart at distances of 0, 2, 4, 8, and 16 m. The trap pairs were oriented perpendicular to the mean wind direction and were randomized in different areas, which were at least 25 m apart, each day. Beetles were collected each day, cleaned in solvent, and sex was determined.

In August 1985, a similar test at site B was conducted for six, 1-day-long, replicates but at distances of 0, 0.5, 1.5, and 3 m between traps in a pair. At the same time, at site B, a test of trap pairs (baited the same way) vertically spaced apart at distances of 0, 0.5, 1.5, and 3 m was conducted. The "bottom" traps were placed at 1.2 m height with the "top" trap at the respective distances above the bottom trap. Trap pairs were switched each day (1-day-long replicates) so that top and bottom placements occurred equally among the treatments, while randomization of trap pairs between areas occurred every second day, three times.

Treatment effects within pairs were analyzed by Wilcoxon matched-pair tests both for total catch and male–female numbers. The sex ratios of catch on treatments within and between trap pairs were determined as were 95% binomial confidence limits (Byers and Wood, 1980), and chi-square tests were performed to test for differences. A nonlinear relationship between trap catch and distance of component separation may be expected based on the nature of the wind–plume interactions over time. Therefore, several linear and nonlinear regressions were performed to determine which curve best fits the data (linear, logarithmic, exponential, power, $Y = a + bX^2$, and $Y = a + b/X$). This was done to be able to predict catches at various distances not tested here. Exponential regression was found to fit the data best (highest r^2 values) and was used to draw the lines in Figures 1–3.

Theoretical Model of Interactions of Odor Plumes. Elkinton and Cardé (1984) show the Gaussian distribution of the "active space" of pheromone concentration for a 3-min time-averaged plume as modified from Slade (1968). In Figure 4, two such plumes have been intersected. Based on the understanding of this figure, one can theorize about the concentrations of each component when the component odor plumes have specified standard deviations and distances of separation. It can be assumed that both E and F, which have similar molecular weights and volatilities, will have similar Gaussian plumes. Thus, the shape of the intersection area of the plumes where both compounds are present (Figure 5) and the intersection midline where the ratio is 1:1 (H) can be calculated iteratively by computer from the normal probability density function:

$$\int \text{rel} = 1/(\sigma\sqrt{2\pi})e^{-(x-\mu)^2/(2\sigma^2)}$$

where σ is the standard deviation (1), μ is the mean (4.5 or 7.5), and x is any point on the x axis. The above equation can be used to solve for $H = (\int \text{rel})$ at

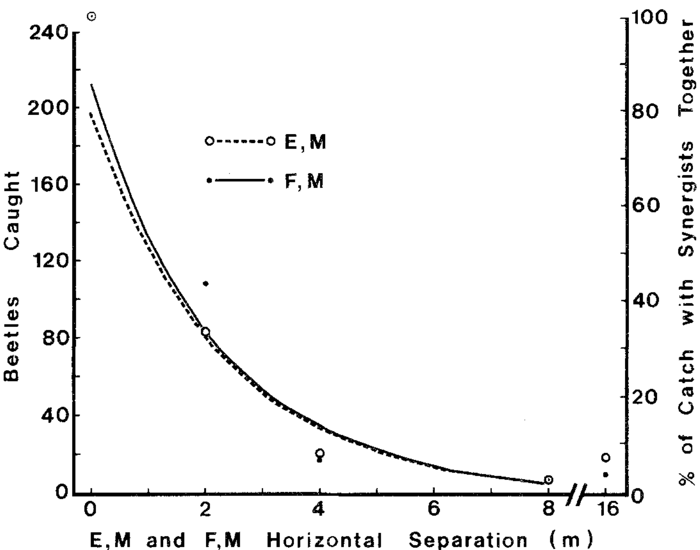

FIG. 1. Reduction in catch of *D. brevicomis* at sources of the pheromone synergists *exo*-brevicomin (E) and frontalin (F) with increasing horizontal distance of separation between sources. Each point represents a total of 11 one-day replicates. The pheromone components, each with myrcene (M), were each released at about 1.5 mg/day from sticky traps at 1.5 m height in the Sierra National Forest, California (September 17–28, 1978).

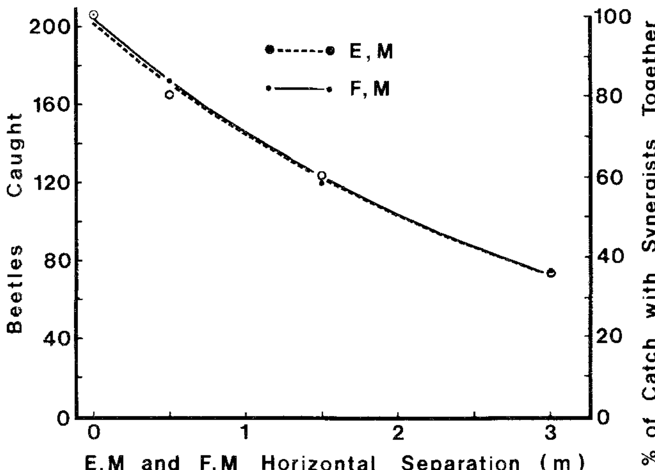

FIG. 2. Reduction in catch of *D. brevicomis* at sources of the pheromone synergists *exo*-brevicomin (E) and frontalin (F) with increasing horizontal distance of separation between sources. Each point represents a total of six one-day replicates. The pheromone components, each with myrcene (M), were each released at about 1.5 mg/day from sticky traps at 1.5 m height in the Sierra National Forest, California (August 20–26, 1985).

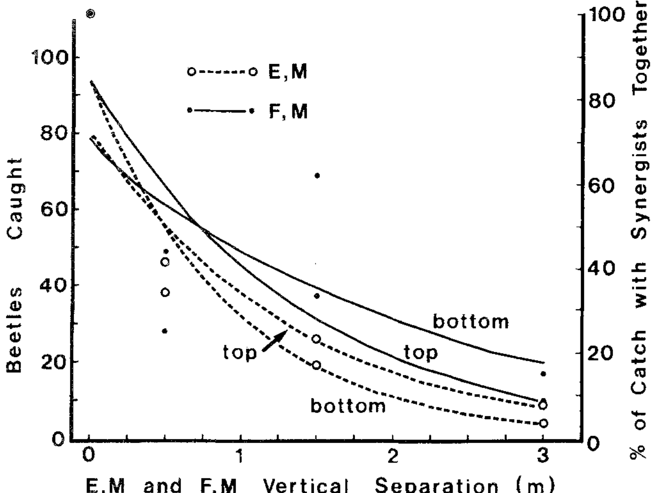

FIG. 3. Reduction in catch of *D. brevicomis* at sources of the pheromone synergists *exo*-brevicomin (E) and frontalin (F) with increasing vertical distance of separation between sources. Each point represents a total of three 1-day replicates. The pheromone components, each with myrcene (M), were each released at about 1.5 mg/day from sticky traps at 1.5 m (bottom trap) or more height (top trap) in the Sierra National Forest, California (August 20–26, 1985).

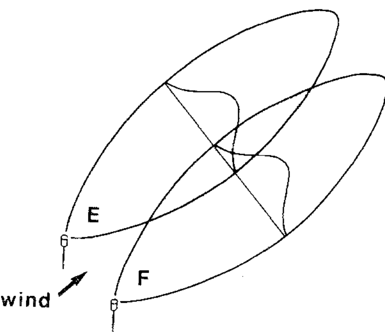

FIG. 4. Diagrammatic representation of the "active space" intersection area (shaded area) of two synergistic Gaussian plumes with 3-min averaging times (modified from Elkinton and Cardé after Slade, 1968).

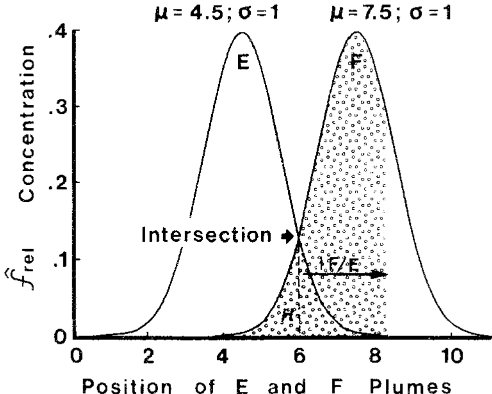

FIG. 5. Graphic representation of the cross-section of the concentration distributions of two Gaussian plumes of the pheromone synergists (E and F). The "active space" is related to the height of the dashed line (H) and the width of the shaded area, and it does not have a Gaussian distribution as do E or F with means of 4.5 or 7.5 and standard deviations of 1. Flight-path deviations along the x axis, for example to the right, would increase the ratio of F/E dramatically and unnaturally compared to natural pheromone plumes.

$x = 6$. The height of the intersection or point where both components are equal (H) can be iteratively calculated for varying degrees of plume intersection (Figure 6) with the following BASIC program that utilizes the above equation:

```
FOR W = I + M TO I + M + S STEP SS:
    Y = 1/(SD*SQR(2*PI))*EXP (1)^(-((I - W)^2)/(2*SD^2)):
    X = 2*M + (W - (I + M))*2:PRINT X, Y:NEXT W
```

where I is the intersection point (e.g., 6), M is the starting distance of either mean to intersection, S is the maximum distance means will be separated, SS is the step size on x axis for each calculation, SD is the standard deviation of the plumes (equal for both plumes), X is the x axis value or separation of component plumes, and Y is the y axis value or H of the intersection midline.

The ratio of F to E that an insect would encounter as it traverses laterally over the plume intersection area is depicted in Figure 5. The precise relationship beginning at a ratio of 1 at the intersection point (H) and moving to the right is shown in Figure 7. The results were calculated iteratively by computer assuming that the E and F plumes have equal standard deviations but the following equation will also work on unequal variances:

$$\text{Ratio F/E} = [1/(\sigma_F\sqrt{2\pi})e^{-(x-\mu_F)^2/(2\sigma_F^2)}]/[1/(\sigma_E\sqrt{2\pi})e^{-(x-\mu_E)^2/(2\sigma_E^2)}]$$

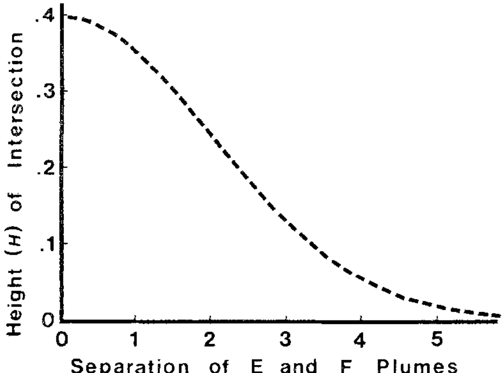

FIG. 6. Gaussian relationship between height of the intersection midline (concentration) of two separated synergist plumes (dashed line in Figure 5) and the separation distance between the longitudinal axes of the plumes.

where σ_F and σ_E are the standard deviations of F and E, respectively, μ_F and μ_E are the means of F and E, respectively, and x is any point on the x axis. Exponential regression was then performed on the results to obtain the equation of the curve in Figure 7.

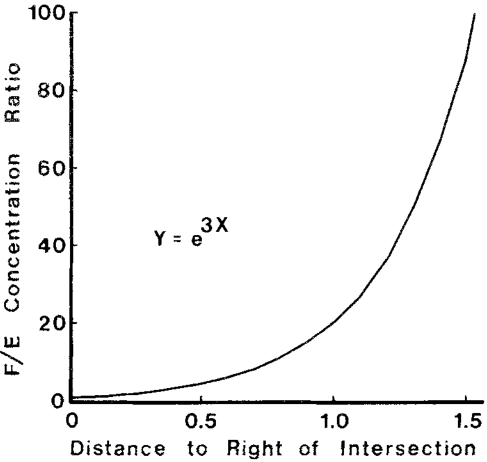

FIG. 7. Exponential relationship between the ratio of F/E concentrations (Figure 5) within two intersecting synergist plumes and the distance to the right of the longitudinal intersection midline (dashed line in Figure 5) of the plumes.

RESULTS

Interacting Exo-*brevicomin (E) and Frontalin (F) Odor Plumes.* The catches of *D. brevicomis* on E, M and F, M trap pairs spaced apart horizontally at various distances from 0 to 16 m in 1978 are shown in Figure 1. The points at 16 m were not used in calculating the exponential regression curves because these values were not appreciably different from those at 8 m, indicating that interaction effects were negligible at distances >8 m. It can be seen that trap catches on E, M ($Y(\%) = 79.62e^{-0.448X}$, $r^2 = 0.95$) were similar to corresponding catches on F, M ($Y(\%) = 85.64e^{-0.461X}$, $r^2 = 0.92$) within a pair at any separation distance. The interactions between the E and F synergists were insignificant when the distance of their separation was increased farther than 4 m. When the horizontal separation test was repeated in 1985 at distances from 0 to 3 m, a similar relationship occurred (Figure 2). Again the trap catches on E, M ($Y(\%) = 97.91e^{-0.334X}$, $r^2 = 1.00$) were almost identical to corresponding catches on F, M ($Y(\%) = 98.83e^{-0.337X}$, $r^2 = 1.00$).

In the 1985 test of E, M and F, M trap pairs spaced apart vertically at distances from 0 to 3 m, the results have been presented with respect to the special symmetry of "top" and "bottom" (Figure 3). The catches on top and bottom traps with either E, M or F, M are similar, although F, M appears to have attracted more beetles. The relationships between percent of catch when synergists were together and the vertical separation distance for the respective traps are given by the following exponential equations: top F, M ($Y(\%) = 85.25e^{-0.738X}$, $r^2 = 0.95$); bottom F, M ($Y(\%) = 69.13e^{-0.452X}$, $r^2 = 0.49$); top E, M ($Y(\%) = 72.75e^{-0.754X}$, $r^2 = 0.92$); bottom E, M ($Y(\%) = 85.14e^{-1.067X}$, $r^2 = 0.99$).

Although the total (male + female) catches appear similar on E, M and F, M traps in the experiments (Figures 1–3), there are significant, but no dramatic, male–female differences as reflected in the Yates chi-square test and Wilcoxon matched-pair test (Table 1). In most cases, the F, M trap had a lower sex ratio (proportionately less males) than the E, M trap within a pair, both for horizontally and vertically placed traps (Table 1). The Wilcoxon tests also showed, in many cases, that the distribution of male, or female, catches on the replicates within a trap pair were significantly different (Table 1). A comparison of E, M and F, M vertical pairs with the Wilcoxon test, without regard to position, showed that at 1.5 m separation the female as well as the total catches had significantly different distributions on the synergists. Also at 3 m separation, the male, female, and total catches had significantly different distributions ($P < 0.05$, Wilcoxon). The sex ratios and (95% binomial confidence limits) for the vertical pairs are: E, M (≥0.5 m) = 0.84 (0.64–1.10) and F, M (≥0.5 m) = 1.54 (1.10–2.15), which were different at $P < 0.05$, Yates χ^2.

Furthermore, when the total catch on F, M traps is compared to E, M traps

for all horizontally or vertically paired traps (separated by at least 0.5 m), there are significant differences in the sex ratios in all cases except the "top" vertical traps (Table 1). In two of the four cases, the sex ratio on F, M was significantly different from the control, while in the other two cases, the sex ratio on E, M was significantly different. From the sex ratios alone it is impossible to determine if males or females or both prefer one of the synergists, but the Wilcoxon tests indicate that males prefer E, M while females prefer F, M. The sex ratios were virtually identical on the top and bottom traps, 1.10 (0.83–1.47) and 1.04 (0.77–1.40), respectively. However, these ratios were significantly different from the control where the synergists were placed together ($P < 0.05$), although they were not different from the "horizontal control" which was placed in the same area at the same time (Table 1).

Temnochila chlorodia (Mannerheim), a predator of *D. brevicomis* and known to be attracted to E (Bedard et al., 1969), was caught in 1978 only on the traps containing E, M (11 beetles) except for one caught on F, M at the 2-m spacing. In 1985 on the horizontal traps, *T. chlorodia* were caught only on the E, M-containing traps (16 males, 6 females) except for two males and one female on the F, M traps at 1.5 m. The vertical traps caught these predatory beetles again only on traps with E, M (18 males, 6 females) except for one male and two females on F, M at 1.5 m and one female on F, M at 0.5 m.

Theoretical Model of Interactions of Odor Plumes. In Figure 4, two 3-min time-averaged plumes are shown coalescing when the mean wind direction is perpendicular to the two sources. The "active space" (cf. Elkinton and Cardé, 1984) where the two components (E and F) are both above the threshold of response (cf. Roelofs, 1978) is shown in the shaded area (Figure 4). The two bell-shaped curves represent the Gaussian distribution of concentration for each component. The "active space" as shown in Figure 4 actually is fundamentally different from the normal active space in which both components vary similarly based on a Gaussian distribution. In Figure 5 the relative concentrations of each component along the latitudinal axis are shown and demonstrate the peculiar properties of the intersection area of the two plumes. The intersection midline where the two components are of equal concentration (presumed most favorable for orientation) is represented by *H* and the dashed line (Figure 5). If the two odor sources (shown in Figure 5) are placed together and then physically separated until the two plumes do not intersect, then the relative concentration at the intersection midline (*H*) decreases, as shown in Figure 6, according to a normal curve.

Referring to Figure 5, if an insect were flying upwind along the intersection midline and then veered more into the F odor plume, then the ratio of F/E would increase exponentially according to Figure 7 ($r^2 = 1$). The exponential increase in the ratio would continue even if the insect flew to the outside (right) of the F concentration peak. Exponential relationships result for all Gaussian distri-

TABLE 1. SEX RATIOS OF CATCH OF *D. brevicomis* ON HORIZONTAL OR VERTICAL TRAP PAIRS SPACED DIFFERENT DISTANCES APART AND CONTAINING PHEROMONE COMPONENTS F, M (FRONTALIN + MYRCENE) OR E, M (*exo*-BREVICOMIN + MYRCENE)

[a]95% binomial confidence limits for sex ratios (Byers and Wood, 1980).
[b]Combined catches for top and bottom traps that were placed together.
[c]1, 2, and 3 indicate the treatments within a trap pair differed in their distributions of males (1), females (2), or total (3) caught, $P < 0.05$, Wilcoxon matched-pairs test.
[d]Indicates the sex ratios within a trap pair were significantly different, $P < 0.05$, chi square with Yates.
[e]Indicates the sex ratio was significantly different from E, M + F, M (0 m) control, $P < 0.05$, chi square with Yates.

butions with equal variances. Ratio changes also occur for distributions with unequal variances, but the relationships are more complicated (but can be calculated with the ratio equation).

DISCUSSION

The release of E, M and F, M from separate points situated either vertically or horizontally might appear to be possible in nature on standing or fallen trees. However, a "pioneer" female would release E, M in small amounts only until she was joined by other females and males during the initial stages of the mass attack. Based on the results presented here, she would most likely attract a male to the area. Once both attractants are released from the pioneering pair, then a "balanced" sex ratio occurs (Vité and Pitman, 1969a). As mentioned above, several earlier studies, and the present one, indicate that relatively more males are attracted to E, E, M, or E + oleoresin while more females are attracted to F, F, M, or F + oleoresin. However, it must be noted that the respective attraction rates to each component were much less than to the synergistic blend.

There are no apparent differences between the sexes in attraction to a concentration range of E, F, M (1 : 1 : 1) covering five orders of magnitude in the laboratory (Byers and Wood, 1981) and three orders in the field (Tilden and Bedard, 1985). Thus, it is difficult to find an explanation for the sexual preferences for the respective components. It would not seem adaptive for a male to release F unless he was with a female in her gallery, and males are not known to initiate attacks and "call" for females. Therefore, it would appear females never have the opportunity to respond to F alone. Although Libbey et al. (1974) did find F was released from male + male confinement in glass tubes, males never are found in galleries in this way (Byers et al., 1984). On the other hand, the male preference for E could possibly be adaptive if males use it to seek females after landing on the tree. Could it be that these sexual preferences are the "behavioral remnants" of a previous era when the sexes sought each other (true sex pheromones)? Later in evolution each sex could have relied on the opposite-sex component as the primary one that is synergized by the same-sex produced component. Analysis of the attraction response of each sex to various component ratios may indicate which component is synergizing which component or whether they are mutually synergistic (Byers, 1987).

Linn and Gaston (1981) have performed wind-tunnel tests with male cabbage looper moths in which two pheromone component plumes were allowed to intersect between 35 and 85 cm downwind of the sources. They found no effect on upwind orientation by separating the components 12 cm apart (85-cm downwind plume intersection), but when the separation was only 8 cm (35-cm downwind intersection) there were significantly less moths approaching the

sources. However, one of the components is attractive alone while the other is not, so the case is different than if neither component is significantly active alone, as in the Western pine beetle. The male moths were apparently "confused" as they flew out of the intersecting plumes (removal of the inactive-alone component 35 cm downwind) during their upwind flight to the active-alone component, as if they had suddenly passed by a female (full blend). When the plumes were further apart, the moths were essentially only flying up the active-alone plume, presumably in a long-range orientation mode.

In field studies with the Western pine beetle, the relationships between catch and component separation distance (Figures 1–3) have underlying causes which are apparently very complex. In nature the wind direction can vary widely and, although the trap pairs were placed perpendicular to the prevailing wind, sometimes the wind carried the odor of one component directly through the source of the other component (this error should not have occurred with the vertically placed trap pairs). Considering a constant perpendicular mean wind direction, however, there are several differences between the geometries of the active spaces of an idealized plume of a two-component blend and that of two coalescing single-component plumes. For the coalescing plumes (Figure 5), the active space is narrower and shorter than in a normal blend, and the "head" of the active space is far from either source and oriented between the sources compared to a normal blend with the "head" at the source. Another difference is due to the fact that the periphery of a plume is more variable in time with regard to concentration (Elkinton and Cardé, 1984), and it is the peripheries of plumes that comprise the active space of coalescing plumes. Finally, Figure 5 shows the concentration ratios of the two components for a particular degree of plume intersection. This is quite different from the case with the normal blend where both components have corresponding Gaussian distributions. Significant effects on behavior of various component ratios are well known in moths (Roelofs, 1978; Roelofs and Cardé, 1977; Baker and Cardé, 1979) and, more recently, in bark beetles (Schlyter et al., 1987b; Tilden and Bedard, 1985; Byers, 1987). The theoretical relationships have been considered for time-averaged plumes which are, in fact, filamentary in an instantaneous sense (Okubo, 1980), but the theories here would still generally apply to such plumes.

The concept of using multicomponent pheromones in a blend that is released from many scattered sources in the field for mating disruption and insect control is well established. However, the field and theoretical results presented here indicate that release of the individual components from a mosaic mixture of sources may be more disruptive of olfactory communication than use of full blends. It is hoped that the considerations presented here on interacting component plumes will inspire new types of experiments at both basic and applied levels.

Acknowledgments—I am appreciative of the USFS and W.D. Bedard, P.E. Tilden, and M.I. Haverty for providing the facilities for research in the field. I am especially grateful to P.E. Tilden who provided helpful assistance and information concerning my field studies. I would like to thank D.L. Wood, Department of Entomological Sciences, University of California, Berkeley, for providing me with a research base in collaboration with J. Löfqvist and the Department of Animal Ecology, University of Lund, Sweden.

(Received September 15, 1986; accepted December 31, 1986)

Abstract—The chirality of the pheromone of the rice weevil, *Sitophilus oryzae* (L.), and the maize weevil, *S. zeamais* (Motschulsky), 5-hydroxy-4-methyl-3-heptanone, was determined using an acetyl lactate derivatization procedure. Maize weevils were shown to produce >98% 4*S*,5*R*. Determination was more difficult with rice weevils due to a smaller quantity of insect extract, but they were shown to produce at least 92% 4*S*,5*R*.

The attractancy of the four synthetic stereoisomers of 5-hydroxy-4-methyl-3-heptanone was tested using rice and maize weevils. As expected, both species were most strongly attracted to the 4*S*,5*R* enantiomer. Maize weevils also showed low but significant responses ($P < 0.05$) to both 4*R*,5*R* and 4*S*,5*S*. Rice weevils showed a highly significant ($P < 0.01$) response to 4*R*,5*S*, although it was only about one third the response to 4*S*,5*R*. Thus, (4*S*,5*R*)-5-hydroxy-4-methyl-3-heptanone is clearly the major component of the pheromone of both *S. zeamais* and *S. oryzae*.

Key Words—Chirality, enantiomers, 5-hyroxy-4-methyl-3-heptanone, stereoisomer, *Sitophilus oryzae*, *Sitophilus zeamais*, rice weevil, maize weevil, aggregation pheromone, Coleoptera, Curculionidae.

INTRODUCTION

Sitophilus spp. weevils cause severe damage to cereal grains throughout the world, through direct feeding on grain kernels. The male-produced aggregation pheromone of the rice weevil, *Sitophilus oryzae* (L.) and the maize weevil, *S. zeamais* Motschulsky, has been identified as (R^*,S^*)-5-hydroxy-4-methyl-3-heptanone,[2] of unknown enantiomeric composition (Schmuff et al., 1984; Phillips et al., 1985). Some response to the R^*,R^* diastereomer by both species was observed in the laboratory, but this compound was present at less than 0.5% in natural pheromone samples.

5-Hydroxy-4-methyl-3-heptanone possesses two asymmetric centers and thus can exist as four different stereoisomers (Figure 1). The asymmetric center at position four is adjacent to the ketone and as such is susceptible to racemization by either acid or especially base. The hydroxyl group beta to the ketone makes the molecule even more labile in that retro aldol cleavage or facile dehydration can occur with complete loss of stereochemistry. At the outset of this work we were unsure as to whether these properties would prevent the determination of the chirality through racemization or elimination of the required acetyl lactate diastereomeric ester. The objective of this work was to determine the natural enantiomeric ratios in maize and rice weevils, and to examine the ability of both species to distinguish between the four synthetic stereoisomers.

METHODS AND MATERIALS

Insects. Rice and maize weevils were obtained from laboratory stock cultures and were reared according to procedures previously described (Phillips and Burkholder, 1981; Walgenbach et al., 1983).

Weevils for experimental use were collected on day of emergence by sieving and were separated by sex according to dimorphic rostral characteristics (Halstead, 1963). Weevils were held on wheat at constant densities on a 16:8 light–dark regime and 27° ± 1°C and 65 ± 5% relative humidity.

Extracts. Collections of pheromone from individual virgin male maize and rice weevils were made as previously described (Phillips and Burkholder, 1981). Parallel collections from cracked wheat controls were made at the same time.

[2] R^*,S^* represents an unknown mixture of the $4R,5S$ and $4S,5R$ enantiomers. Similarly, R^*,R^* represents an unknown mixture of $4R,5R$ and $4S,5S$.

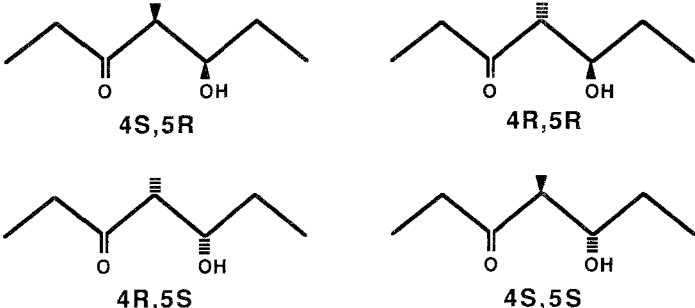

FIG. 1. Stereoisomers of 5-hydroxy-4-methyl-3-heptanone.

Glass wool-filtered hexane extracts containing 1152 insect-day equivalents (IDE) (two samples) for maize weevils, 1464 and 1500 IDE for rice weevils, and 1000 DE (two samples) for the cracked wheat control were each divided into two portions. Half the material was purified on Florisil by elution with hexane–diethyl ether (1 : 1) as previously described (Phillips et al., 1985). The samples were concentrated under N_2 to approximately 200 μl and placed in silanized screw-top vials fitted with a Teflon liner. The four samples for each species and cracked wheat control, plus the chiral standards, were shipped via air express to Vancouver, in a container maintained at −78.5°C by dry ice. On arrival, samples were transferred to a low-temperature freezer for continued maintenance at −78.5°C.

Synthetic Standards. A racemic sample of 5-hydroxy-4-methyl-3-heptanone containing approximately equal amounts of R^*,S^* and R^*,R^* diastereomers (Phillips et al., 1985) was used to establish reaction conditions, capillary gas chromatograph column selection, and the operating conditions. The four optically pure stereoisomers of 5-hydroxy-4-methyl-3-heptanone used as standards in this study were synthesized by Mori and Ebata (1986). Chemical purity for all four samples was >98%.

Analyses. Splitless capillary gas chromatography was carried out on a Hewlett Packard HP 5890 using a 30-m × 0.25-mm ID fused silica column with injector and detector temperatures of 250°C. The column, SP-2340 (Supelco Inc., Bellefonte, Pennsylvania), was temperature programmed as follows: 100°C for 2 min, 20°C/min to 150°C, and isothermal at 150°C. Flame ionization detection was employed with a helium carrier and makeup gas. All samples were chromatographed to ascertain concentrations and ensure that no underlying impurity existed at the retention time of the acetyl lactate derivatives. Splitless gas chromatography–mass spectroscopy (GC-MS) was carried out on a Hewlett Packard HP 5985B in which the same SP-2340 column had been

installed. The temperature program was identical, except the initial temperature of 100°C was held for only 1 min.

Derivatization of Samples. To the sample contained in 10 μl of hexane, a benzene solution (5 μl) containing dimethylaminopyridine (250 μg) was added followed immediately by the acetyl lactate reagent [8 μl of methylene dichloride solution containing 200 μg of the acetyl lactyl chloride prepared as previously described (Slessor et al., 1985)]. When larger or smaller aliquots were used, the reagent amounts were scaled proportionately. The reactions were sealed in micro vials and kept at room temperature for 24–48 hr. Work-up involved the addition of 10 μl hexane followed by washes with 1% aqueous HCl (1× 50 μl), 5% aqueous NaOH (4× 50 μl), 5% aqueous $NaHCO_3$ (1× 50 μl), and finally water (1× 50 μl).

Bioassay. The dual-choice pitfall bioassay developed by Phillips and Burkholder (1981) was used to test the attractancy of synthetic stereoisomers. Bioassays were conducted as previously described (Walgenbach et al., 1983) except that they ran for 30 min.

For the first experiment, (4*R*,5*S*), (4*S*,5*R*), and *RS*, a racemic mixture of the two enantiomers, were tested. In the second experiment, (4*R*,5*R*), (4*S*,5*S*), and *RR* (racemic mixture) were tested, with a 4*S*,5*R* series included as a positive control.

Test samples were diluted in UV-grade hexane such that 2 μl of solvent was applied. The same amount of solvent was used in the control vessel of each pitfall chamber. For rice weevils, 38 ng of each stereoisomer or mixture were tested. Maize weevils were tested using 100 ng.

Statistical Analysis. Response (treatment − control) was calculated and paired t-tests were used to determine the attractancy of each isomer. Isomers were compared using an analysis of variance (ANOVA). Significance was accepted at $P < 0.05$ for both tests. When the F test proved significant, means were compared using a Duncan's (1955) multiple-range test, also at $P < 0.05$. If male and female responses were statistically equivalent, results were pooled.

The sum of treatment and control was also calculated and was used as a measure of insect activity. Insect activities generated by the isomers were compared using ANOVA at $P < 0.05$.

RESULTS

Determination of Chirality. Concentrations of the pheromone samples ranged from 20 to 24 ng/μl for the maize weevil and 7 to 32 ng/μl for the rice weevil. All insect extracts showed the later eluting R^*,S^* diastereomer to be predominant, indicating that little, if any, epimerization had occurred on preparation and transfer of the samples.

Acetyl lactate formation and work-up of the dilute synthetic pheromone produced a sample which exhibited four baseline separated peaks when gas chromatographed on a 30-m SP-2340 capillary column. Other columns used gave varying degrees of separation, none of which were as good as the SP-2340. GC-MS showed virtually identical fragmentation patterns for all of the four diastereomers, with intense ions at *m/z* 115(71); 97(45); 87(75); 70(40); 57(100); 43(35).

Derivatization of the maize weevil pheromone in both purified and crude preparations showed 90–99% of the 4*S*,5*R* stereoisomer (Table 1), with a small amount of material running marginally faster than the 4*R*,5*R*. Examination of the GC-MS of maize weevil sample 2, Florisil acetyl lactate derivative (96%), revealed the latter peak to be primarily an impurity [*m/z* 133(100); 57(43)] and comprised of at most 50% 4*R*,5*R* isomer. The maize weevil pheromone is accordingly 98% or higher (4*S*,5*R*)-5-hydroxy-4-methyl-3-heptanone.

The lower pheromone amounts produced by the rice weevil yielded samples with larger impurity concentrations for a given amount of pheromone. This led to much more varied (55–97%) and less accurate determinations, but all showed high 4*S*,5*R* chirality. Again, the marginally faster peak was present in the region of the 4*R*,5*R* isomer and in about the same absolute amount found in maize weevil samples. GC-MS of rice weevil sample 4, crude acetyl lactate derivative, indicated the same impurity containing no more than 50% 4*R*,5*R* isomer. These results indicate the chirality to be at least 92% 4*S*,5*R*, and rice weevil sample 2, Florisil acetyl lactate derivative, showed this value to be at least 97%. These results indicate that the rice weevil pheromone is greater than 92% (4*S*,5*R*)-5-hydroxy-4-methyl-3-heptanone.

Weevil Response to Synthetic Stereoisomers. In the first experiment, maize weevils were most strongly attracted to 4*S*,5*R* with a mean response of 7.1 ($P < 0.001$; Figure 2a). The response to 4*R*,5*S* was not significant ($\bar{X} = 1.2$; $P > 0.05$). The response to the *RS* mixture fell between the responses to the two enantiomers and was highly significant ($\bar{X} = 4.3$; $P < 0.001$). ANOVA indicated that the responses to the *RS* mixture and 4*S*,5*R* were significantly higher than the response to 4*R*,5*S*. However, all activity values were high ($\bar{X}$ range 6.5–8.3) and were not significantly different from one another. The 4*R*,5*S* isomer is apparently close enough to the pheromone to get the insects moving, but not close enough to direct them, and they fall randomly into the treatment and control traps.

In experiment 2, 4*S*,5*R* again proved strongly attractive ($\bar{X} = 6.3$; $P < 0.001$) (Figure 2b). Low, but significant responses to 4*S*,5*S* ($\bar{X} = 1.7$; $P < 0.05$) and 4*R*,5*R* ($\bar{X} = 1.0$; $P < 0.05$) were observed. However, response to the *RR* mixture was not significant ($\bar{X} = 0.6$; $P > 0.05$). The activity values were correspondingly low. Responses to (4*R*,5*R*), (4*S*,5*S*), and *RR* were statistically equivalent, but 4*S*,5*R* was significantly more attractive than all others.

[a] MW = maize weevil; RW = rice weevil; CW = cracked wheat control. Integrator counts are proportional to peak area.

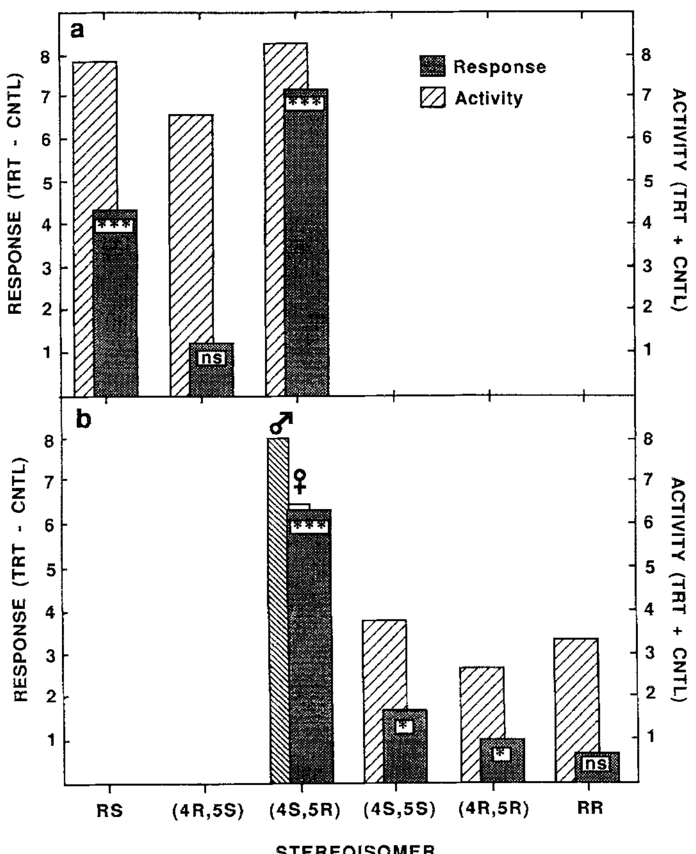

FIG. 2. Mean response (treatment − control) and activity (treatment + control) of maize weevils to stereoisomers of 5-hydroxy-4-methyl-3-heptanone. Male and female results combined for analysis, unless significantly different, as indicated. $^{***}P < 0.001$; $^{*}P < 0.05$; ns, not significant, Student's t test for paired data. (a) experiment 1; (b) experiment 2.

The rice weevil profile for both experiments was similar to that of the maize weevil (Figure 3). In experiment 1, response was strongest to 4*S*,5*R* ($\bar{X} = 7.5$; $P < 0.001$), followed closely by the *RS* mixture ($\bar{X} = 5.8$; $P < 0.001$). The 4*R*,5*S* enantiomer proved least attractive, but in contrast to the maize weevil, the lower response still proved highly significant ($\bar{X} = 2.6$; $P < 0.01$). The response to 4*R*,5*S* was significantly lower than the response to either the *RS* mixture or 4*S*,5*R*. This trend held true for activity as well. All activity values were high (>6.4), but activation by both *RS* and 4*S*,5*R* was significantly greater than for 4*R*,5*S*.

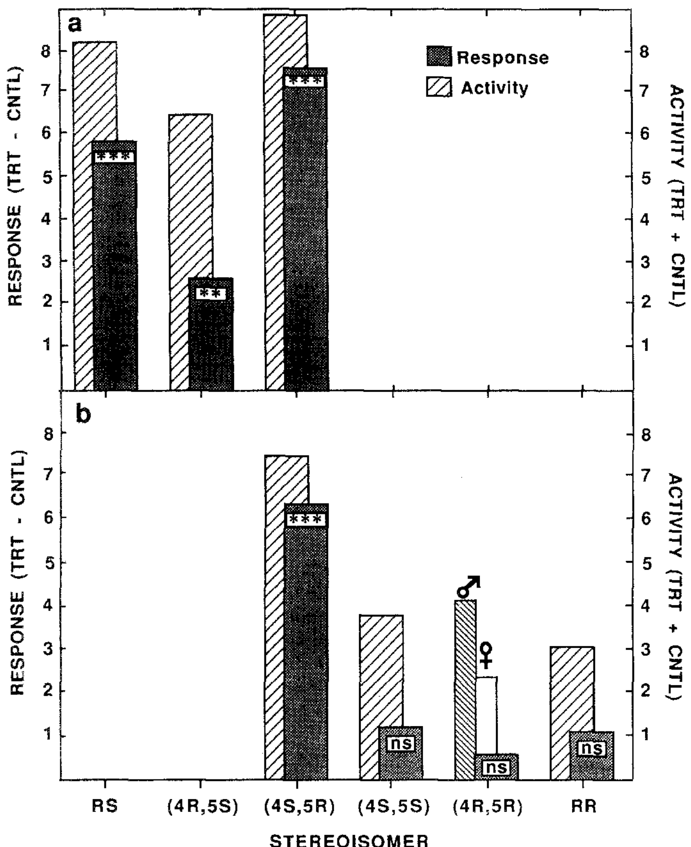

FIG. 3. Mean response (treatment − control) and activity (treatment + control) of rice weevils to stereoisomers of 5-hydroxy-4-methyl-3-heptanone. Male and female results combined for analysis, unless significantly different, as indicated. $^{***}P < 0.001$; $^{**}P < 0.01$; ns, not significant, Student's t test for paired data. (a) experiment 1; (b) experiment 2.

In experiment 2, rice weevil results were again similar to those of the maize weevil (Figure 3b). The 4*S*,5*R* isomer generated a mean response of 6.3 ($P < 0.001$). However, rice weevils did not respond significantly to 4*S*,5*S* ($\overline{X} = 1.2$; $P > 0.05$) nor 4*R*,5*R* ($\overline{X} = 0.6$; $P > 0.05$), as had maize weevils. Neither was there a significant response to the *RR* mixture ($\overline{X} = 1.1$; $P > 0.05$). These results were paralleled by low activity values. As with maize weevils, the response to 4*S*,5*R* was significantly higher than the responses to all other isomers.

DISCUSSION

It is clear that the pheromone of the *S. zeamais* and *S. oryzae* is defined by its optical as well as chemical properties. This is well-documented in other beetle species as well as in other groups of insects (Silverstein, 1979; Mori, 1984). Both maize and rice weevils responded most strongly to the 4*S*,5*R* isomer of 5-hydroxy-4-methyl-3-heptanone, and it has been proven to be the major component of the aggregation pheromone of both species. In addition, some interesting differences were observed in the specificity of the response of the two species to the other three stereoisomers.

In both species, the *RS* enantiomeric mixture produced somewhat lower responses than 4*S*,5*R* alone. However, only half as much 4*S*,5*R* was tested in the *RS* mixture, and thus the effect could simply be due to the lower concentration of this enantiomer.

The low responses observed by both species to the *RR* enantiomeric mixture contradict previous work (Phillips et al., 1985), where both species showed comparable responses to (R^*,S^*), (R^*,R^*), and a racemic mixture of the diastereomers. Since the present study indicated that optically pure 4*S*,5*S* and 4*R*,5*R* generated responses much lower than to the 4*S*,5*R* stereoisomer or the *RS* mixture, contamination of the mixtures used in the 1985 study is implied. Indeed, examination of gas chromatograph traces of R^*,R^* used in the previous study suggest the presence of 2–4% R^*,S^*. This represents $<$1–8 ng of 4*S*,5*R* in the 1985 work, but maize weevils are known to respond to amounts this low (Walgenbach et al., 1983).

Walgenbach and Burkholder (1986) showed that weevil activity (treatment + control) was a valuable additional tool in interpreting pitfall bioassay results. In the present study, activity appears to be a gauge of the relative "closeness" of the stereoisomer to 4*S*,5*R*. For instance, for these species, both response and activity to 4*S*,5*R* were high, indicating that many weevils were trapped in the treatment receptacle and few in the control receptacle. Similarly, low responses and activities were observed for the 4*R*,5*R* and 4*S*,5*S* stereoisomers, indicating that few insects were trapped in either receptacle. However, activities to 4*R*,5*S* were high compared to relatively low responses. This indicates that many insects left the pitfall chamber and were trapped, but they fell more or less randomly into both receptacles. Using this activity information in conjunction with response data may thus be helpful in interpreting which characteristics of the molecule are important in receptor specificity. When response and activity are both high, it is an indication that the weevils are not only activated, but their response is directional, since few incorrect (i.e., control) choices are made. Almost all responses are to the treatment, so response (T − C) and activity (T + C) are very close. For compounds where the receptor fit is interpreted to be nearly correct, high activities, but low responses are observed. The compound

is able to "activate" the insects, but is not able to direct them to its source. Thus, for maize and rice weevils, the need for the chiral centers to have opposite configurations is nearly as important to receptor binding as the specific orientation at each center.

The major component of the pheromone of both *S. zeamais* and *S. oryzae* has herein been shown to be (4*S*,5*R*)-5-hydroxy-4-methyl-3-heptanone. While the differential attractiveness of the other stereoisomers may simply reflect imperfect receptor specificity, it is possible that these responses reflect differences in the makeup of the maize and rice weevil pheromones, which could have important implications in reproductive isolation, as well as interspecific competition.

Acknowledgments—We thank John Andersen, Janet Klein, and James Walgenbach for their helpful reviews of this manuscript and for helpful discussion. We also thank Melissa Curtis, Joan Robers, and Steve Walkowski for technical assistance. The advice and cooperation of Allen Budde and J.P. Helgeson, ARS, USDA, for capillary GLC analyses is gratefully acknowledged. Partial support for this work came from the Natural Sciences and Engineering Research Council of Canada (Operating Grant A3785 and Strategic Grant G0958). This research was supported by the College of Agriculture and Life Sciences, University of Wisconsin, Madison, and by a cooperative agreement between the University of Wisconsin and ARS-USDA.
