(Received August 15, 1985; accepted January 6, 1986)

Abstract—Tiger salamanders generalize behaviorally between carbonyl-containing odorants (e.g., aldehydes or cycloalkanones). However, responding does not generalize from such odorants to stimulus compounds with comparable molecular shapes and dimensions but different functional groups. Discrimination between aldehydes and a ketone is temporarily impaired by two-step covalent modification of the olfactory epithelium. Two-step modification of the olfactory epithelia also impairs, but does not obliterate, olfactory detection, and generalization persists even during the period of impairment. These results are interpreted as implying the existence of carbonyl-binding, ''generalist'' olfactory receptors in addition to other classes of ''generalist'' receptors that are not affected by two-step modification. Generalization is inferred to require overlap in the response profile of more than one class of receptor.

Key Words—Tiger salamander, *Ambystoma tigrinum*, carbonyl function, generalist receptor, olfactory discrimination.

INTRODUCTION

Chemoreceptors may be portrayed as falling into two categories, ''specialists'' and "generalists" (Schneider, 1969). Specialists represent receptors that respond to a specific stimulant molecule (and, perhaps, to a few closely related

0098-0331/87/0100-0001$05.00/0 © 1987 Plenum Publishing Corporation

analogs). Pheromones, for instance, may interact with such specialized receptors. Generalists, on the other hand, represent receptors that respond to a range of molecules, which share some common feature. Animals might use such generalist receptors, for example, in detecting volatile food cues and to identify and distinguish potential hosts or prey.

Although the distinction between specialist and generalist may, in practice, be less clear-cut than it is in principle, it raises the issue of how one might ascertain experimentally whether two different molecules interact with a given receptor site. In studies of pheromone detection, it is sometimes assumed that if a molecule triggers a receptor, then the response will be the same regardless of the identity of the stimulus. By the same token, if two different molecules elicit the same response, it is often concluded that they must have interacted with the same receptor (Chapman et al., 1978). Such assumptions may not be warranted in the case of generalist receptors. We would like to draw parallels between generalist receptors and the behavioral phenomenon of generalization, which can be combined with chemical manipulation of the receptor in an effort to assess whether two different molecules bind at the same site.

In human subjects, the phenomena of adaptation and cross-adaptation have been explored in an effort to answer this type of question (Köster, 1971). However, the facts that: (1) adaptation appears to involve both central and peripheral mechanisms, and (2) the ability to recognize or distinguish odors does not seem to be necessary for the central component to function, (Eichenbaum et al., 1983) complicates the interpretation of experimental data on human beings. Behavioral experiments with animals cannot ordinarily ask the detailed sorts of psychophysical questions that can be studied with humans. But a major advantage of studying animals is that the subjects' sensory systems or CNS can be modified in the course of experimentation. This paper will discuss the application of chemical modification of the olfactory epithelium to the study of generalization.

Choice of species for experimentation was based on the following considerations. First, the test animals had to be air-breathing vertebrates for which behavioral assays had been developed. Second, the olfactory epithelium in the species of choice had to be accessible to chemical manipulation. Adult tiger salamanders (*Ambystoma tigrinum*) were chosen because they are air-breathing vertebrates that can be classically conditioned to discriminate and generalize among reagent-grade odorants (Mason et al., 1980, 1981; Mason and Stevens, 1981a,b). Also, their simple nasal cavities permit direct chemical treatment of the olfactory epithelium (Mason and Morton, 1982, 1984; Mason et al., 1984, 1985).

METHODS AND MATERIALS

Subjects. Adult tiger salamanders were purchased from Charles D. Sullivan Company, Inc., Nashville, Tennessee. All of these animals had been land-

phase (air-breathing) for two or more years and were collected from two ponds about 2.5 km apart in Wilson and Sumner Counties, Tennessee (Sullivan, personal communication).

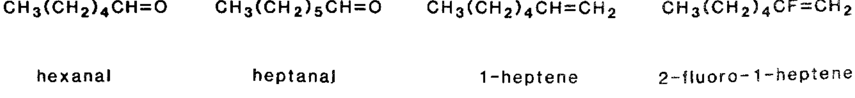
While these animals are probably all from the same breeding population, we believe that their data are representative of the species. There are several grounds for this inference. First, animals collected in other geographic locations (e.g., New Mexico, Arizona) are readily conditioned to respond to simple odorants and show discrimination and generalization among odorants similar to that reported here (e.g., Mason and Stevens, 1981a; Mason et al., 1984). Second, larval tiger salamanders that metamorphosed in our laboratory show similar response patterns to those purchased from Sullivan, Inc. (Arzt et al., 1986).

While in the laboratory, the salamanders were housed in plastic boxes in a refrigerator at 5–8 °C. Refrigeration permitted the animals to be kept without weight loss and essentially disease-free for several months. Mealworms were hand-fed to animals every 14 days.

The boxes in which the salamanders were housed were lined with paper towels moistened with dechlorinated water. Liners were changed every third day. All animals were used within two months of arrival in the laboratory. Thirty minutes before each experimental session, the salamanders were removed from the refrigerator and placed in plastic tubs. Each tub contained about 100 ml of dechlorinated water. Testing occurred in a room with an ambient temperature of 23° ± 1 °C.

Chemicals. Molecular structures of odorants used in these studies are drawn in Figure 1. Cyclohexanone, cyclopentanone, 1-butanol, ethyl acetoacetate, 1-heptene, hexanal, heptanal, 2-heptanone, and pristane (2,6,10,14-tetramethylpentadecane) were purchased commercially. Cyclohexanone and ethyl acetoacetate were redistilled at atmospheric pressure. The other odorants were used without additional purification.

Among the odorants used for generalization studies, a fluoroalkene was included as an example of an odorant molecule with molecular dimensions similar to an aldehyde, which also possesses a large permanent dipole moment, but without an aldehyde's ability to bind covalently as a Schiff base. 2-Fluoro-1-heptene was prepared from 2-bromo-1-heptene, which in turn, was prepared by reaction of 2,3-dibromopropene with *n*-butylmagnesium chloride (Lespieau and Bourguel, 1941). *N*-Bromoacetamide (1.66 g, 0.012 mol) was suspended in a mixture of 15 ml dry tetrahydrofuran and 15 ml dichloromethane and cooled in a Dry Ice–acetone slush. Excess liquid hydrogen fluoride (approximately 5 ml) was added, followed by addition of 2-bromo-1-heptene (1.77 g, 0.010 mol) in a mixture of 25 ml dry tetrahydrofuran and 15 ml dichloromethane. The reaction mixture was kept cold for 3 hr and allowed to warm slowly to room temperature. Stirring was continued for 16 hr at room temperature, and the reaction mixture was then worked up by adding 50 ml of ether and washing with water, saturated sodium bicarbonate solution, and brine. Removal of solvent afforded



$CH_3(CH_2)_4COCH_3$ $CH_3COCH_2COOCH_2CH_3$ O O

2-heptanone ethyl acetoacetate cyclohexanone cyclopentanone

FIG. 1. Structures of odorant molecules used in the present study.

2.62 g of 1,2-dibromo-2-fluoroheptane (9.5 mmol, 95% yield), for which [^{19}F]NMR showed a multiplet 99 ppm upfield from $CFCl_3$; [^{1}H]NMR ($CDCl_3$): δ 4.3 (d, J_{HF} = 10 Hz, 2H), 4.0 (m, 2H), 16–1.6 (m, 6H), 0.85 (t, 6 Hz, 3H).

The dibromo compound was then dehalogenated (Daub et al., 1985). A 5.0-g portion of zinc–copper couple (prepared according to Lambert et al., 1971) was added to a stirred solution of 9.0 g (33 mmol) 1,2-dibromo-2-fluoroheptane in 50 ml ether at 0°C, and the reaction mixture was allowed to warm to room temperature and stirred for 12 hr. The mixture was then filtered, the ether carefully distilled, and the residue vacuum-distilled at room temperature through a succession of three vacuum traps cooled to −23°C, −63°C, and −195°C. The first efficiently trapped 2-bromo-1-heptene and the last ether. The −63°C trap contained 1.1 g (10 mmol, 29% yield) of 2-fluoro-1-heptene: IR (neat film) 3140, 2900, 1675 cm^{-1}; [^{19}F]NMR (acetone-d$_6$): δ −94.0 (m); [^{1}H]NMR δ 4.53 (m, J^{cis}_{H-F} 17.6 Hz, J^{trans}_{H-F} 50.3 Hz, J_{H-H} 2.4 Hz, 3H), 2.8 (J_{H-F} 16.1 Hz, 2H), 1.7–1.1 (m, 6H), 0.89 (t, J = 7 Hz, 3H); [^{13}C]NMR δ 167.0 (J_{CF} = 256.3 Hz), 89.1 (J_{CF} = 19.5 Hz), 31.8 (J_{CF} = 26.8 Hz), 31.1, 25.7, 22.4, 13.9; mass spectrum (70 eV) m/z (rel intensity), 116 (11), 96 (10), 88 (10), 81 (14), 73 (24), 61 (26), 60 (22), 59 (18), 58 (19), 56 (100), 55 (22), 41 (90); $M^{\cdot+}$ 116.1003 (calc'd 116.1001). Presence of a small impurity attributed to trace 1,2-heptadiene was inferred on the basis of a variable band in the infrared spectrum at 1970 cm^{-1}.

Apparatus. The apparatus was similar to that described by Mason and Morton (1982). A flow dilution olfactometer generated volatile stimuli from neat samples of hexanal, cyclohexanone, cyclopentanone, 1-butanol, and ethyl acetoacetate, or from pristane solutions of other odorants. Stimuli were delivered in an airflow of approximately 100 ml per minute via an elliptical glass funnel that passed through the front wall of a stainless-steel conditioning chamber, as shown in Figure 2. Unless otherwise specified, odor stimuli from neat samples were presented at approximately 2.0–2.5% of vapor saturation. Salamanders

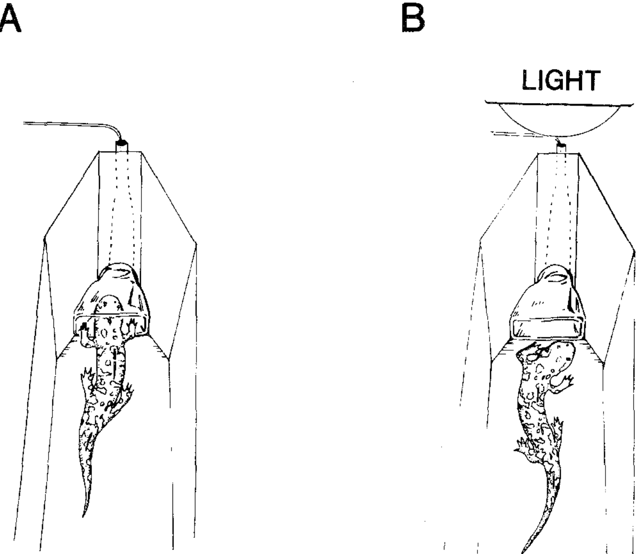


FIG. 2. Conditioning chamber for classical avoidance training of a tiger salamander. (A) Experimental animal positioned in odorant airflow. If the subject remains in this position, with its head in the glass sniffing port during presentation of odorant, a lack of avoidance is scored. (B) Experimental animal removing its head from sniffing port. If the subject removes its head during odorant presentation, an avoidance is scored. A light above the sniffing port is used as negative reinforcer. If the subject removes its head during reinforcement, an escape response is scored.

were placed in the conditioning chamber so that their heads rested in the sniffing port, and odorants were delivered to the port via separate pieces of Teflon spaghetti tubing (Mason and Stevens, 1981a). Concentrations of odorant stimuli in pristane were calculated using Raoult's Law. Specifically, for the 2% (w/v) solutions in pristane, the percent vapor saturation of the odorant at equilibrium with the solution (relative to neat odorant) was estimated to be 6%, equal to the mole fraction of the odorant in the solution, 0.06.

Procedure. Training involved placing the animals in the conditioning chamber with their heads resting in the sniffing port (Figure 2). Approximately 15 sec later, a 15-sec pulse of odorant–air mixture was delivered. Immediately after presentations of S+ odorant, a 300-W projector lamp was turned on to produce an aversive light reinforcer (Kuntz, 1923). The lamp was fitted with a condensing lens and was directed into the front of the conditioning chamber from 12 cm above. Although a small amount of radiant heat reaching the animal might have contributed to the aversive character of the stimulus, the light presentations did not appreciably change the temperature near the sniffing port, even though they continued for 60-sec or until the animal backed away from

the sniffing port. If backing away occurred during presentations of the S+ odorant, an avoidance response was scored. However, if backing away occurred after light onset, an escape response was scored. Unreinforced presentations (S–) of *n*-butanol or filtered air were randomly interspersed with presentations of the S+ odorant. Such presentations provided a day-to-day measure of differences in the animal's level of responsivity and an assessment of whether conditioning to the S+ odorant had occurred. Training continued until animals showed ≥80% avoidance to presentations of S+, and ≤20% avoidance to presentations of S–.

Experiment 1. Twelve salamanders were randomly assigned to two groups ($N = 6$ per group). The first group was trained to respond to hexanal (as S+), presented at 2.5% of vapor saturation. The S– was filtered air. After criterion responding was achieved (eight days), concentration–response tests were conducted over five consecutive days. For these tests, animals were presented with varied S+ odorant concentrations using a temporal forced-choice method of limits (Mason and Stevens, 1981b). Unreinforced presentations of air passed over pristane (as S–) were randomly interspersed with the S+ presentations. On each day of testing, animals were initially presented with hexanal at 2.5% of vapor saturation. Over subsequent trials, the hexanal concentration was reduced until animals failed to exhibit avoidance on two successive trials. At that point, odorant concentrations were increased until avoidance responding was again exhibited.

Following the response–concentration tests using vapors from neat hexanal, additional training trials (two days) were given using a 2.0% (w/v) hexanal solution for which the diluent was pristane, an odorless alkane of low volatility. When criterion responding was achieved, additional response–concentration trials were administered (three days) using the same procedures as those described above. After this second series of tests, three days of generalization trials were given among hexanal, 1-heptene, 2-fluoro-1-heptene, and pristane. The odorants were dissolved in pristane at a concentration of 2.0% (w/v), and volatiles above these solutions were presented (five presentations of each, in a randomized order, per session) to animals without further air dilution. All hexanal presentations during generalization were reinforced. Generalization among these odorants was followed by three days of generalization among hexanal, heptanal, 2-heptanone, and pristane. In all of these generalization tests (1) odorants were dissolved in pristane at a concentration of 2% (w/v), and (2) volatiles from these solutions were presented to animals without further air dilution.

The second group ($N = 5$) was trained to respond to 2% (w/v) hexanal in pristane, interspersed with unreinforced presentation of clean air blown over pristane. Once all subjects had reached criterion (after five days), generalization trials were run with heptanal and 2-heptanone, as described above. After three days, the animals were anesthetized, and lavage was administered to both ol-

factory sacs of each subject. Animals were anesthetized by immersion in a 0.5% aqueous solution of Tricaine. Anesthetized animals were randomly assigned to two subgroups. One subgroup ($N = 2$) was given nasal lavage with 50 mM aqueous sodium cyanoborohydride, while the other ($N = 3$) received lavage with 0.5 mM ethyl acetoacetate, followed by 50 mM sodium cyanoborohydride (Mason et al., 1985). Lavage with either ethyl acetoacetate or sodium cyanoborohydride involved injection of fluids into the olfactory sacs via the external nares. Excess fluid was absorbed at the internal nares with paper wicks. Each naris was rinsed with 100 μl of saline immediately following experimental treatments, and 2 min later, each animal was rinsed in dechlorinated water and placed in a tub containing 100 ml of dechlorinated water to recover from anesthesia. After recovery, the animals were returned to the refrigerator. On each of the six days following lavage, the animals were given generalization trials identical to those described above.

Experiment 2. Twelve salamanders was randomly assigned to three groups ($N = 4$ per group). Each group was trained to respond to one odorant (as S+) at 2% of vapor saturation. Group 1 was trained with cyclohexanone, while groups 2 and 3 were given training with cyclopentanone and ethyl acetoacetate, respectively. Group 3 did not exhibit acquisition of conditioned avoidance, as though insensitive to ethyl acetoacetate. When this odorant was replaced by a cycloalkanone, avoidance acquisition was observed (see below). For all three groups, unreinforced presentations of *n*-butanol (as S−) were randomly interspersed with presentations of S+ odorants.

After training to criterion, groups 1 and 2 were given generalization trials between cyclohexanone and cyclopentanone for six days. On each of these days, animals were given 20 unreinforced test trials (10 per odorant), preceded by five reinforced S+ trials interspersed with five S− presentations. These daily pretest trials served to prevent extinction and to provide a measure of each animal's level of activity.

Following generalization tests, the animals that had been presented with ethyl acetoacetate during the original training trials were randomly assigned to either the cyclohexanone (CH) or cyclopentanone (CP) group. These two groups of animals ($N = 6$ per group) were given five additional days of training, and then each group was divided into two subgroups ($N = 3$ per subgroup); CH-E, CH-C, and CP-E and CP-C, respectively. CH-C and CP-C animals were anesthetized and given a control lavage of 50 mM $NaBH_3CN$ (100 μl into each naris). CH-E and CP-E animals were anesthetized and given nasal lavages of 0.5 mM ethyl acetoacetate followed by 50 mM $NaBH_3CN$ (100 μl of each per naris). After lavage, all animals were rinsed in dechlorinated water and placed in their home cages to recover. On each of the six days following lavage, the animals were given generalization trials identical to those described above.

Analysis. For experiment 1, a series of two-way repeated measures analyses of variance (ANOVAs) were used to assess training periods, response-

concentration curves, and generalization tests. Tukey b post-hoc tests were used to isolate significant differences among means (Winer, 1962). For experiment 2, data from both acquisition and generalization periods were assessed using three-way analyses of variance with repeated measures on two factors (days and odorants). The independent factor in each analysis was groups.

RESULTS

Experiment 1

Group 1. In the first set of experiments, subjects were trained to respond to hexanal. During initial training, there were significant differences among days (F (7,35) = 4.5, $P < 0.001$), and between hexanal and filtered air (F (1,5) = 308.5, $P < 0.0001$). The interaction between days and stimuli was also significant (F (7,35) = 4.2, $P < 0.002$), and the analysis was interpreted in terms of that effect. Tukey tests showed that avoidance responding to presentations of hexanal increased over days (Ps < 0.01), while responding to filtered air remained consistently low ($P > 0.25$).

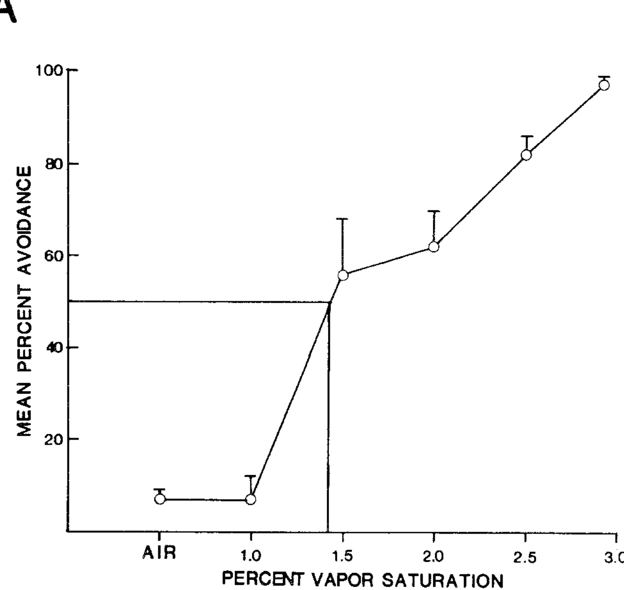
Analysis of the initial response-concentration test period (neat hexanal) revealed significant differences in responding over days (F (4,20) = 8.5, $P <$ 0.001) and among hexanal concentrations (F (4,20) = 56.7, $P < 0.0001$; Figure 3). The interaction of these terms was also significant (F (16,80) = 14.3, $P < 0.0001$), and the analysis was interpreted in terms of that effect. Post-hoc tests revealed that, over days, lower concentrations of hexanal elicited avoidance responses (Ps < 0.01). Once responding stabilized, however, a concentration between 1 and 1.5% of vapor saturation was found to elicit avoidance responses 50% of the time. This concentration was operationally defined as threshold (Mason and Stevens, 1981b).

During the second training period (hexanal in pristane), the only significant difference was in responding to hexanal versus pristane (F (1,5) = 783.6, $P <$ 0.0001). There were no significant differences between days ($P > 0.25$), and no interaction ($P > 0.25$). Animals exhibited nearly perfect transfer of training, and exhibited 9.3 ± 1.0 responses (out of 10) to hexanal but only 0.70 ± 1.0 (out of 10) responses to pristane on the first day of training.

During the second concentration–response period, the only significant difference was among odorant concentrations (F (5,25) = 55.9, $P < 0.0001$). Post-hoc tests revealed a pattern of results similar to those obtained with air dilutions of pure pristane, but a concentration estimated between 2 and 3% of vapor saturation was found to elicit avoidance responses 50% of the time. These higher threshold values were taken to indicate that the effective vapor concentration above the solutions was less than the equilibrium vapor pressure calculated for an ideal solution.

Results for unreinforced trials are summarized in Table 1. Analysis of generalization among hexanal, 2-fluoro-1-heptene, 1-heptene, and pristane re-

A



B

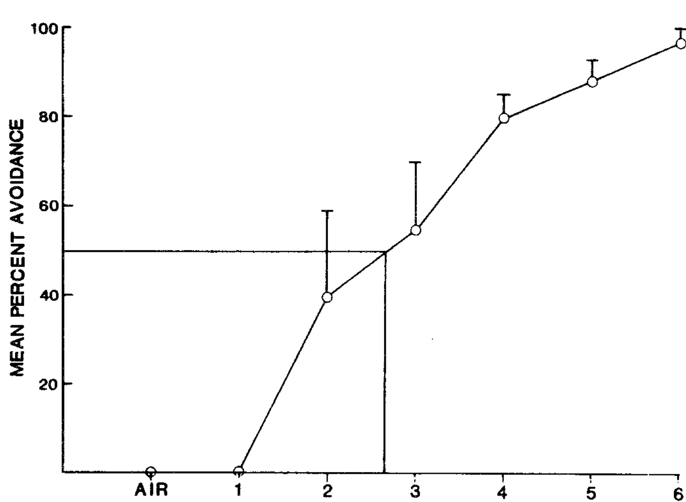


FIG. 3. Concentration–response data for hexanal. (A) Mean percent avoidance for tiger salamanders (N = 6) presented with various air dilutions of vapors from neat hexanal. Threshold for 50% avoidance as represented by the intersection of the horizontal and vertical lines, lies between 1.0 and 1.5% of vapor saturation. Capped vertical bars represent standard errors of the means. (B) Mean percent avoidance for tiger salamanders (N = 6) presented with various air dilutions of a 2.0% (w/v) solution of hexanal in pristane. From Raoult's law, the equilibrium vapor pressure over this solution is estimated to be 6% of vapor saturation. Threshold for 50% avoidance, as represented by the intersection of vertical and horizontal lines, corresponds to a value between 2% and 3% of vapor saturation. Capped vertical bars represent standard errors of the means.

TABLE 1. MEAN RESPONSES (OUT OF 5 PRESENTATIONS PER SESSION) FOR TWO GENERALIZATION EXPERIMENTS ($N = 6$ FOR EACH) BETWEEN HEXANAL AND OTHER ODORANTS[a]

	Session			Session		
Odorant	1	2	Odorant	3	4	5
Hexanal	5.00	5.00	Hexanal	5.00	5.00	5.00
2-Fluoro-1-heptene	0.00	0.33	Heptanal	**3.50**	**3.33**	3.17
1-Heptene	1.00	0.33	2-Heptanone	0.67	0.67	0.83
Air (passed over pristane)	0.00	0.00	Air (passed over pristane)	0.00	0.00	0.00

[a] Significant generalization observed only for heptanal. Entries in boldface meet significance criterion $P < 0.001$ for comparison between responding to 2-heptanone and heptanal. Responding to 2-fluoro-1-heptene, 2-heptanone, or 1-heptene failed to meet the significance criterion $P < 0.05$ when compared to air (except for 1-heptene in session 1, which failed to meet significance criterion $P < 0.02$).

vealed a significant difference among odorants ($F(3,15) = 630.0$, $P < 0.0001$). There were no differences among days ($P > 0.25$), and no interaction between days and odorants ($P > 0.25$). Post-hoc tests revealed that while animals continued to show avoidance of hexanal presentations, they failed to generalize such avoidance to the other odorants ($P < 0.01$).

Analysis of generalization among hexanal, 2-heptanone, and heptanal revealed a significant difference among odorants ($F(3,15) = 59.5$, $P < 0.0001$) but, again, no difference among days ($P > 0.25$), and no interaction between days and odorants ($P > 0.25$). Post-hoc tests revealed that animals exhibited the highest rate of avoidance to presentations of hexanal, an intermediate rate to heptanal, and almost no avoidance of 2-heptanone or pristane (Ps < 0.01). Also, animals failed to exhibit significant generalization of avoidance between hexanal and three other compounds with similar molecular shape and dimensions: 1-heptene, 2-fluoro-1-heptene, and 2-heptanone. As Table 1 summarizes, responding to heptanal is significantly less than responding to hexanal. We infer that these two odorants were perceived as similar, but not identical.

Group 2. Analysis of acquisition revealed that there were differences among days ($F(3,12) = 14.2$, $P < 0.0001$) and between responses to hexanal and pristane ($F(1,4) = 321.8$, $P < 0.0001$). The two-day interaction between days and odorants was also significant ($F(3,12) = 51.6$, $P < 0.0001$), and Tukey tests indicated that avoidance responses to hexanal presentations increased over days (Ps < 0.01) while avoidance responses to pristane remained consistently low.

Analysis of generalization (combined pre- and postlavage) revealed significant differences between subgroups ($F(1,4) = 17.9$, $P < 0.01$), among

odorants (F (6,24) = 5.1, $P < 0.002$), and among days (F (2,8) = 101.7, $P < 0.0001$). Also, there were significant two-way interactions between subgroups and days (F (6,24) = 6.4, $P < 0.001$), subgroups and odorants (F (2,8) = 5.4, $P < 0.05$), and days and odorants (F (12,48) = 2.4, $P < 0.02$). Because the three-way interaction among subgroups, days, and odorants was significant (F (12,48) = 2.95, $P < 0.05$), the analysis was interpreted in terms of that effect. Tukey tests revealed that, prior to lavage, animals exhibited high rates of avoidance responding toward hexanal and heptanal, but low rates toward 2-heptanone (Figure 4; Ps < 0.05). During tests on the first three days after lavage, animals given lavages with ethyl acetoacetate followed by $NaBH_3CN$ exhibited low responding toward all odorants (relative to animals lavaged with $NaBH_3CN$ alone; Ps < 0.05). Animals given lavage with $NaBH_3CN$ alone exhibited no change in responding and continued to avoid presentations of hexanal and heptanal but not presentations of 2-heptanone (P

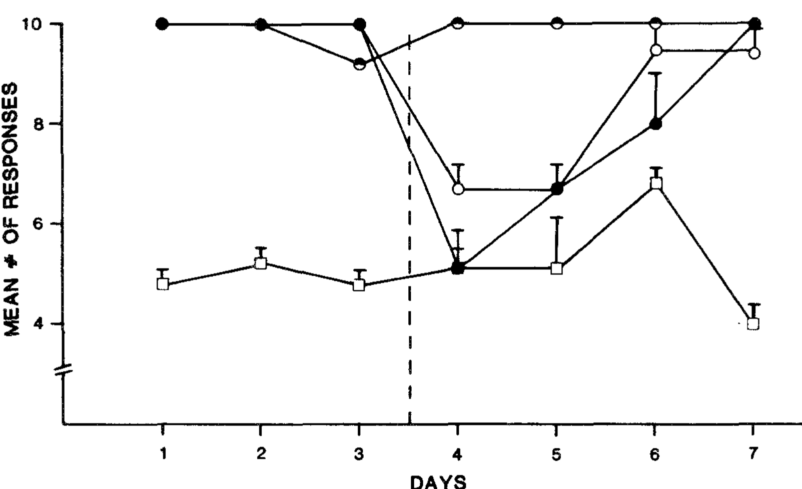

FIG. 4. Effects of chemical modification on generalization among aldehydes for subjects (N = 5) trained on hexanal as S+. In postlavage sessions, half-shaded circles without error bars represent controls (N = 2) that received lavage with 50 mM $NaBH_3CN$ alone. Circles with error bars represent experimental subjects (N = 3) that received two-step lavage (ethyl acetoacetate followed by $NaBH_3CN$). Squares represent mean response to 2-heptanone for all five animals. Dashed line represents point at which lavage was administered.

< 0.05). Responding by animals given combined lavages of ethyl acetoacetate and $NaBH_3CN$ gradually increased over days $P < 0.05$), and by the fourth postlavage test, there were no differences between subgroups ($P > 0.25$).

Experiment 2

Analysis of the initial training period using cyclopentanone and cyclohexanone as stimuli showed that there were no differences between groups ($Ps > 0.25$), although there were significant differences among days ($F(5,30) = 18.3$, $P < 0.0001$), and between responding to S+ and S− ($F(1,6) = 1193.5$, $P < 0.0001$). The interaction between days and odorants was significant ($F(5,30) = 39.4$, $P < 0.0001$), and Tukey tests showed that while avoidance responding to S+ presentations increased over days ($P < 0.01$), responding to S− presentations remained consistently low (Figure 5). Analysis of the initial generalization period (Figure 5) showed that there were no differences between groups ($P > 0.25$), or among days ($Ps > 0.25$). The only significant effect was a two-way interaction between groups and odorants ($F(1,6) = 15.8$, $P < 0.007$). Tukey tests indicated that animals exhibited relatively higher overall levels of responding to their respective training odorant ($Ps < 0.01$). However, both groups showed high levels of responding to both cyclohexanone and cyclopentanone.

During the second training period, there were significant differences between groups ($F(3,8) = 9.3$, $P < 0.006$), between stimuli ($F(1,8) = 1048.9$, $P < 0.0001$), and across days ($F(4,32) = 3.2$, $P < 0.027$). Also, there was a significant interaction between odorant stimuli and days ($F(4,32) = 30.2$, $P < 0.0001$). Tukey tests showed that animals trained with cyclohexanone exhibited higher overall levels of responding than animals trained with cyclopentanone ($P < 0.05$). However, both groups exhibited high response levels to S+ presentations that increased across days while responding to S− presentations remained consistently low ($P < 0.01$).

Analysis of the second series of generalization tests revealed significant differences among subgroups ($F(3,8) = 39.9$, $P < 0.0001$), among odorants ($F(2,16) = 513.5$, $P < 0.0001$), and across days ($F(6,48) = 22.9$, $P < 0.0001$). Also, there were significant two-way interactions between subgroups and odorants ($F(6,16) = 20.6$, $P < 0.0001$), between subgroups and days ($F(18,48) = 5.6$, $P < 0.0001$), and between odorants and days ($F(12,96) = 16.8$, $P < 0.0001$). Because the three-way interaction between subgroups, odorants, and days was significant ($F(36,96) = 4.3$, $P < 0.0001$), the analysis was interpreted in terms of this highest order effect. Post-hoc tests indicated that CH-E and CP-E animals exhibited avoidance decrements ($Ps < 0.01$), while CH-C and CP-C animals did not ($Ps > 0.25$; Figure 6). CH-E and CP-E performance decrements were not permanent, however, and avoidance of cyclohexanone and cyclopentanone increased over days ($Ps < 0.01$). Perfor-

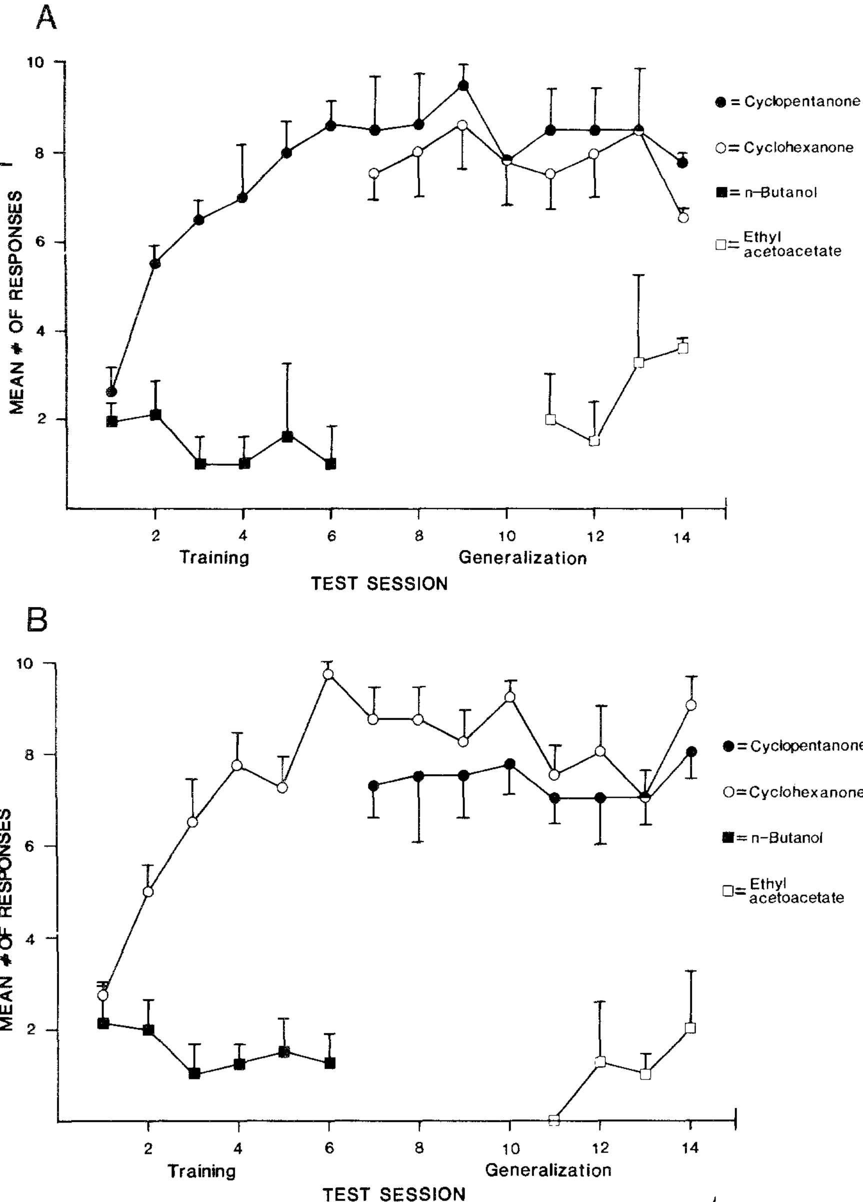

FIG. 5. Generalization between two cycloalkanones over a period of eight days. (A) Results for tiger salamanders ($N = 4$) trained on cyclopentanone (as S+) concurrently with unreinforced presentations of *n*-butanol. Responding to unreinforced presentations of cyclohexanone is significantly lower ($P < 0.01$ by ANOVA of repeated measures) than to unreinforced presentations of cyclopentanone, but generalization between the two odorants is apparent. No generalization to ethyl acetoacetate is observed. (B) Results for tiger salamanders ($N = 4$) trained on cyclohexanone (as S+) concurrently with unreinforced presentations of *n*-butanol. Responding to unreinforced presentations of cyclopentanone is significantly lower ($P < 0.01$ by ANOVA of repeated measures) than to unreinforced presentations of cyclohexanone, but generalization between the two odorants is apparent. No generalization to ethyl acetoacetate is observed.

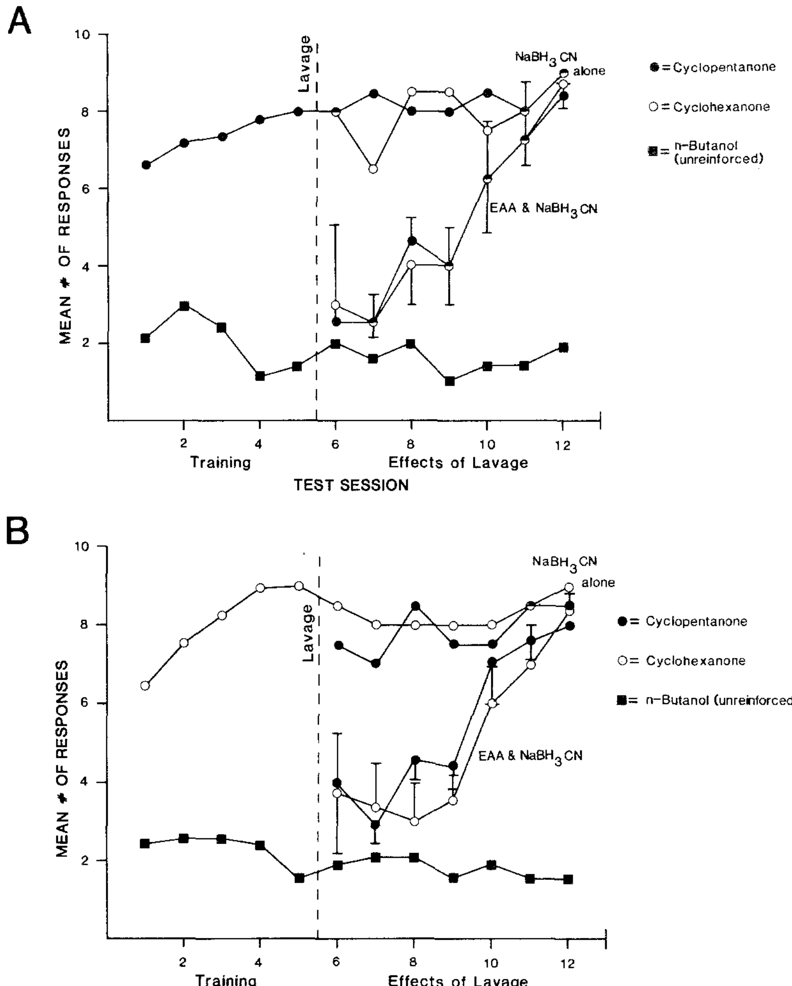

FIG. 6. Effects of chemical modification on olfactory detection and generalization for cycloalkanones. (A) Results for tiger salamanders ($N = 5$) trained on cyclopentanone (as S+) concurrently with unreinforced presentations of *n*-butanol. Lavage with 0.5 mM ethyl acetoacetate followed by 50 mM sodium cyanoborohydride was administered to three animals (represented by points with error bars), and responding to cyclopentanone and cyclohexanone in unreinforced postlavage trials dropped off significantly for four postlavage sessions. Lavage with 50 mM sodium cyanoborohydride alone was administered to two animals (represented by points without error bars). Responding to cyclopentanone and generalization to cyclohexanone were unaffected during postlavage sessions. Responding to *n*-butanol presentations were monitored throughout. (B) Results for tiger salamanders ($N = 5$) trained on cyclohexanone (as S+) with unreinforced presentations of *n*-butanol. Experimental conditions as in A, but with the roles of cyclohexanone and cyclopentanone transposed.

mance improvements were not different between CH-E and CP-E animals ($P > 0.10$).

DISCUSSION

Tiger salamanders generalize from one aldehyde, hexanal, to its next highest homolog, heptanal. However, because presentations of the latter elicit significantly fewer avoidances than presentations of the former, we infer that these odorants are discriminable. Likewise, we infer that hexanal is discriminable from 1-heptene, 2-fluoro-1-heptene, and 2-heptanone, insofar as little or no avoidance generalization to these odorants was observed. Tiger salamanders generalize between cyclopentanone and cyclohexanone, but we infer that these two odorants are discriminable, because groups show significantly greater responding to their respective training odorant during generalization tests.

Two-step modification impairs detection of both aldehydes and of cycloalkanones. Figure 6 shows that, after lavage of the olfactory epithelium, there is no significant difference between responding to S+ and responding to the new odor. Significant impairment of detection occurs only if blocker and fixer are both applied. As shown for the controls in Figure 6, lavage with fixer by itself does not reduce the level of avoidance significantly. We have previously shown that lavage with ethyl acetoacetate alone at a concentration ≤ 1.0 mM has no effect on responding (Mason and Morton, 1982, 1984; Mason et al., 1984, 1985). An important feature of Figure 6 is that discrimination of cycloalkanones from *n*-butanol is not completely abolished by two-step modification. Although dramatically reduced, significant levels of avoidance to both cycloalkanones persist after lavage with the blocker fixer sequence. Generalization persists, as well.

The results of two-step modification are consistent with the hypothesis that the two aldehydes and the two cycloalkanones interact with the same class of receptor. The two steps consist of a reversible covalent attachment of a site-specific ligand (blocker) followed by conversion to an irreversible linkage (via a fixer). In these experiments the blocker was ethyl acetoacetate and the fixer was sodium cyanoborohydride, which have previously been shown to label Schiff base-forming proteins specifically in vitro (Mason et al., 1985). This same procedure, when applied to the olfactory epithelium, produces a selective hyposmia to ketones (Mason et al., 1984, 1985) and aldehydes. The control animals, treated with fixer by itself, exhibit no evidence of impaired olfactory function.

Several investigators have proposed that covalent modification of specific amino acid residues can impair chemoreceptor function (Cagan, 1981; D'Ischia, et al., 1982; Mason et al., 1984, 1985). Antifeedant activity of 9β-polygodial and its 9α-hydroxy analog, warburganal, has been attributed to a specific reaction with primary amino groups, such as lysine residues (D'Ischia et al.,

1982). Two-step modification with acetoacetic ester as blocker followed by cyanoborohydride as fixer has been shown to selectively label the active site of a Schiff base-forming enzyme in vitro and to selectively impair detection of ketone-containing odorants in vivo (Mason et al., 1984, 1985). The suggested mechanism invokes irreversible covalent attachment to especially reactive lysine residues. One advantage of using a blocker–fixer sequence is that control experiments can be performed, in which one of the steps is omitted. As Figures 4 and 6 summarize, omission of blocker prevents impairment.

When an animal is trained to avoid one carbonyl compound, it may generalize to another. Lavage with acetoacetic ester followed by cyanoborohydride impairs responding to both odorants. This suggests that the two different molecules interact with the same class of receptor. Both aldehydes and ketones interact with this class of receptors, but generalization does not occur among all simple carbonyls. For instance, animals trained on hexanal do not generalize to 2-heptanone, even though they do generalize to heptanal.

The effect of covalent modification may be agonistic rather than antagonistic. Chemical steps by which Schiff base-forming sites are blocked by two-step modification have been described (Mason et al., 1985), and it seems unlikely that a very large fraction of olfactory receptor sites can be labeled in this fashion. Since, as previously reported, increasing the dose of labeling reagent increases the duration of selective hyposmia, and not its profundity, we are led to propose the following hypothesis. When an olfactory receptor site is covalently modified, it generates a continuous output. If the covalent modification is irreversible, this output continues unabated and causes a high level of background signal, which effectively masks the response to any new odorant molecules that interact with that channel. As can be seen from Figure 6, covalent blockade did not completely obliterate responding to either cycloalkanone. This is taken to imply that the cycloalkanones also interact with receptors that are unaffected by covalent modification. As might be expected (since cyclohexanone and cyclopentanone are similar in molecular volume, dipole moment, etc.), responding to both odorants is about the same, even during the postlavage interval, where olfactory detection of ketones is greatly impaired. We infer that both cycloalkanones interact with Schiff base-forming receptor sites, but that this is not the sole basis for generalization.

Results presented here add to an increasing body of data that supports the existence of carbonyl-binding, generalist receptors in tiger salamanders. The effects of two-step modification suggest that these receptors attach odorant molecules covalently as Schiff bases. A role for other types of receptors in detection and discrimination of ketones and aldehydes is also deduced, since chemical modification impairs responding, but neither obliterates detection nor eradicates generalization. We infer that generalist olfactory receptors have the following characteristics. A given class of receptors will bind a number of odorants. At

the same time, any given molecule can interact with more than one class of receptors. For generalization to take place, two different compounds must have similar interactions with more than one receptor class. Since nature rarely presents pure compounds as stimuli, the ability to generalize, even in the presence of distractors, must be balanced against the ability to suppress false alarms and discriminate against mimics. This picture may offer an optimum strategy for dealing with natural fluctuations in the composition of olfactory cues.

Acknowledgments—The authors are grateful to Ms. Cheryl Boehm for assistance in performing double-blind behavioral studies and for preparing the figures. PHYTOTOXIC PROPERTIES OF CNICIN, A SESQUITERPENE LACTONE FROM *Centaurea maculosa* (SPOTTED KNAPWEED)

RICK G. KELSEY and LAURA J. LOCKEN

Department of Chemistry, University of Montana, Missoula, Montana 59812

(Received July 31, 1985; accepted January 6, 1986)

Abstract—Water and solvent extracts from the aerial tissues of *Centaurea maculosa*, spotted knapweed, inhibited the root growth of lettuce. Column chromatography and lettuce bioassay of a chloroform extract led to the isolation of cnicin, a sesquiterpene lactone. Pure cnicin was bioassayed at 0, 1, 2, 4, 6, 8, and 10 mg/5 ml water with lettuce, created wheatgrass, bluebunch wheatgrass, rough fescue, western larch, lodgepole pine, and spotted knapweed. Germination was inhibited at one or more concentrations for all species except lodgepole pine and spotted knapweed. Growth, particularly of the roots, was retarded between 1 and 4 mg of cnicin. Lettuce, bluebunch wheatgrass, and spotted knapweed were inhibited significantly at all concentrations tested.

Key Words—Allelopathy, spotted knapweed, *Centaurea maculosa*, sesquiterpene lactones, cnicin, phytotoxin, germination inhibitor, growth inhibitor.

INTRODUCTION

Spotted knapweed (*Centaurea maculosa* Lam.) was introduced to the Pacific Northwest from Eurasia around the turn of the century (Strang et al., 1979). First reported in Montana during the 1920s (French and Lacey, 1983; Chicoine, 1984) plants can now be found in every county of the state, and they infest an estimated 0.8 million hectares. The annual rate of spread has been calculated at 27.4% (Lacey, 1983), and man's activities have been an important component in this rapidly expanding distribution (Strang et al., 1979).

Spotted knapweed is a pioneer species that thrives on dry disturbed sites (Watson and Renney, 1974). Being a prolific seed producer (Schirman, 1981, 1984) and efficient competitor for nutrients (Belles et al., 1980) and water,

0098-0331/87/0100-0019$05.00/0 © 1987 Plenum Publishing Corporation

knapweed has proven to be an aggressive invader of dry pastures and native rangelands (Harris and Cranston, 1979). Part of its success has been attributed to the lack of natural herbivores and diseases that were left behind in the Old World. Productivity of desirable forage plants decreases significantly as the knapweed density increases (Harris and Cranston, 1979; Maddox, 1979). Annual forage losses in Montana from the present infestation have been estimated at $4.5 million. Recent studies indicate that Montana has 13.7 million hectares of range and grazable woodlands vulnerable to knapweed invasion (Bucher, 1984; Chicoine, 1984). Forage losses could reach $155.7 million annually if all of these sites were invaded.

In 1963 Fletcher and Renney demonstrated that Russian knapweed (*Centaurea repens* L.), diffuse knapweed (*C. diffusa* Lam.), and spotted knapweed tissues, particularly the leaves, contained phytotoxic compounds that inhibited the germination and growth of barley and lettuce. Extracts from Russian knapweed were the most potent inhibitors, and those from spotted knapweed the weakest. Soils naturally infested with Russian knapweed retarded the growth of tomato and barley; however, soils infested with diffuse and spotted knapweed were never tested for toxicity. Fletcher and Renney (1963) were unable to identify the active compounds. As part of a project to evaluate the allelopathic influence of spotted knapweed, in this paper we report the isolation of a phytotoxic sesquiterpene lactone, cnicin, and its effects on the germination and growth of several native plant species.

METHODS AND MATERIALS

Preparation of Knapweed Extracts. Knapweed plants were collected during the last week of April 1983 at a study site in the Rattlesnake Creek drainage, about three miles north of the University of Montana campus. Whole plants, possessing a previous year's stem, were removed from the soil with approximately 15 cm of root attached. After discarding dead stems and leaves, the green rosette leaves and roots were returned to the laboratory on ice. Ten grams of fresh roots and leaves, cut into small pieces before weighing, were each extracted by soaking in 90 ml of distilled water for 15 hr (moisture content was determined with duplicate samples oven dried at 100°C overnight, desiccated for 30 min, and weighed). These solutions were filtered through paper into a 100-ml graduated cylinder. The extracted residue was rinsed with distilled water and filtered, bringing the final volume to 100 ml. An equal volume of distilled water was filtered for the control. Five milliliters of each solution was added to 10 Petri dishes and bioassayed with lettuce. Five dishes from each treatment were randomly selected for measurement and statistical analysis.

Unused leaves and roots were air-dried. Leaves were crushed by hand and three 5.0 g samples weighed (moisture content was measured as described

above). One sample was Soxhlet extracted for 8 hr with diethyl ether, then filtered through paper giving about 40 ml of extract. A white residue on the sides of the distillation–collection flask would not redissolve in either but was soluble in chloroform, which was added to the ether giving a final volume of 100 ml. A second 5 g of leaves were washed in chloroform for 5 min, with slow stirring. After filtering, the final volume was adjusted to 100 ml by rinsing the leaf residue. A water extract was prepared from the third leaf sample following the same procedure used for fresh tissue. Five-milliliter aliquots of these solutions were bioassayed with lettuce (five Petri dishes per treatment). Distilled water, ether, and chloroform were used in separate controls.

Isolation and Identification of Cnicin. In mid-June, green leaves and stems were collected from the Rattlesnake study site. Fresh tissue (649 g), cut into 7- to 10-cm pieces, was washed for 5 min in chloroform (7000 ml for extraction and 1000 ml for rinse), filtered, and the solvent evaporated. A white crystalline material precipitated from the concentrated extract and was removed by filtration (2.39 g). The remaining chloroform was evaporated and the residue dissolved in 50 ml of hot ethanol. After transferring to a separatory funnel, an equal volume of water was added. This solution was washed with hexanes (4×50 ml) and then extracted with chloroform (2×100 ml). The initial chloroform extract, combined hexane washes, final chloroform extract, and hexane and chloroform controls were bioassayed with lettuce (two Petri dishes per treatment). Germination and root growth were most inhibited by the final chloroform extract, which was further fractionated by column chromatography on silica gel eluted with chloroform and increasing proportions of ethyl acetate. Ethanol was used to clear the column. Fractions containing similar chemical components by TLC were combined to give a total of seventeen. After adjusting to equal volumes, each fraction was bioassayed with lettuce (two Petri dishes per fraction). Five milliliters of chloroform were added and dried in the control dishes.

Crystals isolated from fraction 15 were purified by recrystallization. Thin-layer chromatography indicated it was the same compound that had crystallized from the original chloroform extract. It was identified as the sesquiterpene lactone, cnicin, by TLC, NMR, and direct IR comparison with a reference sample. Toxicity of recrystallized cnicin was tested by bioassaying with lettuce, crested wheatgrass, and five native species including knapweed. In each experiment, 40 seeds from one species (20 per Petri dish) were exposed to six different concentrations of cnicin; the entire experiment was then duplicated.

Bioassay Procedures. Petri dishes were lined with three sheets of Whatman No. 1 filter paper, followed by 5 ml of the test solution. Crystalline cnicin has limited water solubility, so solutions were prepared fresh in chloroform–ethanol (23 : 2) to deliver 0, 1, 2, 4, 6, 8, and 10 mg of cnicin per 5-ml aliquot. Dishes containing organic solvents were air-dried in a fumehood, and then remoistened with 5 ml of distilled water. If cnicin were completely soluble in

water, these concentrations would range from 5.29 to 52.9 $\times 10^{-4}$ M. Twenty Black Seeded Simpson lettuce seeds were sown in each dish and the dishes placed into a germinator (continuous fluorescent light, 24–26°C for 72 hr).

Seeds from two tree species, western larch (*Larix occidentalis* Nutt.), and lodgepole pine (*Pinus contorta* Dougl. ex Loud.), were stratified before use. They were soaked for 24 hr in tap water, drained, sealed in a Ziploc plastic bag, and placed in the refrigerator at 0°C for a minimum of two weeks (34 days was the longest cold treatment). Seeds of rough fescue (*Festuca scabrella* Torr.), a native grass, were soaked for 24 hr in tap water and then sown into Petri dishes containing the cnicin-treated filter paper with 5 ml water. Dishes were placed directly into the refrigerator for stratification (a minimum of two weeks). Other species bioassayed without stratification included crested wheatgrass [*Agropyron cristatum* (L.) Gaertn.], bluebunch wheatgrass [*Agropyron spicatum* (Pursh) Scribn. & Smith], and spotted knapweed. All seeds, except lettuce, were surface sterilized with Clorox solution (3% solution of commercial Clorox) before sowing, and Captan fungicide (0.25 g/L) was added to the distilled water to retard fungal growth.

Bluebunch wheatgrass, western larch, and lodgepole pine were grown in continuous light with the same conditions as lettuce. Spotted knapweed was grown with 9 hr dark (20°C) and 15 hr fluroescent light (26°C). Crested wheatgrass and rough fescue were bioassayed in one experiment with continuous light and the other with alternating day/night cycles, with temperatures the same as knapweed. Except for lettuce, the length of time in the germinator varied (5–12 days) to meet the requirements of a particular species. During an experiment additional water was added to all dishes, as needed.

Measurements. After recording germination, seedlings were photographed with black and white film. Their negative image was projected onto a Ladd Graphical Digitizer. Initially root lengths were to be measured for all species, but in experiments where root growth was severely inhibited it was difficult to clearly distinguish root tissue, so seedling lengths (from cotyledon attachment to root tip, or seed coat to root tip) were measured instead. Root lengths were measured for grass species and some lettuce experiments. Since root growth was very sensitive to cnicin, ungerminated seeds were recorded as zero growth and used to determine average length.

Data Analysis. Percent germination was calculated in each Petri dish, then transformed (arcsine), and analyzed by one-way analysis of variance (ANOVA). In nearly all experiments the variances were positively correlated with the mean root length, or mean seedling length, and logarithmic or square root transformations did not remedy the problem. Consequently, seedings were ranked by Kruskal-Wallis, compensating for ties. Rank averages were calculated for each Petri dish and then analyzed by one-way ANOVA. When root or seedling length variances were homogeneous, one-way ANOVA was used. The

0.05 level of probability was applied in all cases, and significantly different means were detected by Duncan's multiple-range test.

RESULTS

A 10% water extract of fresh knapweed roots (3.93 g dry weight) had no effect on the germination and growth of lettuce (Table 1). A similar extract of fresh leaves (1.94 g dry weight) also had no effect on lettuce germination, but limited root growth to 68% of the control. In an attempt to approximate the earlier results of Fletcher and Renney (1963), 5 g of crushed air-dried leaves (4.57 g dry weight) were extracted with water, ether, or chloroform. All extracts inhibited germination, but not to any great extent (Table 2). Seedling growth was severely retarded, particularly the roots, in all treatments with levels of inhibition similar to that reported by Fletcher and Renney (1963).

To isolate the active compound(s), 649 g of fresh knapweed tissue was washed with excess chloroform. While concentrating the extract, a white crystalline precipitate was filtered from the solution. The concentrated extract was

redissolved in ethanol–water, washed with hexanes, and then extracted back into chloroform. Lettuce bioassays indicated the toxin(s) were concentrated in the final chloroform solution. Column chromatography provided 17 fractions for bioassay. Only a few fractions inhibited lettuce germination, whereas nearly all of them retarded seedling growth (Fig. 1). A crystalline compound was isolated from the fraction most inhibitory to growth, and subsequently identified as the sesquiterpene lactone, cnicin. This was the same compound that had precipitated from the initial chloroform extract.

The toxicity of impure and recrystallized cnicin was tested with lettuce and found to be very active. Germination was unaffected by 1 mg of cnicin, but gradually decreased as the concentration went up (Table 3). Seedling growth was more severely affected (Table 4). At 2 mg of cnicin, roots were approximately 1 mm or less in length and brown in color up to the hypocotyls, which were also very short compared to the controls, but otherwise still green and healthy looking. At higher concentrations, the hypocotyls also turned dark brown. It was difficult to accurately distinguish root tissue at higher concentrations, so seedling lengths were measured instead.

Germination of the three grass species was largely unaffected by 1 or 2 mg of cnicin (Table 3). At higher concentrations their responses varied. With 4 mg or greater, crested wheatgrass germination was about 50% of control or lower, whereas bluebunch wheatgrass seldom dropped much below 70%. Rough fescue demonstrated decreasing germination between 4 and 10 mg of cnicin, but with different intensities between duplicate experiments; at 8 and 10 mg, germination was below 50% of control in both experiments. Root growth was more sensitive to cnicin with some inhibition at nearly all levels tested (Table 4).

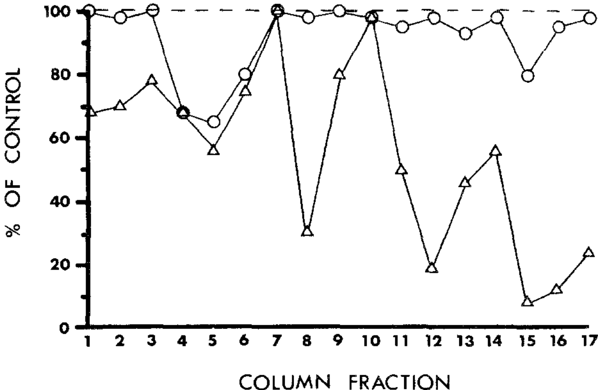

FIG. 1. Effect of column chromatography fractions, from a knapweed chloroform extract, on the germination (○) and growth (△, seedling length) of lettuce. Germination of fractions 4–6, 11, 13, and 15 are significantly different from the control. Seedling lengths in all fractions are significantly different from the control, except 7 and 10.

[a] Means followed by different letters are significantly different at $P < 0.05$.
[b] Cnicin used in this experiment was the crude crystalline precipitate obtained during the concentration of the chloroform extract. The 6- and 8-mg concentrations were not tested (NT).
[c] TS = total seedling length, r = root length.

Greatest variation was recorded with 1 mg, where growth was stimulated rather than inhibited in two experiments. Cnicin had signficant impact on all grass roots starting at the 4-mg level; however, none of them exhibited the dark brown discoloration or severe damage as did lettuce.

Of the two tree species tested, western larch appeared more sensitive to cnicin; germination began to decrease about 6 mg and was near 50% of the control at 8 and 10 mg (Table 3). Seedling size (Table 4) was much smaller than the control at all concentrations, with significant differences occurring at 4 mg cnicin or greater. At these higher levels, roots appeared heavily damaged. Lodgepole pine germination did not decrease much even at the highest cnicin concentrations (Table 3). Seedling size was inhibited at all levels, but significant differences were recorded in only one of the experiments (Table 4). Again the roots appeared heavily damaged at the high concentrations. In the mixed conifer forests of northwestern Montana, field observations suggest that western larch has difficulty regenerating from seed in the presence of dense knapweed stands (B. Wilson, personal communication). Lodgepole pine is apparently more competitive and is capable of seedling establishment within the knapweed.

One of the most interesting results of these experiments was the response of spotted knapweed when bioassayed with cnicin. Germination was unaffected (Table 3), whereas seedling growth was strongly retarded (Table 4). At 1 mg cnicin, seedlings were 60% of the control and significantly different, in both experiments. Size decreased with increasing concentrations, reaching only 10% of the control at 10 mg of cnicin. Under the conditions of these experiments knapweed is just as sensitive, if not more sensitive to cnicin, as the other species tested.

DISCUSSION

Politis (1946a,b) reported the isolation of bitter-tasting cnicin from the glandular trichomes of holy thistle (*Cnicus benedictus* L.) Its structure was difficult to solve and required several revisions (Suchy and Herout, 1962; Suchy et al., 1959, 1962, 1965). The currently accepted structure was assigned by Samek et al. in 1969. Cavallito and Bailey (1949) were probably the first to obtain crystalline cnicin from *Centaurea maculosa,* although they were unable to identify it. Data from their chemical analyses leaves little doubt that it was cnicin they had isolated. Cnicin has been extracted from numerous other *Centaurea* species in recent years (Suchy and Herout, 1962; Gonzalez et al., 1978; Rustaiyan et al., 1982; Seaman, 1982; Geppert et al., 1983; Muir and Majak, 1983).

Cavallito and Bailey (1949) were interested in cnicin because of its antimicrobial properties toward both gram-positive and gram-negative organisms. It inhibited the growth of some bacterial species at 25–50 μg/ml. It was bac-

tericidal to the sensitive species at higher concentrations. Similar experiments have been repeated and gave comparable results (Vanhaelen-Fastré, 1972; Vanhaelen-Fastré and Vanhaelen, 1976). In cytotoxicity tests, cnicin was found to be active toward KB and HeLa human carcinoma cells in vitro (Vanhalen-Fastré and Vanhaelen, 1976; Gonzalez et al., 1978). In vivo it was active against L-1210 leukemia (Vanhaelen-Fastré and Vanhaelen, 1976). This is not unusual since sesquiterpene lactones exhibit a variety of such activities (Rodriguez et al., 1976), including phytotoxicity.

The allelopathic potential of sesquiterpene lactones has been documented by numerous bioassay experiments (Dalvi et al., 1971; Garciduenas et al., 1972; McCahon et al., 1973; Kanchan, 1975; Amo and Anaya, 1978; Asakawa and Takemoto, 1979; Picman and Picman, 1984a; Spencer et al., 1984; Fischer and Quijano, 1985; Stevens and Merrill, 1985). The most thoroughly investigated example of an allelopathic sesquiterpene lactone is parthenin in the tropical weed *Parthenium hysterophorus* L. (Kanchan, 1975; Kanchan and Jayachandra, 1979a,b, 1980; Picman and Picman, 1984a). It was the most abundant inhibitor in the aerial tissues of this plant and was present in leaf washes and the rhizosphere soil.

Very little information is available on the precise mode of action of sesquiterpene lactones within plant tissues; however, there is substantial data from other organisms that provides insight for potential mechanisms. The presence of an α-methylene-γ-lactone (Dupuis et al., 1980; Hall et al., 1980a,b; Spring et al., 1982; Elissalde et al., 1983; Picman and Picman, 1984b; Abeysekera et al., 1985;), and/or an α,β-unsubstituted cyclopentenone (Lee et al., 1971, 1977b, 1981) is frequently associated with biological activity, but not always (Picman and Towers, 1983; Harmatha and Nawrot, 1984; Marchant et al., 1984; Picman, 1984). Within cells the lactones can inhibit DNA synthesis (Lee et al., 1977a; Woynarowski and Konopa, 1981; Woynarowski et al., 1981), RNA synthesis (Spring et al., 1982), protein synthesis (Liou et al., 1983), respiration (Van Aswegen et al., 1982), and can interfere with the normal functioning of various enzymes (Hall et al., 1980a,b), the net result being impaired growth and development. α-Methylene-γ-lactones, and α,β-unsubstituted cyclopentenones are reactive sites because they bind easily with free —SH groups in amino acids and proteins, resulting in nonreversible alkylation (Rodriguez et al., 1976; Lee et al., 1977a; Dupuis et al., 1980; Spring and Hager, 1982) that can destroy enzymatic activity. There is no doubt that these same sort of reactions take place in plant cells.

Since the initial isolation of phytotoxic extracts from the tissues of three knapweed species (Fletcher and Renney, 1963), there have been no studies to thoroughly evaluate the ecological significance of allelopathy in any of these species, even though their infestations exhibit allelopathic characteristics, and they are rapidly becoming some of the most noxious weeds in the Pacific Northwest. Several phytotoxic sesquiterpene lactones have been isolated from Rus-

sian knapweed (Stevens, 1982; Stevens and Merrill, 1985), but it is not known if they are responsible for the soil toxicity associated with this species.

A study very similar to ours was just completed with diffuse knapweed (Muir and Majak, 1983). A polar and a nonpolar inhibitor were detected in the aerial tissues. Root extracts also had activity. Column fractionation of a chloroform extract from leaves and stems bioassayed with ryegrass (*Lolium multiflorum* L.), lead to the isolation of cnicin. Impure cnicin, and the column fraction it was isolated from, both inhibited ryegrass seedlings growth at 0.4 mg/ml (the same as our 2 mg/Petri dish). Purified cnicin, at the same concentration, failed to retard germination or growth and was rejected as a major inhibitor by itself. The polar inhibitor was not identified.

In our study cnicin was phytotoxic for all species tested, root growth was most sensitive, and the level of inhibition was concentration- and species-dependent. Cnicin's potential to function as an effective allelopathic agent will be determined by the concentrations in the soil and the associated species in the community. Knapweed root growth is very sensitive to this compound and, unless these plants have some mechanism for eliminating, avoiding, or minimizing cnicin's effect under natural conditions, then knapweed' competitive ability could be diminished. Secondary metabolites (including the two sesquiterpene lactones, parthenin and coronopilin) from *Parthenium hysterophorus* are allelopathic and autotoxic, inhibiting the germination and growth of *Parthenium* seedlings and older plants (Picman and Picman, 1984a).

It was hypothesized that the autotoxicity is a mechanism for population regulation and timing the process of germination. Autotoxicity does not appear to be functioning within knapweed populations. Cnicin does not retard knapweed germination. In the field, germination can occur after seed dispersal in the fall, if water is adequate, otherwise large numbers of seeds germinate the following spring. Knapweed has no apparent difficulty reestablishing itself in the presence of older plants. In Montana, Chicoine (1984) reported 62 mature plants with 178 seedlings per square meter at one study site, and 60 mature plants with 1808 seedlings per square meter at another. Competition could account for eventual decreases in plant numbers.

Other toxic compounds, besides cnicin, were also present in spotted knapweed. As indicated in Figure 1, most column fractions from the chloroform extract inhibited lettuce growth. Their concentrations were not as high as cnicin, but their effects could be additive (Mandava, 1985).

In addition to allelopathy, cnicin might be important in other ecological interactions. As discussed above, cnicin is antimicrobial and could possibly function as a defense against disease organisms, as suggested for the sesquiterpene lactone parthenolide in *Chrysantemum parthenium* Bernh. (Blakeman and Atkinson, 1979). As with many sesquiterpene lactones, cnicin is bitter tasting (Wagner, 1977) and could influence palatability. Cattle and horses limit their consumption of knapweed, particularly when more desirable forage species are

available, and none of the New World insects defoliate spotted knapweed to any significant extent. Glaucolide-A is a bitter tasting sesquiterpene lactone from *Vernonia* that affects the feeding preference of wild rabbits and whitetail deer. Both animals avoid eating *Vernonia* species containing, or artificially coated with glaucolide-A (Burnett et al., 1977; Mabry and Gill, 1979). This compound has also been extensively tested with insect herbivores. In the laboratory it deterred the feeding of various lepidopterous larvae, particularly the southern armyworm, *Spodoptera eridania* (Cramer), and the fall armyworm, *S. frugiperda* (J.E. Smith) (Burnett et al., 1974). Their growth and survival was reduced significantly when reared on diets containing this lactone (Jones et al., 1979). Field experiments failed to substantiate glaucolide-A as a chemical defense against insect herbivores, but it is still considered an effective mammalian feeding deterrent (Burnett et al., 1977, 1978).

CONCLUSION

Green aerial tissues of spotted knapweed contain the sesquiterpene lactone cnicin that is phytotoxic in laboratory bioassays. It retarded the germination of some plants at the higher concentrations tested, but was not a strong germination inhibitor. Cnicin was most active toward seedling growth, particularly roots, causing significant inhibition in all species tested, including spotted knapweed. This compound could be allelopathic under the appropriate environmental and biotic conditions, possibly contributing to the ecological success of spotted knapweed.

Acknowledgments—The authors wish to thank The McKnight Foundation, Minneapolis, Minnesota for financial support. They also thank Dr. R. Vanhaelen-Fastré, Universite de Bruxelles, Brussels, and Dr. T.J. Mabry, University of Texas, Austin, for reference samples of cnicin.

DEFENSIVE STEROIDS FROM A CARRION BEETLE (*Silpha novaboracensis*)[1]

J. MEINWALD,[2] B. ROACH,[2] and T. EISNER[3]

[2]*Department of Chemistry*
[3]*Section of Neurobiology and Behavior*
Cornell University, Ithaca, New York 14853

(Received November 14, 1985; accepted January 13, 1986)

Abstract—Two novel steroids, 3α,7β-dihydroxy-14β-pregn-4-en-15,20-dione (1) and 3α,7β,20ξ-trihydroxy-14β-pregn-4-en-15-one (4), have been characterized from the rectal gland of *Silpha novaboracensis* (Coleoptera: Silphidae). Judging from the function of comparable pregnanes in another species of *Silpha*, the compounds may play an antipredator role.

Key Words—Coleoptera, Silphidae, *Silpha novaboracensis*, steroids, pregnanes.

We recently described a series of oxygenated pregnanes that serve a defensive role in *Silpha americana*, a carrion beetle (Meinwald et al., 1985). The compounds are produced by a glandular annex of the rectum and are discharged from the anus, together with enteric fluid, when the beetle is disturbed. Bioassays of a representative pair of these pregnanes showed the compounds to be deterrent to jumping spiders. We now report the isolation of two new pregnanes from *Silpha novaboracensis*, also produced by the rectal gland of the beetle. Several hundred glands from beetles collected at bait (dead chickens) near Ithaca, New York, were extracted with 1 : 1 dichloromethane–methanol mixture (ca. 15 μl per beetle). Both thin-layer chromatography and high-performance liquid chromatography (HPLC) showed the extract to contain two major components, totaling ca. 10 μg per beetle, designated as A and B. These were isolated in pure form by preparative HPLC (C-18 column; linear gradient elution with 25% acetonitrile–75% water to pure acetonitrile).

High-resolution mass spectrometry showed A, the major component, to

have the molecular formula $C_{21}H_{30}O_4$ (m/z 346.2129, calc. 346.2144). The 300-MHz ($CDCl_3$) [^{1}H]NMR spectrum of A suggested a steroidal structure, with characteristic singlet angular methyl group resonances at δ 1.17 and 0.94 (Jackman and Sternhell, 1969). A vinylic proton at δ 5.53 and two protons geminal to hydroxyl groups, at δ 4.41 and 4.04, were also apparent. In addition, the infrared spectrum of A showed two carbonyl absorption bands at 1733 and 1704 cm^{-1}. From these data, A can be recognized as a C_{21} steroid with one trisubstituted double bond, two secondary hydroxyl groups, and two carbonyl groups.

The [^{1}H]NMR spectrum of A showed an additional methyl singlet at δ 2.27, characteristic of a C-21 methyl group in a C-20 keto-steroid. The 1704 cm^{-1} carbonyl absorption supports this assignment, and the remaining carbonyl group (1733 cm^{-1}), clearly in a five-membered ring, must be at C-15 or C-16.

An extensive series of proton decoupling experiments (the results of which are summarized in Table 1) allowed the measurement of chemical shifts and coupling constants such that the substitution patterns and stereochemistry at C-2 to C-9 and C-14 to C-17 could be deduced. These data led to the characterization of A as 3α,7β-dihydroxy-14β-pregn-4-en-15,20-dione (I).

Chemical support for this assignment was obtained by sequential conversion of I to II and III as described below. Oxidation of a 20-μg sample of A with manganese dioxide produced a single product with characteristic conjugated enone absorption in the ultraviolet (λ_{max} 240 nm), and a mass spectrum showing an intense fragment at m/z 124 diagnostic of steroidal 3-ene-4-ones (Zaretskii, 1976). These data, along with characteristic [^{1}H]NMR chemical shifts of the angular methyl groups (δ 1.21 and 1.16), provide excellent support for structure II. Treatment of II with methanesulfonyl chloride in triethylamine

gave a product with intense dienone ultraviolet absorption at 280 nm, as expected for loss of the esterified 7-hydroxyl substituent of II to give 14β-pregna-4,6-diene-3,15,20-trione (III).

Spectral data led us to characterize component B (ca. 10% of A) as 3α,7β,20ξ-trihydroxy-14β-pregn-4-en-15-one (IV). The electron impact mass spectrum (EI-MS) of B shows a parent ion at *m/z* 348, corresponding to the molecular formula $C_{21}H_{32}O_4$, a dihydro derivative of A. The EI-MS also exhibits fragments corresponding to the loss of three molecules of water, suggesting the presence of three hydroxyl groups. The peak at *m/z* 141 (33%), attributed to the D-ring fragment formed by scission of the C-8,C-14, and C-12,C-13 bonds, suggested that B is a 15-keto-20-hydroxy steroid (a corresponding fragment at *m/z* 139 is observed in the mass spectra of I and II). The $[^1H]$NMR spectrum of B (in C_6D_6) is similar to that of I, with a few critical differences. Chief among these is the replacement of the C-21 methyl singlet by a methyl doublet (δ 0.64; note large upfield shift attributable to aromatic solvent), confirming the change from a C-20 ketone to a C-20 alcohol.

In summary, the major defensive steroid from *S. novaboracensis* is characterized as I; the minor constituent is the closely related pregnane IV, whose configuration at C-20 remains unassigned.

Acknowledgments—Study supported in part by NIH grants AI-02908 and AI-12020. One of us (J.M.) is deeply grateful to the NIH Fogarty Scholar-in-Residence program for its hospitality during the preparation of this manuscript. We thank K. Hicks and J. Eidens for helping in the not too pleasant task of collecting the beetles.

GROWTH OF *Leptinotarsa decemlineata* LARVAE IN RESPONSE TO SIMULTANEOUS VARIATION IN PROTEIN AND GLYCOALKALOID CONCENTRATION

J. DANIEL HARE[1]

Department of Entomology
The Connecticut Agricultural Experiment Station
New Haven, Connecticut 06504

(Received November 4, 1985; accepted January 13, 1986)

Abstract—Growth of larvae of the Colorado potato beetle, *Leptinotarsa decemlineata* (Say), as measured by weight gain, was determined when larvae were reared on synthetic diets containing measured quantities of protein and one of five *Solanum* glycoalkaloids. Data were analyzed to determine if growth was affected by these two aspects of phytochemical variation independently, or if there was a significant interaction component in larval weight gain to simultaneous variation in protein and glycoalkaloid concentration. For four of the five glycoalkaloids examined, a bivariate regression model without interaction accurately accounted for growth of *L. decemlineata* larvae. For alpha-tomatine, however, a regression model with the addition of a (protein × glycoalkaloid) interaction term more accurately accounted for larval growth. The influence of this interaction was less than either protein or glycoalkaloid concentration alone. The variation in protein concentration accounted for most of the variation in larval growth, and high protein concentrations could more than offset the effect of high concentration of any of the five glycoalkaloids.

Key Words—*Solanum*, glycoalkaloid, *Leptinotarsa decemlineata*, protein, growth, Coleoptera, Chrysomelidae, α-tomatine, α-solamarine, β-solamarine, α-solamine, α-chacomine.

INTRODUCTION

Feeding activity in phytophagous insects is mediated in part by the presence and quantity of particular phytochemicals eliciting or suppressing feeding be-

[1]Present Address: Department of Entomology, University of California, Riverside, California 92521.

havior (Schoonhoven, 1982). Insect feeding and growth rates are also affected by the nutritional quality of the host, and insects may adjust their feeding rates in order to compensate for variation in nutrient (e.g., nitrogen) concentration in ingested food (Slansky and Feeny, 1977; Scriber and Slansky, 1981). Seasonal variation in the concentration of most phytochemicals occurs widely, and the acceptability as well as the nutritional quality of host plants often varies simultaneously over time (Denno and McClure, 1983).

In order to predict how phytophagous insects utilize these varying resources, the following questions must be answered: (1) How do insects respond to quantitative variation in the concentrations of phytochemicals affecting feeding behavior? (2) How do insects respond to variation in the concentration of primary nutrients? (3) Is there any synergism or interference in the insects' responses to these two aspects of phytochemical variation?

Feeding behavior in the Colorado potato beetle, *Leptinotarsa decemlineata* is influenced by a number of phytochemicals. Several sugars and amino acids stimulate feeding (Hsiao and Fraenkel, 1968), and the insect has specialized chemosensory receptors to detect these compounds (Mitchell and Schoonhoven, 1974). Other plant compounds, notably some of the steroidal glycoalkaloids, deter feeding (Hsiao, 1974), although the insect apparently has no chemoreceptors specific for these phytochemicals (Mitchell and Harrison, 1985). Therefore, feeding and growth in *L. decemlineata* is thought to be mediated by the insects's joint responses to a number of plant compounds, only some of which are required for normal growth and development (Hsiao, 1974).

In a previous investigation on the responses of *L. decemlineata* to seasonal phytochemical variation in *Solanum dulcamara* L., Hare (1983) showed that larval survival increased with increasing concentration of extractable foliar protein and declined with increasing concentration of two glycoalkaloids, α- and β-solamarine. In a preliminary study, these two glycoalkaloids also reduced feeding and growth of *L. decemlineata* larvae when incorporated into a synthetic diet. The present study was undertaken to examine in more detail how simultaneous variation in the quantities of protein and glycoalkaloids affected the growth of *L. decemlineata* larvae in the laboratory. The primary objective was to determine if variation in growth of *L. decemlineata* larvae could be modeled as a simple additive function of protein and glycoalkaloid concentration or if it were necessary to include a protein $\times$ glycoalkaloid interaction term into the regression equation in order to accurately model larval growth.

Five glycoalkaloids were examined. Two, α- and β-solamarine, were extracted from *S. dulcamara*, the most common wild host of *L. decemlineata* in Connecticut (Hare, 1983). The responses of *L. decemlineata* larvae to these glycoalkaloids were compared to α-solanine and α-chaconine, the two glycoalkaloids characteristic of the cultivated potato, *Solanum tuberosum* L., *L. decemlineata's* most suitable host, and to α-tomatine, the characteristic glycoal-

kaloid of a less-suitable host plant, the cultivated tomato, *Lycopersicon esculentum* Mill. α-Tomatine has been reported previously to be a strong feeding deterrent to *L. decemlineata* (Hsiao and Fraenkel, 1968) and therefore was included as a reference point to evaluate the activities of the other glycoalkaloids.

METHODS AND MATERIALS

Each of five glycoalkaloids was incorporated at four concentrations in synthetic diets containing one of three concentrations of protein, and the growth of *L. decemlineata* larvae, as defined as the gain in weight after feeding on these diets for 24 hr, was determined. The range of glycoalkaloid concentrations (2, 4, 8, and 16 mg/ml plus a 0 mg/ml control) was chosen to encompass the reported range of concentration in intact plants. For example, Hare (1983) reported the concentration of α- and β-solamarine to vary between 5.9 and 41.6 mg/g (dry wt). This is equivalent to 1.5–10.5 mg/g fresh weight, based upon the observed water content of ca. 75% (Hare, 1983). Similar ranges of 4.6–51.0 mg/g (dry wt) have been reported for tomatine in tomato (Sinden et al., 1978). Glycoalkaloid concentration in commercial and hybrid potato varieties is somewhat lower, ranging from ca. 0.4 to 5.5 mg/g (fresh wt) (Sinden et al., 1980).

Chemical Procedures. α-Tomatine was obtained commercially (Sigma Chemical Co., St. Louis, MO., lot 24F-0090). The other glycoalkaloids were extracted from plant tissue and separated by preparative TLC using methods described previously (Hare, 1983). Identities of the glycoalkaloids from *S. tuberosum* and *S. dulcamara* were determined by hydrolyzing the glycoalkaloid and identifying and quantifying the resulting sugars and aglycones using methods modified from Sinden et al. (1980). Samples (5 g) of each were hydrolyzed under reflux in 10 ml HCl–methanol (1 : 8) for 4 hr. The sample was then evaporated to dryness under vacuum at 18°C. Aglycones were dissolved in chloroform, and the sugars were dissolved in distilled water. The aglycones were identified by their TLC mobility relative to tomatidine (ICN Pharmaceuticals, Cleveland, OH.) and solanidine [prepared by hydrolyzing commercially obtained α-chaconine (Sigma Chemical Co., lot 48C-7520)]. The TLC solvent systems used were hexane–ethyl acetate (1 : 1), CH_2Cl_2–methanol (9 : 1), and CH_2Cl_2–acetone (4 : 1). Identities of the aglycones were confirmed by spraying the plates with 50% aqueous sulfuric acid and noting their characteristic colors before and after heating the plates to 80°C (Hunter et al., 1976).

Identities of the sugars from the hydrolysis (glucose, galactose, and rhamnose from α-solanine and α-solamarine, and glucose and rhamnose from α-chaconine and β-solamarine) were determined by TLC on microcrystalline cellulose plates in *n*-butanol–benzene–pyridine–distilled water (5 : 1 : 3 : 3) (Har-

borne, 1973). Plates were sprayed with aniline hydrogen phthalate and heated at 105°C for 5 min. The mobilities and colors of the sugars from hydrolysis were compared to those of reference standards. The separation of glucose and galactose was achieved by running the plate twice in solvent after allowing the plate to dry between runs.

Glycoalkaloids were incorporated into a completely defined agar-based diet modified from Hsiao and Fraenkel (1968) (Table 1). Protein concentrations used in the present experiment (25, 50, and 100 mg/ml) were $\frac{1}{2}\times$, $1\times$, and $2\times$ the concentration used in the initial study. Because these glycoalkaloids are only soluble in water at acidic pH (e.g., Mitchell and Harrison, 1985), the glycoalkaloids were ground to a fine powder, mixed with the powdered cellulose, and the dry ingredients were thoroughly mixed into the diet. Diets were poured into sterile Petri dishes set and rapidly cooled at 5°C in a refrigerator so that the dry ingredients would not settle out before the diet solidified.

Fourth-instar *L. decemlineata* larvae weighing between 60 and 80 mg were collected from a colony maintained on potted potatoes (cv. 'Katahdin') in the greenhouse. Larvae were starved for 6 hr, weighed, placed in labeled Petri dishes, and given ~0.3 ml of one of the diets. Petri dishes containing larvae and diets were then placed on enamel trays and enclosed in a clear polyethylene bag containing moist paper towels to maintain ~100% humidity. Trays with larvae were placed in a constant-temperature room (25°C, 16-hr photoperiod). Petri dishes were cleaned, diets were replaced after 12 hr, and final weights of larvae were obtained after 24 hr. Relative weight change was computed for each larva as the difference between the final and initial weights divided by the initial weight. Two groups of 15 larvae were used in each of the 15 combinations of protein and glycoalkaloid treatments.

Multiple regression was used to analyze larval growth as a function of protein concentration, glycoalkaloid concentration, and the protein × glycoalkaloid interaction. Regressions were calculated without transformation and with the (log + 1) transformation applied to protein and glycoalkaloid concentrations. Regression analyses were performed first using only protein and glycoalkaloid concentrations as "main" effects, then regression analyses were repeated after incorporating a protein × glycoalkaloid interaction term into the model. Regression analyses yielded similar results for both the untransformed and transformed independent variables. Because the concentrations of protein and glycoalkaloids were equally spaced after transformation, regression analyses on transformed data are probably more valid.

RESULTS AND DISCUSSION

In general, larval growth increased with increasing protein concentration and decreased with increasing concentration of all glycoalkaloids (Table 2). The regression coefficients between larval growth and protein concentration were statistically significant at $P \leq 0.001$ in all cases (Table 3). Regression coefficients between larval growth and glycoalkaloid concentration were statistically significant ($P \leq 0.05$) for all glycoalkaloids except alpha α-solamarine. These two "main" effects accounted for 67–77% of the variation in the means of larval growth in all experiments. Protein concentration was always the more important factor, accounting for 55–70% of the variation in larval growth alone.

The protein × glycoalkaloid interaction term did not significantly improve the fit of any regression model except for α-tomatine (Table 3). In this one case, the protein × glycoalkaloid interaction accounted for 5.3% of the total variation and raised the total percent of variation explained to 76.4%.

The significant inhibition of larval growth by all five glycoalkaloids, including those from potato, is not entirely unexpected. Although Hsiao and Fraenkel (1968) concluded that solanine would have little, if any effect on *L. decemlineata* at concentrations occurring in potato foliage, *L. decemlineata* growth was reduced in their experiments more than 20% by solanine at concentration of 0.9%. Absolute larval growth declined significantly with the logarithm of solanine concentration ($b = -14.64$, $P \leq 0.05$, calculated from published data); the effect of chaconine was not examined.

Although tomatine was a stronger inhibitor of larval growth than the potato alkaloids in the present study, it was not the "order of magnitude" more effective as was found in previous studies (Hsiao and Fraenkel, 1968; Hsiao, 1974). It is not clear whether these differences might have been due to differences in the diets used or variation among *L. decemlineata* populations in their susceptibility to tomatine.

Finally, the variation in casein content was clearly the more important.

TABLE 2. MEAN (AND STANDARD ERROR)[a] PERCENT WEIGHT CHANGE AFTER 24 HR OF LARVAE FED SYNTHETIC DIETS CONTAINING SPECIFIED CONCENTRATIONS OF GLYCOALKALOIDS AND CASEIN

[b] R^2 is the proportion of the total variance "explained" by each factor.

Although the nutritional suitability of casein may differ from that of *Solanum* leaf protein, results presented here suggest that the absolute level of growth inhibition by any glycoalkaloid may depend upon the "background" nutritional quality of the substrate used. Because of the great likelihood of inter- and intraspecific variation in protein content of different host species (e.g., Hare, 1983), attempts to relate differences in susceptibility of *Solanum* species or cultivars only to variation in glycoalkaloid concentration without considering the possibility of simultaneous variation in host nutritional quality may lead to erroneous conclusions. With one exception, these results indicate that the use of simple bivariate regression models without interaction (e.g., stepwise multiple regression) are appropriate for the analysis of growth responses of *L. de-*

cemlineata to simultanenous variation in quantities of protein and glycoalkaloids.

Acknowledgments—The technical assistance of K. Fournier, V. Schweitzer, and J. Wrinn is greatly appreciated, as are the valuable comments and suggestions provided by T. Baker, S. Duffey, and J. Trumble on a previous draft of the manuscript.

Abstract—This paper is the first in a series on cardenolide fingerprinting of monarch butterflies and their host-plant milkweeds in the eastern United States. Spectrophotometric determinations of the gross cardenolide content of 60 *Asclepias viridis* plants in northwestern Louisiana indicate a positively skewed variation ranging from 95 to 432 μg/0.1 g dry weight with a mean of 245 μg/0.1 g. Butterflies reared individually on these plants contained a normal cardenolide distribution ranging from 73 to 591 μg/0.1 g dry weight with a mean of 337 μg/0.1 g. The uptake of cardenolide by the butterflies best fit a logarithmic function of the plant concentration. Female monarchs (385 μg/0.1 g) contained significantly greater mean cardenolide concentrations than did males (287 μg/0.1 g). No indications of a metabolic cost for either cardenolide ingestion or storage were adduced from size or dry weight data. Thin-layer chromatograms of 24 individual plant–butterfly pairs developed in two solvent systems resolved 21 individual spots in the plants and 15 in the butterflies. *A. viridis* plants appear to contain several relatively nonpolar cardenolides of the calotropagenin series which are metabolized to the more polar 3′-hydroxy derivatives calactin and calotropin as well as to calotropagenin in the butterflies. The epoxy cardenolides labriformin and labriformidin were absent, although desglucosyrioside (a 3′-hydroxy derivative) appeared present in both plants and butterflies. Quantitative evaluation of the R_f values, spot intensities, and probabilities of occurrence in the chloroform–methanol—formamide TLC system produced a cardenolide finger-

print clearly distinct from those previously established for monarchs reared on other *Asclepias* species, supporting the use of fingerprints to make ecological predictions concerning larval host-plant utilization. *A. viridis* is the predominant early spring milkweed throughout most of the south central United States and may be important in providing chemical protection to spring and early summer generation monarchs in the eastern United States.

Key Words—*Asclepias viridis*, milkweed, Asclepiadaceae, *Danaus plexippus*, Lepidoptera, Danaidae, monarch butterfly, cardenolide, cardiac glycoside, digitoxin, chemical ecology, chemical defense, thin-layer chromatography, plant–insect interactions, coevolution.

INTRODUCTION

While other danaid butterflies are restricted to subtropical and tropical climates and food resources, the monarch butterfly, *Danaus plexippus* L., has developed a migratory strategy which enables it to avoid competition for larval host-plants by utilizing the abundant temperate milkweeds in the genus *Asclepias* L. (Asclepiadaceae). Unable to overwinter in freezing temperate climates, each fall millions of monarchs in the eastern United States leave their North American breeding grounds and fly southward to the Gulf Coast and to the volcanic plain of eastern Michoacan, Mexico (Urquhart and Urquhart, 1978; Brower, 1977). Nesting in the trees at elevations of 11,000–12,000 ft, as many as 50 million monarchs hibernate in a few dense colonies in a forested region only a few square miles in area (Brower et al., 1977). Monarchs which breed in the western United States comprise an entirely separate population long known to overwinter along the California coast.

Since the discovery of the Mexican overwintering site in 1976 (Urquhart and Urquhart, 1976), much effort has been made to document the arrival, overwintering behavior, and spring breakup of these spectacular colonies (Brower et al., 1977; Calvert and Brower, 1982; Calvert et al., 1979, 1982; Fink and Brower, 1981). Little is known, however, about the ecology of these monarchs as they recolonize their temperate breeding grounds in eastern North America. For those monarchs remigrating through Texas and Louisiana, *Asclepias viridis* and *A. asperula* probably represent the first common and widespread milkweeds they encounter. From western Florida eastward and northward along the Atlantic coastal plain *A. viridis* is more localized and *A. humistrata* is more heavily utilized for oviposition by monarchs (Brower, 1961, 1962; Cohen and Brower, 1982). Clearly, these three species are the principal milkweeds which migrant monarchs encounter as they reach the temperate United States and serve as larval host-plants for many, if not most, of the first spring generation monarch larvae.

The breeding cycle in the southern states is short lived, however, since the first monarchs arrive in late March and by early May monarchs in all life stages

are essentially absent. The fates of both the original remigrants and the first spring generation are unclear. By mid-summer monarchs are widely dispersed throughout much of the northeastern U.S. and southeastern Canada. *A. syriaca* and *A. speciosa* are probably the major food source for monarch larvae during the summer breeding season (Urquhart, 1960; Fink and Brower, 1981), although several other milkweed species are abundant and serve as monarch host-plants, particularly along the western margins of their distribution in the eastern U.S.

Most milkweed species contain a variety of highly emetic and toxic cardenolides which have an effect similar to digitalis on the vertebrate heart. In contrast to most other milkweed herbivores examined, the monarch has been found to effectively sequester these compounds in their tissues. Only the lygaeid bugs, *Oncopeltus* and *Lygaeus*, appear more efficient on an insect weight basis (Duffey, 1977; Isman et al., 1977; Blum, 1981; Cohen, 1985). Most research has also shown that monarch larvae are able to avoid the toxic effects of cardenolides (Erickson, 1973; Dixon et al., 1978) although Cohen (1985) has recently found a significant negative correlation between wing length and cardenolide concentration in wild Florida adult males and females. Brower et al. (1982, 1984a,b) have analyzed the cardenolide contents of monarchs reared on three specific host-plants in California, *A. eriocarpa*, *A. speciosa*, and *A. californica*. They found that larvae selectively store the more polar cardenolides found in their host-plants and apparently convert some of the less polar forms to more polar forms. In addition, they have successfully established that monarchs reared on these three species each possess a distinctive thin-layer chromatography (TLC) pattern of cardenolides that is reflective of the pattern found in its host-plant species, supporting their hypothesis that TLC "fingerprints" could be developed to identify the host-plant origins of wild-caught monarchs.

Adult monarchs rich in cardenolides have been shown to be both emetic and distasteful to blue jays and other bird species, suggesting that they are defended chemically against many potential vertebrate predators (Brower et al., 1975, 1982). However, many adult monarchs contain little or no cardenolide in their tissues. Brower et al. (1972) and Brower and Moffitt (1974) found a broad spectrum of gross cardenolide content in populations of eastern U.S. monarchs, indicating some butterflies were palatable, some subpalatable, and some highly toxic. Fink and Brower (1981) found that only 10% of the butterflies they examined at the Mexican overwintering site contained more than one emetic dose of cardenolide and that a high percentage contained little or no cardenolide. Although Fink and Brower (1981) suggest that a large proportion of these butterflies fed on *A. syriaca*, *A. speciosa*, or other low-potency cardenolide-poor milkweeds, no cardenolide fingerprint profiles or pairwise concentration analyses have yet been published for monarchs feeding on milkweeds in eastern North America.

In this paper we present the first analysis in a series of investigations of

monarch remigration and recolonization along the western margins of their distribution in the eastern United States. Our purposes are to establish the timing and extent of host-plant utilization by monarchs as they remigrate into temperate North America, establish the quantitative variation in cardenolide contents of butterflies as they relate to their host-plants and to develop thin-layer chromatography cardenolide fingerprints of adult monarchs for milkweed species commonly utilized during recolonization. We now report on the cardenolide characteristics of monarch butterflies reared as larvae on *Asclepias viridis* Walt. in northwestern Louisiana.

METHODS AND MATERIALS

Geographic and Ecological Distribution of Asclepias viridis. *Asclepias viridis* Walt., a relatively common milkweed of the subgenus Asclepiodora, has a widespread distribution in the southeastern United States. It naturally occurs in glades, prairies, dry hillsides, and pine barrens. The species may be found as far south and east as the Florida Keys, with populations extending northward along the Appalachians to Ohio and westward across the southern United States to central Texas, Oklahoma, Kansas, and southern Nebraska. Figure 1 illustrates the known distribution of *A. viridis*.

Along the western boundary of its distribution *A. viridis* is often abundant in open fields and pastures, and often occurs in close sympatry with *Asclepias asperula* subsp. *capricornu* (Woods.) Woods., a morphologically similar yet distinct milkweed of the same subgenus. Although they largely remain distinct, individuals with intermediate vegetative and floral morphology may occur, suggesting occasional hybridization between the two species (Lynch, personal observation). In northwestern Louisiana *A. asperula* is absent but *A. viridis* is often abundant in pastures and openings and margins of piney woods. Other milkweed species do occur in this region but are only occasional and produce less biomass. East of the Mississippi River, *A. viridis* becomes increasingly less abundant and *A. humistrata* Walt., *A. tuberosa* L., and to a lesser extent *A. tomentosa* Ell. produce the principal milkweed biomass in the southeastern United States.

Location, Methods, and Dates of Sample Collections. During the spring of 1981, immature monarchs (*Danaus plexippus* L.) were collected from milkweeds in Caddo Parish, Louisiana, at a site south of Shreveport, 0.5 miles north of Wallace Lake on Wallace Lake Road. The site consists of a series of open, lightly grazed fields covered with both native and introduced grasses and forbs. The fields are surrounded by piney woods dominated by shortleaf and loblolly pines (*Pinus echinata* Mill. and *P. taeda* L.), sweet gum (*Liquidambar styraciflua* L.), sugarberry (*Celtis laevigata* Willd.), honeylocust (*Gleditsia triacanthos* L.), and several species of oak (*Quercus* spp.)

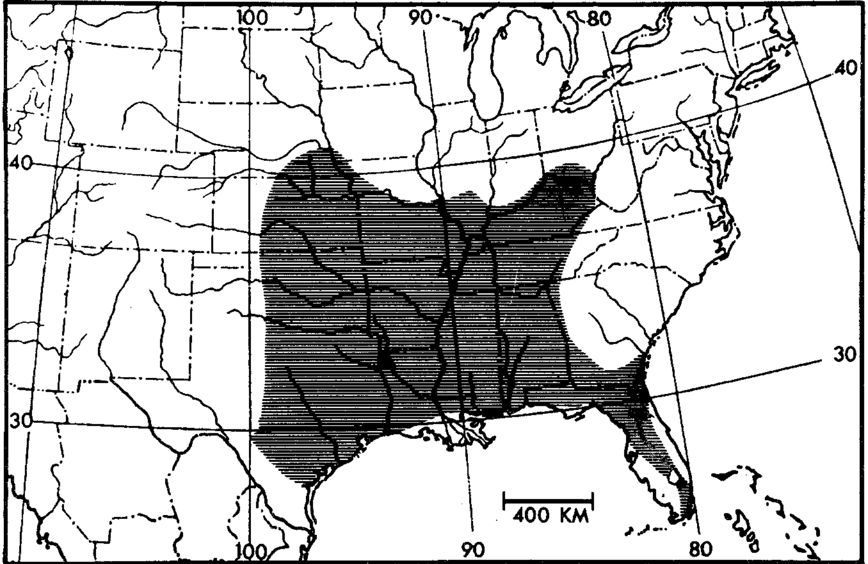

FIG. 1. The known geographic distribution of the milkweed *Asclepias viridis* Walt. in the United States (after Woodson, 1954). The triangle locates the northwest Louisiana population analyzed in this study. See text for discussion of relative abundance.

Collections of individually matched plant–butterfly pairs generally followed the procedures established in Brower et al. (1982, 1984a,b) with some minor revisions. Fifth-instar larvae were collected along with a sample of leaves from their individual host-plant. A portion of this material was placed with the larva into an 8-oz clear plastic food container (Sweetheart Plastics No. 40, Wilmington, Maryland), and the remaining leaves were placed in one-pint freezer bags and frozen for later chemical analysis.

Within three days each fifth-instar larva had spun a silken pad on the lid of the container, attached itself to the pad by its cremaster, and hung upside down to shed its last larval skin. Failure to hang free invariably resulted in a distorted chrysalid and either terminated further development or resulted in a badly disfigured adult. After pupation, the remaining leaves in the container were discarded, and a Whatman No. 1 filter paper was placed on the bottom to reduce humidity and to soak up fluids evacuated during emergence. The containers were stored at room temperature until emergence. Deposition of pigments into the adult monarch exoskeleton generally occurred the evening and night prior to emergence. Upon darkening of the chrysalids, small cylinders of metal window screen were sandwiched between the lid and bottom of the container, creating an open air cage in which the emerging adults could hang to expand and dry their wings.

Approximately 12 h after emergence, each butterfly was placed in a glassine envelope and frozen for later measurement and chemical analysis. Each plant–butterfly pair was provided with a collection number (S.P. Lynch, unpublished field catalog). A single digit alphabetical suffix was used to identify more than one butterfly collected from the same host-plant.

In addition to searching for and collecting wild fifth-instar larvae, several small larvae were bagged with nylon net bags and later collected as chrysalids or as late fifth-instar larvae. The rearing of the butterflies and the treatment of plant material following collection was identical for both bagged and unbagged material. Any chrysalids collected from bags were removed along with their silken pads which were then taped to the lid of the container. In all, 60 pairwise butterflies, 31 females and 29 males, were analyzed from 48 individual plants.

Determination of Total Cardenolide Content. The individual plant and butterfly samples were prepared and extracted with 95% ethanol as described by Brower et al. (1972). Spectrophotometric determinations were performed at 626 nm with a Gilford 280 single-beam UV–visible spectrophotometer at 20.0°C or ambient temperature (22°C), following the 2,2′,4,4′-tetranitrodiphenyl (TNDP) method of Brower et al. (1972, 1975) and Brower and Moffitt (1974). Those absorbances obtained at ambient temperature were determined in stoppered 1-cm polystyrene cuvettes (Kartell, matched within 0.005 A) whereas absorbances at 20.0°C were determined in matched glass cuvettes in a temperature-controlled cuvette holder. A minor change in dilution of the cuvette contents was necessary to minimize precipitation. The sample cell contained 0.5 ml of plant or butterfly extract, 0.8 ml of 95% ethanol, 1.0 ml of 0.15% TNDP in 95% ethanol, and 0.2 ml of 0.1 N sodium hydroxide in 50:50 water–95% ethanol. The reference cell contained the same except for the replacement of the 1.0 ml TNDP solution with 1.0 ml 95% ethanol. Freshly prepared TNDP solutions were used and stored in a refrigerator for no longer than 10 days. In the absence of the molar absorptivities of the TNDP complex of the *A. viridis* cardenolides, estimates were obtained using a digitoxin standard and reported in μg (equivalent to digitoxin) per 0.1 g dry weight (Roeske et al., 1976; Brower et al., 1982).

Thin-layer Chromatography (TLC). Pigments and other interfering substances were removed in a lead acetate precipitation procedure (Nelson et al., 1981; Brower et al., 1982) which utilized 6 ml of the *A. viridis* extract or 3 ml of the butterfly extract. After cleanup, the evaporated residue was dissolved in a calculated amount of chloroform in order to deliver 50, 75, 100, 125, or 150 μg/20 μl of solution.

Twenty microliters of the plant and butterfly samples were spotted with Drummond Wiretrol 5-μl pipets onto a heat-activated 20 × 20-cm TLC plate (0.25 mm, EM Science 5765 Silica Gel 60 F-254), providing six plant–butterfly pairs and five digitoxin and digitoxigenin standards (Sigma Chemical Co.) per plate. Development was in preequilibrated filter paper-lined glass chambers in

chloroform–methanol–formamide (CMF system, 90:6:1 by volume) four times or in ethyl acetate–methanol (EM system, 97:3 by volume) two times (Brower et al., 1982). The plates were visualized by spraying with 20 ml of 0.4% TNDP in toluene followed by 20 ml of 10% potassium hydroxide in 50% aqueous methanol. The plates were photographed within 1 min using Kodachrome 25 film and a Pentax Spotmatic 35-mm camera equipped with a Pentax ringstrobe. Pooled samples of both plants and butterflies were also run spotting approximately 100 μg of cardenolide in each position.

Four plates were run in the CMF solvent system. Plates 2 and 4 each contained six female plant–butterfly pairs, two pairs each selected from the low, middle, and high ranges of plant cardenolide concentration based on spectroassay results. Similarly, plates 1 and 3 were spotted with male plant–butterfly pairs except for one middle range female pair which was erroneously included on plate 1. This resulted in a total of 13 female and 11 male plant–butterfly pairs analyzed by the CMF system. Concentration ranges were intentionally placed in different regions on each plate to reduce or eliminate error due to plate position. The two standards, digitoxin and digitoxigenin, were run as a mixture in the outermost positions and in the central position of each plate, and each standard was run independently, immediately flanking the central channel. In a similar manner, two plates of pooled plant and butterfly extracts were chromatographed in adjacent positions, one plate in CMF and the other in EM. Because of poorer resolution of individual spots, no individual pairwise plates were run using the EM system (see Results section).

The digitoxin migration values from each origin were calculated by drawing a line from the outer digitoxin spots to the central spot and measuring from the origin to the line intersect. The distance of the concentrated centers of each spot from the origin was measured to the nearest 0.5 mm and later converted to an $R_{\text{digitoxin}}$ (R_d) value by dividing the spot migration distance by the calculated digitoxin migration distance. In addition to quantifying the relative positions of the various spots, comparisons of TLC patterns were also based on the mean and standard deviations of each spot's intensity value (SI) as well as each spot's probability of occurrence PO. Spot intensity was determined using a subjective but consistent visual 1–5 scale with 1 being the lightest and 5 the darkest.

Statistical Analyses. Statistical analyses were made on an IBM 3330 computer housed at Louisiana State University in Baton Rouge utilizing SAS statistical software, release 82.2 (SAS, 1982). We analyzed dry weights, wing and body measurements, cardenolide concentrations, and total cardenolide content of the butterflies, as well as the cardenolide concentrations of the plants. Using the Kolmogorov D statistic, only the cardenolide concentration data for plants were not normal ($P = 0.03$, HO $= P < 0.05$). A $\log_{10}$ transformation produced a normalized distribution for the plant concentrations ($P = 0.10$), and the fit to the model was improved in each case.

Two-step regressions were used to fit least-squares estimates to models

comparing cardenolide concentrations and total cardenolide contents of individual butterflies (Y, the dependent variable) to the cardenolide concentrations of the individual plants which the larvae had eaten (X, the independent variable). The first step considered the overall relation of Y to X, the calculated r^2, the slope, and the intercept; and the second step analyzed the dependence of the butterfly cardenolide concentration, butterfly dry weight, and the total cardenolide per butterfly on the cardenolide concentration of the plants (total and by sex).

Two way analyses of variance (ANOVA) on the TLC data were used to determine the influence of sex and plate number and their interaction on both R_d values and on SI values. Brower et al. (1982, 1984a,b) have pointed out that the reliability of cardenolide fingerprinting depends upon a high degree of correlations between the R_d values of the respective cardenolides in the plants and butterflies. Although we realize that our TLC spot comparison methodology largely predetermines the correspondence of the respective plant and butterfly spots for each plant–butterfly pair, the SAS linear regression program allows for the simultaneous testing of the dependence of the R_d values or the SI values for all butterfly spots on the corresponding values of their respective plant spots as affected by plate variation or sex in the entire sample.

RESULTS

Measurements of Gross Cardenolide Content. We found *A. viridis* host-plants to be rich in cardenolides. Each of the 60 plants used in this study contained measurable amounts of cardenolide, with concentrations ranging from 95 to 432 μg/0.1 g dry weight. The mean concentration for all plants measured was 245 μg/0.1 g dry weight with a standard deviation of 69.8 μg (Table 1). The pattern of variation is shown in Figure 2. The curves over the histograms for both plants and butterflies display the limits of the expected normal distributions calculated by the z statistic (Steel and Torrie, 1960). The overall dis-

TABLE 1. CARDENOLIDE CONCENTRATIONS OF MONARCH BUTTERFLIES AND THEIR HOST-PLANT MILKWEED, *Asclepias viridis* WALT.[a]

		Plant material			Butterfly material		
	N	Mean	SD	Range	Mean	SD	Range
Males	29	229.62	64.64	95–432	286.67	98.59	73–482
Females	31	259.21	72.46	130–432	384.76	89.29	216–591
Total	60	244.91	69.82	95–432	337.35	105.41	73–591

[a] Data are μg (equivalent to digitoxin) per 0.1 g dry wt of butterfly or plant material.

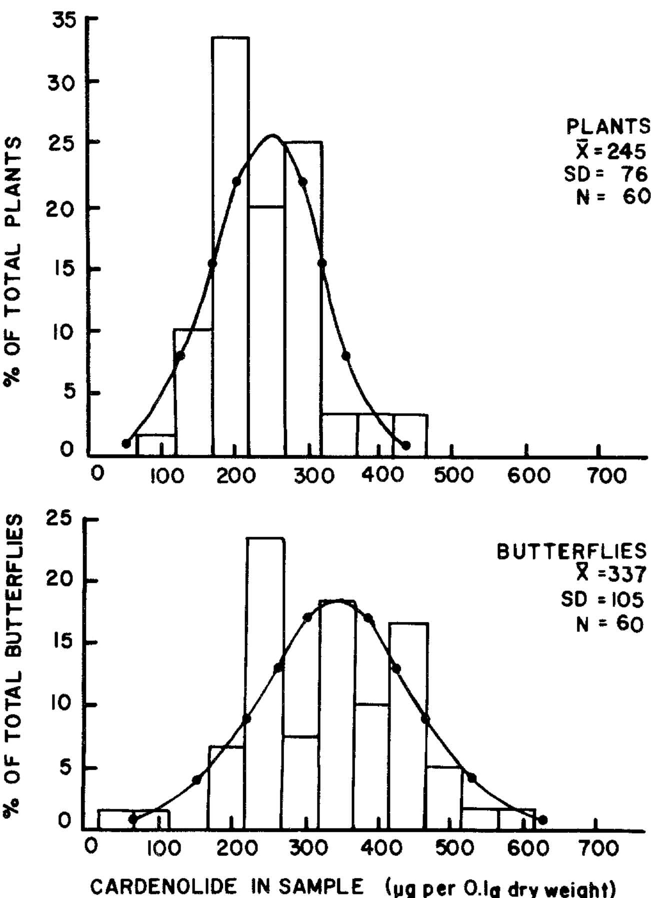

FIG. 2. Frequency distributions of the gross cardenolide content of 60 *Asclepias viridis* plants and 60 monarch butterflies reared thereon. Concentrations are expressed as μg/0.1 g dry weight, equivalent to digitoxin. The width of each bar is 50 μg. The curves above the histograms are the normal distributions calculated by the z statistic (Steel and Torrie, 1960).

tribution for the plants was positively skewed so that the majority of plants contained less than the mean concentration of cardenolide (moment of skewness = 0.79; mean and median, respectively, 244.9 and 235.0 μg; $D = 0.121$, $P < 0.03$). The $\log_{10}$-transformed data, however, did not depart significantly from normality (moment of skewness = −0.32; mean and median = 5.46; $D = 0.104$, $P > 0.10$). Further statistical analyses involving plant concentrations were therefore based on the $\log_{10}$-transformed data.

Butterflies reared on *A. viridis* were also found to be cardenolide-rich, with an even greater mean of 337 μg cardenolide/0.1 g dry weight. The range of cardenolide concentrations in the butterflies, 73–591 μg/0.1 g dry weight, was also greater than the range in the plant samples (Table 1). The pattern of variation in cardenolide concentration in the butteflies (Figure 2) was normally distributed (N = 60; mean and median, 337.3 and 341.0 μg, respectively; D = 0.075, $P > 0.15$).

Although Table 1 shows differences in the mean cardenolide concentrations of plants fed on by male vs. female butterflies, an analysis of the variance indicated that the difference in the plants according to the sex of the butterfly was not significant ($P < 0.36$). However, differences in the means for cardenolide concentrations in male and female butterflies were significant ($F = 16.35$, $P < 0.0002$; $r^2 = 0.22$). The grand variances of the cardenolide concentrations of the plants upon which male and female butterflies were reared were not significantly different (for the s^2 female/s^2 male, $F = 1.26$ with 28 and 30 *df*, $P = 0.54$) nor were the grand variances of the cardenolide concentrations between the male and female butterflies ($F = 1.22$ with 28 and 30 *df*, $P = 0.590$).

The mean cardenolide concentration in the butterflies was 92.4 μg (1.4 times) greater than that of their respective plants, but the overall range of variation in the butterflies (SD = 105.4) was also greater than that in the plants (SD = 69.8) so that the lowest (73 μg/0.1 g) and the highest (591 μg/0.1 g) concentrations were found in the butterflies. Figure 3 illustrates butterfly concentrations (Y, the dependent variable) plotted against plant concentrations (X, the independent variable) for all 60 plant–butterfly pairs. The main regression model (Table 2A) confirmed the logarithmic relationship $Y = 401.961 \log_{10} x = 616.021$ ($r = 0.476$; $P < 0.0001$). Both the slope ($P < 0.0001$) and the intercept ($P < 0.0101$) were significantly different from 0.

In a second set of regressions comparing plant and butterfly cardenolide concentrations by the sex of the butterfly (Table 2B) we found that while the overall model was highly significant ($P < 0.0001$) neither plant concentration, nor sex, nor their interaction were significant using type II sums of squares statistics. By running separate regressions on the sexes, we found that while in both sexes there was a positive correlation between butterfly concentration and plant concentration, in the females it was significant ($P < 0.0023$), while in the males it was not ($P > 0.0647$).

Table 3 lists the dry weights and total cardenolide content of the butterflies. The dry weights were normally distributed (mean and median, respectively = 0.178 and 0.181 g; $D = 0.088$, $P > 0.15$) with the average male butterfly being slightly heavier (0.185 g) than the female (0.172 g). The total cardenolide contents were also normally distributed (mean and median, respectively = 591 and 603 μg; $D = 0.090$, $P > 0.15$). The variances for the two sexes did not differ significantly for either dry weight ($F = 1.17$; $df = 28, 30$; $P = 0.67$) or total cardenolide ($F = 1.15$; $df = 28, 30$; $P = 0.70$). Analyses of the variances

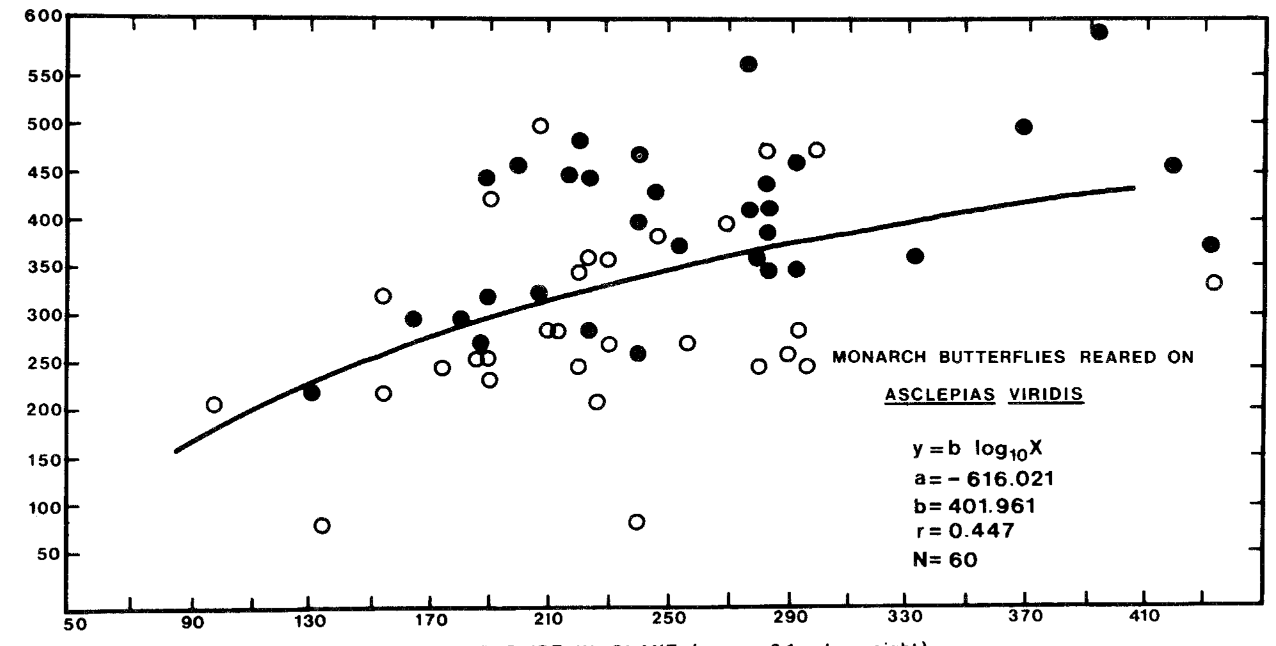

FIG. 3. Cardenolide concentrations of monarch butterflies (Y axis) as a function of the cardenolide concentrations of their larval food plant, *Asclepias viridis* Walt. (X axis). Each of the 60 data points represents one plant-butterfly pair. Open circles are males and solid circles are females. The line is derived from the regression equation $Y = b(\log_{10}X) + a$.

[a] Micrograms per 0.1 g dry wt. in butterflies (Y = dependent variable) vs. cardenolide concentrations ($\log_{10}$ μg/0.1 g dry wt) in their respective plants, according to function $Y = b(\log_{10} x) + a$.

TABLE 3. SUMMARY OF DRY WEIGHTS AND TOTAL CARDENOLIDE CONTENT IN BUTTERFLIES REARED ON *Asclepias viridis* WALT.

		Dry weight (g)			Total cardenolide (μg)		
	N	Mean	SD	Range	Mean	SD	Range
Males	29	0.185	0.026	0.126–0.232	523	179	146–990
Females	31	0.172	0.028	0.110–0.212	655	167	411–973
Both	60	0.178	0.027	0.110–0.232	591	184	146–990

indicated that the mean dry weights of the two sexes were not significantly different ($F = 3.62$, $P < 0.0621$) but that the mean total cardenolide content in the female butterflies (655 μg) was significantly greater ($F = 8.81$, $P < 0.0043$) than in the males (523 μg).

A regression analysis was run to determine the relationship of the butterfly dry weights (Y) to the $\log_{10}$ cardenolide concentrations of the plants (X). The overall model indicated no significant correlation ($r^2 = 0.023$; $F = 1.333$, $P > 0.253$) as did models with either sex. The dry weights of the butterflies were similarly compared to the cardenolide concentrations of the butterflies. The main regression model indicated a significant negative correlation between butterfly dry weight and cardenolide concentration ($Y = -0.94x + 2099.11$; $r^2 = 0.13$; $P < 0.0047$). However, the second regression model, which also included sex and the log plant concentration as covariates, indicated no overall significant correlation ($R^2 = 0.189$; $F = 1.73$, $P < 0.1218$) and that, using type II sums of squares statistics, none of the variables or their interactions were significant predictors of butterfly dry weight (all P values > 0.26).

The same linear regression model as those comparing butterfly cardenolide concentrations and dry weights was run to relate total cardenolide in the butterflies to the $\log_{10}$ plant concentrations. We found butterfly total cardenolide is highly dependent on the $\log_{10}$ plant concentration ($r^2 = 0.43$; $F = 13.37$, $P < 0.0006$) and that both sexes individually showed similar dependence. Based on the equation $Y = 637.33(\log_{10} x) - 920.32$, the overall model predicts that butterflies which fed on plants containing 95 μg/0.1 g cardenolide (the lowest plant concentration in our study) would contain approximately 340 μg, those which fed on 245-μg plants (the mean plant concentration) would contain 602 μg, and those which fed on 432-μg plants (the highest plant concentration in our study) would contain 759 μg. The second regression for total cardenolide indicated that neither the log plant concentration nor the sex of the butterflies nor their interaction were significant predictors when using types II or IV partial sums of squares statistics.

TLC Cardenolide Profiles of Plants and Butterflies. Although TLC plates were run in two separate solvent systems, only those plates run in the chloroform–methanol–formamide (CMF) system were analyzed quantitatively. As found by Brower et al. (1982, 1984a,b) with three California milkweeds, the ethyl acetate–methanol (EM) system resolved fewer cardenolides in *A. viridis* than did the CMF system, and the individual spots were larger and less well defined. While the EM system may eventually provide information on the identity of individual cardenolide compounds by confirmation with known standards and may prove useful in their isolation and purification, the CMF system has proven more valuable in the quantitative analyses of individual cardenolides and in the establishment of TLC "fingerprint" profiles. For these reasons the remaining discussion will be concerned entirely with the CMF profiles.

Figure 4 is a photograph of portions of two plates run in the CMF system.

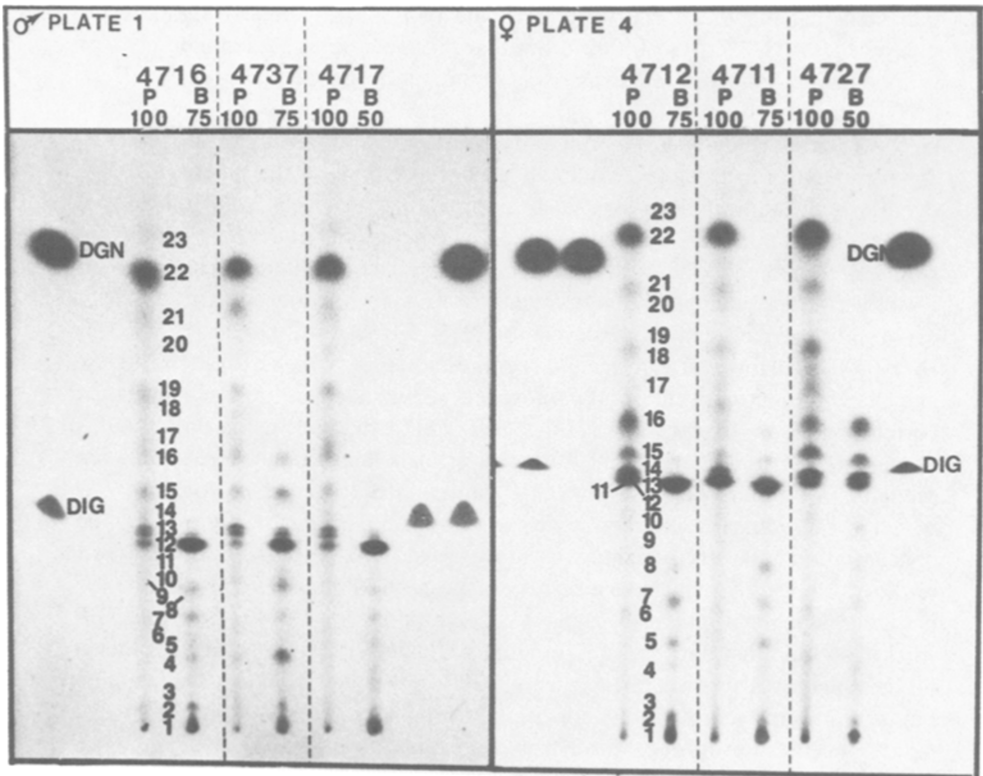

FIG. 4 Photographic reproduction of the thin-layer chromatographic profiles of the cardenolides present in monarch butterflies and their host-plant, *Asclepias viridis* Walt. Represented are six plant–butterfly pairs run in the chloroform–methanol–formamide system including three males (Plate 1: Nos. 4716, 4737, and 4717) and three females (Plate 4: Nos. 4712, 4711, and 4727). Twenty-three individual spots were resolved, including 21 in the plants (all except spots 2 and 3) and 15 in the butterflies (all except spots 6 and 17–23). Also included are two standards, digitoxin (DIG) and digitoxigenin (DGN), which were run on each plate. Several spots with low color intensity are visualized poorly through photographic reproduction (but see the generalized drawing in Figure 5). See text for discussion of possible identities of individual spots.

Represented are six butterfly–plant pairs including three female butterflies and three male butterflies. The number sequence of the individual spots is in the channel between the first plant–butterfly pair and each standard is identified. Headings for each pair include the research number (top), identity as either plant (P) or butterfly (B), and the approximate amount of cardenolide spotted in μg (lowest figures). Table 4 summarizes the means and standard deviations for both $R_{\text{digitoxin}}$ (R_d) and spot intensity (SI) values for all the spots in the 24

TABLE 4. SUMMARY OF MEANS AND STANDARD DEVIATIONS FOR $R_{digitoxin}$ (R_d) VALUES AND SPOT INTENSITIES (SI'S) FOR 23 CARDENOLIDES AND PROBABILITY OF THEIR OCCURRENCE IN 24 PAIRED PLANTS AND BUTTERFLIES[a]

[a] Data are based on chromatograms of 24 butterflies and the corresponding plants on which they were reared (chloroform–methanol–formamide system).

plant and butterfly samples analyzed by TLC. Also included in Table 4 is the probability of occurrence of each spot (PO) based on the proportion of plants or butterflies in which each spot occurred and the subsample size or number of times each spot was detected.

The mean migration distance for the 12 digitoxin references (three on each plate) was 57.3 mm with a range of 47.0–67.5 mm and a SD of 6.8 mm. The 12 corresponding digitoxigenin references had a mean migration distance of 115.9 mm with a range of 110.0–120.0 mm and a SD of 3.3. The mean R_d value for digitoxigenin in the 12 reference channels was 2.05 with a range of 1.74–2.43 and a SD of 0.22.

Relatively weak spots were occasionally absent or difficult to discern in individual plants or butterflies, yet the standard deviations of the R_d values are low, indicating the resolution of the cardenolides is good. In general, the overall SIs were lower than expected for both the plants and butterflies. The apparently lower concentration in the cleaned extracts and on the plates may be due to cardenolide loss during the cleanup procedure. It is also possible that noncardenolide substances, present in the crude extract may have produced a false-positive response in the spectroassay and were either removed in the lead acetate cleanup or moved with the solvent front to the leading edge of the plate.

Figure 5 represents the mean cardenolide profile for the 24 plants and butterflies utilized in the TLC analysis. The relative positions and darkness of the spots are calculated from the mean R_d and SI values presented in Table 4. The shapes and sizes of the spots are drawn from a representative TLC plate and then generalized in the figure. The mean R_d values for the 12 digitoxin and digitoxigenin standards are also indicated as dotted lines across the profile. In all, 23 spots were resolved in the CMF system. Twenty-one spots were discerned in the plants and 15 in the butterflies. Spots 2 and 3 were not present in any of the plants while spots 6 and 17–23 were absent in the butterflies.

In the plants there were seven spots (Nos. 1, 4, 5, and 7–10) which were detected in less than 50% of the samples ($PO < 0.50$), although we found these spots consistently present in pooled samples spotted with an estimated 100 μg of cardenolide. This left 14 spots present in the majority of individual profiles and useful as diagnostic characters (Nos. 6, and 11–23). Nine spots (43%) had an $R_d > 1.0$ (above digitoxin) while 12 spots (57%) had an $R_d < 1.0$. Only spot 23 was consistently above digitoxigenin, although spot 22 occasionally migrated slightly above digitoxigenin's position and had a mean R_d value essentially the same as the standard's (2.05). Spots 11–13, 15, 19, 21, and 22 were present in all 24 plant channels and generally had the highest spot intensities.

In the butterflies, four spots had a $PO < 0.50$ (Nos. 3, 9, 10, and 14) leaving 11 as diagnostic. Only two spots had an $R_d > 1.0$ (13%, spots 15 and 16), while the remaining spots (87%) were below digitoxin. The butterflies only stored cardenolides within the lowest 55% of the R_d range of cardenolides pres-

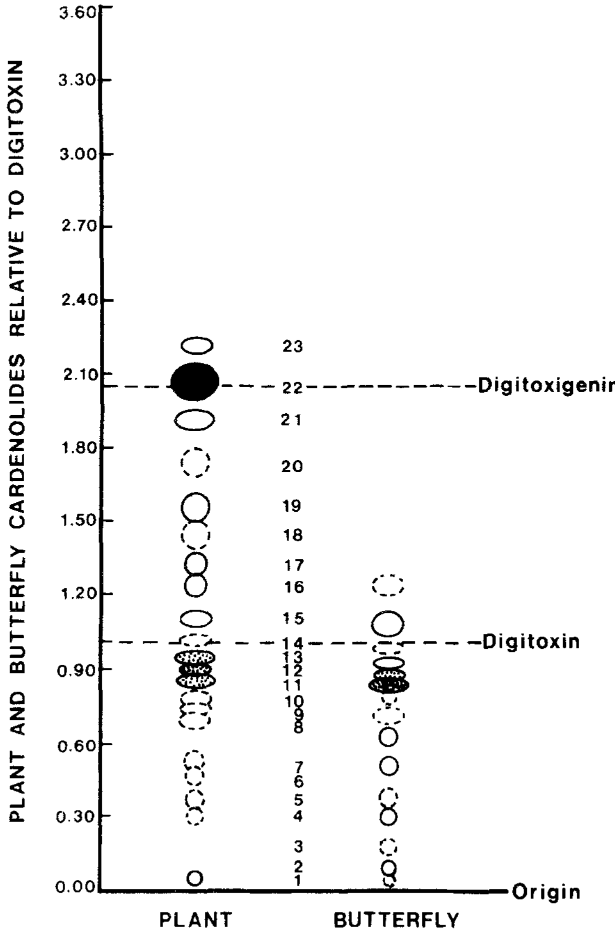

FIG. 5 The mean cardenolide profiles for 24 monarch butterflies and their individual *Asclepias viridis* host-plants based on the chloroform-methanol-formamide TLC system. Shown are the mean $R_{\text{digitoxin}}$ and spot intensity values for 21 plant and 15 butterfly cardenolide spots. Spot intensities are represented as follows: 1.00 < 1.25, dotted circle; 1.25 < 2.00 closed circle; 2.00 < 3.00, light stipple; 3.00 < 4.00, dark stipple; 4.00-5.00, black circle. The mean $R_{\text{digitoxin}}$ value for digitoxigenin was 2.05.

ent in the plants. Only spots 7, 11, and 12 were observed in all 24 butterflies, although several spots (Nos. 2, 4, 5, 8, 15, and 16) were present in 83–96% of the samples. Butterfly spots 1, 4, 5, 7, 8, and 11, all with an $R_d < 0.85$, have significantly greater mean SIs than do their corresponding plant spots, while butterfly spots 13, 15, and 16, with an $R_d > 0.90$, have significantly lower mean SIs than their corresponding plant spots. In addition, spots 2 and 3

are present only in the butterflies. These data indicate sequestration is greater for cardenolides represented by spots below an R_d value of approximately 0.85.

Several regression analyses were run to determine the dependence of butterfly R_ds and SIs on the corresponding plant R_ds. Because of the low *PO*s of several of the 16 spots in common, only 133 of a possible 384 (24 plant–butterfly pairs × 16) spot-pairs were present and used in this analysis. Our initial regression model examined the dependency of the butterfly R_ds on the plant R_ds alone. As expected, we found a high degree of correlation ($F = 17138$, $P < 0.0001$; $r^2 = 0.992$). This near one-to-one relationship of the paired plant–butterfly R_d values is indicated by the predicted regression equation $Y = 0.9784x + 0.0011$.

A problem arose in our analysis because of plate to plate variation in the R_d values and because the sexes (with one exception) were separated onto different plates. Statistics from a multiple regression model including both sex and plate effects as independent covariates with the plant R_ds could be misleading due to the production of singular matrices and to problems of interpretation resulting from the high degree of overlap in the variation. We ran several preliminary regressions, therefore, to determine the individual and additive effects of sex and plate number on the dependence of the butterfly R_ds on the plant R_ds. The addition of sex only to the model did not significantly increase the correlation ($F = 2.04$, $P < 0.156$), whereas the addition of plate only did ($F = 3.97$, $P < 0.010$), suggesting that any differences attributable to sex are too small to be separated from the effects of plate-to-plate variation.

For the above reasons, our second regression model contained only the effects of the plant R_ds, the plate number, and their interaction. Using type II SS statistics, the only significant predictors of the butterfly R_ds in this model are the plant R_ds ($F = 17160$, $P < 0.001$) since both plate and their interaction are insignificant ($P < 0.87$ and 0.67, respectively). Duncan's option indicated that plate 2 (all females) and plate 3 (all males) were not significantly different while plate 1 (five males and 1 female) and plate 4 (all females) were each significantly different from the other three plates. The experimental variable created by differential migration rates on the plates for separate TLC runs is difficult to control, but fortunately, although statistically significant, its magnitude is not great. In subsequent studies we strongly suggest that both sexes be run on each plate so that the differences attributable to sex and plates can be separated more clearly.

Similar regression analyses were run for the spot intensities without the difficulty of plate-to-plate variation found with the R_d values. Again, our initial regression model examined the dependency of the butterfly SIs on the plant SIs alone. This regression indicated a significant correlation ($F = 65.37$, $P < 0.0001$; $r^2 = 0.333$) and produced the equation for the line $Y = 0.7767x + 0.49$. In preliminary regression models neither sex ($F = 0.30$, $P < 0.5834$; $R^2 = 0.334$) nor plate ($F = 0.52$, $P < 0.6760$; $R^2 = 0.341$) contributed signifi-

cantly to the model. To remain consistent with our treatment of the R_d values, our second regression contained only the effects of the plant SIs, the plate number, and their interaction. Again, only the plant SIs contributed significantly to the model ($F = 57.82$, $P < 0.0001$), and the R^2 (0.352) was only slightly greater than the r^2 (0.333) of the effect of the plant SIs alone. Duncan's option indicated that plate 3 (all males) had a significantly lower mean SI than plate 4 (all females) but that none of the other plates or their combinations were significantly different.

DISCUSSION

General Field Observations during Sample Collections. For those monarch butterflies returning to temperate North America through Texas and Louisiana from their overwintering sites in Michoacan, Mexico, *Asclepias viridis* and the more narrowly distributed *A. asperula* subsp. *capricornu* (Woods.) Woods. probably represent the first abundant and widespread milkweed they encounter. It is likely, therefore, that a large number if not the majority of second-generation monarchs that continue the summer reproductive cycle of the monarch utilize these two species as their larval food plant. In western and central Florida, *A. viridis* is more localized and Brower (1961, 1962) and Cohen and Brower (1982) report that *A. humistrata* Walt. is more heavily utilized by the incoming monarchs. Both *A. viridis* and *A. humistrata* occur in Mississippi and Alabama, although the former species becomes increasingly more widespread and prevalent from western Florida to eastern Louisiana.

Other milkweed species in our region are either less common (e.g., *A. amplexicaulis* Sm., *A. longifolia* Michx., *A. michauxii* Dcne., *A. variegata* L.) or do not begin their development until after most migratory monarchs have passed northward (e.g., *A. tuberosa* L., *A. viridiflora* Raf., *A. perennis* Walt.). Lynch, Martin, and Riley (unpublished data) have observed large instar larvae on *A. amplexicaulis*, *A. longifolia*, and *A. viridiflora*, but have not observed successful feeding by monarchs on other species in Louisiana or eastern Texas.

In our area the first monarchs arrive in late March and numerous instars may be found on *A. viridis* by early April. First-, second-, and early third-instar larvae usually feed on floral parts, remaining hidden in the more compact preanthesis inflorescences. Later instar larvae usually feed on the leaves. We suggest that positional feeding preferences may be related to avoidance of predation and parasitism by other arthropods. Spiders, ants, and tachinid flies were observed to take a heavy toll of small larvae, and only a small percentage reached the fourth and fifth instar stages (Lynch and Martin, manuscript in preparation). Cohen and Brower (1982, and personal communication) report similarly low survivorships by monarchs feeding on Florida milkweeds.

By removing crab spiders from the plants and bagging only first- and second-instar larvae, spider predation was virtually eliminated and tachinid para-

sitism was rare. Ant predation, however, continued to be a problem. Bagging provided the further advantage of knowing without question that larvae ate only on the individual plants from which they were collected. In contrast to western U.S. monarchs which nearly always form their chrysalids upon their host plant (Brower et al., 1982, 1984a,b), no chrysalids were found on unbagged plants. Even bagged monarchs tended to spin their pads on the nylon net bags rather than on the leaves of the plant. By carefully selecting larvae from widely spaced plants where extensive feeding was apparent, we are confident that even unbagged plant–butterfly pairs were true to our pairwise analyses.

Quantitative Variation of Plant and Butterfly Cardenolides. Wide variation occurred in the cardenolide concentrations of both *A. viridis* plants and their respective butterflies. The positive logarithmic relationship we observed between individual plant and butterfly concentrations (Figure 3) is consistent with the observations of Seiber et al. (1980) that monarchs sequester cardenolides more efficiently when present in low concentrations, with uptake generally conforming to an inverse logarithmic relationship with increasing concentrations. Duffey et al. (1978) have suggested that cardenolides in *Oncopeltus*, a common milkweed bug, are sequestered in the dorsolateral spaces through a physical process involving a high concentration of nonpolar emulsion-phase droplets dispersed in the aqueous space fluid and that the amount sequestered is proportional to free hemolymph concentrations.

While the mechanisms for cardenolide uptake in monarchs are unknown, patterns of cardenolide uptake observed in all monarch–milkweed pairwise analyses to data could fit a physical uptake model. In the 60 *A. viridis* butterflies examined, both the mean (337 μg/0.1 g) and the range of cardenolide concentrations (73–591 μg) were greater than those in their host plants (245 μg/0.1 g and 95–432 μg). Similar patterns were found by Brower et al. (1984a,b) in *A. californica* and *A. speciosa* butterfly–plant pairs. Both species have a lower mean cardenolide concentration than *A. viridis*. However, in *A. eriocarpa*, a species with a significantly higher cardenolide content, the butterflies had a lower mean concentration (318 μg/0.1 g) and a narrower concentration range (136–606 μg) than their host plants (421 μg/0.1 g and 102–919 μg) (Brower et al., 1982). If host-plant concentrations approach or exceed the physical limits of uptake by the butterflies, mean concentrations and variation may be largely restricted by relatively fixed physical limitations on cardenolide absorption. Variation in relatively low host-plant concentrations, however, would compound any other individual variations present. The overall result would be a narrower range of cardenolide concentrations in monarchs than in their host milkweeds since rapid uptake would occur at low concentrations and uptake at high concentrations would be slowed.

The higher mean concentration of cardenolide we observed in female butterflies compared to male butterflies reared on *A. viridis* has also been demonstrated in butterflies reared on several other *Asclepias* species (Brower and Gla-

zier, 1975; Brower et al., 1975, 1982, 1984b) and in wild-caught adults from summer breeding populations in the eastern United States (Brower et al., 1972, Brower and Moffitt, 1974). The higher mean concentrations in female monarchs may simply reflect differences in the reproductive morphology between males and females. Brower (1984) cites work of Thomashow (unpublished) in which cardenolides were found in all life stages of monarchs reared on *A. curassavica*. Of particular interest, eggs were found to contain higher levels of cardenolide (0.6% by dry weight) than adults (0.4%). Since a female may lay as many as 100 (Erickson, 1973) to 400 eggs (Urquhart, 1960), as much as 97–388 μg of cardenolide could be present in the female reproductive tract. In the laboratory, Dixon et al. (1978) found that monarch females that had laid all their eggs were less emetic to pigeons than freshly eclosed females.

The female butterflies, while lighter than the males, also fed on plants containing a greater mean cardenolide concentration. The regression analyses showed that while there was a significant negative correlation between butterfly dry weight and concentration, when the plant concentrations and sex were added, neither the model nor any interactions were significant. No evidence, therefore, is provided by the dry weight data for a metabolic cost for either cardenolide ingestion or storage.

Qualitative Analyses of Plant and Butterfly Cardenolides. Comparisons were made of TLC R_f values of *A. viridis* cardenolides in both the CMF and EM solvent systems with desglucosyrioside, labriformin, and labriformidin standards run in our laboratory and with values published in Seiber et al. (1983) for 30 *Asclepias* cardenolides and reference standards. The coincidence of R_f values strongly indicates that spots 10 and 14 in the CMF system are calotropagenin and calotropin, respectively. Calactin may also be present at spot 14. Spots 19, 20, 21, and 22 appear to be uscharin, uscharidin, uzarigenin, and vorusharin, respectively, although only uscharidin is well confirmed in the EM system. All these cardenolides are members of a series derived from the genin calotropagenin (Bruschweiler et al., 1969; Seiber et al., 1983, 1984). Marty and Krieger (1984) and Brower et al. (1984b) cite evidence that calactin and calotropin are the principle cardenolides stored when monarchs feed on plants containing calotropagenin glycosides and that the 3′-keto glycoside uscharidin and its 3′-spiro derivatives uscharin and vorushcarin are not stored by monarchs but are metabolized by feeding larvae to the isomeric 3′-OH derivatives calactin and calotropin. Spot 15 appears to be desglucosyrioside, a 3′-OH derivative of the epoxy cardenolides labriformidin and labriformin known to occur in *A. labriformis* and *A. eriocarpa* of the *Asclepias* series roseae (Brower et al., 1982). Neither labriformin nor labriformidin were detected in either the CMF or EM systems.

Although unique, the general TLC patterns of *A. viridis* plant and butterfly cardenolides conform to those observed by Brower et al. (1982, 1984a,b) with *A. eriocarpa*, *A. speciosa*, and *A. californica*. Since larval metabolites are more

polar than their parent cardenolides, monarch profiles are distinct from the plants, favoring cardenolides with lower R_f values. The more polar metabolites desglucosyrioside, calactin, and calotropin, along with other low R_f cardenolides, produce the cardenolide profile of freshly emerged adults. While the general storage pattern appears consistent for those milkweed species examined so far and while the calotropagenin series occurs in several other species of *Asclepias*, and in *Calotropis*, *Gomphocarpus*, and *Pergularia* as well, similarities in certain cardenolides or even entire series do not preclude the possiblity of distinguishing among cardenolide patterns for butterflies reared on different milkweeds.

If remigrating monarch do, in fact, oviposit predominately on *A. viridis* as they reenter the temperate United States through Louisiana and Texas, the majority of late spring and early summer breeding monarchs seen in the northern midwestern and central United States would possess the *A. viridis* TLC profile. As additional monarch–milkweed pairwise analyses are completed, fingerprints of individuals from the spring and summer breeding populations can be compared with those from fall emigrating and Mexican overwintering populations with increasing accuracy, providing key data to our understanding of the monarch butterfly's remarkable life history. Determinations of the structural identity of individual cardenolides will further clarify ecological predictions based on these TLC profiles and may provide valuable insight into the infrageneric relationships of the more than 108 North American species of *Asclepias*.

Acknowledgments—We are grateful to Jerry Leglue, John Hull, Laura Clark, Linda Clark, and Mary Lowery for their assistance in the field and in the laboratory. We also thank Dr. James Hubbard and Lee Bairnsfather for their assistance in the statistical analyses. Dr. Lincoln P. Brower has been particularly helpful in overcoming technical problems in the laboratory and in manuscript preparation, and Dr. James Seiber generously provided us with cardenolide standards. This research has been supported by the American Heart Association, Louisiana, Inc., and by LSU Shreveport Faculty Research Grants.

(Received June 27, 1985; accepted January 13, 1986)

Abstract—The qualitative and quantitative composition of the principal lipid constituents of Siberian musk deer (*Moschus moschiferus*) preputial gland secretion, main odor carriers and potential precursors of odorous substances, was investigated by means of high-performance liquid chromatography. Free fatty acids and phenols (10%), waxes (38%), and steroids (38%) were found to be the main groups of the secretion lipids. Cholestanol (I), cholesterol (II), androsterone (III), Δ^4-3α-hydroxy-17-ketoandrostene (IV), 5β, 3α-hydroxy-17-ketoandrostane (V), 5α, 3β, 17α-dihydroxyandrostane (VI), 5β, 3α, 17β-dihydroxyandrostane (VII), and 5β, 3α, 17α-dihydroxyandrostane (VIII) were isolated from the steroid fraction and their structures confirmed by IR, PMR, and mass spectra. 3-Methylpentadecanone (muscone) was not identified among the secretion lipids. Preputial gland secretion stimulated sex behavior of musk deer females.

Key Words—Musk deer, *Moschus moschiferus,* preputial gland, chemical composition, secretion, androgens, odor, androsterone, steroids, muscone, pheromone.

INTRODUCTION

The musk deer (*Moschus moschiferus*) has a preputial gland, which is found only in sexually mature males. Its secretion has a specific musk odor, and therefore the secretion's chemical constituents can be involved in chemical communication, encoding at least the information about sex and maturity. Earlier,

muscone (macrocyclic ketone, the principal odoriferous component of musk deer) (Ruzicka, 1926), a host of macrocyclic molecules (Mookherjee and Ledig, 1970), waxes and steroids (Do et al., 1975), muscopyridine (Schinz et al., 1946), and hydroxymuscopyridines (Yu and Das, 1983) were identified as components of preputial gland secretion. Muscone is claimed to be the sexual attractant for musk deer females (Mookherjee and Wilson, 1982).

The solving of chemical ecology problems for every species requires knowledge of the qualitative and quantitative composition of the compounds excreted by an animal, and their informative significance. The musk pouch composition of Siberia-dwelling musk deer has not been so far investigated by means of standard analytical techniques, and whether it is similar to that of other populations or species, and if so, to what extent, is not yet clear. Such knowledge would contribute to elucidation of the taxonomic status of the species under study and of related species. Furthermore, the standardized and quantitative analysis of skin gland secretions will be of importance in estimating the effect of chemical substances on animal interrelations.

To investigate the qualitative and quantitative composition of the main lipids (present at concentrations more than 0.5%) from preputial gland secretion, we employed high-performance liquid chromatography (HPLC), the structure of compounds isolated being confirmed by their infrared (IR), proton magnetic resonance (PMR), and mass spectral data and by comparison of the physicochemical properties with the authentic samples.

METHODS AND MATERIALS

Biological Material. The samples of the musk pouches were obtained from the animals from the area southeast of the Baykal Lake, in Siberia. This population geographically and taxonomically should be defined as *Moschus moschiferus*. The specimens from 18 individuals were obtained in the period from October to February (1979–1980), which coincided with the rutting season. The musk pouches were removed from killed animals and then air-dried by a standard method, i.e., it was exposed to open air temperatures, not exceeding 40°C, during one week. The largest pouches were obtained from adult musk deer (older than 2 years), whose preputial glands are developed to a much greater extent than those of younger sexually mature animals.

Behavioral Observations. The behavioral observations were carried out with 10 breeding musk deer females, kept in open air cages, Moscow Region, between 1976 and 1984. Five individuals were captured in Siberia, and five were born in captivity.

Chemicals. Solvents used in extraction and HPLC were of reaction grade and distilled before use. The samples of free fatty acids, their methyl esters and *p*-, *m*- and *o*-cresols were obtained from Chem. Service (West Chester, Pennsylvania). The samples of I–III, V, VII, and Δ^4-3, 17-diketoandrostene were

purchased by Sigma Chemical Company (St. Louis, Missouri). The sample of rac-muscone was the gift of Dr. G. Ohloff (Firmenich SA, Geneva Switzerland).

Instrumentation. Analytical gas chromatography (GC) was performed with a Pye Unicam 104 gas chromatograph (FID) using a 2.1-m × 4-mm glass column with 3% SE-30. Gas chromatograms of methyl esters of fatty acids were obtained at isothermal conditions (205°) or temperature programming: 110° (10 min), 10°/min to 230°; chromatograms of the alcohol fraction (after waxes fraction saponification) were obtained at isothermal (214°) or programmed [85° (5 min), 10°/min to 230°] conditions.

Analytical HPLC was carried out using a DuPont 8800 multisolvent liquid chromatograph equipped with a high-sensitivity refractive index (RI) detector (Erma Optical Works, Japan, model ERC-7510), two solvent degassers (ERC-3320, Erma Optical Works), UV spectrophotometric detector (DuPont) and a 3380A reporting integrator (Hewlett Packard; the accuracy of integrating was approximately 5%). It was necessary to install the additional home-made magnetic mixing chamber (volume about 6 ml) on the high-pressure line of the chromatographic pump in order to provide stability of the RI detector at the highest sensitivities. DuPont packed analytical columns (Zorbax Sil and Zorbax ODS, 0.46 × 25 cm) were used for normal and reversed-phase HPLC.

Preparative HPLC was performed using a DuPont 830 preparative liquid chromatograph equipped with a Chrompack-packed preparative column (2.24 × 25 cm, containing Lichrosorb SI 60, 7 mkm) and DuPont RI detector (a Nupro needle valve was employed to divide the flow in a ratio of approximately 1:20; the smaller part of the flow was directed to RI detector).

Mass spectrometry was carried out using an LKB 9000 instrument (70 eV). IR spectra were measured on a Beckman Acculab VI spectrophotometer (5% carbon tetrachloride solutions). PMR spectra were obtained using a Brucker 250 MHz spectrometer ($CDCl_3$, tetramethylsilane internal standard).

Mobile Phases for HPLC. The mobile phases were: normal phase preparative HPLC, hexane–ethyl acetate, 6:4; normal phase analytical HPLC, hexane–chloroform, 1:3 (A), hexane–ethyl acetate, 4:6 (B); reversed-phase analytical HPLC, isopropanol–acetonitrile, 1:1 (C), methanol–acetonitrile–water, 4:3:3 (D).

Extraction of Secretion Lipids. The preputial gland secretion from five animals (dark-red substance, 60 g) was extracted with 0.5 liters of diethyl ether in a Soxhlet apparatus, solvent was removed in vacuo, residue (red oil having a distinctive odor, 10% of secretion weight) was dissolved in 150 ml of ether, and an equal amount of 0.3 M NaOH solution added. From the organic layer, the fraction of neutral compounds was obtained, and from water solution, after acidification to pH 2 and ethyl acetate extraction, the fraction of free fatty acids and phenolic compounds (10% of extract weight) was isolated.

Separation of Fraction of Neutral Compounds. This fraction, obtained in

the general extraction procedure and forming ~90% of the extract weight, was applied to the conventional column with 60 g of silica gel, elution with a mixture of hexane–ether (95:5) followed by ether gave a waxy fraction (38% of the extract weight) and a fraction of steroids (38%).

RESULTS

Analysis of Free Fatty Acids and Phenolic Compounds Fraction. The composition of this fraction was analyzed by GC of the methyl esters (after CH_2N_2 treatment). Aliphatic acids C_{10}–C_{24} (C_{16}–C_{24} predominating) and phenylacetic acid were found to be the main constituents of the "acidic" fraction.

Using an Zorbax Sil HPLC column, operated in analytical and semipreparative mode, *p*-cresol was isolated and identified in the secretion extract (mobile phase A, pressure 68 bar, flow 1 ml/min, UV (254 nm) detector, retention time was 6.3 min, and coincided with authentic sample (separation factor for *p*- and *m*-cresols was 1.048) (Schabron et al., 1979). The content of *p*-cresol in the secretion extract was 0.5%.

Analysis of Waxes Fraction. Waxes were saponified with methanolic alkali (Kates, 1972), and the reaction mixture was treated with hexane. From the organic layer, the fraction of the alcohols was obtained, and from the water–methanolic solution, the fraction of acids. Aliphatic alcohols C_{14}–C_{18} (unsaturated and iso-compounds predominating) and cholesterol were identified by GC and HPLC in the alcohols fraction, and fatty acids C_{10}–C_{24} (C_{16}–C_{24} predominating) in the acids fraction.

Investigation of Steroid Fraction. The fraction of steroid compounds was separated using a preparative HPLC on a Lichrosorb SI 60 column (Figure 1). The mixture of unresolved V and VI was subjected to the additional separation by reversed-phase HPLC (semipreparative mode, up to 10 mg of the mixture) on a Zorbax ODS column (mobile phase D, see Table 1). The following steroids were found to present in the preputial gland secretion (homogeneity of the individual components confirmed by normal and reversed-phase analytical HPLC, retention data given in Table 1, PMR data and melting points in Table 2):

For compounds I–III, V, and VII (Scheme 1), IR, mass spectra, and retention in HPLC were identical to those of the authentic samples.

For compound IV, IR: 3520(OH), 1740(C=O), 1650(C=C), 1080(O—CC=C) cm^{-1}; mass spectrum: 288(M^+, 0.8%), 270(M^+—H_2O, 0.25), 234(0.5), 218(0.9), 149(1.2), 120(1.8), 119(1.6), 118(1.9), 117(1.1), 105(4.4), 87(10.3), 86(3.8), 85(64.9), 84(4.3), 83(100).

For compound VI, IR: 3500–3200(OH), 1040(C—O) cm^{-1}; mass spectrum: 292(M^+, 20%), 277(8), 274(10), 259(9), 233(18), 215(22), 201(6), 185(6), 174(10), 166(19), 165(18), 157(14), 155(13), 149(37), 148(24), 147(18), 133(14), 131(15), 122(16), 121(21), 120(23), 119(22), 118(21),

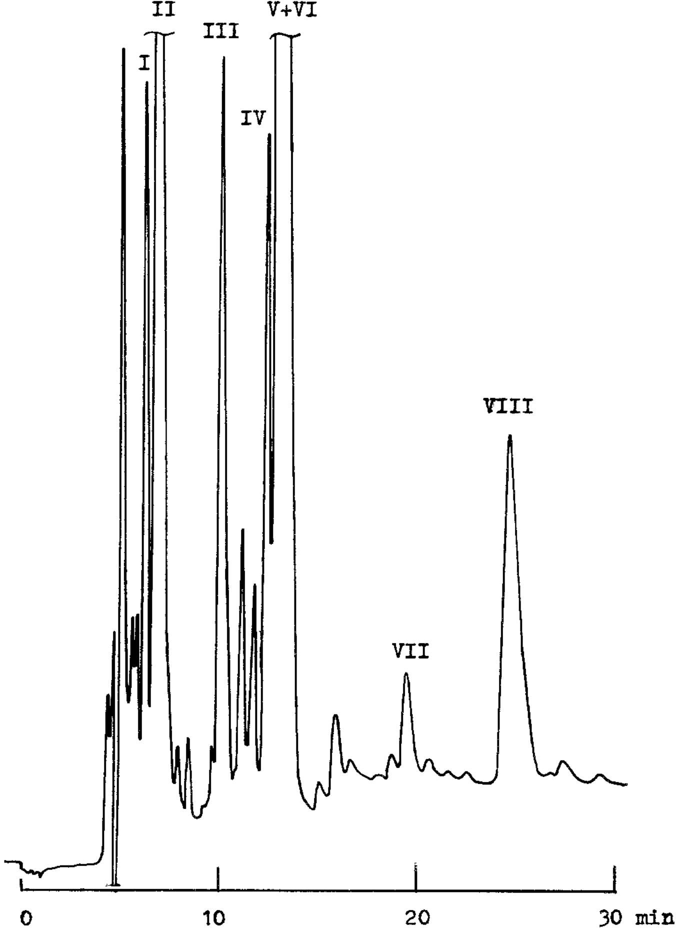

FIG. 1. Preparative HPLC separation of the steroid fraction. Pressure 55 bar, flow rate 25 ml/min, RI detector (attenuation 2×10^{-3} RI units/full scale). Sample: 300 mg.

117(22), 108(17), 107(25), 105(22), 95(23), 93(22), 87(31), 86(24), 85(72), 84(52), 83(100).

For compound VII, IR: 3500–3200(OH), 1040(C—O) cm^{-1}; mass spectrum: 292(M^+, 7%), 274($M^+ - H_2O$, 0.9), 256(87), 241(47), 230(40), 215(100), 149(40), 147(40), 95(60), 93(60), 81(73); diacetate 380(M^+).

3-Methylpentadecanone (Muscone). All attempts to reveal the presence of muscone in secretion lipids (detection limit was ~0.05%) failed.

Other components of the secretion lipids (their content is less than 0.5%) remained unidentified. The composition of secretion constituents, which can be distilled in vacuo, is being investigated at the present time.

DISCUSSION

The preputial musk gland is located in the abdominal region near the penis, and its duct opens near the urethra (Sokolov, 1982). According to our observations, by the time the gland becomes active (10–18 months), young musk deer have attained sexual maturity, and the secretion structure changes. The amount of secretion increases, moisture content decreases, and a specific musk odor appears, detectable as early as in 5-month-old males. It has recently been found that musk secretion is androgen-dependent: testosterone administration induces an increase of musk secretion up to 114% (Wang and Huang, 1980). As previously believed, the biological significance of the gland secretion is to attract the females to males during the rutting season, to mark territory (Cherkasov, 1884; Flerov, 1952; Tarasov, 1960) and also to mark covered females (Shaposhnikov, 1956).

Observations of musk deer females olfactory behavior showed that before and during the rutting season (October–March) all mature females (in contrast to males) react to the preputial gland secretion, left in marking the female's territory, by showing specific reactions: nondirectional, fast, and prolonged running behavior, which testifies to the strong excitement of the animal. From two to three weeks before the rutting season, the females, when contacting with male, sniffed the preputial gland region. Before this prerutting period the male, approaching the female closer than 6–7 m, induces an aggressive behavior. Thus, the odor of preputial gland secretion and male urine (which normally

acquires a musk smell during rutting) probably reduces the aggressive reaction of females and stimulates sexual behavior.

The first stage of our study of the possible role of secretion chemicals in musk deer ecology and ethology consisted in the investigation of the secretion main lipids (down to 0.5%) by means of modern preparative and analytical methods of isolation and identification of the chemical structure. Simple lipids constitute the bulk of odoriferous compounds, and lipid components of other types may serve as potential precusors of those compounds.

The secretion of the preputial gland was extracted by ether to isolate the great bulk of odoriferous components. Free fatty acids and phenolics were separated by alkaline solution treatment and, after rapid conventional silica gel chromatography and preparative HPLC, the qualitative and quantitative composition of lipid extract was determined.

It was found that waxes, esters of cholesterol, and aliphatic long-chain alcohols and fatty acids account for the 38% of the extract weight, a value by far greater than the one previously reported for Nepal musk deer (17%, Do et al., 1975). The waxes can serve as inert material, prolonging the action of odoriferous components, and also as the source of free fatty acids (for example, in bacterial transformation), as indicated by the similar composition of free and bound (in waxes) fatty acids.

Steroid compounds are the second large group of secretion lipid components (38%), which agrees with previously reported data (46%, Do et al., 1975). These are cholestanol, cholesterol, and a number of the androstane derivatives. It was the most complicated part of our research to isolate, purify, and identify the components from this group. Various modes of HPLC, widely employed recently in chemistry, biology, and medicine, were used in this study. Normal-phase analytical HPLC conditions of the steroid fraction (Table 1, Zorbax Sil column) were adjusted for the preparative HPLC. Complete separation was achieved, however, only after reversed-phase HPLC. A number of reversed phase HPLC methods were developed recently to separate androgens (Sunde and Lindmo, 1982; Lin and Heftmann, 1982). We used the triple mixture of methanol, acetonitrile, and water in HPLC on Zorbax ODS column (Table 1) to verify the homogeneity of components, isolated by preparative HPLC and/or to separate by semipreparative HPLC the mixture of compounds which could not be separated with an adsorption HPLC. Isolated compounds were characterized by their spectral data and by direct comparison of chromatographic retention on HPLC along with the authentic samples available.

The composition of lipids from the Siberian musk deer preputial gland secretion only partially coincides with data reported by Do et al. (1975) (see Table 3). The waxes, steroids, and muscone account for 86% of secretion extract for Nepal musk deer, whereas waxes and steroids from the Siberian musk deer constitute 76% and muscone is totally absent. Of the steroids, both Nepal

and Siberian musk deer contain, in amounts greater than 0.5%, II, III, and V–VIII. We failed to reveal the presence of 5α- and 5β,3,17-diketoandrostanes, Δ^4-3,17-diketoandrostene, $\Delta^{4,6}$-3,17-diketoandrostadiene, and Δ^5-3β-hydroxy-17-ketoandrostene at concentrations reported for Nepal musk deer. Compounds I and IV have not been described by Do et al. (1975).

The structure of IV was established as follows. The molecular weight was determined to be 288 (mass spectrum). From IR and PMR data the presence of one hydroxyl (3520 cm^{-1}; δ 4.09, 1H), one carbonyl (1740 cm^{-1}; δ 2.28, 2H), and trisubstituted double bond (1650 cm^{-1}; δ 5.49, 1H, doublet, $J = 4.8$ Hz), adjacent to a methine proton, was deduced. The allylic arrangement of hydroxy group is shown by converting the signal from olefinic proton to a singlet and reducing the multiplicity of methine proton signal in double resonance experiments. Chemical shift and multiplicity of the signal from proton, geminal to the hydroxy group at C_3 (δ 4.09, $J = 2$–3 Hz), pointed to the equatorial position of this proton, and, correspondingly, to the 3α orientation of hydroxyl (this signal in PMR spectra of 3-hydroxy-steroids, having the equatorial hydroxy group, has δ 3.6 ppm) (see Table 2 and Williams and Bhacca, 1964). PMR

spectral data and the melting point value coincided with those reported previously (Paradisi et al., 1977). Oxidation of compound IV by pyridinium chlorochromate gave Δ^4-3, 17-diketoandrostene, identical to the authentic sample. In addition, successive treatment of *O*-tetrahydropyranyl-protected testosterone by lithium aluminum hydride, acetic anhydride, HCl, pyridinium chlorochromate, and methanolic alkali gave Δ^4-3β-hydroxy-17-ketoandrostene, which was not identical to IV in chromatographic mobility at HPLC.

It is not yet known which components of preputial gland secretion (separately and/or in combination) act as stimuli. It seems possible that monofunctional chemicals of medium molecular weight could be the candidates to mammalian pheromones, because their volatility allows them to reach olfactory receptors at above-threshold concentrations. From this point of view, free fatty acids, *p*-cresol, and other similar compounds could be pheromone components, and bifunctional steroids (present in the secretion at rather high concentrations) may perform the androgen functions and/or stimulate the accessory olfactory system. It is not clear, however, whether the concentration of bifunctional steroids (relatively polar molecules) in vapor phase over secretion is sufficient to excite the main olfactory receptors. Data concerning the odor of bi- and polyfunctional steroids and available at present, are not very reliable, because no special checks for purity or the absence of odoriferous impurities have been taken. Due to these considerations, we investigated the possibility of androsterone (III), one of the components of preputial gland secretion having an odor in humans, and we found that this compound really has a santal odor. It is known that Δ^{16}-5α, 3α-hydroxyandrostene, one of the boar pheromone components (Reed et al., 1974), causes two types of odor, urinous and santal, in humans (Ohloff et al., 1983).

The same sample of III was subjected to successive purification by normal and reversed phase HPLC, and the following mobile-phase fractions were investigated olfactorally by panelists sensitive to santal odor: the fraction before the peak, containing the peak, and after the peak of III. It was found that the only fractions having santal odor were those containing androsterone (III). The purification of androsterone carried out by means of such fundamentally different (from the chemical point of view) techniques as normal and reversed-phase HPLC, practically guarantees the absence of the impurities, which can distort the results of olfactory analysis. Thus, bifunctional steroids at normal conditions can be volatile enough to excite the olfactory receptors. We believe it possible that it is androsterone (III), having both the odor and androgenic activity, that is most likely the sex pheromone of musk deer males. The functional role of separate lipid components from preputial gland secretion and their combinations will be the subject of further research.

The difference in chemical composition of Siberian musk deer preputial gland secretion, found in our research and reported previously (Ruzicka, 1926; Mookherjee and Ledig, 1970 and, in particular, Do et al. 1975) (see Table 3),

cannot be explained by the different analytical techniques employed. Moreover, we carried out additional experiments to determine the presence of secretion components (i.e., muscone and Δ^5-3β-hydroxy-17-ketoandrostene) reported earlier. Most likely, these differences are due to dissimilarities in the taxonomy and ecology of the subjects. One of the latest manuals on mammalian taxonomy (Honachi et al., 1982) splits *Moschus* into four geographically separated species. Based on this manual, we studied the individuals of *Moschus moschiferus*, whereas the musk pouches, investigated by the South Korean group (Do et al., 1975), were obtained from Nepal musk deer, which should be assigned to *M. chrysogaster*. Thus the differences in the chemical composition of preputial gland secretion, at least in this case, are presumably interspecific. But, in spite of the inferences drawn from musk deer taxonomy, one should not exclude the possibility of some differences in chemical constituents of the secretion arising from the dissimilar ecology of the population under study (including feeding specialization). The knowledge of variability of mammalian gland secretions, including skin glands, is one of the still obscure and intriguing fields of chemical ecology.

Acknowledgments—The authors are grateful to Dr. G. Ohloff for a generous gift of muscone.

(Received July 15, 1985; accepted January 15, 1986)

Abstract—The number of western pine beetles, *Dendroctonus brevicomis*, trapped at the center of three 90 × 90-m plots was reduced during a 16-hr period after surrounding an attractive source of *exo*-brevicomin, frontalin, and myrcene with 16, 48, or 168 sources of the same attractant. Compounds were released from the center of the plot at 1 mg/16 hr/compound, and from the surrounding sources at 4–280 mg/16 hr/compound. About half of these amounts was released between 1530 hr and 1930 hr, the period of peak beetle flight. No treatment differences were apparent in reduction of catch within the range of release rates and spacings tested. When compounds were released continuously from 168 stations for 17 days, catch at the center of a plot was generally lower than catch before or after this period, but fluctuated daily. More beetles were caught on traps hung on ponderosa pines within a plot and the number of these traps catching beetles was greater when compounds were released from all stations than from only the center station. Beetles caught on traps were attracted into the plots from the surrounding forest, but appeared to be dispersed within the plot when compounds were released from many stations. *D. brevicomis* attacked at least 91 trees in the plots, of which 25 were killed during two summers.

Key Words—*Dendroctonus brevicomis*, Coleoptera, Scolytidae, bark beetle, western pine beetle, pheromone, interruption, behavior, release device.

INTRODUCTION

The response of the western pine beetle *Dendroctonus brevicomis* LeConte to the attractive mixture of racemic *exo*-brevicomin (E), racemic frontalin (F), and myrcene (M) and to an attractive bolt cut from a tree being colonized by *D. brevicomis* was interrupted in 90 × 90-m plots by surrounding the source of attraction with 48 stations releasing EFM at 2 mg/24 hr/compound (Tilden et al., 1981). Beetles attracted from the surrounding forest, however, attacked and killed trees in the plots. Richerson et al. (1980) disrupted mass attack of host trees by the southern pine beetle *D. frontalis* Zimmerman by baiting other trees previously killed by the beetle with the attractive mixture of frontalin and alpha-pinene. The effects of varying the attractant release rate or the spacing between release devices were not examined in these studies.

The orientation of male moths to female moths in agricultural fields was interrupted by permeating the air with a synthetic pheromone (Shorey et al., 1972) or an attractive compound (McLaughlin et al., 1972) at several release rates and spacings. Shorey et al. (1972) speculated that the amount of pheromone released was more important than the distribution of release points in disrupting male orientation.

The tests described below were performed to see if aggregation of *D. brevicomis* at a single source of attractant could be interrupted by surrounding it with other sources of attractant released at several rates from variously spaced release devices. This design was based on our assumption that lowered catch at a single trap might be indicative of a treatment's potential to interrupt aggregation at trees in large plots. We anticipated that beetles attracted from the surrounding forest might attack and kill trees in our small plots (Tilden et al., 1981). We also assumed, however, that such tree mortality might not occur in large plots because beetles would be dispersed rather than concentrated, the treatment would be released over a period of many days instead of a few hours, and edges of large plots would be away from host trees.

METHODS AND MATERIALS

The tests were performed during August and September 1974 and July to October 1975, near Bass Lake and Cedar Valley, Madera County, California (1100–1300 m elevation). Each year, three 90 × 90-m plots (Tilden et al., 1981) at least 3.2 km apart were installed in stands of ponderosa pine, *Pinus ponderosa* Dougl. ex Laws., where similar numbers of *D. brevicomis* were caught at traps baited with EFM during a three-week period preceding the tests. No trees under attack or with emerging brood were within 200 m of the plots. Two plots were in the same locations both years; the third plot was in a different location each year.

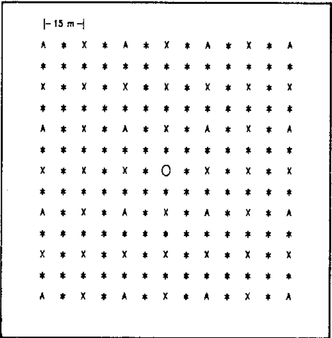

FIG. 1. Plot in which *exo*-brevicomin, frontalin, and myrcene were released at three spacings surrounding a source of the same compounds released at the plot center (0). A = 16 release stations 30 m apart; A and X = 48 release stations 15 m apart; A, X, and * = 168 release stations 7.5 m apart.

Each plot consisted of 168 pheromone release stations 7.5 m apart surrounding a center station (Figure 1). The EFM mixture was released from the center station inside a cylindrical hardware-cloth sticky trap placed 1.5 m above ground on a steel pipe (Bedard and Browne, 1969). The compounds evaporated at about 1 mg/16 hr/compound from glass tubes inside an inverted glass salt shaker covered with aluminum foil (Tilden et al., 1981). EFM attractant was also released at some or all of the remaining 168 stations from devices attached to the top of wooden stakes, 1 cm × 4 cm × 1.5 m, in three grid patterns (Figure 1): 13 × 13 (168 stakes 7.5 m apart); 7 × 7 (48 stakes 15 m apart); and 4 × 4 (16 stakes 30 m apart). Total EFM attractant released from stations surrounding the center trap was divided among the number of stations in each test. When using fewer than 168 stations, release devices were attached to the 16 or 48 wooden stakes in nearly equal numbers.

Each plot plus an additional 15-m-wide strip around its perimeter was divided into 64 15 × 15-m blocks (Figure 1). One unbaited 30.5 × 61-cm hardware-cloth sticky trap was hung 1.5 m above ground on each of 64 ponderosa pines >25 cm DBH per plot to monitor *D. brevicomis* visitation. One tree from each 15 × 15-m block was chosen; but if a block had no trees, two or more trees from an adjacent block were chosen. All traps were coated with melted Stikem Special®.

Each test ran a sequence of two days per plot. EFM attractant was released from the center trap only on day 1 (control) and from the center trap plus surrounding stations on day 2 (treatment). No compounds were released in a plot on the next two days so that attracted beetles could disperse. This procedure was followed once per plot for each treatment, for a total of three replicates. We assumed that most variation in catch between day 1 and day 2 would be

due to the treatment, although daily catch at a source of attractant is variable (Bedard et al., 1980; Tilden et al., 1983). Interaction could also occur between days. Beetles caught on day 1 could not be caught on day 2, or beetles attracted and not caught on day 1 would be available to be caught on day 2. We felt that a single source of attractant (control) on the day preceding treatment would introduce less bias than if treatment preceded control.

Compounds were released in a plot for about 16 hr, from 1530 hr of one day until 0730 hr the next morning, but most beetle flight occurred during the afternoon and early evening. A treatment was presented in only one of the three plots each day to minimize the number of release devices needed. *D. brevicomis* were picked from all traps every morning, after removing compounds from the plots, and placed in labeled vials of solvent (Chevron-325®) for later counting. Also, every ponderosa pine in and within 30 m of the plots was examined for signs of attack by *D. brevicomis*.

We planned to release the compounds at three rates tenfold apart in 1974 and at two rates tenfold apart in 1975. Tests were randomly assigned to plots and days. In 1974, however, the 1× and 10× treatments were completed before the 100× treatments were begun because we felt that trees would most likely be attacked during the latter treatments.

Three types of devices were used to release EFM from the stations surrounding the center trap (Table 1). One device was made from 1-μl glass pipets (Drummond Microcaps®) 32 mm long × 0.20 mm ID, filled to about half their capacity. Pipets containing E had both ends open; those containing F had one end flame-sealed. Pipets containing M initially had both ends open, but were later flame-sealed at one end because of excessive loss of material. Two pipets each of E and F and one (both ends open) or two (one end sealed) of M were attached to a small card with a piece of transparent tape and laid horizontally inside the lid of a perforated aluminum tea ball 5 cm maximum diam. × 6 cm high to provide protection from sun and wind. The small chain and hook normally attached to the lid of the tea ball was attached instead to the apex of its

TABLE 1. DEVICES USED TO RELEASE *exo*-BREVICOMIN, FRONTALIN, AND MYRCENE IN 90 × 90 m PLOTS FROM TREATMENT STATIONS[a]

[b] See text for description of devices.

body, so that it hung with the lid down from the top of a wooden stake. A total of 336 pipets of each compound or 168 of M with both ends open were used for the 1× rate in 1975.

The second device, a polyethylene capsule containing about 25 mg of compound, was made by plugging both ends of a 15-mm-long piece of 3.17 mm ID × 6.35 mm OD polyethylene tubing with a 5-mm-long piece of 3.17 mm diam. polyethylene rod. The ends of the capsule were heat-sealed to prevent leakage. The release rate was regulated by enclosing each capsule in a tightly fitting sleeve cut from thin-walled Teflon® tubing. Pheromone diffused through the polyethylene and evaporated from the surface of the capsule through one or two holes cut in the Teflon sleeve: for E, one 6-mm-diam. hole; for F, one 3-mm-diam. hole; and for M, two 6-mm-diam. holes diametrically opposed. One capsule of each compound was placed inside the lid of an aluminum tea ball. Sixteen capsules of each compound were used for the 1× rate in 1974; 168 capsules of each compound were used for the 10× rate in 1974 and 1975 (Table 1).

The third device, glass tubes placed inside an inverted salt shaker, was the same device which released EFM from the center trap. A total of 336 tubes of each compound were used for the 100× rate in 1974.

We measured daily pheromone loss from 10 treatment devices placed randomly in a plot, with no two devices at the same release station on the same day. These devices were marked for identification and were included in the total number of devices for each treatment. We also measured release rates of EFM from the glass tubes at the center of a plot. The amount of material lost from glass tubes and polyethylene capsules was measured gravimetrically. The amount of material lost from pipets was measured with a micrometer eyepiece in a microscope.

To estimate pheromone release rates during the period of peak beetle flight, the weight loss of EFM from polyethylene capsules and glass tubes was measured on four consecutive days in 1974 in an area separate from the test plots. One glass tube of each compound was in each of nine salt shakers, and two polyethylene capsules were in each of nine tea balls. Each release device was hung from the top of a 1.5-m-high wooden stake. Weight loss was measured daily after 4-hr exposure (1530–1930 hr, the period of greatest beetle flight) and after subsequent 12-hr exposure (1930–0730 hr).

Following the 16-hr tests in 1974, a long-term test was conducted in two of the plots. In each plot, EFM attractant was released continuously for 24 days from the trap at the plot center. Compounds evaporated from release devices—the glass tubes used in earlier tests—at about 2 mg/24 hr. From the fourth through twentieth days, EFM attractant was also released from the other 168 stations in each plot, from 1-μl glass pipets; two each of E and F, and four of M with one end sealed. This was essentially the 1× treatment used during the 16-hr tests. Pipets were removed from the 168 treatment stations on the morning

[a] *exo*-Brevicomin, frontalin, and myrcene released from plot center at ca. 1 mg/16 hr/compound.
[b] Bass Lake and Cedar Valley, Madera County, California, August 3 to September 25, 1974, and July 17 to August 10, 1975.
[c] One unbaited trap 1.5 m above ground on each of 64 trees per plot. Number in parentheses is number of trees on whch *D. brevicomis* were trapped.
[d] Planned relative release rate of *exo*-brevicomin, frontalin, myrcene per plot. See Table 3 for estimated release rates. Treatment released at stations which were 30 m apart (16 stations), 15 m apart (48 stations), or 7.5 m apart (168 stations).
[e] At least one tree with a trap was attacked by *D. brevicomis*.

of the twenty-first day. Each morning, we picked *D. brevicomis* from all traps and examined ponderosa pines in and near the plots for signs of attack.

Interruption of aggregation at the center trap was evaluated by comparing the number of beetles caught there when treatment was absent with the number caught when treatment was present. For the 16-hr tests, catch on the first day (treatment absent) was compared with catch on the second day (treatment pres-

ent). For the long-term test, catch on the first three and last four days was compared with catch on the fourth through twentieth days. We did not conduct formal statistical evaluations of the results, since the several factors—days, plots, and treatments—were confounded in the design, and the experiment was not extensive enough to incorporate adjustments for these factors into an analytical model. Trees attacked by beetles attracted into the plots were also a confounding factor.

RESULTS

For each pair of treatment and control days during the 16-hr tests, fewer *D. brevicomis* were caught on the trap at the plot center when it was surrounded by 16, 48, or 168 sources of attractant (day 2) than when it was not (day 1) (Table 2). The mean numbers of *D. brevicomis* caught at the center trap on control days (day 1) and on treatment days (day 2) were as follows (numbers in parentheses are standard deviation and number of days):

	1974	1975
Control	56.7 (48.3, 21)	97.0 (100.0, 18)
1×	11.0 (3.5, 3)	10.1 (7.8, 9)
10×	1.9 (1.4, 9)	1.8 (2.1, 9)
100×	1.4 (1.5, 9)	

More *D. brevicomis* were trapped on trees—in every case but two—when a treatment was in a plot than when it was not (Table 2). Beetles were trapped on more trees—in every case but one—when treatment was in a plot than when it was not (Table 2, numbers in parentheses). On days when one or more of the trees with traps were attacked by *D. brevicomis*, most of the trapped beetles were caught on these trees.

During the long-term test, August to September 1975, catch at the plot center fluctuated daily, but was generally lower during the 17 treatment days than on the three days before and four days after treatment in both plots (Figures 2 and 3). The mean number of *D. brevicomis* caught at the center trap on control and treatment days was as follows (standard deviation in parentheses):

	Plot A	Plot B
7 control days	41.0 (11.9)	31.7 (11.0)
17 treatment days	15.9 (8.7)	10.9 (9.1)

Total catch on the 64 trees with traps in each plot was low prior to treatment, then peaked during the middle of the treatment period. The number of *D. brevicomis* trapped on trees declined after treatment was removed in plot A

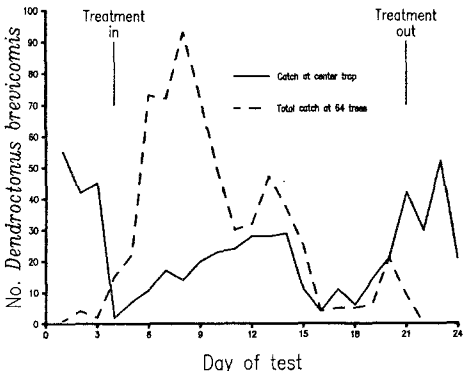

FIG. 2. Catch of *Dendroctonus brevicomis* at two types of traps in a 0.81-hectare plot in which *exo*-brevicomin, frontalin, and myrcene were released from a center trap for 24 days and from 168 treatment stations surrounding the center trap on days 4–20. Plot A, August 26 to September 18, 1975.

(Figure 2). None of these trees was successfully attacked. The number of *D. brevicomis* trapped on trees increased after treatment was removed in plot B (Figure 3), since one of these trees was successfully attacked by *D. brevicomis* and caught most of the beetles.

Several pines in the plots were attacked, and some were killed by *D. brevicomis* during the tests. A tree was counted as attacked if one or more pitch tubes were seen. A tree was counted as killed if subsequent examination revealed successful egg galleries and faded foliage. In 1974, 64 trees in the three

plots were attacked and 17 of these were killed. In 1975, during the 16-hr tests, 20 trees in the three plots were attacked and six of these were killed. During the long-term test, seven trees were attacked in the two plots and two of these were killed.

Results of the daily measurements of material lost from 10 devices exposed at treatment stations (Table 3) were used to estimate the total amounts of EFM that were released in a plot (Table 4). Release rates of compounds from these devices varied daily as much as 100%, and partitioning of variance components showed that most of this was probably due to variation in environmental conditions rather than individual devices. Tenfold differences in release rates between treatments were planned, but this succeeded only for the 1× and 10× treatments in 1974. About fivefold differences occurred between the 10× and 100× treatments in 1974 and between the 1× and 10× treatments in 1975 (Table 4). Results of the weight loss measurements made of the polyethylene capsules and glass tubes in an area separate from the plots (Table 5) indicated that about half the amount of EFM was released during the four-hour period (1530–1930 hr), corresponding to the period of greatest beetle flight.

DISCUSSION

We speculate that fewer *D. brevicomis* were caught at the center trap on days when treatment was present than when it was not because aggregation at

the center was interrupted by competing sources of attractant. Further study would be needed, however, to correlate reduction in catch at a baited trap with reduction in aggregation on trees low enough to protect them from mass attack. The greater catch at trees in a plot on treatment days—compared to nontreatment days—could be due to the increased level of pheromone attracting more beetles (Tilden et al., 1983) as well as the tendency for beetles to land on vertical silhouettes near sources of attractant (Bedard et al., unpublished observations). We have no measure of how many beetles may have landed on trees without traps or on portions of a tree not covered by the small trap.

During the one-day tests when attractants were released for 16 hr, beetles could disperse into the surrounding forest during the two-day hiatus in attractant release following treatment. Natural sources of attractant from trees under attack could, however, keep beetles in a plot and attract new beetles. During the long-term test, beetles probably did not disperse, and additional beetles could be attracted each day. In either case, with attractants released in a small area, beetles were concentrated instead of dispersed, which probably contributed to trees being attacked in the plots. This is a major problem in using a small plot to evaluate treatments to be applied over a large area. We also noticed that beetles sometimes bored into a tree behind the sticky trap, which may have increased the changes that the tree and neighboring trees would be successfully attacked and killed.

A lowered catch at the plot center occurred in our tests at total amounts of EFM of about 14–750 mg/16 hr/0.81 hectare (Table 4), which correspond to about 34–1850 mg/day/hectare. This assumes that the amount released in 24 hr is twice that released in 16 hr (Tilden, unpublished data). We speculate that many sources of attractant emitted over a large area at something near the lowest level tested might interrupt the response of *D. brevicomis* to initial attacks on ponderosa pines by dispersing the beetles over the treated area. Applying many devices releasing small amounts of attractant may also reduce the risk of producing sharp gradients in attractant, which could increase the probability of beetles attacking trees near the edges of areas of little or no attactant.

A large-scale interruption test would require aerial application of long-lasting chemical release devices (Furniss et al., 1981), which are not available for *D. brevicomis*. Important considerations in developing devices for deployment of attractants are their longevity, flatness of the emission decay curve, variation in release rates from individual devices due to environmental conditions, and the height above ground for deployment.

Acknowledgments—We thank Robert Pool, Lisa Gittlesohn, Frank Waters, William Simerly, John Douglas, and Debbie Pietrzak for assistance with the field work; and Gerald Lanier, John Peacock, Jim Richerson, and Lee Ryker for helpful reviews of the manuscript.

(Received November 18, 1985; accepted January 23, 1986)

Abstract—Hexane and ethanol extracts of seeds from 22 species of plants of the family Meliaceae from a number of countries were prepared. The extracts were submitted to antifeedant and toxicity bioassays utilizing fall armyworm [*Spodoptera frugiperda* (J.E. Smith)] (Lepidoptera: Noctuidae) larvae and striped cucumber beetle [*Acalymma vittatum* (F.)] (Coleoptera: Chrysomelidae) adults. Toxicity tests were also performed with brine shrimp, *Artemia salina* Leach. Feeding inhibition and mortality produced by some of these extracts were comparable to and, in certain cases, slightly greater than the effects produced by comparable neem (*Azadiracta indica* A. Juss.) seed preparations. Brine shrimp toxicity data do not extrapolate to insect activity, and vice versa.

Key Words—*Spodoptera frugiperda*, Lepidoptera, Noctuidae, *Acalymma vittatum*, Coleoptera, Chrysomelidae, brine shrimp, *Artemia salina*, insecticides, antifeedants, Meliaceae, neem, limonoids, azadiractin, seeds.

INTRODUCTION

While the search for natural pest control agents among plant "secondary metabolites" has extended into many different families of plants, the species currently receiving most worldwide attention is *Azadiracta indica* A. Juss. (neem

tree, Meliaceae). Since Warthen (1979) summarized the literature describing the effects of neem preparations on various insects, many additional publications have appeared addressing various aspects of insect control using crude neem preparations as well as its principal active constituent, azadiractin. These reports encompass subjects ranging from effects on certain insects (Reed et al., 1982), to field trials on specific crops (Adhikary, 1984; Meisner et al., 1983; Mariappan and Saxena, 1983), to systemic-type greenhouse applications (Larew et al., 1985). A number of recent basic studies designed to show how these materials disrupt normal insect behavior and development have also been reported (Chiu et al., 1984; Ladd et al., 1984; Rembold, 1984; Zebitz, 1984; Saxena and Khan, 1985).

Although some 280 limonoids, including azadiractin, have been isolated from plants of the Meliaceae and identified (Taylor, 1984), new compounds from neem (Kubo et al., 1984) and certain other species (Nakatani et al., 1984, 1985) are still being discovered.

The molecular complexity of azadiractin precludes an economically feasible route of synthesis. In addition, the structure of this compound has been challenged and recent revisions proposed (Rembold, 1984; Bilton et al., 1985). Because of these factors, it seems likely that commercial development of products with these potent insect control properties will be based on neem tissues and extractives rather than on synthetic materials. Although current emphasis is on neem, other plants of the Meliaceae are widely distributed in tropical and subtropical areas of the world and may serve as sources of materials which are just as effective as those from neem. In addition, new compounds, perhaps simpler than azadiractin and therefore more amenable to chemical synthesis, may be found. If the suggestion made by Taylor (1984) that "indications are that insects may adapt to limonoids rather quickly" proves to be true, this approach may be even more meritorious.

Although the effects of neem seed and chinaberry (*Melia azedarach*) fruit extracts have recently been compared (Lee et al., 1985), the activity of other meliaceous plant materials compared to neem has not been investigated; hence, the current study was initiated to provide such a comparison. Effects of hexane and ethanol extracts of seeds from 21 Meliaceae species were compared to those of comparable neem seed extracts in bioassays utilizing the fall armyworm (FAW), *Spodoptera frugiperda* (J.E. Smith), and the striped cucumber beetle (SCB), *Acalymma vittatum* (F.). Additional toxicity tests were done with brine shrimp (BS), *Artemia salina* Leach, to determine if this procedure (Meyer et al., 1982) might be useful as a screening technique.

METHODS AND MATERIALS

Extracts. Seeds (collected and identified by USDA botanists, Beltsville, Maryland) were ground to the consistency of commercial corn meal and were

Soxhlet extracted, first with *n*-hexane and then after drying, the meal, with 95% ethanol. Solvent was removed at 40°C on a rotary evaporator and the extracts were refrigerated.

FAW Two-Choice Antifeedant Bioassay. The procedure used was based on the leaf disk bioassay described by Kubo and Nakanishi (1977). Disposable Petri dishes (100 × 15 mm) were inverted, and a moistened filter paper disk large enough to cover the bottom was placed in each dish. Green bean leaf disks (1.0 cm diam.) were dipped for 5 sec either in a 5% (w/v) solution of the extract being tested or in solvent (control); ethanol extracts were redissolved in ethanol and hexane extracts in pentane. After allowing 5 min for solvent to evaporate, three sample-treated disks and three control disks were arranged alternately in each Petri dish around and about 0.5 cm inward from the circumference. Three FAW larvae that had been reared on pinto bean artificial diet (Shorey and Hale, 1965) for 7–11 days posteclosion and starved overnight were placed in the center of each Petri dish and were permitted to feed 2 hr (10- to 11-day-old larvae) or 3 hr (7- to 9-day-old larvae). Assays were conducted in darkness at 26–28°C and 55–65% relative humidity in three simultaneous replicates.

The percentage of each disk eaten was estimated visually, and feeding ratios, defined as percentages of extract-treated disks consumed/percentage of control disks consumed, were calculated. A feeding ratio of 1.00 means that equal quantities of treated and control leaf tissue were eaten (no deterrency), and a ratio of 0.25 or less was arbitrarily set as being indicative of strong feeding deterrency by that particular extract.

FAW No-Choice Toxicity Bioassay. Seed extracts were incorporated into pinto bean diet at the 1% (w/v) level. Ethanol extract (0.120 g), dissolved in 1 ml of ethanol, was placed in a shallow agate mortar, the solvent was allowed to evaporate, and the residue was mixed thoroughly with 12 cc of prepared diet. This mixture was packed into a 10-cc disposable hypodermic syringe barrel that had been cut off at the zero mark, and 1-cc plugs were extruded into each of 10 1-oz plastic cups.

Diet containing hexane extracts was prepared in the same manner except that a pentane solution of the sample was applied to the surface of 12 cc of diet spread out in the mortar and the solvent was allowed to evaporate prior to mixing. Control cups were set up identically using solvent only, and blank cups contained only diet that had not been exposed to either extract or solvent.

One 6-day-old FAW larva was introduced into each cup which was then capped with the usual paper lid, a layer of aluminum foil, and a plastic cap to minimize moisture loss. Bioassays were run at 26–28°C, 55–65% relative humidity, under a 16:8 light–dark cycle. Each larva was observed on day 4, 11, and 18, when the assay was terminated. Every group of 10 extracts (each in 10 replicates) was accompanied by three control sets and one blank set, also in 10 replicates.

BS Toxicity Bioassay. This bioassay was conducted basically as described

by Meyer et al. (1982), except that 4 mg of crude extract in either methanol or dichloromethane solution was applied to each paper disk and the disks were allowed to air dry. Mortality counts were made at 24 and 48 hr. Five replicates with 10 BS in each were done. If control deaths occurred, the bioassay was repeated.

SCB Two-Choice Leaf Disk Bioassays. The two-choice leaf disk antifeedant tests were performed with Burpee Hybrid cantaloupe leaves as reported by Reed et al. (1981, 1982). Appropriate quantities of the extracts were suspended in acetone, diluted with water containing 0.01% of Tween 20 to a sample concentration of 0.5% (w/v), and then emulsified with a Brinkman Polytron homogenizer. The 0.1% solutions were derived by dilution of the 0.5% solution. Leaf disks (2.0 cm diam.) were dipped in either the sample homogenate or a corresponding homogenate containing no sample (control disks), air dried, and then two of each type of disk were arranged alternately around 93-mm-diam. × 73-mm-deep polyethylene dishes. Five newly emerged female SCB, after being starved for 24 hr, were introduced into each chamber, and the chambers were covered with muslin; these covers were kept moist during the first 6 hr of the bioassay by misting them periodically with water. Tests were conducted in two replicates under ambient greenhouse conditions. Observations were made at 3, 6, and 22 hr to estimate visually the amount of leaf tissue consumed and to check for deaths.

Data are presented as a consumption index, which is defined as percentage of treated disks consumed × 100/(percentage of control disks consumed + percentage of treated disks consumed). A value of 50 indicates treated and untreated disks have been consumed in equal amounts; an extract that gives an index of 20 or less is considered highly deterrent in these bioassays.

SCB No-Choice Leaf Disk Bioassay: For the no-choice feeding study, extract samples were prepared (0.5% w/v solutions only), leaf disks (1.5 cm diam.) were treated and dried, and the insects used were as described for the two choice bioassay. Single treated disks were placed in individual 2-dram glass vials, and one SCB was introduced into each vial. Water was provided by a soaked 0.5-cm length of dental wick and the vials were stoppered with cotton plugs. The bioassays were done in 10 replicates under ambient greenhouse conditions; leaf consumption and mortality data were taken daily for three days. Data are presented as percent of leaf disks consumed.

RESULTS AND DISCUSSION

FAW Bioassays. Results of the FAW feeding experiments are presented in Table 1. Ethanol extracts of seeds from *Aglaia cordata*, *Azadiracta indica* (neem), *Dysoxylum malabaricum*, *D. reticulatum*, *D. spectabile*, *Melia dubia*, *Sandoricum koetjape*, *Swietenia mahogani*, *Trichilia connaroides*, *T. prieu-*

reana, and *T. roka* all exhibited comparable, high levels of activity in both bioassays. All of these extracts strongly inhibited feeding (feeding ratio <0.25) in the two-choice leaf disk bioassay and also resulted in high mortality (>80%) in the no-choice artificial diet bioassay. At the other extreme, ethanol extracts of *Aglaia odoratissima*, *M. azedarach*, *Toona sinensis*, and *Trichilia triphyllaria* had minimal antifeedant effects and produced no mortality over the time span of the experiment. However, of this group, only the insects on diets which contained *A. odoratissima* and *T. sinensis* extracts pupated normally.

Of the ethanol extracts giving intermediate results, those from *Chickrassia tabularis* and *D. binectariferum* produced moderately reduced feeding ratios of 0.52 and 0.36, but caused high mortalities of 100% and 90%, respectively, in the no-choice bioassay. Conversely, extracts of *Carapa procera*, *Lansium domesticum*, and *Swietenia macrophylla* seeds were highly deterrent (feeding ratios of <0.04), but produced <20% mortality when consumed in artificial diet. At termination of the bioassay, however, no insects in this group had pupated and all larvae were small.

Three of the hexane extracted seed oils, from *A. cordata*, *Chickrassia tabularis*, and *Sandoricum koetjape* were as potent as neem seed extract in both FAW tests. Very effective deterrency was achieved with oils from *Carapa procera*, *D. malabaricum*, *L. domesticum*, *M. dubia*, *Swietenia macrophylla*, and *S. mahogani*, but no more than 20% the test insects died in the no-choice bioassays. Overall pupation in this group of six bioassays was 80% compared to the controls at 18 days.

Oils resulting in intermediate mortality (30–60%) and low feeding ratios (<0.15) were from *D. binectariferum*, *D. reticulatum*, *M. toosendan*, and *T. prieureana*. In this case, only seven of the 23 survivors pupated.

Four seed oils, from *A. odoratissima*, *Toona sinensis*, *Trichilia connaroides*, and *T. triphyllaria*, had no apparent deleterious effects on the FAW larvae in either of the bioassays.

SCB Bioassays. Results of the SCB two-choice and no-choice leaf disk bioassays are given in Table 2. Two dose levels (leaf dipping solutions of 0.5% and 0.1%, w/v) of both the ethanol and hexane seed extracts were used. Data for the 3-hr observation of the two-choice test and for the two-day observation of the no-choice test were omitted because they increased the complexity of the table while contributing little to overall conclusions. However, certain unusual values for 3-hr observations are footnoted.

Only four of the ethanol extracts at the 0.5% level did not strongly inhibit feeding (consumption index <20) in the two-choice bioassay up to the 22 hr termination; they were from *L. domesticum*, *M. azedarach*, *Toona sinensis*, and *Trichilia triphyllaria* seeds. At the 0.1% level, only neem seed extract totally prevented feeding until 22 hr. However, other ethanol extracts that demonstrated good antifeedant properties against the SCB at this level were those from

both *Aglaia* species, *Carapa procera*, *Chickrassia tabularis*, *D. malabaricum*, *Sandoricum koetjape*, *Swietenia mahogani*, and *T. roka*.

The hexane extracts, as a group, possessed considerably lower antifeedant activity with the SCB than did the ethanol extracts. Good feeding inhibition held to 22 hr in the 0.5% level two-choice bioassay for extracts of *A. cordata*, neem, *C. tabularis*, *D. malabaricum*, *M. toosendan*, and *T. connaroides* seeds. Activity observed with a number of other hexane extracts to 6 hr did not persist until 22 hr. At the 0.1% concentration, only *A. cordata*, neem, *C. tabularis*, and *D. binectariferum* inhibited feeding and then only to 6 hr; *A. cordata* and *C. tabularis* gave the lowest consumption indexes of this group.

The SCB no-choice leaf disk feeding bioassays were conducted using only 0.5% solutions of the ethanol and hexane seed extracts. Ethanol extracts from *D. binectariferum*, *L. domesticum*, *M. toosendan*, *Sandoricum koetjape*, *Swietenia mahogani*, *T. prieureana*, and *T. roka* gave good antifeedant activity up to the three-day limit of the test. All of these appeared more effective than neem extract in this bioassay.

High deterrency in the no-choice bioassay was provided by only two hexane extracts, those from *A. cordata* and *Sandoricum koetjape*, until three days, although *C. tabularis* extract allowed only 26% of the leaf disks to be consumed in three days.

Some insect mortality was observed in these SCB bioassays with two ethanol extracts and four hexane extracts; the greatest mortality (30%) was caused by the hexane extract of *M. burmanica*.

BS Bioassay. Results of the BS toxicity studies (Table 1) indicate that the ethanol extracts, with exception of those from the two *Swietenia* species, tend to kill most or all of the shrimp or to have little or no effect. Three *Dysoxylum* species ethanol extracts caused 100% mortality while that of *D. spectabile* caused none. Similarly, ethanol extracts of two of the four *Trichilia* species killed all of the organisms while those from the other two species were without effect.

Hexane extracts of *A. cordata*, *S. macrophylla*, *S. mahogani*, and *Toona sinensis* exhibited moderate toxicity at 24 hr and the values increased at 48 hr. In spite of the fact that the bioassay results are reproducible, the relative lack of activity observed with hexane extracts may be partially attributable to their reduced solubility in the aqueous system.

The data in Tables 1 and 2 also reveal that activity in the BS system cannot be extrapolated into similar effects on FAW or SCB, or vice versa. Hence, if one is searching for insect-active materials, this BS bioassay cannot be used as the sole screen. Once the presence of insect activity has been established in any particular extract, and if BS respond similarly, then in some cases this procedure might find limited use as a rapid, economical monitor for subsequent fractionation. However, appropriate insect bioassays would still be required to reliably

document that the BS toxic entities being concentrated produce the desired effect in the target insect.

SUMMARY

Some limonoids, isolated from a number of Meliaceae species listed in Table 1, have been investigated (Taylor, 1984), although not usually from an insect activity standpoint. Species of those listed in Table 1 that have received the greatest attention, in addition to neem, are *C. procera*, *M. azedarach* (chinaberry), and *S. macrophylla*. More recently, the properties and structures of trichilins, potent limonoid antifeedants from *T. roka* root bark, have been investigated (Nakatani et al., 1984, 1985). The ethanol extract of *T. roka* seeds, also is very potent, as seen in Tables 1 and 2.

Components of chinaberry (*M. azedarach*) fruit have been reported to possess antifeedant (Lavie et al., 1967) and insecticidal (Lee et al., 1985) properties; however, extracts from our seed sample were virtually devoid of activity in all bioassays. We feel that this anomaly is due to unknown characteristics inherent in the particular seed sample we received and that usually plant material from this species will show activity. Other extracts producing minimal overall effects in this group of bioassays were those of *A. odoratissima*, *Toona sinensis*, and *Trichilia triphyllaria*.

Azadiractin (and probably some other limonoids) have significant solubility in lipophylic solvents such as hexane, and this property probably accounts for the observed potent activity in both extracts of some seeds. However, little or no activity is detected in hexane extracts of other seeds that show strong ethanol-extractable activity; this variation may indicate the presence of types of active materials different from azadiractin, and these extracts warrant further investigation from this standpoint. Lack of stability of a number of limonoids (Taylor, 1984), particularly in solution (Zanno et al., 1975), should be borne in mind when comparing relative magnitudes of activities reported.

Thus, we have demonstrated that seed extracts of plants of the Meliaceae produce effects ranging from none to total inhibition of feeding in both the FAW and SCB and 100% mortality in the FAW. Although seeds are the subject of this communication, there is reason to expect that other plant parts would also be good sources of similar activity. A few extracts, notably those from *A. cordata*, *Chickrassia tabularis*, and *Sandoricum koetjape*, exhibit overall total activity in these bioassays exceeding that of neem seed extracts. Further biological testing is continuing with a number of these extracts; isolation and chemical identification of active components are also being initiated in our laboratory.

Acknowledgments—The authors thank Bruce W. Zilkowski, Barry E. Jones, Marge V. Wakeman, and Naomi J. Tromley for technical assistance, and Dr. Frank M. Davis for supplying FAW egg masses.

(Received November 1, 1985; accepted January 23, 1985)

Abstract—The host-finding responses of the egg parasite, *Trichogramma minutum* Riley, reared from its natural host, *Choristoneura fumiferana* (Clemens) and a laboratory host, *Sitotroga cerealella* (Oliver), to hexane extracts of scales of these hosts were compared in laboratory experiments. When presented with *C. fumiferana* eggs on filter papers treated with hexane and hexane extract of grain moth scales, egg finding by *T. minutum* was random. When presented with budworm eggs on filter papers treated with hexane and hexane extract of budworm scales, *T. minutum* found significantly more eggs on extract-treated filter papers, indicating the presence of kairomones on the scales of spruce budworms. *T. minutum* responded to kairomone-treated patches with a localized search behavior characterized by intense antennal tapping, decreased locomotion and increased turning within the patch, and repeated returns to the patch. In the absence of successful host finding, this response slowly waned. No significant difference in behavior of *T. minutum* reared on either *C. fumiferana* or *S. cerealella* was observed.

Key Words—*Trichogramma minutum*, Hymenoptera, Trichogrammatidae, *Choristoneura fumiferana*, Lepidoptera, Tortricidae, moth scale, kairomone, mass rearing, parasitism.

INTRODUCTION

The most important insect pest in the spruce–fir forests of northeastern North America is the spruce budworm (SBW), *Choristoneura fumiferana* (Clemens) (Lepidoptera: Tortricidae). Outbreaks of this pest currently are treated with aerial applications of chemical insecticides or *Bacillus thuringiensis* Berl. (Bt). While both of these are effective, Bt is relatively expensive and alternatives of chemical insecticides are desirable in sensitive areas such as parklands and

0098-0331/87/0100-0113$05.00/0 © 1987 Plenum Publishing Corporation

aquatic environments. As such areas may contain tree stands of considerable value, other methods are being explored to provide protection against outbreaks of SBW. The naturally occurring egg parasite of SBW, *Trichogramma minutum* Riley (TM) (Hymenoptera: Trichogrammatidae), is being evaluated as an inundative control agent and is most economically reared on eggs of the facultative host, the Angoumois grain moth (AGM), *Sitotroga cerealella* (Olivier) (Lepidoptera: Gelichiidae) (Houseweart et al., 1984; Smith, 1984).

During preliminary field trials with TM in Ontario, Smith (1984) observed that parasites reared in the facultative host appeared to parasitize fewer spruce budworm eggs after release than did their "wild" progeny. One of several possible explanations for this observation is that extended rearing on AGM reduced the parasites' ability to locate natural hosts in the wild. Kairomones have repeatedly been shown to act as critical cues in host finding (Lewis et al., 1976), and previous studies have demonstrated that kairomones on moth scales play an important role in guiding *Trichogramma* spp. to their hosts in agroecosystems (Lewis et al., 1971, 1972; Nordlund et al., 1981). Although it has been suggested that extended rearing on an alternate host can influence host acceptance or the host preference of a parasite (Narayanan and Subba Rao, 1955; Taylor and Stern, 1971), little is known of the host's influence on kairomone utilization by a parasite during host finding. The possibility that extended rearing on AGM may impair the host finding ability of TM could influence the choice of hosts on which the parasite is reared for use in inundative releases against SBW. The objectives of this study were to determine if *T. minutum* uses scale kairomones while searching for SBW hosts, to determine the behavioral response of TM to these kairomones, and to determine if this behavioral response is affected by extended rearing on the facultative host, AGM.

METHODS AND MATERIALS

Cultures of Trichogramma minutum. The colony of the TM strain used in this study was established at the Biological Control Laboratory, University of Guelph, from parasitized eggs of SBW collected near Hearst, Ontario, in 1983, and was reared for 21 generations on AGM. Subsequently, two smaller experimental cultures were established from this parent colony; one was reared continuously on AGM and the other was reared continuously on SBW. Eggs of AGM were obtained from the Biological Control Laboratory at the University of Guelph, and eggs of SBW were obtained from the Great Lakes Forest Research Centre (GLFRC), Sault Ste. Marie, Ontario. All eggs were refrigerated until exposed to parasites. Eggs were glued with wallpaper paste to strips of white construction paper (2 × 8 cm), killed by exposure to ultraviolet light (254 nm) for 30 to 40 min, then exposed to adult TM in corked glass vials for 24 hr. Parasitized egg cards were then transferred to clean glass vials and placed

in a growth room at 25 ± 1°C and 16:8 hr light–dark. Relative humidity was maintained at 75% by keeping the vials over saturated NaCl solutions in covered clear plastic vegetable crispers (Winston and Bates, 1960). Under these conditions, adult parasites emerged 10–12 days after host eggs were parasitized. All parasites used in the experiments were 0- to 24-hr-old females.

Scale Extracts. Scales of SBW were collected from air filters at GLFRC and scales of AGM were collected from an egg/scale separator in the Biological Control Laboratory. Weighed scales were placed in a coarse glass fritted funnel and washed with 5 ml of hexane/100 mg of scales. The washings were concentrated under reduced pressure and stored at −20°C. Solutions of 10 μg scales/ml were prepared from these stock solutions by dilution with hexane, as needed.

Bioassays. Filter papers (1.5 × 1.5 cm Whatman No. 1) were treated with 25 μl of hexane alone (control) or one of the hexane extracts (treatment) for use in bioassays. After air-drying for 30 min, an egg of SBW was attached to each filter paper at its center with shellac gel. Both a treated and a control filter paper were placed in a 5.5-cm-diameter plastic Petri dish with a tight-fitting lid. An AGM-reared or SBW-reared TM was placed on the Petri dish lid and allowed to search until it made contact with one of the eggs. The choice of egg found by the parasite was recorded, and the filter papers and TM were replaced. Parasites that flew before finding an egg or remained inactive for 15 min were discarded.

The experiment was repeated a minimum of 60 times for each of the four combinations of filter paper treatment and host of rearing. Data collected on different days were pooled after appropriate tests for homogeneity. The hypothesis that eggs finding was independent of filter paper treatment was tested for each of the four host of rearing/extract combinations using an adjusted chi-square test. The hypothesis that the responses of SBW-reared and AGM-reared TM did not differ was tested for each of the scale extracts using an interaction chi-square test.

Behavioral response experiments were conducted on 11-cm-diameter filter papers inscribed in pencil with three concentric circles of 5, 7, and 10 cm diameter. The area within the inner circle was treated with 400 μl of either hexane (control) or SBW extract (treatment) to form a patch. The area between the two inner circles was designated the patch boundary, and the area between the two circles was designated the arena. A single female TM, reared in either AGM or SBW, was released in the center of the patch and the total time spent by the parasite in each of the three regions before first leaving the arena was recorded. In addition, the number of times that TM left and returned to the patch before going beyond the patch boundary was recorded as patch reentries. Parasites that flew before leaving the arena or remained inactive for 15 sec were discarded.

The experiment was repeated nine times for each of the four hosts of rearing/patch treatment combinations. The data were arranged and analyzed as a three-factor (host of rearing/patch treatment/filter paper region) completely ran-

dom design experiment after applying a log $(X + 1)$ transformation to stabilized variance. Hypotheses tested were that there was no interaction between factors, no difference in response due to host of rearing, no difference in response due to patch treatment, and no difference in response between the three filter paper regions. Mean numbers of patch reentries for each of the four host of rearing/ patch treatment combinations were calculated and compared.

RESULTS

Free-Choice Experiments. When presented with eggs attached to hexane-treated and AGM scale extract-treated filter papers, both AGM-reared and SBW-reared TM found eggs randomly (Table 1). However, when presented with eggs attached to hexane-treated and SBW scale extract-treated filter papers, both AGM-reared and SBW-reared TM found significantly more eggs ($P < 0.05$) on the extract-treated filter papers (Table 1). The proportion of eggs found on extract-treated filter papers by AGM-reared TM was not significantly different from that found by SBW-reared TM ($\chi^2 = 1.26$, 1 df).

The parasites continuously tapped the substrate with their antennae. Travel by TM was relatively fast and with few turns until it made first physical contact with the SBW scale extract-treated filter paper. When this happened, the TM would usually pause briefly, tapping the filter paper intently with its antennae. Then it would begin an investigation of the filter paper that was characterized by considerably reduced speed and frequent pauses and turns. Although a similar response was not observed on the hexane-treated AGM scale-treated filter papers, TM passing within 2–3 mm of a SBW egg would pause, turn, and slowly advance towards the egg while TM passing slightly farther away would not.

Behavioral Response Experiments. The times spent per unit area for AGM-reared and SBW-reared TM were combined when preliminary analysis showed

TABLE 1. FILTER PAPER TREATMENT OF EGG FIRST FOUND BY *Trichogramma minutum* FEMALES IN FREE-CHOICE EXPERIMENTS

TM host of rearing	N	Distribution of first-found hosts[a]		
		Hexane	AGM extract	SBW extract
AGM	131	60	71	—
SBW	96	45	51	—
AGM	100	37	—	63*
SBW	60	17	—	43**

[a]Distribution significantly different from random by χ^2 test at $P \leq 0.05$* or $P \leq 0.01$**.

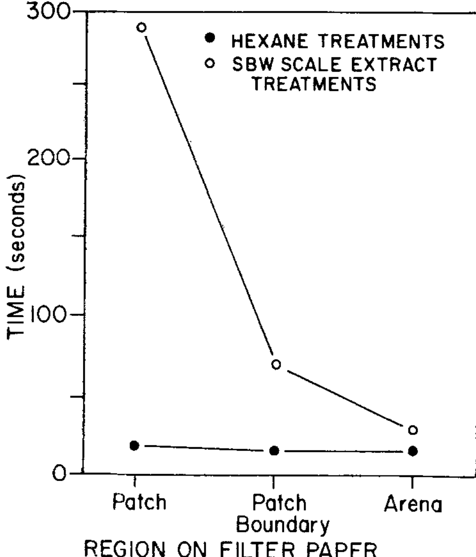

FIG. 1. Mean times spent on filter paper regions by *T. minutum* females released on hexane-treated and spruce budworm scale extract-treated patches. Each mean calculated after log $(X + 1)$ transformation of raw data $(N = 18)$.

that they did not differ significantly. Analysis of variance of the transformed data showed that, while both the patch treatment and filter paper region appeared to influence the parasites' movements, a significant interaction ($P < 0.001$) existed between these two factors.

Examination of simple effects revealed that treatment of the patch with SBW scale extract resulted in significantly more ($P < 0.001$) time being spent in each of the regions compared to the control (Figure 1). In addition, on the SBW scale extract-treated filter paper, times spent in each region differed significantly ($P < 0.001$), with the most time being spent in the patch and the least time being spent in the arena. In contrast, on hexane-treated filter papers, times spent in the boundary and the arena did not differ significantly and time spent in the patch was only slightly greater ($P < 0.05$), a difference that can be attributed to the slightly larger area of the patch. On extract-treated filter papers, AGM-reared TM made 5.0 ± 3.5 patch reentries and SBW-reared TM made 4.9 ± 2.5 patch reentries (Figure 2). No patch reentries were observed on hexane-treated filter papers.

As in the free-choice experiments, it was observed that TM traveled more slowly and with more frequent pauses and turns on SBW scale extract-treated patches than on other surfaces. Observations under a dissecting microscope revealed that TM on extract-treated patches also examined the substrate much

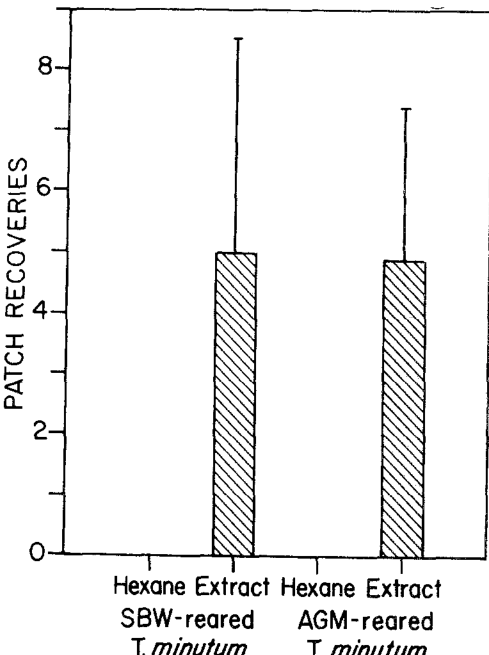

FIG. 2. Mean number of patch recoveries by Angoumois grain moth-reared and spruce budworm-reared *T. minutum* on hexane-treated and spruce budworm scale extract-treated filter papers. (SD = standard deviation; $N = 9$ for each treatment).

more intensely with their antennae than TM on hexane-treated patches. Furthermore, the response on the extract-treated patches was not uniform with time. Travel was slowest, and pauses and turns were most frequent, immediately after contacting the treated patch. As time spent on the patch increased, turns and pauses became less frequent and speed increased, with the result being that an area of increasing size was searched. At first, when a TM wandered off the patch it would stop and return to the patch, but eventually it abandoned the patch completely (i.e., left the arena). Tracings of the movements of AGM-reared and SBW-reared TM on filter papers with hexane-treated and SBW scale extract-treated patches are illustrated in Figure 3.

DISCUSSION

The chemical orientation of insect parasites to their environment during host selection has been extensively studied, and the process has been divided into a number of steps, including host habitat finding, host finding, and host acceptance (Vinson, 1976). In the host-finding step, a parasite can greatly in-

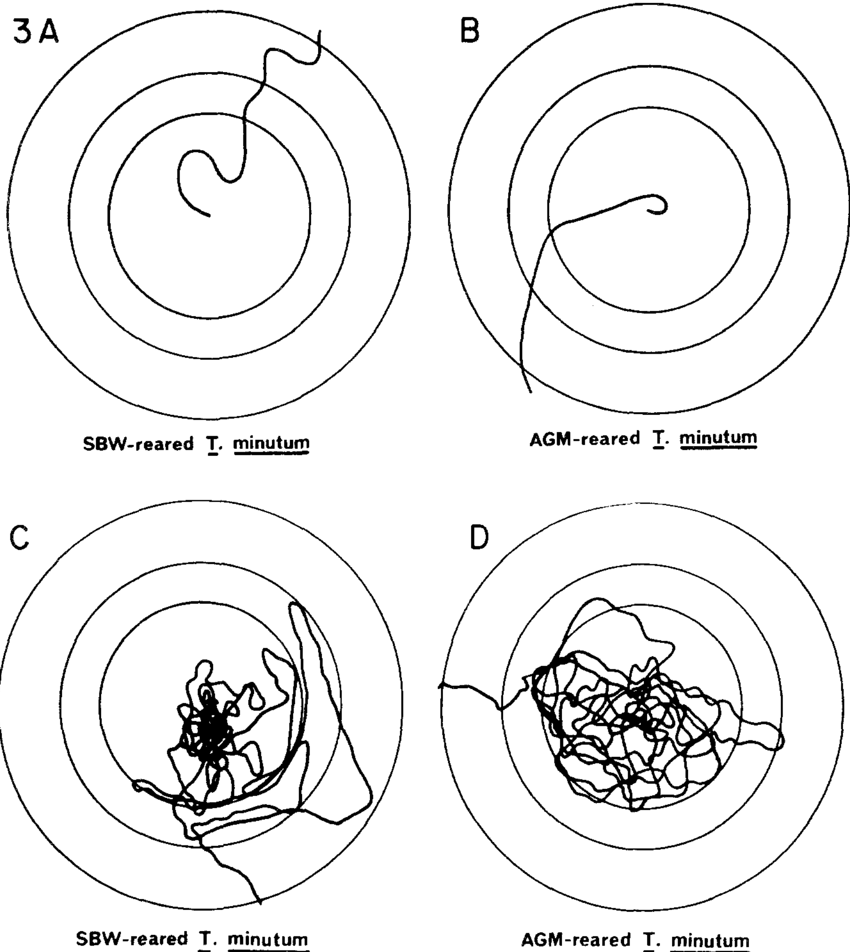

FIG. 3. Tracing of responses of SBW-reared and AGM-reared *T. minutum* to hexane and scale extract-treated filter papers. (A) Response of SBW-reared to hexane, (B) response of AGM-reared to hexane, (C) response of SBW-reared to SBW scale extract, (D) response of AGM-reared to SBW scale extract.

crease the efficiency of its search if it can identify and concentrate its efforts in those sites most likely to contain hosts. Our study suggests that TM uses SBW scale kairomones for this purpose.

Naturally occurring eggs of SBW would often be accompanied by a patch of scales left by the ovipositing moth, thus the behavioral response exhibited by *T. minutum* upon encountering kairomone patches of scale extract can be expected to substantially improve the parasite's searching efficiency. The localized nature of the response allows the parasite to concentrate its search in

small areas likely to harbor hosts. At the same time, the tendency for the intensity of the response to wane allows the parasite to quickly delimit and search the area of the patch, and ultimately allows it to escape unproductive patches. Similar reduction of response has been reported by Waage (1978) in studies on the arrestment behavior of *Nemeritis canescens* (Grav) responding to contact kairomones produced by *Plodia interpunctella* (Hübner). Therefore, such behaviors may be common among parasite species.

T. minutum continuously taps the substrate with its antennae and only shows a behavioral response to the scale extract of SBW after making physical antennal contact with the treated filter paper. This suggests that the kairomone of SBW is a contact chemical that is detected with receptors on the parasite's antennae. Vinson (1976) discussed the importance of contact chemicals in both host location (finding) and host selection (acceptance) and reviewed their use by several parasites. The behavior exhibited by TM in response to the scale extract of SBW is similar to that reported for *Trichogramma pretiosum* (Riley) on patches of scale extract of the corn earworm, *Heliothis zea* (Boddie) (Beevers et al., 1981), as well as for a number of other parasitoids that use contact kairomones. Bell and Tobin (1982) suggest that reduced locomotion and increased turning within patches, accompanied by large abrupt turns at the patch edge, serve to arrest an animal's motion and lock it into a patch.

In the absence of the kairomone of SBW, TM turns towards eggs on hexane-treated filter papers only if it passes very near them. This is similar to the observation of Laing (1937), who found that sight was the sense by which *Trichogramma evanescens* Westwood perceived hosts over short distances. Together with the observation that *T. minutum* would frequently search a kairomone-treated filter paper only to leave without finding the attached egg, this suggests that TM relies on sight to find hosts once it is within a kairomone patch. If this is so, the increased rate of turning observed within kairomone patches would increase the probability of passing within sight of a host.

Differences have been noted between TM reared on more than one host, but whether these are due to host influence or to strain differences is sometimes unclear. Southard et al. (1982) found that the Maine strain of TM reared in AGM were significantly smaller than those reared in SBW. Houseweart et al. (1983) showed that the Maine strain of TM had lower daily progeny production when reared in AGM eggs, but that total progeny production for parasites reared on AGM and SBW eggs was the same, mainly due to differences in longevity. Houseweart et al. (1984) found that the Maine strain of TM reared on AGM significantly out-performed a strain from California originally collected from *Cydia pomonella* (Walsh) and subsequently reared on AGM. This difference was probably due to the strain of TM, not due to a host influence.

There have been suggestions that extended rearing on an alternate host can change the host preference of a parasite. Narayanan and Subba Rao (1955) reported that *Microbracon gelechiae* Ashmead, bred on gram flour moth for

seven years, developed into a distinct race which showed preference for its new host over its natural host, the potato tuber worm, *Gnorimoschema operculella* (Zeller). Unfortunately, they did not compare these data with parasites reared continuously on the natural host. Taylor and Stern (1971) reported a complete reversal of host preference by *Trichogramma semifumatum* (Perkins) reared for 100 generations on AGM, but their interpretation was based on data comparing parasites from what were probably two strains of quite different origin. Reliable interpretation of the influence of the host-selection behavior of parasites can only be made if parasites of one defined strain are reared on different hosts under otherwise identical conditions.

Our experiments show that utilization of SBW kairomone by a defined strain of TM was not different between parasites reared on SBW and parasites reared on AGM. Furthermore, data for these experiments were homogeneous over the 7–10 generations that the parasites were reared on each host, indicating that there was no cumulative influence of the host over this period. Based on these conclusions, the observed difference in levels of parasitism of SBW between generations of TM and their progeny after their release cannot be attributed to an influence of the host on scale kairomone utilization. Other possible explanations are that "wild" parasites are more vigorous than laboratory-reared parasites or simply that there were more parasites in the progeny generation than in the released generation. Laboratory rearing of TM on AGM does not appear to alter the ability of TM to utilize kairomones of SBW.

Acknowledgments—Spruce budworm eggs and scales were provided by Dr. D. Wallace at the Great Lakes Forest Research Centre, Sault Ste. Marie, Ontario. Dr. J.J. Hubert provided valuable statistical advice.

ALDRIN EPOXIDASE ACTIVITY AND CYTOCHROME P-450 CONTENT OF SAWFLY LARVAE, *Pergagrapta polita* Leach (Hymenoptera: Pergidae) FEEDING ON TWO *Eucalyptus* SPECIES

H.A. ROSE

Department of Plant Pathology and Agricultural Entomology
The University of Sidney
Sidney, N.S.W. 2006, Australia

(Received August 30, 1985; accepted January 28, 1986)

Abstract—Aldrin epoxidase and cytochrome P-450 levels were determined in sawfly larvae, *Pergagrapta polita* Leach. Of the tissues examined the anterior portion of the midgut had the highest levels of aldrin epoxidase activity and cytochrome P-450 content, 3.56 nmol dieldrin produced/min/mg protein and 1.28 nmol/mg protein, respectively. No significant differences in aldrin epoxidase activities were observed between groups of larvae representing the last three larval instars and between larvae feeding on two eucalypt species.

Key Words—Sawfly larvae, *Pergagrapta polita*, Hymenoptera, Pergidae, *Eucalyptus* spp., monooxygenases, aldrin epoxidase, cytochrome P-450, allelochemicals, induction, polyphagy.

INTRODUCTION

Monooxygenases convert lipophilic foreign compounds to more polar products that can be excreted easily (Kulkarni and Hodgson, 1980). These enzymes are also used by insects in the detoxification of secondary plant compounds, or allelochemicals, many of which are toxic (Brattsten, 1983).

In Hymenoptera, the honeybee, *Apis mellifera* L., is very susceptible to insecticides (Metcalf and Fukuto, 1965), and Metcalf et al. (1966) suggested that monooxygenases may not even be present among Hymenoptera. Gilbert and Wilkinson (1974) and Yu et al. (1984), however, showed there was some activity in honeybees, while Croft and Mullia (1984) showed that an ectoparasitic hymenopterous species also had some activity. In addition, Krieger et al. (1970) reported monooxygenase levels in a sawfly, *Macremphytus varianus* (Norton).

In general, pergid (sawfly) larvae are monophagous feeders, i.e., they feed on hosts contained within one plant family. In Australia, a number of sawflies feed on *Eucalyptus* spp. (Riek, 1970) which have numerous allelochemicals, especially monoterpenes (Morrow and Fox, 1980). Such compounds have been shown to induce monooxygenases in lepidopterous larvae (Brattsten et al., 1977; Moldenke et al., 1983). Also in lepidopterous larvae, it was shown by Krieger et al. (1971) that polyphagous feeders had much higher monooxygenase activity than monophagous species.

It was therefore of interest to study the monooxygenase system of a monophagous hymenopterous species feeding on hosts containing monoterpenes. The species used was *Pergagrapta polita* Leach, chosen because of its large size and local availability. The activity of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) dependent aldrin epoxidase in various tissues was used as an index of monooxygenase activity. Aldrin was chosen as the substrate as it has been used widely in comparative metabolic studies.

METHODS AND MATERIALS

Insects. Larvae of *P. polita* were collected in September and October 1983 from *Eucalyptus globulus* and *E. parramattensis* growing in the grounds of Macquarie University, Sydney, New South Wales, Australia. Larvae were brought into the laboratory and used immediately.

Chemicals. Glucose-6-phosphate (G6-P), G6-P dehydrogenase, NADP (Boehringer Mannheim), and analytical grade aldrin and dieldrin (Shell Chemical Company, Australia) were purchased. Other chemicals and solvents were of analytical grade.

Enzyme Preparations. Larvae (in groups of one or more, depending on size), were decapitated and the posterior tip of the abdomen removed with scissors. The gut was dissected out, incised longitudinally, freed of its contents, and the various gut portions rinsed in ice-cold 0.1 M phosphate buffer, pH 7.5 (this was the buffer used throughout the study). Fat body was obtained after removal of the gut and slitting the body wall longitudinally. Carcass was also used and is defined as the tissues of the body midsection minus fat body and gut, i.e., essentially integument and muscle. Tissues were ground in a glass tube with ice-cold buffer using a motor-driven Teflon pestle. The homogenate was filtered through cheesecloth and was known as crude homogenate.

Microsomal pellets were prepared by centrifuging crude homogenates for 15 min at 4°C, at 10,000*g*, in an MSE centrifuge. The resulting supernatants were centrifuged for 60 min at 4°C, at 100,000*g*, in an IEC ultracentrifuge. Each microsomal pellet was surface-rinsed and resuspended in buffer.

The protein content of preparations was determined by the method of Lowry et al. (1951) before assays were undertaken.

Enzyme Assays. The aldrin epoxidase assay used was similar to that of Yu

(1982) and Rose (1984). The 5-ml incubation mixture contained buffer, 1.1 μmol NADP, 12.1 μmol G6-P, 2 units of G6-P dehydrogenase, either crude homogenate containing 2 ± 0.2 mg protein homogenate or microsomal suspension containing 1 ± 0.1 mg protein, and 274 nmol of aldrin in 0.1 ml methyl cellosolve to initiate the reaction. The incubations were carried out with shaking at 35°C for 15 min. These conditions were optimal with respect to midgut preparations and were used for all tissues. The reaction was stopped with 2 ml of 3 N HCl. Hexane extracts (10 ml) of the reacted homogenates were then analyzed by electron gas chromatography using a Varian model 3700 equipped with a ^{63}Ni electron capture detector. The glass column, 2.0 m long × 2 mm inside diameter was packed with 5% OV-210 on chromosorb WHP 80-100 mesh. The retention time of dieldrin was 2.9 min under the following conditions: injector temperature 210°C, column temperature 181°C, detector temperature 230°C, N_2 flow rate 86 ml/min. The detection limit of dieldrin was 5 pg, and the amount of dieldrin was quantified by means of the peak height from standard solutions.

Cytochrome P-450 levels in the microsomal suspension were measured by the method of Omura and Sato (1964). Spectra were recorded on a Varian Superscan 3 spectrophotometer.

Some results were analyzed stastically. In such cases data were log transformed and examined by analysis of variance.

RESULTS

Midguts of sawfly larvae consist of anterior and posterior portions separated by gastric cecae (Maxwell, 1955). Aldrin epoxidase activities of crude homogenates are shown in Table 1. Activity was highest in the anterior portion of the midgut. Fat body homogenates were less active than midgut preparations

[b] Mean ± SD of three homogenates.

and both the fore- and hindgut had only negligible activity. The remainder of this study deals with midgut preparations only.

Aldrin epoxidase activities of crude homogenates and microsomes of total midgut and of the two midgut portions are shown in Table 2. On a per milligram protein basis, microsomal activity increased from 1.5- to 2.2-fold over crude homogenates, and on a per milligram individual basis, activity in crude homogenates was 2.7- to 4.4-fold higher than in microsomes. Cytochrome P-450 was greatest in the anterior midgut portion.

The relationship between the age of larvae and aldrin epoxidase activity was investigated (Table 3). Groups of larvae collected from the same host tree were sorted into similar sized individuals before assays were undertaken. The life cycle of this species is unknown, but with another related species, *Perga dorsalis* Leach, when the head capsule widths are plotted against the various instars, a straight line results (A.D. Clift, unpublished observations). Using this criterion for *P. polita*, it would appear that the final three instars were represented in Table 3. An analysis of the data revealed no significant diffences in activities among the groups either on a milligram protein basis or milligram individual basis ($P > 0.05$).

P. polita larvae were collected on three occasions from different trees of *E. parramattensis* and on one occasion from two different trees on *E. globulus*. Analysis showed no significant differences in aldrin epoxidase activities (Table 4) of crude midgut homogenates ($P > 0.05$).

DISCUSSION

Previous monooxygenase studies with larval Hymenoptera have shown that species have only low to moderate activity when compared with other insect species. Whole-body homogenates were used to determine aldrin epoxidase levels in both drone honeybee larvae (Gilbert and Wilkinson, 1974) and in larvae

TABLE 4. ALDRIN EPOXIDASE ACTIVITY OF CRUDE MIDGUT HOMOGENATES OF LARVAE COLLECTED FROM TWO *Eucalyptus* SPECIES

[a]Mean ± SD of *N* homogenates.

of a braconid parasite, *Oncophanes americanus* (Weed) (Croft and Mullin, 1984). Aldrin epoxidase activities were 231 and 0.6 pmol dieldrin/min/mg protein, respectively. Krieger et al. (1970) studied various tissues in a sawfly, *Macremphytus varianus*, and found that microsomes prepared from a gut homogenate yielded an aldrin epoxidase activity of 263 pmol dieldrin/min/mg protein. They found that homogenates prepared from head capsule, fat body, and skeletal tissues were inactive.

My study shows that all tissues examined exhibited aldrin epoxidase activity, with midgut and fat body preparations having the highest activities (Table 1). These results are similar to a number of lepidopterous larvae where gut preparations have higher activities than fat body (e.g., Krieger and Wilkinson, 1969; Krieger et al., 1976; Rose, 1984). Carcass activities of lepidopterous larvae are higher than those reported here (Farnsworth et al., 1981; Moldenke et al., 1983). This study also shows that the anterior part of the midgut has considerably higher activity than the posterior part. The significance of this result is unknown at this stage. The aldrin epoxidase activity recorded for anterior midgut microsomes is 13.5-fold greater than that of gut microsomes of *M. varianus* (Krieger et al., 1970). This value of 3.56 nmol dieldrin/min/mg protein (Table 2) is comparable to the highest activities reported in only a few lepidopterous larvae (e.g., Yu et al., 1979; Farnsworth et al., 1981).

The cytochrome P-450 value of 0.73 nmol/mg protein for total midgut (Table 2) was greater than that found by Krieger et al. (1970) for *M. varianus* (0.23–0.35). The value for anterior midgut, 1.28, is quite high compared to most lepidopterous larvae which have gut values generally below 0.5 nmol/mg protein (Wilkinson and Brattsen, 1972). This value is also higher than that found in the liver of a number of vertebrate species (Hodgson, 1985).

Monooxygenase activity of final instar larvae of Lepidoptera invariably have higher activity than earlier instars (e.g., Krieger and Wilkinson, 1969;

Berry et al., 1980) and so too with drone honeybee larvae (Gilbert and Wilkinson, 1974). With *P. polita*, however, no significant differences were observed in aldrin epoxidase activities between the final three instars either on a milligram protein or milligram individual basis (Table 3). It cannot be concluded from these data that there are no differences in activities between these instars until age profiles are undertaken. In some lepidopterous species, large variations in activity may occur within a single instar (Wilkinson and Brattsen, 1972), a possibility not examined in this study.

Midgut homogenates of *P. polita* larvae collected from *E. parramattensis* and *E. globulus* had similar levels of aldrin epoxidase activity (Table 4). Marty et al. (1982) found that there were no differences in aldrin epoxidase levels of the monarch butterfly, *Danaus plexippus* (L.) which had fed on four different species of *Asclepias*. Yu (1982), however, found that with another lepidopterous species, *Spodoptera frugiperda* (Smith), larvae fed immature tops of leaves from 7-week-old corn plants contained only one half the activity compared with those fed on mature leaves from plants of the same age.

The high activity of aldrin epoxidase in the midgut of *P. polita* is most likely due to the presence of monoterpenes in eucalypts (Morrow et al., 1976). A variety of monoterpenes have been shown by Moldenke et al. (1983) to induce aldrin epoxidase in a lepidopterous species. There are, however, other allelochemicals present in eucalypts (Morrow and Fox, 1980), and their effects on monooxygenase activities of *P. polita* are unknown.

It is widely acknowledged that in lepidopterous larvae, monooxygenases act as an effective biochemical defense against allelochemicals (Brattsten, 1979; Ahmad, 1982; Scriber, 1984; Terriere, 1984). The gut is the first organ to encounter dietary allelochemicals, so high monooxygenase activity in this tissue is essential for effective detoxification of toxic allelochemicals before they enter the hemolymph. This explanation appears to fit the results obtained with *P. polita* which consumes a wide variety of allelochemicals. This species, however, is monophagous and does not fit the widely held hypothesis of Krieger et al. (1971) that polyphagous feeders have much higher activities than monophagous feeders. The activity obtained in this species is similar to larval Lepidoptera which feed on hosts containing monoterpenes regardless of whether the larvae are polyphagous or not (Rose, 1985). Additional research will be required, however, to resolve whether aldrin epoxidase activity typifies generalized monooxygenase activity.

Also, whether monoterpenes are being detoxified by *P. polita* is unknown. It is possible, as Gould (1984) has suggested, that induction could occur in the absence of detoxification. For example, Morrow and Fox (1980) found that beetles feeding on leaves did not detoxify the essential oils of eucalypts. While no detailed studies have been undertaken with metabolism of eucalypt leaves by sawfly larvae, Morrow et al. (1976) showed that, chromatographically, midgut and fecal pellet extracts were much less complex than leaf extracts. This

suggests that sawflies are capable of metabolizing essential oils. Brattsten (1983) has shown indirectly the involvement of monooxygenases in the metabolism of a number of monoterpenes by *Spodoptera eridania* Cramer, a lepidopterous species. This issue of metabolism of monoterpenes by monooxygenases in sawfly larvae is being investigated in my laboratory.

Acknowledgments—I thank Douglas Rugg for technical assistance.

LINAMARIN AND HISTAMINE IN THE DEFENSE OF ADULT *Zygaena filipendulae*

HALA MUHTASIB and DAVID L. EVANS

Department of Biology
American University of Beirut
850 Third Ave., New York, New York 10022

(Received August 29, 1985; accepted February 3, 1986)

Abstract—We determined the protective values of histamine and linamarin to an aposematic moth, *Zygaena filipendulae*. Using ion-exchange resin techniques, we found that the mean histamine concentrations in the wings were 0.061 ± 0.047 μg/mg and 0.013 ± 0.0051 in the moths' bodies (totals: 0.586 μg and 2.921 μg, respectively, all wet weights). Average HCN evolution (mainly from the bitter cyanogen linamarin) from the wings was 0.049 ± 0.41 μg/mg (0.426 μg/ml of linamarin could produce this amount of HCN) and 0.029 ± 0.0026 μg/mg HCN (0.281 μg/mg linamarin) evolved from the bodies (total linamarin 4.09 μg and 61.258 μg, respectively, all wet weights). Therefore, higher concentrations of toxicants were found in the part of the body most liable to initial attack. We found, in offering various toxic solutions to 10 common quails, that 0.1% linamarin (mean linamarin consumed equal to about 70% of the average total wing content) but 1.0% histamine (mean histamine consumed equal to that found in about 8.9 average wing sets) solutions significantly lowered drinking rates. However, combination solutions were still effectively aversive at 0.001% histamine plus 0.028% linamarin. This synergism would allow a moth under local abiotic or dietary stress to elaborate substantially less of one or both compounds than that normally synthesized. The implications to kin selection are discussed.

Key Words—*Zygaena filipendulae*, Lepidoptera, Zygaenidae, allomone, histamine, linamarin, cyanoglycosides, defense, synergism, avian insectivory, aposematic coloration.

INTRODUCTION

Zygaena filipendulae L. (Lepidoptera: Zygaenidae, the six-spotted Burnet moth) has a brilliant red and black aposematic coloration and is known to be unacceptable to a wide variety of vertebrate predators (Wiklund and Järvi, 1982;

0098-0331/87/0100-0133$05.00/0 © 1987 Plenum Publishing Corporation

Evans et al., 1985). Larvae and imagines of *Zygaena* are cyanogenic (Jones et al., 1962), and the adults have histamine-like activity in their body tissues (Frazer and Rothschild, 1960). The sources of cyanide are the internally synthesized bitter cyanoglycosides, linamarin and lotaustralin (Davis and Nahrstedt, 1984). The major contributor is the former (Davis and Nahrstedt, 1979, 1981, 1984). Behavioral studies with avian insectivores have indicated gustatory sensitivity and aversion to bitter substances (Brower, 1969; Alcock, 1970; Lea and Turner, 1972). Since a defensive role of these glycosides has not been demonstrated (Davis and Nahrstedt, 1981), we were interested in determining the protective value of the cyanogens and histamine in the levels actually found in the insect.

Many noxious prey have their aversive quality most highly concentrated in areas of the body most likely to receive an initial predatory attack (e.g., monarch butterflies, Brower and Glazier, 1975; and chrysomelid beetles, Pasteels et al., 1978; *Ambystoma* salamanders, Di Giovanni and Brodie, 1981). Avian insectivores usually first peck at a moth's wings (Evans, 1983); therefore, an optimal defensive strategy is the allocation of greater concentrations of protective resources in the wings. An earlier test for histamine-like activity using the inaccurate rabbit-ileum bioassay had indicated that Lebanese *Z. filipendulae* had higher levels of histamine in the wings (D.L. Evans, personal communication). A greatly improved technique (Sekardi and Friedberg, 1981) has now made it possible for us to determine accurately the concentrations of the toxin in the wings and in the bodies. This has enabled us to evaluate the defensive roles of the natural concentrations of histamine and that of cyanogens by offering these chemicals in single solutions or in combinations to avian insectivores.

METHODS AND MATERIALS

The specimens of *Z. filipendulae* were collected from various locations along the valley of the Nahr Ibrahim, Lebanon, from mid-April to mid-June, 1984 and 1985. The wings and bodies of cooled (4°C) (freezing has the effect of substantially reducing histamine content), living Burnet moths were separated, weighed, and analyzed. Half the moths from each collection were allocated to the histamine determination and half to the cyanogen tests.

The histamine assays followed the techniques of Sekardi and Friedberg (1981), used successfully by other workers (Robinson-White and Beavan, 1982). This method is summarized in Figure 1. In brief, the recovery of histamine was determined by comparing the relative fluorescence intensity of histamine coupled directly with ophthaldialdehyde and the same samples after ethanol extraction and isolation on a cation-exchange resin. Relative recovery of authentic knowns was 86.50 ± 2.49%. The linearity of the relative fluorescence intensity to histamine concentration was checked by the addition of 0.5, 1.0, 2.0, and

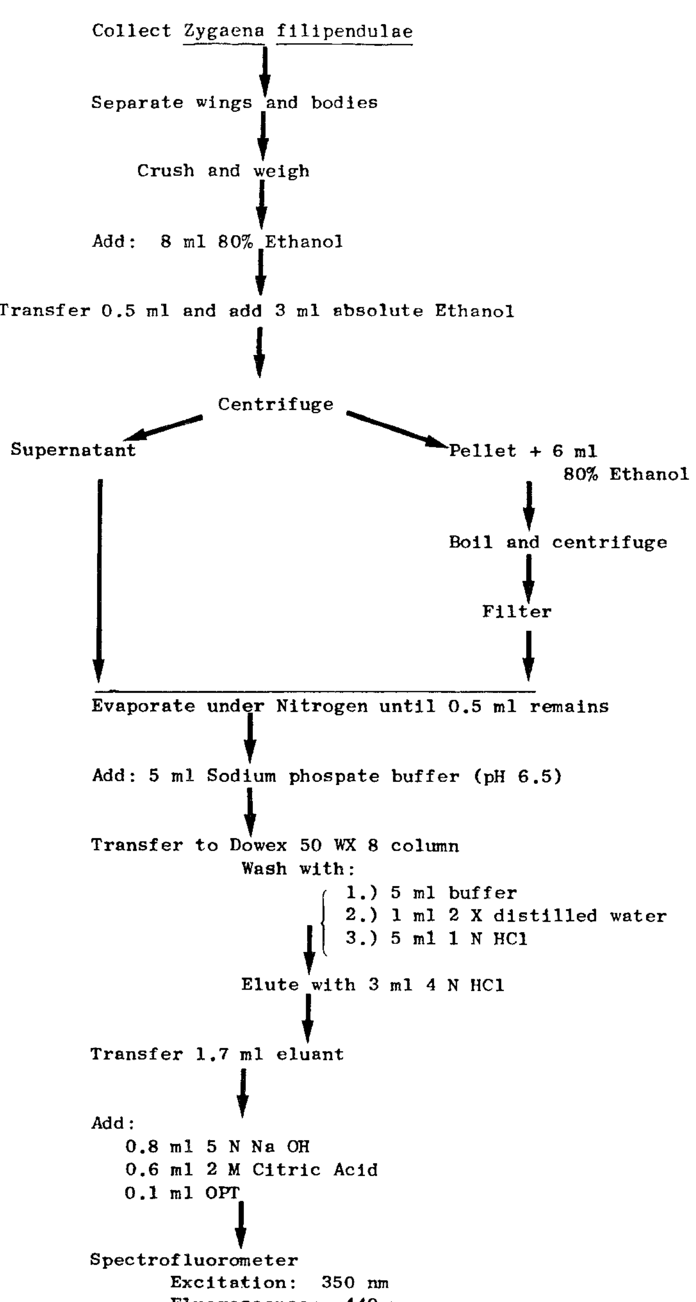

FIG. 1. Protocol for histamine determination in summary; see text for further details.

5.0 μg histamine dihydrochloride to moth tissues. Further confirmation of the results came from an earlier rabbit ileum test which indicated histamine-like activity in the same ranges as we found using the ion-exchange technique in the wings and in the bodies.

We used micro-diffusion procedures with colorimetric methods which were first coupled by Feldstein et al. (1954) to determine cyanide and, hence, cyanogen levels. This method is summarized in Figure 2 and is accurate to 1.0 ng. We checked our accuracy by means of known dish and tube standards and linearity of cyanide calibration curves. We obtained further confirmation by using a Fisher $^{-}$CN/$^{-}$I ion-selective electrode with portions of samples.

We used 10 hand-reared common quails, *Coturnix coturnix coturnix* L., to test various toxic solutions because quail tastes are better known than other easily maintained birds. In addition, low population densities of other avian insectivores in Lebanon make it difficult, practically and ethically, to experiment with other species. No quail died during these taste tests.

We used in our solutions commercially available linamarin and histamine hydrochloride. Davis and Nahrstedt (1979, 1981, 1984) have shown that linamarin and lotaustralin are the cyanogens in adult *Z. filipendulae.* We used only linamarin because: (1) it is usually present in substantially higher concentrations than lotaustralin and (2) lotaustralin is not available commercially and is difficult to isolate or to synthesize. Therefore, we allowed linamarin to act for both cyanogens, an approach also used by Witthohn and Naumann (1984).

In the solution test series, we allowed the 10 quails to choose to drink, in isolation, from two 25-ml bird fountains: one containing the toxic solution and the other distilled water (for further details, see Schuler, 1983). We adjusted for losses due to evaporation in each case. We used distilled water as an alternative rather than a sugar solution because in preliminary work we had found that there was no significant difference in the birds' choices between water and

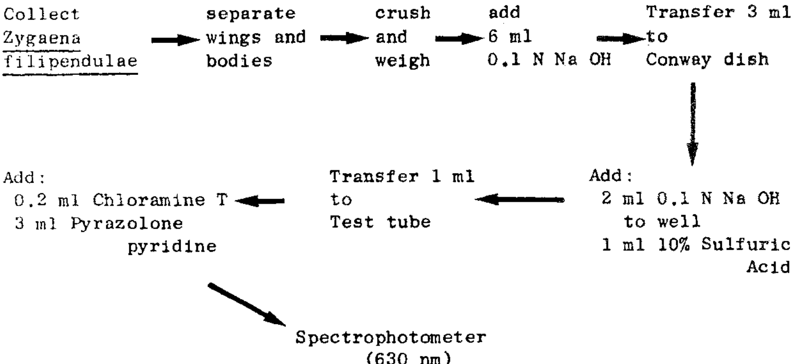

FIG. 2. Steps in cyanide quantification as outlined by Feldstein et al. (1954).

IM D-glucose ($P > 0.05$, Wilcoxon-Mann-Whitney U test; Sokal and Rohlf, 1980). The positions of test and alternative solutions were alternated to avoid the development of side preference (Evans, 1978).

It was necessary to use nonparametric statistical analyses between samples since there was significant skewness (m_3) and kurtosis (m_4) (Sokal and Rohlf, 1980).

RESULTS

The average *Zygaena filipendulae* body contained 2.92 μg of histamine and 1.632 μg HCN (61.258 μg linamarin equivalence), while the average set of wings contained 1.586 μg histamine and 0.422 μg HCN (equivalent to 4.09 μg linamarin) (all are wet weights). Insectivorous birds usually only hold unpalatable moths in their beaks rather than consuming them (Evans, 1983). Therefore, it seems to be more relevant to discuss concentrations likely to be tasted rather than contents of entire structures.

The mean concentrations of histamine and cyanogens (Table 1) were significantly different when comparing the wings versus the bodies (Wilcoxon-Mann-Whitney U tests, $P \gg 0.01$; Sokal and Rohlf, 1980). There was considerable intersample variation within the wings group and the bodies group with respect to toxin concentration. However, within some samples (each containing 6–10 moths), the histamine concentration was near the maximum but the cyanogen concentration at the minimum and vice versa. For example, a sample of wings from Ghazir, Lebanon, collected on April 18, 1985, produced 0.019 μg/mg HCN but had 0.11 μg/mg of histamine. A similar phenomenon could be demonstrated when comparing wing versus body concentrations.

We wished to determine the actual selective value to the moths of these concentrations of poisons. Merely finding something toxic in an animal does not prove that this phenomenon is useful in the creature's defense against predation. It is possible, for instance, that certain compounds are intermediates or products of some novel metabolic pathway and have no protective value whatever. Although the quails, on the average, drank lower amounts of the 1.0% histamine and the 0.1% linamarin solutions (there was a relatively high consumption of the water accompanying the 0.1% linamarin) (Table 2), a Kruskal-Wallis ANOVA test demonstrated no statistical significance ($P > 0.1$; Sokal and Rohlf, 1980) when comparing the various toxic solutions. However, Wilcoxon-Mann-Whitney U tests showed that there were significant differences between the mean amounts drunk from the poison-containing solutions and the pure water. An average concentration of linamarin in either the wings [0.462%, near the rat LD_{50} (Philbrick et al., 1977)] or the bodies (0.281%) might alone offer protection to the moths. However, no *Z. filipendulae* sample contained the

necessary 1.0% (Table 2) concentration of histamine. Significant feeding aversion could occur if a quail had eaten about 70% of the average (Table 2) total set of moth wings if linamarin were the only noxious compound present. On the other hand, feeding avoidance could only be achieved (if histamine occurred alone) when an average quail had eaten 8.9 sets of moth wings (Table 2).

Separate screening tests have also shown that 1.0% acetylcholine was the minimum aversive level, comparable to the toxic concentration of β-cyanoalanine (Ressler, 1962) found in *Z. trifolii* larvae (Witthohn and Naumann, 1984). By definition, not all samples have levels as high as the mean. However, many experimental feeding studies with several avian species (e.g., Wiklund and Järvi,

1982; Evans et al., 1985) have shown that *Z. filipendulae* are not usually handled roughly enough in birds' beaks to be killed and are rarely, if ever, eaten. Clearly, even moths with low cyanogen levels are protected.

We attempted to elucidate the role of histamine when linamarin levels were minimal. We began testing the quails' drinking rates of solutions with the highest nonsignificant linamarin solution (0.04%, Table 2) and the 0.006% mean histamine concentration actually found in the body samples. To our surprise, the birds were significantly more likely to drink distilled water ($P < 0.05$). We continued to reduce both concentrations in further trials. We next offered a solution with 10% of the mean concentration of body linamarin and with an amount of histamine equal to the lowest single solution previously offered. Significantly less of this combination toxic solution was consumed ($P = 0.05$). We diluted this latter solution by half and found no significant difference. A further dilution confirmed this latter result (Table 2).

All dosage curves were sharply sigmoidal (Table 2) with a clear threshold of aversion. The combination of both toxicants is present in substantially larger concentrations than that actually required to prevent further consumption by the birds. In a separate, ongoing set of learning experiments involving feeding on pastry worms, even the minimal histamine–linamarin combination here reported was significantly deterrent. The excessive amounts of defensive compounds usually present in the moths seem to be necessary so that the individual insects may powerfully deter feeding (and, thus, possibly instructing a predator capable of remembering the accompanying warning signal) and also be so repellent as to avoid rough handling which might lead to death or loss of reproductive potential. Hence, individual fitness is enhanced (see also Wiklund and Järvi, 1982; Evans et al., 1986).

DISCUSSION

The wings of *Z. filipendulae* usually contain a higher concentration of cyanogens and histamine than do the bodies. These concentrations are more than sufficient to induce taste aversion. Therefore, the part of the body most likely to be attacked first by insectivorous birds (Evans, 1983) has the greatest concentration of protective compounds. Evans et al. (1985) had found that naive quails did pick up the moths by the wings but then dropped the insects without further damaging the prey (see also Wiklund and Järvi, 1982).

The effect of the combination of the two poisons was greater than that of the sum of each toxicant by itself, i.e., synergism. Histamine is normally very rapidly cleared from avian circulatory systems and, in any case, gut microflora convert this compound to the inactive, *N*-acetyl histamine (Robinson-White and Beavan, 1982). Possibly, the released HCN blocks one or more of these processes. It is possible that other ratios and concentrations of these two toxins

would also be effectively deterrent. Local abiotic or dietary factors or metabolic turnover might make it impossible for an individual to elaborate or to maintain a large amount of one of the poisons throughout imaginal life. By having at least two (there are probably others; Rothschild et al., 1970; Jones et al., 1962) deterrent toxins which can act synergistically, the moth is efficiently defended even if relatively low levels of protective compounds are synthesized. Binary systems of chemical defenses have been noted before, and it has been suggested that the allelochemicals would be directed at different predatory types (Järvi et al., 1981). While this may be generally true, and operant in *Z. filipendulae* as well, it is obvious that this double system can allow for lower, effective poison levels. This powerful feeding deterrent allows for the selection of aposematism without necessarily relying on kin.

SEX PHEROMONE BLEND DISCRIMINATION BY MALE MOTHS FROM *E* AND *Z* STRAINS OF EUROPEAN CORN BORER

T.J. GLOVER,[1] X.-H. TANG, and W.L. ROELOFS

Department of Entomology
New York State Agricultural Experiment Station
Cornell University
Geneva, New York 14456

(Received October 28, 1985; accepted February 3, 1986)

Abstract—Sex pheromone behavioral responses were analyzed in a flight tunnel with European corn borer, *Ostrinia nubilalis* (Hübner), males from three distinct populations. Males from a bivoltine and a univoltine biotype using a 97.8:2.2 blend (*Z* strains) of (*Z*)- and (*E*)-11-tetradecenyl acetate were assayed with treatments containing 0, 0.5, 1, and 3% of the *E* isomer. Males from neither population oriented in the plume to the 100% *Z* treatment, but bivoltine males oriented and flew to the source to the other three treatments, whereas univoltine males oriented and flew to the source only to the 1% and 3% *E* treatments. Males from a bivoltine biotype using a 1:99 blend of *Z/E* isomers (*E* strain) were assayed with sources containing 0, 0.5, 1, and 3% of the *Z* isomer. Males did not orient to the 0% *Z* source, but oriented and flew to the source to the other three treatments. In addition to using opposite geometric isomers for the main pheromone component, the bivoltine *E* strain differed from the bivoltine *Z* strain by producing and responding better to 1% of the minor component and by storing 3 times more pheromone in the female glands. Contrary to previous reports, the blend of two pheromone components is significantly better than the main component alone in eliciting oriented flight and close-range behavior with males from all three populations of European corn borer.

Key Words—European corn borer, *Ostrinia nubilalis, Lepidoptera,* Pyralidae, (*Z*)-11-tet-radecenyl acetate, (*E*)-11-tetradecenyl acetate, pheromone, flight tunnel.

INTRODUCTION

The European corn borer (ECB), *Ostrinia nubilalis* (Hübner), is a cosmopolitan species from Europe that was introduced into North America on at least two and probably three separate occasions during the early 20th century (Caffrey and Worthley, 1927). The populations presently established in New York have distinct voltinism (Eckenrode et al., 1983) and pheromone blend characteristics. The initial infestations in New York were univoltine (Hervey and Carruth, 1939), with a bivoltine biotype initially introduced in eastern Massachusetts, spreading into New York and heavily infesting Long Island and the Hudson River Valley by 1939. The history of these biotypes in New York is outlined in Roelofs et al. (1985) and the references therein. In addition to voltinism differences, ECB populations have been found that utilize two distinct sex pheromone communication systems: a *Z* strain using a 97:3 mix of (*Z*)- and (*E*)-11-tetradecenyl acetates (*Z*11-14:OAc and *E*11-14:OAc) (Klun et al., 1973), and an *E* strain using a 4:96 blend of (*Z/E*11-14:OAcs (Kochansky et al., 1975). Roelofs et al. (1985) describe several New York populations including a bivoltine *Z*, a univoltine *Z*, and a bivoltine *E*, as well as mixed populations.

Trapping studies have demonstrated that the greatest capture of *Z* strain ECBs occurs using a 97:3 blend of *Z*11-14:OAc and *E*11-14:OAc (Klun et al., 1973, 1979; Klun and cooperators, 1975, Cardé et al., 1975). Since some trap capture also occurs with *Z*11-14:OAc alone, Webster and Cardé (1984) have suggested that *E*11-14:OAc is not required for attraction of males in this strain. They reported the results of a study involving various concentrations of the 97:3 *Z/E*11-14:OAc blend and of *Z*11-14:OAc alone. Behavioral analysis of upwind walking, wing fanning, and clasper extrusion of *Z* strain ECB males in orientation tube olfactometers with these treatments did not reveal a significant difference between the blend and the *Z*11-14:OAc alone. Although this study supported the conclusion of Chapman et al. (1975a,b) that precopulatory behavior in the *Z* strain could be elicited in the absence of the *E* isomer component, Webster and Cardé did suggest that flight-tunnel bioassays should be conducted to determine the precise behavioral responses.

In this paper we report the results of flight-tunnel studies that show the importance of the natural pheromone blend of the three ECB populations compared to the single major component and also describe important differences in behavior between the univoltine Z and bivoltine Z population described by Roelofs et al. (1985). In this paper, populations differing in voltinism are referred to as biotypes, whereas those differing in pheromone blends are referred to as strains.

METHODS AND MATERIALS

Rearing. The univoltine *Z* culture was started from field-collected larvae, pupae, and adults from corn stubble near Paris, New York, during July 1984.

The bivoltine *Z* culture was started from field-collected larvae, pupae, and adults from corn stubble near Eden, New York, during August 1984. The bivoltine *E* culture was started from adults emerging from corn stubble collected near Geneva, New York, during May 1985. The culture techniques and wheat-germ diet were the same as described in Roelofs et al. (1985). Larvae were reared at 30°C with a 16-hr photophase, and the adults were kept in a fluctuating temperature regime (27°–18°C) with a 16-hr photophase.

Pheromone Blend Sources. The *E*11–14 : OAc was TLC-purified material and the *Z*11–14 : OAc was purchased from Dr. S. Voerman at The Institute for Pesticide Research, The Netherlands. Purity of the starting materials and composition of the blends were determined by capillary GLC with a 30-m Supelcowax 10 column (bonded Carbowax 20 M, Supelco Inc.), 0.32 mm ID, using temperature programming from 80°C to 180°C at 10°/min. Both the *E*11–14 : OAc and *Z*11–14 : OAc are >98.6% pure by GLC analysis and both contain <0.05% of the opposite isomer. Blends were made in concentrations of 1 mg/ml using redistilled Skelly B as solvent. An appropriate amount of solution was then applied to 5 × 9-mm rubber stoppers (Arthur H. Thomas Company, catalog No. 8753-D22) so that the final amount of each blend was 30 μg. The 30-μg dosage was chosen after preliminary studies indicated that it was the lowest concentration to elicit maximum behavioral responses. Each stopper was allowed to stand in a hood 2–4 hr before use in the flight tunnel.

Flight Tunnel. The flight tunnel was constructed of rectangular pieces of glass with aluminum framing. The outside dimensions of the tunnel were 183 cm (72 in.) long, 61 cm (24 in.) high, and 61 cm (24 in.) wide. The wind source was a 61-cm household fan supported by brackets 30 cm from the upwind end of the tunnel with a sleeve of heavy clear plastic sheeting connecting the fan to the aluminum and glass tunnel. A wooden frame the size of the tunnel opening and covered with cheesecloth was situated between the fan sleeve and the tunnel proper. The floor of the tunnel had a pattern consisting of alternating black and white stripes 9 cm wide. Diffuse light was supplied by eight 7.5-W, 120-V GE red bulb indicator lights suspended above the tunnel from wooden framing. Single sheets of chromatography paper between the lights and the tunnel ceiling served to diffuse the light so that the illumination was uniformly 11 lux at the tunnel floor.

The downwind end of the tunnel was covered with screening to prevent insects from escaping or being sucked into the 30-cm exhaust, which was positioned 15 cm outside the end of the tunnel. The wind speed during all flights was maintained at 0.25 m/sec. The front of the tunnel consisted of a pair of sliding glass doors that facilitated recapture of the insects. The rubber stopper lures were placed 30 cm inside the upwind end of the tunnel on a stand made of 0.95 cm ($\frac{3}{8}$ in.) copper tubing. The stand consisted of a coiled base with a removable vertical section. The small end of the rubber stopper was slipped into the opening in the copper tubing, allowing the larger end to remain exposed

to the air stream at a height of 12 cm from the tunnel floor. A screen cylinder 10 cm high and 6 cm in diameter was placed 30 cm inside the downwind end of the tunnel to serve as a release stand for the males.

Flight Tunnel Protocol. Individual insects were placed in 3-cm × 6-cm screen cylinders, which in turn were placed on the release stand with the open end of the cylinder upwind. The insects were tested individually in the flight tunnel and were allowed 30–60 sec to take flight. The amount of time required to initiate flight was recorded with a stop watch. The final behavioral response was recorded using the following sequence of criteria: NR, not responding; ACT, activation, rapid wing beating, and walking; TF, taking flight; OR, orientation flight in the pheromone plume; 30 cm, flight in the plume to within 30 cm of the pheromone source; TS, touching source, landing on the pheromone stand, and touching the rubber stopper; DIS, display, clasper extrusion with wings held vertically and abdomen waving slowly from side to side. All moths tested were either flown naively or, in one specific test, were flown first to a 100% *Z* pheromone source and then within 10–30 min reflown to a 3% *E* pheromone source. All flights were conducted at 18 ± 1°C, 3–5 hr into scotophase. All insects were aged 2–3 days after eclosion in the absence of females before being used in the bioassays. The flights were conducted from August 6 to October 7, 1985.

Analysis of Natural Sex Pheromone Blends. Female ECB sex pheromone glands were analyzed similarly to the techniques described in Roelofs et al. (1985), except that tips were pooled in the present study for isomer ratios and were analyzed on the Supercowax 10 column described above. Quantitation of pheromone in single glands was carried out by adding 5 ng of standard tridecenyl acetate in 10 μl of Skelly B to the tip extract with subsequent analysis by capillary GLC.

RESULTS

Z Strains. The 2-day-old male ECBs from the bivoltine *Z* strain and the univoltine *Z* strain were flown to a series of pheromone sources that varied in the percentage of the *E* isomer from 3% to 0%. Final behavior exhibited by each moth was recorded and is summarized in Table 1. We consider any moth that touches the pheromone source to have completed the behavioral response to the source and have lumped the insects with TS and DIS responses together in our analyses. Within each strain, there were significant differences in the numbers of individuals completing the behavioral sequence at various percentages of the E isomer. The K-sample binomial test for equal proportions (Marascuilo and McSweeney, 1977) yielded chi-square values of 63.17 for the univoltine population and 69.24 for the bivoltine population ($P < 0.01$). Post hoc multiple comparisons using the simultaneous $\sqrt{\chi^2}$ procedure to generate confi-

[a] Percentages in the same row followed by the same letter are not significantly different at the 5% level using the post hoc multiple comparisons procedure of simultaneous $\sqrt{\chi^2}$ to generate confidence intervals for simple contrasts. NR = not responding; ACT = activation; TF = taking flight; OR = orientation flight in pheromone plume; 30 cm = flight in plume to within 30 cm from source; TS = touching source; DIS = display.

dence intervals for the simple contrasts (Marascuilo and McSweeney, 1977) show that in the bivoltine population the 0% *E* treatment has significantly ($P < 0.01$) fewer insects completing the behavior sequence than the other three treatments. The 3% *E*, 1% *E*, and 0.5% *E* treatments are not significantly different from each other according to this analysis. The univoltine population shows a different pattern with both the 0.5% *E* and 0% *E* sources eliciting significantly fewer responses than the 3% *E* and 1% *E* sources ($P < 0.01$).

Table 2 summarizes the amount of time required for the insects to take flight when presented with various pheromone blends. In the bivoltine population, times for five of the males flown to the 3% *E* and six of the males flown to the 0% *E* were not recorded. The time required to take flight generally increased as the percent *E* in the pheromone blend decreased in both the univoltine and bivoltine populations. This relationship also was evident in those individ-

[a] Means in the same row followed by the same letter are not significantly different at the 5% level as determined by Duncan's multiple-range test for unequal sample sizes.
[b] Means at 3% *E* and 1% *E* are significantly different at the 5% level using a *t* test for samples with unequal variances.

uals who completed the behavioral sequence except in those treatments with very few responding insects.

The results of flights of insects flown first to 0% *E* then to 3% *E* sources within 30 min are summarized in Table 3. With the bivoltine population, only 20% of the sample completed the behavioral sequence to 0% *E*, but then 97% of this sample completed the sequence to 3% *E*. These percentages are significantly different at the 0.001 level using a *t* test for proportions. All insects that displayed at 0% also displayed or touched the source at 3% *E*, with the mean time to take flight at 0% *E* of 12.3 ± 13.9 sec and at 3% *E* of 3.5 ± 6.0 sec. The univoltine population again exhibited lower sensitivity to the pheromone sources with only 7% completing the behavior sequence at 0% *E*, and then 83% of the same sample displaying or touching the source at 3% *E*. The mean time to take flight at 0% *E* was 20.4 ± 21.2 sec and at 3% *E* was 11.8 ± 19.3 sec, both of which are significantly longer than the bivoltine times as determined via *t* tests.

E *Strain.* Table 4 shows the response of *E* strain males to blends containing 0, 0.5, 1, and 3% of *Z* isomer. Statistical analysis of the data as described above shows that the 0% *Z* treatment has significantly ($P < 0.01$) fewer insects completing the behavioral sequence than the other three treatments. Fifty percent of the males presented the 0% *Z* treatment failed to orient to the pheromone

plume and only 17% were able to complete the flight to the pheromone source. High percentages of males did orient in the plume and complete the sequence to the other three treatments, similar to the bivoltine *Z* strain. With the *E* strain, however, the 1% treatment produced a higher percentage of insects completing the behavioral sequence than did the 3% treatment. This difference was not statistically significant under the analyses applied.

Analyses of Natural Sex Pheromone Blends. Female sex pheromone glands (pools of 10 glands, three replicates) of each ECB race were analyzed by capillary GLC for the amount of the minor isomer in the populations used for this study. The bivoltine *E* strain had 1.0% *Z* isomer in *E*11–14:OAc, whereas the bivoltine Z strain had 2.2% *E* isomer in Z11–14:OAc, and the univoltine *Z* strain had 2.0% *E*. Quantitation of the pheromone showed that females of the *E* strain stored substantially larger quantities of pheromone than either *Z* strain population: bivoltine $E = 13.8 \pm 10.6$ ng ($N = 89$); bivoltine $Z = 4.2 \pm 3.6$ ng ($N = 15$); univoltine $Z = 2.5 \pm 1.5$ ng ($N = 27$).

DISCUSSION

These experiments demonstrate that in the majority of the insects the natural blend is important for orientation, upwind flight, and source location. The two Z populations have different sensitivities for responding to the ratio of the minor component, with the majority of the bivoltine Z borers completing the behavioral sequence to a blend containing 0.5% *E*, whereas the univoltine borers require at least 1% *E* for a similar response. The 0% *E* pheromone source elicits activity and/or random flight in the majority of the moths tested [40/42 bivoltine Z (BZ) and 23/32 univoltine Z (UZ)]. This general activity has been reported previously by Webster and Cardé (1984) using glass tube olfactometers, but their study was unable to determine any behavioral differences between the 0% *E* and 3% *E* treatments. We found that very few of the moths were able to orient to and find the pure Z11–14:OAc component. Since 95% of the moths presented the optimal blend of 97:3 *Z/E*11–14:OAc were able to complete the behavioral sequence, we have shown that the pheromone blend significantly improves both populations' ability to locate pheromone sources in flight tunnel situations.

Studies with the bivoltine *E* strain also show that a blend of the two pheromone components is necessary for orientation and subsequent behavioral responses and that it is similar to the bivoltine *Z* strain in its high sensitivity to the 99.5:0.5 blend of isomers. However, with the bivoltine *E* strain, the 99:1 blend elicited the highest percentage of response. This follows female production since the *E* strain was found to produce a 99:1 *E/Z* ratio and the bivoltine *Z* strain was found to produce a 97.8:2.2 *Z/E* ratio. While the studies reported

here reveal the importance of both pheromone components in the ECB pheromone blend, they are part of a larger study presently underway designed to characterize the genetic basis for response differences in these three ECB populations.

Acknowledgments—We thank Dr. C.J. Eckenrode, Jr., P.S. Robbins, and M.L. Hessney for generously supplying ECB adults from the three distinct populations, and Dr. C.E. Linn for assistance in the behavioral analysis. This research was supported in part by NSF grant BSR-8500234.

ODOR SIMILARITY BETWEEN STRESS-INDUCING ODORANTS IN WISTAR RATS

A.M. FOMBON and E.H. POLAK*

Laboratoire de Neurophysiologie Comparée
Université Paris VI
9 quai Saint-Bernard, 75005 Paris, France

(Received October 23, 1985; accepted February 3, 1986)

Abstract—Odor similarity to the odor of 4-mercapto-4-methyl-2-pentanone (I) was measured on eight rats by generalization of a conditioned avoidance response to *cis*- and *trans*-8-mercapto-*p*-menthan-3-one (II and III), 3-mercapto-3-methyl-2-pentanone (V), and *t*-amyl mercaptan (VI). Previously, these odorants had been found to induce stress in rats in an open-field situation. In the present experiment, rats generalized the avoidance response learned with I, for V, VI, and to a lesser extent *trans*-isomer III, implying odor similarities; *cis* isomer II was discriminated. Odor similarity between mercapto ketone I and mercaptan VI is surprising since VI lacks the keto group.

Key Words—Avoidance behavior, generalized avoidance, mercapto ketones, mercaptans, odor similarity, rat, stress, structure activity relationship.

INTRODUCTION

In a previous experiment, Vernet-Maury et al. (1984) found that several mercapto compounds induced stress response in Wistar rats placed in an open-field situation. Stress was analyzed by quantifying several stress behavior responses and by measuring plasma corticosterone concentrations. The mercapto compounds were either synthetic equivalents or were structurally related to volatiles identified in fox droppings.

Stress response of the laboratory rat is apparently inherited and is probably related to particular components of the complex odorous signals released by the fox. Among the odorants inducing a stress response were several mercaptoketones (I, II, III, V) and one mercaptan (VI) (Figure 1). These have similar odor quality for humans and are reminiscent of male cat urine[1] (Polak et al., 1987).

[1] It has not yet been reported whether these odorants actually occur in cat urine.

FIG. 1. Structural formulae of odorants used.

The purpose of the present experiment was to evaluate whether analogous odor similarities and structure odor relationships would be found in the rat by a generalization procedure.

An extensive literature in vision and audition has shown that an animal trained by conditioning to respond to one stimulus will subsequently give responses that may vary with related stimuli. Generally, such experiments produce a gradient of response generalization (e.g., Guttman and Kalish, 1956), representing the stimulus variation along a known physical dimension. With olfactory stimuli, such generalization experiments are more difficult to design, because the quality of the stimulus cannot be modified along one physically measurable dimension equivalent to, e.g., wavelength. Mason and Stevens (1981) showed that salamanders trained to avoid one odor stimulus subsequently avoided two homologs. Rats trained to discriminate between two sexual odors (Slotnick and Born, 1979), or pure odorants without bilogoical relevance (Braun and Marcus, 1969), generalized to two related odors. However, for mice, the introduction of four new odorants during the generalization phase caused general response inhibition (Kaneko, 1979). Aversive conditioning of rats with lithium chloride, as used with taste (Halpern and Tapper, 1971; Domjan, 1975; Dugas du Villard et al., 1981), has been tried by us for several years (Polak, 1978). Unfortunately, reliable generalization (nondiscrimination) responses

could not be obtained due to the extinction of aversive learning during the first test session.

In the present experiment, we have used a method which in principle is the same as that used by Slotnick and Born (1979) and Braun and Marcus (1969). Thirsty rats were trained to discriminate between 4-mercapto-4-methyl-2-pentanone (I) and isoamyl acetate and tested for generalization of the response to odorants structurally related to I, namely *cis*-8-mercapto-*p*-menthan-3-one (II), *trans*-8-mercapto-*p*-menthan-3-one (III), 3-mercapto-3-methyl-2-pentanone (V), and *t*-amyl mercaptan (VI) (Figure 1), as well as the unrelated odorants decanal (fatty odor), 2-phenylethanol (rose odor), anethole (anise odor), and methyl anthranilate (tangerine odor).

Our goal was to test as many odorants as possible per rat, in order to detect individual characteristics of the response patterns. Consequently, we have tested all four pairs on each of a small number of rats ($N = 8$) rather than each pair separately on four sets of rats.

METHODS AND MATERIALS

Stimuli

Odorants. The structural formulas of odorants used in this study are shown in Figure 1. In Table 1 are given the chemical name, code in Roman numeral, the supplier, the purity, the method of analysis (GLC or TLC), the purification

TABLE 1.

Code	Name	Source	Estimated purity
I	4-mercapto-4-methyl-2-pentanone (19872-62-7)	Givaudan Research, Dubendorf, Switzerland	TLC: one spot
II	*cis*-8-mercapto-p-menthan-3-one (34349-25-2)	[a]	TLC: ±99%, one impurity
III	*trans*-8-mercapto-*p*-menthan-3-one	[a]	TLC: one spot
V	3-mercapto-3-methyl-2-pentanone	PFW B.V., Amersfoort, Holland	TLC: one spot GLC: 99%
VI	*t*-amyl mercaptan (2-methyl-2-butanethiol) (1679-09-0)	Jansen Chimica, Beerse, Belgium[b]	GLC: 99.5%

[a] The mixture of *cis*(+) and *trans*(−) isomers (ratio 40:60) was furnished by Givaudan. The isomers were separated and purified by M. Colin, I.C.S.N.-CNRS, Gif-sur-Yvette, France, according to an LLC procedure furnished by K.B. de Roos, Research Laboratory, PFW B.V., Amersfoort, Holland, using deactivated silica gel.

[b] The technical grade (GLC 98.7%) was purchased from Jansen, Beerse, Belgium, and purified by PFW B.V. by preparative LLC and GLC to 99.5%.

method where applicable, and the Chemical Abstracts registry number in parentheses. Chemical Abstracts nomenclature has been added in parentheses wherever it differs from the common usage names used in the text.

Isoamnyl acetate (AA), decanal (DE), phenylethanol (PE), anethole (AN), and methyl anthranilate (MA) were of best commercial quality available. These were not analyzed further.

Solvents. An odorless grade of diethylene glycol (DEG) was used as solvent to prepare odorant dilutions. An odorless grade of commercial mineral water was used, pretreated with 6 mg/liter of odorless chelating agent, ethylenediamine tetraacetic acid tetrasodium salt (EDTA) (J.T. Baker Chemicals B.V., Deventer, Holland). This treatment is essential to complex traces of heavy metal ions capable of neutralizing the mercapto (thiol) odor. Dissolved EDTA did not change the odor background for humans.

Stimuli Concentrations. These are listed in Table 2. Odorants were prediluted in DEG (0.1–0.0001%) and added to EDTA-treated water immediately prior to use each day. All concentrations were volume/volume in DEG or water. Headspace concentrations were not determined.

Stability of Stimuli. Because mercaptoketones and mercaptans are unstable and prone to oxidation to less intense odors in the presence of air, light, and trace metals, they were stored at low temperature ($<0°C$) as such or in DEG solutions.

Animals

Eight adult male Wistar rats (6–8 weeks old, 250 g) were housed in individual cages in a temperature-controlled room (23°C) provided with food pellets and water. Water deprivation began 24 hr after arrival in order to motivate

TABLE 2. CONCENTRATIONS USED

Odorants	Concentration (10^{-3} μl/liter water, equivalent to ppb)
I	0.1, 0.25, 0.5,[a] 1

Phenylethanol	10,000
Anethole	5000
Methyl anthranilate	50

[a] Concentration used during training

drinking during the experimental sessions. Water intake was limited to 16–20 ml/24 hr, and the weight of each rat was thus kept at 80% of ad libitum weight. Rats were weighed daily, just before the experimental session. Eight rats was the maximum that could be handled in eight successive 1-hr daily individual sessions.

Apparatus

The apparatus consisted of a 24.5 × 20 × 24-cm steel box from Cambden Instrument (USA). The front wall was a door made from clear plexiglas through which the rat's behavior was observed. The floor was a 1-cm spaced steel bar grill (Figures 2A, B).

Odor stimulus was delivered by unassisted evaporation from a film formed on the ball-bearing closing the nickel water-delivery spout. The evaporating film was estimated to have a surface of 20 mm^2. The water spout was attached to a 2-ml Plexiglas syringe containing an aqueous solution of the odorant. This removable syringe was clipped into a Plexiglas holder attached to the box. It was introduced for 10 sec through a 2-cm-diameter hole in the wall at 10 cm above the floor. In front of the spout was placed a vertical brass barrier (2.5 × 2 cm), with a 0.5-cm-diameter hole through which the rat could smell and lick. The tongue alone could touch the spout. The rat made approximately 60 licks per 10 sec, drinking 0.2 ml of aromatized water.

In the presence of a negatively reinforced stimulus (odorant I, see below), each lick induced an electric shock to the tongue with a constant intensity of 100 μA; the rat closed the circuit by simultaneously touching the spout and the brass barrier with its tongue.

Odor Stimulus

Odorant dilutions were prepared fresh every day, in 100 ml water pretreated with 6 ppm EDTA. DEG was adjusted so that the final concentration in all trials was the same (100 μl/100 ml water). During the session, the syringe was filled just before the trial with an aqueous solution. The concentrations used in water were adjusted so as to be just perceptible by the experimenter at the water spout exit. The concentrations used are listed in Table 2. It should be noted that, prior to the experiment, response thresholds of the nonmercapto odors were evaluated with naive rats. Behavioral threshold concentrations were a minimum of 10× lower than those actually used in the present experiment.

Procedure

The experiment began one week after arrival of the rats. Each rat had a 1-hr daily session at 24-hr intervals during six days per week for about six weeks.

Pretraining. On each of five days prior to conditioning, each rat spent 20

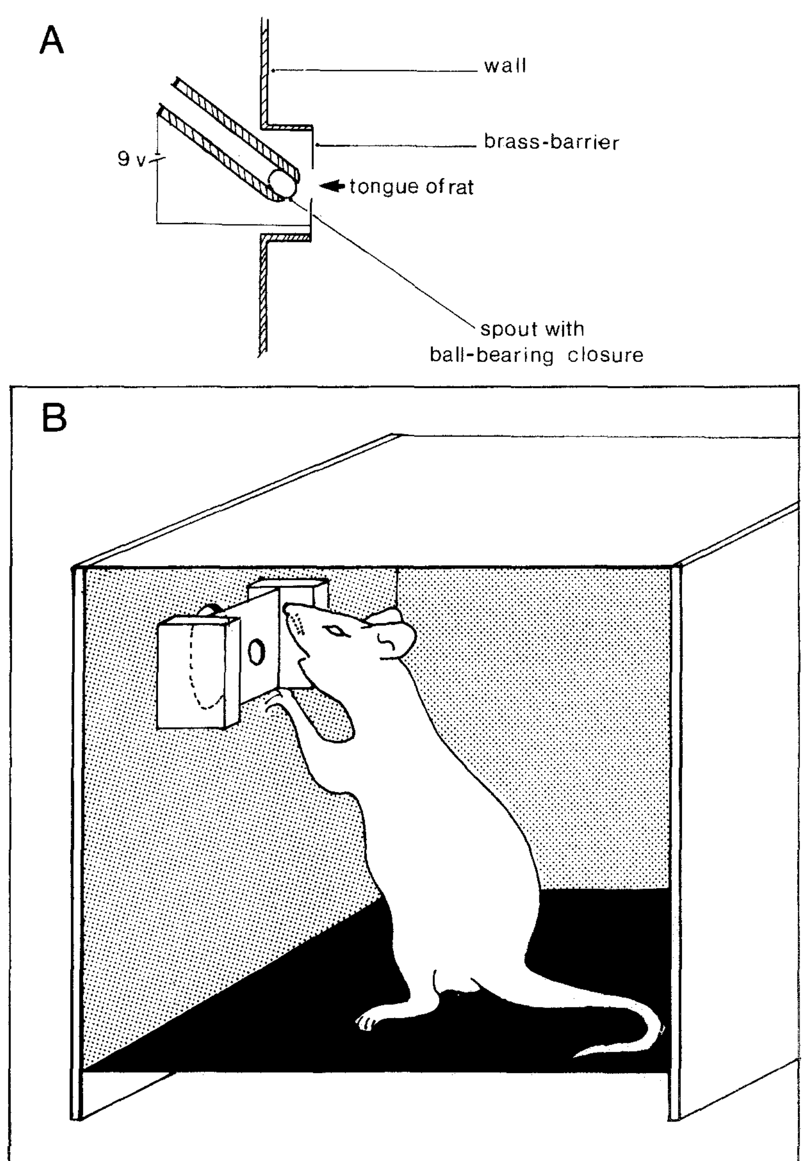

FIG. 2. Experimental box, general view (B) and detail of stimulus delivery (A). For description see text.

min in the experiment box in order to learn to drink water from the spout without shock. The duration of each trial was reduced from one day to the next, attaining 10 sec on the fifth day.

Training. Rats were trained to discriminate between isoamyl acetate (5 ppm) and mercapto odorant I (0.5 ppb) during 1-h sessions. In a training session, each of these two odorants was presented for 20 trials according to a pseudorandom sequence that allowed no more than three consecutive presentations of the same odorant. For all animals isoamyl acetate (AA) was the positive stimulus (S^+) and the mercapto odorant I was the negative stimulus (S^-). An approach response was defined as the first lick made on the spout. During the S^+ trials rats were positively reinforced by being allowed to drink from the spout for 10 sec. During the S^- trials, rats were negatively reinforced by an electrical shock on the tongue with each lick. An avoidance response was defined as the absence of licking for 10 sec.

The trial began with the introduction of a syringe holding aromatized water solution and ended with withdrawal of it. In the case of an approach response with S^-, the syringe was removed as soon as the rat withdrew from the spout after a few licks with shock.

To minimize pheromonal odor markings (Stevens and Koster, 1972; Valenta and Rigby, 1968), syringes and spouts were changed for each trial. After one session, spouts were washed with alcohol and water, attached to other syringes, and the inside of the box was wiped with water, before introducing the next rat.

Rats received a water ration in the home cage, 1 hr after the end of their session.

The criterion of learning was set at 15/20 correct approach responses to S^+ or avoidance responses to S^-.

Extension to Several Intensity Levels. During training, AA and I were presented at one concentration level. When the learning criterion was reached, these odorants were presented at different concentrations five times at each session, in order to minimize responses based on intensity rather than quality (Table 2).

Generalization to Other Odorants. In this phase of the experiment, the same eight rats were tested for responses to four mercapto odorants and four nonmercapto odorants. A total of 50 trials per rat were given per daily session in which one new mercapto odorant and one nonmercapto odorant were tested for generalization. Each new odorant pair was tested during three successive sessions, so that each rat was exposed to four new odorant pairs in 12 sessions.

The session began with 10 training trials. Five presentations of S^+ (AA) with positive reinforcement were given interspersed with five presentations of S^- (I) with negative reinforcement. Subsequently, 28 generalization trials were given; six presentations of each new product (mercapto or nonmercapto) were interspersed with eight presentations of S^+ and eight presentations of S^-. In

trials with a new product, no shock was given, and the rats were given an opportunity of positive reinforcement by allowing them to drink for 10 seconds in the case of a nonavoidance response. This modification of classical methods of generalization, where negative or positive reinforcement is not given, was necessitated by the mode of presentation of the odorant stimulus. The session ended with 12 retraining trials, with six presentations of S^+ and six presentations of S^-.

Because only eight animals were used in this experiment, the sequence of odor pairs presented was the same for all rats (VII with decanal, V with phenylethanol, III with anethole, II with methyl anthranilate).

RESULTS

Training

The performance of eight rats during training is shown in Figure 3. AA and stimulus I were effective stimuli for conditioning. Because approach responses with S^+ rapidly reached a maximum of 20/20 and were not affected by any experimental modifications, we have considered the responses with S^-.

The mean number of trials necessary to obtain the learning criterion (15/20) avoidance responses for S^- was 209 $\pm$ 39 and was reached within nine days.

In two subsequent training sessions with four concentrations of the stimuli, avoidance responses with the lowest level of S^- were less than 75%, but never lower than 58%. They were unchanged at the other concentrations.

Generalization

Student's test for paired samples showed that the mean total of avoidance responses with S^- (I) decreased only in the first generalization session in comparison to the last training session (t = 3.41; $P < 0.05$) (Figure 4). This perturbation of performance was certainly due to modifications in the experimental situation (increase in number of trials, introduction of new odorants such as decanal, etc.), rather than to a process of extinction. In the following sessions, the performance improved again.

Group results for the tested odorants are shown in Figure 5. The percentage of avoidance responses concerns the 20 generalization trials given per session (six trials with each new odorant and eight trials with S^-).

The mean percentage avoidance responses were transformed into an arcsin score for each group of products and subjected to two-way within-subjects ANOVA. Tukey's test was then performed to determine whether response differences occurred.

Group VI, DE, I. Analysis showed differences between odorants [$F(2, 14)$

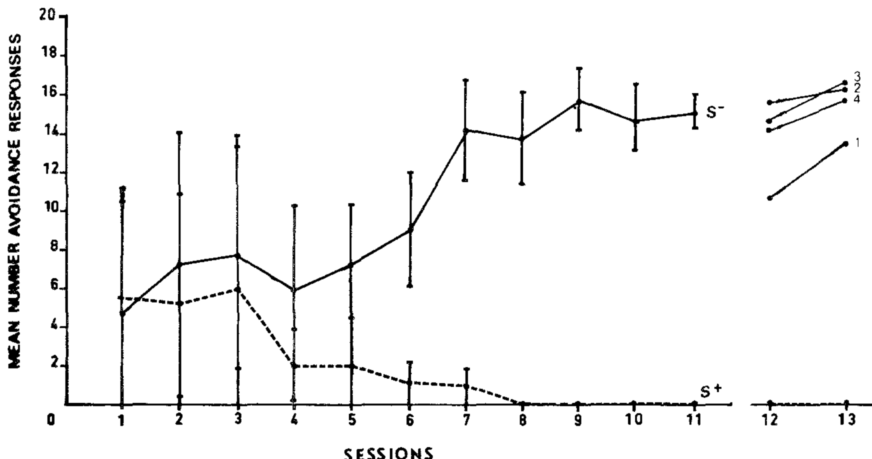

FIG. 3. Mean of avoidance responses for eight rats during training (13 sessions). Solid line: S^- is 4-mercapto-4-methyl-2-pentanone (I); dotted line: S^+ is isoamyl acetate (AA). After criterion was reached (sessions 12, 13), S^- and S^+ were presented at four concentration levels (v/v) for S^-: 1 = 0.1 ppb, 2 = 0.25 ppb, 3 = 0.50 ppb, and 4 = 1 ppb; for S^+: 1 = 1000 ppb, 2 = 2500 ppb, 3 = 5000 ppb, and 4 = 10,000 ppb.

= 32.56, $P < 0.001$] and between sessions [$F(2,14) = 12.77$, $P < 0.001$]. Tukey's test ($P = 0.05$) on the odorant variable showed that the responses in all three sessions differentiate decanal (DE) from VI and I and that VI was not differentiated from I, despite the fact that avoidance to VI decreased significantly across sessions.

Group V, PE, I. Analysis showed a difference between odorants [$F(2, 14) = 65.02$, $P < 0.001$] and between sessions [$F(2, 14) = 13.81$, $P < 0.001$]. Tukey's test showed that V differed in response to both I and phenylethanol (PE), while in the second and third sessions the response of V did not differ any longer from that of PE. The latter differed from I in all three sessions.

Group III, AN, I. Analysis showed a difference between odorants [$F(2, 14) = 20.44$, $P < 0.001$] and between rats [$F(7, 28) = 5.54$, $P < 0.01$], but not between sessions. Because of this response variability, differences could not be analyzed group-wise. A chi-square test done on individual rat frequency avoidance responses showed that two rats avoided III as often as I ($\chi^2 = 0.13$, and $\chi^2 = 1.95$), one rat avoided III less than I ($\chi^2 = 7.08$, $P < 0.01$) but more than anethole (AN) ($\chi^2 = 7.09$, $P < 0.01$), and five rats did not avoid III significantly compared to AN.

Group II, MA, I. Analysis showed only a difference between odorants [$F(2, 14) = 218.4$, $P < 0.01$]. Tukey's test showed that II and MAN, both with few avoidance responses, did not differ from each other, but did differ from I.

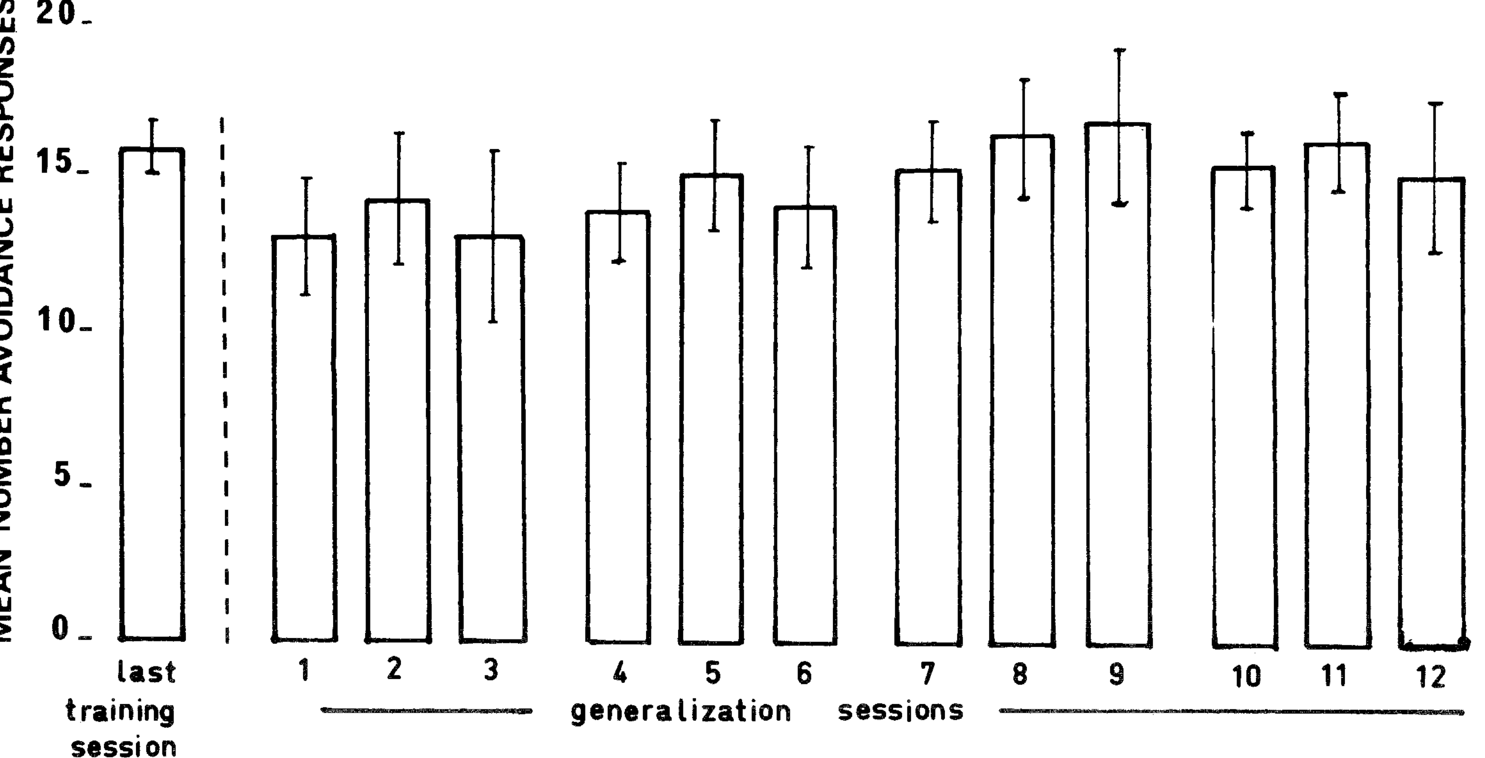

FIG. 4. Mean of avoidance responses with training odorant 4-mercapto-4-methyl-2-pentanone (I) during the last training session, and during generalization sessions (20 trials with I per session). $N = 8$ rats. *t*-Amylmercaptan (VI) and decanal (DE) were tested in sessions 1, 2, and 3; 3-mercapto-3-methyl-2-pentanone (V) and phenylethanol (PE) in sessions 4, 5, and 6; *trans*-8-mercapto-*p*-menthan-3-one (III) and anethole (AN) in sessions 7, 8, and 9; and *cis*-8-mercapto-*p*-menthan-3-one (II) and methyl anthranilate (MA) in sessions 10, 11, and 12.

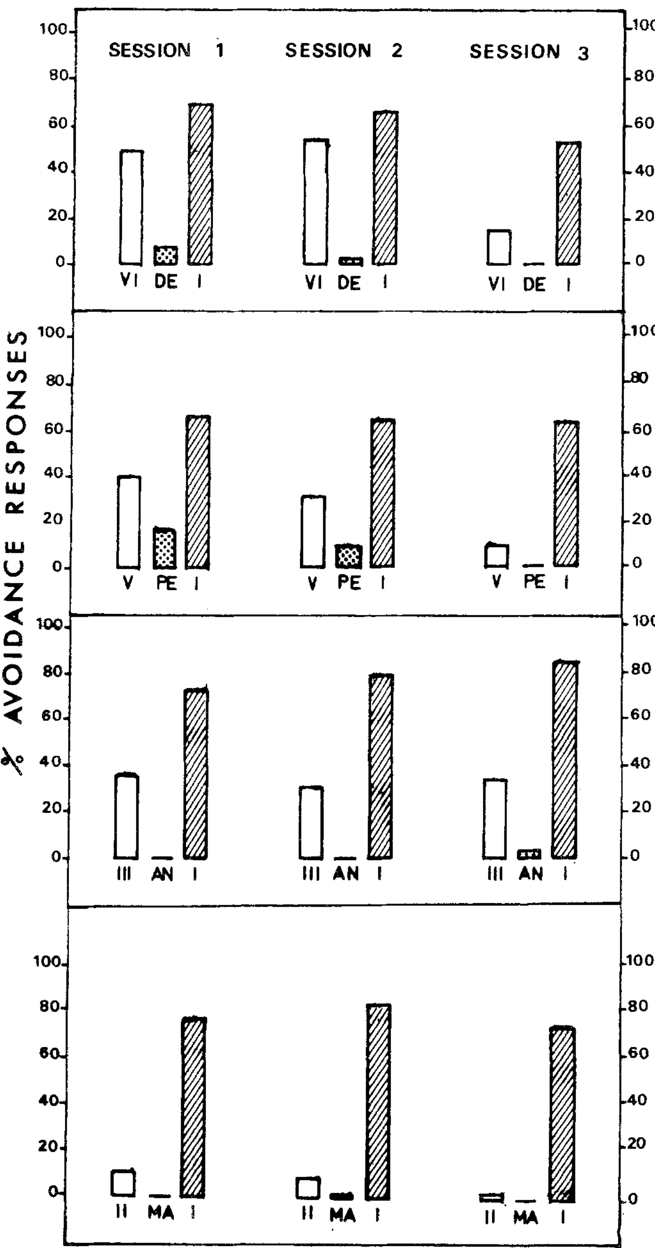

FIG. 5. Total percentage of avoidance responses for eight rats with mercapto odorants VI, V, III, II (open histograms); nonmercapto odorants DE, PE, AN, MA (stippled histograms) and training odorant I (striped histograms) during the three generalization sessions. For statistical analysis, see Results in text.

DISCUSSION

In the experiment of Vernet-Maury et al. (1984), the behavioral stress response was assessed by observing naive unconditioned rats upon entry into a standard ''open field'' box containing odorized air. In addition, physiological stress was determined by measuring the plasma corticosterone concentration.

While we did not quantify the behavior, signs of stress behavior, such as freezing (Cattarelli et al., 1974a, b; Riess, 1945) were never observed at any of the odorant concentrations tested under our experimental conditions. When training began, the rats approached the water spout spontaneously and drank water flavored with either isoamyl acetate or with mercaptoketone I in the same manner and with similar response latency (median 0.62 sec with AA and 0.65 sec with I). Odorant I was thus an effective stimulus for eliciting a conditioned response. Learning criterion was not reached faster with it than with a neutral odorant such as octanol-2 as S^- versus isoamyl acetate (Polak, 1983). In the generalization phase, avoidance responses observed with the mercapto odorants show that the rats were able to generalize the response learned to stimuli other than the training stimulus. The low percentage of avoidance responses with nonmercapto odorants proves that the rats did not systematically avoid any new odorant, it also suggests that avoidance response with new mercapto odorants is due to common odor properties with the training odorant I.

However, the generalization is only partial and decreases with time. This could be due to our experimental procedure. Thus, odor concentrations were not adjusted to equal intensity per rat. Only training odors I and isoamyl acetate were presented at four different concentrations with a 20-fold spread. We do not know whether all rats perceived the test odorants within this intensity range. The interaction between quality and intensity for the test odors could be different from I and consequently reduce the strength of conditioned association (Panhuber, 1982).

Also, the rats had the option of drinking water flavored with all odorants except S^- (I). This generalization procedure differs from usual methods (e.g., Braun and Marcus, 1969) that suppress any reinforcement during generalization sequence. Our procedure may lead rats to seek small differences between training stimulus and test stimuli and thus reduce the generalization responses.

In addition, results show that the first odorant (VI) was more avoided than the last one (II). New odorants were presented in a fixed order and not with a random series, and this order effect could have contributed to an extinction of generalization. But, if this order effect dominated, a continuous decrease of avoidance responses would be expected from the end of testing one mercapto odorant to the start of the next one. Figure 5 shows that any order effect, if present, did not mask qualitative generalization.

In spite of these reservations, the results suggest that odorants V and VI share similar odor aspects with the training stimulus (I), while for III this applies

to only three of eight rats. For human subjects, these mercapto odorants (I, II, III, V, VI) were quite similar, as shown by poor discrimination (Polak et al., 1987).

In terms of odor structure relationships, the similar odorants also share certain structural features as already discussed elsewhere (Polak, 1983; Vernet-Maury et al., 1984; Polak et al., 1987). In this experiment too we made the surprising observation that the keto group is not essential to odor similarity, since mercaptoketone I is confused with mercaptan VI. Dreiding models of the alkyl mercapto odorants (I, V, VI) can take up spatial conformations that overlap equally well with either the *cis* isomer (II) or the *trans* isomer (III) of the larger cyclical molecule 8-mercapto-*p*-menthan-3-one. Since *cis* (II) was better descriminated from I than *trans* (III) was, it suggests that the odor-active conformers of I, V, and VI correspond closer to the configuration of III than that of II.

CONCLUSION

When several odorants cause a stress response, it does not necessarily follow that they all have similar odor quality. It could signify recognition of a common origin, such as a predator.

2,4,5-Trimethyl-Δ^3-thiazoline, an active principle of fox droppings (Vernet-Maury, 1980) was found to be equally or more stressful to rats than the mercaptoketones (Vernet-Maury et al., 1984), which to humans at least are of an entirely different odor type.

Of the five mercapto compounds common to the present experiment and the stress experiment, three [4-mercapto-4-methyl-2-pentanone (I), 3-mercapto-3-methyl-2-pentanone (V), *t*-amyl mercaptan (2-methyl-2-butanethiol) (VI)] were all stressful (Vernet et al., 1984) and frequently confused by most rats. In contrast, *cis*-8-mercapto-*p*-menthan-3-one (II) was as stressful as I, but was discriminated from I by all rats in the present experiment. The stressful stimulus *trans*-8-mercapto-*p*-menthan-3-one (III) was intermediate and not uniformly generalized. Finally, this experiment suggests that the odor similarity to I can be principal element of the stress response for V and VI, but not for II.

Acknowledgments—We express our gratitude for gifts of mercapto odorants from P.F.W. and Givaudan, for helpful discussions with P. MacLeod, and for odorant purifications by M. Colin and PFW B.V.

RESIDUAL ACTIVITY OF OVIPOSITION-DETERRING PHEROMONE IN *Rhagoletis pomonella* (Diptera: Tephritidae) AND FEMALE RESPONSE TO INFESTED FRUIT

ANNE L. AVERILL[1] and RONALD J. PROKOPY

Department of Entomology
University of Massachusetts
Amherst, Massachusetts 01003

(Received May 28, 1985; accepted February 6, 1986)

Abstract—Under dry conditions, oviposition-deterring pheromone (ODP) of the apple maggot fly (*Rhagoletis pomonella* Walsh) on host fruit proved deterrent to ovipositing females for at least three weeks, with a half-life of ca. 11 days. There was no difference in decline of residual activity under lab vs. field conditions or between fly-deposited ODP vs. an application of a water extract of ODP. A decline in pheromone activity resulted from exposure to both natural and simulated rainfall. For natural rainfall, greatest losses (50–61%) in activity resulted from high-intensity rains, with substantially less activity lost (13–35%) following light or moderate intensity rains. *R. pomonella* females discriminated against fruit without ODP but with conspecific larvae. Discrimination against infested fruit was manifested within fewer days following infestation of small fruit (9 mm diam.) as compared to larger fruit (15 mm diam.).

Key Words—*Rhagoletis pomonella*, apple maggot fly, pheromone, oviposition deterrent, Diptera, Tephritidae.

INTRODUCTION

A resource partitioning system that relies on a chemical stimulus such as a pheromone to mediate against overcrowding may be influenced by a diversity of factors such as the production, release, reception, and residual properties of the stimulus involved. In regard to the latter, persistence of a pheromone may

[1] Present address: Department of Entomology, New York State Agricultural Experiment Station, Geneva, New York 14456.

0098-0331/87/0100-0167$05.00/0 © 1987 Plenum Publishing Corporation

vary over time according to the species of insect and the nature of the message conveyed. For example, a repellent pheromone deposited by *Xylocopa* bees following extraction of nectar from passion flowers persists for only about 10 min, the time required for at least partial nectar replenishment (Frankie and Vinson, 1977), whereas *Pieris brassicae* butterflies deposit an oviposition-deterring pheromone (ODP) during egg-laying that is deterrent for more than 14 days, the maximum time required for egg incubation (Schoonhoven et al., 1981).

Among other phytophagous insects that utilize oviposition-deterring pheromones to signal recognition of previously infested plants or plant parts, deterrent components from occupied resources may be emitted until completion of larval development, such as pheromonal release by larvae of *Ephestia*, *Plodia*, and *Heliothis* (Prokopy et al., 1984). On the other hand, as far as is known, the ODPs produced by over a dozen different species of tephritid fruit flies are characterized by moderate residual activity and water solubility (Averill and Prokopy, 1987). As a result, several researchers have questioned the effectiveness of these pheromones as mediators of uniform egg dispersion and larval competition: pheromonal activity may break down prior to completion of larval development and, in climates with moderate to high precipitation, activity conceivably may be lost rather quickly (Katsoyannos, 1975; Girolami et al., 1981; Prokopy et al., 1984). Here, one might suspect selection would favor female detection of larvae, or their effects.

Although studies aimed at understanding the ecological significance of these chemical stimuli are of interest to many researchers, most data concerning residual activity of ODPs have been generated by applied entomologists: if ODPs could be isolated, identified, and synthesized, spraying host crops might become an important new approach to pest management, especially if used in conjunction with appropriate traps to capture deterred females (Prokopy, 1972, 1975; Boller, 1981).

In the laboratory and field, we investigated the residual activity of *R. pomonella* ODP over time under dry conditions as well as following exposure to varying intensities and durations of natural and simulated rainfall. Further, because it appeared that host discrimination mediated by pheromone broke down before completion of larval development, we determined whether females could discriminate against larva-infested fruit.

METHODS AND MATERIALS

All flies bioassayed in lab tests and utilized for fruit infestations or for pheromone collections emerged from puparia formed by larvae that infested *Crataegus* hawthorns. (Hawthorn is the native host fruit of *R. pomonella*). Adults were maintained at 25°C, 60% relative humidity, and 16hr:8hr light–dark photoperiod in 30 × 30 × 30-cm Plexiglass-screen cages and provided a diet of sucrose, enzymatic yeast hydrolyzate, and water.

Unless indicated, for all bioassays of female response to various fruit treatments, Downy hawthorns (*Crataegus mollis*) were used. A total of 5–9 treated and control assay fruit was hung 6–8 cm apart from the ceiling of a Plexiglass-screen observation cage (30 × 30 × 30 cm). Unless otherwise stated, four cages were observed simultaneously and at least 20 different flies were bioassayed. A single mature *R. pomonella* female, which had just begun oviposition in a clean fruit attached to the end of a dissecting probe, was introduced into the assay cage by placing the probe near the cage floor. The female was allowed to fly to an assay fruit overhead and subsequently allowed to visit assay fruit for up to 2 hr. Females were excluded from tests if they rejected several (ca. 5) successive clean fruit. Acceptance (attempting oviposition before leaving) or rejection (leaving without attempting oviposition) was recorded for each visit to a fruit. When a female did accept a fruit, she was, immediately following egg deposition, gently transferred to a nonassay fruit, where she commenced and completed ovipositior dragging. In this way, contamination of assay fruit with pheromone was minimized.

Residual Activity of ODP over Time under Dry Conditions. Fresh-picked, 15-mm-diam. sour cherries were placed in a high humidity plastic box, and either 14, 10, 7, 3, or 0 days prior to behavioral bioassays of pheromone activity, each of several fruit was pheromone marked by five *R. pomonella* females. This level of pheromone deposition is known to be highly deterrent to arriving females (Averill and Prokopy, unpublished data). We used cherries in place of hawthorns because they were available and less likely to rot as rapidly. To obtain pheromone-marked fruit free of egg infestation, females that had just oviposited in nonassay fruit were transferred to assay fruit, where they commenced and completed ovipositor dragging. Unmarked control fruit were held in an identical manner as treated fruit. All treatments were bioassayed simultaneously. Bioassays were run with five treated fruit (marked 14, 10, 7, 3, or 0 days prior to bioassay) plus two clean control fruit. The experiment was replicated twice.

A second series of sour cherries was maintained as above, but at 14, 10, 7, 3, or 0 days prior to bioassay, several fruit were swabbed with a water extract of ODP. Pheromone extract was prepared as follows: pheromone was collected by rinsing hawthorns used for oviposition with a known volume of distilled water. The amount of pheromone collected was estimated by counting the number of oviposition punctures in each washed fruit: 1 puncture = 1 dragging bout equivalent (DE). In this experiment, we applied a concentration of 30 DE/fruit, an amount known to elicit a high level (ca. 89%) of fruit rejection by egg-laying females (Averill and Prokopy, unpublished data). Bioassays were set up as in the above experiment, and the experiment was replicated twice.

Residual activity of pheromone in the field was evaluated using 18- or 19-mm-diam. unpicked *C. mollis* fruit. Five *R. pomonella* females were allowed to deposit pheromone on a single fruit either 21, 16, 12, 8, 4, or 0 days prior

to bioassay (= treated fruit). As with laboratory-held fruit, marking females were not allowed to oviposit in the assay fruit. All pheromone-marked and clean control fruit were protected from rainfall by plastic hoods with mesh sides and bottom. Bioassays were run with six treated fruit plus two clean, control fruit.

Effect of Rainfall on Activity of ODP. C. mollis fruit, 15–16 mm diam, which had been picked the previous season and refrigerated for up to nine months, were pheromone-marked in the lab. Females were allowed to deposit an amount of pheromone equivalent to 6 dragging circles/fruit (1 dragging circle = ovipositor extended over a distance equivalent to the circumference of the fruit). Fruit were pheromone-marked 10 min to 2 hr prior to rainfall initiation, and along with clean control fruit, where hung by wires among natural growing clusters of *C. mollis* in the field. Several additional pheromone-marked fruit were similarly hung, but were rain-protected by plastic hoods as described above. Individual bioassays were run with two each of: rain-exposed, clean control fruit; rain-exposed, pheromone-marked fruit; and non-rain-exposed, pheromone-marked fruit. Following each rain event, fruit were bioassayed using a minimum of 12 flies.

Effect of Simulated Rain on Activity of ODP. Fruit were prepared as for field tests, but were hung on wires and exposed to simulated rainfall. Artificial rain was produced using an adjustable sprinkler attached to a garden hose. Fruit, 16 mm diam., marked with six dragging circles were bioassayed following two different intensities of artificial rain: light–moderate (4.5 mm/hr) and extremely heavy (32 mm/hr). Several of these fruit were collected following each of 0, $\frac{1}{2}$, 1, or 2 hr of rain exposure (= treated fruit). Unmarked control fruit were exposed to the rainfall for 2 hr. Bioassays consisted of four treated and two control fruit. Each simulated rain type was replicated twice, on different days.

In both the natural and simulated rainfall tests, percentage loss in pheromone activity following a rain treatment was established by: (1) calculating the difference between percentage acceptance of clean control fruit and pheromone-marked, non-rain-exposed fruit, (2) calculating the difference between percentage acceptance of pheromone-marked, rain-exposed fruit and pheromone-marked, non-rain-exposed fruit, and (3) determining percentage loss by calculating what percentage the second value was of the first.

Effect of Presence of Developing Larva on Fruit Acceptance by Ovipositing Females. We ran the following tests using picked sour cherries and *C. oxyacantha* hawthorns because a bacterial rot destroyed the unpicked *C. mollis* fruit we initially infested.

Fresh-picked, 15-mm-diam. sour cherries were placed in a high-humidity plastic box (= day 0). On days 0, 5, and 9, several fruit were infested by allowing a female to oviposit a single egg. Females were not allowed to deposit pheromone. Control fruit were held in an identical manner as infested fruit. Bioassay of infested fruit was run on day 14, so that fruit possibly containing a single first, second, or third instar larva could be bioassayed simultaneously.

The response of a total of nine individual flies was observed in each of three bioassay cages containing six presumably infested fruit plus two control fruit. Upon completion of bioassays, dissection of fruit revealed that a total of five bioassay fruit contained no larvae, five contained a first instar, four a second instar, and five a third instar.

For *C. oxyacantha* tests, naturally infested, 9-mm-diam. fruit were picked on the day of bioassay. Fruit were inspected for oviposition punctures, thoroughly washed to remove ODP, and then six singly punctured fruit and two unpunctured fruit were included in a bioassay. Fifteen flies were observed in each of four bioassay cages. Dissection of the presumably infested fruit revealed that two contained no larvae, four contained a first instar, six a second instar, and 12 a third instar.

RESULTS

Under dry conditions, a relatively linear decline in activity of *R. pomonella* ODP over time was observed both under lab and field conditions (Figure 1). Analysis of covariance (Dunn and Clark, 1974) to test for differences among the separate least-squares lines of the three test conditions ($F = 0.29, p > 0.10$,

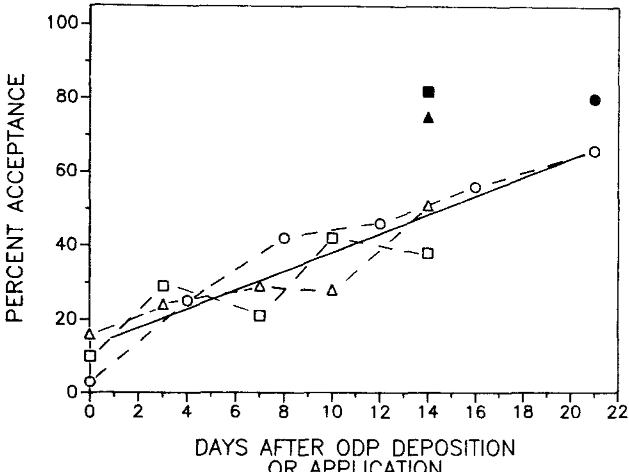

FIG. 1. The residual activity over time of *R. pomonella* ODP under dry conditions in the lab or field. Treatments were: fly-marked fruit that were held in the lab (□) and the corresponding clean control fruit (■); field-exposed, fly-marked fruit (○) and control fruit (●); ODP-extract-marked fruit that were held in the lab (△) and control fruit (◀). "Fly-marked" fruit were pheromone-marked by five *R. pomonella* females. All treatments within a test were bioassayed simultaneously; thus, values for control fruit are represented by a single point. The least-squares regression line for all data points (solid line) is shown ($y = 12.6 + 2.5x$; $r^2 = 0.86$, $N = 16$).

NS) indicated that the combined data could be well described by a single regression line. Thus, there were no significant differences in rate of decline of activity under lab vs. field conditions or between female-deposited vs. extract applied ODP. Further, the pheromone proved moderately stable, even on growing fruit under natural conditions, with some activity persisting after three weeks. For the combined data, the half-life of ODP was 10.7 days. This was calculated from the regression equation of days after ODP deposition or application against the log of percent rejection of fruit treatments: $y = 4.29 - 0.0645x$. Because overall rejection of unmarked control fruit was approximately 20%, the regression line was shifted by subtracting 20% from each percent rejection value to account for this "background."

A distinct decline in pheromone activity resulted from exposure to both natural and simulated rainfall (Figures 2 and 3). In nature, the most severe impact on pheromone persistence followed a torrential 20 min downpour (9 mm) and a heavy $4\frac{1}{2}$-hr rain (25 mm) where 61% and 50%, respectively, of activity was lost. Substantially less activity (ca. 13%) was lost following ex-

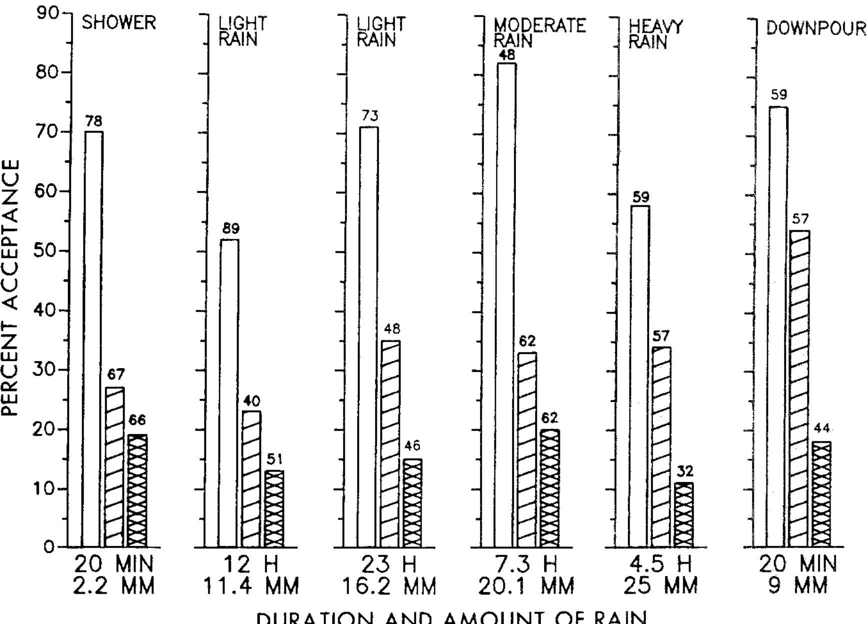

FIG. 2. The residual activity of *R. pomonella* ODP exposed to various durations and intensities of natural rainfall. Treatments were: clean control, rain-exposed fruit ([open bar]); ODP-marked, non-rain-exposed fruit ([cross-hatched bar]); ODP-marked, rain-exposed fruit ([hatched bar]). Values above bars represent the number of female arrivals on each fruit treatment.

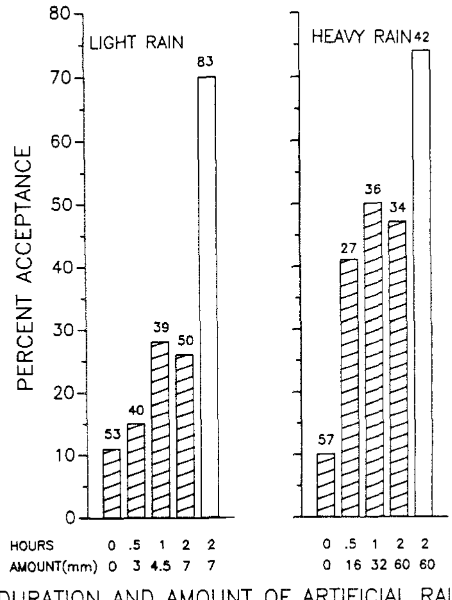

FIG. 3 The residual activity of *R. pomonella* ODP exposed to various durations of a light or heavy simulated rainfall. Treatments were ODP-marked, rain-exposed fruit (▨) and clean control, rain-exposed fruit (▭). Values above bars represent the number of female arrivals on each fruit treatment.

posure to a 20-min shower (2.2 mm), whereas an intermediate loss (21–35%) in activity resulted from two longer-term (12 and 23 hr) light rains (11.4 and 16.2 mm) and a 7.3-hr moderate rain (20.1 mm) (Figure 2). Tests of simulated rainfall (Figure 3) produced similar losses in ODP activity: following $\frac{1}{2}$-, 1-, or 2-hr exposures to a light–moderate rain (3, 4.5, or 7 mm), approximately 8, 34, and 30% total activity, respectively, was lost. Following $\frac{1}{2}$-, 1- or 2-hr exposures to a very heavy simulated rainfall (16, 32, or 60 mm), approximately 62, 76, and 70% total activity, respectively, was lost.

Females were able to discriminate against fruit containing second or third instar conspecific larvae (Table 1). Fewer ($P < 0.05$, G test) females attempted oviposition in cherries (test A) that contained a third-instar larva (31% acceptance) than in controls (70%) or fruit containing a first-instar larva (63%). Discrimination against infested fruit was stronger in the smaller *C. oxyacantha* hawthorns (test B). Acceptance of fruit containing a second-instar larva (33%) was less ($P < 0.05$, G test) than that of controls (56%) or fruit containing a first-instar larva (53%), and only 2% of arriving females accepted fruit containing a third-instar larva.

TABLE 1. FEMALE *R. pomonella* ACCEPTANCE OF 15-mm-diam. SOUR CHERRIES (TEST A) OR 9-mm-diam. *Crataegus oxyacantha* HAWTHORNS (TEST B) INFESTED WITH 1 CONSPECIFIC LARVA

Treatment	Number of female arrivals on fruit	boring attempts (%)[a]
Test A		
Clean control	33	70 a
1st instar	32	63 a
2nd instar	31	52 ab
3rd instar	32	31 b

1st instar	15	53 a
2nd instar	40	33 b
3rd instar	106	2 c

[a] Values in the same column followed by the same letter are not significantly different at the 5% level according to a pairwise *G* test.

DISCUSSION

Stability over time of the ODP of *R. pomonella*, as demonstrated here, confirms and expands on earlier work that showed high persistence of this pheromone for at least four days under dry laboratory conditions (Prokopy, 1972). Studies of several other tephritids have also shown moderate to substantial persistence in ODP activity under dry conditions (Averill and Prokopy, 1987). Perhaps the active components of these ODPs are similar in chemical identity.

Other phytophagous insects respond to oviposition deterrents (of either insect or plant origin) that persist for days or weeks, including those of the sorghum shootfly, *Atherigona soccata* (Raina, 1981), *Pieris brassicae* butterflies (Schoonhoven et al., 1981), and the European corn borer, *Ostrinia nubilalis* (Dittrick et al., 1983).

Data presented here and in other studies (Prokopy, 1972; Prokopy et al., 1982) demonstrate that *R. pomonella* ODP is highly soluble in water. Indeed, most known oviposition deterrents of phytophagous insects are water soluble, including the ODPs of all tephritids investigated to date (Averill and Prokopy, 1987), as well as of the alfalfa blotch leafminer (*Agromyza frontella*) (McNeil and Quiring, 1983), the sorghum shootfly (Raina, 1981), the European corn borer (Dittrick et al., 1983), and *P. brassicae* (Schoonhoven et al., 1981).

The water solubility of *R. pomonella* OPD may lessen its efficacy in field applications. Indeed, Katsoyannos and Boller (1980), found a reduced effect of

Rhagoletis cerasi ODP sprays on cherry trees following a heavy rainfall. In our simulated rain tests, some pheromone activity remained even following a 2-hr heavy washing. Perhaps some ODP compounds bind to fruit surface components, or, because ODP is released with gut contents during deposition of a pheromone trail (Prokopy et al., 1982), perhaps the presence of feces slows the removal or decay of ODP. This possibility, combined with partial protection of ODP-marked fruit afforded by foliage cover, may result in at least some retention of pheromone effectiveness even under substantial rainfall conditions.

Although *R. pomonella* ODP might seem a poor resource partitioning cue because of its water solubility and only moderate stability, its disadvantages may be balanced by such considerations as low physiological cost of producing ODP (Prokopy, 1981). Alternatively, ODP deposition and recognition may originally have served to deter a female from hawthorn fruit already containing one of her own eggs. In such a case, the pheromone may need be only short-lived, owing to the fact that a foraging female tends to lay a single egg per fruit until all clean fruit are exhausted in a cluster (Averill and Prokopy, unpublished data). She then usually moves to adjacent clusters until she has laid about 10 or so eggs per day. In the evening, the female often moves to and remains in tree top (Prokopy et al., 1972) and, because there usually are thousands of hawthorn fruit per host tree, it would be unlikely she would revisit the same clusters during the next few days.

Further, the pheromone may deter egg-laying initially, and, after time, other partioning factors may come into play. For example, *R. pomonella* larval infestation promotes premature abcission, and, as we have shown, females are able to detect developing larvae or their effects. With small fruit (ca. 9 mm), where larval competition is exceptionally intense (Averill, 1985), we found that females clearly were able to discriminate against fruit within 8–10 days following introduction of an egg. In larger fruit (15 mm diam.), significant discrimination occurred against fruit 12–14 days following infestation (when third-instar larvae were present), although reduced acceptibility occurred after 8–10 days.

The tephritids *R. fausta* and *A. suspensa*, which also lay a single egg per fruit, were not influenced by presence of first- or second-instar larvae in 15-mm-diam. host fruit (Prokopy et al., 1977), but response to presence of third-instar larvae or to larvae developing in smaller fruit was not tested. Among tephritids that lay a clutch of eggs per ovipositional bout, *R. completa*, *C. capitata*, *Dacus cucurbitae*, and *D. tyroni* all discriminate against fruit infested with early instar larvae (Cirio, 1972; Fitt, 1984; Prokopy and Koyama, 1982; Prokopy et al., 1978). As in *R. pomonella*, Fitt (1984) found that *D. tyroni* females more strongly discriminate against small fruit containing larvae. He suggested that in such fruit, larvae are relatively closer to the fruit surface than would be the case in a larger fruit. Thus, larval activity (movement) or effects (e.g., release of volatile deterrents of larval or fruit origin from lacerated tissue) would be more easily detected by ovipositing females.

We did not study how *R. pomonella* females discriminated against larval infested fruit. Discrimination occurred after landing, because similar numbers of females visited infested and uninfested fruit. Further, neural receptors on the ovipositor apparently were not involved because females were able to discriminate against infested fruit without probing. Females that did insert the ovipositor were just as likely to complete egg-laying in infested fruit as in uninfested fruit. These results suggest that females utilize short-range olfactory receptors or contact chemoreceptors or mechanoreceptors to discriminate against fruit containing larvae. In studies of other tephritids, Girolami et al. (1981) reported that volatile deterrents released form olive tissues attacked by *Dacus oleae* elicit female deterrence, and Fitt (1984) showed that oviposition was inhibited by decomposed host tissue from which larvae had been removed. Fitt (1984) suggested that chemical changes in the host may be due to proliferation of bacteria that release an inhibitory chemical. Bacteria are thought to be important or essential for larval development of several tephritid species, including *R. pomonella* (Allen and Riker, 1932; Allen et al., 1934; Prokopy, 1977; but see Howard et al., 1985). Further, the possibility that female *R. pomonella* are able to detect larval movements within the fruit cannot be ruled out. Two parasitic wasps, *Biosteres longicaudatus* and *Opius oelleus*, utilize host vibration cues to locate their larval hosts (Lawrence, 1981; Glas and Vet, 1983).

Acknowledgments—We gratefully acknowledge the excellent assistance of Martha Averill, Hedera Hoover, and Juliet Tang. (Received October 16, 1985; accepted February 10, 1986)

Abstract—A simple stereospecific synthesis of (*Z*,*Z*)-3,5-tetradecadienoic acid is described based upon coupling of 1-decyne and 3-butyn-1-ol to give 3,5-tetradecadiyn-1-ol. Subsequent reduction of the diyne to (*Z*,*Z*)-3,5-tetradecadien-1-ol and oxidation of the dienol gave the desired acid. *Attagenus elongatulus* were strongly attracted to the pure acid.

Key Words—Coleoptera, Dermestidae, *Attagenus elongatulus*, (*Z*,*Z*)-3,5-tetradecadienoic acid, Pheromone.

INTRODUCTION

A major component of the sex pheromone of the dermestid beetle *Attagenus elongatulus* (Casey) was identified as (Z,Z)-3,5-tetradecadienoic acid (Fukui et al., 1977). The synthesis of this acid has been reported (Silverstein et al., 1967; Rodin et al., 1970) by methods which depended upon gas chromatographic separation of geometrical isomers. Here we report a simplified, stereospecific synthesis of (*Z*,*Z*)-3,5-tetradecadienoic acid.

METHODS AND MATERIALS

1-Decyne and 3-butyn-1-ol were purchased (Farchan Div., Albany International).

0098-0331/87/0100-0179$05.00/0 © 1987 Plenum Publishing Corporation

1-Bromo-1-decyne was prepared by a reported method for a homolog (Brandsma, 1971) in 88% yield, bp 55–57°/0.5 torr, pure by GC (EGSS-X). [^{13}C]NMR (delta values–assigned carbon): 14.03–C10, 19.75–C3, 22.08–C9, 31.80–C8, 37.43–C1, 80.52–C2.

3,5-Tetradecadiyn-1-ol was prepared as described by Brandsma (1971) for a homolog in 88% yield following low-temperature crystallization from pentane–hexane, 98% pure by GC (EGSS-X). [^{13}C]NMR: 14.03–C14, 19.17–C7, 22.68–C13, 23.72–C2, 31.84–C12, 60.96–C1, 65.05, 67.32, 73.69, 78.44–C3–6.

(Z,Z)-3,5-Tetradecadien-1-ol was prepared by reduction of the above diynol with dicyclohexylborane as described for reduction of a similar diynol (Svirskaya et al., 1980; see also Zweifel and Polston, 1970) in 82% yield, bp 112–114°/0.1 torr, pure by GC (EGSS-X and 007-CPS-2 50 m capillary, Quadrex Corp.). [^{13}C]NMR: 14.10–C14, 22.74–C13, 27.62–C7, 31.19–C2, 31.97–C12, 62.39–C1, 123.35. 126.66, 126.86, 133.48–C3–6.

(Z,Z)-3,5-Tetradecadienoic acid was prepared by oxidation of the alcohol with Jones reagent (Djerassi, 1956), i.e., 2.67 M CrO_3 in H_2SO_4. A number of experiments was carried out to determine suitable conditions. A typical experiment was as follows: To a solution of 2.0 g (9.52 mmol) of (Z,Z)-3,5-tetradecadien-1-ol in 200 ml acetone was added dropwise at 10–16°C 14.2 ml Jones reagent while stirring vigorously under N_2. After 10 min, the mixture was poured into 500 ml ice and saline (saturated NaCl solution). The product was extracted with ether and washed twice with saline. The ether solution was dried and, after filtration and evaporation, gave 1.76 g of yellow oil.

The crude product was applied in approximately four equal portions to a column (4.7 × 45 cm) of 30 μm silica gel and eluted with 1% methanol in hexane. The eluate was monitored with a UV detector at 256 nm. The last eluted peaks from each run were combined to give 0.8 g of oil that was crystallized from hexane to give 0.11 g colorless crystals. GC of a methylated sample (diazomethane) on the 007-CPS-2 capillary showed only one peak. The filtrate was evaporated to yield 0.54 g of oil that was purified on a reversed-phase C-18 column to separate 0.14 g (Z,Z)-3,5-tetradecadienoic acid. Nonanoic acid was identified as the main acid impurity by MW (MS) and comparison with the GC retention of an authentic sample of the methyl ester. GC of the methyl esters of the crude acid fraction also had trace amounts of two tetradecadienoate isomers. These isomers were separated on both the 007-CPS-2 and on a 30 m DB-1 (J & W Scientific) capillary that was coupled to a Finnegan mass spectrometer equipped for CI (chemical ionization) with isobutane. The structure of the (Z,Z)-3,5-tetradecadienoic acid was confirmed by [^{13}C]NMR: 177.7–C1; 134.8, 127.0, 122.6, 120.9–C3–6; 32.8–C2; 31.9–C12; 27.7–C7; 22.7–C13; 14.06–C14; and by MS-CI which gave MW 238.

RESULTS AND DISCUSSION

The syntheses scheme is outlined in Figure 1. The conversion of 1-decyne to 1-bromo-1-decyne was effected by Brandsma's (1971) procedure. The bromodecyne was coupled by Chodkiewitz reaction (Brandsma, 1971) to yield 3,5-tetradecadiyn-1-ol. The alternative coupling of 1-decyne and 4-bromo-3-butyn-1-ol gave only ca. 38% conversion in our hands.

Our attempts to reduce 3,5-tetradecadiyn-1-ol by hydrogenation over Lindlar's catalyst (Lindlar and Dubuis, 1966) were unsatisfactory, giving a complex mixture of products. Chemical reduction using dicyclohexylborane gave smooth conversion of 3,5-tetradecadiyn-1-ol to (*Z,Z*)-3,5-tetradecadien-1-ol (Svirskaya et al., 1980).

Oxidation of (*Z,Z*)-3,5-tetradecadien-1-ol to the corresponding acid was carried out in moderate yield with the Jones reagent (Djerassi, 1956). Oxidation of an alcohol to the corresponding acid with chromic acid has been plagued by oxidation of the in situ-formed hemiacetal to ester (Craig and Horning, 1960) so that yields in the 20–50% range are obtained (Holland and Gilman, 1974). Holland and Gilman reported an improved procedure involving reversed addition, i.e., slow addition of the alcohol to the chromic acid solution, and were able to reduce the yield of ester substantially. In our hands this method gave good results with a model compound but poorer results than we obtained with the normal addition procedure with tetradecadienol as substrate, probably due

$$CH_3(CH_2)_7C{\equiv}CH \xrightarrow[\text{2) } Br_2]{\text{1) } n\text{-}C_4H_9Li} CH_3(CH_2)_7C{\equiv}CBr \quad \text{yield 88\%}$$

$$\xrightarrow[\text{Chodkiewitz}]{HC{\equiv}C(CH_2)_2OH} CH_3(CH_2)_7C{\equiv}C\text{-}C{\equiv}C(CH_2)_2OH \quad \text{yield 88\%}$$

$$\xrightarrow{(C_6H_{11})_2BH} CH_3(CH_2)_7\underset{H}{C}{=}\underset{H}{C}\text{-}\underset{H}{C}{=}\underset{H}{C}(CH_2)_2OH \quad \text{yield 82\%}$$

$$\xrightarrow{CrO_3} CH_3(CH_2)_7\underset{H}{C}{=}\underset{H}{C}\underset{H}{C}{=}\underset{H}{C}CH_2CO_2H \quad \text{yield 35\%}$$

FIG. 1. Scheme for synthesis of (*Z,Z*)-3,5-tetradecadienoic acid.

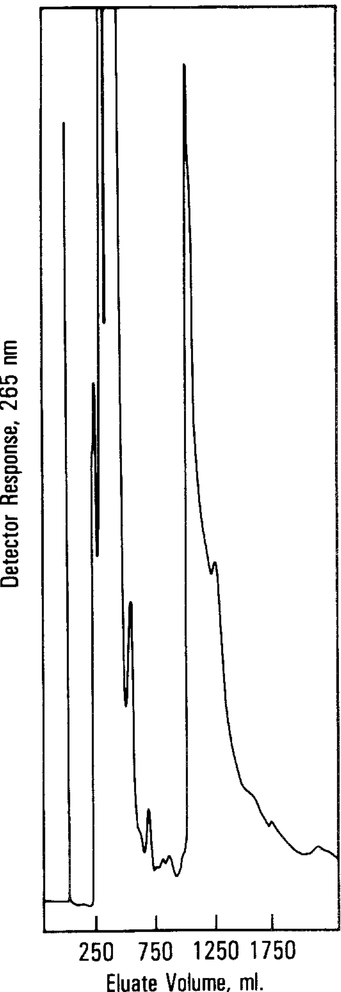

FIG. 2. Separation of acid fraction on 45 × 4.7-cm silica column. Eluent: 12 ml/min of 1% methanol in hexane. Detector: UV, 265 nm, and 2 AUFS. Sample: 305 mg of oxidized (*Z*,*Z*)-3,5-tetradecadien-1-ol. The acid fraction comprised eluate volume from 750 to 1500 ml.

to over oxidation. The Holland and Gilman method subjects the oxidation products to prolonged contact with excess oxidant.

Rodin et al. (1970) reported oxidation of (*Z*)-5-tetradecen-3-yn-1-ol with chromic acid of unspecified strength [reference is made to Fieser and Fieser (1967), but several different chromic acid compositions are mentioned on the cited page including that which we used]. A yield of 67% was reported, but no

purity was specified. A subsequent purification was effected by preparative GC to furnish a purified methyl ester in unspecified yield.

Pyridinium dichromate (Corey and Schmidt, 1979) oxidation of the tetradecadienol gave substantial amounts of α,β-unsaturated acids. Similar results were obtained when a stepwise approach was tried by oxidation of the dienol to aldehyde with dipyridine chromic anhydride complex (Valicenti and Holman, 1976). The aldehyde contained much α,β-unsaturation.

Phase transfer oxidation of alcohols to aldehydes and ketones has been described (Pletcher and Tait, 1978; Landini et al., 1979; Brown et al., 1971). The method of Brown does not require a phase transfer agent, but was applied only to secondary alcohols. We investigated a similar procedure to Brown's for the oxidation of 1-octanol in ether. The product mixture contained 1-octanol, octanal, octyl octanoate, octanoic acid and probably octanal trimer, but all of these were resolvable on a 10-ft Carbowax MTPA glass GC column so that oxidation could conveniently be followed by GC. A simple procedure of shaking 5 min while cooling with tap water an ether solution (25 or 250 ml) of 10 mmol 1-octanol with 0.5, 1, or 2 equivalents of Jones reagent (an equivalent = oxidation to acid) was followed. This procedure with two equivalents of oxidant at the higher dilution gave an 80% yield of octanoic acid and only 12% of octyl octanoate or about the same yields as reported by Gilman and Holland. When this procedure was applied to oxidation of the dienol, we obtained a 61% yield of crude acids, of which 24% was at the desired acid retention (GC of methyl esters) and 36% had retention equivalent to methyl nonanoate.

The best result in the oxidation of the dienol to (Z,Z)-3,5-tetradecadienoic acid was obtained using a 200% excess of the Jones reagent, whereby 71% of the product weight was estimated to be in the acid fraction. The acid fraction consisted principally of the desired dienoic acid (ca. 53%) and nonanoic acid (ca. 35%) (Fig. 2). Trace amounts of isomeric dienoic acids were also present as established by capillary GC-MS-CI. The (Z,Z)-3,5-dienoic acid was separated by reversed-phase chromatography or by crystallization. Absence of isomers in the purified acid was established by capillary GC (007-CPS-2).

Test showed (Z,Z)-3,5-tetradecadienoic acid attractive to *Attagenus elongatulus* (Burkholder, personal communication).

(Received October 18, 1985; accepted February 10, 1986)

Abstract—The presence of Palmer amaranth (AMAPA) residues in the soil reduced fresh weight accumulation in onions and carrots and markedly decreased seedling field establishment of carrots. Solid-phase separation techniques were used to isolate fractions containing water-soluble organic compounds from AMAPA residues and soil amended with such residues. At concentrations of 20–100 mg/liter most of the organic solids thus extracted were inactive in seed germination assays using onion, carrot, AMAPA, and tomato seeds. Extracts from the roots of AMAPA increased 72-hr germination percentages in carrot, AMAPA, and tomato. A time-study of AMAPA residue decomposition in soil showed an increase in extractable inhibitors of onion germination after 62 days but no other significant changes in the activity. The most active allelochemicals from AMAPA proved to be volatile compounds. Volatiles emitted by soil containing AMAPA residues and by the dried and partially rehydrated leaf and flower residues themselves reduced carrot and tomato seed germination to less than 7%. Freshly harvested aerial AMAPA inhibited only carrot seed. Germination of AMAPA and carrot seeds was retarded by exposure to volatiles from dried AMAPA residues. Residues from AMAPA grown in Texas and Louisiana exhibited comparable inhibitory activity after air-drying two weeks. Onion seeds were also inhibited by volatiles from AMAPA residues.

Key Words—Allelopathy, seed germination, *Amaranthus palmeri*, *Allium cepa*, *Daucus carota*, *Lycopersicon esculentum*, onion, carrot, tomato, volatiles, aqueous extracts, weed residues.

INTRODUCTION

Inhibitory allelochemical effects have been attributed to both crop residues (Barnes and Putnam, 1983; Guenzi and McCalla, 1962; Guenzi et al., 1967; Kimber, 1967, 1973; McCalla and Duley, 1949; McCalla and Haskins, 1964; Patrick et al., 1963) and weed residues (Bhowmik and Doll, 1982, 1983, 1984). Water extracts of various weeds have been shown to inhibit plant growth (Bhowmik and Doll, 1984; Gressel and Holm, 1964; Guenzi and McCalla, 1962; Guenzi et al., 1967; Kimber 1967, 1973; Patrick et al., 1963) and seed germination (Bieber and Hoveland, 1968; Bradow, 1985; McCalla and Duley, 1949), and there is evidence that volatile substances released by plants and plant residues also inhibit plant growth (Del Moral and Muller, 1970; Heisey and Delwiche, 1983; 1984; Katsin et al., 1977; Vokou and Margaris, 1982) and seed germination (Evenari, 1949; French and Leather, 1979; Holm, 1972; Katsin et al., 1977; Vokou and Margaris, 1982).

Field studies (Menges, 1985) and laboratory seed germination studies of aqueous and organic solvent extracts (Bradow, 1985; Fischer and Quijano, 1985) indicated the presence of both inhibitory and promotive allelochemicals in *Amaranthus palmeri* S. Wats. (Palmer amaranth, AMAPA). Because fresh weight accumulation and time of maturity can be significantly influenced by the amount of time seedlings require to emerge (Currah, 1978), and because field emergence is related to the germination properties of onion and carrot seeds (Bedford and Mackay, 1973), seed germination assays were used for further screening. Although tomato was not part of the field studies, tomato seeds were quite sensitive in the preliminary studies and were thus included in these bioassays (Bradow, 1985). Volatiles and water-soluble organic compounds isolated from AMAPA residues and soil containing AMAPA residues were screened for biological activity. The paper describes laboratory and greenhouse experiments undertaken to locate and identify those volatile and water-soluble organic compound released by AMAPA residues which may inhibit seed germination in carrot, onion, and AMAPA itself.

METHODS AND MATERIALS

Aqueous Extracts from AMAPA and Soil. Aqueous extracts were prepared from the following soil samples: (1) soil (Hidalgo sandy clay loam from Weslaco, Texas); (2) soil + AMAPA, the same soil amended with 1.2 g/kg AMAPA residues (Menges, 1985); and (3) soil + AMAPA incubated in the greenhouse for 0, 20, 41, or 62 days. In this time study, 2000-g samples of soil + AMAPA were placed in 3.8-liter plastic nursery pots, wet to field capacity, and incubated (mean daily ambient temperature = 18–29°C). Uniform moisture content was maintained by bottom irrigation with deionized water.

For each extraction, 2000 g of specific soil sample was added to 1.5 liters deionized water, pH 6.8. The slurry was stirred briefly, covered with aluminum foil, and allowed to stand at room temperature (21°C, average) for 2 days with occasional stirring. The slurry was filtered through a layer of Celite Analytical Filter Aid (Fisher No. 0211) above a sheet of Whatman No. 2 filter paper in a 32-cm porcelain Buchner funnel, and the soil cake was washed with 200 ml deionized water. The filtrate, pH 7.5, was additionally filtered through a Durapore® HVLP 0.15-μm filter (Millipore) fitted with a prefilter. This aqueous extract was subjected to the solid-phase treatment described below. An additional 200-g sample of soil + AMAPA was separately extracted with 150 ml deionized water, and the filtered solution (pH 7.4) was used directly in the in vitro seed germination bioassays described below.

Similarly, water extracts were made from the aerial and root portions of AMAPA plants field-grown at the Southern Regional Research Center (SRRC) from seeds collected in Weslaco, Texas. The plants were harvested at a height of 1.2–1.7 m after flower anthesis but before seed dispersal. The day after harvesting, aerial and root AMAPA were chopped into segments less than 3 cm in length. A 300-g sample of chopped aerial AMAPA was extracted with 3 liters deionized water (pH 5.5 after filtration) and subjected to the solid-phase separation sequence below. A 100 g-sample of chopped root AMAPA was extracted with 1 liter deionized water (pH 5.9 postfiltration) and similarly treated.

Aqueous-Extract Solid-Phase Separations. The specific aqueous extracts were separately subjected to the following series of solid-phase separations. An aqueous extraction filtrate was drawn by vacuum through two SepPak® C_{18} cartridges (Waters Assoc., No. 51910) connected in series. Adsorbed organic compounds were eluted from this pair of cartridges with 10 ml acetonitrile, followed by 10 ml methanol. The combined eluant solutions (containing a precipitate) were placed on a rotary evaporator and taken to dryness under vacuum (neutral residue).

Eluant passing through the first SepPak® pair was acidified to pH 3 with concentrated HCl and passed through a fresh SepPak® pair. Elution of adsorbed organic compounds from the cartridges and collection of the acidified residue were identical with that used to obtain the neutral residue.

The acidified eluant from the second solid-phase separation was extracted with 3 × 50 ml dichloromethane. The combined extracts were dried over anhydrous sodium sulfate, and the volatiles removed on a rotary evaporator with a room temperature water bath (dichloromethane residue). When the aqueous extracts from soil, soil + AMAPA, aerial AMAPA, or root AMAPA were fractionated using the solid-phase separation scheme described, no starting substrate yielded sufficient dichloromethane residue for bioassay, indicating the effectiveness of the C_{18} packing in removing organic compounds from the aqueous solution. The aqueous layer was reduced to dryness, using an 80°C water bath (final residue).

The water-extracted soil + AMAPA/Celite cake was air-dried, broken into small pieces, and added to 1 liter 0.3 M ethylenediaminetetraacetic acid disodium salt dihydrate (EDTA) solution which had been adjusted to pH 7.5 with NaOH (Kaminsky and Muller, 1977). After standing overnight, the mixture was filtered as described in the previous section for the primary aqueous extraction of soil samples (EDTA-treated residue). The EDTA treatment was omitted in the case of the soil-less AMAPA samples.

In Vitro Seed Germination Bioassay. Dried soil and plant extract residues obtained from the solid-phase separations were dissolved in deionized water, pH 6.8 at 20, 50, or 100 mg/liter. Germination of seeds of onion, *Allium cepa* L., cv. Texas Early Grand 502 (Baxter's, Weslaco, Texas); carrot, *Daucus carota* L., cv. Danvers Half-long (Burpee's, Warminster, Pennsylvania); tomato, *Lycopersicon esculentum* Mill., cv. Homestead (Burpee's) and AMAPA collected in Weslaco, Texas, were used to compare the bioactivities of these solutions and parallel deionized water controls. Assay seeds were incubated in the dark as previously described (Bradow, 1985), except that a temperature cycle of 10 hr at 31°C and 14 hr at 21°C was substituted for isothermal incubation at 25°C. Osmolarities of the test solutions were determined with an Osmette A (Precision).

Seed Germination Bioassays of Volatiles from Soil and AMAPA Residues. Using separate 160-mm (id) glass desiccators, seeds of onion, carrot, AMAPA, or tomato, as described in the in vitro aqueous extract assays, were germinated on porcelain desiccator plates covered with double sheets of deionized water-saturated Whatman No. 1 filter paper. Circles (22 mm diameter) had been removed from the center of the paper to allow diffusion of volatiles from samples in the desiccator wells. The filter paper sheets were divided into eight equal segments containing the same number of seeds (25 AMAPA, or 20 of the other three species), and each segment was treated as a replicate for purposes of statistical analysis.

Test samples consisted of one of the following: 170 g soil, 170 g soil + AMAPA from a field amended with 8 or 1.5 kg AMAPA/m^2 (Menges, 1985), 20 g fresh weight or 5 g dry weight of root or aerial AMAPA. Aerial and root AMAPA were chopped into segments smaller than 3 cm before drying. Portions of SRRC-grown aerial AMAPA were air-dried in the laboratory for up to 22 weeks before assay for bioactive volatiles. Weslaco AMAPA was shipped in Dry Ice from Texas, and all refrigerated or frozen AMAPA was allowed to dry in the open at room temperature for 24 hr before use. Weslaco AMAPA was divided into roots, mature seedheads, green stems, red pigmented woody mature stems, and leaves and flowers. Portions of the Weslaco aerial AMAPA were air-dried 15 days, and part of the Weslaco root AMAPA was dried 1 week in the laboratory before comparative assays. Controls consisted of 50 g fine sand.

A test sample or control in a 5 × 10-cm glass crystallizing dish was placed

in each desiccator well and 10 ml deionized water were added. Each desiccator was sealed with minimal stopcock grease, wrapped light-tight in aluminum foil, and placed on a greenhouse bench or in a biological incubator (Percival I-32LLVL) operated on a 10 hr/31°C day/21°C night cycle. During the periods of the greenhouse experiments, the mean daily ambient air temperature varied from 18 to 29°C with a maximum of 34°C and a minimum of 15.5°C. Seed germination, using radicle emergence as the criterion, was evaluated after 72 hr incubation. In most experiments the crystallizing dish and contents were removed and an additional 10 ml deionized water were added to each desiccator well. The seeds were then further incubated in the resealed desiccators for 96 hr before a second evaluation of germination and relative seedling growth. In several experiments the test samples were allowed to remain throughout the 7-day germination period. Control assays were repeated at bimonthly intervals as checks on assay seed vitality.

Statistical Analyses. Data from the completely random experimental designs for each seed species were analyzed separately. Germination count data were normalized by the transformation $(X + 0.5)^{1/2}$ and subjected to appropriate analyses of variance (Sokal and Rohlf, 1981). A significance level of $P = 0.05$ was used for the aqueous extract data and of $P = 0.01$ for the volatiles data. The time-study data were also subjected to regression analysis (significance level, $P = 0.05$).

RESULTS AND DISCUSSION

Solid-Phase Separation of Aqueous Extracts of Soil and Soil + AMAPA Mixtures. Like the aqueous extracts from aerial AMAPA residues (Bradow, 1985), the aqueous extract from soil + AMAPA residues had sufficient osmotic activity (50 mosm) to inhibit seed germination in carrot, AMAPA, and tomato (59%, 24%, and 94% inhibition, respectively). Onion seeds were unaffected. Dilution of the extract 1:1 with deionized water produced a solution of 24 mosm which inhibited tomato 79% and had no significant effect on the other assay seeds. The bioassay seeds incubated in 50 mosm solutions of polyethylene glycol 8000 (Michel, 1983) were similarly inhibited (data not shown).

The fractionation of the extracts from soil and soil + AMAPA resulted in milligram quantities of the neutral and acidified residues which were tested at a maximum level of 20 mg/liter. The osmolarities of the resuspended residues never exceeded 10 mosm, and the initial solution pH levels were circumneutral.

When applied as solutions with osmolarities below inhibitory levels, none of the redissolved extracts from soil or soil + AMAPA had any significant effect on AMAPA germination, and the extracts from soil + AMAPA had no effect on either carrot or onion germination (Table 1). Secondary treatment with EDTA produced an acid residue from soil which increased onion germination

[a] Percentages are means of eight replications. Asterisk (*) indicates values significantly different from parallel deionized water control ($P = 0.05$) according to linear contrast testing. Control values are experiment means, shown for comparison.

while significantly inhibiting that of tomato and carrot. The EDTA/acid residue from soil + AMAPA also inhibited tomato seeds to a lesser degree. The EDTA/ neutral residue from soil + AMAPA increased tomato seed germination, while the initial neutral residue from that source was highly inhibitory of the same seed species. Where sufficient extract residues were obtained to increase the bioassay level to 100 mg/liter, all soil + AMAPA residues were inactive. Carrot and tomato seeds were inhibited by 100 mg/liter final residue from soil, but not soil + AMAPA. Any further increase in residue concentration raised the test solution osmolarity above 20 mosm.

Time Study of Changes in Activity of Solid-Phase Separation Extracts from Soil + AMAPA. Incubating the soil + AMAPA mixture under greenhouse conditions produced no significant changes in the activity of the various extract residues with respect to carrot or AMAPA germination (data not shown).

Onion germination was unaffected by the initial neutral residue (Table 2), but the EDTA/neutral residue from 41-day soil + AMAPA promoted onion germination at 100 mg/liter, and the 62-day EDTA/neutral residue very significantly inhibited onion seeds. At 100 mg/liter, the acid residue also inhibited onion germination, and the final residue showed a linear increase in inhibitors of onion seed germination over the 62-day incubation. Concentration was a significant factor only in the activity of the acid residue at 62 days. Incubation time was the significant factor in the effects of the residues on tomato germination as well. The initial neutral residue markedly inhibited, but after 20 days the activity of this residue became promotive. There was also a linear increase with time in tomato seed germination promotion by the final residue. Germination in the parallel water controls remained constant during the nine weeks of the experiment (analysis of variance insignificant at $P = 0.01$). Again, concentration was a significant factor only in assays of the acid residue effects. The 100 mg/liter solutions of the comparable 20-day acid residue inhibited tomato seeds and the comparable 41-day residue had no effect at 100 mg/liter and promoted at 20 mg/liter.

With time, water-extractable inhibitors of onion and promoters of tomato seed germination accumulated in soil amended with AMAPA. However, within the constraint of osmolarity below the inhibitory threshold, nothing in the results from the solid-phase separations indicates any significant or consistent suppression of seed germination by water-soluble substances from AMAPA or soil-containing AMAPA residues.

Solid-Phase Separation of Aqueous Extracts from Root and Aerial AMAPA. To avoid osmotically active salts found in extracts from soil-containing samples, root and aerial AMAPA samples were separately subjected to solid-phase separation. Significant differences existed in the responses of all four test seeds to root versus aerial extract residues (Table 3). Neutral, acid, and final root residues significantly promoted onion, carrot, and tomato seed germination at 20 mg/liter. Increasing the concentration to 100 mg/liter had no effect on the

[b] Assayed at 20 and 50 mg/liter.

activities of the neutral and acid root residue solutions, but the 100 mg/liter final root residue had no effect on onion or carrot seeds. Only the 20 mg/liter final root residue promoted AMAPA germination. In contrast, aerial residues had no effect on carrot germination. At 20 mg/liter, the final aerial residue increased onion germination, and all aerial residues but the 20 mg/liter neutral inhibited AMAPA seeds, in comparison to the parallel controls. The neutral aerial and 100 mg/liter final aerial residues promoted tomato seed germination.

The solid-phase separation technique was ineffective in separating the aqueous root extract into neutral, acid, and final residues of differing bioassay activities. The C_{18} cartridge pairs may have become saturated, allowing the extract components to pass through into the next separation stage; or different compounds of the extract may account for the activity found in the neutral and acid residues. Again, the results from the solid-phase separation of aqueous extracts from aerial root portions of AMAPA do not indicate the presence of water-soluble germination inhibitors.

Volatiles from Soil Containing AMAPA Residues. Under greenhouse (GH) conditions (Table 4), onion, carrot, and tomato seed germination was markedly inhibited by volatiles emitted from soil amended with AMAPA residues. The unamended soil had no effect, compared to the GH control No. 1 which was incubated under the same GH temperature conditions (mean day temperature, 26°C; mean night temperature, 20°C). When the GH controls were repeated during a 7-day period while the mean day temperature was 29°C and the mean night temperature was 20°C, germination of onion, carrot, and tomato seeds was significantly reduced, while that of AMAPA seeds increased (GH control No. 1 vs. GH control No. 2). This lack of reproducibility under GH conditions led to the use of an environmental chamber (EC) operated at temperatures (31°C day, 21°C night) which approximated the temperature conditions in Weslaco during the summer field tests.

After three days of exposure to volatiles from soil + AMAPA, carrot seed germination was markedly reduced, in comparison to both seeds exposed to volatiles from soil and the controls. Soil + AMAPA volatiles also inhibited tomato seeds to a lesser, but still significant, degree. AMAPA seeds were not affected.

Under EC conditions, both the controls and the unamended soil assays were reproducible for all four test seeds, but the inhibition of onion seeds by AMAPA residues in the soil was considerably less than under the first set of GH conditions. The degree of homogeneity in the soil + AMAPA samples also significantly affected the test results. The second soil + AMAPA replicate in the EC tomato seed bioassay contained less apparent AMAPA residue and proved to be significantly less inhibitory than the earlier replicate using a more representative soil + AMAPA sample. Volatiles from soil amended with 1.5 kg AMAPA/m^2 did not inhibit any of the assay seeds (data not shown). This level of residues was not active in field studies (Menges, 1985).

[a] Percentages are the means of eight replications within a single desiccator. Values in columns which are followed by the same letter are not significantly different ($P = 0.01$) according to linear contrast testing.
[b] Seeds exposed to volatiles throughout 7-day assay period.

After 3-day incubations under GH or EC conditions, the soil samples were removed from the desiccators and the seeds allowed to incubate an additional 4 days. After the 7 days, both the GH and EC onion and tomato bioassays showed no significant residual effects from exposure to soil or soil + AMAPA. When the AMAPA-amended soil remained in the desiccators throughout the entire 7-day EC incubation, only carrot was significantly inhibited. The decreases in tomato and carrot germination after a 3-day exposure to AMAPA volatiles were retardations of germination, rather than reductions in the capacity to germinate. With time, tomato seeds overcame this retardation in the presence of the AMAPA volatiles, but continued exposure markedly reduced carrot seed germination.

Volatiles from Freshly Harvested and Air-Dried AMAPA Residues. Compared to the appropriate controls, a 3-day exposure to volatiles from freshly harvested aerial AMAPA significantly inhibited only carrot germination (Table 5). Aerial AMAPA lost an average of 75% fresh weight after one week of air-drying; the dry weight then stabilized. The sample weights of dried aerial AMAPA were decreased to reflect this water loss. Aerial AMAPA, dried one week and partially rehydrated by the addition of 10 ml H_2O during the assays, released volatiles which significantly inhibited all four seed species at 3 days. The dried aerial AMAPA remained inhibitory of all but onion seeds throughout 22 weeks of air-drying. Onion seeds were not significantly inhibited by volatiles from the dried AMAPA after the second week of drying until, at 22 weeks, volatiles inhibitory of onion seed germination were again present.

When the freshly harvested root and aerial AMAPA samples were removed from the desiccators, all four test seeds reached germination percentages which were not significantly different from those of the controls. The 1-week dried aerial AMAPA residually inhibited onion, carrot, and AMAPA seed germination. This significant residual inhibition of carrot and AMAPA by the dried AMAPA persisted throughout the 22-week period. The 2-week and 6-week dried aerial AMAPA also had a residual inhibitory effect on tomato germination recovery. The 9-week dried data was lost in a power and equipment failure.

Comparison of Activities of Volatiles from Weslaco and AMAPA SRRC Residues. Aerial and root AMAPA, shipped in Dry Ice from Weslaco, also emitted volatiles inhibitory of seed germination (Table 6). The Weslaco aerial AMAPA and mature seedheads were highly inhibitory of all the assay seeds. This is in marked contrast to the inactivity of freshly harvested SRRC aerial AMAPA which had no effect except in the carrot bioassay. The green stem tissue from Weslaco was significantly inhibitory of onion and tomato germination, but less so than the leaves and seed heads. The mature woody stems did not inhibit carrot, AMAPA, or tomato germination significantly. Only the Weslaco seedhead AMAPA had significant residual effect on the germination of all four seeds. Exposure to volatiles from nonwoody Weslaco aerial AMAPA also

had a residual inhibitory effect on onion seeds. AMAPA seed germination was residually retarded by Weslaco seedheads and leaves and flowers.

Volatiles from freshly harvested SRRC-grown AMAPA significantly inhibited only carrot germination and had no residual effect on any of the assay seed species. Weslaco AMAPA roots emitted volatiles which reduced onion, carrot, and AMAPA germination after 3 days of exposure, the carrot germination reduction persisting after the volatiles source was removed.

After drying for 2 weeks and partial rehydration, Weslaco leaf/flowers and seedhead AMAPA were still highly inhibitory of onion, carrot, and tomato (Table 7). Dried SRRC Aerial AMAPA inhibited carrot, AMAPA, and tomato.

Volatiles from 1-week dried roots of SRRC AMAPA inhibited tomato and particularly carrot seeds. Weslaco root volatiles were less active.

Residual inhibition in carrot, AMAPA, and tomato seeds exposed to volatiles from dried Weslaco AMAPA was generally less profound than that observed in seeds exposed to dried SRRC aerial AMAPA. After 7 days, carrot seed germination was reduced by less than 20% by the 3-day exposure to Weslaco seedhead AMAPA, while similar exposure to 2-week dried SRRC aerial AMAPA nearly eliminated carrot germination. Volatiles from the dried Weslaco seedhead AMAPA residually inhibited onion and AMAPA germination, and AMAPA seeds showed continuing effects from exposure to Weslaco leaves/flowers AMAPA.

Before air-drying, the woodier stem and root AMAPA samples were less inhibitory of seed germination than the Weslaco leaves/flowers and seedhead AMAPA. Except in the carrot assay, freshly harvested SRRC aerial and root AMAPA were inactive. Air-drying for a week or more increased the inhibitory activity of freshly harvested AMAPA, but decreased that of the Weslaco aerial and seedhead AMAPA. This suggests that biochemical decomposition and tissue disruption beyond the chopping process common to all samples increased the production or release of the inhibitory volatiles.

One possible source for such inhibitors would be the microflora present on all the AMAPA samples. After the 3-day desiccator incubation, all AMAPA samples showed visible fungal populations, and preliminary electron micrographs have shown similar extensive mixed fungal (and bacterial) growth on the fresh SRRC aerial AMAPA, the freshly thawed Weslaco AMAPA, and on both the air-dried Weslaco and SRRC AMAPA samples. With similar fungal networks on both noninhibitory and inhibitory AMAPA samples, equivalent O_2/CO_2 ratios should exist in all assays, but the possibility that germination was reduced by increased CO_2 concentrations due to the presence of microflora will be examined in studies designed to investigate the effects of specific volatile inhibitors upon seed respiration. The possibility that the fungi are the source of the inhibitory volatiles is also being investigated, although preliminary studies indicate that fungi collected from the AMAPA samples and cultured on potato dextrose agar (PDA) emit no volatiles which inhibit onion, carrot, or AMAPA

germination. Germination of tomato seeds incubated 3 days above fungi on PDA was reduced to 62% of that of a control incubated above sand.

The dramatic reductions and residual inhibitions of seed germination in four different seed species by volatiles from AMAPA residues and soil containing those residues indicate the presence of a very important factor in allelopathic interactions which has been mostly overlooked. Classic natural products and allelochemical isolations generally involve freeze-drying and/or multiple solvent removal steps, all of which remove any volatile compounds of the plant residues and soil under study. The potent volatile inhibitors emitted from AMAPA residues could well explain the decreased stands of carrots in fields amended with such residues, and the residual effects of exposure to the volatiles could be important factors in fresh weight reduction and delayed maturity in crops. Delay in seed germination and seedling emergence reduce yields in carrots and onions, particularly under less than ideal growing conditions (Bedford and Mackay, 1973). Volatiles from AMAPA residues are clearly an important factor in the system under study, and current efforts are directed toward identification and bioassay of the inhibitory components of the volatiles.

OZONE-INDUCED CHANGES IN HOST-PLANT SUITABILITY: INTERACTIONS of *Keiferia lycopersicella* AND *Lycopersicon esculentum*

JOHN T. TRUMBLE,[1] J. DANIEL HARE,[1] ROBERT C. MUSSELMAN,[2] and PATRICK M. McCOOL[2]

(Received November 25, 1985; accepted February 10, 1986)

Abstract—Tomato pinworms, *Keiferia lycopersicella* (Walsingham), survived better and developed faster on tomato plants, *Lycopersicon esculentum* Mill., damaged by ozone than on plants not subjected to ozone fumigation. Other measures of fitness, including survival during pupation, sex ratio of adults, female longevity, and fecundity, were not affected. Analyses of ozonated foliage at zero, two, and seven days following fumigation demonstrated a transient but significant increase (18–24%) in soluble protein concentration. Although the concentration of the total free amino acids in ozonated foliage did not increase significantly, significant changes were observed in at least 10 specific amino acids, some of which are critical for either insect development or the production of plant defensive chemicals. A reduction in total nitrogen in ozonated foliage at seven days postfumigation indicated that nitrogen was being translocated to other portions of the plant. The implications of increases in assimilable forms of nitrogen in ozonated foliage, which lead to improved host-plant suitability for insect herbivores, are discussed both in relation to some current ecological theories and in regard to pest-management strategies.

Key Words—Ozone, nutrition, insect–plant interactions, nitrogen, secondary plant compounds, *Keiferia lycopersicella* Lepidoptera, Gellechiidae, tomato, *Lycopersicon esculentum.*

INTRODUCTION

Ozone, a colorless, highly reactive gas formed from the interaction of the products of fossil fuel combustion and oxygen, causes more plant damage in the United States than any other air pollutant (EPA, 1978). Losses in southern California are reportedly in excess of 275 million dollars annually (Leung et al., 1982). Upon entering leaves through the stomata (Dugger et al., 1962), ozone reacts with plant membranes and cellular structures such as chloroplasts, resulting in structural damage and, in some cases, the onset of premature senescence (Mudd et al., 1969; Chang, 1971a; Heath, 1980). Such physiological changes reportedly decrease photosynthesis in several species (Ormrod et al., 1981; Reich and Amundson, 1985); both photosynthesis (Todd and Probst, 1963) and partitioning of photosynthates are affected in tomatoes (McCool and Menge, 1983).

An important action of ozone on foliar tissues is the apparent release of large amounts of soluble nitrogenous compounds from plant structural forms. Nitrogen in soluble form (soluble proteins and free amino acids) is apparently more easily digested by insects than many protein complexes in plants (Slansky and Feeny, 1977). Ozone has been shown to preferentially oxidize certain amino acids, specifically cysteine, methionine, tyrosine, histidine, and cystine (Chang, 1971b; Mudd and Freeman, 1977). This action breaks structural proteins into their component parts, causing membrane dissociation and producing significant increases in free amino acid concentrations (Menzel, 1971; Ting and Mukerji, 1971; Craker and Starbuck, 1972), and in some reports, soluble protein levels (Beckerson and Hofstra, 1979). However, these results cannot be generalized across all plant species, as some exceptions have been reported (Ting and Mukerji, 1971; Tingey et al., 1973).

The implications of increased concentrations of readily available forms of nitrogen for insect herbivore development are considerable (Mattson, 1980; White, 1984). Researchers have clearly demonstrated that nitrogen availability affects such basic life processes as growth rates, survival, and reproductive capacity (Onuf, 1978; Prestidge, 1982). White (1984) speculated that improved host quality resulting from an increase in free amino acid concentration following an episode of plant stress would greatly enhance survival of newly enclosed larvae. Although a variety of physiological changes have been reported for plants (primarily evergreens) stressed by SO_2 (Alstad et al., 1982), increased concentrations of free amino acids in foliage due to SO_2 injury have been suggested as the causal factors for improved survival in both aphids (Dohmen et al., 1984) and beetles (Jaeger et al., 1972). Since air-pollution incidents typically occur over broad areas of crop production (Perkins, 1974), the cumulative effects on herbivores at the population level may be quite significant. Thus, potential changes in plant physiology due to stress or direct injury resulting from air

pollutants may well have more serious consequences than surveys of direct economic losses have suggested.

Little research is available concerning the impact of ozone on insect–plant interactions. In the most detailed study to date, Endress and Post (1985) demonstrated that the Mexican bean beetle preferred to feed on excised soybean foliage damaged by ozone, but the authors only speculated as to the physiological mechanisms underlying the changes in foliage suitability. In a related study, Jeffords and Endress (1984) reported a preference by gypsy moth larvae for ozonated foliage excised from white oak. Hughes et al. (1981) showed a similar preference by the Mexican bean beetle for foliage damaged by SO_2.

Earlier research on the direct impact of ozone on insects suggested there were no significant effects on two species of cockroaches or on fire ants (Levy et al., 1974). Prolonged exposure to high ozone concentrations on housefly populations caused insignificant variations in growth and survival, but apparently stimulated oviposition (Beard, 1965). However, insects in these two latter studies were not fed living plant material, so any potential ozone-induced changes in nutritional quality of their food source would not occur.

The first objective of the study reported here was to evaluate the influence of ozone on interactions between *K. lycopersicella*, a specialist herbivore of economic significance in the United States, and its host plant, *L. esculentum*. Secondly, we wished to document some of the chemical and physiological changes in ozonated tomato plants which might alter the nutritional or defensive status of the foliage.

METHODS AND MATERIALS

Tomato pinworm (TPW) larvae, *K. lycopersicella*, used in all tests were reared in the laboratory from a colony initiated in 1982 with insects collected from commercial tomatoes in Orange County, California. The culture was maintained at 26 ± 1°C in a photoperiod of 14L : 10D on tomato plants (variety VFN 7718). All tomatoes used in these studies (VFN 7718) were grown from the same seedlot in a glasshouse and were planted in one-gallon pots containing UC soil mixture (Matkin and Chandler, 1957). Fertilization was standardized within each test. All plants were eight weeks old (six true leaf stage) at the initiation of each experiment.

Ozone fumigation chambers utilized in these tests were either large (2.5 m diameter) outdoor chambers (Musselman et al., 1986) or smaller (1.37 m diameter) chambers located in a glasshouse (1.1 air exchanges/min, similar to Heck et al., 1978). Temperatures and relative humidities during fumigation ranged from 20 to 25.5°C and 35 to 42%, respectively. The outdoor chambers operated continuously, and plants received all ambient ozone present. Glass-

house fumigation chambers, which are suitable for precise metering of ozone, were utilized for developmental tests since temperature could be maintained near 26°C, the optimum for TPW (Lin and Trumble, 1985). Regardless of size, both multiple chamber facilities were equipped with electrical arc ozone generators and activated charcoal filters for filtered air (low ozone) fumigation. Ozone concentrations within individual chambers were recorded using Dasibi UV ozone monitors linked to data loggers.

Insect Development, Survival, and Fitness: TPW developmental rates and survival on ozonated plants, and the potential effects of direct exposure to ozone, were evaluated in glasshouse chambers using three treatments: (1) control, no ozone; (2) two ozone fumigations prior to TPW infestation of plants; and (3) two ozone fumigations prior to, and two fumigations after, TPW infestation. All fumigations lasted three hours and were two to three days apart; treated plants received 0.28 ppm ozone and control plants received filtered air. Such concentrations of ozone are not unrealistic for agroecosystems in the Los Angeles–Riverside area, as ozone levels usually exceed 0.20 ppm (first-stage alert) on at least 30 days per year, and levels of 0.35 ppm (second-stage alert) occur annually.

Five plants with 10 eggs per plant (i.e., 50 eggs/treatment) were exposed in each treatment. Age of the eggs was standardized by using eggs oviposited during a 2-hr period. Eggs were transferred to test plants prior to randomization for the three ozone treatments. Following the last fumigation, the tomato plants were moved to the laboratory (maintained at 26 $\pm$ 2°C) and placed on trays covered with sand. The pots were covered at this time to prevent larvae exiting the foliage from pupating in the soil.

The time of host abandonment, signaling the cessation of feeding and the onset of the prepupal stage, was used to determine developmental rate and survival of larvae. The sand, serving as a pupation medium for larvae exiting the leaves, was sifted at 8-hr intervals until all surviving larvae had exited the leaves. The numbers of larvae successfully pupating and emerging as adults were subsequently recorded.

A second experiment, designed to evaluate general fitness parameters of TPW, was conducted in the outdoor fumigation chambers. Three treatments were investigated: high ozone = 35.8 ppm-hours (ambient levels plus four, 4-hr fumigations with 0.28 ppm ozone over the course of 10 days); ambient ozone concentrations = 31.6 ppm-hours; and a filtered air control = 7.7 ppm-hours. Total dose is reported because the daily ozone dosage varies with ambient in field studies. The filtered air treatments contained background levels of ozone due to the inability of the activated carbon filters to completely remove ozone. Forty-five plants per treatment were arranged in a randomized complete block design within nine fumigation chambers which had been previously selected at random for treatments. Each plant was infested with five eggs, for a total of

225 eggs/treatment, prior to randomization. Following the fumigations, the plants were returned to the laboratory and prepared as in the previous test. The pupation medium was sifted at 24-hr intervals, and all pupae were segregated by treatment and held to adult emergence. The first time this experiment was conducted, only sex ratio data were collected. In a second trial, with the identical exposure and infestation schedule (high ozone = 38.8 ppm-hours; ambient = 34.2 ppm-hours; control = 12.4 ppm-hours), males and females emerging from within each treatment were paired and allowed to oviposit on an artificial substrate (Schuster and Burton, 1982). Total egg production by each female was recorded at 48-hr intervals. Longevity of the females was assessed by recording survival at 24 hr intervals. All data from these experiments were analyzed using analysis of variance followed by Duncan's (1955) multiple-range test (DMRT) as appropriate.

Nitrogen, Free Amino Acid, and Chlorogenic Acid Analyses: Eighteen tomato plants were exposed to four, 2-hr, 0.18 ppm ozone fumigations at three-day intervals in glasshouse chambers. Eighteen control plants received identical treatment but were fumigated with ozone-free air. Immediately following the last fumigation, individual leaves, consisting of seven leaflets each, from six randomly chosen plants per treatment were divided into roughly equal aliquots for analysis of total nitrogen, soluble proteins, free amino acids, and chlorogenic acid. Samples were weighed immediately after collection and frozen for later analysis. Enough foliage was available on a single plant to provide four pairs of samples for each of the variables analyzed. Leaves were chosen on the basis of position on the main stem, starting with the third fully expanded leaf from the top; above this level not all leaves had been exposed to all four fumigations. At 7 and 14 days postfumigation, foliage from six ozone-fumigated plants and six control plants were evaluated in an identical fashion, except that only soluble protein and chlorogenic acid concentrations were assessed at 14 days postfumigation.

In a related test, five tomato plants were exposed to two, 3-hr fumigations at 0.28 ppm of ozone. Fumigations were three days apart. As in the previous trial, five additional plants were fumigated for an equivalent time with ozone-free air. Two foliage samples per plant from control and treated plants were collected at two days postfumigation as described previously and analyzed for soluble protein content.

Total nitrogen was analyzed using the micro-Kjeldahl technique (McKenzie and Wallace, 1954). The technique was modified by replacing the mercuric oxide catalyst with copper sulfate and by utilizing bromocresol green in place of methylene blue as an indicator.

Soluble protein was quantified using methods modified from Hare (1983, Jones, Hare, and Compton, unpublished). Frozen samples (1–2 g fresh weight) were ground and extracted with 10 ml 0.1 M NaOH for 30 min at room tem-

perature. Leaf tissue was removed by centrifugation (11,500*g* for 10 min) and the supernatant was brought to 10 ml. Protein concentration of the NaOH solution was measured with the Bradford (1976) reagent using ribulose 1,5-biphosphate carboxylase (RuBPCase) (Sigma Chemical Co.) as the standard. Samples were diluted when necessary to avoid deviations from linearity due to NaOH at high protein concentrations. Duplicate readings were made on each extraction. Values are reported as milligrams RuBPCase equivalent protein per gram (fresh weight) of foliage.

Free amino acids were qualitatively and quantitatively evaluated by extraction from additional foliage samples (1–2 g, fresh weight) with 10 ml 0.2 M trichloroacetic acid (TCA) for 30 min at room temperature. Samples were gravity-filtered through Whatman No. 1 filter paper to remove leaf tissue and then centrifuged at 11,500*g* for 10 min to remove small particles and precipitated protein. The filtrate was subsequently brought to a volume (in ml) 10 times the original weight of the leaf tissue, diluted 1:4 with additional TCA, and analyzed by automated ion-exchange chromatography at the Biotechnological Instrumentation Facility at the University of California, Riverside. Specific amino acid concentrations are reported as micrograms of amino acid per gram (fresh weight) of foliage. Total amino acid concentration was calculated as the sum of the individual amino acids per sample.

Chlorogenic acid content of foliage was quantified using high-pressure liquid chromatography (after Elliger et al., 1981).

Chemical data were analyzed by nested analysis of variance (ANOVA). The variation between treatments was tested over the variation among plants within treatments, and the variation among plants was tested over the variation between samples within plants.

Pearson product-moment correlation coefficients were calculated between plant means of percent nitrogen, soluble protein concentration, and total free amino acid concentration in order to determine if these three parameters varied independently.

RESULTS AND DISCUSSION

Insect Survival, Development, and Fitness. Survival of larvae developing on ozonated foliage was significantly greater than larvae fed control plants (Table 1). Survival was more than doubled for TPW fed plants exposed to two fumigations. A significant decrease in survival was observed for TPW developing on foliage exposed to four fumigations, as opposed to two fumigations. Whether such an effect was due to contact toxicity, irritation, or some other cause, warrants additional investigation. Upon entering the tentiform leaf-mining stage (instars 3 and 4), adverse effects of ozone were apparently lessened, as counts of mines on the foliage equaled numbers of larvae exiting from leaves.

TABLE 1. DEVELOPMENTAL RESPONSE OF *K. lycopersicella* TO OZONATED AND CONTROL *L. esculentum*[a]

Treatment	% Completing larval development	% Successfully pupating[b]	% Adult emergence[b]
Control	28 a	93 a	100 a
Two O_3 fumigations	62 c	94 a	95 a
Four O_3 fumigations	46 b	100 a	94 a

[a] Five replicates of 10 larvae per treatment; numbers in column followed by the same letter are not significantly different ($P \leq 0.05$), arcsine transformation, DNMRT.
[b] Percentage of those individuals completing the previous stage.

No significant differences were detected in either percent pupation or successful adult emergence from pupal cases (Table 1). Although TPW larvae feeding on ozonated plants survived better, no corresponding improvement in other fitness parameters was observed; significant differences were not detected for ratios of males to females, female longevity, or fecundity (Table 2).

Developmental rates for TPW larvae feeding on ozonated tomato plants were faster by more than 32 hr than larvae feeding on control plants (Figure 1). Mean times for emergence from the plants (setting the first emergence as time zero) were 75.9 hr for larvae fed control foliage, 55.5 hr for TPW fed on plants exposed to two ozone fumigations, and 49.4 hr for larvae fed tomatoes fumigated four times. These values represent increases in overall larval development

TABLE 2. INFLUENCE OF OZONATED AND CONTROL PLANTS ON SELECTED BIOLOGICAL PARAMETERS OF *K. lycopersicella*

Treatment	Test[a]	Sex ratio (male–female)	Mean longevity per female (days)[b]	Mean No. eggs per female (N)[c]

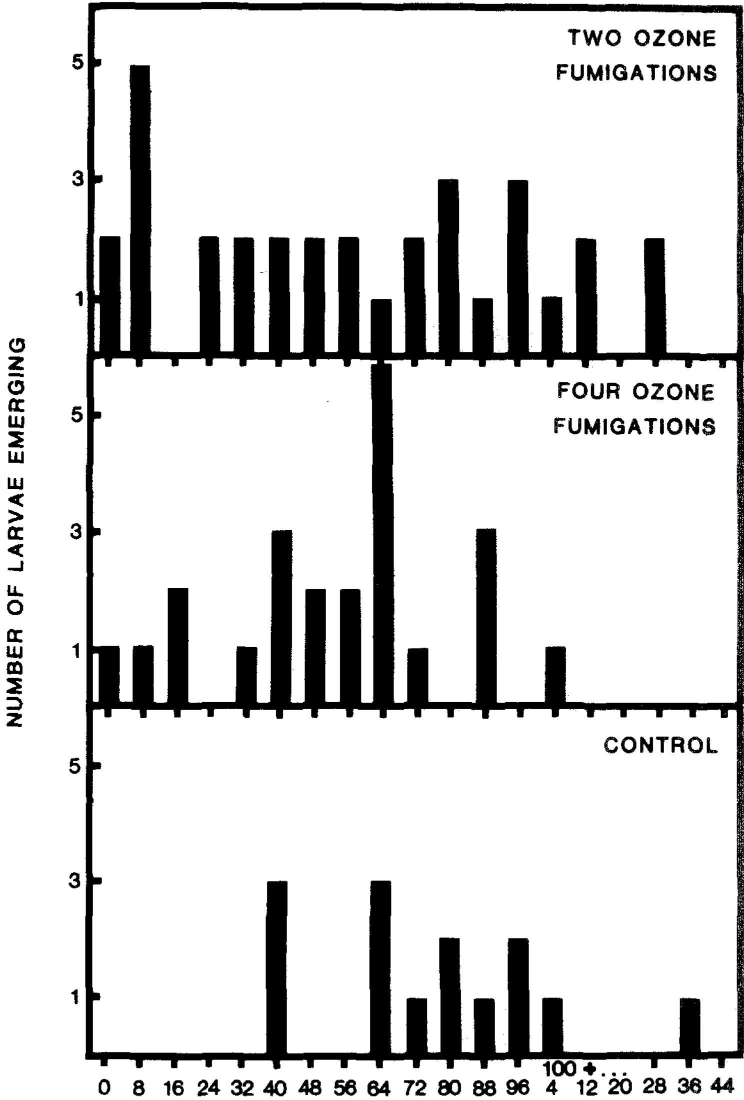

FIG. 1. Effects of ozone fumigation on time of emergence for larvae exiting ozonated and control foliage. Ozone fumigations in glasshouse chambers; dosage for each fumigation was 0.28 ppm.

rates of 1.3%, 7.1%, and 10.6%, respectively, as compared to expected larval developmental time predicted at 26°C by Lin and Trumble (1985). Although the observed increase in developmental rate may have occurred in response to ozone-induced stomatal closure in tomato foliage (which would elevate temperature through a decrease in evaporative cooling), Dugger et al. (1962) reported that ozone fumigation resulted in either no change or an increase in stomatal opening in beans.

If the observed effect of increased survival and developmental rate on ozonated plants proves applicable to other agricultural systems, two interesting implications for pest management programs become evident. First, programs dependent on developmental models driven by temperature will underestimate both stage of development and population size. To our knowledge, this effect has not yet been reported, but this manuscript reports the first results suggesting that the exposure of host plants to ozone is an important developmental factor for phytophagous insects. Also, those programs dependent on monitoring fruit and/or foliage for determination of threshold levels may require more frequent sampling (examples for the TPW include Wellik et al., 1979; and Wolfenbarger et al., 1975). Second, increased developmental rates may affect the success of biological control agents. For example, even though increased density of TPW may allow increases in the most common parasite species (Oatman et al., 1979), the time period for most successful parasitization would be shortened to less than the reported 48-hr period (2- to 3-day-old TPW at 26°C; Cardona and Oatman, 1971), thus decreasing the opportunity for parasites to utilize the most effective "window" for oviposition.

Nitrogen, Free Amino Acid, and Chlorogenic Acid Analyses. Since the biological effects of feeding on ozonated foliage were more evident for larvae than adults, we speculated that either the nutritional suitability of the foliage was improved for the neonate larvae as suggested for stressed plants by White (1984), or the plant's "defensive" system was being adversely affected. Analyses of total nitrogen content suggested that ozone-damaged foliage should be less nutritious than untreated leaves by one week following exposure to ozone fumigations (Table 3). However, total nitrogen analysis with the Kjeldahl method also includes nitrogen from structural proteins, nonprotein amino acids, and nitrogen incorporated in defensive compounds (Hare, 1983). Significant enhancement of soluble protein concentrations for up to two days postfumigation provided an increase in readily assimilable nitrogen available for the larvae, which suggests a plausible explanation for the observed improvement in larval survival. Similar increases in soluble protein concentrations have been documented for beans exposed to ozone (Beckerson and Hofstra, 1979), but reports in the literature have not been consistent (Ting and Mukerji, 1971).

Ten of the 20 amino acids quantified from ozonated foliage varied significantly from concentrations in control leaves (Table 4). Reductions in methionine and tyrosine immediately following fumigation were anticipated from ear-

TABLE 3. ANALYSES OF SOLUBLE PROTEINS AND TOTAL NITROGEN IN OZONATED AND CONTROL PLANTS AT SELECTED INTERVALS POSTFUMIGATION

Days post fumigation	No. of fumigations	Fumigation interval (days)	Ozone (ppm) concentration	Soluble protein		% Total nitrogen	
				Ozone	Control	Ozone	Control
0	4	3	0.18	14.699[a]	12.025	5.483[b]	5.190
2	2	3	0.28	6.638[c]	6.592	—	—

Histidine	7.99 NS	7.29	85.55 *	68.72
Methionine	5.89 **	9.46	4.52 NS	7.49
Proline	67.01 **	107.20	96.11 **	178.18
Serine	141.61 **	113.12	919.23 *	442.88
Tyrosine	9.98 **	16.63	39.91 **	77.74
Valine	68.89 **	54.83	246.30 NS	238.83

[a] Includes only those amino acids with substantial changes in concentration, amino acid concentration in $\mu g/g$. Horizontal comparisons within 0 or 7 days postfumigation are not significant (NS), significant at the $P \leq 0.1$ level (*), or significant at the $P \leq 0.05$ level (**) as noted.

lier reports (Chang, 1971b; Mudd and Freeman, 1977), but significant reductions in glutamine (57%) and proline (37%) had not been previously noted. Of the other amino acids which reportedly react with ozone, cysteine and cystine were only nominally present in tomato foliage, and histidine was not significantly affected. Unlike previous studies (Menzel, 1971; Craker and Starbuck, 1972), significant increases in the total pool of free amino acids were not detected. However, a trend toward higher concentrations of total free amino acids in ozone-treated plants was evident (ozonated plants = 1020.1 and 3310.5 $\mu g/g$; control plants = 968.6 and 2601.3 $\mu g/g$ at 0 and 7 days postfumigation, respectively).

Comparisons between amino acid concentrations immediately following fumigation and concentrations at seven days postfumigation suggest an explanation for the variable reports of amino acid fluctuations in the literature. While proportions of some amino acids remained approximately the same on both sampling dates, the relative amounts of others, specifically serine, glutamine, histidine, and valine, increased considerably. Whether the tomato plant is stimulated to compensate for ozone-induced reductions in certain amino acids such as glutamine, or if the leaves are entering a premature senescence causing nitrogenous compounds to be converted to soluble forms available for reallocation, should be the focus for additional research. The general increase in free amino acid concentration in both ozonated and control plants over the course of the experiment probably reflects a general mobilization of energy reserves from the leaves to flowers or immature fruit (Ting, 1982). Regardless of the

cause of amino acid concentration differences between ozonated and control plants, time elapsed between ozone fumigation and leaf sampling can affect the quantities of amino acids, soluble protein, and total nitrogen measured.

The implications of ozone-induced changes in amino acid concentrations are potentially quite significant for insect populations. Of the 10 rat-essential amino acids generally considered necessary for insect growth (Dadd, 1973), only methionine and valine differed significantly in ozonated foliage. Since growth of TPW was not inhibited by the transient reduction in methionine concentration, and valine concentrations increased, changes in these amino acids were not limiting. Vanderzant (1966) reported that even relatively small changes in concentrations of free amino acids can have significant and negative effects on insect development if the amino acids compete for sites on the absorption system. House and Barlow (1964) documented the negative effects of increasing the amounts of amino acids in an artificial diet, and thereby altering the osmotic balance of the diet. However, since our data indicated: (1) the total pool of free amino acids was not significantly increased at either 0 or 7 days following ozone fumigation, (2) the increase in total free amino acids between day 0 and day 7 was greater than the increase between ozonated and control foliage, and (3) the concentrations of free amino acids in ozonated and control plants were similar to those used in successful artificial diets for other phytophagous lepidopterans (Vanderzant, 1957; Arai and Ito, 1964), neither competition for absorption sites nor changes in osmotic balance of the host would be likely to exert a negative effect in our system.

Potentially critical changes in free amino acid concentrations occurred in the key supplementary amino acids (terminology after Dadd, 1973), all of which increased significantly in ozonated foliage. Alanine, glycine, aspartic acid, and serine have been reported as important growth factors for the silkworm (Ito and Arai, 1966, 1967), while proline was documented as "semi-essential" for the silkworm (Ito and Arai, 1965) and critical to the development of many dipterans (Friend, 1968; Gingrich, 1964). Thus, since changes in concentrations of these amino acids were relatively major (up to 207% increase for serine), increased availability of supplementary amino acids probably accounts for at least some of the improved survival demonstrated for TPW fed on ozonated tomato foliage. None of the correlation coefficients between percent nitrogen, soluble protein, or total free amino acid concentration were significantly different from zero in either data set, suggesting that exposure to ozone affected these three aspects of plant nitrogen metabolism independently.

Since insect survival could also have been affected by the concentration of plant defensive chemicals, we considered which compounds would be most likely to be affected by ozone. Of the secondary plant compounds documented in commercial tomatoes which have proven antibiotic properties against lepidopterans, only chlorogenic acid has an "exposed" double bond susceptible to rapid oxidation by ozone (J. Kumamoto, personal communication). Ozone-in-

duced reductions in tyrosine would not effectively inhibit productivity of chlorogenic acid in tomatoes, since this amino acid is only an important precursor in monocotyledonous plants (Rhodes and Wooltorton, 1978). Since chlorogenic acid production can be an induced response, occurring after stress from either disease (Carrasco et al., 1978) or insects (Elliger et al., 1981), oxidation should prevent chlorogenic acid levels from increasing as long as contact with ozone is frequent. We found that chlorogenic acid levels did not differ significantly from controls either immediately following the last fumigation or at seven days postfumigation. However, by 14 days after the last fumigation, significant increases in chlorogenic acid concentration were observed in ozonated plants (ozone-treated plants = 31.1 μg/g fresh weight, control plants = 16.3 μg/g, ANOVA, $P \leq 0.05$). Therefore, although stress generated by ozone may induce chlorogenic acid production in tomato plants, benefits relating to insect control may be minimized by repetitive exposures and subsequent oxidation. Nonetheless, the increase in developmental rates and survival of TPW on ozonated foliage cannot be explained by suppression of chlorogenic acid production in our experiments.

CONCLUSIONS

The observed increase in survival and developmental rates of TPW larvae feeding on ozonated tomato foliage was due to a complex of factors, the most important of which were nutritional. Concentrations of readily assimilable nitrogenous compounds such as soluble protein and important supplementary amino acids proved to be considerably better indicators of host suitability than total nitrogen analysis. Although chlorogenic acid production in tomatoes may be induced by exposure to ozone, the plant response occurred too late to effect the enhanced growth and survival of TPW and could therefore be eliminated as a primary cause for the observed effects.

Although our data show an increase in soluble nitrogenous compounds as predicted by White's (1984) hypothesis, this apparent agreement may be an artifact. White proposed that the breakdown of insoluble proteins to smaller, more soluble compounds was a general response to plant stress and adaptive to the extent that the increase in free amino acid concentration stimulated seed production during stressful periods. While this may be true for some stresses, (e.g., drought), we do not believe that our results necessarily reflect an adaptive response of plants to ozone damage. Rather, the increases in concentration of soluble nitrogen following ozone exposure are more likely to be simply the direct consequence of the chemical reactivity of ozone with plant proteins and amino acids (Craker and Starbuck, 1972; Mudd and Freeman, 1977).

Acknowledgments—We wish to thank R. Teso for assistance with ozone fumigations, and H. Nakakihara, W. Carson, A. Tarshis, and I. Ramadan for assistance with plant production and

chemical analyses. The reviews of W. Osbrink, B. Martens, W. Wiesenborn, and W. Moar are appreciated. This research was supported in part by a grant from the Academic Senate, University of California, Riverside.

OVIPOSITION DETERRENT FROM EGGS OF *Callosobruchus maculatus*: Spacing Mechanism or Artifact?

FRANK J. MESSINA,[1] JOYCE L. BARMORE, and J.A.A. RENWICK

Boyce Thompson Institute for Plant Research
Tower Road, Ithaca, New York 14853

(Received December 6, 1985; accepted February 11, 1986)

Abstract—Females of *Callosobruchus maculatus* (F.) avoid ovipositing on host seeds already bearing conspecific eggs, and thus distribute eggs evenly among seeds. This behavior was presumed to be mediated by an ether-soluble "oviposition marker" that is deposited with the egg and can be extracted from egg-laden artificial hosts (glass beads). Ablation experiments revealed that the true factors promoting an even dispersion of eggs were perceived by the maxillary and labial palpi. In contrast, receptors on the antennae were largely responsible for avoidance of seeds treated with "oviposition marker." Taken together, these results suggest that a careful distinction should be drawn between factors that promote spacing of eggs under natural conditions and general oviposition deterrents that may be isolated from both sexes.

Key Words—Ablation, egg dispersion, oviposition deterrent, foretarsi, palpi, antennae, Coleoptera, Bruchidae, *Callosobruchus maculatus*.

INTRODUCTION

Female insects use a variety of cues to locate suitable oviposition sites. In some phytophagous species, females tend to reject host plants that already bear conspecific eggs (Prokopy et al., 1984). This behavior produces a statistically uniform (nonrandom) dispersion of eggs among hosts. Not surprisingly, detection and avoidance of egg-laden hosts seems especially prevalent in species where the potential for competition among larvae is relatively high (Rausher, 1979). "Egg-load assessment" (Rothschild and Schoonhoven, 1977) may be elicited by visual, olfactory, or tactile stimuli, but in most cases studied so far, it is

mediated by contact chemoreception of pheromones deposited during or following egg-laying (Prokopy et al., 1984; Städler, 1984).

Seed beetles (Bruchidae) of the genus *Callosobruchus* are well known to distribute eggs evenly among seeds (e.g., Avidov et al., 1965). The legless hatching larva must develop within the seed upon which the egg is laid, and a clear fitness advantage is conferred on females that seek unused hosts (Mitchell, 1975). Gravid females of *C. maculatus* (F.) not only distinguish between egg-laden and pristine seeds, but also assess egg loads quantitatively, i.e., when all seeds bear eggs, females prefer to oviposit on seeds with below-average egg densities (Messina and Renwick, 1985a). This tendency appears to be adaptive, since larval survivorship decreases linearly with small increases in larval density within seeds (Messina and Renwick, 1985b). A chemical basis of egg recognition is likely because females lay more eggs on clean seeds than on seeds from which an egg has been removed (Giga and Smith, 1985; Wasserman, 1985; Messina and Renwick, 1985c). Physical (tactile) cues may also be involved; attachment of egg models to seeds deters oviposition to some extent (Messina and Renwick, 1985c).

Oshima et al. (1973) and Messina and Renwick (1985c) extracted chemical oviposition deterrents from glass beads laden with eggs of *C. chinensis* (L.) and *C. maculatus*, respectively. In both studies, however, deterrents were similarly obtained from egg-free beads that had been exposed to males. Such lack of specificity casts doubt on the role of these chemicals as "oviposition markers." The ability of females to perceive differences in egg density implies that the relevant cues are deposited only during each previous oviposition. Females were not deterred from ovipositing on egg-free seeds that had been directly exposed to males or virgin females (Messina and Renwick, 1985c).

In order to help identify the stimulus used in egg recognition, we determine in this study the sense organs involved. We compare how ablation of female sense organs influences both the ability to disperse eggs evenly and the response to oviposition marker. In a previous study on the sensory basis of bruchid egg recognition, Avidov et al. (1965) found that *C. chinensis* females distributed eggs uniformly among seeds despite antennectomy.

METHODS AND MATERIALS

A laboratory colony of *C. maculatus* was established in 1982 from infested cowpea seeds [*Vigna unguiculata* (L.) Walp.] in northern Cameroon. We maintained the colony and conducted all experiments in a dark incubator at 30°C and 50–60% relative humidity. Black bean seeds (*Phaseolus vulgaris* L.) were used as the experimental host because their dark coats permit high visibility of eggs.

Ablations were performed by anesthetizing newly emerged females with CO_2 for ca. 1 min and placing them under a dissecting microscope. Fine forceps were used to snip off each organ at its base. Antennae (A), foretarsi (F), and palpi (P, maxillary and labial) were removed alone or in combination. To test the ability of females to disperse eggs evenly, we placed each female plus one male into a Petri dish containing 15 seeds. Control females in this experiment were similarly anesthetized, and were subjected to removal of an elytron. Each female was allowed to lay her lifetime complement of eggs (usually 40–80 eggs) on her allotment of 15 seeds. After the female died, we calculated the mean egg density and the variance in egg density. The variance–mean ratio was used as a standard, unbiased index of dispersion (Myers, 1978), where $s^2 < \overline{X}$ indicates an even distribution, and $s^2 > \overline{X}$ indicates a clumped distribution. We conducted 2×2 contingency tests (with Yates' correction) to compare control and treated females in the frequency at which they distributed eggs evenly or unevenly. Fifty to seventy-five females were used per ablation treatment. We discarded a small number of dishes in which the female laid <20 eggs, as these individuals were probably injured during ablation.

We used the method of Oshima et al. (1973) and Messina and Renwick (1985c) for extracting chemical deterrents. Five hundred mated females were placed into a jar containing 400 g of glass beads ($\simeq 1500$ beads of 3–5 mm diameter). Beetles were sieved off after four days. We sampled 20 beads to estimate the mean number of eggs/bead. Beads were washed vigorously for ca. 1 min with 200–300 ml of diethyl ether, and each wash was divided in half for use in two separate trials. The half-strength wash was then concentrated to 70 ml. For each trial, 200 seeds were dipped into the 70 ml of ether wash (treated) or into plain ether (control). Seeds were apportioned into 20 divided Petri dishes, with 10 control and 10 treated seeds/dish (5 seeds/quadrant). Each dish received three females whose sense organs had been ablated unilaterally (10 dishes) or bilaterally (10 dishes). Unilateral ablations served to check the activity of the extract and to control for any traumatic effect of the procedure. After 16 hr, we recorded the number of eggs laid on control or treated seeds in each set of dishes. Data were analyzed with paired t tests.

RESULTS

Lifetime fecundity was similar among females in the control and ablation treatments, even though ablated females lost up to three sense organs (Table 1; means were not compared statistically because females were not always derived from a single batch). Since most females deposited 60–70 eggs on the 15 available seeds, mean egg density in a dish was typically 4–5 eggs/seed. As expected, 80% of the control group tended to distribute eggs evenly, i.e., the

[b]Maxillary plus labial palpi.

variance in egg density was lower than the mean (Table 1). The median s^2/X ratio for the 56 control females was well below unity. The tendency toward uniform distribution of eggs persisted after removal of antennae or foretarsi. Thus any impairment of locomotion caused by removal of foretarsi was too slight to affect egg dispersions. However, removal of the palpi, alone or in combination with other organs, caused a reversal in oviposition behavior; most females tended to clump their eggs ($s^2 > \bar{X}$), and the median $s^2/\bar{X}$ ratio rose accordingly (Table 1). In no treatment was there an approximately equal number of females distributing eggs evenly and unevenly, which would be expected if a particular ablation led to random oviposition.

Two results suggest that the antennae and foretarsi could play a minor or supplementary role in egg recognition: (1) a slightly higher proportion of females distributed eggs unevenly in the A + F treatment than in the control treatment (and the median $s^2/\bar{X}$ ratio rose slightly), and (2) virtually all females clumped their eggs in the A + F + P treatment (Table 1). Alternatively, females in the A + F + P treatment may have been so drastically deprived of sensory input that they continued to oviposit but stopped moving between seeds.

Mean egg densities ranged between 8 and 12 eggs/glass bead after 500 females were allowed to oviposit on 1500 beads for four days. Thus between 12,000 and 18,000 eggs contributed to each ether wash, which was then divided in half. Since ca. 4 ml of the 70 ml, half-strength wash was taken up in coating the 200 dipped seeds, each treated seed used in the choice-test bioassay received roughly 1.5–3.0 egg-equivalents of ether-soluble material.

TABLE 2. OVIPOSITION PREFERENCES OF *C. maculatus* FEMALES SUBJECTED TO UNILATERAL OR BILATERAL ABLATIONS AND OFFERED SEEDS DIPPED IN ETHER (CONTROL) OR ETHER WASHES OF EGG-LADEN GLASS BEADS (TREATED)

	Unilateral, eggs added to			Bilateral, eggs added to		
Ablation	Control	Treated	P^a	Control	Treated	P^a

F + P	127	51	<0.05	63	41	>0.10

[a] Paired *t* test, 10 replicate dishes/trial.

Females subjected to unilateral ablations consistently laid more eggs on control seeds than on seeds dipped in washes of glass beads (Table 2). This confirmed the deterrence of the extract and ruled out any negative effect of the ablation procedure. Avoidance of treated seeds continued after bilateral ablation of foretarsi or palpi, but disappeared after bilateral ablation of antennae, whether antennae were removed alone or in combination with other organs (Table 2). An unexpected result was that removal of the foretarsi and palpi also caused a lack of significant discrimination (F + P, Table 2), although females still tended to lay more eggs on control seeds.

DISCUSSION

The results in Tables 1 and 2 present a paradox. Females deprived of maxillary and labial palpi, but bearing intact antennae, failed to distribute eggs evenly, and in fact usually aggregated their eggs. Yet the putative oviposition marker was mainly perceived by the antennae, as antennectomized females bearing intact palpi no longer discriminated between control and extract-treated seeds. We must conclude that a different factor was influencing behavior in each bioassay. The ether-soluble "oviposition marker" probably has no relevance to the natural spacing of eggs, otherwise females missing their palpi but retaining their antennae would have distributed eggs evenly (Table 1). Conversely, the true factor(s) promoting an even dispersion of eggs must not have been present in detectable amounts in the ether-extract bioassay, otherwise females missing their antennae but retaining their palpi would have avoided the treated seeds (Table 2). We cannot reject the hypothesis that the ether-soluble material plays an auxiliary role in egg dispersion, but we have no evidence that it does.

A distinction should therefore be drawn between general oviposition deterrents, which may be identified from choice-tests (as in this study), and factors that promote an even spacing of eggs. Uniform dispersion of eggs by *C. maculatus* may well be mediated by an ether-insoluble chemical or by the physical shape of the egg. This may explain why females continue to avoid ovipositing on egg-laden seeds despite repeated washing of seeds with ether (Messina and Renwick, 1895c). Giga and Smith (1985) claimed that ether-soaked, egg-laden seeds inhibited oviposition less than control, egg-laden seeds, but their data showed little difference in oviposition rate on the two seed types (3.31 vs. 3.19) and no statistical comparison was given.

Other studies may also be interpreted as showing that isolation of an oviposition-deterring chemical is not tantamount to explaining an observed even spacing of eggs. Using a behavioral assay, Prokopy et al. (1982) isolated oviposition deterrents from several body parts of the apple maggot fly, *Rhagoletis pomonella* (Walsh), but in an electrophysiological assay, only a few of the extracts stimulated tarsal hairs known to be receptive to the true oviposition-deterring pheromone. The behaviorally deterrent extracts that failed to stimulate the tarsal hairs may contain compounds that are of little importance in explaining the fly's avoidance of occupied hosts. Szentesi (1981) obtained strong oviposition deterrents from seeds exposed to either sex of the dry bean weevil, *Acanthoscelides obtectus* Say, yet this insect tends to distribute eggs in a random or clumped manner (Umeya and Kato, 1970; Pouzat, 1983; Jarry and Chacon, 1983). Thus, extraction of an oviposition deterrent need not imply an even distribution of eggs in nature. For an insect such as *C. maculatus* that does disperse its eggs evenly, the likelihood that an isolated oviposition deterrent is indeed the natural spacing mechanism will be increased if ablation of the sense organ responding to the chemical also leads to random or aggregated oviposition.

The maxillary and labial palpi were the primary organs used for egg recognition by *C. maculatus.* Removal of palpi did not simply lead to random oviposition; females deprived of these organs tended to clump their eggs. This reversal in behavior was not completely unexpected. Once egg loads on seeds no longer influence oviposition choices, a female may prefer particular seeds because her remaining sense organs respond to subtle variation in seed size or texture (cf. Mitchell, 1975; Pouzat, 1983). In various Bruchidae, the palpi are already known to play a dominant role in legume host recognition, in plant-mediated stimulation of oogenesis (Szentesi, 1976; Pouzat, 1978), and in discrimination between host species (Messina, Renwick and Barmore, unpublished). The sensory basis of avoidance of egg-laden hosts is known for only a few phytophagous insects (e.g., Crjnar and Prokopy, 1982; Städler, 1984), but in at least one species, the large cabbage white butterfly (*Pieris brassicae* L.),

the same sense organ mediates chemoreception of both host plants and conspecific eggs (Behan and Schoonhoven, 1978; Klijnstra, 1985).

(Received October 30, 1985; accepted February 13, 1986)

Abstract—Detailed chemical characterizations are provided for the species-specific mixtures of marking pheromones utilized by the male beewolves *Philanthus basilaris* and *P. bicinctus*. Successful analysis of these complex mixtures of 2-ketones, fatty acids, ethyl esters, and aldehydes was facilitated by the treatment of the crude extracts with 1,1-dimethylhydrazine and direct analysis of the resulting hydrazones, methyl esters, and starting ethyl esters by GC-MS.

Key Words—*Philanthus*, Hymenoptera, Sphecidae, pheromone, scent-marking, 2-alkanones, fatty acids, ethyl esters, alkenals, *N,N*-dimethylhydrazine, methyl esters, EI-MS, CI-MS, methoxymercuration, methylthiolation.

INTRODUCTION

Male sphecid wasps in the genus *Philanthus* are known to be territorial and to display a striking behavior that has been called "abdomen dragging." This

0098-0331/87/0200-0227$05.00/0 © 1987 Plenum Publishing Corporation

behavior consists of alighting on plants within their territories and walking up and down the stem or leaf while pressing the hair brushes located at the base of their mandibles and/or the venter of their abdomens against the plant surface (Alcock, 1975; Borg-Karlson and Tengö, 1980; Evans, 1983; Gwynne, 1978; O'Neill, 1979, 1983). Since it is known that these males also possess large paired mandibular glands that open at the base of the mandibles adjacent to the hair brushes, a logical hypothesis is that these glands are the source of a pheromonal mixture that is being deposited while the wasps are "abdomen dragging" (Gwynne, 1978; O'Neill, 1979). Direct confirmation of this hypothesis was recently provided plus preliminary chemical evidence for the nature of the pheromonal blends (Schmidt et al., 1985). This paper provides a detailed chemical analysis of the pheromonal components deposited by *Philanthus basilaris* (Cresson) and *P. bicinctus* (Mickel) while "abdomen dragging" on the plant surfaces.

METHODS AND MATERIALS

Mandibular glands were obtained as previously described (Schmidt et al., 1985). Five to ten pairs of glands were pooled by species and suspended in ca. 200 μl of distilled-in-glass methylene chloride (Burdick and Jackson Co. Muskeegon, Mich.).[6] Aliquots of these stock solutions were used for subsequent analyses.

Derivatizations were conducted in 5 ml Reactivials (Pierce Chemical Company, Rockford, Illinois) with heating (when necessary) provided by a Reactitherm unit. *N,N*-Dimethylhydrazones were prepared as previously reported (McDaniel and Howard, 1985). Methyl esters were prepared either using diazomethane (Schlenk and Gellerman, 1960), or 1,1-dimethylhydrazine (McDaniel and Howard, 1985). Double-bond positions were determined either by gas chromatographic–mass spectrometric (GS-MS) analyses of methoxy ethers which were prepared by methoxymercuration–demercuration (Abley et al., 1970; Blomquist et al., 1980), sometimes with subsequent hydrogenation (Plattner et al., 1975), or by GC-MS analyses of methyl thioethers (Francis and Veland, 1981). Double-bond stereochemistries were determined by comparison of gas chromatograph (GC) retention times and coinjection with authentic standards using a 6-m × 2-mm ID stainless-steel column of 15% OV-275 on 100/120 Chromosorb P AW-DMCS operated isothermally at 220° in a Hewlett Packard 5710A gas chromatograph.

GC-MS analyses were conducted using a Hewlett Packard 5710A GC interfaced to a Hewlett Packard 5982 mass spectrometer equipped with a Hewlett Packard 5933 data system. The GC contained 1.8-m × 2-mm ID glass columns packed with either SP-2100 on 100/120 mesh Supelcoport or 0.65% OV-17 +

[6] Mention of a company or trade name is for identification purposes only and does not imply endorsement by the U.S. Department of Agriculture.

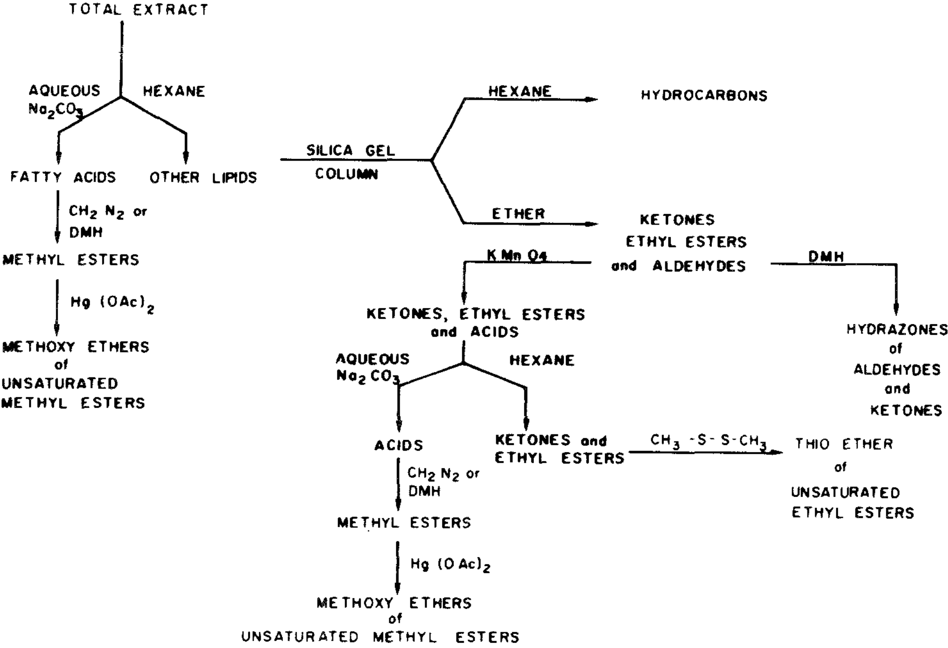

FIG. 1. Separation and analysis flowchart for the marking pheromone of *Philanthus basilaris* and *P. bicinctus*.

0.5% OV-210 on 100/120 mesh Ultrabond 20 M. Analyses involved temperature programming from 100 to 280°C at 8°/min. Electron-impact mass spectra (EI-MS) were generated at 70 eV; chemical-ionization mass spectra (CI-MS) were generated at 200 eV using ultrapure methane as both carrier and ionizing gas at a flow rate of 13 ml/min which generated an internal source pressure of 0.5 torr.

Figure 1 is a flow chart outlining the separation and derivatization procedures used in the course of the analyses.

RESULTS

The exocrine products of the sympatric species *P. basilaris* and *P. bicinctus* are essentially those of carbonyl compounds. Although quantitatively different, both species contain the same homologous series of 2-ketones and saturated and unsaturated carboxylic acids. They contain different unsaturated aldehydes, however, and *P. bicinctus* is also characterized by a homologous series of saturated and unsaturated ethyl esters that are not present in *P. basilaris*. A detailed analysis of each class of carbonyl compound is presented below and summarized in Table 1.

TABLE 1. DIAGNOSTIC MASS SPECTRAL DATA FROM MANDIBULAR GLAND COMPONENTS (OR THEIR DERIVATIVES) FROM *Philanthus basilaris* and *P. bicinctus*

Compound	Molecular formula	Molecular weight	Free compounds		EI-MS			
			EI	CI	Methyl esters	Methoxy ethers	Dithiomethyl ethers	*N,N*-Dimethyl hydrazones

Ketones. These compounds are readily characterized by mass spectrometry. Their EI-MS contain characteristic ions at *m/z* 58 as the base peak and parent ions of approximately 3–5% intensity. CI-MS of these compounds contain the M+1 ion as the base peaks and small (1–2%) M-18 ions. Confirmation of these assignments were made by an analysis of the mass spectra of their *N,N*-dimethylhydrazones; EI-MS of these hydrazones contain ions at *m/z* = 100 as the base peak, with parent ions of ca. 20% abundance and significant M-44 ions which correspond to the loss of a dimethylamino radical from the parent species. CI-MS of the *N,N*-dimethylhydrazones contain the M+1 ion as the base peak and significant M-42 ions which presumably arise from the loss of methylimine from the protonated parent species.

Aldehydes. EI mass spectra of the unsaturated aldehydes contained no parent ions and only modest amounts (2–3%) of a M-18 ion. By contrast, the CI-MS of these compounds had the M+1 ion as their base peaks and significant (20–90%) M-17 ions, which presumably arise from a loss of water from the protonated parent species. These data, however, did not allow an unequivocal distinction between monounsaturated aldehydes and diunsaturated alcohols of the same carbon number.

Treatment of the mixture with 1,1-dimethylhydrazine (DMH), however, quantitatively converted all of the presumptive aldehydes to the corresponding hydrazones within 10 min. EI-MS of these hydrazones contained the ion at *m/z* 86 as their base peaks and parent ions of 10–20% abundance. Their CI-MS contained M+1 ions as the base peaks and prominent M-44 ions which probably correspond to the loss of dimethylamine from the protonated parent species.

An initial attempt was made to determine double-bond positions by methoxymercuration–demercuration of the crude glandular extracts (Abley et al., 1970; Blomquist et al., 1980). However, intractable product mixtures resulted; therefore, an aliquot of the crude extract was extracted with sodium carbonate to remove carboxylic acids and then loaded onto a silica gel minicolumn. Elution with hexane removed any possible cuticular hydrocarbon contaminants, and subsequent elution with ether yielded a mixture containing only the aldehydes, ketones, and ethyl esters. This mixture was oxidized using a neutral dilute permanganate solution which oxidized the aldehydes to carboxylic acids without alteration of the ketones or ethyl esters. These acids were partitioned into sodium carbonate solution, acidified, taken into ether, and converted to their methyl esters with diazomethane (Schlenk and Gellerman, 1960). Methoxymercuration–demercuration of these methyl esters proceeded smoothly and the double-bond positions were determined by EI-mass spectrometry. In all cases, the double bonds were Δ^9.

Double-bond stereochemistries of the aldehydes (as methyl esters) were determined via gas chromatography. In all cases only the *Z* stereoisomer was present.

Ethyl Esters. The presence of ethyl esters in *P. bicinctus* extracts was easily recognized by the characteristic ion at *m/z* 88 in their EI mass spectra. Although parent ion abundances were quite low (or sometimes undetectable when only small amounts of material were present), the ions at M-46 arising from a loss of ethanol were typically present in 3–5% abundance. CI-MS of these compounds had M+1 ions as their base peaks and M-45 ions of approximately 20% relative intensity.

As with the aldehydes, attempts to form methoxy derivatives using the crude glandular extracts were unsuccessful. Interestingly, thiomethyl ether formation was successful using the crude extracts (Francis and Veland, 1981). EI mass spectra of the resulting vicinal dithiomethyl ethers allowed the double-bond position of the ethyl esters to be assigned as Δ^9. Stereochemical assignment as the *Z* isomers was again based on GC coelution with known standards.

Carboxylic Acids. The presence of the carboxylic acids in the *Philanthus* extracts was first detected when the addition of 1,1-dimethylhydrazine to the total mixture produced not only the expected hydrazones of the aldehydes and ketones, but also a homologous series of methyl esters (see Discussion). The EI-MS of these methyl esters showed the expected ion at *m/z* 74, small parent ions, and M-32 ions in 3–5% abundance. CI-MS had the M+1 ion as base peak and significant M-31 ions, presumably resulting from loss of methanol from the protonated molecular ion.

To locate the positions and configurations of the double bonds of these acids, they were separated from the crude mixture by extraction with sodium carbonate and converted to their methyl esters using diazomethane. Methoxy ethers were prepared as above, but the resulting mixture of carbon number and positional isomers precluded unequivocal locations of the methoxyl groups. This problem was overcome by using the method of Plattner et al. (1975), whereby the mixture of methoxy ethers was injected onto a GC column in which the first few centimeters was packed with palladium chloride on Chromosorb W, with hydrogen used as the carrier gas. This reduced all remaining double bonds, and the eluting compounds were then all monomethoxyl methyl esters whose EI-MS were readily interpreted. As indicated in Table 1, the double-bond positions in the acids were all Δ^9 or $\Delta^{9,12}$. Assignment of the *Z* configuration to all double bonds was based on GC coelution with known standards.

DISCUSSION

The complex mixtures of carbonyl compounds present in the *Philanthus* mandibular gland secretions present an interesting challenge. The carboxylic acids tailed badly on our nonpolar GC columns and were difficult to detect in their free state. Although the aldehydes chromatographed well, their mass spec-

tra were not easily differentiated from those of diunsaturated alcohols of the same carbon number. Unlike our previous experience with unsaturated cuticular hydrocarbons, the total crude extract was not a suitable mixture for using the technique of methoxymercuration–demercuration to locate double bonds.

The use of DMH to convert the ketones and aldehydes to their hydrazones and the carboxylic acids to methyl esters (McDaniel and Howard, 1985) was the critical step in determining the chemistry of these carbonyl mixtures. DMH treatment of the crude glandular extract followed by direct GC-MS analysis allowed us to readily identify the basic structural features of all the classes of semiochemicals present. In the case of the ketones, the resulting hydrazone spectra were verification of what we had readily deduced from the underivatized parent compounds. In the case of the aldehydes, however, the resulting hydrazone spectra were clearly more diagnostic than those of the free aldehydes (Budzikiewicz et al., 1967; McDaniel and Howard, 1985). Conversion of the free acids to their methyl esters made possible the chromatographic separation and subsequent mass spectral identification of these compounds. All of these derivatizations and analyses were made on nanogram to microgram quantities and, for at least the DMH-induced reactions, all were essentially quantitative. Perhaps the greatest obstacle was the location of the double-bond positions in the aldehydes, acids, and ethyl esters.

Methoxymercuration has been successfully used by us and others to derivatize esters (Abley et al., 1970), alkenes (Blomquist et al., 1980), and dialkyl pyrrolidines (Jones et al., 1982). It is not clear in our case whether it is the free acids, ketones, or aldehydes that are hindering the reaction, either at the initial addition stage or the subsequent reduction step with sodium borohydride. The fact that methylthiolation (which has no reductive step) occurred smoothly with the ethyl esters, even in the crude extract, suggests that the problem with the methoxymercuration may have been in the addition step. Whatever the reason, isolation of the free acids and aldehydes (by oxidation to their respective acids) followed by conversion to their methyl esters allowed us to successfully locate the double bonds using methoxymercuration. In agreement with Plattner et al. (1975), we found that the dienoic compounds gave very complex mixtures of saturated and unsaturated methoxy esters. Their technique of hydrogenating the product mixture, however, eliminated the problem.

Announcement

FOURTH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY

The Fourth Annual Meeting of the International Society of Chemical Ecology will be held at the University of Hull, England from the evening of Monday 13th July through lunch on Friday 17th July 1987.

We are planning 4 symposia on the following topics:

1. The veracity of bioassays
2. Chemical ecology and plant protection
3. The applications of chemical ecology
4. Biochemical mechanisms of defence compounds

These topics are broad enough to include allelopathy, natural marine antifouling agents, pheromones, physiological and behavioral responses to allelochemicals, etc., and we hope that some/many of the contributed papers and poster sessions will reflect the main themes of the meeting. We plan to stimulate commercial and industrial interest in the Society by emphasizing the applications of our studies.

Members (and potential members) of ISCE are asked to send the title and abstract of a paper or poster that they wish to present at the meeting to Professor David A. Jones, ISCE 1987, Department of Plant Biology & Genetics, University of Hull, Hull HU6 7RX, England.

NOTE

The deadline for submitting details of oral presentations is February 28, 1987. There is no deadline for posters, but the sooner you submit your title and abstract the sooner you can receive an acknowledgement that may help you to obtain travel funds!

The full cost of accomodation, all meals, and excursion, the conference fee, and the conference dinner will be £140.00.

A reservation form will be issued to members with the Spring 1987 ISCE Newsletter. Early in 1987, forms will be sent to people who have addressed inquiries directly to David Jones in Hull.

Journal of Chemical Ecology, Vol. 13, No. 2, 1986

PRELIMINARY ISOLATION OF MALE-INHIBITORY PHEROMONE OF THE SPIDER *Schizocosa ocreata* (ARANEAE, LYCOSIDAE)

L. RAO AYYAGARI and W. J. TIETJEN

Department of Biology, Lindenwood College,
Saint Charles, Missouri 63301

(Received December 3, 1985; accepted February 18, 1986)

Abstract—Compounds with pheromone activity were extracted from male *Schizocosa ocreata* silk using methanol as the solvent. Behavioral data suggest that these compounds mediate agonistic encounters among male spiders. Preliminary chemical analyses indicate that the pheromones are low-molecular-weight lipids, one being slightly polar, the other nonpolar.

Key Words—*Schizocosa ocreata,* Araneae, Lycosidae, spider pheromone, male pheromone, agonistic display, courtship inhibitor, pheromone bioassy.

INTRODUCTION

Chemical communication has been long recognized in spiders (Bristowe and Locket, 1926; Crane, 1949; Kaston, 1936). Most of this early research has concentrated on behavioral assays for female-produced sex pheromones, while some studies described chemical communication mediating behaviors associated with species recognition, maintenance of group cohesion (in social spiders), and location of mates. In all of these studies, silk has been used as a pheromone source. Recently, a few researchers have investigated the microscopic structure of spider chemoreceptors, or their electrophysiology. However, no one has reported a chemical analysis of any spider pheromones (reviewed in Tietjen and Rovner, 1982).

Extraction of female silk by common organic and inorganic solvents, such as alcohol and water, was shown to inactivate the pheromone-like activity in several spider species (Gwinner-Hanke, 1970; Hegdekar and Dondale, 1969; Kaston, 1936; Sarinana et al., 1971), a property that has hindered research into the chemical structure. In a few species, however, the successful transfer of an

0098-0331/87/0200-0237$05.00/0 © 1987 Plenum Publishing Corporation

active pheromone from female silk to another substratum has been reported, but no details are given as to the chemical nature of the pheromone (Collatz in Weygoldt, 1977; Kaston, 1936; Suter and Renkes, 1982).

The present study describes the first chemical isolation of a spider pheromone. In this case, we extracted pheromones from the silk of male *Schizocosa ocreata.* Behavioral evidence suggests that these pheromones may be used during male–male interactions to affect the frequency of agonistic display and inhibit courtship behavior. In addition, we provide the first experimental evidence for male-produced pheromones used for a chemical-based mating interference strategy.

METHODS AND MATERIALS

General Methods. Spiders were collected in Saint Charles County, Missouri, as antepenultimate and penultimate instars and were individually raised to adults in 100 × 15-mm plastic Petri dishes. Water was provided ad libitum via a cotton-stoppered vial inserted through a hole in the lid. Adult house flies (*Musca domestica*) and *Tenebrio* sp. larvae were provided at weekly intervals. Upon molting to the adult instar, male spiders were visually isolated from one another (isolation of males makes them more likely to respond to chemical cues; Crane, 1949; Tietjen, 1977, 1979a).

Previous research (Tietjen, 1979a) indicated that pheromones were associated with the silk of various lycosid species, including *S. ocreata.* This being the case, we chose silk as a potential source for extraction of pheromone in these experiments. Silk deposited on 7.5-cm-diam filter paper cage cards was used directly in some experiments or the pheromone was extracted from the silk on the cards as described below.

Pheromone Extraction and Concentration. Spiders were not fed during silk deposition periods in order to decrease extraneous contamination on the cage cards. Preliminary bioassays with extracts of acetone, benzene, hexane, methanol, methylene chloride, and petroleum ether indicated that methanol was most effective in extracting behaviorally active pheromone from silk on male cage cards. Cage cards were soaked in 10 ml of methanol for 15 min. The dissolved pheromone was then deposited on filter paper (7.5 cm diam) and allowed to air-dry for 10 min. These papers provided the experimental stimuli, while papers soaked in methanol (with no dissolved pheromone) and allowed to air-dry provided the control. The dried extract was immediately bioassayed for pheromone activity except when additional chemical extractions of the pheromone was required. In these cases, the extract and stimulus filter papers were stored in a desiccator at −20°C until eventual use. These papers were brought to room temperature by first placing them in a refrigerator at 1.5°C for 20–30 min and then warming the papers to room temperature; this process decreased the amount

of condensation collecting on the stimulus cards and thus minimized any potential inactivation by water.

A relative measure of the amount of pheromone deposited on the experimental substrata was obtained by multiplying the total number of cage cards used in the extraction by the number of days silk was deposited by each spider. This number was then divided by a dilution factor (since only a portion of the extract was deposited on filter paper for the arena tests, and the remainder used for chemical tests) to obtain our estimate of relative pheromone concentration, the number of "silk days." By pooling silk from several spiders and allowing three or more days for deposition of silk by each spider, behaviorally active pheromone concentrations were obtained. This method allowed us to compensate for potential differences both among and between spiders in silk deposition. Three concentrations were used: low, medium, and high, corresponding to 60, 147, and 694 silk days.

To examine the polar–nonpolar nature of the methanol extract, 60 silk day extract was applied on a Florisil column (0.5 × 5.0 cm; Fisher) and the flowthrough was collected. The material which remained bound to the column as a light brown ring was then eluted with methanol. The flowthrough and eluates were then prepared as above for bioassay. In addition, thin-layer chromatographic fractionation of 60 silk day extract was also carried out on silica gel (Eastman Kodak) to separate the polar and nonpolar lipid components in the extract. Two solvent systems (A: diethyl ether–benzene–absolute ethanol–acetic acid, 40 : 50 : 2 : 0.2; B: chloroform–methanol–acetic acid–water, 85 : 15 : 10 : 4) were used. Unfortunately the advanced age of our test animals and the relatively low concentration of the lipid components did not allow further bioassay of these samples.

Bioassay Procedure. Adult males were tested during their period of highest behavioral response (1500–2400 hr), and each male was tested only once per 24 hr. Behavioral responses were observed in an arena which consisted of two parts: A 0.5-cm-thick circular ring (43.2 cm diam × 5.0 cm height) made of nonreflecting nylon was used as the perimeter of the arena. The second part, a 1-mm-thick plastic sheet, served as the bottom of the arena. The top of the arena was open to the air. Both the arena and sheet were washed with water and thoroughly dried between experimental runs. Three experimental filter papers (with dried solvent extract or untreated silk) were placed equidistant from one another along the interior perimeter of the arena. Three additional control filter papers were interspaced among the three experimental substrata.

Individual male spiders were introduced into the center of the arena and allowed to wander freely until they contacted one of the experimental substrata. When exposed to the highest pheromone concentrations, males "froze" on introduction to the arena and, after a minimum of 5 min inactivity, were guided onto an experimental substratum with the aid of a camel's hair brush (such periods of inactivity were only observed in response to the high concentration).

In either case, the behavior of the test male was then recorded at 15-sec intervals for a 5-min test period. Four behavioral responses were recorded: (1) chemoexploration with the palps, (2) foreleg tapping, (3) stridulation, and (4) wave and arch. Descriptions and interpretations of these behaviors can be found in Aspey (1976) and Tietjen (1979a).

Male spiders respond to female silk by exhibiting courtship behavior having the following behavioral components: foreleg and abdominal vibration, and stridulation (Tietjen, unpublished data). In order to determine if the male silk extract had any effect on male courtship behavior, the males were transferred to a female's cage card and the frequency of courtship behavior in response to silk-deposited female sex pheromone was recorded for another 5-min period. Animals that did not court within the 5-min period were scored as "not courting." Since the data did not fit parametric assumptions, and sample sizes were relatively small, nonparametric tests were used for all analyses (Conover, 1971).

RESULTS

Bioassay. The frequencies of the behaviors were compared among treatments using the chi-square test (Table 1). Foreleg tapping decreased in the presence of high concentrations of extract, the column flowthrough, and the column eluate ($P < 0.01$). Similarly, wave and arch decreased with the high concentration and flowthrough treatments ($P < 0.001$). The frequency of chemoexploration was greatest for the 60 silk days extract ($P < 0.01$). Males exhibited neither chemoexploration nor stridulation in response to the high concentration of extract.

When males were tested on females' cage cards, those who had previously been exposed to high concentrations of male silk extract showed no courtship behavior (Table 1). The methanol eluate decreased the frequency of courtship to the same proportion as that observed with only male silk. The frequency of courtship following the methanol eluate differed from that of the flowthrough ($P < 0.001$).

Overall, a graded response dependent on pheromone concentration was observed. Foreleg tapping, wave and arch, chemoexploration, and courtship percent decreased with an increase in male pheromone concentration, indicating an inhibition of courtship behavior.

Preliminary Characterization of Pheromone. Methanol extracts in solution had an "oily" appearance on the surface of the solvent. When the extracts were deposited on filter paper and then dried, a light tan residue remained. These papers had a "pungent" odor, which decayed with time at room temperature.

The extract did not show free amino acids, polypeptides, sugars, or starch in detectable amounts as tested by biuret, ninhydrin, anthrone, and iodine tests

TABLE 1. BEHAVIORAL RESPONSES OF MALE *Schizocosa ocreata* TO EXPERIMENTAL TREATMENTS IN ARENA AND ON FEMALE CAGE CARDS FOLLOWING ARENA TESTS[a]

Treatments	(*N*)	Behavioral Responses				
		Foreleg tap	Wave and arch	Chemoexploratory behavior	Stridulation	Courtship % on female card
Methanol control	(12)	8.9 ± 1.4 (100.0%)	2.9 ± 1.0 (66.7%)	0.5 ± 0.2 (33.3%)	0.3 ± 0.3 (16.7%)	91.7%
Male silk	(10)	10.6 ± 1.2 (100.0%)	2.7 ± 0.1 (70.0%)	0.8 ± 0.4 (30.0%)	0.3 ± 0.2 (30.0%)	40.0%
Low conc.	(16)	10.0 ± 1.1 (100.0%)	4.8 ± 1.2 (100.0%)	1.6 ± 0.4 (75.0%)	1.3 ± 0.3 (75.0%)	75.0%
Medium conc.	(13)	9.2 ± 1.4 (100.0%)	3.4 ± 1.4 (84.6%)	0.2 ± 0.2 (7.7%)	1.8 ± 0.6 (61.5%)	69.2%

Methanol eluate	(10)	4.3 ± 1.3 (80.0%)	2.3 ± 1.3 (80.0%)	0.7 ± 0.4 (50.0%)	1.4 ± 0.4 (50.0%)	40.0%

[a]The responses to experimental substrata (foreleg tap, wave and arch, chemoexploration, and stridulation) are presented as the mean number of 15-sec intervals having one or more counts of the indicated behavior. The variation is the standard error of the mean and the data in parentheses indicate the percentage of runs with one or more instances of a behavior during the 5-min experimental period. The courtship measures are for tests on female cage cards following the responses to experimental substrata.

(60 days extract was used for these tests by mixing with an equal volume of water and agitating at 25°C for 15 min). The pH of the solution was 6.85, indicating the absence of significant amounts of free fatty acids.

The nonaqueous components of the solution were analyzed by extracting with carbon tetrachloride in a separatory funnel at room temperature for 15 min. The lower organic phase was collected and tested with bromine dissolved in carbon tetrachloride. Results suggest that the compound has a high degree of saturation. Tests for cholesterol and primary or secondary alcohol groups were negative (Libermann-Burchard test, oxidation tests).

Both polar and nonpolar components were present, as indicated by the lack of complete solubility of the dried methanol extract in benzene. This dual-component nature of the extract was also observed in thin-layer chromatographic fractionation, where two lipid spots were found; one a polar component (*Rf* = 0.6; system B, polar solvent system) and the other a nonpolar component (*Rf* = 0.8; system A, nonpolar solvent system).

DISCUSSION

A comparison of the behavioral responses to the low concentration (60 silk day) extract and unextracted male silk indicates that the actual efficiency of our extraction procedure was quite low. However, a significant portion of the inhibitory behavior associated with unextracted silk could be attributed to the mechanical cues provided by the silk (as is the case in other lycosid species; Tietjen 1977). It is important to note that the actual active pheromone concentrations are probably much lower than our estimates. We have recently developed an improved pheromone extraction procedure and have tested it on the related species, *Lycosa punctulata*. Using this method we have observed behavioral activity for concentrations less than 1 silk day.

Aspey (1976) used factor analysis to determine the function of display by male *S. ocreata* during staged agonistic encounters and determined that both foreleg tapping and wave and arch behaviors were indicative of agonistic display. Both behaviors occur spontaneously at a low level and, in addition to stridulation, may serve as an "announcement display." Thus, depending on context, the same behavior may serve for both announcement and agonistic display, with the agonistic displays usually being more vigorous. The present data indicate that the frequency of both behaviors decreases with increasing pheromone concentration and is lowest for the 694 silk days, flowthrough, and eluate. The decrease in announcement displays suggests that the males were intimidated" by high concentrations of pheromone. The observation that all males (100%) "froze" when introduced into the arena in the presence of high pheromone concentration supports our intimidation hypothesis.

The above observations, e.g., complete inactivity of the males on intro-

duction to the arena without contact with the extract, and the decrease in behavioral response toward the extract over several days, suggest that a volatile component of the extract is responsible for the observed behavioral effect. Thus, males confronted with the concentrated pheromone find themselves faced with a superior, but unseen opponent, and choose to abdicate in a potential dispute. Riechert (1984), working with staged contests among *Agelenopsis aperta*, suggested that pheromones could be employed in this way to affect the outcome of territorial disputes. In a similar vein, Tietjen (1979a, b) reported that male *L. rabida* also respond to a possible male-produced pheromone with a decrease in both courtship and chemoexploratory behavior when later tested on female silk. In addition, these spiders deposit greater quantities of silk when following female draglines (Tietjen and Rovner, 1982).

In the present study, high concentrations of extract showed a carry-over effect when males were tested for response to female pheromone following exposure to the stimulus. Males that previously were tested with 694 silk days concentrations exhibited no courtship in response to female silk. Similarly, methanol eluate (which is a further concentration of the 60-day extract) inhibited courtship to a greater degree than the flowthrough. These results and the independent observations in other species provide evidence for a pheromone-based mating interference strategy among male spiders, a behavioral strategy that has been recorded for several other arthropod species (Tietjen and Rovner, 1982).

The results of thin-layer chromatography suggest that both slightly polar and nonpolar lipids were extracted from male silk. Two other observations also suggest a multicomponent nature to the methanol extract: the incomplete solubility of the dried methanol extract in benzene, and the behavioral response (data not shown) seen with extracts of male silk with polar solvents (hexane and methylene chloride). Therefore, we suggest that the flowthrough and methanol eluate represent the nonpolar and slightly polar components of the extract since methanol can extract both components from the silk. We also suggest that these components are neutral lipids with small molecular weights and a volatile nature and are involved in a general way with male recognition. The polar component (methanol eluate) has been shown to affect courtship behavior by males, thus serving as a male inhibitory pheromone. However, further chemical characterization of both components is needed to determine the exact behavioral functions.

(Received November 8, 1985; accepted February 18, 1986)

Abstract—Four stereoisomers of 6-acetoxy-5-hexadecanolide, a mosquito oviposition attractant pheromone, were bioassayed for their activity on mosquitoes. Only (−)-(5*R*,6*S*) isomer was active in attracting *Culex quinquefasciatus* Say females for oviposition at dosages of 0.5 μg/100 ml water and above with the floating-cap method. The activity of this isomer increased 50-fold when it was applied directly to the water surface. The other three isomers, (+)-(5*S*,6*R*), (+)-(5*R*,6*R*), and (−)-(5*S*, 6*S*), were not active. The active isomer was ovipositionally attractive not only to *C. quinquefasciatus* but also to *C. tarsalis* Coquillett; however, it was 100 times more active in the former than in the latter species. *Aedes aegypti* (L.) and *Anopheles quadrimaculatus* Say were not attracted to the pheromone, thus suggesting that the pheromone is genus-specific.

Key Words—(−)-(5*R*,6*S*)-6-Acetoxy-5-hexadecanolides, oviposition attractant pheromone, mosquitoes, *Culex quinquefasciatus*, *Culex tarsalis*, Diptera, Culicidae.

INTRODUCTION

The apical droplets of egg rafts of *Culex pipiens fatigans* Wiedemann contain an oviposition attractant pheromone which induces the oviposition of this and other *Culex* mosquito species (Bruno and Laurence, 1979). The major component of the pheromone was identified as *erythro*-6-acetoxy-5-hexadecanolide,

0098-0331/87/0200-0245$05.00/0 © 1987 Plenum Publishing Corporation

and subsequently the racemates were synthesized from *erythro*-5,6-dihydroxy-hexadecanoic acid by treatment with acetic anhydride in dry pyridine (Laurence and Pickett, 1982).

The synthesis of the two enantiomers of this δ-lactone was accomplished by at least four groups. Fuganti et al. (1982) reported the synthesis of both enantiomers of *erythro*-6-acetoxy-5-hexadecanolide from a chiral C_4 aldehyde via a nonstereoselective route. Mori and Otsuka (1983) synthesized both enantiomers from (±)-1-tridecen-3-ol through its kinetic resolution by enantioselective epoxidation, thus achieving a stereoselective synthesis of the two isomers. Laurence et al. (1985) found that the synthetic (−)-(5*R*,6*S*) enantiomer attracted oviposition of mosquito egg rafts fourfold over the control, whereas the (+)-(5*S*,6*R*) enantiomer did not attract ovipositing females to any significant extent. The absolute configuration of the oviposition attractant pheromone was thus determined to be (−)-(5*R*,6*S*)-6-acetoxy-5-hexadecanolide. Subsequently, Laurence and Pickett (1985) reported the behavior of the gravid females of *C. quinquefasciatus* Say to the pheromone, the effect of modifying the structure of the pheromone on oviposition behavior, and the source and activity of the pheromone in nature. Sakakibara et al. (1984) reported the ovipositional activity of four stereomers of 6-acetoxy-5-hexadecanolide; however, the details of the synthesis of the isomers were not disclosed.

Independently, Lin et al. (1985) synthesized all four stereomers of 6-acetoxy-5-hexadecanolide including two *erythro* forms and two *threo* forms from (*Z*)-2-tridecen-1-01 and its *E* isomer via Sharpless asymmetric expoxidation. To reconfirm the findings of Laurence et al. (1985) and Sakakibara et al. (1984) and to obtain more information on the biological properties of all four isomeric compounds, we conducted the present investigation. Here we report the ovipositional attractancy of the four optical isomers of 6-acetoxy-5-hexadecanolide to *C. quinquefasciatus* (= *C. p. fatigans*) and the determination of the species specificity of the active (5*R*,6*S*) enantiomer among *Culex*, *Aedes*, and *Anopheles* mosquito species.

METHODS AND MATERIALS

Mosquitoes were obtained from our laboratory stock colonies at the University of California, Riverside. The *C. quinquefasciatus* colony was first established in 1950s with a strain obtained from Bakersfield, California. Since then the original strain has been reinforced by local strains from Riverside, California. The *C. tarsalis* colony was established in Riverside in 1984 with a strain from Chino Basin in California. *Aedes aegypti* (L.) and *Anopheles quadrimaculatus* Say were obtained from Gainesville, Florida. Gravid females, blood-fed and 7–10 days old, were chosen for bioassay studies.

Each of the olfactometers constructed and used for studying the oviposi-

tional attractancy of the four stereomers of 6-acetoxy-5-hexadecanolide consisted of: (1) a mosquito cage, (2) two 4-oz waxed paper cups, and (3) two polyethylene vial caps. The mosquito cage, 23 cm height, 23 cm width, and 32.5 cm depth, was constructed by framing it with 2 × 2.5-cm wood. The two sides and the rear were screened with Lumite® (32 × 32 mesh). The bottom was covered with a wood panel. The rear part of the top was covered with a 20.5 × 20.5-cm glass for viewing, and the front part of the top was screened with Lumite. The front was covered with a wood panel with a 15-cm-diameter porthole in its center. The hole is fitted with a muslin sleeve to allow access to the inside of the cage. All wood was painted white with Latex™. The waxed paper cups (7 cm diameter, Sweetheart® ice cream and food cups, No. 5304), each contained 100 ml distilled water and were used as oviposition sites for mosquitoes. The polyethylene vial caps (3 cm diameter) were inverted and used for holding test materials.

In conducting bioassay tests, a stock solution of each compound was made by dissolving the compound (1.0 mg) in 1,2-dichloroethane (10 ml). A predetermined volume of the solution was taken with a microsyringe and placed on the surface of a vial cap, and an equal volume of the solvent was applied onto another vial cap. After the solvent was allowed to evaporate, the two vial caps, one containing the predetermined amount of the compound and the other serving as a control, were each floated on water in the waxed paper cup. This method was termed the "floating-cap method." In some tests in which the so-called "direct method" was used, the solution or the solvent was directly applied on the water surface in the cup without using the vial cap. The two cups were separately placed at the rear corners of the mosquito cage.

Twenty gravid female mosquitoes were introduced into the cage and allowed to choose between the treated and control cups for oviposition. All tests were replicated at least six times in a ventilated room at a constant temperature of 25°C. After the start of the experiment, the room lighting was adjusted to simulate 1 hr dusk, 11 hr darkness, and 1 hr dawn with a combination of fluorescent and incandescent lights which were controlled by an adjustable timer (AMF Paragan-Electric Co., Inc., Two Rivers, Wisconsin, model 4003-05). The numbers of oviposition in the treated and control cups were recorded 1 hr after the resumption of normal lighting. The total duration of the bioassay was about 14 hr. The attractancy of the testing compounds was expressed in terms of an "attractancy ratio" which was the ratio of the number of egg rafts or eggs in the treated cup to those in the control cup. The data were analyzed for significance by the chi-square method.

The (5*R*,6*S*)-, (5*S*,6*R*)-, (5*R*,6*R*)-, and (5*S*,6*S*)-6-acetoxy-5-hexadecanolide, $[\alpha]_D^{20}$ − 37.4°, +37.2°, +14.6°, and −14.1° (c = 1.2 ~ 6, $CHCl_3$), respectively, were obtained by synthesis (Lin et al., 1985). All compounds had an enantiomeric excess of 96–97% and gave proper and required NMR, IR, and mass spectra.

RESULTS AND DISCUSSION

The bioassay tests (Table 1) revealed that, between the two *erythro* forms of 6-acetoxy-5-hexadecanolide, the (−)-(5*R*,6*S*) enantiomer was ovipositionally attractive to gravid females of *C. quinquefasciatus* in the floating-cap method from 0.5 to 50 μg. Laurence et al. (1985) tested the same enantiomers for activity at about 1 egg raft equivalent (0.3 μg) because they found that this level of dosage of the racemic mixture gave a high degree of response but was near the beginning of the steeply downward sloping part of the dosage–response curve. At this dosage, they found that the (−)-(5*R*,6*S*) enantiomer attracted 70 egg rafts, whereas only 17 egg rafts were laid in the control (equivalent to an attractancy ratio of 4.1). In the present study, we found that the attractancy ratio of the (−)-(5*R*,6*S*) enantiomer at 0.5 μg was 4.2. Our results were, therefore, quite comparable to those of Laurence et al. (1985). At higher dosages of 1–50 μg, the (−)-(5*R*,6*S*) enantiomer gave attractancy ratios of 2.3–3.5, all of which were significant at the 0.01 level.

The other *erythro* form, the (+)-(5*S*,6*R*) enantiomer, did not show any significant attractancy at all dosages tested, coinciding with the findings of Laurence et al. (1985). Likewise, neither of the two *threo* forms, (+)-(5*R*,6*R*) and (−)-(5*S*,6*S*) enantiomers, showed any attractancy in the floating-cap method. These results indicate that the interaction between the ovipositional receptor site of the *Culex* mosquito and the ovipositional attractant pheromone is stereospecific and that the receptor accepts only the (−)-(5*R*,6*S*) enantiomer. Not only is the (+)-(5*S*,6*R*) enantiomer not acceptable by the receptor as reported by Laurence et al. (1985), but the two *threo* forms are also unacceptable and elicit no ovipositional response in mosquitoes as shown in the present study.

When bioassayed in the direct method, the (−)-(5*R*,6*S*) isomer exhibited a higher level of attractancy than that in the floating-cap method (Table 2). In the direct method, the attractancy was significant at dosages from 10 through 0.01 μg/100 ml water. The lowest effective dosage in the floating-cap method was 0.5 μg as opposed to 0.01 μg/100 ml water in the direct method. Thus, the lowest effective dosage increased by 50-fold by adopting the direct method. The reason for this increase in activity might be due to the increase of surface area (from 28 to 154 cm^2), thus facilitating the evaporation of the pheromone.

Other stereoisomers were not attractive in the direct method except for the (+)-(5*S*,6*R*) and (−)-(5*S*,6*S*) isomers, which showed significant attractancy only at the high concentration of 10 μg/100 ml water. It should be noted that the enantiomeric excess for each isomer was found to be 96–97%; therefore it was possible that the (+)-(5*S*,6*R*) and (−)-(5*S*,6*S*) isomers contained a small fraction of the active isomer which was sufficient to show some activity. The (+)-(5*R*,6*R*) isomer was inactive at 10 μg; whether this inactivity is due to the absence of the active isomer as a contaminant is not clear at this time.

TABLE 3. ATTRACTANCY RATIOS OF (−)-(5*R*,6*S*)-6-ACETOXY-5-HEXADECANOLIDE TESTED AGAINST *Culex*, *Aedes*, AND *Anopheles* MOSQUITOES IN LABORATORY OLFACTOMETERS BY DIRECT METHOD

Dosage (μg/100 ml H_2O)	Attractancy ratio[a] (Mean No. ± SD)[b]		
	C. tarsalis	*A. aegypti*	*A. quadrimaculatus*
10	2.1*(7.5 ± 3.3)	1.0 (247 ± 100)	0.8 (298 ± 156)
1	3.5*(8.7 ± 3.0)	1.1 (417 ± 74)	0.7 (360 ± 69)
0.1	1.3 (6.3 ± 2.1)	1.4 (236 ± 53)	1.2 (417 ± 204)
0.01	1.3 (6.6 ± 2.4)	1.1 (222 ± 64)	1.2 (347 ± 120)

[a] Attractancy ratio followed by asterisks indicate that the means of oviposition in the treated cups are significantly higher than those in the control cups at the 0.01 level by the chi-square test.
[b] Mean numbers of eggs (*A. aegypti* and *A. quadrimaculatus*) or egg rafts (*C. tarsalis*) in the treated cups with standard deviations.

Three other species of mosquitoes, *Culex tarsalis* Coquillett, *Aedes aegypti* (L.), and *Anopheles quadrimaculatus* Say, were used to study species specificity of the pheromone (Table 3). While *Aedes* and *Anopheles* mosquitoes were not attracted to the pheromone for oviposition, *C. tarsalis* mosquitoes were attracted at dosages of 1 and 10 μg/100 ml water but were not attracted to the lower dosages of 0.1 and 0.01 μg/100 ml water. Hence, the pheromone was at least genus-specific. However, in comparing the minimum effective dosages between the two *Culex* species in the direct method, the pheromone was 100 times more effective in attracting *C. quinquefasciatus* than *C. tarsalis*. Bruno and Laurence (1979) found that *C. tarsalis* responded to the presence of 10 egg rafts but, unlike *C. p. fatigans*, not to the presence of one egg raft. Our results are almost in line with these previous findings. It is therefore apparent that, among the four stereoisomers of 6-acetoxy-5-hexadecanolide, only (−)-(5*R*,6*S*) isomer is active in inducing a positive ovipositional response in *C. quinquefasciatus*. The other sources, (+)-(5*S*,6*R*), (+)-(5*R*,6*R*), and (−)-(5*S*,6*S*) isomers, show little or no activity. The ovipositional activity of the attractant pheromone is more prominent in the direct method than in the floating-cap method. In addition, the pheromone seems to be genus-specific, showing effectiveness only on *Culex* mosquitoes; however, it is much more attractive to *C. quinquefasciatus* than to *C. tarsalis*. Sakakibara et al. (1984) reported that the pheromone ovipositionally attracted *C. p. molestus* Forskal and *C. p. pallens* Coquillett but failed to attract *A. stephensi* Liston and *A. aegypti*, thus proving the pheromone to be genus-specific. Their findings were, therefore, in agreement with ours.

Abstract—Volatile constituents produced by ant workers belonging to the species *Tapinoma melanocephalum* and *T. erraticum* have been analyzed by gas chromatography–mass spectrometry. The pygidial (= anal) gland secretion of *T. melanocephalum* is fortified with 6-methyl-5-hepten-2-one and actinidine (the mass spectrum of which is corrected in this paper). An unidentified compound was detected in cephalic extracts. The pygidial gland secretion of *T. erraticum* was also dominated by 6-methyl-5-hepten-2-one, in addition to two isomers of iridodial, and iridomyrmecin. The sternal glands contained iridodial and C_{15}–C_{20} hydrocarbons. Workers of *T. melanocephalum* effectively utilize their pygidial gland secretions as an alarm–defense system during aggressive encounters with workers of *Solenopsis geminata*. 6-Methyl-5-hepten-2-one is active as a releaser of alarm behavior, and actinidine is repellent to workers of *T. melanocephalum*. Cephalic extracts possessed attractant and arrestant properties for workers of this species.

Key Words—*Tapinoma melanocephalum*, *Tapinoma erraticum*, pygidial gland, sternal gland, actinidine, chemistry, attractant, arrestant, repellent, alarm behavior, cephalic extract, *Solenopsis geminata*.

INTRODUCTION

A key element in the high degree of ecological success enjoyed by ants in the genus *Tapinoma* may be their effective utilization of defensive secretions during encounters with other ant species. For example, *T. sessile*, an economically important North American species, employs secretions from its pygidial gland to ward off attacks from the pugnacious Argentine ant, *Iridomymex humilis* (Woodward, 1910, cited in Smith, 1928). Further, Weber (1961) described workers of *T. nigerrimum* discharging a substance from the gaster to repel workers of *Monomorium subopacum* during confrontations over food.

Mixtures of iridodial(s) and ketone(s) characterize the exocrine gland products of every species of ant belonging to the genus *Tapinoma* that has been examined so far. The pygidial glands of *T. sessile* produce iridodial and isoiridomyrmecin (McGurk et al., 1968), and the former compound also occurs in the pygidial glands of *T. nigerrimum* (Trave and Pavan, 1956) and *T. simrothi* (Hefetz and Lloyd, 1983). The widely distributed alarm releaser, 6-methyl-5-hepten-2-one, accompanies the cyclopentanoids in all three species. *Tapinoma nigerrimum* and *T. simrothi* also produce the apparently *Tapinoma*-specific alarm pheromone, 2-methyl-4-heptanone (Trave and Pavan, 1956; Hefetz and Lloyd, 1983). In addition, Hefetz and Lloyd (1983) found 4-heptanone and 4-hydroxy-4-methyl-2-pentanone in the pygidial gland products of *T. simrothi*.

Another highly successful, yet little studied, species of *Tapinoma* is *T. melanocephalum*. This ant, probably of African or Oriental origin, was introduced into the United States and now occurs in abundance in southern Florida. *Tapinoma melanocephalum* forms polygynous colonies that may contain large numbers of workers which nest opportunistically in soil, rotten wood, or other cavities. Its exploitative nesting habits and extensive foraging systems enable the ant to colonize a variety of habitats, including houses and other dwellings (Smith, 1965).

Chemical effrontery may also contribute to the success of *T. melanocephalum*, and in this report we describe the chemistry of exocrine products of this species as well as their utilization during interspecific encounters. We also examined the chemistry of the exocrine products of *T. erraticum*.

METHODS AND MATERIALS

Ants. Several colonies of *T. melanocephalum* and *S. geminata* were collected from Marathon Key, Bahia Honda Key, Big Pine Key, or Key West, Florida, and placed in separate, 35 × 16 × 9-cm plastic boxes, the sides of which were coated with Fluon GP-lR (I.C.I., United States, Inc.) to prevent the escape of ants. All colonies were composed of numerous workers, functional queen or queens, and brood in various stages of development. Ants were

allowed to nest in Petri dishes with moistened Castone® (Ransom and Randolph Co., Toledo, Ohio) flooring. The floor of each container served as a foraging arena where minced insects, honey, and water were provided ad libitum.

Chemical Analysis. Workers of *T. melanocephalum* (Florida Keys, U.S.A) were killed by freezing in Dry Ice for 5 min, extracted in 1–2 ml of methylene chloride or pentane, and then examined by gas chromatography–mass spectrometry (LKB-9000 equipped with a 2-m × 2-mm column packed with 1%, OV-17, 1% SP-1000, and 30-m capillary columns of SP-1000 and SE-30, with column temperature programmed from 30° to 240°C at 8°C/min. Whole-body methylene chloride extracts of *T. melanocephalum* workers from the Ivory Coast, Africa, were also analyzed by GC-MS.

To determine the source of the detected compounds, frozen workers were trisected into head, thorax, and gaster, and separately extracted in organic solvent. Preliminary bioassays suggested that cephalic preparations evoked behavioral responses. Thus, an additional 2000–3000 heads were collected as follows: five groups of 400–600 ants each in 20-ml glass vials were plunged in liquid nitrogen for 5 min. Vials were immediately placed on a vortex mixer and rapidly shaken for 2–3 min, thus producing separate head, thorax, gaster, and head–thorax sections. Since thoracic extracts did not have any effects on worker behavior, further efforts to separate heads from thoraces were not attempted. Head and head–thorax sections were combined, homogenized 5× in 250-μl aliquots of pentane, and then the extract fractionated by preparative GC (0.25-in. × 6-ft stainless-steel column packed with 10% OV-17 on Gas Chrom Q). Fractions were collected, redissolved in pentane, and bioassayed as subsequently described.

Secretions from the pygidial glands were collected on filter paper squares by prodding workers with forceps. Papers were then placed in organic solvent after they had been daubed by 3–5 workers. The exocrine gland products of approximately 100 ants were accumulated per vial.

The amounts of both 6-methyl-5-hepten-2-one and actinidine per ant were estimated. The GC peaks obtained from the analysis of five extracts, each containing 100 workers in approximately 1 ml of methylene chloride, were compared to calibrated GC peaks from dilutions of these compounds. Samples were run on a Gow-Mac Model 750P GC equipped with a 2-m × 2-mm ID glass column packed with 5% SP-1000 on 100/120 Supelcoport and temperature programmed from 40° to 200°C at 10°C/min.

Workers of *T. erraticum* were collected in Toulouse, France, and extracted in methylene chloride. Pygidial gland secretion was collected and extracted using methods described above. Sternal glands were also dissected from workers and extracted in the same solvent. Extracts were analyzed by GC-MS (LKB 9000) equipped with a 25-m column of SE-30, temperature programmed from 55° to 300° C at 10°C/min.

Confrontational Studies. Competitive encounters between foraging workers of *T. melanocephalum* and *S. geminata* were analyzed in the laboratory in order to determine the possible role of pygidial gland secretions in such contexts. The foraging area of a colony of each species was connected to a small plastic "confrontation" tray via 3.0-mm ID × 22-cm-long glass tubes. A piece of filter paper was placed in the bottom of the tray to retard static electricity, and the sides brushed with talcum powder to prevent the escape of ants. When the tray simultaneously contained one or two workers of each species, a small piece of mealworm (*Tenebrio molitor*) was placed near the tube entrance to stimulate recruitment from colonies of both species. Thereafter, the mealworms were moved to the center of the arena, thus promoting confrontations between similar numbers of ants from the two colonies.

Other Behavioral Investigations. Observations were made on the reactions of workers of *T. melanocephalum* to (1) stressed nestmates; (2) pentane extracts of head, thorax, or gastric sections (0.2 section equivalents per μl pentane); (3) GC fractions from head–thorax extracts (see below); and (4) synthetic 6-methyl-5-hepten-2-one (Aldrich Chemical Co., Inc.) and actinidine (Wuest et al., 1977) using methods similar to that of Howard et al. (1982). The responses of the workers to body section extracts were recorded using a Panasonic Omnipro PK-956 video camera equipped with an F/1.4 variable-speed zoom lens with macro function, and a Panasonic PV-5000 series video recorder with stop and slow action, and timing capabilities. Responses were quantified by counting the number of ants contacting a test substrate within the first minute, and the time that 10 randomly chosen ants remained within 1 c of it.

RESULTS

Chemical Analysis. Gas chromatography–mass spectrometry of methylene chloride extracts of workers of *T. melanocephalum* shows that they contain 6-methyl-5-hepten-2-one and actinidine as well as alkanes and alkenes. On all columns the earliest-eluting and most abundant compound had retention times and mass spectra (*m/z* 126, 111, 108, 43) identical to synthetic 6-methyl-5-hepten-2-one. The second component had retention times and mass spectra (*m/z* 147, 146, 132, 117; see below and Figure 1) identical to synthetic actinidine prepared according to the method of Wuest et al. (1977). A third compound, in greater concentration than actinidine, eluting shortly afterwards, is presumably an olefin corresponding to $C_{19}H_{38}$. The position of the double bond is unknown. This alkene was subsequently determined to be of cephalic origin. The natural and synthetic ketone and base had identical gas chromatographic retention times to their corresponding standards on two different columns (OV-25, SP-1000). In addition to these, iridodial and C_{28}–C_{30} normal and branched alkanes and alkenes were observed in quantities similar to the methyl heptenone.

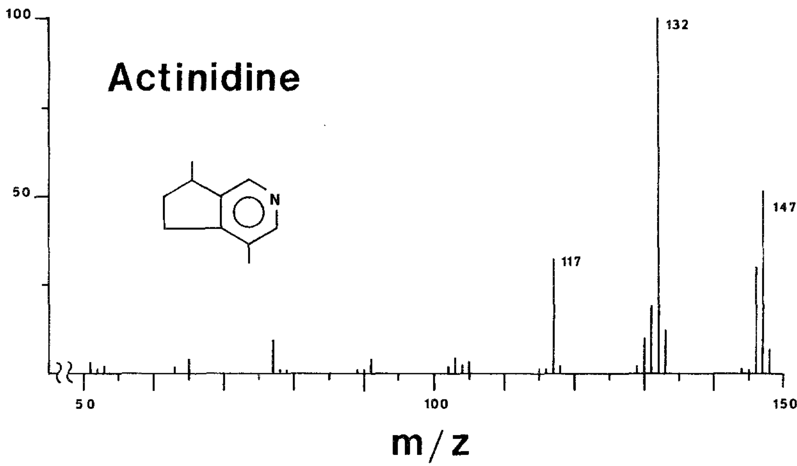

FIG. 1 Mass spectrum of synthetic (+)-actinidine that is identical to actinidine found in *T. melanocephalum*.

The mass spectrum of actinidine recorded in the literature is in error (Auda et al., 1967; Sastry, 1972). Speculations about *m/z* 89 which is not actually present must be discounted. The correct mass spectrum, reported here, was obtained using actinidine from *T. melanocephalum*, synthetic material, and a sample of *Actidinia polygama* extract from which it was originally found. All spectra were identical even when run at widely different times. No substance corresponding to the previously reported mass spectrum was detected. The spectrum of actinidine reported here resembles more closely that obtained from a different instrument by Wheeler et al. (1977).

Analysis of trisected ants and pygidial gland exudates demonstrated that the pygidial glands were the source of 6-methyl-5-hepten-2-one and actinidine. No volatiles were detected in the extracts of thoraces of this species.

We estimate that each ant contains approximately 0.53 μg $\pm$ 0.03 μg (mean $\pm$ SE) of 6-methyl-5-hepten-2-one and 0.29 μg $\pm$ 0.05 μg of actinidine.

Whole worker extracts and pygidial gland secretion of *T. erraticum* were dominated by 6-methyl-5-hepten-2-one. In addition, three iridoids were present: two isomers of iridodial, and iridomyrmecin. The later-eluting isomer, presumably the *trans,trans* isomer of iridodial, was also found in the sternal glands in admixture with C_{15}–C_{20} hydrocarbons.

Confrontational Studies. In the majority of skirmishes with *S. geminata*, workers of *T. melanocephalum* displayed alerting, alarm behavior, and the daubing of pygidial gland products. The initial contact between two ants often resulted in a condition of alertness whereby a *Tapinoma* worker with mandibles open slowly closed on the foreign ant while closely antennating the intruder's body. Movement by the alien ant at this time nearly always produced an in-

stantaneous alarm response which was characterized by frenzied running, with the head and sometimes gaster elevated, and the mandibles open. Contact with an alien ant at this juncture (and sometimes even their own sisters) elicited any one or a combination of the following aggressive behaviors: biting, assumption of a defensive posture, and the daubing of secretion from the pygidial gland. Biting was performed by a quick lunge forward and immediate recoil with a snapping of the mandibles at the point of contact with the intruder. Nipping, rather than grasping with the mandibles, appeared to be the preferred method of attack.

The most common form of aggressive behavior observed for workers of *T. melanocephalum* was the daubing of pygidial gland secretions. This maneuver was accomplished from a defensive stance in which the *Tapinoma* worker lowered its head and thorax while elevating its abdomen. The worker then turned its head to the side and quickly moved backward, guiding the tip of the gaster to make a fleeting contact with the body of the alien ant. The secretion was expressed as a clear droplet, which quickly became viscous and sticky upon exposure to air. Under low magnification (40–60 ×), the exudate appeared as a shiny, clear, convex globule on the surface of the cuticle.

Contact with the pygidial gland secretion prompted pronounced reactions from the affected ant. The alien worker immediately backed away while dragging the contaminated body part. It staggered prostrate with its legs extended outward while opening and closing its mandibles. Application of this secretion to the legs or antennae of a foreign ant often resulted in a hindrance of movement or in the limbs adhering together.

Further contact with *Tapinoma* workers seldom elicited aggressive responses from the daubed ants. In fact, some of these treated individuals, which were observed for as long as 10–15 min, exhibited no apparent responses after contact with *Tapinoma* workers.

The pygidial gland products may also be repellent, as indicated by the fact that the recruitment of *S. geminata* workers was halted when a *Tapinoma* worker daubed a fire ant while both were inside the tube connecting the arena with the *Tapinoma* colony. Ants of both species avoided passing through that spot in the tube for about 10 min.

Behavioral Assays. When individual workers held with forceps were positioned above and just out of reach of workers on a foraging trail, foragers quickly congregated beneath the restrained ant. The attracted workers moved at an accelerated and erratic pace while probing at the source with their antennae extended and their mandibles open. Dried or previously extracted workers, as well as small filter paper disks held in a similar manner, elicited weak responses at best.

Differences were observed between the ants' responses to paper disks containing head vs. gastric extracts. Gastric extracts released behaviors character-

istic of aggressive alarm behavior. Workers in the immediate vicinity of the disk promptly increased their rate of movement, and when encountering the disk, they pointed their gasters upward, nipped, and often dragged the filter paper about the foraging arena. Meanwhile numerous other workers ran in a frenzied and erratic manner over and around the test substrate. In contrast, workers that were attracted to cephalic extracts seldom molested the disks, but rather remained within a few centimeters of the cephalic extract for several seconds (Figure 2). The numbers of workers contacting the disks impregnated with 1 ant equivalent of cephalic or gasteric extract within the first minute of a trial were not significantly different (Table 1). However, duration of contact with the cephalic extract was over four times longer than that for the gaster and nearly twice as long as that spent at the controls. Behavioral responses to thoracic extracts were not detected.

Synthetic 6-methyl-5-hepten-2-one and actinidine induced different responses when presented to workers of *T. melanocephalum*. One to two micrograms of the methyl heptenone added to filter paper disks immediately released alarm reactions similar to those induced by gastric extracts. However, the same amounts of actinidine, while not eliciting any discernable alarm reactions, were repellent to ants within a 5- to 10-mm zone. An actinidine-treated disk gently

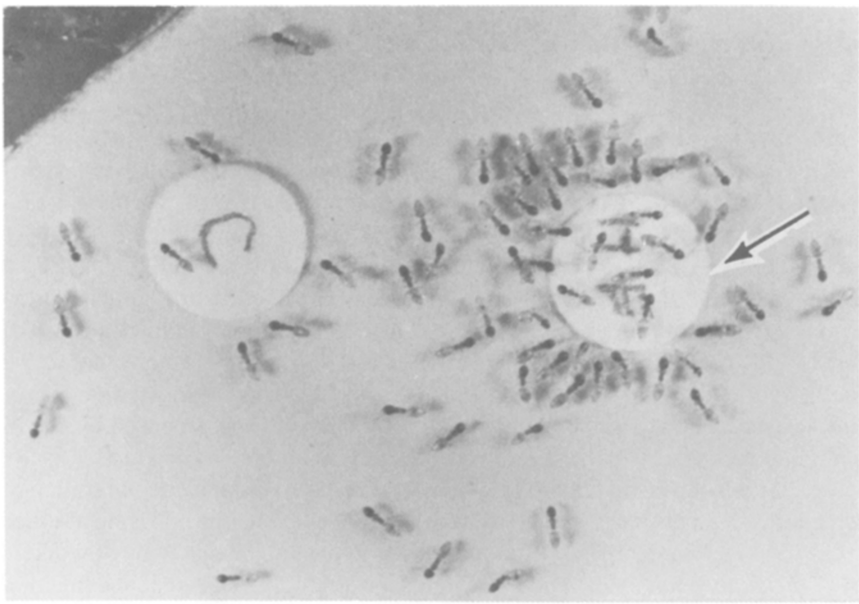

FIG. 2. The response of workers of *T. melanocephalum* to two ant equivalents of cephalic extract (arrow). The methylene chloride-treated control disk (C) is opposite.

TABLE 1. BEHAVIORAL RESPONSES OF WORKERS OF *T. melanocephalum* TO EXTRACTS OF CONSPECIFIC HEADS AND GASTERS

	Number of ants contacting disk within initial 60 sec (mean ±SE, N = 5 trials)	Time (sec) spent in contact with test disk (mean ±SE, N = 10 ants)
Control (pentane)	8.4 ± 2 a[a]	4.6 ± 0.8 b
Gastric extract	34.6 ± 7 b	1.7 ± 0.2 a
Cephalic extract	48.2 ± 7 b	9.0 ± 1.2 c

placed inside the nest resulted in an ant-free zone approximately 20 mm in diameter within 2 min. Pentane-treated disks elicited only transitory responses, and after 30 sec were ignored.

DISCUSSION

6-Methyl-5-hepten-2-one, one of the pygidial gland products of both *T. melanocephalum* and *T. erraticum*, is a typical dolichoderine natural product. However, the absence of 2-methyl-4-heptanone in both species, and the presence of actinidine in *T. melanocephalum*, and several isomers of iridodial in *T. erraticum*, lend the composition of the pygidial gland secretions of these two species somewhat distinctive chemical signatures. The acyclic alarm pheromone, 2-methyl-4-heptanone, has only been identified in other *Tapinoma* species (Trave and Pavan, 1956; Blum and Wheeler, 1975, unpublished data; Hefetz and Lloyd, 1983), but actinidine has not been previously detected as a *Tapinoma* natural product and has only been identified in the dolichoderine genera *Monacis* (Blum and Wheeler, 1978), *Iridomyrmex* (Cavill et al., 1980, 1982, 1984), and *Conomyrma* (Wheeler et al., 1977). Also interesting is the fact that iridodial was not detected in workers of *T. melanocephalum*. Thus, this key intermediate in the terpenoid biosynthetic pathway proposed by Cavill and Hinterberger (1960, 1962) is not coincident with the end product.

The well-developed pygidial glands of dolichoderine ants are the source of terpenoids that have been shown to have defensive and alarm-releasing abilities (Blum and Hermann, 1978). From our observations on the reactions of workers of *T. melanocephalum* to 1 and 2 μg of this alkaloid, it appears that one function of actinidine is to act as a repellent.

The cephalic extracts of dolichoderine species, although not well studied, are nevertheless known to be a source of volatile compounds. Three alkylpyr-

azines of unknown function have been identified in the cephalic extracts of *I. humilis* (Cavill and Houghton, 1974a, b). In this species, secretions from the mandibular gland are known to have a transitory releasing effect on trail-following behavior (Robertson et al., 1980). Our results with cephalic extracts of *T. melanocephalum* demonstrate the presence of a volatile component(s) having significant attractant and arrestant properties.

Trail-laying and mass-recruitment behaviors are well described in dolichoderine ants. The sternal gland (= Pavan's gland) is the source of volatile secretions that form the odor trail for all dolichoderine ants investigated (Wilson and Pavan, 1959; Hölldobler and Engel, 1978; Robertson et al., 1980, Cavill et al., 1979). In *T. melanocephalum*, workers rapidly tap the abdomen along the ground as they return to the nest from a food source. Once in the nest, the worker runs around erratically, rapidly antennating numerous sister workers (unpublished). This behavior, which we speculate occurs in combination with the release of attractant(s) from the head, may induce the recipient workers to stream out of the colony. Szlep and Jacobi (1976) have reported similar trail-laying, head-pushing, and accelerated antennal-beating behaviors for workers of *T. israelis* and *T. simrothi* returning from food sources. Further work is needed to characterize the role of cephalic and gastric secretions in the recruitment and mass foraging behaviors for workers of *T. melanocephalum.*

Wilson (1971) describes swift-running ant species that are more adept at locating and exploiting an ephemeral resource than are their competitors, as "opportunists." If a more aggressive species subsequently arrives in large numbers, the opportunist withdraws. Clark et al. (1982) observed that, although workers of *T. melanocephalum* displaced few other ant species from their baits, the high percentage of sole occupancy of *Tapinoma* workers at food stations may be attributable to their tendency towards rapid utilization of unoccupied baits rather than interspecific exclusion. Our observations confirm the existence of an opportunistic *modus operandi* for *T. melanocephalum*, and also suggest that potent defensive secretions may significantly contribute to the success of this species.

Acknowledgments—We would like to thank Dr. L. Lacy (USDA, Gainesville) for providing *T. melanocephalum* from the Ivory Coast, Africa, and Dena Watkins for providing ants from Miami, Florida. Samples of *Actidinia polygama* were kindly provided by Professor George R. Waller (Oklahoma State University). Also, we offer our thanks to Dr. Walter Tschinkel (Florida State University) for his critical review of the manuscript.

(Received October 10, 1985; accepted February 20, 1986)

Abstract—An original homologous series of di-*n*-alkyl ethers has been revealed in the cuticular waxes of *Locusta migratoria cinerascens*. The mass spectrometry-electron impact, and positive and negative chemical ionization of these derivatives has been investigated in order to define the optimal conditions for structural determination. The quantitative analyses have shown that the ethers $C_{n1}H_{2n1+1}-O-C_{n2}H_{2n2+1}$ with an odd number of carbon atoms ($n1$ even and $n2$ odd) are clearly predominant. Furthermore, they have made a double phasal dimorphism appear: heavier ethers in the case of the solitary insects and majority participation of *n*-alkyl chains in C_{16} (60%) in the case of the gregarious locusts and in C_{18} (50%) in the solitary ones.

Key Words—Locusts, *Locusta migratoria*, cuticular waxes, aliphatic ethers, mass spectrometry, phase polymorphism, Orthoptera, Locustidae.

INTRODUCTION

The cuticular waxes which cover the surface of insects are made up mainly of aliphatic hydrocarbons. Among the other compounds present, the most common are primary fatty acids and alcohols; esters of these acids and alcohols; and acetates, ketones, and aldehydes, all saturated or unsaturated, linear or branched. Lastly, less frequently occurring compounds have been characterized in different species of insects: secondary alcohols and esters of secondary alcohols, α-hydroxy acids, diols, steroids, and terpenes (Blomquist and Jackson, 1979; Hadley, 1981).

0098-0331/87/0200-0265$05.00/0 © 1987 Plenum Publishing Corporation

In *Locusta migratoria,* only the hydrocarbons have been studied so far. They comprise 54% of the extracts from the wings of these insects (Lockey, 1976) and 52–78% of the total cuticular extracts according to the age, sex, and phase (gregarious or solitary) of the locusts (Génin et al., 1985). A not insignificant portion of the cutical of these insects thus remained unknown. So we analyzed this as thoroughly as possible, bearing in mind the possible role of the polar compounds in the chemical communication between insects.

We also thought it would be interesting to find out if the phasal dimorphism that we had observed in hydrocarbons (Génin et al., 1985) could also be found in nonhydrocarbon compounds.

We describe here a homologous series of di-*n*-alkyl ethers, cuticular components of *Locusta migratoria cinerascens.* As far as we know, this is the first time that such compounds are reported in a biological environment. We determined them by mass spectrometry in the complex mixtures of which cuticular waxes consist. Their spectra were recorded under electron impact ionization and positive and negative chemical ionization conditions (at different temperatures and pressures in the ionization chamber) and compared.

Qualitative and quantitative analyses of the ether mixtures of the same mass, not resolved on the gas chromatograms, were carried out in order to determine the possible predominances and to pose the problem of the biosynthesis of these derivatives. Finally, comparisons were made between larvae and adult, male and female, and solitary and gregarious locusts.

METHODS AND MATERIALS

The insects used were last larval instar and mature adult, male and female, gregarious and solitary. They were raised at the Insect Biology Laboratory. The strain was *Locusta migratoria cinerascens* from Sardinia. Gregarious locusts were bred in groups of 200 individuals in cages of 40 × 40 × 60 cm. Solitary locusts were maintained from birth in individual 1 liter containers in a separate breeding room. Each room was submitted to a regular change of air 12 times an hour. The photo- and thermoperiods were 12/12 hr with temperatures of 25 ± 1°C (night) and 35 ± 1°C (day). Separate evaluation of characteristics such as behavior (Nicolas, 1972; Gillett et al., 1972), morphometrics (Nicolas, 1973; Minato et al., 1973), pigmentation and fecundity (Nicolas, 1972) had shown that, under our laboratory conditions, the locusts isolated from birth are conspicuously different from the crowded ones bred simultaneously. All locusts were fed on fresh corn shoots and bran every day of the week with no interruption.

The same numbers of animals of both sexes used were: 23 gregarious, last-instar larvae, 2–3 days old; 5 gregarious, mature adults, 34 days old; 10 soli-

tary, last-instar larvae, 2–3 days old; and 21 solitary, mature adults, 21 days old.

All the solitary locusts used were light beige as this color was close to that of the white paper surrounding them to keep them separated. Each insect was killed by freezing at −20°C, then extracted by stirring for 10 min in Mallinckrodt nanograde hexane (5 ml per adult and 3 ml per larva). The total extracts, after being weighed, were fragmented by thin-layer chromatography (Merck 10 × 20-cm plates of silica gel 60 F254 with concentration zone). A first elution with hexane made it possible to eliminate the hydrocarbons. A second elution with a mixture of hexane and ethyl acetate (50 : 1) eluted a band with the second solvent front. The latter turned out to comprise, among other things, a homologous series of lipid ethers, which are the object of the present study.

Analyses were carried out by combined gas chromatography–mass spectrometry using a Nermag R10-10 spectrometer interfaced to a PDP8 calculator (Digital Equipment) and coupled to a Girdel 31 chromatograph equipped with an all-glass injector. Fractions were temperature programmed from 160 to 300°C at 3°/min then held at 300° on a 25-m capillary column, 0.32 mm wide, coated with CpSil 5 CB Chrompack. The carrier gas was helium and inlet pressure 0.25 bar. Mass spectra were recorded in the electron impact ionization mode at 70 eV, in the ammonia positive chemical ionization mode (total source pressure: 0.03–0.2 torr; source temperature: 110–300°C) and in the negative chemical ionization mode using a mixture of N_2O–CH_4 (10 : 1) as a reagent gas (total source pressure: 0.1–0.2 torr; source temperature: 110–300°C). Integration of chromatographic peaks was carried out with a Hewlett-Packard integrator coupled to a Varian 3700 chromatograph with the 25-m column mentioned above, programmed from 40 to 300°C at 4°/min then held at 300° with a flow rate of helium of 18 cm/sec; an "on column" injector was used.

The retention indices, *I*, (Ettre, 1964) were calculated using the *n*-alkanes of C_{25} to C_{37} present on the chromatograms of the ether fragments.

The *n*-undecyl *n*-eicosyl ether, *n*-tridecyl *n*-octadecyl ether (Kobayashi, 1976), *n*-tetradecyl *n*-heptadecyl ether, *n*-pentadecyl *n*-hexadecyl ether, and di-*n*-hexadecyl ether (Senderens, 1925; Perron and Paquot, 1950) were synthesized according to the method described by Barry et al. (1984). The infrared spectra (CCL_4 as solvent) of these synthetic compounds all show a similar absorption in the 1112 ± 2 cm^{-2} region due to C—O—C antisymmetric stretching. In the same way, [^{1}H] NMR spectra (250 MHz, $CDCl_3$, TMS internal reference) show similar chemical shifts: δ R—$\underline{CH_2}$—O = 3.39 ± 0.01 ppm (triplet, 4H); δ R—$\underline{CH_2}CH_2$—O = 1.56 ± 0.01 ppm (multiplet, 4H); δ other methylenes = 1.26 ± 0.01 ppm (broad singlet, 50H; 52H for C_{16}—O—C_{16}); δ CH_3 = 0.88 ± 0.01 ppm (triplet, 6H).

All the bar charts (Figures 7 and 8) were constructed from the ether percentage columns shown in Table 1.

RESULTS AND DISCUSSION

The aliphatic ethers identified in *Locusta migratoria cinerascens* comprise between 4% and 5% of total cuticular waxes. These results have been deduced from the percentages in weight, compared with the total extracts, of the elution bands taken off after thin-layer chromatography and the percentages of the ether peaks of the gas chromatograms obtained from these elution bands.

Their identification results from similarity of mass spectra and retention time of the mixture of the four synthetic ethers in C_{31} with the corresponding natural products. Moreover, the [^{1}H] NMR spectrum (250 MHz, $CDCl_3$/TMS) of the ether fraction of Figure 1 shows the same peak as the synthetic ethers with the same chemical shifts. The retention indices (C_{29} ethers: $I = 2943$; C_{31} ethers, synthetic and natural: $I = 3143$; etc.) and the differences in retention indices, dI, between these ethers and the n-alkanes with the same number of carbons ($dI = 43$) confirm the homogeneity of the series described here. They range from $C_{25}H_{52}O$ (M = 368) to $C_{37}H_{76}O$ (M = 536), those with odd numbers of carbons being predominant. Furthermore, each one is made up of one or several structural isomers (except for the C_{25} ethers) not resolved (except for the C_{27} ethers) on the chromatograms (flame ionization detector or mass spectrometer) (Figure 1).

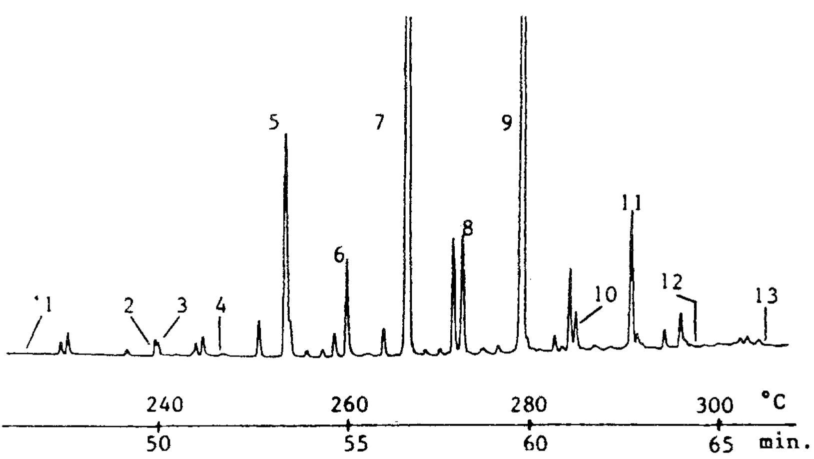

FIG. 1. Gas chromatogram of an ether fraction of male gregarious adult of *Locusta migratoria cinerascens*. CpSil 5 CB Chrompack capillary column of 25 m/0.32 mm, temperature programmed from 40 to 300° at 4°/min. then held at 300°; "on column" type injector.

Table 1 shows the relative percentages of the ethers compared with each other as well as the group of isomers identified, according to the age, sex and phase of the insects.

The complexity of the mixtures of ethers identified was determined by mass spectrometry. Different investigations carried out under 70 eV (McLafferty, 1957; Budzikiewicz et al., 1967; Beynon et al., 1968; Van de Sande, 1980) have established certain similarities between the spectra of the ethers R_1-O-R_2 and those of the alcohols $R_1-C(OH)-R_2$, the amines $R_1-N(R_3)-R_2$, and the sulfides R_1-S-R_2. Indeed, in all cases, the presence of the heteroatom determines the main fragmentation (Scheme 1).

SCHEME 1.

When the aliphatic chains lengthen, there is a rapid reduction of the α cleavages and the molecular ion disappears. As illustrated in Figure 2A for *n*-pentadecyl *n*-hexadecyl ether, this process continues beyond the di-*n*-decyl ether at which McLafferty stopped; it ends up with the complete disappearance of the α cleavages for out products and under our experimental conditions. The essential part of the ion current comes then from the fragments of the *n*-alkyl chains, the ipso cleavage rate maintaining itself at a constant level. Furthermore, the electron impact spectra of the ethers of *Locusta migratoria cinerascens* are complicated by the multiplicity and the weak intensity of the fragmentation ions R_1^+ and R_2^+ of the various structural isomers present. The spectrum of a mixture of ethers of the empirical formula $C_{31}H_{64}O$ (product No. 7 in Table 1) is shown in Figure 2B.

Spiteller-Friedman and Spiteller (1967) have shown elsewhere the advantages to be gained from lowering the source temperature (70–80°) and/or the ionization energy (12–20 eV) to maximize the ipso cleavages and the molecular ion of the ether. However, these operational conditions are not very compatible with the study of complex mixtures by GC-MS. In fact, reduction of ionization energy brings about a loss of sensitivity which is inconvenient when only a small quantity of extract is available. Moreover, the reduction of source temperature induces condensation in the source.

For all these reasons, identification of the ethers of *Locusta migratoria cinerascens* has led us to explore the techniques of chemical ionization, making it possible to identify and localize the functional groups, and to maximize the intensity of the quasimolecular ions.

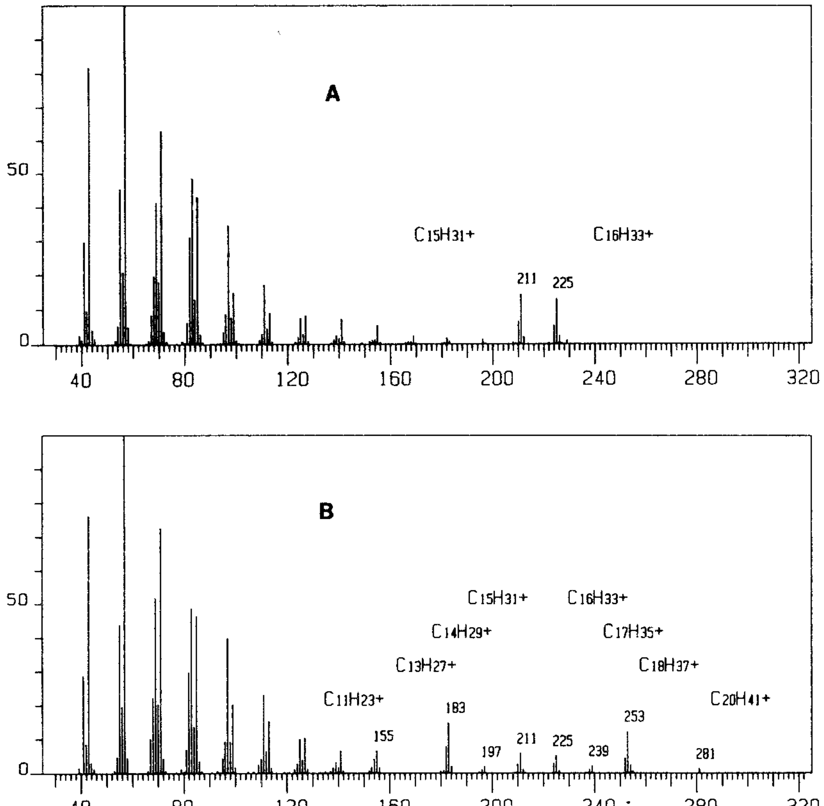

FIG. 2. (A) Electronic impact mass spectrum of pentadecyl hexadecyl ether. Ionization voltage: 70 eV; source temperature: 110°. (B) Electronic impact mass spectrum of GC peak 7 (solitary locusts: see Table 1). Ionization voltage: 70 eV; source temperature: 110°.

As yet, little has been done on the OH^- negative chemical ionization of the ethers. The spectra are characterized by RO^- type ions coming from nucleophilic attack by the hydroxyl ion on the carbons situated in the α positions in relation to the oxygen atom and the consecutive cleavage of the C—O bond (Scheme 2).

$$R'_1\text{-}CH_2 - O - CH_2\text{-}R'_2 \rightarrow R_1O^-,\ R_2O^- \quad (OH^-)$$

SCHEME 2.

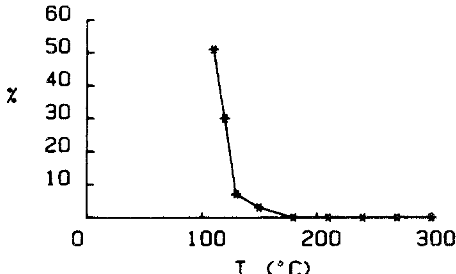

FIG. 3. Evolution of the relative intensity of the $(M + OH)^-$ ion in terms of the source temperature in the negative chemical ionization mass spectrum of pentadecyl hexadecyl ether.

Absence of the quasimolecular ion $(M - H)^-$ suggests weak acidity of the hydrogen atoms borne by these carbons. Lastly, ions of weak intensity of the $(M - 3H)^-$ and $RO - 2H)^-$ type can be observed and are explained by stabilization of the negative charge (Smit and Field, 1977; Budzikiewicz, 1981). In an effort to obtain a quasimolecular ion in the negative chemical ionization mode, we lowered the source temperature (Budzikiewicz, 1981) (Figure 3).

Beyond 150°C the latter is composed mainly of the R_1O^- and R_2O^- ions (Figure 4A). At 150° and below, a M + 17 peak appears; this reaches its highest intensity at 110° (Figures 3 and 4B). Kajdas (1971) had already noted the presence of an $(M + 17)^-$ ion in the negative ion current obtained by electron impact on saturated aliphatic hydrocarbons. This ion, resulting from an electrostatic interaction between OH^- and the initial molecule, increases in intensity with the molecular mass of the hydrocarbon. Furthermore, it appears only at low source temperature. The formation of a complex $(M + OH)^-$ is also very frequent in the case of alcohols (George, 1984). In the case of cyclic molecules, the $(M + OH)^-$ ion would seem to result from a nucleophilic attack of OH^- with a cleavage in the consecutive ring (Smit and Field, 1978). Dreifuss et al. (1983) suggest that the interaction of OH^- with the initial molecule is more likely to be produced through a hydroxyl–carbon bond than by an attachment to a hydrogen atom.

In the case of the aliphatic ethers studied here, the formation of a complex, as shown Scheme 3, can be envisaged. Such a complex could tend to cleave the C—O bond, depending on its internal energy (source temperature). The

analysis, under these experimental conditions, of an extract from *Locusta migratoria cinerascens* has shown that the formation of this M + 17 peak could be reproduced and generalized for all the ethers present in these insects (Figure 4C).

Finally, the presence of $(R_1O - 2H)^-$, $(R_2O - 2H)^-$, $(R_1O + 44)^-$, $(R_2O + 44)^-$ ions was observed; the last two could have resulted from the nucleophilic attack of the R_1O^- and R_2O^- ions on the nitrous oxide (N_2O). No dependency was observed between the intensity, always weak, of these ions and the source temperature. $(M - H + 44)^-$ type ions had already been pointed out for unsaturated hydrocarbons (Smit and Field, 1977; George, 1984).

In ammonia positive chemical ionization, as in Figure 5A for *n*-pentadecyl *n*-hexadecyl ether, the molecular mass can be immediately deduced from the only observed ions, $M(NH_4)^+$ and MH^+. We thought it would be interesting to know to what extent the variation of the experimental parameters could make it possible to observe fragmentation ions in the positive mode. Increasing the source temperature, with a constant ammonia pressure of 0.2 torr (Figure 5A and B) does not cause any fragmentation. This increase in source temperature shows only that the proportion of the intensities (M + 18)/(M + 1) varies in inverse ratio to the temperature. On the other hand, variations of pressure are decisive, as Figure 5C shows. Influence of the ammonia pressure on the degree of fragmentation of methoxy derivatives had already been observed in our laboratory (Péchiné et al., 1985). Figure 6 shows the evolution, depending on the ammonia pressure, of the relative intensity of the R_1^+ (*m/z* = 211) ion in relation to the base peak (generally MH^+ at the temperature used) of the spectrum of *n*-pentadecyl *n*-hexadecyl ether. An identical curve is obtained for the R_2^+ (*m/z* = 225 ion. At 0.1 tor of ammonia, the mechanisms of positive chemical ionization become weaker to the benefit of

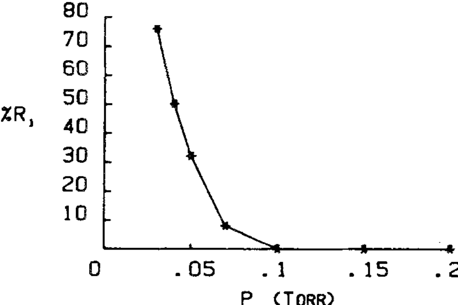

FIG. 6. Evolution of the relative intensity of the R_1^+ ion in terms of the source pressure in the NH_3 chemical ionization mass spectrum of pentadecyl hexadecyl ether. Source temperature: 180°.

an electron impact ionization, the R_1^+ and the R_2^+ ions appearing on the spectra, alongside the cleavage ions of the apliphatic chains. The abundance of these ions continues increasing as the pressure decreases; simultaneously, that of the $(M + 1)^+$ and (M + 18) diminishes. Thus, at 180° and 0.03 torr of ammonia, the $(M + 1)^+$ ion, the base peak at higher pressures, represents only 30% of the new base peak (m/z + 111) and the $(M + 18)^+$ ion has disappeared.

By these mass spectrometry techniques, we were able to obtain the results tabulated in Table 1. Examination of the global percentages of the isomer mixture reveals variations between gregarious and solitary insects (larvae and adults,

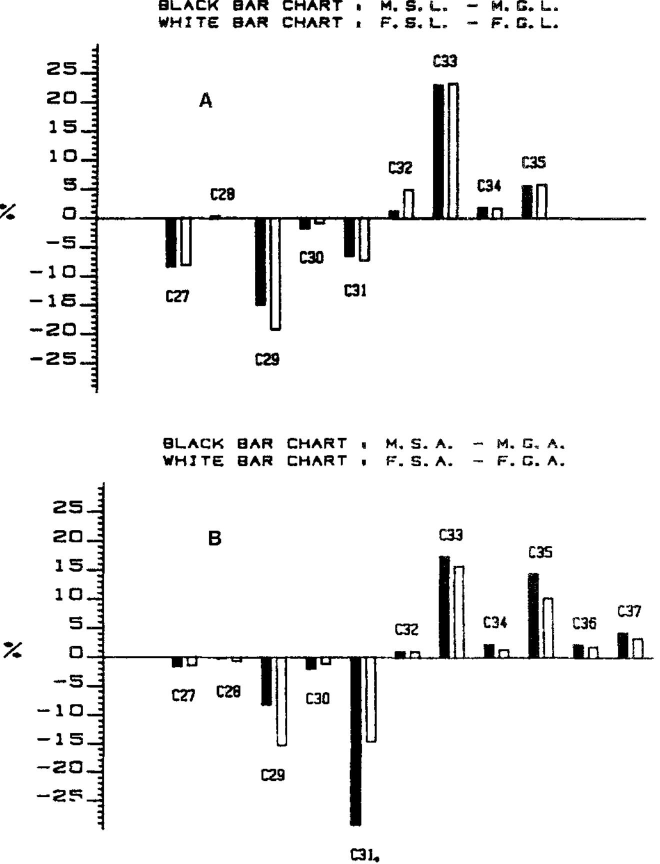

FIG. 7. (A) %MSL – %MGL (black bar chart); %FSL – %FGL (white bar chart). (B) %MSA – %MGA (black bar chart); %FSA – %FGA (white bar chart). MSL: male solitary larvae; MGL: male gregarious larvae; FSL: female solitary larvae; FGL: female gregarious larvae; MSA: male solitary adult; MGA: male gregarious adult; FSA: female solitary adult; FGA: female gregarious adult.

males and females) and between larvae and adults (gregarious and solitary, males and females). The differential histograms (Figures 7 and 8) show these results. They display, in the case of the solitary insects, an average reduction of 35% in the ethers from $C_{27}H_{56}O$ to $C_{31}H_{64}O$ and a same average augmentation in the ethers from $C_{32}H_{66}O$ to $C_{37}H_{76}O$ (Figure 7A and B). Displacement of the cuticular compositions of the solitary locusts, compared with the gregarious ones, towards the heaviest ethers, is quite parallel to that already observed in the case of hydrocarbons (Génin et al., 1985). It constitutes another example of phasal dimorphism connected with the lipid epicuticle or the insects, independent of their age and sex. Such an evolution towards the heaviest ethers also takes place when the locusts become mature. The histograms shown in Figure 8A and B establish the comparisons between the fifth instar larvae and

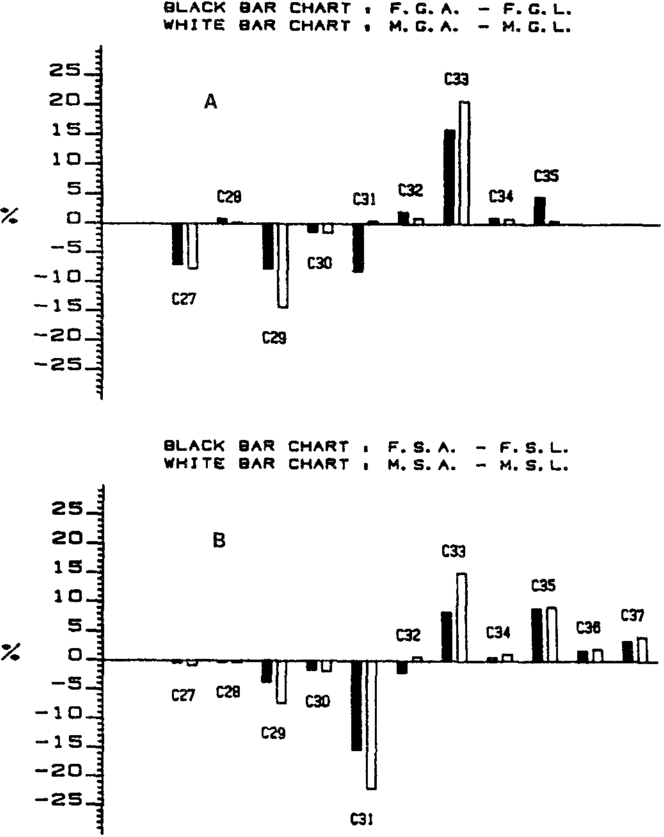

FIG. 8. (A) %FGA − %FGL (black bar chart); %MGA − %MGL (white bar chart). (B) %FSA − %FSL (black bar chart); %MSA − %MSL (white bar chart).

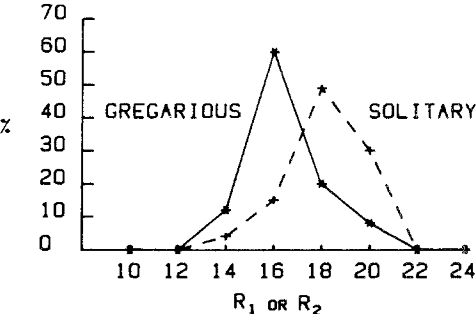

FIG. 9 Frequency of the even alkyl chains R_1 and R_2 in the gregarious and the solitary locusts.

the adults. Finally, the comparisons between sexes do not seem to imply noticeable differences, suggesting here a weak probability of a pheromonal role of a sexual kind for these aliphatic ethers.

These quantitative results have proved to be quite parallel in the cases of other populations also studied. Only slight variations in the absolute percentages of the ethers appeared.

Table 1 also gives the relative percentages of the structural isomers of the ethers identified. These results were obtained in negative chemical ionization (source temperature: 250°) by integration of the R_1O^- and R_2O^- ions of the various isomers present under a given total ion current peak (Figure 4C). The selected ion monitoring analyses have shown that the retention times of these isomers would seem to differ slightly from each other and increase in the dissymetry of the two chains R_1 and R_2, causing a lengthening of the retention time with broadening of the peak. Presented here for the adult solitary females and the adult gregarious females, these integrations can be generalized to apply to adult male locusts and to the larval stage and reveal, in all cases, a clear phasal dimorphism. It appears in particular (Figure 9) that the frequency of the chains R_1 and R_2 with an even number of carbons depends on the phase of the insects. Thus, in the case of the gregarious locusts, close to 60% (surface percentage) of the ethers have an R_1 or R_2 chain in C_{16} and 20% have a chain in C_{18}. The proportions are in inverse ratio in the case of solitary locusts: 17% of the ethers have a chain in C_{16} and 50% a chain in C_{18}. This phasal character diminishes for the heaviest ethers ($C_{35}H_{72}O$, $C_{36}H_{74}O$, and $C_{37}H_{76}O$), those with a chain in C_{17} becoming predominant, independently of the phase of the insects.

CONCLUSIONS

We have shown that negative chemical ionization of lipid ethers maximizes the R_1O^- and R_2O^- ions without an upper limit of source temperature. It allows

a quantitative analysis of the isomer mixtures by searching and integration of the different RO^- ions. Furthermore, molecular masses are detected due to $(M + 17)^-$ ion. A temperature of 150° has appeared to be the most adequate in the negative mode.

Ammonia positive chemical ionization has generated the quasimolecular ions $(M + 1)^+$ and $(M + 18)^+$ independently of the source temperature. Moreover, the appearance of the ions R_1^+ and R_2^+ at low ammonia pressure has made it possible to confirm the position of the functional group. Intermediate conditions (temperature: 180°, and ammonia pressure: 0.04 torr) have proved the most suitable for the various criteria sought: presence of the ions R_1^+, $(M + H)^+$, and $(M + NH_4)^+$, selectivity of the cleavages of the C—O bonds in relation to the C—C bonds; and absence of condensation in the source.

The quantitative analyses have brought out a double phasal dimorphism: on the one hand, in the overall distribution of the cuticular ethers of the locusts (these ethers are heavier in the case of the solitary locusts), and on the other hand, in the frequency of the structural isomers. Among them, those which are predominant have at least one branch in C_{14}, C_{16}, C_{18}, or C_{20}, the branches in C_{16} and C_8 remaining clearly predominant. This observation, connected with the fact that the majority ethers have a total odd number of carbons, is probably an indication for their biosynthesis which remains to be described.

Finally, these quantitative and qualitative results pose the problem of the possible role played by these ethers in the physiology and/or the behavior of *Locusta migratoria cinerascens*.

Abstract—The lubber grasshopper, *Romalea guttata*, produces a metathoracic defensive secretion containing primarily phenolics and quinones. This insect feeds on a wide range of plant species. Insects reared on an artificial diet and a diet of onion, *Allium canadense*, had secretions that contained fewer compounds, lower concentrations of compounds, and markedly altered relative composition of components compared to insects reared on a varied diet of 26 plant species that included onion. The study demonstrates that diet breadth has a major effect on the quality and quantity of the autogenous defensive secretion of this generalist herbivore. The results are compared to diet effects known in chemically defended specialists. Two possible mechanisms explaining the effects of diet breadth are proposed: one involves changes in precursor availability with changing diet breadth; the other suggests that physiological stress due to diet restriction changes allocation of resources to chemical defense.

Key Words—Lubber grasshopper, *Romalea guttata (microptera)*, Orthoptera, Acrididae, generalist herbivore, dietary regime, host plant, artificial diet, autogenous defense, phenolics, quinones, allbomone, sequestration, physiological stress, plant–insect interaction.

INTRODUCTION

Many plant-feeding insects use toxic or repellent chemicals as defenses against predators. These insects either make the chemicals themselves—autogenous defenses—or store, or sequester, chemicals directly from the diet (Duffey, 1980). Most studies on diet and chemical defense have focused on insects that feed on few plant species, such as the specialist monarch butterfly (e.g., Brower et al., 1982, 1984), and have not examined generalist insects that feed on many plants. We wanted to know if diet had any effect on the chemical defenses of a generalist.

The lubber grasshopper, *Romalea guttata* Houttuyn (Orthoptera; Romaleidae) (=*R. microptera* Beavois; Kevan, 1980), is a warningly colored generalist herbivore that is unpalatable to a number of different predators (Whitman, Jones and Blum, unpublished data). The insect produces a frothy, metathoracic spiracular secretion that is primarily comprised of phenolics and quinones (Jones et al., 1986) and is repellent to certain ants (Eisner et al., 1971). This defensive secretion shows extreme idiosyncratic chemical variation among individuals within wild populations, with certain phenolic and quinone compounds being absent in some individuals and present in others, and with concentrations varying over two to three orders of magnitude (Jones et al., 1986).

Although secretion composition has been examined (Eisner et al., 1971; Jones et al., 1986), the origin of the secretion components is not known. Since *R. guttata* may sequester certain compounds (Eisner et al., 1971; Berger, 1976), it was important to establish whether or not the compounds we previously analyzed were autogenous or were sequestered from the diet. We also wished to determine whether or not the extensive interindividual variation was diet-related. In the wild, each polyphagous individual insect consumes a different diet (Jones, Whitman and Blum, unpublished data). It was possible that the varied diet caused the variation in the defensive chemistry. To address these two questions, we needed to rear insects on a defined diet that lacked the compounds we analyzed, and a uniform diet that ensured that each individual consumed the same diet. Such defined and uniform diets inevitably lacked the diversity of plant material found in the wild and were of restricted diet breadth. We therefore reared grasshoppers on diets of one plant species and on an artificial diet, and compared the defensive secretion chemistry with secretions from insects reared on a varied diet of 26 species that included the same plant species as that used in one of the restricted diets.

METHODS AND MATERIALS

Rearing of Insects. R. guttata were reared from first instar to adult in cages, each containing about 30 insects. Cages were maintained at 30 ± 1°C with 65 ± 5% relative humidity and a 12 : 12-hr light–dark cycle. *Romalea* were reared

on three different diets: (1) A "natural diet" consisted of leaves of 26 species from 15 families of shrubs, herbs, forbs, and grasses known to be eaten by *Romalea* in the field (Jones, Whitman and Blum, unpublished data). This diet was selected to represent the varied generalist diet. Plant material was collected daily and the cut petioles or stems placed in water. The families and species of plants were: Apiaceae: *Daucus carota;* Asteraceae: *Lactuca sativa*, *Sonchus asper*, *Sonchus oleraceus*, *Taraxacum officinale*, *Erigeron canadensis;* Brassicaceae: *Lepidium virginicum;* Caprifoliaceae: *Lonicera japonica;* Chenopodiaceae: *Chenopodium album;* Cucurbitaceae: *Melothria pendula;* Euphorbiaceae: *Euphorbia supina;* Fabaceae: *Pueraria lobata*, *Trifolium repens;* Liliaceae: *Allium canadense;* Malvaceae: *Modiola virginicum;* Oxalidaceae: *Oxalis dillenii;* Plantaginaceae: *Plantago lanceolata;* Poaceae: *Sorghum halepense*, *Poa* sp., *Festuca* sp., *Cynodon dactylon*, *Digitaria sanguinalis;* Polygonaceae: *Rumex acetosella*, *Rumex crispus*, *Polygonum aviculare;* Solanaceae: *Solanum carolinianum.* (2) A single host-plant diet of freshly cut leaves of *Allium canadense* in water was chosen as the uniform plant diet of restricted breadth. This species was included in the natural diet and is a preferred food plant of *Romalea* in the field and in laboratory preference studies (Jones, Whitman and Blum, unpublished data). (3) An artificial diet formulated according to Dadd (1960) was selected to be a defined, restricted diet that lacked fresh plant material and the phenolic and quinonoid compounds. The dry powder diet contained cellulose, sucrose, dextrin, a salt mixture, cholesterol, linoleic acid, casein, peptone, egg albumen, ascorbic acid, and 10 water-soluble vitamins of the B complex. The diet was presented as a moist cake by addition of water.

Secretion Collection. The defensive secretion is eliminated at each molt and replenished thereafter. Metathoracic spiracular secretions were collected at the eighth day after molt to adult by milking with a microcapillary as described by Jones et al. (1986). Samples were stored at $-10°C$. We quantified secretions of 10 individuals of each sex on each diet, with the exception of males on natural diet ($N = 11$) and females on onion diet ($N = 11$).

Secretion Analysis. Compounds were identified by gas chromatography–mass spectroscopy (GC-MS). Secretions were analyzed by gradient reversed-phase high-performance liquid chromatography (HPLC) on a C_{18} bonded-phase silica column with a guard column and a convex elution gradient of methanol, water, and 1% H_3PO_4. Peaks were detected at 254 nm (UV). Full details on GC-MS and HPLC, including use of internal standards and detection thresholds, are reported in Jones et al. (1986).

RESULTS

The metathoracic secretion of lubber grasshoppers is chemically complex and contains over 40 components (Meinwald et al., 1968; Eisner et al., 1971; Jones et al., 1986). We restricted our analyses to seven compounds: hydro-

quinone, catechol, *p*-benzoquinone, phenol, guaiacol, 4-methoxybenzaldehyde, and a partially characterized unknown. These are the major HPLC/254-nm-detectable components, are repellent to ants (Eisner et al., 1971), and are the same compounds that were analyzed for interindividual variability within a wild population in a previous study (Jones et al., 1986). The absence or presence and quantity of these seven components in defensive secretions were determined for individuals of both sexes reared on the three diets.

Origin of Secretion Components. We reasoned that if the seven compounds we analyzed were directly sequestered from plants, they would be absent in all individuals reared on an artificial diet that did not contain these compounds. If these compounds were made by the insect, they would be present in at least some individuals, irrespective of diet. The compounds would not necessarily be expected to occur in all individuals because of the underlying qualitative variation (Jones et al., 1986). We looked at the frequency of occurrence of the seven compounds in individuals reared on the artificial diet. At least some individual males and/or females contained all the compounds when reared on the artificial diet (Figure 1). We infer from these data that these compounds are of autogenous origin and are not sequestered from the diet. However, such a result does not preclude the possibility that the same compounds could be sequestered as well as synthesized under some circumstances. Nevertheless, under these conditions, any effects of diet on chemical defense in *R. guttata* would be indirect.

Occurrence of Compounds in Individuals. The frequency of occurrence of the seven compounds in secretions of individuals reared on the natural diet was not significantly different from that of insects in wild populations (χ^2, $P > 0.1$) (see Jones et al., 1986). Consequently, the natural diet was equivalent to the wild situation from the perspective of defensive secretion quality. In contrast, insects reared on both the artificial diet and onion diet had reduced frequencies of occurrence of compounds in individuals (Figure 1). This was the case for two of seven compounds for females, and four of seven compounds for males on artificial diets, and six of seven compounds for females and two of seven compounds for males on onion diets. Since there was a considerable degree of qualitative variation between individuals on the natural diet, only eight of fifteen of the cases of reduced frequency on artificial and onion diets were significant (χ^2, $P \leq 0.05$).

Sexual differences in the frequency of occurrence of compounds were also evident. For example, on the onion diet all female secretions lacked catechol and *p*-benzoquinone, while at least some male secretions had these compounds. Similarly, on the artificial diet all male secretions lacked catechol and guaiacol, while some female secretions had catechol and all female secretions had guaiacol. Since there is an inherent tendency for secretion components to be absent in certain individuals (Jones et al., 1986), and since the biosynthetic origins of, and relationships between, compounds are not known, it is not possible at

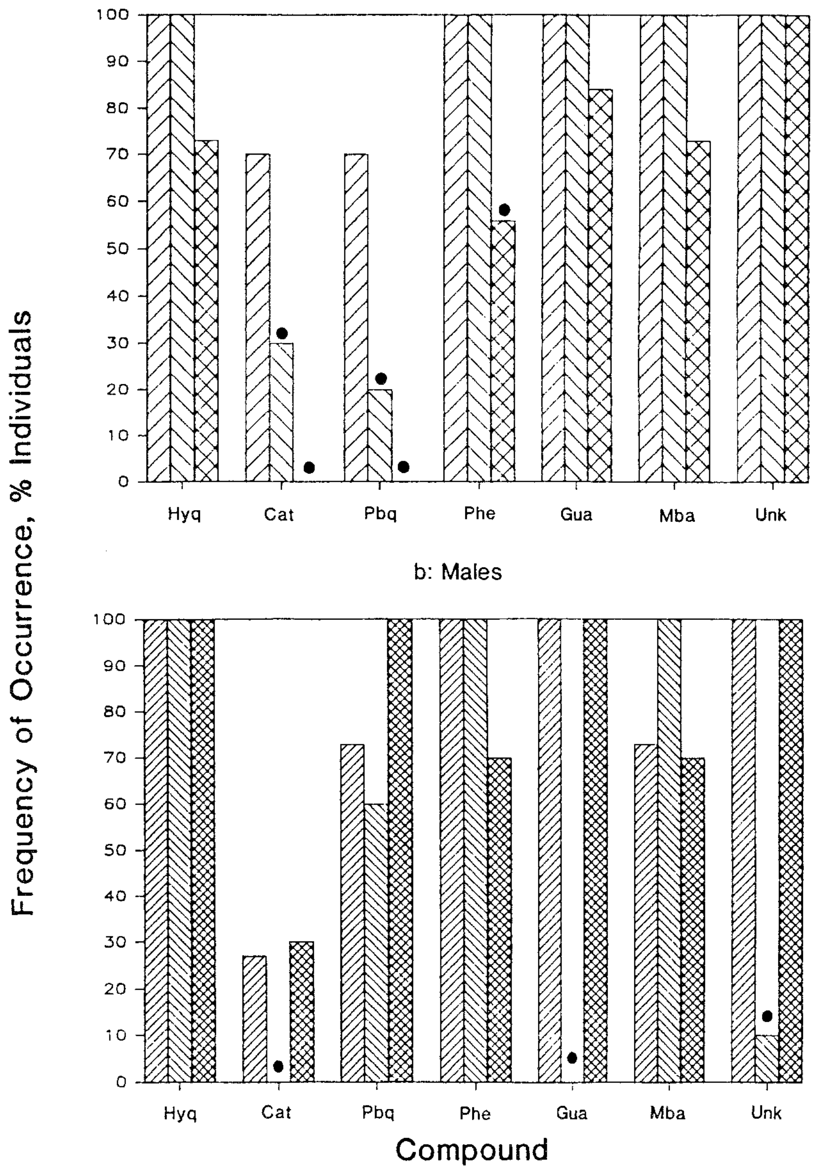

FIG. 1. Frequency of occurrence of phenolics, quinones, and an unknown compound in secretions of individual adult *R. guttata*. (a) Females: ▨ = natural diet; ▧ = artificial diet; ⊠ = onion diet. (b) Males: ▨ = natural diet; ▧ = artificial diet; ▩ = onion diet. this juncture to understand specifically why certain compounds are absent for different diets and sexes. However, it is clear that a reduction in diet breadth results in a reduced probability of an individual containing a given compound, with the strongest effects occurring with females on a single-plant diet.

Effects on Overall Secretion Complexity. A direct consequence of a change in the probability of occurrence of a given compound was a change in secretion complexity. There were significant reductions in the mean number of secretion components for females reared on artificial and onion diets and males on artificial diets (Figure 2). Consequently a reduction in diet breadth resulted in a reduced number of secretion components. Compounds that had a ubiquitous distribution in individuals of both sexes on natural diets became sporadically distributed on restricted diets. Compounds that were sporadically distributed in females on natural diets became more so on restricted diets.

Variation in Secretion Complexity within Treatments. A reduction in the mean number of secretion components due to restricted diet breadth did not reduce the amount of variation in the number of secretion components. The range of values for the number of secretion components on natural diets more

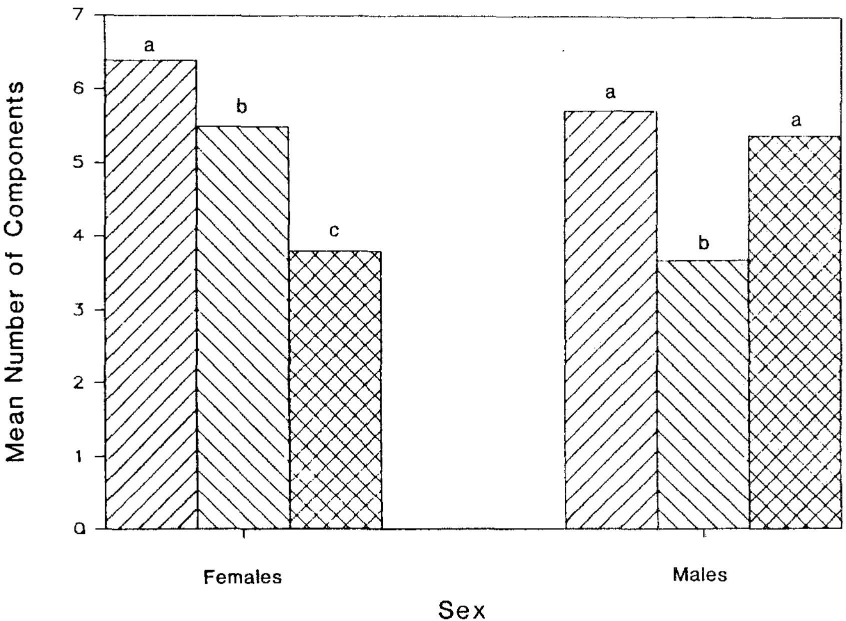

FIG. 2. Mean number of components (phenolics, quinones, and an unknown) in the secretion of adult female and male *R. guttata* reared on three different diets. [natural pattern] = natural diet; [artificial pattern] = artificial diet; [onion pattern] = onion diet. [a,b,c]Means followed by different letters, are significantly different within a sex between diets (t test, $P \leq 0.05$).

than doubled on onion diets, despite a 60% reduction in the mean number of components. This increase in variance was most noticeable in the pronounced skewness of the frequency distribution values for the number of compounds on onion diets and in increased values for the coefficients of variation (Figure 3).

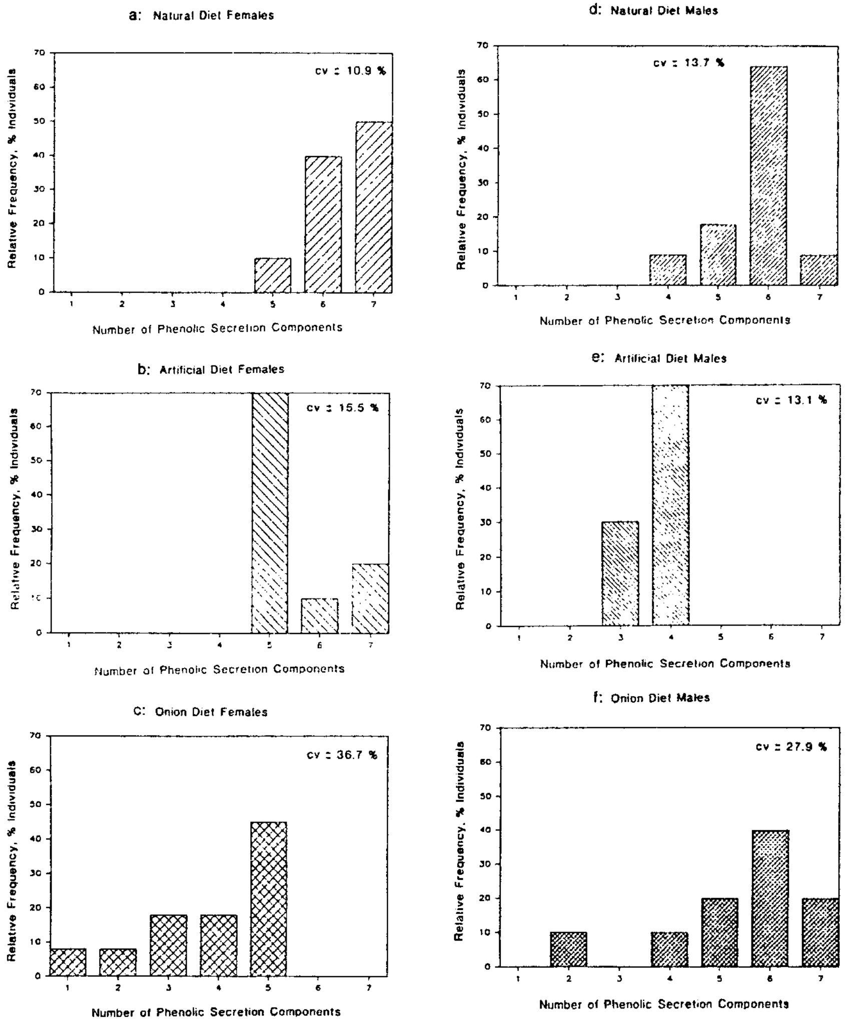

FIG. 3. Relative frequency distributions, as percent individuals with a given number of phenolic secretion components (= phenolics, quinones, and an unknown), for the secretions of adult *R. guttata*. a, ▨: natural diet females; b, ▧: artificial diet females; c, ⊠: onion diet females; d, ▨: natural diet males; e, ▨: artificial diet males; f, ▩: onion diet males. cv = coefficient of variation ($s/\bar{x}$, %).

Thus, a population of insects reared on restricted diets not only had fewer secretion components than the natural diet but were also as much or more variable in regard to the number of compounds likely to be found in a given individual.

Effects of Diet on Secretion Component Quantity. Concentrations of all seven compounds in secretions of insects reared on the natural diet were not significantly different from those found in wild insects (t tests, $P > 0.1$) (see Jones et al., 1986). As with secretion component quality, it appears that the natural diet was equivalent to wild diets from the quantitative viewpoint. Secretions from females reared on onion diets had significantly lower concentrations of all the compounds detected in secretions from females on natural diets (Figure 4). The same was true for all but two compounds (p-benzoquinone and phenol) for female secretions from artificial diets. There was a tendency for female secretions from onion diets to have the lowest combined concentrations of these phenolics and quinones. While similar trends occurred for male secretions, differences were not significant for detected compounds. The lack of significant differences in these cases, despite considerable reductions in concentration (e.g., one order of magnitude difference for catechol in males) are likely due to the large amounts of natural variation in concentration (Jones et al., 1986, and see later) superimposed on generally low concentrations.

The lack of significant differences should not be taken as implying equality of the means, but rather as inadequate sample sizes to detect significant differences, given the exceedingly large variation. The significant differences in concentrations between sexes found on natural diets (t tests, $P \leq 0.05$; except for catechol and p-benzoquinone) disappeared on both artificial (t tests, $P > 0.05$; except for phenol, $P \leq 0.05$; and catechol and guaiacol, which were absent in males) and onion diets (t tests, $P > 0.05$; except catechol and p-benzoquinone, which were absent in females). Thus a reduction in diet breadth reduced the concentrations of defensive components and eliminated the sexual differences in concentrations that were noticeable on natural diets.

Variation in Secretion Component Quantity. Variation among individuals in concentrations of specific components is considerable in wild lubber populations, ranging up to three orders of magnitude (Jones et al., 1986). Coefficients of variation for compound concentrations in individuals reared on natural diets were not obviously higher or lower than those for artificial or onion diets (Figure 4) (F tests, $P > 0.5$). Since, however, the restricted diets had compound concentrations that were lower by one to two orders of magnitude, it is surprising that there was no noticeable reduction in relative variation. Thus a reduction in dietary breadth may affect concentration of defensive components, but does not have a major effect on the considerable amounts of variability between individuals.

Changes in Secretion Composition. The overall composition of a chemical defense may be relevant to signal recognition by predators (Pasteels et al., 1983a; Pasteels and Grégoire, 1984; Jones et al., 1986). The changes in per-

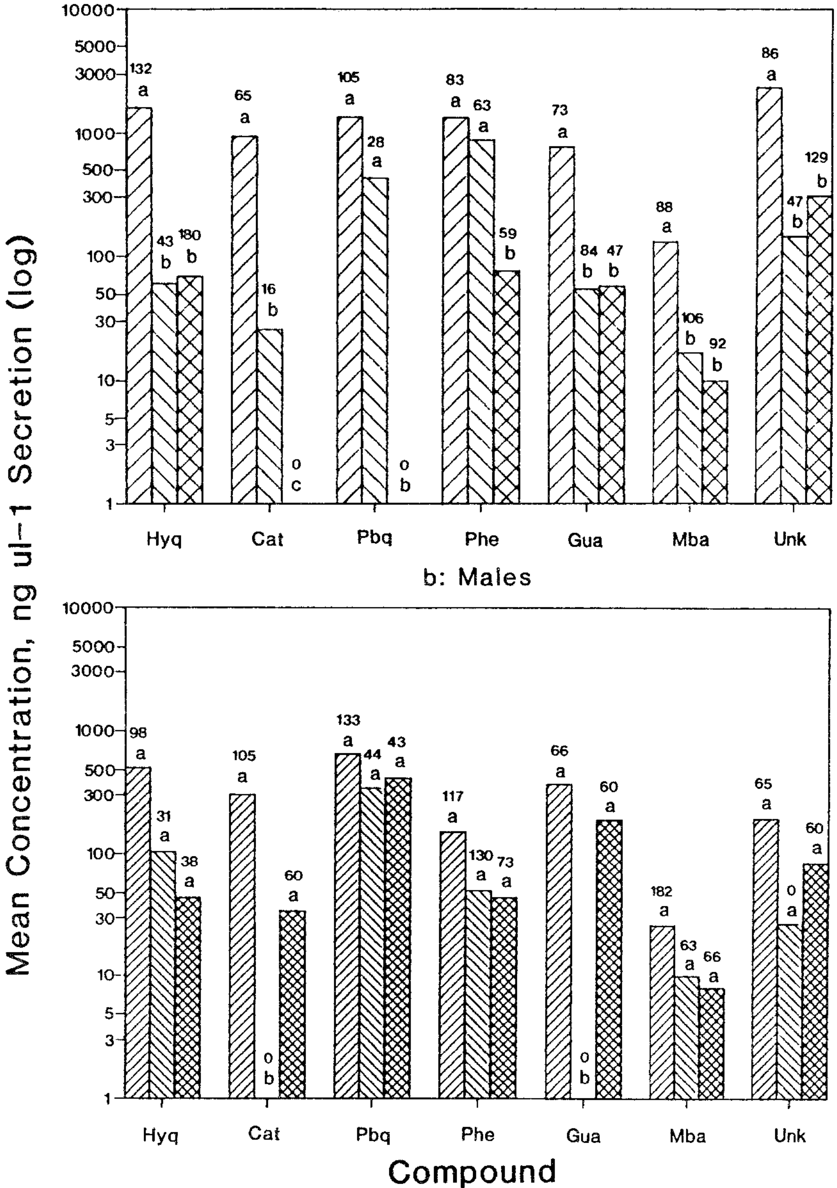

FIG. 4. Mean concentration of phenolics, quinones, and an unknown compound (as equivalents of the internal standard, 4-hydroxybenzoic acid) (log scale) in secretions of adult *R. guttata*. For abbreviations of compounds, see Figure 1. (a) Females: [pattern] = natural diet; [pattern] = artificial diet; [pattern] = onion diet. (b) Males: [pattern] = natural diet; [pattern] = artificial diet; [pattern] = onion diet. Numbers above histogram bars are coefficients of variation ($s/\bar{x}$, %) in concentrations.

cent composition due to restriction of diet breadth were considerable (Figure 5). It is clear that secretions from insects on natural diets had a more even composition than those from insects on artificial or onion diets. For example, the deviation in value for percent composition for each compound from an ex-

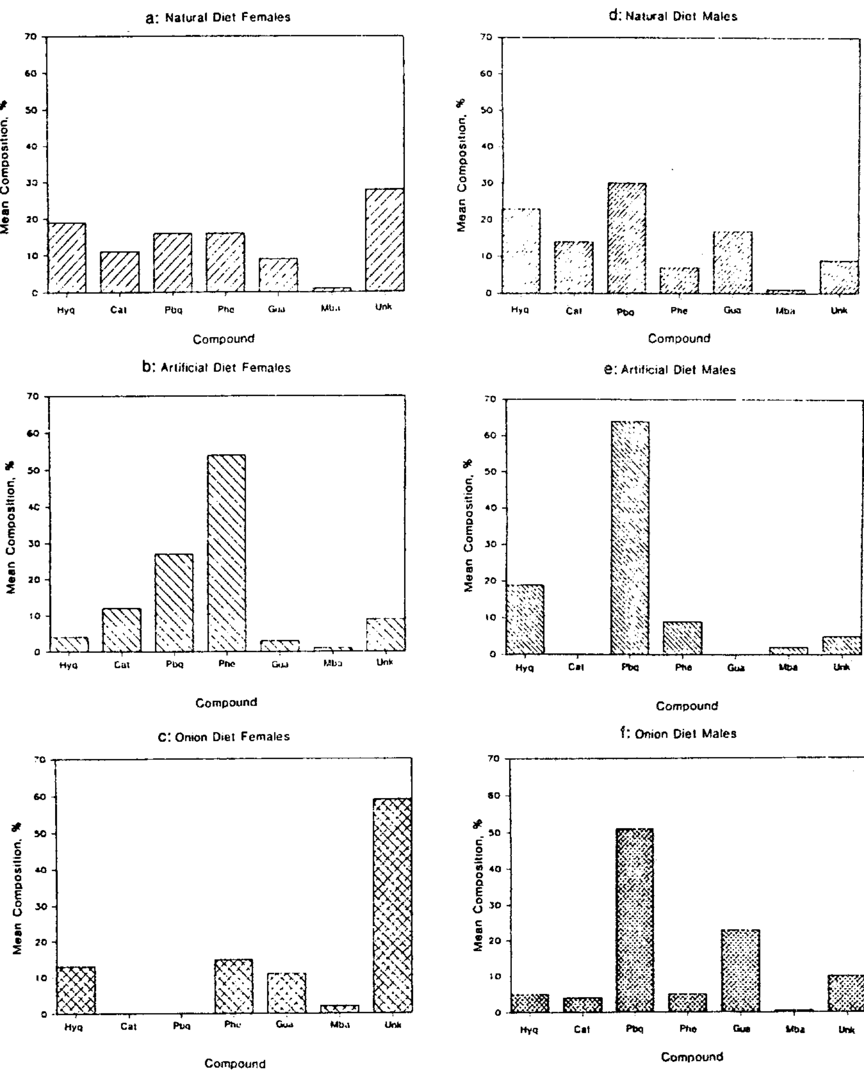

FIG. 5. Mean composition of defensive secretions, based on seven compounds (phenolics, quinones, and an unknown) for *R. guttata*. For abbreviations of compounds, see Figure 1. a, [pattern]: natural diet females; b, [pattern]: artificial diet females; c, [pattern]: onion diet females; d, [pattern]: natural diet males; e, [pattern]: artificial diet males; f, [pattern]: onion diet males.

pected value (expected = 100/7 = 14%), when averaged for all seven compounds, was 6% for females and 8% for males on natural diets, 13% (female) and 16% (male) for artificial diets, and 13% (female) and 13% (male) for onion diets. So, restricting diet breadth changed the balance of components.

Relative Importance of Dietary Effects. Variation among individuals (Jones et al., 1986), effects of diet and sex, and the interaction of diet and sex were all possible factors that contributed to variation in the concentration of defensive secretion components. A previous study showed that interindividual variation accounted for 60–88% of the total quantitative variation in concentrations of compounds in defensive secretions of a wild population, and sex accounted for 9–39% (Jones et al., 1986). Diet was assumed to be the same for all individuals in that population. We applied the same type of analysis to these data (Table 1). The average importance of the three factors and their interaction were: individuals, 57%; diet, 21%; sex, 9%; diet/sex interactions, 9%. Thus the reduction in secretion component quantity due directly or indirectly to diet was a major factor accounting for an average of 30% of the total quantitative variation.

Similar estimates for variation in secretion quality were more difficult to derive. The same type of analysis was applied to the number of compounds in the defensive secretion (see Figure 2). While this was by no means a complete representation of secretion quality (e.g., it ignores which compounds are present or absent in which individuals), the variation was distributed as follows: individuals, 49%; diet, 25%; sex, 1%; diet/sex interactions, 25%. Again, direct and indirect effects of diet emerge as a major factor, accounting for 50% of variation in this characteristic of secretion quality. We concluded that direct

and indirect effects of dietary restriction on autogenous defensive secretion quality and quantity were considerable and second only to interindividual variability. However, the large portion of the variation that was still attributable to individuals indicated that a substantial amount of the quantitative and qualitative variation between wild individuals was not due to diet, but was an innate characteristic of *R. guttata*.

DISCUSSION

Our study clearly demonstrates that diet can have a major effect on the quality and quantity of autogenous defensive secretions of *R. guttata*. The effects are indirect and are not due to sequestration of the phenolics and quinones from the diet, although sequestration of these compounds might occur under different circumstances. Furthermore, the effects of diet were relatively independent of the extensive interindividual variability. Rather, the major effects of restricting diet breadth were to reduce the probability of compounds occurring in individuals, thereby reducing the number of secretion components, reduce the concentration of secretion components, and change the composition of the secretion. While all of these effects occurred for both artificial and single host-plant diets, restriction to a single host-plant produced the more dramatic effects. Similarly, effects of dietary restriction affected females more than males.

To our knowledge, this study is the first to investigate the effects of diet on autogenous defensive secretions for a generalist insect. The focus on the influence of diet breadth permits comparison of our data to some analogous studies with specialist insects producing autogenous defenses on their host plants. Pasteels and Daloze (1977; Daloze and Pasteels, 1979) showed that the cardenolide defenses of the chrysomelid beetles *Chrysolina* and *Chrysochloa* were autogenous and apparently unaffected by the host plant. Presumably the host plants did not vary significantly in their provision of sterol dietary precursors from which the insect cardenolides were synthesized (Pasteels and Daloze, 1977).

In contrast, Pasteels et al. (1983b) showed that larvae of certain chrysomelids feeding on *Salix* or *Populus* used the host-plant phenylglucoside salicin as the sole source of a defensive compound, salicylaldehyde. In this case there is obviously a very close biochemical coupling between the precursor and the defense and is similar to direct sequestration of plant compounds. Larvae and adults of other, related chrysomelid species feeding on other host plants produce autogenous methylcyclopentanoid monoterpenes, with no obvious host-plant effects. Similarly, Nahrstedt and Davis (1983) showed that the cyanogenic glucoside defenses linamarin and lotaustralin found in neotropical Heliconiini (Lepidoptera, Nymphalidae) were synthesized from valine and isoleucine of the host plant (Wray et al., 1983). Interestingly, these host plants also contained

cyanogenic glucosides, but of a different structural type and biogenetic origin (Conn, 1980).

Many studies on biosyntheses of defensive compounds, using administration of pure radiolabeled compounds, reveal a dependence on specific precursors that presumably do occur in the host (for reviews, see Duffey, 1976; Blum, 1981). It seems reasonable that variation in precursor type and abundance in the diet and biochemical similarity of precursor and defense could affect defensive quality and quantity in some cases, although experimental tests of these phenomena are lacking. The above studies clearly show that diet can have a major effect on autogenous defenses in specialists under some circumstances, and have no obvious effect in others.

The generalist feeding behavior of *R. guttata* may create a somewhat different situation from that found in specialists. We think there are two possible explanations for our results, one relating to precursor availability, the other to physiological effects of restricted diets. First, in contrast to extreme specialists where the single host plant is the sole source of precursors for autogenous defenses, a generalist such as *R. guttata* has a potentially large number of sources of precursors for its defenses. This assumes relative ubiquity of common precursors in host plants. Consequently, a lack of precursors—and detrimental effects on the defensive secretion—are unlikely to occur when the diet consumed is a varied one. However, the probability of consuming a diet that lacks adequate quantities of precursors should increase with decreasing diet breadth. This would be especially true if host-plant precursors are not ubiquitous, but are nonuniformly distributed and restricted to only some food plants. Restricted diets may therefore lead to an autogenous defense reduced in complexity and concentration because of a lack of adequate precursors on some single host-plant diets. Since we do not yet know what precursors are involved, it is not yet possible to determine whether or not this hypothesis is correct.

A second, and equally plausible, explanation is that restricting diet breadth causes a physiological stress on the insect. Under these conditions, allocation of energy and resources by the insect to growth and maintenance may take precedence over allocation to defense, biosynthesis of defensive compounds is reduced, and therefore the quality and quantity of the defensive secretion decreases. This hypothesis is compatible with our data showing that the greatest effects of diet restriction on defense occur with females. Females have a larger body size and much faster growth rate than males. Females triple the body weight following the molt to adult because they must allocate considerable resources to egg production. Male body weight only increases about 20% (Whitman, Jones and Blum, unpublished data). Consequently, under conditions of restricted diets, females are probably under considerable metabolic stress following the molt to adult, while males simply need to maintain their weight and may have sufficient resources to allocate to defense.

While the exact mechanisms must await further study, the effects of diet

that we observed raise some immediate methodological concerns. Many studies on arthropod defenses have examined a multitude of factors that might cause variation in the composition of autogenous defenses. These include age, sex, season, instar, caste, population, and genotype or colony (see reviews by Blum, 1981; Pasteels et al., 1983a; Prestwich, 1983). In many of these studies, the possible influence of diet due to local specialization (sensu Fox and Morrow, 1981) within or between insect populations on particular hosts has not been taken into account. In those studies in which dietary sources of variation have been examined, it is usual to investigate the influences of direct sequestration (e.g., Brower et al., 1982, 1984) or the direct role of specific host precursors in vitro (e.g., Nahrstedt and Davis, 1983). If the results we found for *R. guttata* hold for other insects, it may necessitate a reexamination of variation previously attributed to nondietary factors. In addition, while it is expected that dietary effects would be more noticeable in phytophages, it is quite possible that diet may also affect autogenous defenses in predaceous arthropods. The factors that influence the quality and quantity of autogenous chemical defenses in insects are likely to be complex. However, a better understanding of the ecological role of these defenses cannot be achieved without elucidating these factors and their interrelationships. In the case of *R. guttata*, it would appear the breadth of the diet is one such major factor.

ALLELOPATHIC EFFECTS OF *Chrysanthemum morifolium* ON GERMINATION AND GROWTH OF SEVERAL HERBACEOUS PLANTS

BONG-SEOP KIL and SEOUNG YOUB LEE

Department of Biology Education and Department of Agronomy
Won Kwang University
Iri, Republic of Korea

(Received July 29, 1985; accepted February 26, 1986)

Abstract—Aqueous extracts obtained from young green tops of *Chrysanthemum morifolium* inhibited the germination of six flowering plants, including chrysanthemum itself, provided for experiments. The same phenomenon was also clearly observed when powder made from young green tops and old leaves of chrysanthemum was used. Moreover, the growth of seedlings planted again in garden soil which was once used for the culture of chrysanthemum was greatly interrupted. Chrysanthemum cultured in used garden soil showed far less dry weight than that cultured in fresh garden soil. The weight of chrysanthemum cultured using its root exudates was also less than that cultured with water leachate of fresh garden soil, and therefore these results may be considered to indicate allelopathic effects. In order to find the allelochemicals related to this phenomenon, benzoic acid and phenolic acids such as salicylic, *p*-hydroxybenzoic, vanillic, gentisic, protocatechuic, syringic, gallic, ferulic, and caffeic acids were identified by gas chromatography.

Key Words—*Chrysanthemum morifolium*, Allelopathy, aqueous extract, used garden soil, phenolic acids, gas chromatography, continuous cropping, germination inhibition rate, autointoxication.

INTRODUCTION

From the interference viewpoint, allelopathy is an important phenomenon in plant–plant interaction. Since Molisch (1937) coined the word, allelopathy has been studied by many scholars. There have been numerous reports of the production by plants of phytotoxic substances which inhibit seed germination and seedling growth of the same and other plants (Muller, 1969; Chou and Lin,

0098-0331/87/0200-0299$05.00/0 © 1987 Plenum Publishing Corporation

1976; Dalrymple and Rogers, 1983; Rice, 1984). It has also been shown that continuous cropping causes a harmful effect on the growth of some crops such as tomato, red pepper, Korean ginseng, and chrysanthemum, and therefore crop rotation is essential. Tukey (1969) reported that chrysanthemum cannot grow for several years in the same soil, Ballantyne (1962) demonstrated that growth inhibitors are released from the roots of chrysanthemum, and Lee and Chang (1969) stated that soil-sickness is caused by toxic substances secreted from the roots of chrysanthemum. Kozel and Tukey (1969) identified phenolic compounds as the toxic substances by the foliage of chrysanthemum, and Osawa et al. (1973) identified chlorochrymonin, a sesquiterpene lactone from chrysanthemum.

Although these studies were carried out in various ways, few comprehensive reports have dealt intensively with allelopathy of chrysanthemum or investigated minutely its phytotoxic substances. Therefore, it was intended in this study to (1) investigate the effects of young green tops, leaves, and garden soil of chrysanthemum on seed germination and growth of some selected plant species and (2) identify phytotoxins of chrysanthemum using chemical methods.

METHODS AND MATERIALS

Aqueous Extracts of Chrysanthemum and Garden Soil. One hundred grams of chrysanthemum green tops were put into 3000 ml of distilled water and ground fine, so that aqueous extracts could be obtained. After two sheets of filter paper (11 cm in diameter) were spread on Petri plates (12 cm in diameter) and 100 grains of sample seeds, that is, *Chrysanthemum morifolium*, *Callistephus chinensis*, *Cosmos bipinatus*, *Petunia hybrida*, *Celosia cristata*, or *Coleus Blumen*, were sown on it, 100 ml of aqueous extracts were applied to each Petri plate and then water was given to control plates. These plates were sealed and kept in a 25°C growth chamber. The aqueous extract and water were applied to each plate every two days and seed germination was recorded every day. This experiment was repeated three times.

It was intended in this study to introduce the concept of percent germination inhibition rate (GIR) in order to evaluate quantitatively the effect of phytotoxic substances of chrysanthemum according to concentration gradient on the germination of experimental species. The following formula was employed for the calculation of GIR.

$$\text{GIR} = \left(1 - \frac{\text{Germination rate of experimental species}}{\text{Germination rate of control species}}\right) \times 100$$

About 20 days after chrysanthemum bloomed in the previous year, its leaves and young green tops 10–15 cm in length were collected, dried, powdered, and passed through a #40 mesh sieve. After one sheet of filter paper (14

cm in diameter) was placed in each Petri plate (12 cm in diameter), 0.5 or 1 g of the powder was spread over each plate and 20 ml of distilled water added. The plates were sealed, kept for 20 h at 25°C, and filtered. Aqueous extracts thus obtained were used for germination experiments, 10 ml added to each plate, and water was used for the control. One hundred each of the sample seeds of *Callistephus chinensis*, *Cosmos bipinnatus*, *Tagetes electa*, *Petunia hybrida*, *Celosia cristata*, *Salvia splendens*, and *Portulaca grandiflora*, was planted in each pot, covered with 20 g of vermiculite, and distilled water was added. Ten days after germination, 200 ml of Boysen Jensen's nutrient solution were supplied once every four or five days. The plants were harvested in 55 days, washed clean, and dried in an oven at 80°C. This experiment was repeated three times.

Root exudate was obtained by culturing chrysanthemum to a height of about 30 cm in the same flowerpots used the previous year and pouring distilled water into them for 24 h. Root exudate thus gathered was poured continuously over fresh garden soil in flowerpots and distilled water was used for the control. Plastic pots (each 12 × 7 cm) were filled with 300 g of vermiculite and 50 seeds of *Callistephus chinensis*, *Cosmos bipinnatus*, *Tagetes electa*, *Petunia hybrida*, *Celosia cristata*, *Salvia splendens*, or *Portulaca grandiflora*, were sown in each pot. After germination, 200 ml of the root exudate were supplied every two days. The same procedure as above was applied in supplying nutrient solution and harvesting after germination and growth. This experiment also was repeated three times.

Identification by Gas Chromatography. The analysis of various extracts was performed using a Varian 2440 gas chromatograph equipped with 6-ft × $\frac{1}{8}$-in. (inside diameter) stainless-steel column packed with 2.5% SE-30 on ABS 90–100 mesh sieve. The flow rate of helium carrier gas was 40 ml/min. The flame ionization detection was set at a sensitivity of 2 × 10 mv. Injection port and detector temperature were held at 230°C and 205°C, respectively. The column temperature was programmed at a rate of 6°/min from 100°C to 250°C. One microliter sample injection was made with a 5-ml SGE syringe employing the solvent flush technique. Otherwise, the extraction and procedures of gas chromatography were as before (Kil and Yim, 1983).

RESULTS

Germination Experiment. The germination of six species, including *Chrysanthemum moriflorium*, was determined using aqueous extracts of young green tops of chrysanthemum (Table 1). All of these showed a significant inhibition of germination rate compared with the control at the 5% level. Although chrysanthemum itself showed germination inhibition by its own extract, the degree of its harmful effect was not so severe. However, the germination inhibition

TABLE 1. EFFECTS OF AQUEOUS EXTRACTS OF CHRYSANTHEMUM SEEDLING GREEN TOPS ON PERCENT GERMINATION

Species	Germination (%)		GIR
	Control	Test	
Chrysanthemum morifolium	61.3	52.0[a]	15.2
Callistephus chinensis	65.7	52.0[a]	20.9
Cosmos bipinnatus	78.3	65.7[a]	16.7

Celosia cristata	81.8	72.7[a]	11.1
Coleus Blumen	65.0	54.7[a]	15.9

[a]Significantly different from control at 5% level by *t* test comparison.

rate (GIR) of *Petunia hybrida* and *Celosia cristata* showed less effect of the extracts than the other five species. *P. hybrida* belongs to the Solanaceae and *C. cristata* to the Amaranthaceae, while the remaining five species belong to the Compositae.

Aqueous extracts of young green tops and old leaves of chrysanthemum inhibited seed germination of all species compared with the control (Table 2). Moreover, the germination rate was lower in the high concentrations of the extracts (B in Table 2) than in low concentrations. Especially severe inhibitory effects were observed in the germination of treated *Callistephus chinensis* and *Cosmos bipinnatus*. According to the results of Duncan's multiple-range test, such germination inhibitory effects were significant at the 5% level.

[a] Significantly different from control at 1% level by *t* test comparison.

experiment was markedly lowered when they were cultured in garden soil used in the previous year (Table 3), indicating an allelopathic phenomenon. Dry weight of the seedlings of *Celosia cristata* harvested from the experimental plot 55 days after sowing was 414.04 mg and that of the control was 935.36 mg, thereby showing only 44.3% growth of the control. Similar results could also be observed in *Petunia hybrida*, i.e., 846.32 mg of the control and 436.24 mg of the experimental plot in dry weight or 51.5% of the control.

Seedling growth of the seven experimental species cultured with water leachate obtained by washing the roots of chrysanthemum was markedly inhibited (Table 4). The growth of *Celosia cristata* and *Petunia hybrida* was severely

affected by the leachate of chrysanthemum, whereas the other five species were less affected in their growth.

Identification of Phytotoxic Substances. The leaves, roots, young green tops, and old leaves of *C. morifolium* were analyzed by gas chromatography (Table 5, Figures 1 and 2). Benzoic acid and nine kinds of phenolic acids were detected; i.e., salicylic, *p*-hydroxybenzoic, vanillic, gentisic, protocatechuic,

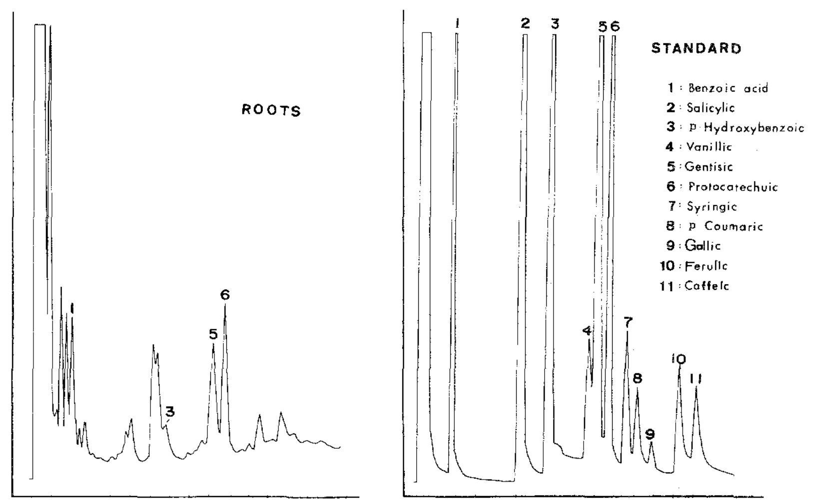

FIG. 1. Gas chromatograms of chemical substances from *Chrysanthemum morifolium* roots.

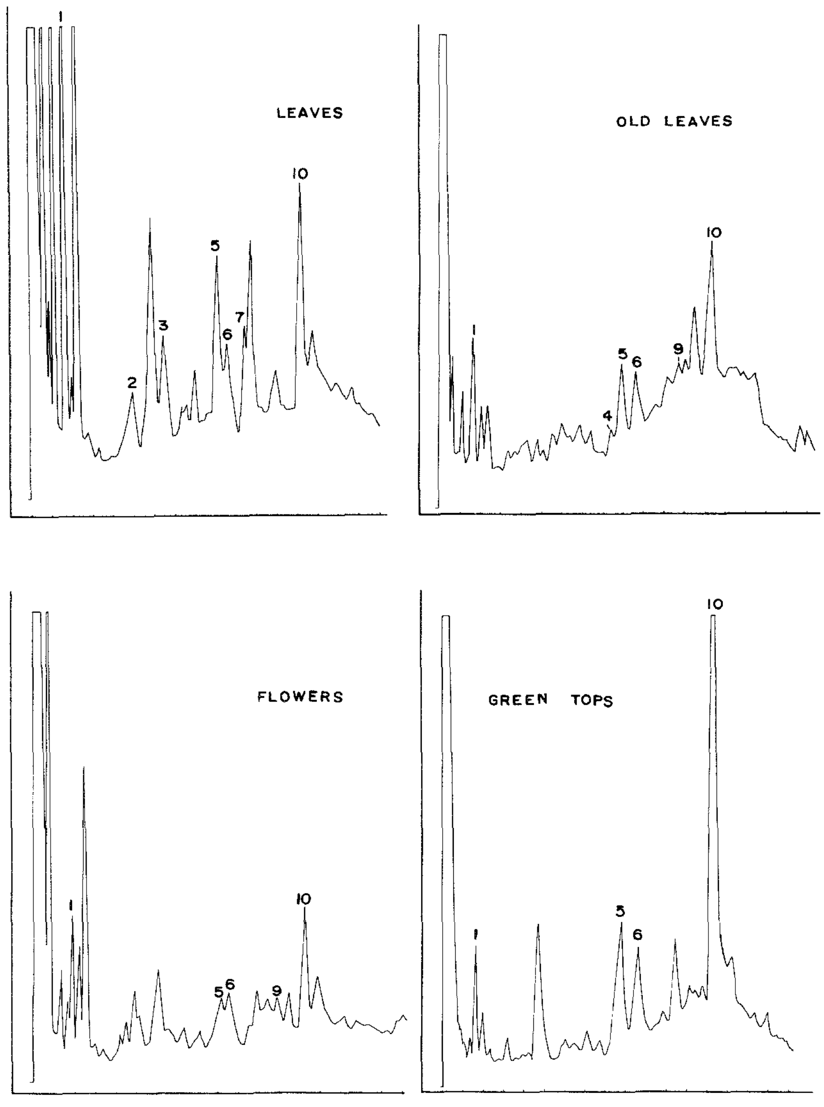

FIG. 2. Gas chromatograms of chemical substances from *Chrysanthemum morifolium* shoots.

syringic, gallic, ferulic, and caffeic acids. It was also confirmed that benzoic, gentisic, protocatechuic, and ferulic acids were contained abundantly in all materials used for the analysis (Figures 1 and 2). Seven kinds of compounds were detected from the leaves and flowers of chrysanthemum, six from old leaves and five from roots and young green tops.

DISCUSSION

The experimental data given in Table 1 show that the aqueous extracts of chrysanthemum had an inhibitory effect on the germination of other experimental species. The aqueous extract of young green tops of chrysanthemum was harmful to all test species. This fact suggests that both the young leaves and stems of chrysanthemum contain phytotoxic substances.

Considering results of the experiments, it is apparent that seed germination of chrysanthemum is inhibited by chemical substances contained in chrysanthemum itself, indicating an autointoxication phenomenon as reported by other researchers (Chou and Lin, 1976; Hussain et al., 1983). The experimental species *P. hybrida* and *C. cristata*, which are different from the chrysanthemum family, were lower in GIR than those belonging to the same family. This finding agrees with the results reported by other researchers (Hayashi and Takiyo, 1959; Lee and Lee, 1982).

On the other hand, the seed germination of every experimental species was severely inhibited by the aqueous extract of the leaves of chrysanthemum. Now, there remains a question of which chemical substances contained in chrysanthemum exert an inhibitory action on the seed germination of plants. In order to solve this problem, different experiments were carried out, and the results obtained are presented in Table 2. Aqueous extracts of chrysanthemum in low and high concentration were used in this experiment. The germination rate of the experimental plot showed far greater inhibition than that of control. Moreover, the germination inhibition rate was statistically significant in all experimental species, and therefore it seems that the young green tops of chrysanthemum also contain certain germination inhibitors, a fact already reported (Ashraf and Sen, 1978; Datta and Chattergee, 1980; Chou and Yang, 1982; Schon and Einhellig, 1983; Kil and Yim, 1983).

Chrysanthemum apparently secreted phytotoxic substances, and therefore the growth of its seedlings was inhibited when cultured in used garden soil. There have been many reports proving that plants secrete phytotoxic substances into the soil in which they grow (Guenzi and McCalla, 1966; Wang et al., 1967; Patrick, 1971; Carballeira, 1980). It is well known that when a farmer cultures chrysanthemums again in previously used garden soil, the yield is reduced. This result has not been shown to be attributable to any inorganic nutrient contained in the soil or to other factors, but the evidence is strong that it is due to an allelopathic effect. It is clearly proven by the result of the present experiments that even the roots of chrysanthemum produce phytotoxins (Table 4). It may further be interpreted that some toxic substances produced by chrysanthemum are increasingly accumulated and harm other plants.

The results of this growth experiment with seven species show that phytotoxic substances of chrysanthemum had greater inhibitory effects on plants of distant families than on Compositae. This finding agrees with the report that

toxins secreted from the roots of eggplant, tomato, wheat, barley, and rice are harmful to the growth of plants. In other words, chemical substances secreted from a species are usually more harmful to distant plants that those of close relationship (Takiyo and Hayashi, 1959).

Nine kinds of phenolic acids and benzoic acid were identified in the chrysanthemum with gas chromatography. Many researchers have already reported that germination, shoot elongation, and total seedling growth are inhibited by phenolic acids (Olmsted and Rice, 1970; Kaputska and Rice, 1976; Tinnin and Muller, 1972; Rice et al., 1980). Such chemical substances are secreted during the decaying process of plants (Shindo and Kuwatsuka, 1977) or foreign chemical substances exert inhibition only in low nutrient concentrations (Stowe and Osborn, 1980). It is also reported that ferulic and caffeic acid inhibit nitrification (Rice and Pancholy, 1974). In conclusion, the phytotoxins of chrysanthemum have inhibitory effects on the germination of various herbaceous plants including chrysanthemum itself and growth of young plants. The nine phenolic acids and benzoic acid are considered to be important allelochemicals.

PLANT SECONDARY COMPOUNDS AS OVIPOSITION DETERRENTS FOR CABBAGE BUTTERFLY, *Pieris rapae* (LEPIDOPTERA: PIERIDAE)

BRUCE E. TABASHNIK

Department of Entomology, University of Hawaii
Honolulu, Hawaii 96822

(Received November 12, 1985; accepted February 26, 1986)

Abstract—Oviposition by *Pieris rapae* butterflies was deterred by spraying the plant secondary compounds coumarin and rutin on cabbage plants in greenhouse choice tests. In no-choice tests ranging from 5 min to 24 hr, acceptance of rutin-treated plants for oviposition increased with trial duration. Both coumarin and rutin deterred oviposition primarily by affecting prealighting rather than postalighting behavior, indicating that deterrence was mediated by noncontact cues.

Key Words—Oviposition deterrence, oviposition behavior, *Pieris rapae*, cabbage butterfly, Lepidoptera, Pieridae, coumarin, rutin, plant secondary compounds, insect-plant interactions, cabbage, Cruciferae.

INTRODUCTION

For insects such as Lepidoptera, host selection by mobile adults is crucial in determining the fitness of their less mobile offspring (Scriber, 1984; Tabashnik and Slansky, 1987). Egg-laying females identify suitable plants by chemical and physical stimuli that characterize such plants (Miller and Strickler, 1984). Plant secondary compounds (allelochemicals) typical of a given plant may be oviposition stimulants for insects which feed on that plant (e.g., Gupta and Thorsteinson, 1960; Rodman and Chew, 1980; Renwick and Radke, 1983). In contrast, oviposition by a particular insect may be deterred by compounds that occur at high levels in unsuitable plants, but not in suitable plants (Tingle and Mitchell, 1984; Mitchell and Heath, 1985). Plants suitable for a particular insect may also contain compounds that deter oviposition by that insect (Renwick and Radke 1981, 1985). Oviposition deterrence by plant compounds could have significant consequences for management of crop pests.

Previous work showed that chemical extracts from noncruficerous plants deter oviposition by the crucifer-feeding cabbage butterfly, *Pieris rapae* L. (Lundgren, 1975; Renwick and Radke, 1985). However, relatively little is known about the effects of individual compounds as oviposition deterrents. The plant secondary compounds coumarin and rutin are potential oviposition deterrents for *P. rapae* because they do not occur in crucifers at substantial levels, but they are present at high concentrations in many noncruciferous herbs. Coumarin occurs in members of several plant families (e.g., Compositae, Lauraceae, Leguminosae, Umbelliferae), in some cases as the major aromatic constituent (Leung, 1980). Rutin is a nonvolatile flavonoid pigment found in numerous plant families, with concentrations of up to 24% of leaf dry weight recorded for some species (Leung, 1980). Both coumarin and rutin deterred oviposition by the crucifer pest, *Plutella xylostella* L. (Tabashnik, 1985).

The study reported here examined how *P. rapae* oviposition is affected by application of coumarin and rutin to cabbage plants. The effects of the compounds on oviposition, prealighting behavior, and postalighting behavior were investigated using choice and no-choice behavioral assays.

METHODS AND MATERIALS

Insects. Adults were obtained from a laboratory colony 5–8 generations removed from field populations at the Pearl City Instructional Facility community garden, Oahu, Hawaii. Crucifers available for oviposition at the Pearl City field site include broccoli, cabbage, and watercress; larvae were fed broccoli in the laboratory colony (Haji-Mamat, 1984).

Plants. Cabbage plants were grown from seed ("C-G Cross," Takii and Co., Ltd.) in the greenhouse in plastic pots (9.5 × 10 × 10 cm) filled with vermiculite. Seedlings were fertilized with dilute Ortho-Gro® Liquid Plant Food 12-6-6 (1 ml : 200 ml H_2O) within one week after planting. Plants used in behavioral assays were treated with either a control solution of 0.5% Tween 80 (polyoxyethylene sorbitan monooleate, Sigma) in water or a solution of 0.5% Tween 80 in water plus the test material. Solutions tested were coumarin (Kodak) and rutin (Sigma). Solutions were thoroughly shaken in a 235-ml polyethylene jar, then sprayed on upper and lower plant surfaces for about 3 sec using aerosol propellant (Sigma spray kit). The amount of solution applied to leaves was estimated by weighing 10 leaves immediately before and after spraying. The estimated mean volume of solution sprayed on leaves was 0.294 ml (±0.022 SE)/g leaf fresh weight, indicating that leaves sprayed with coumarin solutions of 0.1 M and 0.01 M had approximately 4.3 mg and 0.43 mg coumarin/g leaf fresh weight, respectively. Estimated values for applied rutin concentration were 19.6 and 1.96 mg/g leaf fresh weight, for 0.1 M and 0.01 M solutions, respectively.

Behavioral Assays. All behavioral assays were conducted between February and June 1984 in the Entomology Department greenhouse at the University of Hawaii Manoa Campus. Daily maximum temperatures were 29 ± 2°C and daily minimums were 22 ± 2°C; the natural photoperiod (ca. 12 hr light) was used. Groups of females (3–10) with approximately equal numbers of males were tested in screen cages (50 cm on each side) in all experiments. Cotton dental wicks immersed in dilute honey-water (1 ml : 5 ml) solutions in open vials were suspended from the cage tops to provide food for adults. Within the constraints imposed by confinement, behavior of females in the assays was similar to their field behavior (Chew 1977); females laid their eggs singly and usually flew off the plant after oviposition.

Choice Tests. One plant treated with control solution and another treated with either a coumarin or rutin solution were placed in diagonally opposite corners of each cage. Trials lasted 2–3 days. Eggs were counted after each trial, and plant positions in the cage were alternated in successive trials.

No-Choice Tests. Females were offered either two control plants or two treated plants (either coumarin or rutin at 0.1 M). Plants were placed in diagonally opposite corners of the cage. In the 5-min no-choice tests, each group of females was tested for 10 trials, consisting of an alternating sequence of control and treated plants offered for 5-min periods, with less than 1 min between trials. For no-choice tests lasting 15 min, 60 min, and 24 hr, groups of females were paired so that one group was offered two control plants while, at the same time, a matched group of equal numbers and age was offered treated plants. In the next trial, the plants were switched so that the first group received treated plants while the second group received controls.

Pre- and Postalighting Behavior. Females were observed during behavioral assays to determine how coumarin and rutin influenced their pre- and postalighting behavior. "Contacts" were recorded when females touched a plant with one or more legs.

Analysis. G tests for goodness of fit, adjusted for sample size as necessary (Sokal and Rohlf, 1969), were used throughout. The statistical significance of deterrence was determined by contrasting observed frequencies of behaviors (ovipositions or contacts) on control vs. test plants with the 1 : 1 frequency of behaviors expected if butterflies did not differentiate between treatments. Ratios of behaviors (eggs laid/contact) on control vs. test plants were contrasted by testing for independence in 2×2 contingency tables (Sokal and Rohlf, 1969). The 2×2 contingency analysis was also used to compare frequencies of eggs on control vs. plants treated with rutin (0.1 M) in no-choice tests of various duration. Means (±SE) for percentages of eggs on treated plants were calculated to provide a rough index of variation among replicates. Statistical inferences from ANOVA on the percentages were generally consistent with the G tests.

RESULTS

Choice Tests. Both coumarin and rutin deterred oviposition by *P. rapae* (Table 1). At both concentrations tested, coumarin was a weak deterrent. Rutin at 0.1 M caused a fivefold reduction in oviposition, but 0.01 M rutin did not deter oviposition.

No-Choice Tests. Responses to cabbage plants treated with 0.1 M rutin in no-choice tests depended on the trial duration, with observed deterrence inversely related to trial duration (Table 2). Deterrence was strongest in the 5-min no-choice test, intermediate in 15- and 60-min no-choice tests, and weakest in the 24-hr no-choice test.

Pre- and Postalighting Behavior. Coumarin and rutin deterred oviposition primarily by affecting prealighting rather than postalighting behavior. Direct behavioral observations showed that both compounds significantly reduced the number of contacts with plants (Table 3). Analysis of the ratio of eggs laid/contact showed that after contacting a plant, females were somewhat less likely

to oviposit on treated plants than on control plants (Table 3). However, the effects of coumarin and rutin on postalighting behavior were small compared to the prealighting effects.

DISCUSSION

The results of this study support the view that host acceptance by insect herbivores is mediated by positive and negative stimuli from plants and by internal levels of satiation (Dethier, 1982). Both coumarin and rutin deterred oviposition by *P. rapae*, yet females laid some eggs on treated plants in nearly all experiments. These results suggest that the cabbage plants provided strong positive stimuli, whereas the applied compounds were negative stimuli that reduced the acceptability of treated cabbage plants significantly, but not completely.

In no-choice tests, acceptance of rutin-treated plants relative to control plants increased with trial duration. It is unlikely that the reduced deterrence of rutin seen in prolonged no-choice tests was due to rutin concentration declining through time. Rutin's deterrence remained effective in choice tests lasting 2–3 days (Table 1) and plants treated with rutin 24 hr before testing did not show reduced deterrence compared to plants treated with rutin immediately before testing. Another possibility is that the control plants became less acceptable as the number of eggs per control plant increased in no-choice tests of increasing duration. Egg-load assessment is reported to ocur for some *P. rapae* populations (Rothschild and Schoonhoven, 1977) but not others (Ives, 1978; Traynier, 1979; Shapiro, 1981). Results from a no-choice test in the present study show that the rate of oviposition on a clean control plant (9.3 eggs laid/female/hr) was not greater than the rate of oviposition on a control plant with 56 eggs (10.0 eggs

laid/female/hr), suggesting that acceptance of control plants in no-choice tests did not decline due to egg-load assessment. It seems that increased acceptance of rutin-treated plants occurred because females were deprived of the opportunity to oviposit on untreated plants. This type of behavior is analogous to increased acceptance of nonpreferred host-plant species when preferred species are unavailable (e.g., Singer, 1982, 1983; Tabashnik, 1983a, b; Tabashnik et al., 1985).

Time available for oviposition may be a limiting factor for butterflies like *P. rapae*, which lay their eggs singly (Tabashnik 1983a). Thus, single egg-layers may accept nonpreferred plants for oviposition more readily than cluster egg-layers. The results show that during 5-min trials, *P. rapae* consistently rejected treated plants, while consistently accepting untreated plants (Table 2). During trials of 15 min or longer, however, females accepted treated plants, indicating that the "discrimination phase" (Singer, 1982) for *P. rapae* in these experiments was between 5 and 15 min. These results are consistent with earlier findings (Tabashnik, 1983a) supporting the hypothesis that single egg-laying butterflies have relatively short discrimination phases.

Analysis of pre- and postalighting behavior revealed that the compounds reduced oviposition primarily by lowering the rate at which females contacted plants, indicating that deterrence was mediated by noncontact cues. These observations conflict with the notion that host-plant chemistry is most important in determining postalighting rather than prealighting behavior. However, secondary compounds were applied topically in this study, and thus their impact on behavior may not mimic the effects of compounds incorporated in leaves. The volatile compound, coumarin, probably deterred oviposition by alteration of olfactory cues. The noncontact effects of the nonvolatile pigment, rutin, were probably mediated by vision.

The results suggest that plants producing a secondary compound typical of nonhosts might gain some protection from specialist herbivores by reducing their acceptance to ovipositing females. If the observed responses to coumarin and rutin by *P. rapae* and *Plutella xylostella* (Tabashnik, 1985) are indicative of general trends, then this protection would only be partial—even when a compound was produced in relatively high quantities. If the compound reduced the plant's suitability, selection would be expected to increase discrimination against it. Alternatively, if the compound had a neutral or positive effect on suitability, selection would act to reduce the deterrent effect of the compound.

The results imply that nonhost-plant secondary compounds might confer partial crop protection by deterring oviposition. Due to increasing acceptance of treated plants when untreated plants are absent, treatments would be most effective when some plants were left untreated as a "trap crop." Application of plant secondary compounds to protect crops poses many of the same problems and hazards as do conventional pesticides, yet this technique offers potential as a tool to be integrated with other pest control measures (Schoonhoven,

1982). Attempts to deter oviposition by mobile adults may be more fruitful than tactics aimed at reducing consumption by immatures.

Acknowledgments—I am especially grateful to J.A.A. Renwick for stimulating my interest in deterrents and for sharing his insights. I thank R.F. Chapman, F. Gould, M.O. Harris, M.W. Johnson, W.J. Mattson, J.R. Miller, L.M. Schoonhoven, M.C. Singer, and C. Wiklund for their comments and encouragement. H.B. Haji-Mamat shared knowledge and butterflies, F. Chang gave excellent technical advice, and S. Arnold provided expert laboratory assistance. Special thanks to R.H. Krakauer for unfaltering moral support. Financial support was provided by a grant from the Research and Training Fund, University of Hawaii and USDA-HAW00947H. This is paper no. 2997 of the Hawaii Inst. of Trop. Ag. and Human Res. Journal Series.

SEPARATION AND IDENTIFICATION OF PHENOLIC ACIDS AND RELATED COMPOUNDS BY GAS CHROMATOGRAPHY AND FOURIER TRANSFORM INFRARED SPECTROSCOPY[1]

J.H. MELHUISH, JR., R.B. WILLIS, and C.S. WRIGHT

USDA-Forest Service Northeastern Forest Experiment Station
1835 Big Hill Road, Berea, Kentucky 40403

(Received November 20, 1985; accepted February 26, 1986)

Abstract—Phenolic acids and related compounds were separated by gas chromatography using three separate columns. One of these columns was coupled to a Fourier transform infrared spectrometer. The trimethylsilyl derivatives could be separated and identified by comparing the relative retention times of the three different columns. However, where there was overlap, the accompanying infrared data clearly distinguished between the questionable derivatives, thus enabling characterization of all derivatives.

Key Words—Phenolic acids, gas chromatography, Fourier transform spectroscopy.

INTRODUCTION

Phenolic acids and related compounds constitute one of the largest groups of secondary metabolites in plants. They are found as esters or as glycosides when combined with sugar and are water soluble and easily leached from plant tissue. These compounds also have been shown to be allelopathic to plant growth (Rice, 1974; Horsley, 1977). Humic acids, produced by oxidation of phenolic acids, increase the production of the superoxide radical O_2^-. This radical is involved in the destruction of cell membranes and is thus highly toxic to biological systems (Vaughan and Ord, 1982). Phenolic acid compounds also have been found

to be inhibitory to certain mycorrhizal fungi that are essential for the establishment and growth of trees on harsh environments such as surface mined areas (Melhuish and Wade, 1985; Schramm, 1966). Therefore, a relatively quick and easy technique for separating and identifying phenolic acids and related compounds would aid in studying their role in vegetational systems.

Gas chromatography is a common and relatively inexpensive method used to separate organic compounds. The separation of phenolic compounds by gas chromatography, using either one or two columns, has been reported (Vande Casteele et al., 1976; Dallos and Koeppl, 1969; Horvat and Senter, 1980). In gas chromatography, however, two or more compounds may have similar retention times on a given column. This peak overlap makes qualitative and quantitative analysis of any compound difficult. It would be advantageous to use more than one column because compounds that are not resolved on one column may be resolved on a column of different chemical composition (Patterson, 1971). If the information obtained from multicolumn gas chromatography can be supplemented by the additional information given by coupled Fourier transform infrared spectroscopy (FTIR), a technique not previously used in these studies, then the indentification of these phenolic compounds can be produced more quickly and accurately than by one or two columns alone. This paper reports on the results of using such a coupling technique.

METHODS AND MATERIALS

Instrumentation. Gas chromatographic analysis was performed using two separate gas chromatographs: a Beckman GC-65 with Beckman 10-in. recorder and Spectra-Physics intergrator, and a Varian 3700 with Varian 9176 recorder and CDS 111 integrator. Two columns were used in the Beckman GC: (1) glass (1.8 m × 6.0 mm OD) with Gas Chrom WHP (80–100 mesh) packed stationary phase and 3% SE-52 liquid phase and (2) stainless steel (4.6 m × 9.6 mm OD) with Gas Chrom Q (100–120 mesh) packed stationary phase and 1% SE-30 liquid phase. One column was used on the Varian GC: stainless steel (2.0 m × 3.2 mm OD) packed with Gas Chrom WHP (80–100 mesh) stationary phase and 3% OV-17 liquid phase. Both the Beckman and Varian instruments were equipped with flame ionization detectors.

Infrared analysis was performed using the Varian 3700 GC described above with an OV-17 column and thermal conductivity detector attached to a Digilab FTS-15C Fourier transform infrared spectrometer. The data were handled using a Data General Nova 3 computer.

Materials. The 25 phenolic and organic compounds analyzed were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin), Sigma Chemical Co. (St. Louis, Missouri), Eastman Kodak Co. (Rochester, New York), and ICN Pharmaceuticals (Cleveland, Ohio). The derivatizing agent was Tri-Sil/

BSA in dimethylformamide manufactured by Pierce Chemical Co. (Rockford, Illinios).

Procedure. Trimethylsilyl (TMS) derivatives of the compounds were formulated using Tri-Sil/BSA because of its one-step simplicity. The derivatizing procedure was followed as described by the manufacturer; 8 mg of the pure compound was heated at 67°C for 8 min to ensure complete silylation. The sensitive nature of some of the compounds required extra care to minimize light and moisture exposure.

For gas chromatography, operating conditions were maintained as similar as possible on all columns. The hydrogen and air flow rates were the same on both instruments—30 cc/min and 300 cc/min, respectively. The helium flow rates were slightly different by column: 20 cc/min (SE-52), 24 cc/min (OV-17), and 30 cc/min (SE-30). The injector and detector temperatures were also slightly different on the two instruments, 230°C and 280°C for the Beckman injector and detector temperatures, and 220°C and 250°C for the Varian injector and detector temperatures. The programmed column temperatures were identical for all columns. The initial temperature of 155°C was held for 2 min, then programmed to rise at 5°C/min to a final temperature of 265°C. One-microliter preparations were injected into the OV-17 and SE-52 columns, and 5-μl injections were used in the SE-30 column because of lack of sensitivity. All derivatives were analyzed three times and standard deviations were calculated.

The complete set of 25 derivatives was analyzed individually by GC-IR to give identifying spectra. A thermal conductivity detector was used in the GC and had a temperature of 250°C, a filament temperature of 310°C, and a filament current of 210 mA. The carrier gas flow rate, injector temperature, and column temperature program were the same as those in the gas chromatographic analysis for the OV-17 column. However, because of the less sensitive nature of the FTIRs liquid nitrogen-cooled, mercury–cadmium telluride photodetector (MCT), aliquots of 7 μl were injected. The FTIRs parameters were set to a resolution of 8, a sensitivity of 16, and a scan range of 4000 cm^{-1} to 650 cm^{-1}. Upon elution from the GC, the FTIR was manually triggered, and 10 scans were taken and averaged to give the spectra. Each derivative was run three times.

RESULTS

Triplicate runs of each derivative on each column resulted in the mean relative retention times given in Table 1. The relative retention times are relative to benzoic acid, which had actual retention times of 0.78 min (OV-17), 1.17 min (SE-52), and 2.55 min (SE-30). The standard deviations of all retention times were between 0.01 and 0.05 min. The longest actual analysis time was 50.57 min for chlorogenic acid on the SE-30 column.

TABLE 1. GAS CHROMATOGRAPHIC RELATIVE RETENTION TIMES OF TMS DERIVATIVES BY COLUMN RELATIVE TO BENZOIC ACID

TMS derivatives	OV-17	SE-52	SE-30
Benzoic acid	1.00	1.00	1.00
Catechol	1.04	1.40	1.35
2-Hydroxybenzyl alcohol	1.55	2.19	1.85
Salicylic acid	2.50	2.95	2.24
8-Hydroxyquinoline	3.54	3.38	2.29
trans-Cinnamic acid	3.59	3.42	2.46
Phloroglucinol	3.64	4.86	3.28
4-Hydroxybenzoic acid	3.81	4.76	3.24
Vanillin	3.82	3.34	2.32
Coumarin	4.05	2.94	1.94
3,4-Dimethoxybenzyl alcohol	4.32	4.08	2.63
Vanillic acid	6.81	6.85	4.17
Photocatechuic acid	7.04	7.91	4.76
alpha-Resorcylic acid	7.29	7.97	4.74
Guaiacol glycerol ether	8.24	7.73	4.68
2,3,4-Trihydroxybenzoic acid	8.68	9.55	5.57
Gallic acid	9.92	10.78	5.99
4-Hydroxycinnamic acid	10.38	9.64	5.61
Syringic acid	10.46	9.09	5.27
4-Hydroxyphenylpyruvic acid	12.04	11.87	6.64
Caffeic acid	14.03	13.26	7.36
Ferulic acid	14.42	12.28	6.76
Chrysophanic acid	26.63	20.76	10.61
Emodin	30.67	25.35	13.71
Chlorogenic acid	33.09	33.63	19.83

The FTIR with GC attachment enabled the vaporized derivatives to be scanned directly from the GC at a rate of 4 scans/sec for 2.5 sec. The computing and averaging of these scans was done by the Data General computer. The major infrared peaks are listed in Table 2 in units of wavenumbers (cm^{-1}). These values are within the operating error of four wavenumbers for the Digilab FTS-15C instrument.

DISCUSSION

The analysis of the gas chromatographic data revealed some general trends in the retention times of the phenolic derivates. With all three columns, and especially the two SE columns, the retention times were generally linear with molecular weight, that is, the compounds with the lowest molecular weight eluted first. The exception is that the more polar compounds, such as the al-

[a]vs = very strong, s = strong, m = medium, w = weak, sh = shoulder, — = no peak, * = peak not resolved from adjacent peaks.

cohols, had the lowest retention times on the SE-30 column. This is expected with a nonpolar column and derivatives that are of intermediate polarity. In fact, this intermediate polarity caused the OV-17 and SE-52 columns to separate the phenolic TMS derivatives more efficiently than the nonpolar SE-30 column. The relative retention times of the derivatives also tended to follow the order: (lowest to highest retention times) benzoics, phenols, coumarins, cinnamics, and anthraquinones. Also because of the placement of substitution on the aromatic ring, there was a trend for the retention time to increase in order of ortho, meta, and para substitution. Other trends in retention times involve the number and type of substituent. Nonsubstituted compounds eluted first followed by mono-, di-, and tri-substituted ones. The type and number of functional groups tended to alter the retention time with 2 OCH_3, 1 OH + 1 OCH_3, and 2 OH eluting in increasingly longer times, respectively. This latter relationship occurs

because the greater the number of OH groups attached to the ring the greater the amount of derivatization at these sites. The TMS radical is much heavier than the OCH_3 radical, resulting in longer retention times.

FTIR data peak assignments for the silylated compounds were in accordance with other researchers (Vande Casteele et al., 1976). The only deviation from normal peak assignment came in the carbonyl peak region where the values were 20 cm^{-1} to 30 cm^{-1} higher than previously reported values. This increase in wavenumber, due to reduced hydrogen bonding at the carbonyl site, occurred because the compounds were in the vapor phase, a result of GC-IR coupling, instead of in the solid or liquid phase. A 20–30 wavenumber shift is normal for the hydrogen bonding effect (Bellamy, 1975).

Each of the three GC columns generally gave good separation of the compounds tested. Tentative identification of most of the reference compounds could be made by using the three relative retention times for each compound. An example of this is the derivatives of 4-hydroxybenzoic acid and vanillin. On the OV-17 column, the relative retention time difference was very close (0.01 min), whereas the difference on the SE-52 column was 1.42 min and on the SE-30 column 0.92 min. The OV-17 column did not separate the two derivatives, but by injecting the derivatives into each of three columns, both separation and tentative identification were performed. There were some compounds with GC retention times so close that, regardless of the column used, further information was needed for identification. Examples of this are the derivatives of 8-hydroxyquinoline and *trans*-cinnamic acid. The greatest difference in the relative retention times was 0.17 min on the SE-30 column. Although this difference is larger than the 0.01- to 0.05-min standard deviation for the column, identification was unambiguous when the FTIR spectra were considered. 8-Hydroxyquinoline lacked a carbonyl peak in the 1600 cm^{-1} to 1800 cm^{-1} region, whereas *trans*-cinnamic acid showed a strong peak at 1713 cm^{-1}. Use of FTIR data in conjunction with GC data enabled us to separate and identify all the standards we used.

Because of the importance for the study of phenolic acids and related compounds in different biological disciplines, quick and accurate methods for separating and identifying these acids are needed. Although NMR and/or MS would be desirable to more exactly establish the identity of these compounds, our techniques may be a useful substitute for those laboratories not having the more expensive equipment.

Ridai-cho, Okayama 700, Japan

(Received November 26, 1985; accepted February 26, 1986)

Abstract—The synthesis of the racemate and two enantiomers of 15-methyltritriacontane (**1**), an active component of the sex-stimulant pheromone of *Stomoxys calcitrans* L., is described. Racemic 15-methyltritriacontane was synthesized in four steps from 1-hexadecene with a 72% overall yield. Both the *R*- and *S*-enantiomers were synthesized in eight steps, respectively, starting from optically pure (*R*)-(+)-pulegone.

Key Words—Stable fly, *Stomoxys calcitrans*, Diptera, Muscidae, sex-stimulant pheromone, methyl-branched hydrocarbon, 15-methyltritriacontane, pulegone, enantiomer.

INTRODUCTION

A number of methyl-branched hydrocarbons have recently been isolated from cuticular lipids of various fly species (Nelson, 1978; Carlson et al., 1984). Several hydrocarbons, selected as targets, have been synthesized as racemates, meso forms, or enantiomers, and their biological activities evaluated. It is of interest to note that only the meso form of 17,21-dimethylheptatriacontane, a component of the contact sex pheromone of *Glossina morsitans morsitans*, showed a pheromone activity (Ade et al., 1980; Helmchen and Langley, 1981), while all of the four stereoisomers of 15,19,23-trimethylheptatriacontane were equally active on the fly species (Helmchen and Langley, 1981). An active principle of the sex-stimulant pheromone of the stable fly, *Stomoxys calcitrans* L., 15-methyltritriacontane (**1**), was synthesized either as a racemate by Sonnet et al. (1977) or as two enantiomers by Sonnet (1984). There was no description

0098-0331/87/0200-0325$05.00/0 © 1987 Plenum Publishing Corporation

of the overall yield of the synthesized racemate or of the optical activity of the two synthesized enantiomers.

A matter of interest is the pheromone activities for the stereoisomers of methyl-branched hydrocarbons such as **1** (Scheme 1) in terms of the relationship

$$n\text{-}C_{14}H_{29}\text{CH=CH}_2 \longrightarrow n\text{-}C_{14}H_{29}\text{CH(CH}_3\text{)OH} \longrightarrow n\text{-}C_{14}H_{29}\text{C(CH}_3\text{)=O}$$

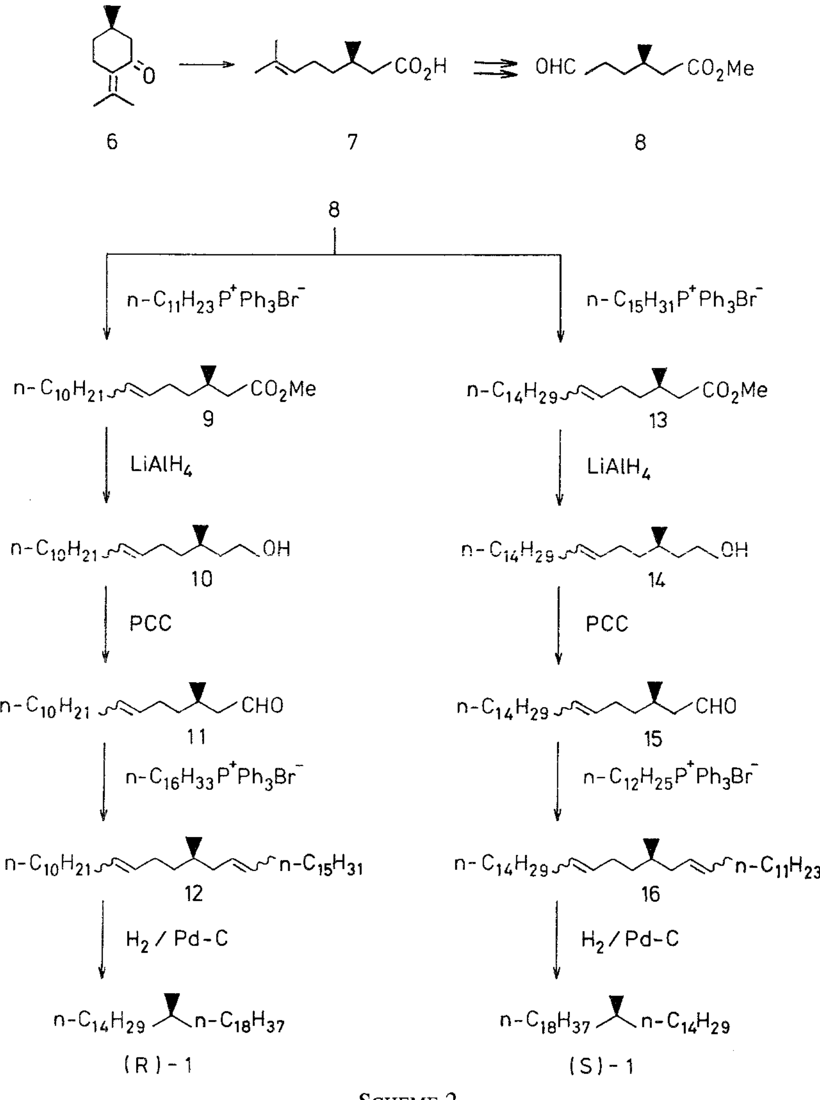
between absolute configuration and pheromone activity. Our synthetic approach is based on the Wittig reaction aimed at the synthesis of racemic **1** and the *R*- and *S*-enantiomers of **1** and includes the use of 1-hexadecene (**2**) and optically pure (*R*)-(+)-pulegone (**6**), respectively, as the starting materials (Scheme 2).

METHODS AND MATERIALS

Column chromatography was carried out employing 70–230 mesh silica gel (Merck Kieselgel 60 Art 7734). All solvent systems were expressed in ratios by volume (v/v). IR spectra were determined on a Hitachi model 270-30 spectrometer. [^{1}H]- and [^{13}C]NMR spectra were obtained on a Hitachi model R-24B spectrometer and on a Hitachi model R-90H Fourier transform NMR spectrometer, respectively, in $CDCl_3$ solutions using Me_4Si as an internal standard. EI and CI mass spectra were recorded on a JEOL model JMS-D300 double-focusing mass spectrometer at 70 eV and 200 eV, respectively, using a direct insertion probe. Optical rotations were determined on a JASCO model DIP-140 polarimeter. GLC analysis for the determination of the purity of the products was made isothermally at 250°C (N_2, 60 ml/min), employing a Hitachi model 163 gas chromatograph equipped with a 1-m × 3-mm glass column of 3% OV-1 on 80–100 mesh Chromosorb W AW DMCS. HPLC was performed on a Gasukuro Kogyo model 572 liquid chromatograph equipped with a UV detector. A Unisil Q 100-5 4.6-mm × 25-cm column was used with *n*-hexane–THF



SCHEME 2.

(10:1, 0.5 ml/min) as solvent. Solvents were purified and dried by standard methods.

15-Methyl-15-tritriacontene (5). Octadecyltriphenylphosphonium bromide, which was freshly prepared from triphenylphosphine (2.2 g, 8.4 mmol) and 1-bromooctadecane (2.7 g, 8 mmol), was dissolved in dry 1,2-dimethoxyethane (50 ml). The cooled solution was stirred while 5.2 ml of 1.6N *n*-BuLi in hexane (Aldrich) was added dropwise, and the mixture allowed to stir for 1

hr at room temperature. After the resulting phosphorus ylid solution had been cooled to $-30°C$, a solution of **4** (1 g, 4.2 mmol) in dry 1,2-dimethoxyethane (15 ml) was added dropwise over a period of 20 min. The reaction mixture was allowed to warm gradually to room temperature with stirring, and stirring was continued for 5 hr at 40°C. The mixture was quenched with a saturated NH_4Cl solution under ice-cooling, diluted with water, and extracted with ether. The aqueous layer was saturated with NaCl and then extracted with additional ether. The combined ethereal solutions were washed with water and brine and dried over Na_2SO_4. After evaporation of the solvent, the semicrystalline residue was triturated with *n*-hexane. The solid thus obtained was removed by filtration, and the filtrate was concentrated in vacuo. The resulting slightly yellow liquid was purified by column chromatography on silica gel (100 g) with *n*-hexane followed by removal of the low boiling impurities in vacuo giving **5** as a colorless viscous liquid (1.6 g, 81.4% from **4**), which solidified during storage in a refrigerator. IR (neat): 2930, 2850, 1470, 1380, 720 cm^{-1}. [^{1}H]NMR δ: 0.88 (distorted t, 6H, J = 5 Hz), 1.27 (broad s, 48H), 1.6 (m, 6H), 1.75–2.25 (m, 7H), 5.17 (t, 1H, J = 5 Hz). EI-MS *m/z:* 476 (M^+, 3), 294 (7), 279 (5), 57 (100). CI-MS (isobutane) *m/z:* 477 [$(M + H)^+$, 100].

(R,S)-15-Methyltritriacontane [(R,S)-1]. Hydrogenation of **5** (1.5 g, 3.15 mmol) in a mixture of ethanol (10 ml) and *n*-hexane (10 ml) was carried out in the presence of 10% Pd/C catalyst (0.15 g). After hydrogenation had been completed, the catalyst was filtered off and washed with *n*-hexane. The filtrate and washings were combined and concentrated in vacuo, and the slightly yellow residue was then dissolved in ether. The ethereal solution was washed with brine and dried over Na_2SO_4, and the solvent was evaporated in vacuo to obtain a crude semisolid of racemic **1.** The solid was purified by column chromatography on silica gel (10 g) with *n*-hexane giving (*R,S*)-**1** as a white solid (1.41 g, 94%), which was recrystallized from *n*-hexane: mp 37.5–38°C. IR (KBr): 2925, 2850, 1475, 1380, 720 cm^{-1}. [^{1}H]NMR δ: 0.8–1.0 (m, 9H), 1.25 (broad s, 61H). EI-MS *m/z:* 463 (M-15, 1), 281 (M-$C_{14}H_{29}$, 8), 225 (M-$C_{18}H_{37}$, 11), 57 (100). CI-MS (isobutane) *m/z:* 477 [$(M-H)^+$, 100]. GLC: R_t 16 min (99%), impurity at 10 min (1%). Analysis: Calcd. for $C_{34}H_{70}$: C, 85.27; H, 14.73. Found: C, 84.97; H, 15.06.

Methyl (3R)-6-oxo-3-methylhexanoate (8). Compound **8** was synthesized from (*R*)-pulegone with a 36% yield by the procedures described previously: bp 59–60°C at 0.4 mm Hg; $[\alpha]_D^{20}$ + 5.24° (neat, d[d:]$_4^{20}$ 0.9747) {$[\alpha]_D^{20}$ + 5.00° ± 0.06° (neat), Jackman and Lange, 1983}. IR (neat): 2740, 1735–1745 cm^{-1}. [^{1}H]NMR δ: 0.95 (d, 3H, J = 6 Hz), 3.67 (s, 3H), 9.77 (t, 1H, J = 1.5 Hz). [^{13}C]NMR δ: 19.452, 28.507, 29.849, 41.222, 41.435, 51.375, 172.877, 201.720.

Methyl (R)-3-methyl-6-heptadecenoate (9). Undecyltriphenylphosphonium bromide, which was freshly prepared from triphenylphosphine (4.4 g, 16.8 mmol) and 1-bromoundecane (3.8 g, 16 mmol), was dissolved in dry 1,2-di-

methoxyethane (60 ml) and treated with 10 ml of 1.6N *n*-BuLi in hexane (Aldrich). After the resulting ylid solution had been cooled to −50°C, a solution of **8** (1.33 g, 8.4 mmol) in dry 1,2-dimethoxyethane (20 ml) was added dropwise over a 30-min period. The reaction mixture was allowed to warm slowly to room temperature and left stirring for 4 hr. The mixture was worked up to obtain a pale yellow viscous residue. The residue was purified by column chromatography on silica gel (150 g) with *n*-hexane–ether (30:1) to give a colorless liquid of **9** (2.3 g, 92% from **8**): bp 135–137°C at 0.4 mm Hg. IR (neat): 2930, 2870, 1750, 1205, 1160, 1010 cm^{-1}. [^{1}H]NMR δ: 0.9 (apparent d, 6H, J = 6.5 Hz), 1.25 (broad s, 19H), 1.65–2.37 (m, 6H), 3.6 (s, 3H), 5.27 (t, 2H, J = 5 Hz). [^{13}C]NMR δ: 14.086, 19.604, 22.653, 24.635, 27.227, 29.331, 29.544, 29.636, 29.727, 30.032, 31.892, 36.709, 41.527, 51.222, 129.063, 130.161, 173.365. EI-MS *m/z:* 296 (M^+, 4), 264 (M-CH_3OH, 21), 222 (73), 68 (100). CI-MS (isobutane) *m/z:* 297 [$(M + H)^+$, 100].

*Methyl (*R*)-3-methyl-6-heneicosenate (13).* According to the procedure described above, compound **8** (1 g, 6.3 mmol) was condensed with a Wittig reagent which was prepared from pentadecyltriphenylphosphonium bromide and *n*-BuLi. Column chromatography on silica gel (120 g), with *n*-hexane–ether (30:1), of the product gave **13** as a colorless liquid (2.17 g, 98% from **8**): bp 152–155°C at 0.3 mm Hg. The IR and NMR spectra were identical with those reported (Kuwahara and Mori, 1983).

*(*R*)-3-Methyl-6-heptadecen-1-ol (10).* A solution of **9** (1.56 g, 5.27 mmol) in dry ether (5 ml) was added dropwise to a stirred and cooled suspension of lithium aluminum hydride (0.2 g, 5.26 mmol) in dry ether (10 ml). The mixture was stirred for 2 hr at room temperature. Work-up of the reaction mixture gave a slightly yellow liquid, which was purified by column chromatography on silica gel (20 g) with *n*-hexane–ether (5:1) to give **10** as a colorless liquid (1.36 g, 96%). IR (neat): 3350, 2950, 2870, 1475, 1380, 1070, 720 cm^{-1}. [^{1}H]NMR δ: 0.91 (apparent d, 6H, J = 6 Hz), 1.26 (broad s, 21H), 1.75–2.35 (m, 5H), 3.67 (t, 2H, J = 6 Hz), 5.25 (t, 2H, J = 5 Hz). [^{13}C]NMR δ: 14.086, 19.543, 22.684, 24.696, 27.257, 29.331, 29.636, 30.794, 31.922, 37.167, 39.911, 61.071, 129.551, 129.917. EI-MS *m/z:* 250 (M-H_2O, 4), 80 (100). CI-MS (isobutane) *m/z:* 266 [$(M + H)^+$, 100].

*(*R*)-3-Methyl-6-heneicosen-1-ol (14).* As described for **9**, compound **13** (2.17 g, 6.2 mmol) was reduced with lithium aluminum hydride (0.24 g, 6.2 mmol). Column chromatography on silica gel (20 g) with *n*-hexane–ether (5:1) gave **14** as a colorless liquid (1.95 g, 97%). IR (neat): 3350, 2940, 2850, 1470, 1380, 1060, 720 cm^{-1}. [^{1}H]NMR δ: 0.90 (apparent d, 6H, J = 6 Hz), 1.25 (broad s, 29H), 1.8–2.3 (m, 5H), 3.62 (t, 2H, J = 6 Hz), 5.25 (t, 2H, J = 5 Hz). [^{13}C]NMR δ: 14.086, 19.513, 22.684, 24.666, 27.227, 29.239, 29.331, 29.666, 31.892, 37.136, 39.911, 61.101, 129.520, 129.886. EI-MS *m/z:* 306 (M-H_2O, 5), 81 (100). CI-MS (isobutane) *m/z:* 325 [$(M + H)^+$, 100].

*(*R*)-3-Methyl-6-heptadecenal (11).* A solution of **10** (1.35 g, 5 mmol) in

dry dichloromethane (5 ml) was added dropwise to a stirred and cooled suspension of pyridinium chlorochromate (2.44 g, 11.3 mmol) in dry dichloromethane (20 ml). The mixture was allowed to stir for 1 hr at room temperature. Work-up of the reaction mixture gave a yellow liquid, which was purified by column chromatography on silica gel (10 g) with *n*-hexane–ether (30 : 1) to give **13** as a colorless liquid (1.14 g, 85%). IR (neat): 2945, 2855, 2710, 1730, 1470, 1380, 720 cm^{-1}. [^{1}H]NMR δ: 0.8–1.02 (m, 6H), 1.25 (broad s, 18H), 1.8–2.35 (m, 7H), 5.3 (t, 2H, J = 5 Hz), 9.67 (t, 1H, J = 1.5 Hz).

(R)-3-Methyl-6-heneicosenal (15). As described for **10**, compound **14** (1.6 g, 4.9 mmol) was oxidized with pyridinium chlorochromate (2.44 g, 11 mmol). Column chromatography on silica gel (15 g) with *n*-hexane–ether (30 : 1) gave **15** as a colorless liquid (1.35 g, 85%). IR (neat): 2950, 2860, 2710, 1735, 1470, 1385, 720 cm^{-1}. [^{1}H]NMR δ: 0.85–1.0 (m, 6H), 1.25 (broad s, 28H), 1.75–2.4 (m, 7H), 5.28 (t, 2H, J = 5 Hz), 9.63 (t, 1H, J = 1.5 Hz).

(R)-15-Methyl-11,17-tritriacontadiene (12). Hexadecyltriphenylphosphonium bromide, which was freshly prepared from triphenylphosphine (2 g, 7.6 mmol) and 1-bromohexadecane (2.3 g, 7.15 mmol), was dissolved in dry 1,2-dimethoxyethane (40 ml) and treated with 5 ml of 1.6N *n*-BuLi in hexane (Aldrich). After the resulting ylid solution had been cooled to −30°C, a solution of **11** (1 g, 3.8 mmol) in dry 1,2-dimethoxyethane (15 ml) was added dropwise over a 20-min period. The reaction mixture was allowed to warm slowly to room temperature and left stirring for 4 hr. Work-up of the mixture gave a slightly yellow viscous liquid, which was purified by column chromatography on silica gel (100 g) with *n*-hexane followed by removal of the low-boiling impurities in vacuo giving **12** as a colorless liquid (1.47 g, 82% from **11**), which was solidified during storage in a refrigerator. IR spectral data indicated it to be a mixture of geometric isomers. IR (neat): 3020, 2930, 2850, 1655, 1470, 1380, 970 (very weak), 720 cm^{-1}. [^{1}H]NMR δ: 0.8–0.95 (m, 9H), 1.25 (broad s, 45H), 1.74–2.36 (m, 8H), 5.28 (m, 4H). EI-MS *m/z:* 474 (M^+, 2), 320 (3), 250 (5), 81 (100). GLC: R_t 14 min (98%), impurity at 10.5 min (2%).

(R)-15-Methyl-12,18-tritriacontadiene (16). According to the procedure described above, compound **15** (0.96 g, 3 mmol) was treated with a Wittig reagent which was prepared from dodecyltriphenylphosphonium bromide and *n*-BuLi. Column chromatography on silica gel (100 g) with *n*-hexane gave **16** as a colorless liquid (0.96 g, 70% from **15**), which solidified during storage in a refrigerator. IR spectral data showed a mixture of geometric isomers. IR (neat): 3020, 2950, 2865, 1660, 1470, 1380, 970 (very weak), 720 cm^{-1}. [^{1}H]NMR δ: 0.8–0.95 (m, 9H), 1.25 (broad s, 45H), 1.8–2.28 (m, 8H), 5.3 (m, 4H). EI-MS *m/z:* 474 (M^+, 2), 306 (4), 264 (6), 81 (100). GLC: R_t 13.8 min (98.5%), impurity at 9.2 min (1.5%).

(R)-15-Methyltritriacontane [(R)-1]. Hydrogenation of **12** (1 g, 2.1 mmol) in a mixture of ethanol (5 ml) and *n*-hexane (5 ml) was carried out in the pres-

ence of 10% Pd/C catalyst (0.1 g). Column chromatography on silica gel (10 g) with *n*-hexane gave (*R*)-**1** as a white solid (0.95 g, 95%), which was recrystallized from *n*-hexane: mp 46–46.5°C. GLC analysis showed the recrystallized sample to be 97.6% pure [R_t 15.8 min, impurities at 11 min (2%) and 11.8 min (0.4%)]. (*R*)-**1** was identical with racemic **1** in its spectral data. Analysis: Calcd. for $C_{34}H_{70}$: C, 85.27; H, 14.73. Found: C, 85.62; H, 14.92.

(S)-15-Methyltritriacontane [(S)-1]. As described for **12,** catalytic hydrogenation of **16** (0.87 g, 1.83 mmol) gave (*S*)-**1** as a white solid, with almost quantitative yield, which was recrystallized from *n*-hexane: mp 46.5–47°C. Spectra matched those of both racemic **1** and (*R*)-**1.** GLC: R_t 16 min (98.2%), impurities at 12 min (1.2%), 3 min (0.3%), and 1.5 min (0.3%). Analysis: Calcd. for $C_{34}H_{70}$: C, 85.27; H, 14.73. Found: C, 85.12; H, 14.85.

DISCUSSION

As shown in Scheme 1 for the synthesis of racemic 15-methyltritriacontane, inexpensive 1-hexadecene (**2**) was chosen for the starting material. The alkene **2** was easily converted to the known ketone **4** (Naoshima et al., 1986), which was subjected to a Wittig reaction with octadecyltriphenylphosphonium bromide and subsequently hydrogenated over palladium charcoal. Thus racemic pheromone (*R,S*)-**1** was synthesized in four steps from **2** with a 72% yield. GLC analysis of the synthesized racemate showed 99% chemical purity. Sonnet et al. (1977) reported a three-step synthesis for racemic **1** employing a Wittig reaction, although the overall yield was not given. Chemical purity of the racemate was reported as 97%.

Readily available (*R*)-(+)-pulegone (**6**), $[\alpha]_D^{20}$ + 22.33° (neat, $d[d:]_4^{20}$ 0.9373), was used for the synthesis of the two enantiomers of **1** as shown in Scheme 2. A basic feature in our synthetic design of the enantiomers is that the chiral center at C-15 comes from pulegone (**6**) which will lead to **1** through ring cleavage and Wittig olefination.

First, **6** was converted via (+)-citronellic acid (**7**), $[\alpha]_D^{20}$ + 8.39° (neat, $d[d:]_4^{20}$ 0.9255), to the formyl ester **8** by known procedures (Overberger and Weise, 1968; Jackman and Lange, 1983; Kuwahara and Mori, 1983). For the synthesis of (*R*)-**1,** the formyl ester **8** underwent a Wittig reaction with undecyltriphenylphosphonium bromide giving the olefinic ester **9** in a 92% yield. In the IR spectrum of **9,** a strong absorption in the region of 965 cm^{-1} was absent, consistent with the major product being the *Z*-isomer. The ester **9** was converted by reduction and subsequent oxidation to the aldehyde **11,** followed by Wittig olefination with hexadecyltriphenylphosphonium bromide to give the long-chain unsaturated hydrocarbon **12** in a 67% yield from **9.** Finally, catalytic hydrogenation of the diene **12** gave the pheromone (*R*)-**1** in a 95% yield and in a 21% overall yield from **6.**

Employing the same procedure described for the synthesis of (*R*)-**1** with the exception that pentadecyltriphenylphosphonium bromide and dodecyltriphenylphosphonium bromide were used for Wittig reaction, the pheromone (*S*)-**1** was synthesized in a 19.5% overall yield from **6.** Although we were unable to determine the optical purities of the two present enantiomers, the pheromones (*R*)- and (*S*)-**1** appeared to be enantiomerically pure, allowing the evaluation of biological activities within the limits of accuracy. The assumption of optical purity is based on the observation that the starting material, (*R*)-pulegone, was found to be highly enentiomerically pure, about 100%, by the HPLC analysis of diastereomeric amides derived from (+)-citronellic acid (**7**) and configurationally pure (*R*)-(+)-1-(1-naphthyl)ethylamine (Mori et al., 1981), and it was assumed that no racemization at the chiral center had occurred during the reaction sequence described above (Overberger and Weise, 1968; Mori and Kuwahara, 1982). It is reasonable that both (*R*)- and (*S*)-**1** exhibited no measurable optical rotation at the sodium D-line, since this finding was consistent with Brewster's empirical calculations relating to optical rotations (Brewster, 1959; for the optical activity of chiral hydrocarbons, see Wynberg et al., 1965; Hoeve and Wynberg, 1980). There was no description of the optical rotation for the two enantiomers synthesized by Sonnet (1984), while the configurational purity for both these enantiomers was determined by GLC analysis of precursors as diastereomeric amides.

Acknowledgments—We wish to thank Prof. C.E. Carraher, Florida Atlantic University, for useful suggestions in the preparation of this paper. Thanks are also due to Takasago Perfumery Co., Ltd. for the generous gift of (*R*)-pulegone.

Abstract—When females of the eulophid parasite *Edovum puttleri* were exposed to an *n*-hexane wash of eggs of the Colorado potato beetle, *Leptinotarsa decemlineata*, their responses indicated that the eggs contained a kairomone which elicited host-finding and host-acceptance behaviors. The host-finding responses included an increased amount of time searching glass beads treated with kairomone, and drumming on the beads with the flagellum of the antennae. Host-acceptance responses included grasping of the beads with the legs, raising of the abdomen, and probing the kairomone-treated surface with the ovipositor. None of these responses were noted in females on beads treated only with hexane, or in males exposed to kairomone-treated beads. When kairomone was applied to a flat surface, filter paper disks, few episodes of drumming and no episodes of probing with the ovipositor were noted. Responses of *E. puttleri* to eggs of Colorado potato beetle were similar to those on kairomone-treated beads, but females normally drilled into eggs and fed on host fluids after retracting the ovipositor. The kairomone is volatile, and responsiveness was reduced in parasites exposed to beads treated several hours previously.

Key Words—Kairomone, parasite, host finding, host acceptance, behavior, *Edovum puttleri*, Hymenoptera, Eulophidae, Colorado potato beetle, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae.

INTRODUCTION

The importance of the role of kairomones as chemical cues to orient parasites to their prey has been demonstrated for an increasing number of species of parasitic Hymenoptera. Kairomones have been shown to function as stimuli to orient parasites to host habitats (reviewed by Vinson, 1981), to locate hosts within the habitat of the host (reviewed by Weseloh, 1981), and to facilitate discrimination of acceptable hosts (reviewed by Arthur, 1981). Herein, we describe host-finding and host-acceptance responses of *Edovum puttleri* Grissell (Hymenoptera: Eulophidae) to a kairomone extracted in *n*-hexane from eggs of Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae).

Edovum puttleri was described from specimens emerging from eggs of the chrysomelid *Leptinotarsa undecemlineata* (Stal) from Columbia, South America. Grissell (1981), in his description, noted the potential of *E. puttleri* as a possible biocontrol agent for the Colorado potato beetle. The host range of *E. puttleri* was examined by Puttler and Long (1983). Of 18 species of chrysomelid eggs exposed to *E. puttleri*, the favored host was the Colorado potato beetle. With the exception of a few eggs of *Labdometa clivicolis* (Kirby), no other species were parasitized.

One important factor that will influence the utilization of *E. puttleri* in biological control strategies is the inability of the parasite to overwinter in temperature areas of the United States (Shroder et al., 1985). Shroder and Athanas (1985) noted consistent performance of the parasite in the field over the past four years and suggested that *E. puttleri* can be an effective integral part of management systems for Colorado potato beetle control. The inability of the parasite to overwinter, however, will require rearing of sufficient numbers of adults for release during each field season.

The kairomone could enhance the use of *E. puttleri* as a biocontrol agent. Several authors (e.g., Lewis et al., 1975a,b; Gross et al., 1975) discuss the possibility of using kairomones to manipulate behavior and increase the effectiveness of parasites. The use of kairomones in situations requiring inundative releases of parasites was reviewed by Gross (1981). In addition to the potential importance of the kairomone in enhancing host finding and host acceptance in field conditions, the kairomone could have utility in the development of methods to facilitate mass rearing of *E. puttleri*.

METHODS AND MATERIALS

Extraction of Kairomone. Preliminary tests were conducted to determine if washes of Colorado potato beetle eggs with various solvents produced a response when presented to female *E. puttleri*. Of the initial solvents tested, dis-

tilled water, methanol, and *n*-hexane, females responded to the *n*-hexane wash of Colorado potato beetle eggs on filter paper by aggregating near and tapping the treated area with their antennae. These responses, however, were weaker than we had observed in previous experiences with kairomonal responses in other species of parasites. Strand and Vinson (1983), and our colleague, H.P. Lee (personal communication) demonstrated that size and shape of treated objects can be important in eliciting kairomonal responses in species of hymenopteran egg parasites. We found that 1-mm-diameter, round, clear glass beads treated with the hexane wash of eggs elicited strong kairomonal responses in *E. puttleri* females.

The *n*-hexane wash of Colorado potato beetle eggs was prepared from fresh egg masses from our colony reared on potato, *Solanum tuberosum*. One thousand eggs were removed from potato leaves, placed in a clean, glass vial, and covered with 2.5 ml of *n*-hexane. After 5 min, the hexane wash was decanted into a vial and stored at 0°C.

Parasite Culture. Edovum puttleri were obtained from the Mission Biological Control Laboratory, USDA, APHIS, PPQ, Edinburg, Texas. Parasites were received as pupae in parasitized eggs of *Leptinotarsa texana* (Schaeffer) and were held at 25°C and 16-hr photophase. On emergence, parasites were transferred to screened, glass jars and provided with distilled water and with honey. Males and females were kept together for mating. Parasites were provided fresh egg masses of Colorado potato beetle to obtain host-experienced females for bioassays, since previous ovipositional experience has been shown to influence responses in some parasites (Lenteren, 1976; Strand and Vinson, 1982).

Bioassays. The test arena was a culture microscope slide with a glass ring 3 mm high and 16 mm in diameter fused to a 76 × 25-mm glass slide. A piece of plastic screening with a mesh opening of 0.8 mm was cut with a cork borer to the inner diameter of the glass ring and placed on the bottom of the arena. Clear glass beads, selected for uniformity in size (1.0 mm) and roundness, were placed on the screened bottom of the test arena in a 5 × 5 bead array in the center of the arena. The screen bottom provided a uniform array of beads and prevented beads from touching. The beads were treated by placing 25 in a clean depression slide. The hexane wash was pipetted on the beads, and the beads were stirred with forceps to aid in coating each bead. After several minutes, the hexane had evaporated and the beads were transferred with forceps to the screened base of the test arena.

Bioassays were conducted in a room maintained at 25 ± 1°C. We found in preliminary tests, however, that parasites responded poorly on some days when exposed to our standard concentration of hexane wash. We have not examined the possible causes of this variation in responsiveness to kairomone, although it appears related to periods of inclement weather or to changes in weather patterns. To maintain as much uniformity as possible in our bioassays,

we first tested several female parasites with our standard concentration of kairomone; if few or no responses were noted, bioassays were not conducted on that day.

For the initial test to compare responses of *E. puttleri* to untreated and to kairomone-treated beads, the control beads were prepared by pipetting 5 μl of *n*-hexane over the beads. After several minutes, the beads were transferred to a test arena in a 5 $\times$ 5 bead array. The test beads received 5 μl of our standard concentration of hexane wash of Colorado potato beetle eggs as detailed above, and, after several minutes, the beads were transferred to the test arena. The arena was covered with a glass cover slip. A mated, host-experienced *E. puttleri* female, 4–5 days old, was placed in the control arena and allowed to acclimate for 1 min. The female was then observed for 5 min with a dissecting microscope illuminated from the microscope base. The number of times the female contacted (walked on) the beads, the time spent on the beads, and behaviors on the beads were recorded. Directly after the 5-min exposure to the control beads, the parasite was transferred on the cover slip to the arena containing treated beads. During the 5-min exposure to treated beads, the data recorded were as above. After exposure to the treated beads, the parasite was discarded, and another female was used. Both the control and test arenas were used only for 1 hr, after which females were exposed to newly prepared arenas.

Some females spent much time walking on the top and sides of the arena, and we wanted to compare differences in behavior of parasites on control and treated beads. Only females that had two or more episodes of walking over the control beads were transferred to the arena containing kairomone-treated beads. A total of 20 such females were tested.

The initial test demonstrated that host-finding and host-acceptance responses occurred with females exposed to kairomone-treated beads. We were interested in eliciting more pronounced responses, particularly host-acceptance responses, and ran preliminary tests to determine whether age of females or increasing the amount of the hexane wash of eggs would influence the level of response. One-day-old females showed no response to treated beads, whereas older females responded to kairomone-treated beads throughout their ovipositional period, which in our laboratory is ca. 30 days. By increasing the dosage and time of exposure, we could increase the incidence of probing responses on beads with the ovipositor. For subsequent tests we utilized host-experienced females of 11–12 days of age, increased the level of kairomone to 10 μl of hexane wash of eggs applied to 25 glass beads, and used an exposure time of 10 min. We also found that females were strongly attracted to white surfaces and that we could conduct our bioassays on a white surface with the light source (cool white, fluorescent) from above, rather than using the reflecting base of a microscope.

To determine whether the attractiveness to kairomone-treated beads declined over time, four arenas were prepared using 25 beads covered with 10 μl

of our standard concentration of hexane wash and were left uncovered. Each hour, starting with hour 1 after the beads were treated, 12 parasites from a cohort of 50 were tested individually. Each parasite was observed for antennal drumming or probing with the ovipositor on the beads. If probing with the ovipositor did not occur within the 10-min test period, the test was ended. Females were returned to the cohort, and the arenas were left uncovered until the next test period.

A reduction in response to kairomone-treated beads over time could be a function of beads exposed previously having been "marked" by previous females to deter other females from searching eggs. To test whether this occurred, an arena of 25 treated beads was prepared, and five 12-day-old, experienced females were placed singly into the arena for a period of 10 min each. Each female was observed and the course of movement over each bead was charted. When antennal drumming responses were noted, the time the female remained on the bead was recorded. After 10 min, the female was replaced with a new female, and data were collected as above. A total of five females were exposed to each arena, and a total of four replicates was run.

To test the responses of females to reduced concentrations of kairomone, 25 beads were treated with 10 μl of kairomone wash, beginning with the standard concentration and in serial dilutions to 6.2% of the standard concentration. The test arenas were set up as above, and a total of 20 *E. puttleri* from a cohort of ca. 100 females were tested for each concentration. Data recorded were antennal drumming and probing with the ovipositor on the treated beads. If probing with the ovipositor did not occur within 10 min, the test was ended.

RESULTS

The exposure of 4- to 5-day-old host-experienced, mated *E. puttleri* females to hexane-treated and subsequently to kairomone-treated glass beads showed about a 10-fold marked increase in the amount of time that females remained on the kairomone-treated beads (Table 1). Of the 20 females tested, two spent less time on the beads treated with kairomone and one spent about the same amount of time on the untreated and treated beads during the 5-min exposure periods. The remaining 17 females spent much more time on the beads coated with kairomone, and 12 females displayed one or more episodes of probing the beads with the ovipositor. Two females were engaged in drumming and probing at the end of the five-min test period, but the additional time spent on the beads is not included in the data.

Antennal drumming and the probing of the beads with the ovipositor were not observed on beads treated only with hexane. Females walked over the control beads rapidly, spending an average of 1.1 sec. on each bead. Normally, they traversed the beads from the one mounted in a line until they reached the

TABLE 1. RESULTS OF PAIRED TESTS OF 20 *E. puttleri* FEMALES EXPOSED FOR 5 MIN TO HEXANE-TREATED (CONTROL) GLASS BEADS AND IMMEDIATELY THEREAFTER TO BEADS TREATED WITH HEXANE WASH OF COLORADO POTATO BEETLE EGGS (KAIROMONE)[a]

	Time (sec) spent on beads			Total No. of probing episodes
	Mean	$SE\bar{X}$	Range	
Kairomone	132.6	19.0	5.2–288.3[b]	21
Control	11.9	2.7	6.1–53.5	0

[a] Probing with the ovipositor occurred after drumming of beads with the antennae, events observed only on kairomone-treated beads.
[b] Time spent on kairomone-treated beads significantly different from time on control beads at $P < 0.05$ using the Wilcoxin Matched-Pairs Signed-Ranked Test.

last bead and exited to the screened base of the arena. While traversing the beads, females would occasionally tap the surface of the beads with the antennae held at an ca. 45° angle to the surface of the beads.

Females responding to kairomone-treated beads did not traverse the beads as rapidly, spending an average of 6.8 sec on each bead. The antennae were brought downward to about a 90° angle and vibrated rapidly, drumming on the surface of the bead with the distal portion of the flagellum as the parasite slowly turned and searched the bead. These behaviors we consider to be host-finding responses.

Antennal drumming always preceded probing of the egg with the ovipositor, but not all episodes of drumming were followed by probing. When probing occurred, females grasped the bead, extended the meso- and metathoracic legs, raised the abdomen, released the ovipositor, and probed the kairomone-treated surface of the bead with the distal tip of the ovipositor. After probing the bead for ca. 30–60 sec, the abdomen was lowered and the ovipositor was ensheathed. These behaviors we consider to be host-acceptance responses. After completion of the probing episode, females remained on the bead for several seconds, then moved to an adjacent bead and repeated the host-finding repertoire or left the beads.

Males were also exposed to kairomone-treated and control beads, but none of the 10 males tested displayed any response to kairomone.

The response of females to beads treated with kairomone for up to 8 hr prior to exposure showed that both antennal drumming and the probing with the ovipositor declined with the age of the kairomone (Figure 1). The drumming response was seen in all females tested at hours 1 and 2, with a gradual decline in females responding until hours 6 through 8, when four of 12 females responded. With the probing response, which was always preceded by drumming,

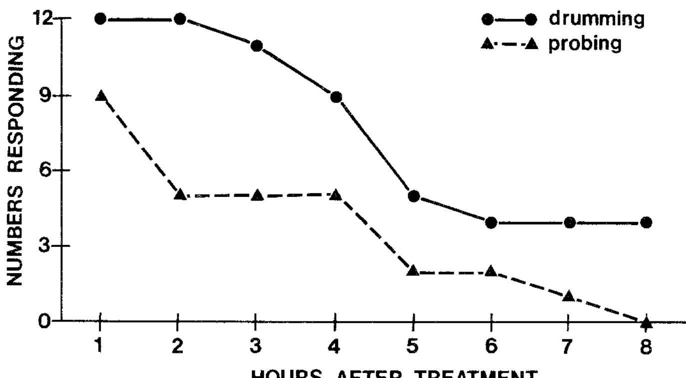

FIG. 1. Responses of female *E. puttleri* to beads treated with hexane wash of Colorado potato beetle eggs one to eight hours prior to exposure. Probing with the ovipositor was preceded by drumming on the bead with the antennal flagellum. Some females drummed, but did not probe with the ovipositor.

the highest numbers responding occurred 1 hr after beads were treated, followed by a drop in numbers responding. At hour 8, no probing with the ovipositor was noted; although four females drummed beads, the concentration of kairomone was apparently not sufficient to elicit the probing response. The reduction in attractiveness of the treated beads was not a function of "marking" of the beads with a substance to deter other females, for the test for marking showed that females spent a mean of 10.9 sec ($N = 45$ episodes, $SE\bar{X} = 0.91$) on beads not previously probed by females and 10.3 sec ($N = 53$ episodes, $SE\bar{X} = 0.66$) on beads previously probed by other females.

The data on responses of females to serial dilutions of kairomone (Figure 2) were similar to those in Figure 1. The first concentrations tested were 100%

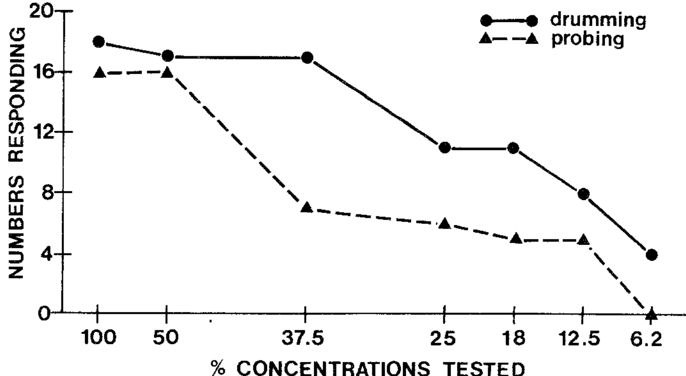

FIG. 2. Responses of female *E. puttleri* to serial dilutions of hexane wash of Colorado potato beetle eggs. The 100% concentration was the standard test concentration of 1000 eggs washed with 2.5 ml of *n*-hexane, with 10 μl applied to 25 glass beads.

(standard), 50%, and 25% of the standard concentration. The sharp reduction in activity at the 25% concentration prompted our testing of a 37.5% concentration. The data for the 37.5% concentration suggest that the greatest loss in activity occurs between 50 and 37.5% concentrations. The lowest dilution for probing beads with the ovipositor was 12.5%; although drumming was noted at 6.2% of the standard concentration, the level of activity of the kairomone was not sufficient to elicit a probing response with the ovipositor.

DISCUSSION

The loss in activity of kairomone in time, as shown in Figure 1, suggests that the kairomone degrades or is volatile. In some instances during bioassays, females on the cover slip above the treated beads extended their antennae downward and walked directly over the beads, but could not contact them with their antennae. A few dropped directly on the beads from the cover slip. We consider this a response to a volatile component of the hexane wash of eggs, rather than to visual cues, since we did not observe females exposed to untreated beads gaining access to the beads from the cover slip.

Our preliminary tests with the hexane wash of Colorado potato beetle eggs applied to filter paper showed weak arrestment responses of *E. puttleri* to the treated spots, little antennal drumming activity, and no attempts to probe with the ovipositor. Strand and Vinson (1983) showed that the parasite *Telenomus heliothidis* Ashmead (Hymenoptera: Scelionidae) required a rounded surface approximating the size and shape of the egg of the noctuid host, *Heliothis virescens* (F.) We also found that *E. puttleri* preferred a rounded surface. Unlike *T. heliothidis*, however, *E. puttleri* responded to 1 mm round glass beads which differ in shape and form from the ovoid egg of the Colorado potato beetle.

The host-finding and host-acceptance behaviors noted on kairomone-treated beads appeared to be the same as when *E. puttleri* were exposed to Colorado potato beetle eggs. The host-acceptance repertoire, however, normally resulted in the successful drilling of the egg with the ovipositor. After removal of the ovipositor, females commonly turned and fed on egg fluids at the wound. We observed no females turning to explore kairomone-treated beads after attempts to probe with the ovipositor.

The serious damage caused by the Colorado potato beetle, and current difficulties in controlling the pest due to high levels of resistance to an array of registered insecticides (Forgash, 1985), stresses the importance of the development of alternative strategies for control. The findings that *E. puttleri* readily parasitizes eggs of the Colorado potato beetle and has a restricted host range (Puttler and Long, 1983) make this insect an excellent candidate as a new, exotic parasite. The finding of a kairomone that elicits host-finding and host-acceptance behaviors in *E. puttleri* may have future application in field situa-

tions. This will, in large measure, depend on the identification and potential for synthesis of the kairomone.

We are interested, as well, in attempts to develop methods that will facilitate the mass rearing of this parasite, for it will be a necessary to release large numbers of parasites during each field season, since *E. puttleri* does not survive the winter in temperate regions. As noted by Strand and Vinson (1983), kairomones attractive to egg parasites constitute an important link in the efforts to develop acceptable artificial hosts for mass production of parasites and may also prove effective in stimulating parasites to attack previously unacceptable hosts which are more readily reared for mass production.

Acknowledgments—We thank Gary Bernon, USDA, APHIS, PPQ, Mission Biological Control Laboratory, Edinburg, Texas, for supplying *Edovum puttleri*; Ms. Marianne Maher for technical assistance in rearing parasites; Dr. Hai Poong Lee, Dongguk University, Seoul, Korea, and currently, Visiting Professor in our department for helpful suggestions on techniques and critical review of the manuscript; and Dr. Ring Cardé for his critical review of the manuscript. The research was supported by a USDA Special Grant on Integrated Pest Management and by the Massachusetts Agricultural Experiment Station and published as Journal Article No. 2747 of the station.

(Received November 12, 1985; accepted February 28, 1986)

Abstract—The copulatory behavior of the male whitemarked tussock moth, *Orgyia leucostigma,* was released by extracts of female body scales applied to rubber septum models baited with a female sex pheromone gland. The major compounds in the scale extracts were identified by GC-MS as a series of *n*-alkanes from C-21 to C-29. Of these, *n*-tricosane, *n*-tetracosane, *n*-pentacosane, and *n*-heptacosane, applied at 10 ng/septum, caused significantly more males to attempt copulation than hexane-treated controls. Mixtures of the *n*-alkanes, resembling the composition in the scale extracts, were no better than the two most active alkanes, *n*-tetracosane and *n*-pentacosane, alone. The releaser effect of the *n*-alkanes was dose dependent. EAG responses to the identified *n*-alkanes were small suggesting, along with the behavioral observations, that their perception occurred at very close range. Other factors releasing male copulatory behavior are discussed.

Key Words—Alkanes, copulation, cuticular hydrocarbons, sexual behavior, moth scales, releaser stimuli, whitemarked tussock moth, Lepidoptera, Lymantriidae, *Orgyia leucostigma.*

INTRODUCTION

In many moth species, including the whitemarked tussock moth (WMTM), *Orgyia leucostigma* (J.E. Smith), male copulatory behavior is released by contact

0098-0331/87/0200-0345$05.00/0 © 1987 Plenum Publishing Corporation

with female scales (Grant 1981; Ono 1974, 1977, 1979, 1980, 1981; Sanders, 1979; Shimizu and Tamaki, 1980). This has been demonstrated by applying scales to surrogate female models treated with female sex pheromone and noting the increase in male copulatory response to these models over models without scales.

The copulation-releasing effect of female scales in most cases appears to be due to their physical characteristics, since extracting them with organic solvents had little or no consequence on their effectiveness as releasers (Ono, 1974; Sanders, 1979; Shimizu and Tamaki, 1980) whereas pulverizing them considerably reduced or eliminated their activity (Ono, 1979; Shimizu and Tamaki, 1980). By contrast, Grant (1981) found that while pulverizing scales of the WMTM reduced their activity, they still retained their ability to elicit a relatively high level of copulation. This result suggested that a chemical stimulus might also be involved in scale-induced copulatory behavior in the WMTM.

We investigated this possibility and in this report demonstrate that female WMTM scales provide a chemical stimulus which releases male copulatory behavior and identify the chemicals responsible.

METHODS AND MATERIALS

Insects. These were obtained from a laboratory culture reared on artificial diet (Grisdale, 1973, 1975). They were sexed as pupae and maintained in separate rooms. Adult males were held in continuous light and tested when two days old (Grant, 1975, 1981).

Bioassay. Female models consisted of sleeve type rubber septa (15 × 9 mm; A.H. Thomas Co.; Philadelphia, Pennsylvania), each baited with an excised female pheromone gland mounted on the small end (Figure 1). Glands were required because the sex pheromone has not been identified. The fringe of terminal abdominal scales protruding over the retracted gland was removed from the female with sticky tape before the glands were excised to avoid contaminating the gland or septum with scales.

The prepared septa were placed individually on filter paper disks lining the bottom of circular plastic arenas (15 cm diameter × 6 cm deep). A virgin male was introduced into each arena and observed for 5 min commencing when the sexually excited male contacted the septum. During the observation period, we recorded whether or not the male attempted copulation and, in some experiments, the duration of each encounter with the septum. A copulation attempt was defined as flexion of the male abdomen toward the model, followed by genital contact. A new septum and filter paper were used for each replicate to avoid possible contamination with extraneous scales. Experiments were carried out from 1000 to 1200 hr each day at ambient temperature and humidity.

Test Stimuli. The orientation of the models in the horizontal and vertical

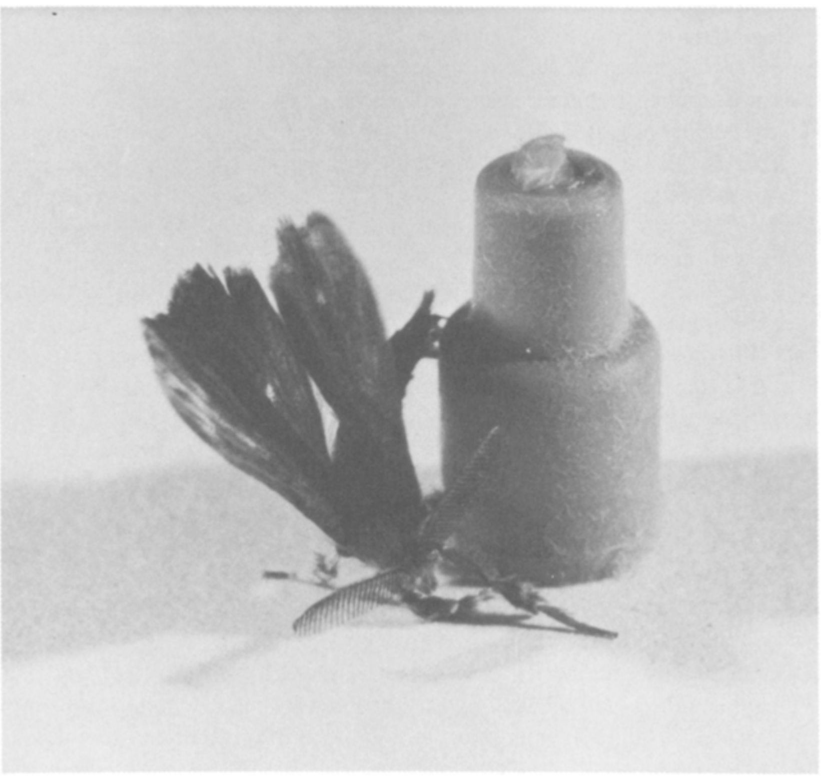

FIG. 1. Male *O. leucostigma* attempting to copulate with a vertical rubber septum model covered with female scales. Note the excised female pheromone gland sitting in the well at the small end of the rubber septum.

(standing on large end) positions was evaluated in the first series of experiments to determine which control model elicited the lowest frequency of copulatory response. The following stimuli were applied individually to the models to evaluate their effectiveness as releasers of male copulatory behavior: female body scales, pulverized female scales, extracts of female body scales, a fractionated whole-body wash of females, a female sex pheromone extract, individual alkanes identified in the scale extracts, and two mixtures, I and II, of these alkanes composed as follows: mixture I, which consisted only of odd chain alkanes, contained 5% *n*-heneicosane, 15% *n*-tricosane, 40% *n*-pentacosane, 20% *n*-heptacosane, and 20% *n*-nonacosane; mixture II, which contained most of the *n*-alkanes found in the scale extracts, consisted of 5% *n*-heneicosane, 10% *n*-tricosane, 15% *n*-tetracosane, 25% *n*-pentacosane, 10% *n*-hexacosane, 15% *n*-heptacosane and 20% *n*-nonacosane.

Untreated septa were coated with intact scales by rubbing them against live females or on the inside of a mortar containing scales removed with forceps from several females. It was estimated that less than 1 female equivalent of scales was applied in either case. Scales around the female genitalia that were likely to be contaminated with sex pheromone were avoided by removing them beforehand with sticky tape. Pulverized scales were produced by grinding with mortar and pestle and applied by rubbing the septa against the inside of the mortar to provide a covering of scale particles estimated to be equivalent to models with intact scales.

Scale extracts were prepared by removing scales from about 150 females and extracting these with 1 ml of hexane. They were applied, 4–5 female equivalents (FE) in 50 μl of hexane, to the outside surface of septa which were then allowed to stand in a fume hood for at least 40 min before testing. Waiting less time produced erratic results. The other test substances were also applied at least 40 min before evaluation. A whole-body extract was produced by immersing females in a minimum volume of hexane for 10 min to extract surface chemicals. It was then chromatographed on a small column to produce two fractions, one containing the alkanes and the other containing the remaining nonalkane material. The column was dry-packed in a Pasteur pipet (Carlson and Service, 1980) and consisted of 1 cm silica gel (J.T. Baker Chemical Co.) over 5 cm of 20% silver nitrate-impregnated silica (Hi-Flosil-Ag, 60/200 mesh; Applied Science Laboratories, Inc.). The extract (200 FE/100 μl) was eluted with 4 ml hexane (2 ml of which were absorbed by the dry column), 3 ml 5% ether–hexane, 3 ml 15% ether–hexane, and 3 ml 50% ether–hexane. The first 1 ml hexane fraction collected contained the alkanes; the second 1 ml contained only traces of alkanes and was discarded. The remaining fractions were combined to form the nonalkane fraction. The alkane and nonalkane fractions (4 FE each) were applied in 20 μl of solvent to separate septa. The female sex pheromone extract was obtained by surface rinsing pheromone glands from 50 virgin females with hexane (Grant, 1975) and applying 2 FE in 20 μl of hexane to the septa. The individual identified alkanes and the two alkane mixtures were applied in 20 μl of hexane. Controls consisted of septa treated with 20–50 μl of hexane and allowed to stand for 40 min before use.

Chemical Analysis of Scale Extracts. Two batches of scales from 120 and 150 females, respectively, were extracted with hexane and analyzed by splitless capillary gas chromatography (SCGC) on a Hewlett-Packard 5880A instrument fitted with a 30-m, 0.25-mm ID DB-1, fused silica cross-linked methyl silicone column (J&W Scientific Inc., Rancho Cordova, California). The column was operated at 80°C isothermal for 2 min, 10°C/min to 180°C, and then 2°C/min to 240°C, with a helium carrier gas flow of 1 ml/min throughout. The injector was maintained at 200°C and the flame ionization detector at 250°C.

Mass spectroscopic analysis (SCGC-MS) was performed with a 30-m, 0.32-mm ID DB-1 column and electron impact ionization. The column was

programmed at 80°C isothermal for 1 min and then 12°C/min to 220°C with a flow rate of about 2 ml/min.

The *n*-alkanes used as chemical standards and for bioassay were obtained from commercial sources (Applied Science Laboratories Inc., State College Pennsylvania; Analabs Inc., New Haven, Connecticut; Chemical Samples Corp., Columbus, Ohio). The compounds used in the behavioral tests were all 99% pure or better.

Electroantennograms (EAGs). EAG responses to *n*-alkane standards (1 μg at source) were obtained as described by Grant et al. (1972). Optimum responses were obtained from fresh (1-day-old) males.

RESULTS

Behavioral Observations. The main elements of the male response to a model treated with active material were similar to those reported earlier (Grant, 1981). The male usually initiated contact by means of his tarsi, and this was quickly followed by antennal contact. The male circled the septum, particularly a vertical one, touching it with his antennae and tarsi, and attempted to copulate while still on the substrate (Figure 1). If the copulation attempt was delayed, the head was kept in close contact with the septum, usually with the palps touching it. Even when models treated with active material failed to elicit copulatory behavior, they could often be distinguished from hexane-treated controls by the position of the male's head. With a vertical septum, males frequently climbed and circled around the top close to the pheromone gland and occasionally attempted to copulate from this position. Much more climbing, less antennal contact, little head contact, and little copulatory behavior were observed with control models.

Copulatory Response to Scales and Model Orientation. The addition of scales to either horizontal or vertical models significantly increased male copulatory attempts over the comparable scaleless models; moreover, the amount of time the males remained in contact with the model was significantly greater (Table 1). The addition of pulverized scales was less effective than intact scales, but their presence did elicit more copulatory responses than the controls, significantly so in the case of the vertical model.

The effect of model orientation on copulatory behavior was clear-cut (Table 1). Vertical models without scales elicited no copulatory responses and produced a significantly shorter contact time ($P < 0.05$, t test) than similar scaleless horizontal models. The horizontal septa elicited copulatory responses from 40% of the males, which was comparable to the 33% response elicited by scaleless horizontal plasticene models reported earlier (Grant, 1981). Because the vertical models produced a much lower control response, they were used in all subsequent tests to maximize the differences between treatments and controls.

TABLE 1. COMPARISON OF COPULATION RELEASING EFFECT OF HORIZONTAL AND VERTICAL RUBBER SEPTUM MODELS (+ FEMALE SEX PHEROMONE GLAND) TREATED WITH INTACT AND PULVERIZED FEMALE BODY SCALES OF *O. leucostigma*

Treatment	No. tests	Tests with at least 1 copulatory attempt (%)[a]	Duration contact with septum, $\bar{X} \pm$ SE (sec)[b]
Horizontal models			
Without scales	15	40 b	97 ± 14 b
With female scales	15	87 a	147 ± 20 a
With pulverized scales	15	53 b	89 ± 11 b
Vertical models			
Without scales	15	0 c	49 ± 05 b
With female scales	15	87 a	92 ± 11 a
With pulverized scales	15	33 b	72 ± 7 a

[a] Percents within the same group (horizontal or vertical model) followed by the same letter are not significantly different by G test, $P = 0.05$.
[b] Means within the same group (horizontal or vertical model) followed by the same letter are not significantly different by Student-Newman-Keuls multiple range test, $P = 0.05$.

Copulatory Response to Scale Extracts. Both of the scale extracts applied to vertical models elicited significantly more copulatory attempts than the hexane controls (Table 2). The sex pheromone gland extract, on the other hand, did not increase copulatory behavior, indicating that pheromone contamination

Treatment	No. tests	Tests with at least 1 copulatory attempt (%)[a]	Duration contact with septum $\bar{X} \pm$ SE (sec)[b]
Hexane (control)	30	3	89 ± 11
Scale extract 1 (5 FE)	13	46 *	101 ± 10
Scale extract 2 (4 FE)	15	33 *	90 ± 11
Whole-body extract			
Alkane fraction (4 FE)	15	40 *	123 ± 14
Nonalkane fraction (4 FE)	15	13	103 ± 13
Sex pheromone gland extract (2 FE)	15	7	74 ± 11

[a] Those percents marked with * are significantly different from control at $P = 0.05$, G test.
[b] None of the averages were significantly different from each other by Student-Newman-Keuls test, $P = 0.05$.

of the scales, if it occurred, was not the cause of the copulation attempts. Comparison of the alkane and nonalkane fraction of the whole-body extract showed that the alkane fraction significantly increased copulatory behavior compared to the control while the nonalkane fraction did not. In contrast to the previous experiment, there was no significant difference in the duration of contact caused by any of the treatments.

Compounds Identified in Scale Extracts. The two hexane extracts analyzed by SCGC were found to be very similar in composition. The major early eluting peaks showed retention times identical to those obtained from straight-chain hydrocarbons (C-19 to C-29). Mass spectral analysis of these mixtures confirmed the hydrocarbon nature of the peaks, exhibiting spectra identical to those obtained for corresponding straight-chain alkane standards. Additional later-eluting peaks were also present in the chromatograms, but these were not pursued. The linear hydrocarbon composition for two separate extracts as determined by SCGC is given in Table 3. The even-numbered hydrocarbons were consistently found in other WMTM scale extracts but not in solvent blanks or in extracts of other moth species analyzed at the same time.

Copulatory Response to Alkanes. Responses significantly greater than the control ($P = 0.05$, G test) were obtained with 10-ng doses of *n*-tricosane, *n*-tetracosane, *n*-pentacosane, and *n*-heptacosane (Figure 2), with the strongest responses elicited by *n*-tetracosane and *n*-pentacosane. Mixtures I and II, also evaluated at 10-ng doses, elicited copulatory responses from 47% of the males, the same as *n*-pentacosane or *n*-tetracosane alone (Figure 2), suggesting that the alkanes were not synergistic.

Effect of Concentration. Preliminary bioassays with whole-body extracts

TABLE 3. RELATIVE LINEAR HYDROCARBON COMPOSITION OF TWO FEMALE *O. leucostigma* SCALE EXTRACTS

n-Octacosane	2.5	1
n-Nonacosane	7	29

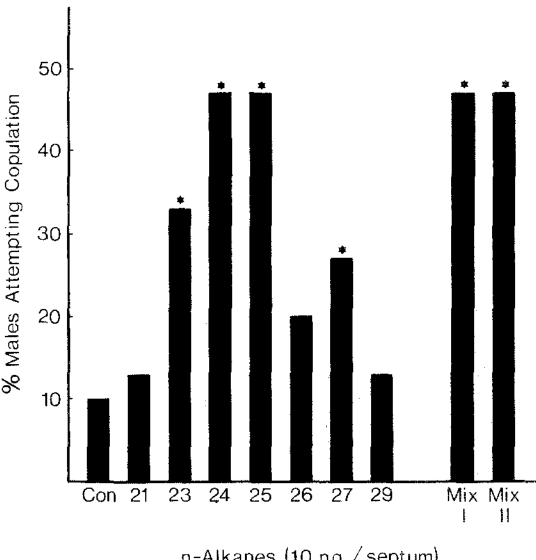

FIG. 2. Effectiveness of identified scale alkanes (10 ng/septum) and mixtures I and II of these alkanes (see text for mixture composition) in releasing *O. leucostigma* (N = 15) copulatory behavior. Controls (N = 30) were treated with 20 μl of hexane. Bars marked with * are significantly different from control at P = 0.05, G test.

and the *n*-alkanes indicated that the copulatory response was dose dependent. To assess this systematically, males were exposed to septa treated with *n*-pentacosane over a range of dosages from 0.1 ng to 10 μg. The maximum response was produced by 10 ng (Figure 3), which was the only dose that was significantly greater than the control (P = 0.05, G test), although substantial responses were elicited by 0.1- to 10-μg quantities. A similar dose–response curve was obtained with a 1 : 1 mixture of *n*-tricosane and *n*-pentacosane over the concentration range of 1 ng to 1 μg (not shown).

EAG Response. The responses to the *n*-alkanes were small, the maximum response being 0.4 mV (Table 4). The EAG response to the same quantity of (*Z*)-6-heneicosen-11-one, a female sex pheromone component (Slessor and Grant, unpublished data), was 2 mV. The most stimulating EAG compounds (tetracosane and tricosane) were also two of the behaviorally most active compounds, but *n*-pentacosane, also strongly active behaviorally, was one of the weakest EAG stimuli.

DISCUSSION

Hydrocarbons are frequently used as semiochemicals by insects (Howard and Blomquist, 1982). In the Lepidoptera, several moth species use saturated

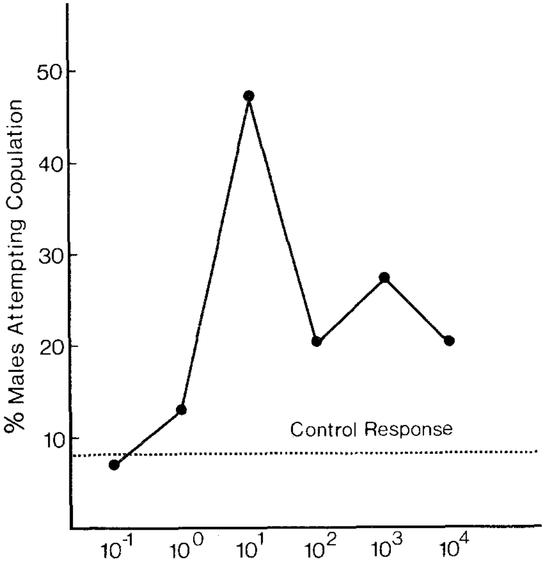

FIG. 3. Effect of concentration of *n*-pentacosane (applied to vertical septa) on percentage of male *O. leucostigma* (N = 15 for each dosage) attempting to copulate.

(Roelofs and Cardé, 1971) and unsaturated (Conner et al., 1980; Wong et al., 1984) hydrocarbons as sex attractants. In *Colias eurytheme,* a butterfly, 13-methylheptacosane found on male wings acts as a close-range "aphrodisiac," inducing acceptance behavior in the female, while two associated wing *n*-alkanes (*n*-heptacosane and *n*-nonacosane) appear to evoke female rejection behavior (Grula et al., 1980). Hymenopterous egg parasites use the alkanes found

in the scales of female *Heliothis zea* moths as kairomones to locate host material for oviposition (Jones et al., 1973).

We have demonstrated that at least four straight-chain alkanes present in the scales of female WMTM function as a copulation releaser pheromone. This is the first demonstration in moths of chemicals other than those originating from the sex pheromone gland (on the 8–9th intersegmental membrane) that are capable of doing so. The copulation releasing effect of these compounds, however, is dependent on the prior stimulation of males with female sex pheromone; that is, the sex pheromone acts as a primer for the releaser stimulus as observed with nonchemical releaser stimuli in other lepidopteran species (Shorey and Gaston, 1970; Haynes and Birch, 1984; Grant, in preparation). By contrast, the action of the copulation releaser pheromone, erectin, of the azuki bean weevil, *Callosobruchus chinensis,* appears to be independent of the sex pheromone (Tanaka et al., 1981), while in some Diptera the sex pheromone is nonvolatile and itself releases copulation when the male contacts the female (Howard and Blomquist, 1982). The chemicals releasing copulation in these species are also cuticular hydrocarbons, although they are somewhat larger and more complex than those of WMTM.

Many of the alkanes with an odd number of carbon chains found in the scales of female WMTM are also found in the scales or body surfaces of many other adult lepidopterans. They occur in male WMTM (unpublished data), both sexes of the cabbage looper, *Trichoplusia ni* (De Renobales and Blomquist, 1983), the corn earworm, *H. zea* (Jones et al., 1973), two species of *Colias* butterflies (Grula et al., 1980), and both sexes of several *Choristoneura* budworm species (unpublished data). The widespread occurrence of these hydrocarbons along with the similar physical characteristics of the scales probably accounts for the "universal" copulatory response (Ono, 1977) of male moths to male and female scales of other species (Grant, 1981; Ono, 1974, 1977, 1979, 1980, 1981; Sanders, 1979; Shimizu and Tamaki, 1980).

The apparent lack of specificity in stimuli which release copulation in these lepidopterans is not surprising because the factor controlling specificity is usually the female sex pheromone (Ono, 1980). Copulation-releasing stimuli such as the WMTM scale alkanes serve simply as sign stimuli indicating that the sex pheromone source is a suitable object for copulation. The system is not foolproof, however, because homocourtships often occur when two or more males arrive at a pheromone source at the same time. The chemical and physical similarity of male and female scales may also be responsible for this behavior.

The quantity (10 ng) of alkane required to elicit a copulatory response was surprisingly low. The EAG results suggest that males can perceive the scale alkanes with olfactory receptors on their antennae; however, the responses obtained with a relatively large stimulus dose (1 μg) were small, as was the case for female *Colias* butterflies stimulated with similar alkanes identified in male *Colias* wings (Grula et al., 1980). The low volatility of these alkanes could

account for the weak EAG responses, but the observation that WMTM males appear to make obligatory tarsal and antennal contact with the female or model before attempting copulation suggests that the alkanes are detected at very close range, probably by contact chemoreceptors. This could explain why *n*-pentacosane elicited a low EAG response. The perceptual mechanism by which the alkanes are detected requires further study.

Although we have demonstrated a role for the scale alkanes in releasing male WMTM copulatory behavior, other stimuli are also effective releasers and may not involve the scales at all. For example, the orientation of the model (vertical vs. horizontal) also affected the release of copulatory behavior, an observation repeated with the male spruce budworm, *C. fumiferana*, exposed to pheromone-treated septa (Grant, in preparation). Why male moths respond differently to horizontal and vertical models is not clear, but it could be related to differences in visual stimuli presented by the two models or to how the antennae or other appendages contact the model. For WMTM, vertical septa without scales may not provide an adequate tactile stimulus to release copulatory behavior.

Acknowledgments—We are grateful to Dail Grisdale and his rearing staff at FPMI for supplying the tussock moths used in this study; the urticating hairs of the larvae made their task particularly difficult.

SYNTHESIS OF ENANTIOMERICALLY ENRICHED 2-HEPTANOL AND 3-OCTANOL BY MICROBIAL REDUCTASES OF *Curvularia falcata* AND *Mucor* SPECIES

JOHN M. BRAND,[1] DIANA L. CRUDEN, and ALLEN J. MARKOVETZ

Microbiology Department, University of Iowa

(Received January 8, 1986; accepted February 28, 1986)

Abstract—Certain insects produce 2-heptanol or 3-octanol in various glandular secretions and recent studies have shown that the 3-octanol of two different genera of ants (*Crematogaster* and *Myrmica*) can be either the (*S*)-(+) or mainly the (*R*)-(−) enantiomer, respectively. Synthesis of each of these alcohols can be achieved in relatively high enantiomeric purity by certain microbial reductases. The corresponding ketone of each alcohol is reduced by *Curvularia falcata*, giving an alcohol which is about 90% the (*S*)-(+) enantiomer, and two *Mucor* species give as much as 80% the (*R*)−(−) enantiomer. The synthesis of certain chiral alcohols from their corresponding ketones by microbial reductases can offer a simple procedure for obtaining sufficient amounts of these substances for certain behavioral studies.

Key Words—Chiral alcohols, 2-heptanol, 3-octanol, microbial reductases, *Curvularia falcata*, *Mucor* species.

INTRODUCTION

The mandibular glands of three species of *Myrmica* ants contain 3-octanol as a component of their alarm pheromone blend, and this alcohol is >90% the (*R*)-(−) enantiomer (Attygalle et al., 1983). Bioassays of the pheromonal activity of the separate enantiomers of 3-octanol for three species of these ants indicated that they respond only to the (*R*)-(−) enantiomer; the (*S*)-(+) enantiomer is

[1] Present address: Biochemistry Department, University of Fort Hare, Alice 5700 Ciskei, South Africa.

0098-0331/87/0200-0357$05.00/0 © 1987 Plenum Publishing Corporation

inactive (Cammaerts et al., 1985). The separate enantiomers of 2-octanol, which are commercially available, gave little or no response with these *Myrmica* ants. In contrast, two species of *Crematogaster* ants produce exclusively (*S*)-(+)-3-octanol in their mandibular glands (Brand, 1985), but no bioassays have been conducted with the separate enantiomers on these species.

The results of Cammaerts et al. (1985) illustrate the need for behavioral studies on the separate enantiomers of such simple alcohols as 3-octanol in insect species that produce them. However, the separate enantiomers generally are not available to the biologist wishing to bioassay them, and a chemist might not be persuaded easily to synthesize the enantiomers of such mundane alcohols. For their bioassays, Cammaerts et al. (1985) isolated (*S*)-(+)-3-octanol by preparative gas chromatography from oil of Japanese peppermint (*Mentha japonica*), and (*R*)-(−)-3-octanol from heads of worker ants of *Myrmica ruginodis*. However, in many cases, the preparation of microliter quantities of a compound from the insects themselves may not be feasible.

The two alcohols, 2-heptanol and 3-octanol, occur in various insect secretions (Blum, 1981). While the separate enantiomers of 2-heptanol are available from Norse Laboratories, Newbury Park, California 91320, the separate enantiomers of 3-octanol are not available commercially. The enantiomers of each of these simple alcohols could be produced by the action of an appropriate dehydrogenase on the corresponding ketone, a reaction obviously taking place in vivo. Reduction of ketones by microbial reductases, using whole cells, often with high yields of only one enantiomer, is quite common, and this procedure can be used to obtain appreciable amounts of product (MacLeod et al., 1964; Sariaslani and Rosazza, 1984, and references therein; Wong and Drueckhammer, 1985, and references therein).

We have synthesized each enantiomer of 2-heptanol and 3-octanol from the corresponding ketone in 80–90% purity with microbial reductases. The chirality of the alcohol obtained was determined by gas chromatography of the (*R*)-(+)-*trans*-chrysanthemoyl esters as described previously (Attygalle et al., 1983; Brand, 1985). *Curvularia falcata* gives approximately 90% (*S*)-(+)-2-heptanol and (*S*)-(+)-3-octanol, and two *Mucor* species produce 70–80% (*R*)-(−)-2-heptanol and (*R*)-(−)-3-octanol. These studies have been done using whole cells in their culture medium and the procedure can be scaled up to produce sufficient quantities of material for behavioral work.

METHODS AND MATERIALS

All fungal strains were obtained from the personal collection of J.P.N. Rosazza, University of Iowa. The successful strains used were *Curvularia falcata* QM-72 D, *Mucor recurvatus* UI-36, and *M. mucedo* 20094 P. The organisms were grown and maintained on soybean meal–glucose medium consisting of (grams per liter distilled water): glucose 20 g, yeast extract 5 g, soybean

meal 5 g, NaCl 5 g, and K_2HPO_4 5 g. The pH of the medium was adjusted to 7.0 before autoclaving.

Cultures were inoculated from an actively growing culture (5% inoculum), and grown with vigorous shaking in 100 ml medium in 250 ml Erlenmeyer flasks or 1 liter medium in Fernbach flasks. After 1 to 3 days of growth, the cultures were placed in an anaerobic chamber (Coy Mfg. Co.; gas phase: 85% N_2, 10% H_2, 5% CO_2) and allowed to become anaerobic for several hours before addition of either 2-heptanone or 3-octanone (200 μl for 100 ml medium or 2 ml for 1 liter medium). Preliminary studies showed that yields of the alcohol were higher with cultures kept anaerobic rather than aerobic. The period of exposure to either ketone varied from 6 hr to 8 days.

After exposure to either ketone, all the cultures were extracted twice with ether and the ether dried over anhydrous Na_2SO_4. *C. falcata* cultures turn black with time, and it is only when the organism is black that it is extracted easily with ether. Extraction of the earlier yellowish-brown stage results in an emulsion that is extremely difficult to break. *Mucor* cultures did not give any extraction problems.

Gas chromatographic determination of the ketone–alcohol ratio was done at 70°C using a Supelcowax 10 fused silica capillary column (15 m). Derivatization of the alcohols was done on the ketone–alcohol mixture with (*R*)-(+)-*trans*-chrysanthemic acid as described previously (Brand, 1985). Separation of the 2-heptanyl esters was achieved at 115°C and the 3-octanyl esters at 130°C on the Supelcowax 10 column. GC-MS of the standard 2-heptanyl and 3-octanyl esters and of the same esters from microbially produced alcohols was carried out on a 5% phenyl methyl silicone fused silica capillary column (25 m) at 140°C, interfaced to a Finnigan 1015 quadrupole mass spectrometer.

RESULTS

Gas chromatography of the ether extracts from *C. falcata* and *Mucor* cultures indicated that the added ketone and its corresponding alcohol were the only major volatile compounds in the extract. The formation of the (*R*)-(+)-*trans*-chrysanthemates was performed on the ketone–alcohol mixture without any further purification. Confirmation of the structures of the (*R*)-(+)-*trans*-chrysanthemoyl esters was obtained by comparison of the retention times with standards on the Supelcowax 10 column, and by GC-MS on the 5% phenyl methyl silicone column interfaced to a Finnigan 1015 quadrupole mass spectrometer. Equivalent mass spectra were obtained from the esters of standard 2-heptanol and 3-octanol and the microbially produced alcohols. The characteristic base peak at *m/e* 123 was obtained in all cases with a molecular ion at *m/e* 266 for the 2-heptanyl ester and at *m/e* 280 for the 3-octanyl ester.

2-Heptanone. *C. falcata* gave 2-heptanol that was 87–90% the (*S*)-(+) enantiomer, *M. recurvatus* gave about 76% the (*R*)-(−) enantiomer, and *M.*

mucedo gave 70–80% the (*R*)-(−) enantiomer. The recovery of the ketone plus alcohol as a percentage of the initial ketone added was as high as 70%.

3-Octanone. *C. falcata* gave 3-octanol that was 86–90% the (*S*)-(+) enantiomer, *M. recurvatus* gave about 76% the (*R*)-(−) enantiomer, and *M. mucedo* gave 75–80% the (*R*)-(−) enantiomer. The recovery of the ketone plus alcohol as a percentage of the initial ketone added was as high as 90%. In one experiment with 3 liters of *C. falcata* treated with 3-octanone and kept anaerobic for eight days, the ratio of ketone to alcohol recovered was 20:80, with the 3-octanol being 90% the (*S*)-(+) enantiomer. In another experiment, 3 liters of *M. mucedo*, kept anaerobic for 6 days, gave 10:90 ketone to alcohol but the 3-octanol was only 61% the (*R*)-(−) enantiomer. In each of these latter two experiments 0.3–0.4 ml of the alcohol was obtained.

DISCUSSION

Cammaerts et al. (1985) conducted satisfactory bioassays on *Myrmica* ants using 3-octanol that is approximately 90% the (*R*)-(−) enantiomer. This illustrates that certain behavioral experiments are possible with an alcohol that is highly enriched in only one enantiomer and that absolute purity of the enantiomer is not necessary for some studies. The (*S*)-(+)-2-heptanol and the (*S*)-(+)-3-octanol of about 90% purity produced by *C. falcata* and the (*R*)-(−) enantiomer of 75–80% purity produced by *M. mucedo* might be adequate for similar behavioral studies on some insects that produce these alcohols. However, the lack of activity of one enantiomer, as is the case with *Myrmica* (Cammaerts et al., 1985), may be an important criterion in the interpretation of bioassay data on alcohols of the above purity. An extensive literature documents the inhibitory effects of small percentages of unnatural enantiomers on the response of certain insects, and a cautionary note is offered on this point when bioassaying enantiomers that are only highly enriched and are not absolutely pure.

Neither the *C. falcata* nor the *Mucor* species reduced all the ketone to the alcohol. The best conversions obtained were a 20:80 ratio of 3-octanone to 3-octanol with *C. falcata* after anaerobic exposure to the ketone for eight days, and a 10:90 ratio with *M. mucedo* after six days. Sih and Chen (1984) have pointed out that a major complication in using intact cells for the reduction of ketones is that the process may be only partially enantioselective. They conclude that this usually arises from the combined action of competing enzymes of opposite chirality in intact cells. A ratio of 9:1 of the *S*:*R* enantiomers was obtained with *C. falcata* whether the exposure time was 6 hr or eight days, and in contrast, the *M. mucedo* usually gave about 80% the (*R*)-(−) enantiomer with an 18-hr exposure, but only 61% after six days. We have not attempted to optimize conditions for these organisms and do not know whether competing enzymes are present. Certain additional microorganisms tested, e.g., *C. pallescens* ATCC 12018 and bakers' yeast, did not produce any alcohol under the

usual conditions employed. However, it seems certain that suitable organisms and conditions could be found that would give better than 90% of either enantiomer in good yield.

As only one enantiomer of the alcohol was a major product, we wondered whether these organisms would selectively oxidize the same enantiomer if given the racemic alcohol under aerobic conditions. Our attempts to do this failed completely, and the reduction of the ketone seems irreversible with these organisms. This irreversibility of reduction has been mentioned by MacLeod et al. (1964) and by Sih and Chen (1984) and is understandable under anaerobic fermentative conditions. We have no explanation as to why our organisms failed to reoxidize any alcohol under aerobic conditions. In previous experiments we have found a fungus that would oxidize racemic *trans*-verbenol to verbenone quantitatively under aerobic conditions (Brand et al., 1976). A different approach employing the enantioselective hydrolysis of certain racemic acyclic alcohol acetates by microbial esterases, to yield chiral alcohols such as (*S*)-(+)-3-octanol, has been described by Oritani and Yamashita (1980).

As the reduction of the ketone is incomplete, solvent extracts of the culture medium contain variable amounts of the added ketone. Separation of the alcohol from the ketone could be achieved by adsorption column chromatography and preparative gas chromatography.

Abstract—In an alpine meadow ecosystem in the Swiss National Park, the lichens *Cetraria islandica* and *Cladonia symphycarpa* occur in small vegetation patches dominated by *Carex firma* (Cyperaceae) and *Sesleria coerulea* (Gramineae). Laboratory food-choice experiments with two oribatid mites *Fuscozetes setosus* and *Carabodes intermedius* show that the thallus structure and secondary products of *C. islandica* are repellent factors against herbivorous mites. In contrast, secondary products of *C. symphycarpa* may be an attractant for the mites.

Key Words—Lichen, herbivores, secondary products, oribatid mites, Acari, food choice, *Cetraria islandica*, *Cladonia symphycarpa*, *Fuscozetes setosus*, *Carabodes intermedius*.

INTRODUCTION

The aim of this study was to investigate the influence of lichen secondary products on the food choice of two mite species, *Fuscozetes setosus* (C.L. Koch, 1841) and *Carabodes intermedius* Willmann, 1951, in an alpine meadow ecosystem in the Swiss National Park.

This meadow, 2550 m above sea level [vegetation type *Caricetum firmae* (Kerner) Br.-Bl.1926] has been studied since 1976 by a team of ecologists. A description of the study site is given by Matthey et al. (1981).

In this habitat, lichen phytomass accounts for only 1.1–5.5% of total phytomass (Galland, personal communication). The most abundant lichen species are *Cetraria islandica* (Iceland moss) and *Cladonia symphycarpa*. The first spe-

0098-0331/87/0200-0363$05.00/0 © 1987 Plenum Publishing Corporation

cies is associated with *Carex firma* (Cyperaceae) and *Sesleria coerulea* (Gramineae) living in small vegetation patches without soil contact, while the second species grows on the edge of the vegetation cluster on disturbed humous subsoil.

About 50 species of oribatid mites occur in the habitat. Of these, 14 fed regularly on lichens, particularly on *C. symphycarpa*. In contrast, *C. islandica* was strictly avoided by all mite species. Two mite species, *F. setosus* and *C. intermedius*, the most active feeders on thalli of *C. symphycarpa* were chosen for food choice experiments. They were also the mite species most easily maintained in the laboratory. Both species belong to the panphytophagous feeding group (after Luxton, 1972). Whereas *F. setosus* is a dominant species that occurs regularly distributed in all vegetation types (Rohrer and Reutimann, 1984), *C. intermedius* was found predominantly associated within the small lichen microhabitats.

METHODS AND MATERIALS

The secondary products of both lichen species were identified by thin-layer chromatography (Culberson and Ammann, 1979). In *Cladonia symphycarpa*, the depside atranorin occurs in the cortex, the depsidone norstictic acid, as well as an unidentified substance occurring in the medulla. In the medulla of *Cetraria islandica* protolichenesterinic acid, an aliphatic lichen acid, as well as the depsidone fumarprotocetraric acid (a bitter substance) have been found (Culberson, 1969; Culberson et al., 1977).

The secondary products of freshly collected thalli of *C. symphycarpa* and *C. islandica* were extracted in acetone up to four times for a period of approx. 20 min each time. Thalli subjected to extraction constituted the substrate types B and G for food choice experiments (Figure 1). Other extracted thalli were then impregnated with the soluble secondary products of the respective species (repeated submersion of the thalli in acetone and desiccation in a thermal cupboard) (substrate types C and F).

The above-mentioned soluble secondary products were also applied on cellulose-free filter paper (diameter 10 mm, Balston Ltd) (substrate types D and E). Traces of secondary products were still detected in thalli B and G after three extractions. Lichenological spot tests (color reaction on lichen after application of an indicator solution) showed, however, typical discoloration of the inoculated lichen material on thalli C and F. Untreated desiccated thalli were used as controls (A and H).

The following eight substrate types were used in dual combinations for food-choice experiments with the mites: A, *C. islandica*, thalli, freshly collected, dried (control); B, *C. islandica*, thalli, with most secondary products

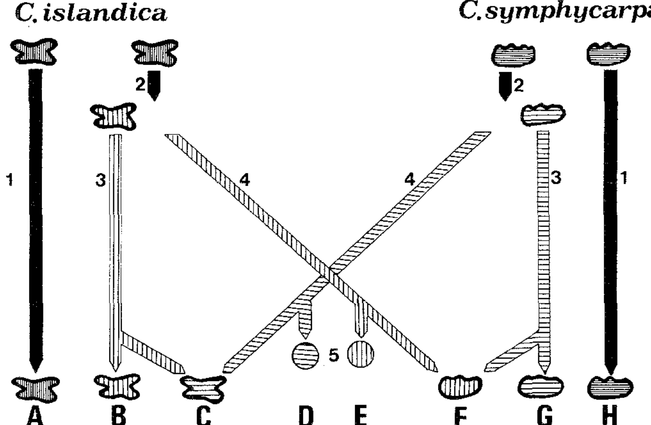

FIG. 1. Diagram of treatments: (1) no treatment, (2) acetone extractions of secondary products, (3) thalli subjected to acetone extractions, (4) acetone-soluble secondary products for impregnations, (5) disks of filter paper with secondary products dissolved in acetone. For further explanation, see text.

removed by acetone extractions; C, *C. islandica*, thalli, treated as in B, but with the secondary products of *C. symphycarpa*, applied in acetone solution; D, *C. islandica*, acetone-extracted secondary products on glass filter paper; E, *C. symphycarpa*, acetone-extracted secondary products on glass filter paper; F, *C. symphycarpa*, thalli, treated as in E, but with the secondary products of *C. islandica* applied in acetone solution; G, *C. symphycarpa*, thalli, with most secondary products removed by acetone extractions; and H, *C. symphycarpa*, thalli, freshly collected, dried (control).

Feeding experiments were conducted in covered glass dishes, 48 mm in diameter, containing substrate made of a mixture of plaster of Paris and charcoal (15 : 1) and with a relative humidity of 90–99%. In each dish, two of the eight food types (A–H, see above), were offered. Five adults of each species were used in each experiment. Seven pairwise combinations were chosen for the experiments (see Table 1 and Figure 1). The animals were kept at 20°C and observed once a day for a period of 6–19 days. Preferences in each pairwise combination were tested for with chi-square tests for goodness of fit (Wonnacott and Wonnacott, 1977). The null hypothesis (no preference) was that mites would be distributed equally between the two substrates. Observations of distribution on substrates were made once daily. Preferences were scored by summing the individual daily observations for the 6–19 days of each experiment. Feeding observations, feeding marks on the substrates, or fecal pellets were recorded as well.

RESULTS

The individuals of both species were repeatedly observed to eat thallus tissue of *Cladonia*. They strictly refuse untreated *Cetraria* (A and H, Table 1). Both species prefer to feed on untreated *Cladonia* even in the presence of *Cetraria* impregnated with *Cladonia* substances (C and H). This indicates a preference for *Cladonia* as substrate.

Carabodes significantly prefer untreated *Cladonia* to *Cladonia* without lichen substances (G and H). *Cetraria* with a reduced concentration of lichen substances are only eaten by *Fuscozetes* (A and B). No feeding attempts were noticed on the glass filter paper. When lichen products were nearly completely removed, lichen thalli of both species were eaten by both *Fuscozetes* and *Carabodes* (B and G).

Examination of gut contents show that both species digest only hyphae of lichen fungi and excrete lichen algae undigested. In laboratory experiments, unicellular green algae (unidentified) are only eaten by *Carabodes* (Reutimann, 1985).

DISCUSSION

Carabodes clearly avoids lichen substances on filter paper, where *Fuscozetes* reacts positively to the *Cladonia* lichen substances (atranorin, norstictic acid, and an unidentified substance) (D and E). Secondary products from *Cladonia* are an important factor leading to acceptance of *Cladonia* by *Fuscozetes*. They seem to have only a limited antiherbivore function against the two mite species (cf.Rundel, 1978). The distal sensory organs of the mite would perceive these compounds in the case of direct contact with the substrate by means of the chemosensory setae on the distal segments of legs I and II as well as the palpi (Krantz, 1978), but the compounds seem to lack a decisive stimulating quality in eliciting feeding behavior.

Lichen substances of *Cetraria* (protolichenesterinic acid, fumarprotocetraric acid) have, on the other hand, a certain repellent effect on these two mite species. The presence of appreciable concentrations of fumarprotocetraric acid (Culberson et al. 1977) might be responsible for this. Various authors report that reindeer avoid *Cladonia* species with fumarprotocetraric acid, whereas they eat species not containing it (Rundel, 1978). In contrast to *Cetraria islandica*, *Cladonia symphycarpa* does not contain these substances (Culberson, 1970; Culberson et al., 1977).

The different reactions of the two mite species to lichens may be seen in the context of other differences in feeding behavior. While both species are classified as panphytophagous feeders (after Luxton, 1972), *Fuscozetes* also captures living (and dead) animal prey (zoophagous and necrophagous feeding

subtype, after Luxton 1972; Reutimann, 1985). It is a relatively active species, unlike *Carabodes*, which seems to be a relatively inactive, predominantly fungivorous species. Patterns of spatial distribution in the habitat showed that *Carabodes* is closely associated with lichens (Reutimann, 1985). *Cladonia* thalli in alpine meadows often show traces of feeding of the type made by these mites.

In addition, *Carabodes* proved to be very constant in its substrate preferences for lichen in laboratory tests with different organic materials (Reutimann, 1985). Lichen-mite associations have been found repeatedly by various authors (e.g, Bellido, 1975; Andre, 1975; Gjelstrup and Søchting, 1979; see Seyd and Seaward, 1984, for a comprehensive view).

A main consequence of the acetone treatment is the abrupt death of the fungal and algal cells in the lichen thalli caused by lysis of the plasmalemmas. In addition, the traces of lichen substances remaining in the thalli B, C, F, and G show that the method should be improved upon for further experimental work. The efficiency of extraction could perhaps be increased with other solvents.

Relatively few studies have documented the ecological importance of lichen products in relation to herbivorous animals. A few lichen products have antibiotic effects. Lichens with certain lichen products (bitter constituents, protocetraric acid, fumarprotocetraric acid) are avoided by a few lichen-eating invertebrates (Gerson and Seaward, 1977). It is not exactly known in individual cases if secondary products ensure effective protection against consumption. Gerson and Seaward (1977) argued that various secondary products do not greatly influence the consumption of lichens.

Lawrey (1983) suspects that secondary products may be only one of several factors affecting food preferences of lichen herbivores. The quality of food may be diminished by a lower concentration of essential nutrients. In this connection the nature of the algal symbiont may be of importance. Lichens with the nitrogen-fixing bluegreen algae may have higher nitrogen contents. The symbiont in the case of the lichens examined in this study is a green alga. Our experiments show definitely that thallus structure is another important factor in mite feeding preferences. The relative importance of secondary products and other factors influencing food preferences may vary among lichen species. These species may be expected to differ in secondary product concentrations. Species with high growth rates, for example, may be able to compensate for herbivore damage, and there may be less selection for antiherbivore defense in these species.

Acknowledgments—This research was carried out as part of the PhD thesis at the University of Basel (Switzerland) and was supported by the Swiss National Foundation (Project Matthey, No. 3.600.-0.79). We are very grateful to Dr. R. Honegger (Zürich), Dr. D. McKey, and Dr. A. van Noordwijk (Basel), and Ph. Clerc (Bern) for their valuable help. We also wish to thank Frau F. Oberli (Bern) for technical assistance in the laboratory.

(Received December 2, 1985; accepted March 10, 1986)

Abstract—From pentane extracts of worker heads of the stingless bee (*Scaptotrigona postica*), 70 volatile compounds were identified by combined gas chromatographic–mass spectroscopic analyses. A bioassay was developed to evaluate intranidal reactions of workers to synthetic volatiles. Thirty-six of the cephalic volatiles were tested. Thirteen types of behavioral reactions were recorded in a semiquantitative manner. The test was run in the brood nest where mainly young nurse bees are present and also in the storage area of the nest with old foragers traffic. The results obtained were compared and discussed in order to understand the chemical communication system of this species. Especially in the dark interior of the nest, which in nature is found in hollow tree cavities, chemical messages obviously play a particularly important role in the communication systems of the bees.

Key Words—Cephalic volatiles, stingless bee workers, intranidal reactions, *Scaptotrigona postica*, Meliponinae, Apidae, Hymenoptera.

INTRODUCTION

The enormous behavioral diversity in the more than 300 species of stingless bees (Hymenoptera: Apidae, Meliponinae) seems to depend on elaborate com-

0098-0331/87/0200-0371$05.00/0 © 1987 Plenum Publishing Corporation

munication systems. Ritualized movements and sound production, as evident in the dance language (von Frisch, 1967) of honeybees (Apinae), seem to be of minor importance in stingless bees (Kerr and Esch, 1965; Gould et al., 1985). They widely use chemical information (Kerr, 1960; Kerr et al., 1963). Scent marks placed by scout bees guide recruited foragers to food sources (Lindauer and Kerr, 1958; Kerr et al., 1981). Massive colony defense is released by alarm pheromones (Blum, 1981) or kairomones (Wittmann, 1985). Drone mating assemblies are probably stabilized by a male-specific aggregation pheromone (Engels and Engels, 1984).

We hypothesize that in stingless bees an expressive chemical communication system is essential for their highly evolved social organization. Nothing is known about pheromones involved in reproduction (Sakagami, 1982; Wille, 1983) and only little about chemocommunication in the dark interior of nest cavities (Keeping et al., 1982). Therefore, we developed a bioassay to be employed within the nest.

Recently we reported a considerable age- and function-dependent variation in the numerous cephalic volatiles found in workers of *Scaptotrigona postica* (Francke et al., 1983); the list of identified compounds is completed here. In order to decode the information transmitted by volatiles, we only tested in this first study worker reactions to single synthetic compounds. The objective was to clarify whether all identified constituents of the cephalic volatiles would release a specific behavioral response. The expected results will enable us to design biotests with various mixtures of volatiles.

METHODS AND MATERIALS

Bees. Free flying *Scaptotrigona postica*[4] (Latreille) colonies of normal size, as found in natural nests, were kept in indoor observation hives in the bee laboratory of the Department of Genetics on the Ribeirão Preto Campus, Sao Paulo State, Brazil.

The nest boxes constructed for the bioassay (Figure 1) are subdivided into a brood nest and a storage part, connected only by two narrow tunnels to avoid rapid odor exchange. The nest entrance leads to the storage area. The brood nest consists of horizontal combs built from bottom to top. New vertical cells are added on the edge of the combs. Following the provisioning of a completed cell with larval food by the nurse bees, and ovipositioning by the queen, the cell is sealed. The brood nest is normally surrounded by several thin layers of cerumen. The uppermost part of this involucrum was always removed in order

[4] According to the subdivision of the *Scaptotrigona postica* superspecies as proposed by Moure (1942), our bees belong to *Sc. depilis.*

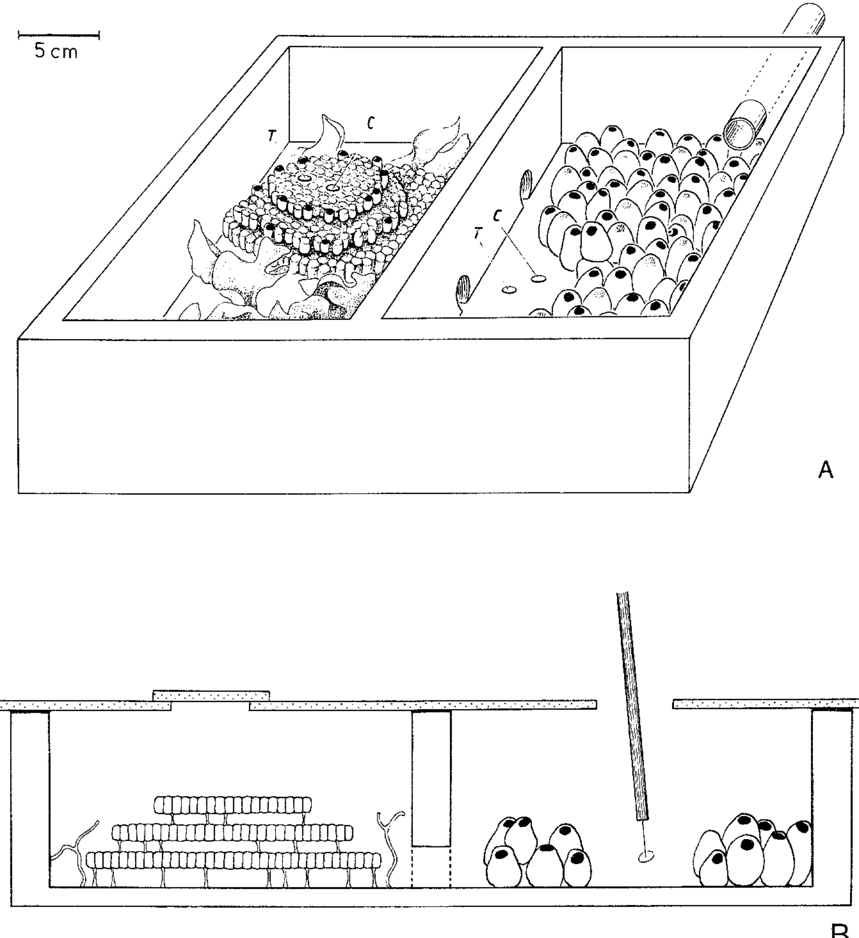

FIG. 1. Experimental wooden nest box used in the volatile bioassay with free flying stingless bee (*Scaptotrigona postica*) colonies. (A) Overview, (B) Cross-section. In order to have two test compartments, the nest box was separated into the brood nest (left) and the storage area (right) connected by two tunnels. The entrance tube led to the storage area with honey and pollen pots which in part are closed. The nest box was covered with a glass plate. Through perforations, normally closed by small pieces of glass, the wax test disks could be manipulated by a stickpin. The test disks were placed on the bottom of the box in a corner free of pots or on the uppermost brood comb. Bees are not shown in this drawing. T = beeswax test disk impregnated with pentane-dissolved synthetic volatiles, C = control disk, impregnated with pure pentane or blank.

to use the upper comb as a test platform. Tests were never run simultaneously in the brood nest and storage area.

Identification of Compounds. Pentane extracts of the heads of old adult worker bees were analyzed using a gas chromatographic–mass spectroscopic coupling system (Varian MAT 311 A) as previously described (Francke et al., 1983). Up to now 70 volatile compounds have been identified, and their relative proportions have been determined. The total amount of volatile material per individual was found to range between 150 and 250 μg. However, the absolute amount of compounds secreted by the bees to produce a distinct odor signal is as yet unknown. The purity of test compounds was higher than 98%; the chiral compounds were racemic. Single components were used as 5% pentane solutions.

Bioassay. Thirty-six of the identified compounds were bioassayed (Table 1). Small disks of beeswax (8 mm diameter) were punched out of comb foundation. Test solutions were applied on the wax disks in aliquots of 1, 2, or 5 μl. According to the actual concentrations of the respective compounds in natural secretions (Table 1), the applied volumes of the test solutions represent 1–500 bee equivalents. Due to the lack of "natural solvents or fixatives" such as high-boiling hydrocarbons and lipids present in the natural secretion, the synthetic compounds evaporated more rapidly during the test runs. The impregnated test disk was immediately transferred into the colony by spitting it on top of a fine pin to avoid tool contamination. The bottom of the storage area or the uppermost brood comb were used as a test compartment. The glass lid of the observation box was perforated to facilitate handling of the wax disk. A blank disk was always placed a few centimeters away from the test disk (Figure 1). After termination of the observation period, the test disk was removed and discarded in order to avoid habituation to odors. Tests were carried out on three different colonies placed in the same observation laboratory. The study site has a wet tropical climate. The tests were usually run in the morning and afternoon and only under favorable weather conditions for normal foraging. Ambient temperatures were between 25 and 35°C. Testing was carried out from October 1983 to November 1984, excluding the dry months June, July, and August, and during March and April 1985.

Bioassay Records. The reactions of the worker bees in the tests were highly specific. General and special behavioral responses could be distinguished (Figure 2). The course of the reactions was recorded every 30 sec over a period of 3–5 min. The number of bees exhibiting any type of reaction towards the test disk was noted and compared with the bees' behavior around the control disk. Our purpose here was to guarantee that specific volatile-released behavior was recorded and not circumstantial excitement. Depending on the type and intensity of the reactions observed, a break of at least 5 min was made between consecutive tests. All compounds were tested on different days, at least two to

[a]The compounds of the different classes are listed according to their relative proportions found in the natural extract. Only substances contributing at least 0.05% were listed. Of the 70 cephalic volatiles, 36 have been used in the bioassay.

three times, in changing random sequences. If alarm was released, a long break was organized so that normal behavior could be reestablished.

Biotest Evaluation. Our semiquantitative records were scaled according to the following classes of reaction intensity: 0 = no reaction; 1 = specific reaction seen in 1–5 bees at the same time or during the first 3 min; 2 = the same

FIG. 2. Intranidal reactions of stingless bee workers (*Scaptotrigona postica*) to pure synthetic volatiles. Semiquantitative records, heights of bars (cf. bottom right) represent means of reaction intensity (1–5) shown in 2–5 test series. Specific reactions released by the various compounds may be compared by reading the table horizontally; vertical reading shows the pattern of different reactions evoked by a single compound. Solid and open bars represent the response obtained in the storage area and the brood nest, respectively. As can be seen from the chart, all single volatiles released a typical behavior.

for 6–10 bees; 3 = 11–15 bees; 4 = 16–25 bees; 5 = 26 bees or more, mostly all bees of the area reacted, i.e., several hundred bees.

RESULTS

Analysis of Cephalic Volatiles in Old Worker Bees. As an increase with age in *Scaptotrigona postica* worker cephalic volatile concentrations was found in most of the compounds (Francke et al., 1983), we used head extracts from old guarding and foraging bees in the present analyses. We could now complete our previous list to 70 compounds (Table 1). Within this bouquet, there is a predominant number (31 identified compounds) and total amount (more than 40% of all volatiles) of esters, (Z)-7-hexadecenyl butanoate alone contributing 16.7%. The 17 alcohols represent about 30%, the 10 carbonyl compounds about 20%, the 5 carboxylic acids about 5%, and 7 hydrocarbons less than 1% of the extract mixture. In this complex multicomponent blend, the seven most abundant compounds (2-tridecanone, 2-pentadecanone, (Z)-7-hexadecenyl butanoate, (Z)-5-tetradecenyl butanoate, the two corresponding secondary alcohols, and 2-heptanol) make up more than 60% of the bouquet. Trace compounds contributing less than 0.05% were not analyzed and are neglected here. About half the identified compounds (36 of the total of 70, Table 1) have been tested. The results are summarized in Figure 2.

General Observations. Stingless bees, especially of this species, immediately remove small intruders or particles found within the nest. Large objects which cannot be bitten into fragments are plastered with cerumen. Pieces of paper, foam rubber, isopore, or wood as well as dead bees—if placed in the nest—always released local alarm, intensive handling or plastering and, therefore, were unsuitable carriers of test volatile compounds. As cerumen is a somewhat changing mixture and normally attractive in itself for all workers, we could not use this material. We found that melted honeybee wax is indifferent and a suitable material for exposing pentane solutions of volatile test compounds.

Reaction Types. We were surprised to find that all the 36 individual compounds tested evoked different behavioral responses. As pointed out above, we tried to avoid any habituation or even conditioning. In the test colonies containing thousands of bees, most of the workers probably reacted only once or a few times to a test disk.

The behavioral responses observed were highly stereotypic and can be easily classified into three general and ten specific reactions (Figure 2). Except for some antennating, pure pentane never released any specific response. As in preliminary tests, other hydrocarbons only released weak or unspecific reactions; at a later stage this class of compounds (Table 1) was not tested extensively.

Overall Reactions. Of the different classes of compounds tested (Table 1), the alcohols released the most diverse and intensive reactions, followed by the esters and the carbonyl compounds. The two carboxylic acids also evoked strong reactions (Figure 2). There was no uniform response to compounds belonging to the same chemical class. Alarm can be taken as an example for this, representing the typical social behavior of colonial bees. In our intranidal bioassay situation, intense alarm was released by six alcohols, two esters, one carbonyl compound, and one carboxylic acid. The response recorded normally included (especially in the brood nest) several other reactions like antennating, cleaning the antennae, fanning, and often also the plastering of the test disk with cerumen particles. But only one alarming compound, 2-heptanol, additionally released the mandibulating of the test disk. This reaction, on the other hand, was also seen after exposing nonalarming attractive odors, and mainly in the storage test area (Figure 2).

General Reactions

1. Attractive. Many workers approached the test disk. Most of the alcohols, several esters and carbonyl compounds, but not the two carboxylic acids tested, were attractive to the bees.

2. Repellent. Bees avoided contact with the test disk. If they got close to it, they immediately retreated. Butanoic and also hexanoic acid were found to release a pronounced repellence both in the brood and storage area of the nest. Besides this, one alcohol, 2-phenylethanol, and one carbonyl compound, (Z)-8-tridecen-2-one, were also strongly repellent, but only in the storage area of the nest.

3. Alarm. Many bees became nervous, ran away, hid, or sought an intruder to attack it. Two alcohols, 2-octanol and 2-heptanol, the ketone 2-nonanone, and butanoic acid released a "big alarm." Several other alcohols and two esters also caused alarm, but to a minor extent.

Specific Reactions

4. Antennate. Most of the compounds tested here caused the bees to antennate more or less intensively. This reaction was more pronounced in the brood nest.

5. Clean antennae. Nearly all antennating was immediately followed by a cleaning of the antennae with a corresponding intensity. Remarkable cleaning activities were released by the two carboxylic acids and the alcohol 2-phenylethanol both in the storage and brood nest.

6. Lick test disk. Approximately half the compounds tested, except for the carboxylic acids, were licked from the test disk. But only a few bees always exhibited this reaction.

7. Fan. The fanning behavior was correlated with alarm in most of the tests and was particularly observed in the alcohols and the carboxylic acids.

None of the esters and only one carbonyl compound, 2-nonanone, released a strong fanning reaction.

8. Bite test disk. This reaction was one of looking aggressive and was especially observed when 2-heptanol impregnated disks were exposed in the brood nest. 2-Phenylethanol and some of the esters released medium attacks. Many other compounds also released disk biting reactions, but only in a few bees.

9. Wing beat. This very characteristic response was directed towards other bees and was observed exclusively in the brood nest. This behavior was released by many compounds, but was especially pronounced when testing the alcohols hexanol, 2-octanol, 2-nonanol, the ester 2-heptyl (*E*)-2-hexenoate, and benzaldehyde.

10. Attack. Many different volatiles evoked aggressive worker interactions. The attacking of other bees was pronounced in the brood nest, where the esters hexyl 3-methylbutanoate and 2-heptyl hexanoate, apart from benzaldehyde, were the most effective aggression releasers.

11. Trophallaxis. A few food-exchange reactions were recorded in many tests, especially with the alcohols. Relatively frequent trophallaxis was noted when testing the ester hexyl pentanoate.

12. Attach cerumen on test disk. This reaction was rare, but also very characteristic. It was released by five of the alcohols, especially by hexanol and 2-heptanol, and a few times also by two esters and two carbonyl compounds. Never more than a few bees deposited pieces of cerumen on the test disk, and there was some correlation with weak alarm reactions.

13. Sit on test disk. This rare, but also highly specific, behavior was released by several compounds of all classes and was mainly observed in the brood nest. The same worker bee was often standing on the wax disk and defending it. If the disk was abandoned, sometimes another worker immediately occupied it.

Reactions to Chemically Related Compounds. Of several possible examples, the reactions released by 2-heptanol and derived esters and carbonyl compounds will be compared here (Figure 2). 2-Heptanol was highly attractive and alarming and also caused intensive fanning and mandibulating of the test disk, especially in the brood nest. 2-Heptyl hexanoate provoked similar reactions, but to a lesser extent and was more pronounced in the storage area. Apart from this, some wing beating and, in particular, attacks on other bees were recorded in the brood nest. 2-Heptyl (*E*)-2-hexenoate was extremely attractive both in the brood and storage area, but only caused minimal alarm in the latter part of the nest. 2-Heptanone clearly released a weaker response. The compound was only slightly attractive in the storage nest. No alarm was recorded at all. The pattern of other specific reactions was a mixture of the responses recorded while testing the alcohol and the esters.

Reaction Patterns. None of the 36 compounds tested only evoked a single specific reaction (Figure 2). The minimal response was obtained with 2-hexyl hexanoate which released four types of reactions, the maximal with 2-phenylethanol and 2-nonanone, both resulting in 12 of the 13 different reactions. The average number of different reactions released by one compound was 9.8 in the alcohols, 8.9 in the carbonyls, 8.2 in the esters, and 5.5 in the carboxylic acids.

There was considerable variation in the type and intensity of reactions recorded in the brood and in the storage test areas. Some compounds evoked exactly the same, others extremely different responses in both parts of the nest. Generally speaking, the bees in the brood nest reacted more strongly than those in the storage area (Figure 2). For instance 2-tridecanol released only two weak reactions in the storage part, but nine of medium intensity in the brood nest.

DISCUSSION

Chemistry of Cephalic Volatiles of Scaptotrigona postica *worker bees.* The overall pattern in the volatile cephalic secretion of *Sc. postica* resembles that of other stingless bees, especially of the tribe Trigonini (Blum et al., 1970; Luby et al., 1973; Blum, 1981; Duffield et al., 1984; Johnson et al., 1985), but also of the Meliponini (Smith and Roubik, 1983). With only a few exceptions (3-methyl-1-butanol and its derivatives, the aromatic compounds, and the terpenoid acids), the identified oxygen-containing compounds obviously originate from the acetate pool and form typical rows of bis homologs. Two principal groups of compounds may be distinguished: one represents methylketones and some of their corresponding chiral reduction products, the methylcarbinols. The second comprises primary alcohols, acids, and the respective esters.

Methylketones and methylcarbinols are particularly widespread among Hymenoptera (Blum, 1981). They also occur as plant volatiles and are probably formed from β-ketoacyl precursors. A particular species may produce them in distinct qualitative and quantitative proportions, and they certainly play a role as intra- and interspecific chemical messengers. It is possible that enantiomeric composition in chiral alcohols and double-bond positions in unsaturated ketones contribute to the specificity of the bouquet. Enantiomeric composition of chiral pheromones often plays an essential role in the optimal activity of a signal. In *Sc. postica* the 2-alkanols could be shown to be approx. 95:5 mixtures of *S*- and *R*-enantiomers (König and Francke, unpublished data). Preliminary tests with a synthetic mixture of enantiomers revealed that the "natural" 2-heptanol evokes a particularly strong alarm and, in contrast to pure (*R*)-(−)-2-heptanol, induces the attaching of cerumen to the test disk. 2-Heptanol was also identified as a major cephalic volatile in other stingless bees of the genera *Trigona* (Kerr et al., 1981) and *Melipona* (Smith and Roubik, 1983), but nothing is known about enantiomeric differences in these cases.

The unsaturated methylketones of *Sc. postica* carry the double bond at even-numbered positions, while the unsaturated esters and primary alcohols show uneven-numbered double-bond positions. Desaturase systems of insects usually insert double bonds at uneven positions in the acyl precursors of respective compounds (Roelofs and Bjostad, 1984). Since during the formation of methylketones by β-oxidation–decarboxylation reactions, the initial C-1 is lost, the double bonds appear to "move" one position towards the new functional end. Because of their stereotyped occurrence and less variable chemical structures, saturated unbranched methylketones and methylcarbinols seem to be less suitable for generating a volatile signal which a conspecific receiver may unambiguously distinguish from the "background noise" caused by the environmental odors.

In contrast, esters form a particularly versatile class of compounds. They may vary in chain length on both sides of the functional group; the insertion of double bonds provides additional information (Francke et al., 1984). (*Z*)-9- and (*Z*)-11-tetradecenol as well as (*Z*)-11-hexadecenol, together with the corresponding acetates, are widespread sex pheromones of Lepidoptera. Respective compounds from *Sc. postica* carry the double bonds in positions 5 and 7 and, thus, are more closely related to certain ant volatiles which show the identical distribution of double bonds (Francke et al., 1985).

It should be mentioned that volatile constituents from individuals of colonies kept in Brazil and Germany were qualitatively identical. Relative proportions were also found to be the same. However, the total amount of volatiles in bees collected in Brazil was higher.

Wax Disk Setup as Behavioral Bioassay to Check Communicative Functions of Volatiles in Bees. Previously there has been no bioassay to test behavioral responses of stingless bees to volatiles within the nest (Hummel and Miller, 1984). In the only intranidal tests yet described (Keeping et al., 1982), dichloromethane head extracts were used. The extracts were placed on a 18-mm-diameter filter paper disk which was located on a piece of paper in the nest container. Reactions were recorded within the surface of the paper. Wing fanning, antennal contacts, walks onto the test disk, and repellence were observed, out of which contacts and repulsions were quantified. In our tests, *Sc. postica* workers attacked all test papers placed in the nest, but they tolerated beeswax. Control wax disks did not interfere with normal behavior at all. As such disks could easily be manipulated in different parts of the nest, our bioassay could be run in the brood nest and in the storage area where distinct age groups of workers are present. Keeping et al. (1982) found *Trigona gribodoi* nurse bees to be totally oblivious to the pheromones exposed. In contrast to this, *Sc. postica* nurse age workers showed pronounced reactions to synthetic volatiles (Figure 2).

In most of the few other papers dealing with the reactions of stingless bees to volatile chemicals, tests were run at the nest entrance. The test samples were

exposed on small rods (Weaver et al., 1975), pieces of filter paper (Johnson et al., 1985), or a cotton wool ball (Kerr et al., 1981). The few behavioral responses obtained in such situations were mainly those of alarm together with attack or repellence, and much circumstantial excitement was observed. Artificial trails made up of filter papers treated with 2-heptanol—the main compound in cephalic extracts of *Trigona spinipes*—were attractive to foraging workers. Therefore, 2-heptanol was considered to be the major trail pheromone constituent in this species (Kerr et al., 1981).

Our intranidal wax disk setup seems to have some advantages when compared with techniques used until now in bioassays of volatiles of stingless bees. The behavioral responses observed could be reproduced sufficiently, and the specific responses consisted of typical sets of a varying number of distinct reactions (Figure 2).

Cephalic Secretion of Scaptotrigona postica*: A "chemical language"?* Today it is generally accepted that in odor communication, insects use mixtures instead of single compounds, and pattern recognition plays an essential role (Schneider, 1980). Stingless bees seem to use a particularly complicated "chemical language." The complex multicomponent mixture secreted by *Sc. postica* is an excellent prerequisite for the formation of unique polyfunctional messages. Depending on the differences in the thermodynamic stability of various components and differences in their vapor pressure, the composition of a released signal will change in a well-defined way and thus inform the receiver about the age of the message and the distance to its origin. Since the composition of the cephalic secretion varies characteristically with age, an individual bee should also be able to recognize the age of its "interlocutor" and its social function within the colony.

As shown in Figure 2, the response to a specific and pure volatile was not one single specific reaction, but a set of reactions. This is true for all 36 synthetic compounds tested and could be interpreted in such a way that the message represents a "sentence." Such a "language" might use classes of compounds for general instructions: for instance, alcohols as alarm releasers, esters as attractants, and carboxylic acids as repellents. But the diversity of test responses recorded here do not fit into such a simple scheme. The comparison of test results revealed that all 36 compounds evoked specific response patterns (Figure 2). For example, the pronounced repellent effects of four compounds within the storage area included not only intensive antennating and cleaning the antennae, but also fanning. Besides this, 2-phenyl-ethanol, (*Z*)-8-tridecen-2-one, and hexanoic acid released some trophallaxis, but butanoic acid did not. The mandibulation of the test disk was seen only in the experiments with the repellent alcohol and carbonyl compounds, but not in the two carboxylic acids. It would seem that the complete information given by the four repellent substances tested here varied to a considerable extent.

Bioassay Reactions Compared with Behavioral Repertoire. Differences in

the responses obtained by the tests in the brood nest and the storage area probably depend on the differences in age and function of the worker bees involved (Engels et al., 1980; Sakagami, 1982). Worker polyethism in stingless bees is pronounced, and young house bees mainly build combs and attend the brood, whereas old field bees forage. We previously described corresponding age-specific variations in the cephalic volatiles in *Scaptotrigona postica* (Francke et al., 1983). Correlated differences in worker responsiveness to pheromonal signals can be expected and have to be tested in more detail.

As young bees contain fewer cephalic volatiles and smaller amounts (Keeping et al., 1982; Francke et al., 1983), it is possible that their use of the chemical communication channel is more restricted and exclusively concerned with intranidal communication. Nothing is known about this, but as the nest interior of all stingless bees is completely dark, only tactile, acoustic, or olfactory stimuli can be used there for interindividual messages. In such an enclosed area with a low level of "background noise," only a simple bouquet is needed for chemical communication.

Old bees defend the nest, carry out garbage, and forage and, therefore, need alarm systems, chemical recruitment, scent marking of the nest entrance as well as of forage trails and routes to filial nests, etc. (Kerr, 1960; Kerr et al., 1963). This broad polyethism (Simões and Bego, 1979) is, of course, related to different ecological situations and probably requires a corresponding complexity of chemocommunication, especially in old worker interactions. Besides this, worker–queen interactions have to be considered. Within the nest, the complicated oviposition behavior of stingless bees (Sakagami and Zucchi, 1963) will probably involve pheromonal messages. Nothing is yet known about these interesting questions. This is also the case for mating and swarming behavior (Imperatriz-Fonseca, 1977) and male aggregations (Engels and Engels, 1984). Consequently, future biotests must include queen and drone reactions. In addition to the test of single compounds, work is in progress to test bioassay mixtures of identified compounds in naturally occurring proportions. Enantiomeric composition of chiral compounds must be determined and tests with respective optically active samples should be carried out.

Various reactions can be reinforced by the release of pheromones by the reacting bees. Under natural conditions, the response to a chemical signal will often include the emittance of a second one. "Chemical dialogues" are probably important elements of behavioral sequences. Of course, any analysis of such complicated relationships requires fundamental knowledge not only of the behavior (Simões and Bego, 1979; Engels et al., 1980), but also of the complete life history of a given species. Although *Scaptotrigona postica* is one of the best known stingless bees (Sakagami, 1982; Engels and Engels, 1984), our knowledge does not yet suffice, especially as this species is considered to have highly evolved communication systems (Lindauer and Kerr, 1958; Kerr et al., 1963).

The data presented here concerning the spectrum of cephalic volatiles and odor-specific reactions in stingless bee workers should be regarded as initial steps. Further work is in progress to investigate the role that chemical messengers play in the sociobiology and ecology of these fascinating tropical insects.

Acknowledgments—E. and W. Engels wish to thank Dr. Lionel S. Gonçalves for his generous hospitality during the various stays in the bee laboratory at Ribeirão Preto. He and Dr. Ronaldo Zucchi always supplied us with stingless bee colonies and equipment. The inspiration to work in Brazil and a lot of information on stingless bee biology derives from Dr. Warwick E. Kerr, João M.F. de Camargo kindly determined the species to which our test colonies belonged. Financial support by the DFG and an exchange grant provided by CNPq/DAAD to W. Engels within the scientific cooperation program Brazil/Germany are gratefully acknowledged. W. Francke wishes to thank the DFG and the Fonds der Chemischen Industrie for financial support. We would like to thank H. Bauschert for designing Figure 1, and G. Manz for Figure 2 and for technical assistance in the data processing.

SEX PHEROMONES OF THE SEA LAMPREY (*Petromyzon marinus*): Steroid Studies

MICHAEL A. ADAMS, JOHN H. TEETER, YAIR KATZ, and PETER B. JOHNSEN

Monell Chemical Senses Center, University of Pennsylvania
3500 Market Street, Philadelphia, Pennsylvania 19104

(Received January 23, 1986; accepted March 10, 1986)

Abstract—Pheromone-containing and pheromone-devoid samples of male sea lamprey (*Petromyzon marinus*) urine were analyzed for the concentrations of nine steroids [dehydroepiandrosterone (DHEA), testosterone (T), dihydrotestosterone (DHT), progesterone (P), androstenedione (A), estrone (E_1), estradiol (E_2), corticosterone (B), and cortisol (F)] by radioimmunoassay (RIA). Samples analyzed included native urine that had been enzymatically hydrolyzed with mixed β-glucuronidase/sulfatase. Values of the analyses were used to prepare solutions of the individual steroids for bioassay at concentrations which bracketed the urinary concentrations. Results show that only testosterone elicited a preference response in spawning-run female sea lampreys, and in concentrations three to four orders of magnitude greater than those found in active, unhydrolyzed male urine. The possibility that testosterone acts as a pheromone in this species is discussed.

Key Words—Sea lamprey, *Petromyzon marinus*, pheromone, urine, steroids, radioimmunoassay, RIA, behavior.

INTRODUCTION

Intraspecific chemical signals (pheromones) have been implicated in a variety of behavioral processes in fish, including schooling, parent–young interactions, homing, pair formation, and spawning (Solomon, 1977; Liley, 1982). Preferences of spawning-run landlocked sea lampreys (*Petromyzon marinus*) for substances released by sexually mature conspecifics of the opposite sex indicate that pheromones may play a role in the reproductive behavior of this species (Teeter, 1980). Pheromone release in sea lampreys coincides with the appearance of secondary sex characteristics. At this time, male sea lampreys release in their urine a pheromone that is attractive to female conspecifics (Teeter, un-

0098-0331/87/0200-0387$05.00/0 © 1987 Plenum Publishing Corporation

published observation). The possibility that this pheromone could be steroidal in nature led us to assay both pheromone-containing (behaviorally active) and pheromone-devoid (behaviorally inactive) male urine for its content of several metabolically important steroids; the values obtained from this analysis were then used to establish concentrations for examining the effects of these compounds on the preference behavior of female sea lampreys.

METHODS AND MATERIALS

Spawning-run sea lampreys (*Petromyzon marinus*) were captured in tributaries of Lake Huron and held in large raceways supplied with lake water at the Hammond Bay Biological Station, Millersburg, Michigan. Urine from both sexually immature and sexually mature male sea lampreys (approximately 400 animals per collection, four collections per day) was expressed by applying gentle abdominal pressure and allowing urine to spray into a Teflon trough. During the collection, the animals were held well away from the trough to ensure that no water, skin mucus, or other material contaminated the urine. Once in the trough, the urine was collected by pipet, pooled in daily batches, and frozen for subsequent bioassay and analysis. The results of previous experiments (Teeter, 1980) showed that the presence of a sex pheromone in male urine (obtained as previously described or by catheterization) was associated with the presence of secondary sex characteristics; milt did not, however, elicit preference responses in spawning-run females. Consequently, urine was collected from "sexually immature" males (those lacking secondary sex characteristics) and from "sexually mature" males (those which displayed secondary sex characteristics). Urine from spermiated males (that which contained a noticeable quantity of milt) was kept in a separate pool and was not used in this study. The urine was separated into pools on the basis of positive or negative preference assays, as described below.

Bioassays. Pooled male urine and steroid solutions were assayed as previously described (see Lisowski et al., 1986, for details of apparatus and procedures) for pheromone content (behavioral activity) using spawning-run female sea lampreys as test subjects in a two-choice preference test tank. As an example of a representative test, females were given a choice between a compartment containing lake water and a compartment containing lake water with 13 μl/liter male urine. Data were analyzed using the Wilcoxon matched-pairs, signed-ranks test (Brown and Hollander, 1977). Presence of a pheromone was indicated if females spent a significantly longer time in the stimulus arm of the apparatus than in the lake water arm. Gender of all animals used in the study was confirmed by autopsy.

Steroid Extraction and Separation. Ten-milliliter aliquots of male sea lamprey urine were used for the radioimmunoassays (RIAs). For samples that were

to be hydrolyzed, a mixture of 15,000 Fishman units of *Helix pomatia* β-glucuronidase/aryl sulfatase (Sigma Chemical Co., St. Louis, Missouri) in 0.8 ml water and 1.2 ml of 1.2 M acetate buffer (pH 4.8) was added; the hydrolysis was allowed to proceed at 37°C for 2 hr. At the end of the hydrolysis period, the mixture was extracted twice with 20-ml portions of acid-washed diethyl ether. Unhydrolyzed samples were also extracted twice with 20-ml portions of diethyl ether. These extracts were dried under a gentle stream of nitrogen in a warm (50°C) sand bath, redissolved in 10 ml of acid-washed diethyl ether, washed with 0.5 ml of 0.5% $NaHCO_3$, and dried again. Each extract was dissolved in 0.1 ml of a mixture of (all freshly distilled) chloroform–*n*-heptane–methanol–water, 500:500:75:3 (Zamecnik et al., 1977) and fractionated on a 2.5-g (8-ml) Sephadex LH-20 column, eluting with the same mixture. Elution patterns and recovery values of tritiated steroids run on these columns are given in Table 1. The glass columns (8 mm ID, acid-washed) and polyethylene fittings (QSH Practicolumns, Isolab Co., Akron, Ohio) were treated for 1 hr with 1% trichloromethylsilane (Aldrich Chemical Co., Milwaukee, Wisconsin) in chloroform prior to packing. Material eluted from the columns was dried and taken up in 1.0 ml steroid radioimmunoassay buffer (0.1 M sodium phosphate in saline, pH 6.9, containing 0.1% gelatin and 0.01% thimerosal).

Steroid RIA. All determinations were done on precoded samples whose identity was known only to an investigator not directly involved in the analytical procedures. Aliquots of the samples in steroid RIA buffer were analyzed in specific RIA systems (Table 2). The following antibodies and tritiated steroids were used: (1) rabbit anti-progesterone-11α-hemisuccinyl-bovine serum albu-

min (BSA) and [1,2,6,7-^{3}H]progesterone, 89 Ci/mmol; (2) rabbit anti-androstenedione-7α-carboxyethylthioether-BSA and [1,2,6,7-^{3}H]-androstenedione, 114 Ci/mmol; (3) rabbit anti-testosterone-7α-carboxymethylthioether-BSA and [1,2,6,7,16,17-^{3}H]testosterone, 150 Ci/mmol; (4) rabbit anti-5α-dihydrotestosterone-1α-carboxyethylthioether-BSA and [1,2,4,5,6,7,16,17-^{3}H]-5α-dihydrotestosterone, 190 Ci/mmol; (5) rabbit anti-estrone-6-(*O*-carboxymethyl)oxime-thyroglobulin and [2,4,6,7-^{3}H]estrone, 85 Ci/mmol; (6) rabbit anti-estradiol-17β-6-(*O*-carboxymethyl)oxime-BSA and [2,4,6,7,16,17-^{3}H]-17β-estradiol, 152 Ci/mmol; (7) rabbit anti-cortisol-21-hemisuccinyl-thyroglobulin and [1,2,6,7-^{3}H]hydrocortisone, 93 Ci/mmol; (8) rabbit anti-dehydroepiandrosterone-15α-carboxymethylthioether-BSA and [1,2,6,7-^{3}H]dehydroepiandrosterone, 79 Ci/mmol; and (9) rabbit anti-corticosterone-21-hemisuccinyl-thyroglobulin and [1,2,6,7-^{3}H]corticosterone, 89 Ci/mmol. All the antibodies were produced by Miles-Yeda, Rehovoth, Israel, except anti-dehydroepiandrosterone (anti-DHEA, Sigma Chemical Co.) and anti-estradiol, which was a gift of Dr. D. T. Armstrong, London, Ontario, Canada; the tritiated steroids were purchased either from New England Nuclear, Boston, Massachusetts, or Amersham Corp., Arlington Heights, Illinois, and were purified before use (on the Sephadex LH-20 columns). Assays were performed as previously described (Katz et al., 1982).

Separation of bound from free steroids in the RIA tubes was effected by dextran-coated charcoal methodology. Centrifuged supernatants were counted

for radioactivity in ACS II aqueous scintillation solution (Amersham) using a Packard Instruments liquid scintillation spectrometer, model 2425, and were corrected for quenching. Data reduction was performed on a Hewlett-Packard 9815A/9871A desktop computer using log–logit transformations. Extraction and recovery procedures were validated using standard steroid mixtures as previously described (Katz et al., 1982).

Behavioral Activity Assays of Urinary Steriods. As little as 0.5 ml (6.5 μl/liter of water) of pooled urine from sexually mature male sea lampreys has been shown to elicit preference responses in females in our two-choice tanks (Teeter, 1980). We arbitrarily use 1 ml of urine per test (13 μl/liter) when determining whether or not a pool of urine contains the pheromone. Consequently, samples of the steroids were tested in the preference tank at the concentrations at which they were determined to be present in 1 ml of behaviorally active male urine by RIA ("active urine–unhydrolyzed," Table 3). Solutions of the steroids were prepared in ethanol and the appropriate amount of material delivered by microliter syringe to the stimulus side of the test tank. An equivalent amount of solvent was added to the blank side of the tank as a control in each experiment.

RESULTS AND DISCUSSION

Urine of sexually immature and sexually mature male sea lampreys was analyzed by RIA for the content of nine steroid hormones (dehydroepiandrosterone, testosterone, dihydrotestosterone, progesterone, androstenedione, estrone, estradiol, corticosterone, and cortisol). To measure the degree of steroid conjugation, both active and inactive urine were hydrolyzed with a sulfatase–

glucuronidase enzyme mixture prior to RIA analysis. Numerical values for these analyses are presented in Table 3 and graphed in Figure 1.

Using results obtained with inactive, unhydrolyzed urine as baseline values, and comparing them with steroid concentrations found in active urine, one may note that testosterone increases threefold, and cortisol increases by 1.5 times; progesterone decreases twofold, and estradiol shows a fourfold decrease, while DHEA and corticosterone decrease to zero. DHT, androstenedione, and estrone concentrations remain roughly the same. Results for hydrolyzed and unhydrolyzed progesterone suggest the presence of a steroid capable of forming a conjugate and capable of cross-reacting with progesterone antibody. One likely candidate for this contaminant is deoxycorticosterone, which is known to cross-

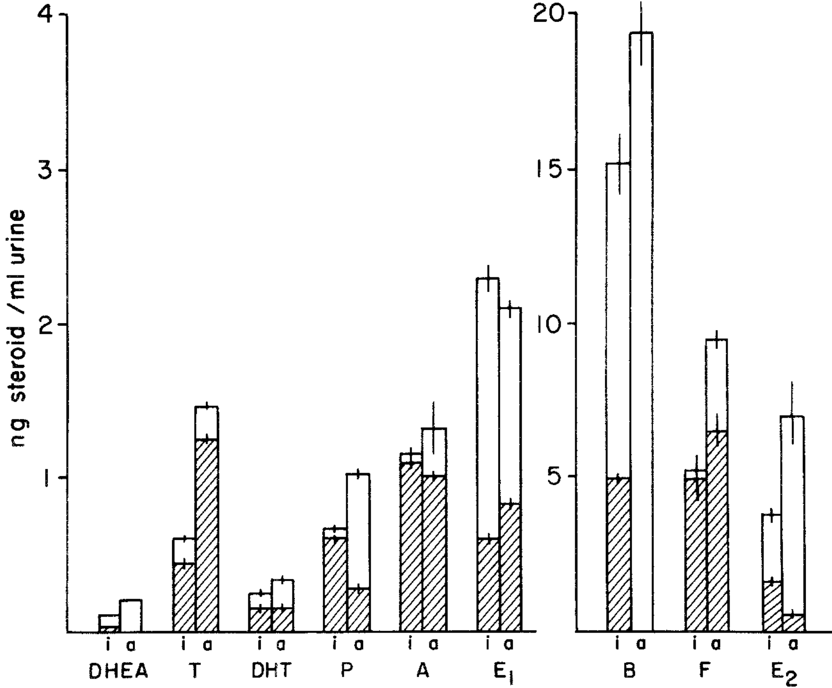

FIG. 1. Steroid content of biologically active, pheromone-containing (a) and biologically inactive, pheromone-devoid (i) male spawning-run sea lamprey urine. Shaded bars show unhydrolyzed values, clear bars represent hydrolyzed values.

react with the antibody and which coelutes with progesterone from the Sephadex LH-20 column.

Using enzyme-hydrolyzed urine as a measure of total steroid content, it can be seen that in all cases but that of estrone, active urine contains a greater quantity of the steroids measured than does inactive urine. The estrone content in hydrolyzed, active urine is not significantly lower than its unhydrolyzed counterpart.

It is known that production and/or release of male pheromone in landlocked sea lampreys corresponds with the onset of sexual maturity and concomitant development of secondary sexual characteristics (Teeter, 1980). It seemed reasonable that sea lampreys might have developed a pheromone communication system using steroid hormones whose concentrations might surge during this period of development. The possibility of chemical communication using an externalized hormone as a signal is generally recognized (Liley, 1982); however, as of the present, this has not been reliably demonstrated for any aquatic species. With the exception of testosterone (see below), the results of our bioassays with unconjugated urinary steroids were uniformly negative. In no case

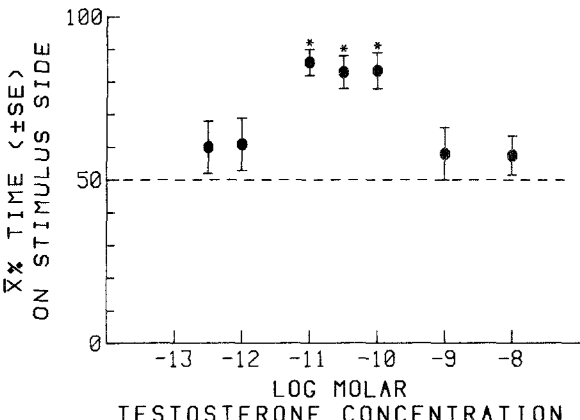

FIG. 2. Plot of log molar testosterone concentration vs. mean percent time that female spawning-run sea lampreys spend on the stimulus side of a two-choice behavioral preference tank. An asterisk denotes a significant preference for testosterone ($P < 0.05$, Wilcoxon matched-pairs, signed-tank test, two-tailed).

did any of the assayed steroids, when presented at concentrations which would be found in 1 ml of male urine (concentrations known to elicit female preference when using bioactive male urine), elicit preference in female lampreys (Table 4). Testosterone was assayed over a range of concentrations, and the results are presented in Figure 2. Bioactive male sea lamprey urine contains approximately 5×10^{-9} M unconjugated testosterone (1.5 ng/ml). When 1 ml of bioactive urine is added to the stimulus side of the behavioral test tank, the testosterone concentration that results from dilution into 78 liters of water is ca. 6.6×10^{-14} M. The behavioral response to pure testosterone occurs at concentrations between 1×10^{-11} M and 1×10^{-10} M (Figure 2). Thus, bioactive male urine may contain a substance other than testosterone which elicits a preference response in female sea lampreys. As the concentration of testosterone was increased above 1×10^{-9} M, the preference effect disappeared (Figure 2). It is clear from these results that females show a preference for water in which testosterone is present. The testosterone concentration necessary to evoke this response is approximately three to four orders of magnitude greater than the testosterone concentration of native, bioactive male lamprey urine that is observed to evoke a preference response in females.

It is possible that the preference shown by spawning-run female sea lampreys for testosterone is of no biological significance. It is also possible that testosterone, or a closely related structural derivative, functions as a sex pheromone in sea lamprey when present at the appropriate concentration. In this case, the testosterone concentrations necessary to elicit a response in females in the bioassay apparatus are representative of the amounts that the female must

sense in the open stream before preference behavior is elicited. This would argue for the release of pheromone by one or more males in close proximity to the female, perhaps taking place over the animals' spawning nest. At close range, dilution of the pheromone would be minimal, and it is possible that the critical concentration range of 10^{-11}–10^{-10} M might be reached. Even if this is the case and testosterone is functioning as a short-range attractant, then our general bioassay results indicate that there is a second substance exerting its attractive effect on females at much lower concentrations. This is evidenced by the fact that 0.5–1.0 ml of bioactive male urine, when placed in the bioassay device, will elicit a behavioral preference response in female lamprey. The concentrations that obtain in this situation are on the order of 6–13 μl of urine per liter of water. This amounts to a 1 : 78,000 dilution of the urine and, for testosterone in male urine, the result is that the concentration is much lower than the effective preference-producing concentration. Thus, the presence of another pheromone is implicated. Experiments directed to isolating and identifying this material are currently being undertaken in our laboratory.

Acknowledgments—We wish to thank the staff of the Hammond Bay Biological Station, U.S. Fish and Wildlife Service, for their assistance. This project was funded through a cooperative agreement with the U.S. Fish and Wildlife Service, the Great Lakes Fishery Commission, and the Monell Chemical Senses Center.

Abstract—Previous studies have shown that larvae of the eastern tent caterpillar (*Malacosoma americanum* F.) mark trails, leading from their tent to feeding sites on host trees, with a pheromone secreted from the posterior tip of the abdominal sternum. 5β-Cholestane-3,24-dione (**1**) has been identified as an active component of the trail. The larvae have a threshold sensitivity to the pheromone of 10^{-11} g/mm of trail. Several related compounds elicit the trail-following response. Two other species of tent caterpillars also responded positively to the pheromone in preliminary laboratory tests.

Key Words—Eastern tent caterpillar, *Malacosoma americanum,* Lepidoptera, Lasiocampidae, larva, trail pheromone, recruitment, 5β-cholestane-3,24-dione.

INTRODUCTION

The presocial eastern tent caterpillar (*Malacosoma americanum*) lives in colonies containing 50–300 or more individuals. Foraging larvae (caterpillars) mark trails with a secretion from the sternum at the posterior tip of the abdomen (Fitzgerald and Edgerly, 1982). Foragers mark exploratory trails as they move from their tent in search of food. Successful foragers over-mark these trails as they follow them back to the tent after feeding. Over-marked trails are analogs

0098-0331/87/0300-0397$05.00/0 © 1987 Plenum Publishing Corporation

of the recruitment trails of the eusocial insects and serve to lead tentmates to patches of young leaves, the preferred larval food (Fitzgerald and Peterson, 1983). Although trail marking by communal and solitary caterpillars has been reported for a number of other species, including economically important defoliators such as the gypsy moth (*Lymantria dispar*) and the large white butterfly (*Pieris brassicae*) (McManus and Smith, 1972; Long, 1955), no larval trail pheromone has been previously isolated or characterized. We report results of a study to identify and synthesize the trail pheromone of the larva of the eastern tent caterpillar, and to assess its activity.

METHODS AND MATERIALS

Bioassay. Eastern tent caterpillar egg masses were collected from several locations in central New York State and held at 2°C until needed. Colonies were hatched at room temperature and fed young leaves of black cherry (*Prunus serotina*). Second-instar larvae were used for the bioassay. Five-microliter quantities of chemical fractions dissolved in hexane were deposited in 2-cm-long lines on paper cards. A caterpillar was placed at one end of a line, and a positive response to the fraction was recorded when the caterpillar traveled to the end of the line, turned, and followed the line back to the starting point. Following the identification and synthesis of the pheromone, additional bioassays were performed with whole colonies foraging in host trees under both simulated and actual field conditions.

Chemical Isolation and Identification. Proton magnetic resonance ($[^1H]$NMR) spectra and carbon magnetic resonance spectra ($[^{13}C]$NMR) were obtained on a Varian FT-80A instrument, and mass spectra on a Shimadzu QP1000 GC-MS instrument, 25 m × 0.2 mm BPI:SGE, 1 min at 250°C, 10°/min to 290°C, splitless, or on a Finnigan 4000, direct inlet instrument. High-resolution mass spectra were obtained on an AEI MS30 instrument. Flash chromatography was performed on silica according to Still et al. (1978) using hexane–ethyl acetate (4:1) for elution. High-pressure liquid chromatography (HPLC) separations were achieved with a Spectra-Physics SP8700 system with a Waters differential refractometer R401 detector and a 25 × 0.4 cm Merck Hibar Lichrosorb RP-18 (5 μm) column using acetonitrile (1 ml/min) as solvent.

Hexane (14 liters) was percolated through 35,000 terminal segments from eastern tent caterpillar larvae to afford a hexane extract that was active in the trail-following bioassay, and the solution was concentrated to a green gum by distillation through a 25-cm Vigreux column.

Purification of 450 mg of the gum in hexane by flash chromatography followed by reverse-phase HPLC gave an active fraction (ca. 0.1 mg) that showed a single peak with the RI detector. The mass spectrum (Shimadzu GC-MS) of this compound suggested a cholestanedione type of structure: M^+ 400(2),

315(2), 314(2), 297(4), 271(9), 231(2), 215(1), 191(2), 147(7), 135(6), 122(7), 121(8), 119(12), 109(12), 107(17), 105(13), 95(21), 93(20), 91(15), 81(34), 79(24), 71(29), 67(25), 57(14), 55(49), 43(100). Peaks in the mass spectrum at 315 and 314 place a cholestanedione side chain carbonyl group at C-24 (315 = M-C_5H_9O, β-cleavage, and 314 = M$-C_5H_{10}O$, McLafferty rearrangement). A peak at 231 (corresponding to a loss of $C_{11}H_{20}O$) is a residue common in steroids, with oxygenation in ring A, after loss of the side chain and ring D with H transfer. This compound was identified as 5β-cholestane-3,24-dione (**1**) after comparison of its GC-MS spectrum with that of **1** prepared from lithocholic acid. Coinjection of the isolated compound and synthesized **1** on capillary GC in addition to identical retention times in sequential experiments on HPLC and GC confirmed its identity. Although the mass spectrum of the 5α epimer (**2**) is similar to that of **1**, these compounds are readily separated on HPLC and capillary GC [reverse phase HPLC, acetonitrile, 1 ml/min, R_t (5β) = 0.8 R_t (5α); capillary GC 25 m BPI, 280°, R_t (5β) = 0.88 R_t (5α)].

Synthesis. 5β-Stigmastan-3-one (**5**) was prepared from β-sitosterol (**9**) by Jones oxidation followed by catalytic hydrogenation (Augustine, 1972a). 5-α-Stigmastan-3-one (**6**) was prepared from β-sitosterol (**9**) by catalytic hydrogenation followed by Jones oxidation (Augustine, 1972b) (see Figure 1).

For 5β-cholestane-3,24-dione (**1**), 3α-hydroxy-5β-cholestan-24-one was prepared from lithocholic acid according to the method of Ochi et al. (1979), then oxidized with the Jones reagent to afford 5β-cholestane-3,24-dione (**1**) as an oil that solidifed on standing but resisted recrystalization. Mass spectrum (Shimadzu GC-MS) M^+ 400(5), 315(3), 314(5), 297(5), 271(10), 231(4), 215(2), 191(2), 147(7), 135(4), 122(7), 121(10), 119(7), 109(10), 107(17), 105(11), 95(10), 93(22), 91(12), 81(27), 79(21), 71(27), 67(27), 57(9), 55(48), 43(100); M^+ calculated for $C_{27}H_{44}O_2$ 400.3341, found 400.3336; [^{13}C]NMR ($CDCl_3$) δ12.18(C-18), 18.42(C-26, C-27), 18.58(C-21), 21.31(C-11), 22.76(C-19), 24.27(C-15), 25.88(C-6), 26.74(C-7), 28.27(C-16), 29.90(C-23), 34.99(C-10), 35.46(C-20), 35.65(C-8), 37.14(C-2), 37.29(C-1, C-22), 40.18(C-12), 40.88(C-9, C-25), 42.45(C-4), 42.87(C-13), 44.43(C-5), 56.23(C-17), 56.55(C-14), 213.25(C-3), 215.32(C-24); [^{1}H]NMR ($CDCl_3$) δ0.68 (s, 3, C-18 Me), 1.02 (s, 3, C-19 Me), 1.08 (d, J = 7 Hz, 6, C-26 and C-27 Me's).

For cholest-4-ene-3,24-dione (**10**), one equivalent of bromine (1 M in acetic acid) was added dropwise at room temperature to 5β-cholestane-3,24-dione (**1**) (130 mg) in acetic acid (2 ml). The mixture was stirred for 5 min, diluted with water, filtered, and the product was taken up in ethyl acetate, dried and evaporated to yield 4-bromo-5β-cholestane-3,24-dione as a solid. The crude product in *N,N*-dimethylacetamide (1 ml) was added to a refluxing mixture of calcium carbonate (150 mg) and *N,N*-dimethylacetamide (5 ml). After heating under reflux for 30 min, the mixture was cooled, diluted with water, and extracted with ether. The ether extracts were washed with dilute HCl, then water, dried, and evaporated. Purification by preparative TLC on silica gel afforded cholest-

4-ene-3,24-dione (**10**) (100 mg) mp 116–118° (MeOH). Mass spectrum (Finnigan) M^+ 398(28), 383(3), 355(5), 313(19), 269(12), 229(17), 124(38), 107(25), 95(27), 93(28), 91(29), 81(28), 79(32), 71(39), 67(28), 55(51), 43(100); [^{1}H]NMR ($CDCl_3$) δ0.71 (s, 3, C-18 Me), 1.08 (d, J = 7 Hz, 6, C-26 and C-27 Me's). 1.17 (s, 3, C-19 Me), 5.65 (bs, 1, C-4H).

For 5α-cholestane-3,24-dione (**2**), cholest-4-ene-3,24-dione (**10**) (100 mg) was hydrogenated (Combe et al., 1967) at 20°C under 1 atm of hydrogen in propan-2-ol (10 ml) with Pd–$CaCO_3$ catalyst (100 mg) to give a mixture of 5β- and 5α-cholestane-3,24-dione 3 : 2 (with Pd-C catalyst the ratio of 5β to 5α = 2 : 1). The products were separated on HPLC (acetonitrile solvent, 1 ml/min) to give pure 5α-cholestane-3,24-dione, mp 125–127° (MeOH). Mass spectrum (Shimadzu) M^+ 400(6), 385(3), 315(9), 314(7), 297(2), 278(9), 271(9), 217(7), 215(5), 209(3), 191(2), 149(9), 147(6), 135(12), 123(15), 121(16), 119(11),

RESULTS AND DISCUSSION

The response of caterpillars to 5β-cholestane-3,24-dione (**1**) and to similar compounds laid out in narrow trails on paper cards is shown in Table 1. The threshold sensitivity of the caterpillars to 5β-cholestane-3,24-dione lies within the range of values previously reported for the trail pheromones of ants (Tumlinson et al., 1972; Jaffe and Howse, 1979; Morgan, 1984).

Caterpillars deposit the pheromone on the surface of the substrate and perceive the nonvolatile compound by contact chemoreception. Since the compounds we bioassayed were dissolved in hexane and applied to absorbent paper cards, the detectable surface residue was probably less than it would have been if an equivalent quantity had been deposited directly by the caterpillar. Indeed, tests of 5β-cholestane-3,24-dione on a nonabsorptive substrate showed threshold activity an order of magnitude lower than on paper. Behavioral threshold concentrations may, therefore, be lower than indicated by this bioassay procedure.

Since these preliminary bioassays were done only on readily available analogs of the pheromone, structure–activity correlations cannot yet be made. Most remarkable, however, is the observation that 5β-cholestan-3-one (**3**) elicits a response at a 10-fold lower concentration than does the pheromone itself (Table 1); thus, the carbonyl oxygen at C-24 is not essential. In two pairings (**1** and **2**, **5** and **6**) the β configuration seems essential.

Although extensive testing of the biological activity of synthetic 5β-cholestane-3,24-dione remains to be done under both laboratory and field conditions, preliminary tests with laboratory colonies maitained under simulated natural conditions showed that the compound at a dose of 10^{-8} to 10^{-10} g/mm is competitive with authentic exploratory trails. In addition, when the compound was used to lay trails to previously unexploited sections of colonized trees in the field, caterpillars concentrated their foraging activity on the treated branches during their next foraging bout. Further testing is needed, however, to determine if additional factors are involved in the recruitment response. Two other species of tent caterpillar, *M. disstria* and *M. neustria* also responded positively to the pheromone in preliminary laboratory tests.

(Received January 16, 1986; accepted March 11, 1986)

Abstract—Previous experiments showed that legumes grown in the presence of living or herbicidally treated quackgrass residues or extracts exhibited reduced seedling root and shoot growth and decreased nodulation and nitrogen fixation. Aqueous extracts of quackgrass shoots were most inhibitory to plant growth. Upon sequential partitioning of an aqueous extract of quackgrass shoots, the ether extract possessed the most activity and caused 50% reductions in radicle elongation of eight crop and weed species at concentrations of less than 240 μg/ml (small-seeded species) and 1000 μg/ml (large-seeded species). Snapbeans (*Phaseolus vulgaris* L. "Bush Blue Lake") grown aseptically in agar containing an ether extract at 100 and 200 μg/ml exhibited severe root browning, lack of root hair formation, and a two- to three-fold reduction in root and shoot dry weights. The ether extract of quackgrass shoots had no inhibitory effect on the growth of four *Rhizobium* species in Petri dishes or two species in broth culture. Inhibitors present in the ether extract may influence the legume *Rhizobium* symbiosis indirectly by reducing legume root growth and root hair formation. The ether extract of quackgrass shoots was separated using high-pressure liquid, thin-layer, and liquid column chromatography in an attempt to isolate and identify the inhibitors responsible for the inhibition of seedling growth. Two closely related flavonoid inhibitors were isolated from the ether extract. One was identified as 5,7,4'-trihydroxy-3',5'-dimethoxyflavone (tricin). Both flavonoids caused 50% inhibition of radicle elongation in cress (*Lepidium sativum* L. "Burpee curly") seeds at concentrations of less than 125 μg/ml. Both flavonoids were found in ether extracts of quackgrass shoots and rhizomes, but the largest amounts of both compounds occurred in quackgrass shoots collected from the field.

INTRODUCTION

Quackgrass is a highly aggressive perennial plant that reproduces mainly by rhizomes (Holm et al., 1977). It is a widespread weed problem in grain, forage, vegetable, and fruit crops grown in the cooler zones of the Northern Hemisphere (Holm et al., 1977; Wyse, 1980).

Previous research in both the field and the greenhouse has demonstrated the detrimental interference of quackgrass on the growth of higher plants. However, the literature concerning quackgrass interference does not clearly differentiate the relative roles of allelopathy and competition in the total interference (Rice, 1984). In the field, quackgrass has been reported as an aggressive competitor for light, water, and nutrients (Kommedahl et al., 1970; Ohman and Kommedahl, 1964). Others have reported considerable allelopathic activity by quackgrass due to the direct production of inhibitors by quackgrass shoots or rhizomes (LeFevre and Clagett, 1960, Oswald, 1948; Phlak, 1967; Welbank, 1960), inhibitors such as acetic and butyric acid (Patrick et al., 1963) which arise from the decay of materials in the soil (Lynch and Penn, 1980; Ohman and Kommedahl, 1964; Toai and Linscott, 1979; Welbank, 1963), or the interaction of decaying quackgrass with pathogenic soil microbes (Penn and Lynch, 1982).

In the field and greenhouse, Weston and Putnam (1985) reported reduced root and shoot growth, nodulation, and nitrogen fixation by legumes grown in the presence of living and herbicidally treated quackgrass. Legumes grown in the presence of quackgrass displayed chlorotic leaves and necrotic roots. In the laboratory, extracts of quackgrass shoots were particularly inhibitory to seed germination, radicle elongation and root growth of legumes. Root systems were stunted, necrotic, and lacked root hairs when grown in the presence of shoot or rhizome extracts, indicating that quackgrass indirectly inhibits the legume-*Rhizobium* symbiosis by inhibiting root hair formation rather than directly inhibiting *Rhizobium* growth (Weston and Putnam, 1986).

The production and release of toxic compounds by quackgrass have been documented in the laboratory. Dried quackgrass rhizomes and leaves were reported by both Toai and Linscott (1979) and Ohman and Kommedahl (1964) to contain water-soluble inhibitors which reduce seedling growth. Two inhibitors from quackgrass rhizomes have been tentatively characterized by Gabor and Veatch (1981) and LeFevre and Clagett (1960); one is suggested to be a glycoside. However, the structures of these inhibitors have never been fully elucidated. Characterization of inhibitors present in quackgrass shoots, the portion of the plant most toxic to seedling growth (Weston and Putnam, 1986), has not been previously reported.

To further explore the possible allelopathic potential of quackgrass shoots under well-controlled conditions, we attempted to: (1) assess the effect of partitioned quackgrass shoot extracts on seed germination, root development, and the legume-*rhizobium* symbiosis, (2) isolate and identify the inhibitors) present in quackgrass shoots responsible for the reduction of seedling root growth, and (3) quantify the amount of inhibitor(s) in aqueous extracts of both field and greenhouse-grown rhizome and shoot tissue.

METHODS AND MATERIALS

Procedure for Collection of Quackgrass Material. Quackgrass was collected from the Horticultural Research Farm, East Lansing, Michigan. The site had a soil classified as a Marlette sandy loam (Glossoboric Hapludalf, fine-loamy, mixed, mesic) and supported a community dominated by quackgrass that had grown undisturbed for approximately 15 years. On June 10, 1984, field-grown quackgrass shoots (25–30 cm in height) were collected and placed in a drying oven at 35–40°C for four days. Rhizomes were also carefully removed from field soil at this time, washed thoroughly with tap and distilled water, and placed in a drying oven under similar conditions.

Sods (0.3 × 0.3 m) were collected from this field site and placed in square wooden flats, 15 cm in depth. Flats were placed under metal halide lighting in the greenhouse with photosynthetic photon flux density (PPFD) of 425 μmol/m^2/sec measured at the top of the canopy. The greenhouse was maintained with a 14-hr- light–10-hr-dark photoperiod at 28 and 22°C. Flats were fertilized once weekly with 600 ml soluble 20-20-20 fertilizer at a rate of 3.9 g/liter of water. When quackgrass shoots reached a height of 20–25 cm, they were repeatedly harvested with shears by trimming 3–4 cm above the soil surface. After 60 days, rhizomes were carefully removed from the flats and washed thoroughly with tap and distilled water. Rhizomes and shoot material were then placed in a drying oven at 35–40°C for four days. The entire process of collecting material from the greenhouse was repeated six times between 1983 and 1985 to gather sufficient material for experimental use.

All field-grown and greenhouse-grown plant material was ground separately in a Wiley mill (mesh screen size 1 mm). Powdered material was stored in tightly closed glass containers until used for extraction and quantification of quackgrass phytotoxins.

Procedure for Extraction of Quackgrass Shoot Material. Shoot tissue (100 g) was extracted for 24 hr with 3 liters of distilled water on a shaker in a 4°C coldroom (Figure 1). The mixture was filtered through four layers of cheesecloth and centrifuged for 20 min at 16,000*g* to remove particulate material. Nine liters of chilled acetone were slowly added to the aqueous extract. The mixture was stirred at slow speed on a stir plate for 24 hr in a 4°C coldroom. Proteinaceous material precipitated out of solution in the presence of acetone and was

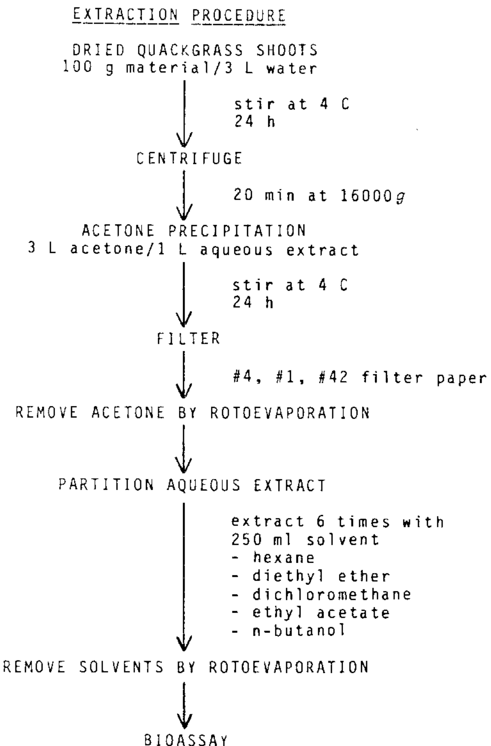

FIG. 1. Flow diagram of the procedure for extraction and partitioning of dried quackgrass shoots.

removed by vacuum filtration through Whatman No. 4, 1, and 42 filter paper and discarded. (This procedure prevents dense emulsions from forming during partitioning). Acetone was removed from the extract by rotary evaporation at 35°C. The clear, aqueous extract was sequentially partitioned with the following solvent series ranging from least polar to most polar: hexane, diethyl ether, dichloromethane, ethyl acetate, and *n*-butanol. Each liter of the aqueous shoot extract was sequentially partitioned six times with 250 ml of each of the five solvents. Solvent was removed from each fraction by rotary evaporation at 35°C. The entire process of extraction and partitioning was repeated five times to gather enough material for experimentation.

Each fraction from the liquid–liquid extractions was redissolved in methanol to form solutions at a concentration of 0.5 mg/ml. One milliliter of each fraction was placed in separate glass Petri dishes (60 × 15 mm), which were lined with filter paper (Whatman No. 1). Methanol was allowed to evaporate from each dish, and 1.5 ml distilled water was added to form a concentration of 0.33 mg material/ml. In addition to the fractions obtained from the liquid–

liquid extractions, the following materials were also tested for toxicity: a distilled water control (applied to the filter paper after evaporating 1.0 ml of methanol), crude aqueous extract of quackgrass shoots, and the aqueous extract of quackgrass shoots remaining after partitioning. Twenty seeds of "Burpee curly" cress were then added to each dish. Radicle elongation of curly cress was consistently used as a bioassay throughout our experiments because of its availability, uniformity, and sensitivity. Three replicates of each treatment were arranged in a completely randomized design and placed in a 26°C growth chamber with relative humidity near saturation. Radicle lengths of seeds were measured at 72 hr. Data were subjected to analysis of variance and means separated by least significant difference (.05).

Influence of Ether Extracts on Radicle Growth. Ether extracts were redissolved in methanol to form a dilution series ranging in concentration from 1600 μg/ml to 25 μg/ml. One milliliter of each treatment solution was applied separately to glass Petri dishes. After the addition of 1.5 ml distilled water per dish, concentrations ranged from 1066.7 μg/ml to 16.7 μg/ml. A distilled water control was also included, and 20 seeds were arranged per dish. Seed indicators used were: "Burpee curly" cress, lettuce (*Lactuca sativa* L. "Ithaca"), alfalfa (*Medicago sativa* L. "Vernal"), redroot pigweed (*Amaranthus retroflexus* L.), soybean [*Glycine max* (L.) Merr. "Corsoy 79"], navybean (*Phaseolus vulgaris* L. "Seafarer"), barnyardgrass [*Echinochloa crus galli* (L.) Beauv.] and smooth crabgrass [*Digitaria ischaemum* (Schreb. ex Schweig.) Schreb. ex Muhl.]. Two replicates of each treatment were arranged in a completely randomized design and placed in a 26°C growth chamber with relative humidity near saturation. Radicle lengths of all species were measured at 72 hr, and data were analyzed as described previously. Standard errors were calculated for each mean.

Influence of Ether Extracts on Aseptically Cultured Snapbeans. Fahraeus medium (125 ml of 1% agar) was poured into 250-ml Ehrlenmeyer flasks. This medium is well suited for culture of legumes in sterile agar culture (Dazzo, 1982), excluding microorganisms which may alter the toxicity of plant compounds. Snapbeans were selected for this bioassay because they can be easily cultured in agar media as opposed to other legume crops. Flasks were closed with styrofoam stoppers and autoclaved at 121°C for 25 min. "Bush Blue Lake" snapbean seeds were placed in a 0.5% solution of calcium hypochlorite for 4.5 min for surface sterilization and then rinsed for 1 min with sterile distilled water. Seeds were placed on moist sterile filter paper in glass Petri dishes in a 27°C growth chamber for four days in the dark.

When seedling radicles were approximately 3 cm in length, the Fahraeus agar in the flasks was remelted by autoclaving at 121°C for 10 min (agar was made beforehand for convenience). Treatment solutions were then added and mixed before the agar solidified; these consisted of ether extracts of quackgrass shoots dissolved in water at two concentrations (12.5 mg/ml and 6.25 mg/ml). To one third of the flasks, 2.0 ml (25 mg) of filter-sterilized extract solution

was added to give a final concentration of 200 μg ether extract/ml agar medium. To another third of the flasks, 2.0 ml (12.5 mg) of filter-sterilized extract solution was added to give a final concentration of 100 μg/ml agar medium. In the controls, 2.5 ml distilled water were added to the agar. The pH of the agar mixtures ranged from 5.2 to 5.4. Pregerminated seeds were planted in the treated agar at a 1.5 cm depth, one seed per flask. Seeds were inoculated with 0.1 ml of *R. phaseoli* in the exponential phase of growth in yeast extract mannitol broth. Flasks were placed in a lighted growth chamber at 27°C day and 23°C night temperatures. A 16-hr photoperiod under fluorescent and incandescent bulbs was maintained with an average PPFD of 175 μmol/m^2/sec at the top of the flasks.

The treatments in the experiment were replicated five times (one flask each) and arranged in a completely randomized design. The experiment was repeated, also using five replicates. Only the plants remaining sterile were harvested after 21 days, when beans reached the second to third trifoliate leaf stage. Root and shoot dry weights were recorded. Data from the two experiments were combined and analyzed using analysis of variance and mean separation by least significant difference (0.05) test.

Isolation and Characterization of Toxins from Ether Extracts of Quackgrass Shoots. The ether extract was further separated in an attempt to isolate and identify the compounds in quackgrass shoots responsible for inhibition of seedling root growth. When the dried ether fraction (240.0 mg) was redissolved in dichloromethane (40 mg/ml), a gold crystalline precipitate was formed. The precipitate was collected in a fritted glass filter and washed with 100 ml hexane followed by 100 ml diethyl ether. The precipitate was dried, weighed (11.3 mg), and bioassayed. The standard bioassay used throughout these separation procedures was the inhibition of the radicle elongation of "Burpee curly" cress measured at 72 hr. Since the precipitate possessed considerable inhibitory activity (I_{50} = 149.0 μg/ml) further separation was conducted using silica gel thin-layer chromatography (TLC) plates (Merck, 0.25 mm, F-254). Plates were run in 8:1 chloroform–methanol. Visualization under shortwave ultraviolet (UV) light at 254 nm and exposure to 5% vanillin in sulfuric acid showed three distinct bands (R_f = 0.20, 0.35, and 0.40). The bands appeared bright yellow, and band 3 (R_f = 0.40 appeared to make up the majority of the mixture.

Band 3 (R_f = 0.40) was scraped off the plate and the scrapings were eluted with 4:1 chloroform–methanol through a fritted glass filter. Band 3 was bioassayed and also subjected to spectral analyses. Band 1 (R_f = 0.20) was also isolated from the TLC plate, but it was in small amounts and was contaminated by some of band 3. Therefore, band 1 was not bioassayed but was subjected to spectral analysis. All spectral analyses were performed at the ARCO Plant Cell Research Institute. UV spectra were obtained with a Perkin Elmer Lambda 5 UV/VIS spectrophometer, while chemical ionization mass spectroscopy (CI-MS) was performed with a VG 7070E direct probe inlet using isobutane or

ammonia as the ionizing gas. Nuclear magnetic resonance spectroscopy (NMR) was performed in deuterated methanol or chloroform on a Varian XL 300 MHz instrument. A dose-response curve was constructed to determine the concentration of this material (compound 1) required for 50% inhibition of cress radicle elongation (I_{50}).

The ether fraction was also separated using liquid column chromatography (LC). This crude material (500 mg) was loaded onto a silica gel (60g Baker, 200–250 mesh) flash column. Pressure for the column was provided with a laboratory air line at a rate of 40 ml solvent/min and eluted with 500 ml 65:35 dichloromethane–ethyl acetate, followed by 500 ml of ethyl acetate and 500 ml methanol. Fractions (25 ml) were collected, examined by TLC (silica gel-eluted with 65:35 dichloromethane–ethyl acetate) and combined to provide 11 distinct fractions. The 11 fractions were bioassayed separately for inhibitory activity using 250 μg material/dish, or 166.7 μg/ml. Activity was concentrated in fractions 6–8, and the material from these fractions was combined.

This material (55.5 mg) was loaded on a silica gel TLC plate and run in 10:1 chloroform–methanol. Seven distinct bands were scraped off the plate after visualization under UV (254 nm) light. Plate scrapings were eluted with 4:1 chloroform–methanol through a fritted glass filter, and the eluent from each zone was collected, dried, weighed, and bioassayed at 250 μg material/dish or 166.7 μg/ml. The majority of the activity occurred in zones 2 (R_f = 0.10–0.21) and 3 (R_f = 0.21–0.30). This material was combined (15.0 mg) and further separated by high-pressure liquid chromatography (HPLC) using a Waters, μBondapak C_{18}, 8-mm × 10-cm radial compression column. The UV detector (Waters Lambda-max model 481) measured absorbance at 380 nm. The solvent system used was 75:25 methanol–water at a flow rate of 1.5 ml/min. The mixture was resolved into two peaks and two fractions were collected after repeated injections.

The two fractions were bioassayed on an equal weight basis at 200 μg material/Petri dish or 133.3 μg/ml after the removal of the solvents by rotary evaporation. Strong inhibitory activity was associated only with fraction 1, which appeared as one large, distinct, needle-shaped peak in a variety of HPLC solvent systems. The material was dried, weighed (6.5 mg), and a small amount was subjected to analysis by TLC (silica gel in 10:1 chloroform–methanol). Visualization by UV (254 nm) light showed one distinct band at R_f = 0.21. Exposure to 5% vanillin in sulfuric acid showed the same band (R_f = 0.21) which turned a pale pink. The material was subjected to spectral analysis by UV, MS, and NMR (as described previously). A dose–response curve was constructed to determine the concentration of this material (compound 2) required for 50% inhibition of cress seed radicle elongation (I_{50}).

HPLC Quantification of Toxins from Various Quackgrass Tissues. An attempt was made to extract and quantify the amounts of compounds 1 and 2 (characterized in the previous section) in rhizomes and shoots grown in two

different environments. Treatments consisted of 100 g each of field- or greenhouse-grown rhizome or shoot tissue, which was extracted separately for 24 hr as described previously. The four extracts were sequentially partitioned with the same solvent series, and the ether extract of each tissue treatment was retained and weighed. Each extract (40 mg) was loaded separately onto a silica gel TLC plate and run in 10:1 chloroform–methanol. Bands tentatively identified as compounds 1 and 2 were observed under UV (254 nm) light in all tissue treatments. Plate scraping was used to separate the mixture before further evaluation by HPLC. Three zones were scraped off each plate (R_f = 0.14–0.34, R_f = 0.34–0.45, and R_f = 0.45–0.55) which contained variable amounts of compounds 1 and 2. All scrapings were eluted in 4:1 chloroform–methanol, and the eluent was filtered and dried. The HPLC system described previously (75:25 methanol–water) was used to separate and quantitate the amount of compounds 1 and 2 in each fraction. Standard curves of each purified compound were generated and used to estimate the total amount of compound 1 and 2 in each tissue extract.

RESULTS AND DISCUSSION

Extraction of Quackgrass Shoot Material. Aqueous extraction of quackgrass shoot material was performed at 4°C to prevent the breakdown of secondary products by microorganisms. Greenhouse-grown tissue was used because of its uniformity of size, its availability, and because it was exposed to more uniform growing conditions throughout the year. The greatest amount of material (mg) was removed from the aqueous shoot extract through partitioning with *n*-butanol (Table 1). However, the most inhibitory activity occurred in the hexane, ether, and ethyl acetate fractions, as measured by the inhibition of cress radicle elongation at 72 hr. Repeated partitioning with a solvent series was successful in removing considerable toxicity from the crude aqueous extract of shoots. Since the greatest toxicity and a comparatively larger weight of material were concentrated in the ether fraction, the crude ether extract was used in further separations and bioassays in an attempt to isolate quackgrass inhibitors responsible for the reduction in seedling growth.

Influence of Ether Extracts on Radicle Growth. The ether extract of quackgrass shoots also caused significant decreases in radicle length of eight crop and weed species after 72 hr of growth (Figure 2). Radicle length was a more sensitive indicator of inhibition than seed germination or shoot length (data not presented). The crude ether extract was more inhibitory to smaller-seeded alfalfa, cress, redroot pigweed, and lettuce (mean I_{50} value, 170 μg/ml) than to larger-seeded soybeans and navybeans (mean I_{50} value, 1000 μg/ml). The smaller-seeded monocots (barnyardgrass and smooth crabgrass) were also inhibited by ether extracts (mean I_{50} value, 242 μg/ml). These experiments in-

dicate that ether extracts of quackgrass shoots are inhibitory to the radicle growth of a variety of crop and weed species when present at relatively low rates.

Influence of Ether Extracts on Aseptically Cultured Snapbeans. Snapbeans grown with 100 or 200 μg/ml ether extract of quackgrass shoots exhibited severe brown discoloration of the root system, swelling of the roots, and a lack of root hair formation. Leaves appeared green but were smaller and cupped. Similar concentrations had also reduced radicle elongation of most seed indicator species (previous section). In comparison, the controls produced a white fibrous root system with a healthy appearance of roots and shoots. A two- to threefold decrease in both root and shoot dry weights occurred in the presence of ether extract as compared to the control (Table 2). These experiments indicate that quackgrass inhibitors are effectively removed from extracts of shoots by ether. Ether-soluble quackgrass inhibitors may reduce nodulation and nitrogen fixation in legumes (Weston and Putnam, 1985) as a result of the reduction in legume root growth and root hair formation, thereby eliminating suitable sites for *Rhizobium* infection.

In previous experiments, aqueous extracts of quackgrass shoots or rhizomes had no effect on the growth of *Rhizobium* bacteria (Weston and Putnam, 1986). The ether fractions from quackgrass shoot extracts at 4.0 or 0.4 mg/ml also had no effect on the growth of four species of *Rhizobium* in Petri dishes (data not presented). When the ether extract was incorporated into yeast extract mannitol or Bergersen's III broths at a concentration of 200 μg/ml, no inhibition of either *R. phaseoli* or *R. japonicum* growth occurred as compared to a control of distilled water (data not presented). Apparently the quackgrass inhibitors which reduce seedling growth do not play a direct role in inhibiting the growth of several common species of *Rhizobium* that participate in the legume-*Rhizobium* symbiosis.

FIG. 3. Flow diagram of the separation procedures used for purification of the ether extract of quackgrass shoots.

Quackgrass Shoots. Two toxic compounds were isolated from the ether extract of greenhouse-grown quackgrass material (Figure 3). It was necessary to extract relatively large amounts of dried quackgrass shoot material (500 g) to obtain enough purified product for the spectroscopic analyses. Since the ether extract was a complex mixture, the isolation of both compounds required the use of a number of chromatographic separation techniques.

Compound 1 was isolated from a gold crystalline material which precipitated when the ether fraction was dissolved in dichloromethane. This gold crystalline material was shown by TLC and HPLC to be three closely eluting compounds. Of these, compound 1 ($R_f = 0.40$) was eventually identified as 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone (tricin), while the running component, compound 3 ($R_f = 0.20$), which was contaminated with a small amount of tricin, was deduced to be 5,7,3′-trihydroxy-4′,5′-dimethoxyflavone.

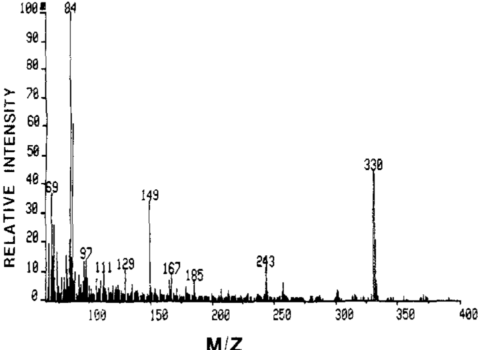

FIG. 4. Chemical ionization mass spectrum (isobutane) of 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone (tricin).

Compound 1 is yellow gold in color and soluble in alcohols. Examination of the EI mass spectrum this compound showed a low intensity ion at *m/z* 330, which indicated a probable molecular ion of 330. Under chemical ionization condition (Figure 4) intense *m/z* 331 and 330 ions showed these to be the $M+H^+$ and M^+ ions, respectively.

Analysis of the [^{1}H]NMR spectrum (Figure 5) of compound 1 in deuterated methanol disclosed information suggesting it to be a substituted methoxyflavone. In this spectrum we may discount certain signals for several impurities associated with the methods used. The singlet at δ 1.27 represents a coeluate from TLC adsorbents, an artifact usually observed when small quantities of material are purified by preparative TLC. Other singlets at δ 3.30, 4.88, and 7.90 correspond to undeuterated methanol, partially deuterated water, and chloroform from the separation procedure, respectively. For compound 1, the six-

trimethoxyflavone

C) $R=H$, $R_I=R_{II}=Me$; 5,7,3'-trihydroxy-4',5'-
dimethoxyflavone

FIG. 6. The molecular structure of 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone (tricin), **A**; 5,7-dihydroxy-3′,4′,5′-trimethoxyflavone, **B**; and 5,7,3′-trimethoxy-4′,5′-dimethoxyflavone, **C**.

proton singlet at δ 3.95 is assigned to two equivalent methoxyl groups which are therefore placed at the 3′ and 5′ positions. The other protons of compound 1 appeared at δ 6.22 (1H, doublet, $J = 2$ Hz, H-6), 6.49 (1H, doublet, $J = 2$ Hz, H-8), 6.68 (1H, singlet, H-3) and 7.28 (2H, singlet, H-2′ and H-6′). The correctness of these assignments was shown by synthesis of 5,7-dihydroxy-3′4,′5′-trimethoxyflavone, **B** (Figure 6), the 4′-*O*-methyl derivative of tricin, from 2′,4′,6′-trihydroxyacetophenone and 3,4,5-trimethoxybenzoyl chloride by the method of Wheeler (1963), and by comparison (Table 3) of the spectrum (Figure 7) of this synthetic compound with that of tricin. From these spectra it is clear that compound 1 with two equivalent methoxyl group at C-3′ and C-5′ lacks the 4′-methoxyl group which appears at δ 3.85 in the spectrum of the synthetic compound. The presence of the 4′-methoxyl in this synthetic 4′-methoxytricin is observed to have small, −0.05 and +0.03 ppm, but distinguishing effects on the chemical shifts of the proton H-3 and the equivalent protons H-2′ and H-6′. The 3′- and 5′-methoxyl groups in both compound 1 (tricin) and the synthetic derivative were equivalent, appearing as singlets (6H) at δ 3.95 and 3.94, respectively.

The structure **A** (Figure 6) for compound 1 (tricin) was further confirmed by examining its UV spectra. Its spectrum under alkali conditions showed the usual bathochromic shift expected of phenolic compounds. In addition, the pattern of the UV spectrum in the presence of aluminum chloride was identical to that of tricin. In 1983, Voiron (1983) published a paper on the identification of methoxyflavones with different patterns of OH and OCH_3 substitution using UV spectral differentiation. The UV spectrum is observed in methanol and also in

[a]Signals assigned by subtracting peaks for tricin.

the presence of methanol plus aluminum chloride, a spectral shift reagent. The majority of flavonoids may be easily identified by their purple fluorescence in UV light and by their spectra in methanol, since they exhibit an absorption maxima in the long UV range (band I) above 326 nm, and generally the ratio of the absorption of band I to band II is greater than 0.7. Compound 1 exhibits a UV maxima at 268 and 350 nm in methanol and, when in the presence of aluminum chloride, exhibits a bathochromic shift to 277 and 393 nm (Figure 8) (Voiron, 1983). This, along with other spectral information, is characteristic only of tricin (5,7,4'-trihydroxy-3',5'-dimethoxyflavone).

Another golden yellow compound ($R_f = 0.20$) which we assigned structure **C** (Figure 6) was also isolated together with tricin. However, because of the small quantities available and the presence of tricin as an impurity, no bioassays

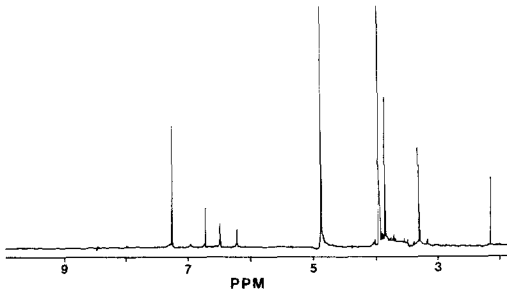

FIG. 7. [¹H]Nuclear magnetic resonance spectrum of synthetic 5,7-dihydroxy-3',4',5'-trimethoxyflavone dissolved in deuterated methanol.

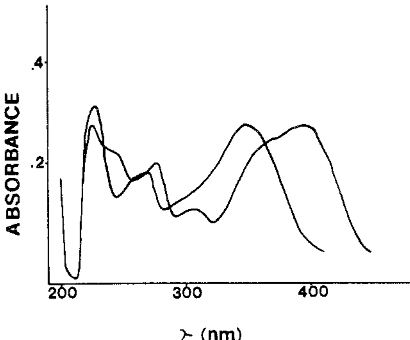

FIG. 8. Ultraviolet absorbance spectrum of 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone (tricin) in methanol and its corresponding bathochromic shift when placed in methanol plus aluminum chloride.

were conducted. The UV spectrum was similar to that of tricin but the method reported by Voiron using aluminum chloride was not effective because of the mixture. However, the [^{1}H]NMR spectrum of the mixture supported the TLC analysis and indicated that the mixture consisted of tricin, **A**, and 5,7,3′-trihydroxy-4′,5′-dimethoxyflavone. The chemical shift assignments for this compound could be deduced by subtracting the peaks for tricin. The values obtained (Table 3) were remarkably consistent with the presence of a 4′-methoxyl group as indicated by two nonequivalent methoxyl groups at δ 3.93 and 3.84 for the methoxyl groups at C-5′ and C-4′, respectively. The singlet for H-2′ and H-6′ appears at δ 7.25, which is identical to the position of H-2′ and H-6′ in the synthetic 4′-methoxyl compound (**B**) and distinctly different from the value (δ 7.28) in tricin. This deduction from the [^{1}H]NMR spectra was supported by MS measurements. An intense ion ($M+H^+$) (100%) at *m/z* 331 in the chemical ionization spectrum of the mixture revealed the molecular species involved and that the molecular weight was identical to that of tricin. This fact, when considered in conjunction with the similarity with [^{1}H]NMR spectra, indicates that the compound ($R_f = 0.20$) is 5,7,3′-trihydroxy-4′,5′-dimethoxyflavone, **C**. This compound has recently been found in extracts of *Poa huecu* Par. (Graminae) by Pomilio and Rofi (1985).

Compound 2 is also golden yellow in color, soluble in alcohols and fluoresces purple under UV (254 nm) light. We believe that compound 2 is also a flavonoid, closely related in structure to tricin. From the HPLC and TLC data obtained, we believed that we had purified the mixture to only one component. The mass spectrum (data not presented) also shows the fragmentation pattern of an oxygen-containing structure. The last discernable fragment occurred at *m/z* 300, (10%) and was not expectedly intense. The true molecular ion, therefore, remains uncertain.

The complexity in the [^{1}H]NMR spectrum indicates the presence of im-

purities (data not presented). However, analytical HPLC using a variety of solvent systems did not resolve compound 2 into anything other than one needle-shaped peak. This, along with the NMR spectrum, suggests that the impurity may be one or more very closely related flavonoids. The NMR spectrum resembles that of compound 1 and the synthesized flavonoid. However, the region from δ 6.7–7.2 is not clearly resolved. The NMR data strongly suggest that compound 2 is also a methoxyflavone, but the presence of impurities prevented the discovery of the substitution pattern upon the A and B rings.

Flavonoids are secondary phenolic compounds that are closely related to both the coumarins and the substituted cinnamic acids. The structural attribute which appears to confer biological activity upon these compounds is substitution upon the benzene moiety. Many possible roles for flavonoids in the physiology of higher plants have been postulated. In particular, flavonoids may play a role as screening pigments for the protection of plant tissues from UV light (Harborne, 1965; McClure, 1977; Robinson, 1980).

The resinous oils of many plants are particularly rich in flavonoid aglycones. Flavonoids are excreted by the root systems of various plants, and some have shown considerable allelopathic activity. For example, in wheat roots, striking inhibition of ion uptake occurs in the presence of various flavones, flavonols, and isoflavones. Various flavonoids also inhibit photophosphorylation in plant mitochondria at extremely low concentrations (McClure, 1977).

Quackgrass extracts contain at least two related flavonoid compounds (tricin and compound 2) which inhibit cress seedling germination and radicle elongation (Table 4). The I_{50} value for tricin upon cress seed radicle elongation is 123.3 μg/ml, while compound 2 has an I_{50} of 59.3 μg/ml. These compounds are both inhibitory to radicle elongation in cress seeds at relatively low concentrations in comparison to several other alleged allelochemicals (Rice, 1984). Neither compound was previously screened for phytotoxic activity. The flavone tricin has also been isolated from the leaves of several *Triticum* species. It appears to be restricted in distribution to a few monocotyledonous plants (Har-

	I_{50} value (μg/ml)[a]
Tricin	123.3
Compound 2	59.3

[a] I_{50} values represent the point at which 50% inhibition of radicle elongation of curly cress occurred. A dose-response curve was calculated on the basis of mean elongation of 40 seeds at five concentrations of the chemicals.

TABLE 5. QUANTITY OF ETHER EXTRACT, TRICIN AND COMPOUND 2 OBTAINED FROM PARTITIONING AND HPLC QUANTIFICATION OF DIFFERENT SOURCES OF QUACKGRASS MATERIAL.

Quackgrass Source	Ether extract	Tricin	Compound 2
		(mg/100 g)	
Greenhouse shoot	66	10	6
Field shoot	208	30	36
Greenhouse rhizome	62	1	8
Field rhizome	375	5	9

borne, 1965). The ether extract of quackgrass shoots not only contains tricin and compound 2, but also appears to contain a number of other closely related flavonoids. These may possess varying degrees of biological activity depending upon the substitution pattern upon the flavonoid rings (McClure, 1977). Previously, Gabor and Veatch (1981) isolated a golden inhibitor, soluble in alcohol, which was extracted from quackgrass rhizomes and characterized as a glycoside. It is possible that the aglycone portion of that molecule was also a flavonoid.

HPLC Quantification of Phytotoxins from Various Quackgrass Tissues. Quackgrass shoots and rhizomes collected from the field produced three to five times more dried ether extracts per 100 g of dried tissue than did shoots or rhizomes grown in the greenhouse (Table 5). The amounts of the two phytotoxic compounds (tricin and compound 2) in field- and greenhouse-grown shoots or rhizomes were also compared by TLC and HPLC quantification (Table 5). Quackgrass shoots grown under field conditions yielded the greatest amounts of both tricin and compound 2 (29.8 and 35.5 mg/100 g dried tissue, respectively) when compared to other tissues. Rhizomes grown in both environments also contained tricin and compound 2, but in generally smaller quantities than those which occurred in the shoots. Rhizomes and shoots grown in the field also yielded higher levels of tricin and compound 2 than did those grown in the greenhouse. This is not surprising, since it is known that plant tissues exposed to greater environmental stress generally produce higher levels of flavonoids (McClure, 1977). The figures shown represent an estimate of the quantities present in the ether extracts and may or may not reflect relative amounts of the two inhibitors present in the whole plant before extraction. However, partitioning with ether did remove the majority of flavonoid compounds from the aqueous extracts (as observed by TLC and the cress bioassay).

These experiments clearly show that quackgrass shoots and rhizomes possess at least two inhibitors that are flavonoid compounds. These flavonoid com-

pounds reduce radicle elongation and root growth. They are present in larger proportions in the ether extracts of quackgrass shoots as compared to extracts of rhizomes. Extracts of quackgrass shoots are also more toxic to seedling root growth in a number of plant species than are extracts of rhizomes (Weston and Putnam, 1986). Tricin and compound 2, along with other related compounds, may be released from plant tissues by exudation or degradation and may play a role in the alleged allelopathic activity of living and dead quackgrass. This observed allelopathic activity includes reductions in root and shoot growth of crop and weed species and inhibition of legume nodulation and nitrogen fixation in the presence of quackgrass or its extracts in the field, greenhouse and laboratory (Weston and Putnam, 1985, 1986). The specific mode of action of the flavonoid compounds, their rate of release from quackgrass tissue, and their role in the soil rhizosphere should be further investigated.

(Received November 12, 1985; accepted March 13, 1986)

Abstract—Midgut microsomes prepared from larvae of the fall armyworm [*Spodoptera frugiperda* (J.E Smith)], a generalist insect, and the velvetbean caterpillar (*Anticarsia gemmatalis* Hubner), a semispecialist, were used to study their oxidative activity toward a variety of allelochemicals. Allelochemicals such as terpenoids, alkaloids, indoles, glucosinolates, flavonoids, coumarins, cardenolides, phenylpropenes, and a ketohydrocarbon were all metabolized by the microsomal cytochrome P-450 monooxygenases in both species. Fall armyworm microsomes oxidized monoterpenes more favorably than other types of terpenes, indicating a preference for these compounds. In all instances, the oxidative metabolism of these allelochemicals can be induced by dietary allelochemicals such as indole 3-carbinol, indole 3-acetonitrile, menthol, flavone, or peppermint oil ranging from 1.3- to 9.5-fold. In the case of certain triterpenes, tetraterpene, alkaloid, coumarin, and cardenolides, metabolic activity can only be observed after induction. The monooxygenase activities toward these allelochemicals were generally higher in the generalist than in the semispecialist. These findings provide strong evidence that microsomal monooxygenases play an important role in the detoxification of plant toxins and hence host-plant selections in herbivorous insects.

Key Words—Allelochemical metabolism, microsomal oxidation, fall armyworm, velvetbean caterpillar, *Spodoptera frugiperda*, *Anticarsia gemmatalis*, Lepidoptera, Noctuidae, enzyme induction.

INTRODUCTION

The microsomal cytochrome P-450 monooxygenase [also known as mixed-function oxidase (MFO)] system of insects plays an important role in the oxi-

0098-0331/87/0300-0423$05.00/0 © 1987 Plenum Publishing Corporation

dative metabolism of various xenobiotics including pesticides (Hodgson, 1985). The versatility of this system is mainly due to its broad substrate specificity, capable of oxidizing various functional groups of lipophilic organic molecules. This system is believed to play a major role in insect herbivory on the basis of the following indirect evidence. First, aldrin epoxidase activity in polyphagous larvae is higher than in monophagous larvae, oligophagous ones being intermediate (Krieger et al., 1971). Second, MFO activity in larvae is low in the nonfeeding stage and high in the actively feeding stage (Krieger and Wilkinson, 1969; Ahmad, 1983). Finally, allelochemicals induce MFO activity which is presumed to enhance the detoxification of allelochemicals (Brattsen et al., 1977, 1984; Yu et al., 1979; Yu, 1983).

However, unlike pesticides, little is known about the microsomal metabolism of allelochemicals in insects. Most of the work has been done in mammals because of the toxicological and pharmacological importance of many allelochemicals in humans and domestic animals. Because of insufficient metabolic data in insects (Dowd et al., 1983), the MFO theory has recently been challenged by Dowd et al. (1983) and Gould (1984). These authors also argue that although allelochemicals induce MFO activity, the inducers have never been shown to stimulate the MFO which detoxifies the inducers.

In the present study, I investigated microsomal oxidations of an array of structurally different allelochemicals in a generalist and a semispecialist insect. The role of enzyme induction in the detoxification of allelochemicals was also examined in these insects.

METHODS AND MATERIALS

Insects. Larvae of the fall armyworm [*Spodoptera frugiperda* (J.E. Smith)], a generalist insect, and the velvetbean caterpillar (*Anticarsia gemmatalis* Hubner), a semispecialist insect, were reared on an artificial diet and maintained in environmental chambers at 25°C with a 16:8 light–dark photoperiod as described previously (Yu, 1982).

Chemicals. The allelochemicals used in this study and their sources were (−)-menthol, β-myrcene, (+)-camphor, geraniol, farnesol, santonin, phytol, gibberellic acid, stigmasterol, sitosterol, squalene, cholesterol, ergosterol, β-carotene, xanthotoxin, rotenone, flavone, nicotine, atropine, strychnine, colchicine, morin, cytisine, indole 3-carbinol, indole 3-acetaldehyde, indole 3-acetonitrile, indole 3-lactic acid, myricetin, estragole, umbelliferone, scopoletin, digitoxin, and eugenol (Sigma Chemical Company, St. Louis, Missouri); (+)-α-pinene, (−)-α-pinene, (−)-β-pinene, (+)-limonene, *l*-menthone, (+)-pulegone, *d*-carvone, (+)-camphene, (−)-camphene, nerolidol, safrole, *trans*-anethole, caffeine, monocrotaline, sinigrin, coumarin, digitoxigenin and digoxigenin (Aldrich Chemical Co., P.O. Box 355, Milwaukee, Wisconsin); myr-

isticin (Saber Laboratories, Inc., Box 232, Morton Grove, Illinois); 2-phenylethyl isothiocyanate, 2-tridecanone, and isosafrole (Fluka Chemical Corp., 255 Oser Avenue, Hauppauge, New York). All other chemicals were of analytical quality and purchased from commercial suppliers.

Treatment of Insects. When the toxicity of allelochemicals was studied, groups of 10 first-instar fall armyworm larvae were individually fed artificial diets containing the allelochemicals and maintained in 1-oz plastic cups. Larval weights were taken 13 days after feeding began. Adult emergence was also recorded at the end of the experiments.

When allelochemicals were used as inducers of microsomal monooxygenases, groups of newly molted sixth-instar larvae were collected from the culture and fed artificial diets containing the allelochemicals for two days. Controls were fed the artificial diet only. At the end of the experiments, larvae were removed from their respective diets and used for enzyme assays. No mortality was observed due to the treatments.

Preparation of Microsomes for Metabolic Studies. To prepare microsomes for the present study, midguts were dissected from 2-day-old sixth-instar larvae and their gut contents removed. They were then washed in 1.15% KCl and homogenized in 25 ml of ice-cold 0.1 M sodium phosphate buffer, pH 7.5, in a motor-driven tissue grinder for 30 sec. The crude homogenate was filtered through cheesecloth, and the filtered homogenate was centrifuged at $10{,}000 g_{max}$ for 15 min in a Beckman L5-50E ultracentrifuge. The pellet (cell debris, nuclei, and mitochrondria) was discarded, and the supernatant was recentrifuged at $105{,}000 g_{max}$ for 1 hr. The microsomal pellet was suspended in ice-cold 0.1 M sodium phosphate buffer, pH 7.5, to make a final concentration of 1 mg protein/ml and was used immediately. The above procedures were conducted at 0–4°C.

Microsomal Oxidation of Allelochemicals. The in vitro oxidative metabolism of allelochemicals was studied using either the NADPH-dependent substrate disappearance method or allelochemical-dependent NADPH oxidation. The former method was used to study the 10 compounds listed in Table 1. The 5-ml incubation mixture contained 1–2 mg of microsomal protein; 0.1 M sodium phosphate buffer, pH 7.5; an NADPH-generating system consisting of 1.8 μmol of NADP, 18 μmol glucose-6-phosphate, and 1 unit of glucose-6-phosphate dehydrogenase; and 10–50 μg of substrate (allelochemical) in 0.1 ml of methyl Cellosolve. Incubation mixture which contained no NADPH-generating system was used as blank. Duplicate incubations were conducted in a water bath with shaking at 30°C in an atmosphere of air for 1 hr. The unreacted parent compound was extracted with 10 ml of chloroform (for xanthotoxin, indole 3-acetonitrile and flavone) or ethyl acetate [for myristicin, safrole, rotenone, nicotine, (+)-pulegone, *trans*-anethole and estragole] by shaking in the water bath for 1 hr. The extracts were then analyzed by either high-pressure liquid chromatography (HPLC) or gas chromatography (GC).

TABLE 1. EFFECT OF ALLELOCHEMICALS IN LARVAL DIET ON DEVELOPMENT OF FALL ARMYWORM

	% of control	
Treatment (0.1% in diet)[a]	Larval weight after 13 days	Adult emergence
Control	100	100
Xanthotoxin	1	0
Rotenone	20	20
Flavone	20	100
Nicotine	0	0
Myristicin	1	10
Safrole	0	0
(+)-Pulegone	0	0
trans-Anethole	0	0
Estragole	0	0
Indole 3-acetonitrile	32	95

[a] First-instar larvae were fed meridic diets containing the allelochemicals.

A Beckman Series 340 high-performance liquid chromatograph equipped with a UV detector was used to analyze the allelochemicals with the exception of nicotine. Two types of columns were used. For normal-phase column (25 cm × 4.6 mm ID, Ultrasphere-Si, Altex), 5% isopropyl alcohol in hexane was used as the solvent system. This column was employed to analyze xanthotoxin, indole 3-acetonitrile, safrole, flavone, and rotenone. For reverse-phase column (25 cm × 4.6 mm ID, Ultrasphere-ODS, Altex), 85% methanol was used as the solvent system. This column was employed to analyze myristicin, (+)-pulegone, *trans*-anethole, and estragole. A flow rate of 1 ml/min was used for both columns.

A Varian model 3740 gas chromatograph equipped with a thermionic specific detector was used to analyze nicotine. The column used was 1.83 m × 2 mm ID glass column packed with 2% OV-101 on 80–100 mesh Ultra-Bond 20 M. The operating conditions were: column, 185°C; injection port, 200°C; detector, 250°C; nitrogen carrier gas, 30 ml/min; air, 175 ml/min; and hydrogen, 4.5 ml/min.

In tests with blank systems (−NADPH), 95–100% of added allelochemicals [xanthotoxin, indole 3-acetonitrile, myristicin, safrole, flavone, rotenone, (+)-pulegone, *trans*-anethole] was recovered by the extraction procedures. When boiled microsomes were used as the tissue source, there was no difference in the recovery rate, indicating that these allelochemicals were not metabolized by microsomes other than MFO under the assay conditions employed. However, a poor recovery (49%) for nicotine was encountered in the blank system. Apparently, nicotine was degraded by microsomes other than MFO since 70%

of added nicotine was recovered using boiled microsomes. Estragole showed a recovery rate of 87% in the blank system; however, the loss was not found to be enzymatic.

For some allelochemicals, especially those which cannot be detected by GC or HPLC, the allelochemical-dependent NADPH oxidation method was used to study their oxidative metabolism. The 4.6-ml mixture which contained 0.5–1 mg microsomal protein, 0.1 M sodium phosphate buffer, pH 7.5, was first incubated for 3 min at 30°C and then 0.1 mM NADPH in 0.4 ml of the same buffer was added and mixed. After the addition of 50 μM substrate (allelochemical) in 5 μl of methyl Cellosolve to 2.5 ml of the mixture, the rate of NADPH oxidation was recorded at 340 nm against the same reaction mixture in the absence of substrate in a Beckman model 5260 UV/VIS spectrophotometer. This system cancels endogenous NADPH oxidation automatically because both reference and sample cuvettes contain microsomes and NADPH.

RESULTS

Toxicity of Allelochemicals to Fall Armyworm Larvae. Ten compounds which were selected for bioassays against fall armyworm larvae included coumarin (xanthotoxin), flavonoids (rotenone, flavone), alkaloid (nicotine), phenylpropenes (myristicin, safrole, *trans*-anethole, estragole), terpenoid [(+)-pulegone] and indole (indole 3-acetonitrile). As shown in Table 1, these allelochemicals were all toxic to the fall armyworm when first-instar larvae were fed artificial diets containing 0.1% of the compounds. In the case of nicotine, safrole, *trans*-anethole, estragole, and (+)-pulegone, none of the test larvae progressed to sixth instar. However, flavone and indole 3-acetonitrile had no marked effect on adult emergence.

Microsomal Oxidation of Allelochemicals. The validity of the NADPH-dependent allelochemical disappearance method is shown in Figure 1 using xanthotoxin as a model substrate. When NADPH was added in the incubation mixture, the level of xanthotoxin decreased 56% as compared with the control (−NADPH). Two metabolites were produced from the metabolism but were not identified. Addition of piperonyl butoxide (PB) (10^{-4} M) or CO (both are known inhibitors of microsomal monooxygenases) caused an 89% reduction in the metabolic activity in each case. The results suggest that xanthotoxin is oxidized by the microsomal cytochrome P-450-dependent monooxygenases in fall armyworm larvae.

Using the NADPH-dependent method described above, we showed that the allelochemicals in Table 2 were all metabolized by a MFO system from fall armyworm larvae. The specific activity for the MFO system ranged from 0.86 to 34.34 nmol/hr/mg protein, estragole being the best substrate for the enzyme among those studied. The metabolism of each compound was inhibited by pi-

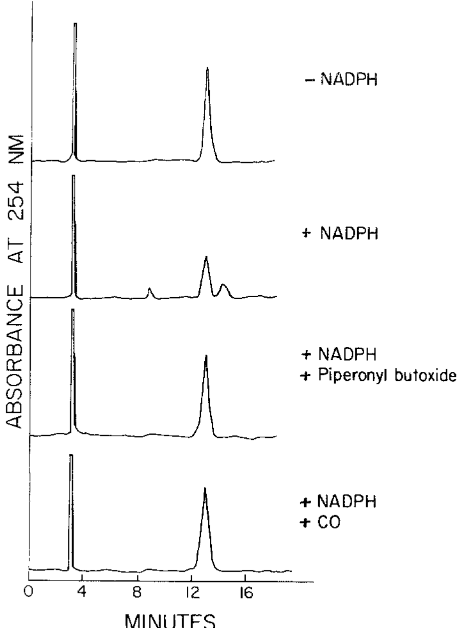

FIG. 1. Liquid chromatograms showing metabolism of xanthotoxin by fall armyworm microsomes under different conditions. Newly molted sixth-instar larvae were fed a diet containing indole 3-carbinol (0.2%) for two days prior to preparation of microsomes. See text for details (incubations were conducted for 15 min).

peronyl butoxide, again indicating the involvement of cytochrome P-450. Data in Table 3 shows that the oxidative metabolism can be enhanced by feeding the larvae with certain allelochemicals such as indole 3-carbinol, indole 3-acetonitrile, menthol, flavone, or peppermint oil, all of which are inducers of various MFO activities in fall armyworms (Yu, 1982, 1983, 1984; Yu and Ing, 1984). The induction ranged from 1.6- to 4.1-fold depending on the allelochemical used as substrate.

Further studies of allelochemical metabolism were made by the allelochemical-dependent NADPH oxidation method. The results are summarized in Tables 4, 5, and 6. It is seen that addition of PB and CO greatly decreased the enzyme activity, indicating the involvement of cytochrome P-450. Data in Table 4 show that fall armyworm microsomes generally oxidize monoterpenes more favorably than other types of terpenes, indicating a preference for these compounds. In addition to terpenoids, other plant toxins such as alkaloids, indoles, glucosinolates, coumarins, cardenolides, ketohydrocarbon, and phenylpropenes were also metabolized by the MFO system (Table 5). In all instances, the oxidative metabolism of these allelochemicals can be induced by dietary indole 3-carbinol ranging from 1.3- to 9.5-fold in this insect. It is interesting to note that in the case of certain triterpenes, tetraterpene, alkaloid, coumarin, and cardenoilides, metabolic activity can only be observed after induction.

Among those studied, santonin, gibberellic acid, cytisine, colchicine, morin, indole 3-lactic acid, myricetin, umbelliferone, and digitoxigenin were not metabolized by the MFO system from fall armyworm larvae. Lack of suitable functional groups, steric/conformation factors, and/or polarity may explain their failure as substrates for these membrane-bound enzymes.

The microsomal monooxygenase system from velvetbean caterpillar larvae (noninduced) also metabolized various allelochemicals. From Table 6, it can be seen that the MFO activities toward these allelochemicals were generally lower in the velvetbean caterpillar than in the fall armyworm with the exception of *d*-carvone, geraniol, nerolidol, farnesol, and cholesterol for which the reverse was true.

DISCUSSION

The results of the present study clearly demonstrate that plant allelochemicals with diverse chemical structures including terpenoids, alkaloids, indoles, glucosinolates, flavonoids, coumarins, cardenolides, phenylpropenes, and ketohydrocarbon are all metabolized by the microsomal monooxygenase system prepared from larvae of the fall armyworm and velvetbean caterpillar. Although attempts were not made to identify the oxidative metabolite(s) from each allelochemical in this study, judging from their structures, most of these compounds were likely to be detoxified via epoxidation or hydroxylation by the

MFO system. The findings provide strong evidence for the current belief that MFOs are important in the selection of host plants by herbivorous insects.

In support of these observations, it has been shown that the botanical insecticides, rotenone, nicotine and pyrethrins, are metabolized by cytochrome P-450 monooxygenase systems in insects. Rotenone is oxidatively metabolized to rotenolone I and II, 6′,7′-dihydro-6′,7′-dihydroxyrotenone, and 8′-hydroxyrotenone in house flies (Fukami et al., 1969). Pyrethrin I is hydroxylated at the *trans*-methyl group on the acid side chain in house flies (Casida et al., 1971). As to nicotine, it is hydroxylated by the MFO system at the C-2 position to produce 2-hydroxynicotine followed by alcohol dehydrogenation to yield continine in tobacco-feeding insects (Self et al., 1964; Matsumura, 1975; Hodgson and Dauterman, 1980).

The metabolism of the furanocoumarin, xanthotoxin, was studied in the black swallowtail butterfly by Ivie et al. (1983). Two metabolites, 7-hydroxy-

8-methoxy-2-oxo-2H-1-benzopyran-6-acetic acid and α,7-dihydro-8-methoxy-oxo-2H-1-benzopyran-6-acetic acid, which were believed to be formed through microsomal oxidation (Kolis et al., 1979), were found in larvae when they were fed xanthotoxin. The ability of the black swallowtail to detoxify this compound explains why this insect can feed on xanthotoxin-containing plants without being poisoned.

A variety of monoterpenes is oxidatively metabolized by insects. α-Pinene is hydroxylated to *trans*-verbenol (Hughes, 1975), myrcene to ipsdienol (Hughes, 1974), and camphene to 6-hydroxycamphene (Renwick et al., 1976) in bark beetles. That MFO is involved in the oxidation of monoterpenes was reported by White et al. (1979), who showed that α-pinene was oxidized to α-pinene epoxide by cytochrome P-450-dependent monooxygenases prepared from bark beetles.

Some plants, such as bracken ferns, were found to contain insect molting hormones (Kaplanis et al., 1967). The phytoecdysone, α-ecdysone, has been shown to be hydroxylated by microsomal oxidase at the C-20 position to become β-ecdysone in the African migratory locust (Feyerisen and Durst, 1978).

The juvenile hormone antagonist, precocene II, was shown to be primarily attacked by microsomal oxidases prepared from the fat body homogenates of cabbage looper larvae (Soderlund et al., 1980). The metabolites were 6-hydroxy, 7-hydroxy, 3,4-dihydro-3-hydroxy, and *cis*- and *trans*-3,4-dihydro-3,4-dihydroxy precocene II. Although precocene 3,4-epoxide was not detected in this study, its formation was believed to be essential as an intermediate for both diols. Because of the extreme reactivity of the epoxide, it was suggested that the epoxide is involved in the allatotoxication of precocene II.

As to the enzyme induction, the results of this study demonstrate that all the allelochemicals previously shown to be MFO inducers (e.g., α-pinene, β-pinene, menthol, menthone, myrcene, limonene, indole 3-carbinol, indole 3-acetonitrile, flavone, and xanthotoxin) (Brattsten et al., 1977, 1984; Yu et al., 1979; Yu, 1983, 1984) were substrates for the MFOs in fall armyworm larvae. Specifically, feeding indole 3-carbinol to fall armyworm larvae increased the MFO activity which oxidized this allelochemical as much as four-fold (Table 4). In this respect, enzyme induction caused by allelochemicals would help the insects detoxify plant toxins in their diets. As a result, they would potentially have a wider host-plant range if enzyme inducers happen to coexist with plant toxins in the same plants, or inducing plants and toxin-containing plants are all available in the same area.

Comparing the MFO activity toward various allelochemicals in the generalist (polyphagous) larvae and the semispecialist (oligophagous) larvae, it is clear that our results are generally in agreement with those of Krieger et al. (1971) showing the correlation between MFO activity and degree of feeding specialization. However, the fact that certain allelochemicals are better substrates for the MFO from velvetbean caterpillar larvae than from fall armyworm

larvae suggests that the MFO in the generalist may be quantitatively as well as qualitatively different from that of the semispecialist. In particular, the isozyme composition of cytochrome P-450 could be different in these two insects as in the case of insecticide-susceptible and resistant insects (Yu and Terriere, 1979). More data from various species of generalist and specialist insects are needed before a firm conclusion can be made.

RADIAL DIFFUSION METHOD FOR DETERMINING TANNIN IN PLANT EXTRACTS

ANN E. HAGERMAN

Department of Chemistry
Miami University
Oxford, Ohio 45056

(Received November 29, 1985; accepted March 13, 1986)

Abstract—Tannin in plant extracts can be determined by reacting the tannin with a protein and quantitating the precipitated complex. In the new assay described here, a tannin-containing solution is placed in a well in a protein-containing agar slab. As the tannin diffuses into the gel and complexes with protein, a visible ring of precipitation develops. The area of the ring is proportional to the amount of tannin in the extract. The detection limit of the method is 0.025 mg tannic acid or condensed tannin and the precision is 6% (relative standard deviation). Tests with extracts of a variety of plants show that the new method gives results comparable to other precipitation methods and that the new method is superior for samples of unusual composition, such as aspen buds. The method has several advantages over other methods for determining tannin: The new method is very simple and requires neither complex reagents nor instruments. Components of the plant extract such as non-tannin phenolics or water-insoluble compounds do not interfere with the method. The assay is not subject to interference from the organic and aqueous solutions which are commonly used to extract tannin from plants.

Key Words—Tannin, proanthocyanidin, protein precipitation, digestibility-reducing substances, phenolic analysis.

INTRODUCTION

Tannins, like many other secondary compounds, are thought to defend plants from herbivores (Swain, 1979). To establish the role of tannin as a defensive compound, the tannin content of various plants must be correlated with patterns of herbivory. Sensitive, specific tannin assays which can easily be run on large numbers of samples are required for such studies of tannin as a defensive compound.

0098-0331/87/0300-0437$05.00/0 © 1987 Plenum Publishing Corporation

The analytical methods currently available for determining tannin have several disadvantages. The functional group methods do not have satisfactory specificity. For example, the redox methods such as the Folin-Denis assay (Folin and Denis, 1915) are not specific for tannin, but detect any phenolic compound. On the other hand, the proanthocyanidin and vanillin assays (Bate-Smith, 1975; Price et al., 1978) are too selective. The hydrolyzable tannins, which are gallic acid derivatives (Haslam, 1979), do not react with acidic butanol or vanillin. Only the flavonoid-based condensed tannins (Haslam, 1979) can be detected with these reagents.

Precipitation assays also have disadvantages. Several methods for determining protein precipitated by the tannin have been described (Bate-Smith, 1973; Hagerman and Butler, 1980a; Martin and Martin, 1983). Although selective, these methods are inconvenient; they may include multiple steps for forming and isolating the precipitate, or they may require special materials such as radiolabeled compounds. Two simple precipitation methods have been described. In one method, a dye-labeled protein is used, and the amount of protein precipitated by the tannin is determined spectrophotometrically (Asquith and Butler, 1985). In another method, the tannin precipitated by excess protein is measured spectrophotometrically after reaction with ferric chloride (Hagerman and Butler, 1978). Although these methods are straightforward, sample preparation for these assays is complicated. Some solvents, such as acetone, interfere with the precipitation and must be removed from the extract before analysis. In addition, water-insoluble compounds frequently found in the tannin extract interfere with precipitation assays (Hagerman and Butler, 1978; Asquith and Butler, 1985).

A new protein precipitation assay that overcomes these problems is described here. In the assay, tannin diffuses through a protein-containing gel, and a visible disk-shaped precipitate develops as the tannin interacts with the protein. The method is simple, sensitive, and specific, and should be especially applicable to studies in which large numbers of samples are to be analyzed.

METHODS AND MATERIALS

Reagents. All reagents were analytical grade or the best grade available. Agarose (type I), bovine serum albumin (BSA) (fatty acid-free fraction V), and catechin were obtained from Sigma Chemical Co. (St. Louis, Missouri). Condensed tannin was prepared from *Sorghum vulgare* IS 4225 by the method of Hagerman and Butler (1980b). Hydrolyzable tannin was purified from commercial tannic acid as described by Hagerman and Klucher (1986). Buffer A consisted of 50 mM acetic acid and 60 μM ascorbic acid adjusted to pH 5.0.

Assay Method. A 1% (w/v) solution of agarose was prepared in buffer A

by heating the suspension of agarose to boiling while stirring. The solution was cooled to 45°C in a water bath, and the protein [0.1% (w/v) BSA] was added while the solution was gently stirred. The solution was dispensed in 9.5-ml aliquots into standard plastic Petri dishes (8.5 cm diameter) and allowed to cool. The agarose solidified on cooling; the plates were always cooled on a level surface to obtain slabs of uniform thickness. Once prepared, the plates were stored at 4°C to prevent bacterial growth.

Uniform wells were punched in the plates with a punch 4.0 mm in diameter (Biorad Co., Richmond, California). The wells were spaced 1.5 cm apart on the plates. The tannin-containing solutions were added to the wells with a Hamilton microsyringe; the capacity of 4.0-mm wells was slightly greater than 8 μl, so the samples were applied in 8-μl aliquots. For dilute samples, several successive 8-μl aliquots were added to a single well as the liquid was absorbed by the gel. Although any organic or aqueous solution could be applied to the wells, solutions containing at least 10% (v/v) water were easier to dispense than neat organic solvents.

After placing the samples in the wells, the Petri dishes were covered and sealed with Parafilm. The dishes were incubated at 30°C for 96–120 h. The diameters of the rings were then measured; for each ring, two diameters at right angles to one another were measured to minimize errors due to nonuniform ring development. Tannin concentration was calculated from the square of the average of the two diameters using an appropriate calibration curve.

Plant Extraction. Plant tissue was extracted for an hour at room temperature with 50% (v/v) aqueous methanol, using a solvent-to-tissue ratio of 0.5 ml solvent per 100 mg tissue. For diffusion assays, 100 mg tissue was an adequate sample size; if other assays were run, the sample size was increased to 300–500 mg. The extracts were applied directly to the diffusion gels without any sample cleanup. Two or three successive aliquots of 8 μl were sufficient to form rings for the plants tested.

If the extracts were to be analyzed with other precipitation tests, the samples were centrifuged (5000*g*, 15 min) and the extract removed from the pelleted tissue. For the protein precipitation assays (Hagerman and Butler, 1978, 1980a), 0.20 ml of the methanol extract was added to 7.0 mg iodine-125-labeled BSA in 2.00 ml acetate buffer. After 15 min, the mixtures were centrifuged. An aliquot of each supernatant was removed for radioactive counting, and the remainder of the supernatants discarded. The pellets were dissolved in triethanolamine reagent (Hagerman and Butler, 1978), ferric chloride was added, and the A_{510} was determined. The amount of protein precipitated was calculated from the radioactive counting data, using a calibration curve prepared with the labeled BSA. The amount of tannin precipitated was determined from a standard curve run with purified tannic acid (Hagerman and Klucher, 1986).

RESULTS

When a solution containing condensed or hydrolyzable tannin was placed in a protein-containing gel, the tannin diffused into the gel and formed a disk-shaped tannin–protein precipitate (Figure 1). No ring formed if the protein was omitted from the gel. Under the conditions described here, the ring was always clearly visible without any staining. The rings appeared similar for condensed tannin obtained from *Sorghum* seeds, for hydrolyzable tannin purified from commercial tannic acid, and for tannin-containing extracts from a variety of plants (Figures 1 and 2).

The rings expanded slowly, and reached their equilibrium sizes only after

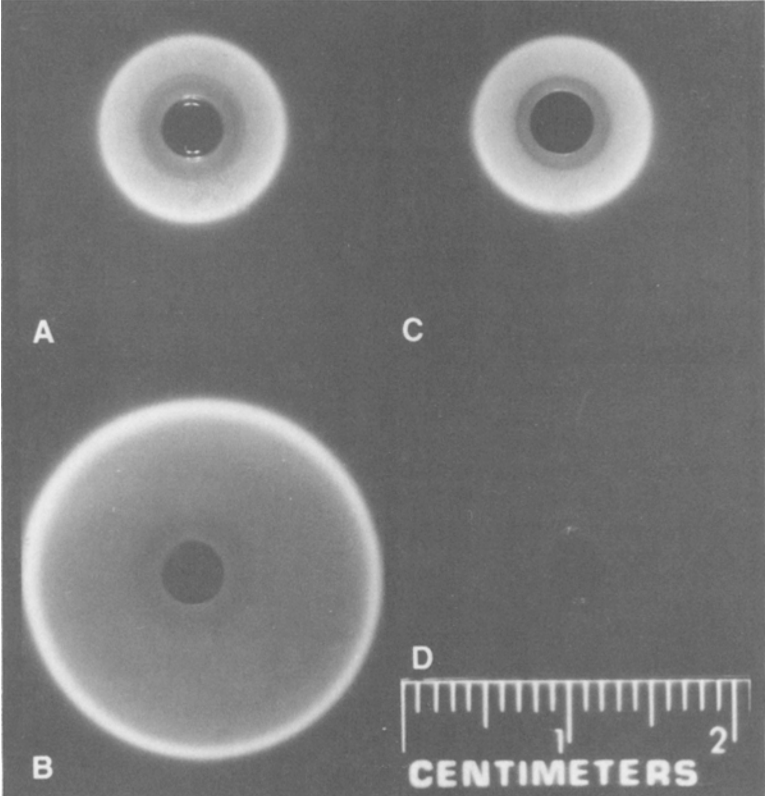

FIG. 1. Radial diffusion assay for tannin. An 8-μl aliquot of the sample dissolved in 70% acetone was placed in each well and photographed after the rings reached equilibrium. (A) 0.60 mg sorghum tannin; (B) 0.60 mg tannic acid; (C) 0.50 mg catechin plus 0.60 mg sorghum tannin; and (D) 0.50 mg catechin.

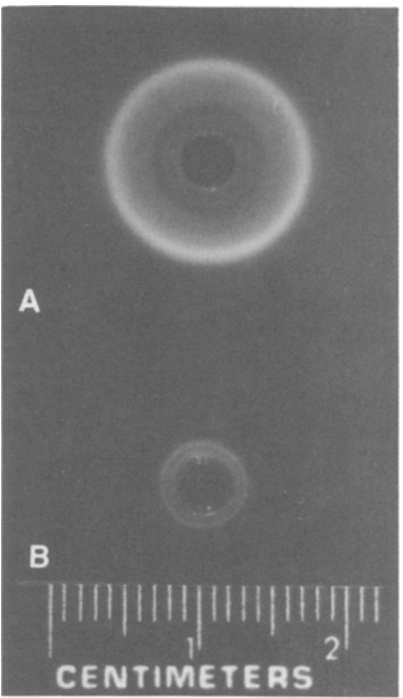

FIG. 2. Plant extracts in radial diffusion assay. Maple leaves (*Acer* sp.) or birch twigs (*Betula* sp.) were extracted with 50% methanol (300 mg tissue/1.5 ml solvent). Two 8-μl aliquots of the maple extract were placed in well A. Three 8-μl aliquots of the birch extract were placed in well B.

long incubation (Figure 3). The rings started to form immediately after the sample was placed in the well, but quantitative analysis was possible only after equilibrium was reached. The amount of time required for the rings to reach equilibrium increased with increasing tannin concentration (Figure 3). An incubation time of 96 hr after sample application was adequate for all samples tested here.

The area of the ring was linearly related to the amount of tannin placed in the well (Figure 4). To simplify calculations, the diameter squared was used instead of the area. The calibration lines had nonzero y intercepts because the wells into which the samples were dispensed had finite areas (0.16 cm^2). The detection limit of the assay was 0.025 mg tannin, and the precision was $\pm 6\%$ (relative standard deviation). The detection limit of the assay depended on the concentration of protein in the plates. The amount of protein used here was chosen to optimize the limit of detection.

A lower response was obtained with condensed tannin than with hydrolyz-

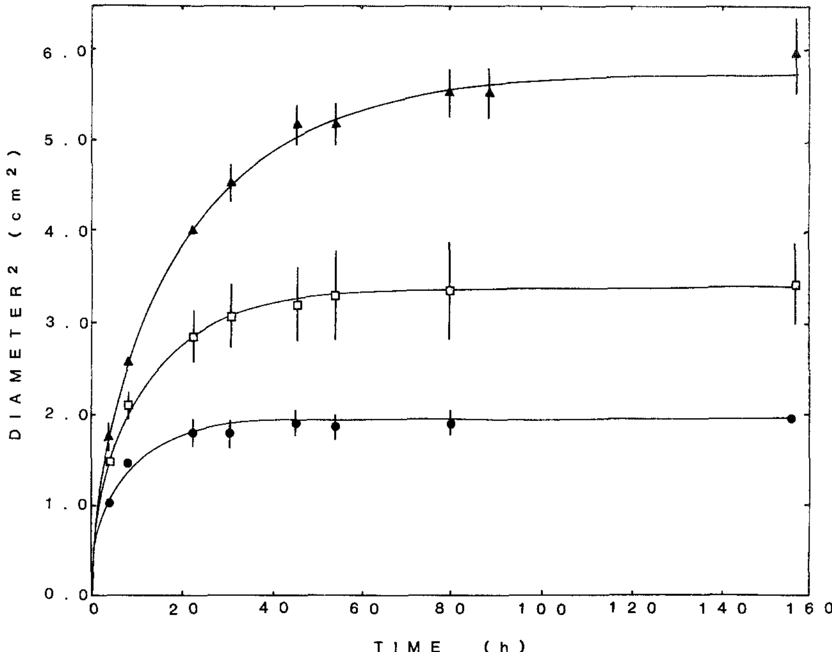

FIG. 3. Kinetics of ring formation. An 8-μl aliquot containing 1.0 mg tannic acid (▲), 0.50 mg tannic acid (□), or 0.25 mg tannic acid (●) was placed in a well and the diameters of the rings were measured at various times. Each point represents the mean ±SD for at least three replicates.

able tannin (Figure 4). Because the two types of tannin are not chemically identical, it is typical to obtain different sensitivities with the same test. For example, the response to condensed tannin in the protein precipitable phenolics assay is only half as large as the response to hydrolyzable tannin because the yield of colored complex differs for the two types of tannin (Hagerman and Butler, 1978). The amount of protein precipitated by the two types of tannin is different (Hagerman and Klucher, 1986). Therefore, it was not surprising that the two types of tannin responded differently in the diffusion assay.

The response of the two types of tannin to the assay was additive, even though the responses were not equivalent. The size of a ring formed by a mixture of tannins was equal to the sum of the sizes of rings formed by the individual samples (Figure 5). Analysis of an extract containing both types of tannin accurately reflected the total tannin content since the response was additive even when one component was present in excess. The method cannot be used to determine the relative amounts of the two types of tannin. Functional group assays are available for chemical characterization of mixtures of tannins.

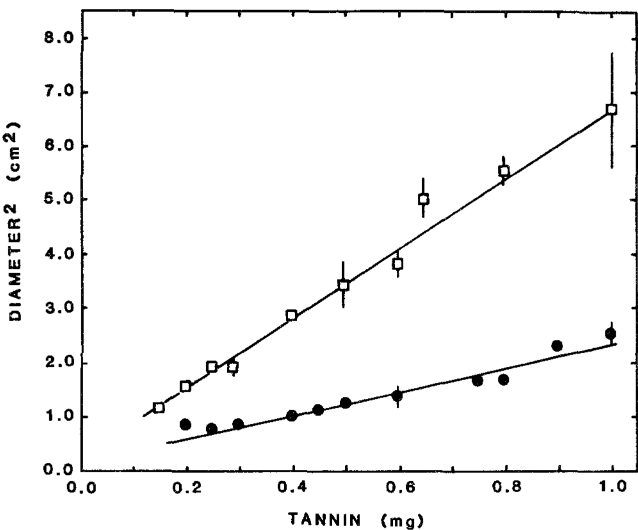

FIG. 4. Calibration curve for condensed and hydrolyzable tannin. An 8-μl aliquot of 70% acetone containing the purified tannin was placed in the well. The diameters of the rings were measured after equilibrium was reached, and the diameter squared was calculated. Each point represents the mean of at least three replicates $\pm$SD. The data was fit to a line using the method of least squares. The diameter^2 is in cm^2; the amount of tannin is in mg. For tannic acid (□): diameter^2 = 6.5 (amount of tannin) + 0.24 (r^2 = 0.94); for sorghum tannin (●): diameter^2 = 2.21 (amount of tannin) + 0.17 (r^2 = 0.92)

Nontannin phenolics such as flavonoids, benzoic acids, or hydroxycinnamic acids did not interfere with the assay. The addition of catechin or gallic acid to purified tannic acid or sorghum tannin had no effect on the ring size (Table 1). Similar data were obtained for hydroxycinnamic acids. If an aliquot of a saturated solution of catechin or gallic acid was applied to the well, a small ring formed rapidly. However, these rings disappeared within an hour and did not contribute to the final size of the ring. Plant extracts which do not contain tannin but do contain nontannin phenolics, such as extracts of leaves of the spider plant, did not form rings. Addition of such tannin-free leaf extracts to solutions of purified or condensed tannin did not affect the ring formation, indicating that nontannin components extracted from the leaf did not interfere with the tannin assay.

The solvent did not affect ring size. Common solvents used to prepare extracts include 50% methanol (methanol–water, 1 : 1 v/v), 70% acetone (acetone–water, 7 : 3 v/v), and 1% HCl in methanol (HCl–methanol, 1 : 99 v/v). None of these solvents affected the response to tannic acid obtained with the assay (Table 2). Similar data were obtained for condensed tannin in the same

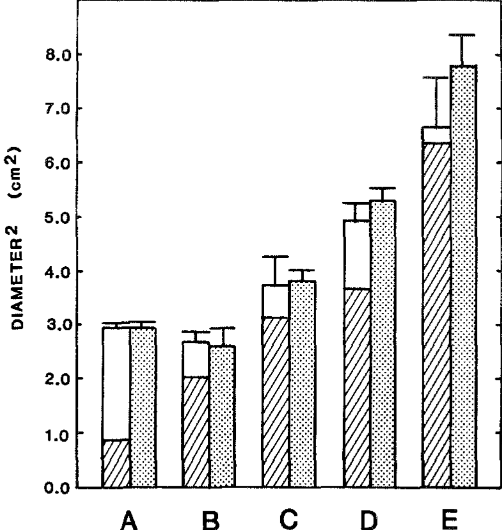

FIG. 5. Analysis of mixtures of condensed and hydrolyzable tannin. An 8-μl aliquot of 70% acetone containing either tannic acid (▨), sorghum tannin (□), or a mixture of the two (⬚) was placed in the well. The diameters of the rings were measured after equilibrium was reached. For each pair of bars, the bar to the left represents the sum of the diameters squared for the two individual solutions, and the bar on the right represents the diameter squared for the mixture. Each value is based on three replicate determinations, and error bars represent 1 SD. (A) 0.091 mg tannic acid, 0.91 mg sorghum tannin; (B) 0.33 mg tannic acid, 0.33 mg sorghum tannin; (C) 0.50 mg tannic acid, 0.25 mg sorghum tannin; (D) 0.50 mg tannic acid, 0.50 mg sorghum tannin; and (E) 0.91 mg tannic acid, 0.091 mg sorghum tannin.

solvents. The addition of antioxidants such as ascorbic acid did not interfere with the assay.

The results obtained with the radial diffusion assay were highly correlated (r^2 = 0.95) with the results obtained with precipitation assays (Figure 6). The radial diffusion assay, the protein precipitable phenolics assay, and the labeled BSA protein precipitation assay were used to analyze extracts of a variety of plants and two *Vaccinium*-containing diets (C. T. Robbins, personal communication). All the assays gave qualitatively similar results. One group of samples was classified as low tannin based on all of the assays (*Ceanothus*, *Sorghum*, 50% *Vaccinium*); another group was classified as intermediate tannin (oak, 75% *Vaccinium*, green tea, dogwood); and a third group was classified as high tannin (fireweed flowers). Quantitatively, the assays gave different values since, with each assay, a different chemical characteristic of tannin is measured. There was a twofold difference between the tannin content determined with the radial diffusion method and the content determined with the protein

TABLE 1. EFFECT OF NONTANNIN PHENOLICS ON SIZE OF RING IN RADIAL DIFFUSION ASSAY[a]

Tannin	Phenolic	Diameter^2 (cm^2)[b]
Tannic acid		
0.30 mg	none	1.98 + 0.04
0.30 mg	catechin	2.10 + 0.10
0.30 mg	gallic acid	2.10 + 0.15
Tannic acid		
0.60 mg	none	4.88 + 0.06
0.60 mg	catechin	4.66 + 0.22
0.60 mg	gallic acid	5.18 + 0.41
Sorghum tannin		
0.30 mg	none	0.83 + 0.03
0.30 mg	catechin	0.87 + 0.05
0.30 mg	gallic acid	0.83 + 0.03
Sorghum tannin		
0.06 mg	none	1.25 + 0.07
0.60 mg	catechin	1.27 + 0.10
0.60 mg	gallic acid	1.28 + 0.10

[a]The indicated amount of tannin or tannin plus 0.50 mg catechin or gallic acid was dissolved in 70% acetone. An 8-μl aliquot was placed in each well and the diameter was measured after equilibrium was reached.
[b]The values shown are the means of three replicates ± 1 SD.

precipitable phenolics method (Figure 6), although tannic acid was used as the standard for both assays. The radial diffusion assay depends only upon the ability of the tannin to interact with protein to form a visible precipitate. The protein precipitable phenolics assay depends both on interaction with protein to form a precipitate and on reaction with ferric chloride to form a colored complex. Be-

TABLE 2. EFFECT OF SOLVENT ON SIZE OF RING IN RADIAL DIFFUSION ASSAY

Solvent[a]	Diameter^2 (cm^2)[b]
50% acetone	3.49 + 0.21
50% methanol	3.74 + 0.23
Buffer A	3.13 + 0.51
1% HCl in methanol	3.49 + 0.21

[a]The indicated solvent, 8 μl, containing 0.50 mg purified tannic acid was placed in the well. The diameter of the ring was measured after the system was at equilibrium.
[b]Values are the mean of three replicates ± 1 SD.

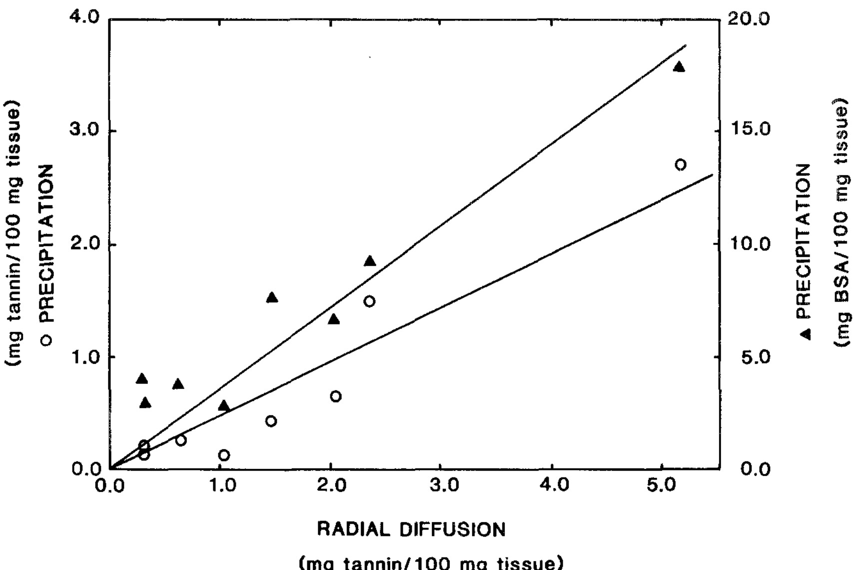

FIG. 6. Comparison of the radial diffusion assay to precipitation assays. A variety of plant tissues were extracted with 50% methanol (300 mg tissue/1.5 ml solvent). The extracts were analyzed by the radial diffusion assay, the protein precipitable phenolics assay, and the labeled protein precipitation assay as described in the text. The data was fit to a line using the method of least squares. For protein precipitable phenolics (○): $y = 0.49x$, $r^2 = 0.95$; for labeled protein precipitation (▲): $y = 4.56x$, $r^2 = 0.95$. The samples analyzed and their tannin content by the radial diffusion method are: *Ceanothus* leaves (0.308 mg tannin/100 mg tissue); *Sorghum vulgare* grain (0.313 mg tannin/100 mg tissue); 50% *Vaccinium* diet (0.642 mg tannin/100 mg tissue); oak leaves (*Quercus* sp.) (1.03 mg tannin/100 mg tissue); 75% *Vaccinium* diet (1.46 mg tannin/100 mg tissue); green tea leaves (2.03 mg tannin/100 mg tissue); red-osier dogwood leaves (*Cornus stolonifera*) (2.36 mg tannin/100 mg tissue); and fireweed (*Epilobium angustifolium*) (5.15 mg tannin/100 mg tissue).

cause the two assays are based on different chemistry, it was not surprising that the assays gave different responses with the plant extracts.

DISCUSSION

The radial diffusion assay is similar to radial immunodiffusion, in which antibodies are quantitated by forming a ring of precipitation in an antigen-containing agarose gel (Becker, 1969; Vaerman, 1981). Application of principles of immunoassays to tannin analysis was undertaken since tannin–protein interactions are similar in some respects to antigen–antibody interactions. In both reactions, a water-soluble precipitating reagent interacts specifically with pro-

teins to form multivalent, precipitable complexes (Hagerman and Butler, 1981). Radial diffusion assays are particularly suitable for tannin analysis. Tannin is water soluble and readily diffuses through the agarose gel. Tannin apparently does not interact to form precipitable complexes with the carbohydrate medium of the gel, since rings of precipitation are not observed if the protein is omitted from the gel.

BSA was selected as the protein to incorporate in the gel because it is homogeneous, soluble, and inexpensive. Tannin is a selective protein-precipitating agent, binding tightly to some proteins and more weakly to others (Hagerman and Butler, 1981; Hagerman and Klucher, 1986). Precipitation assays conducted with inhomogeneous proteins are ambiguous, since the tannin interacts selectively with the proteins in the mixture. Both condensed and hydrolyzable tannin have moderate affinities for BSA (Hagerman and Butler, 1981; Martin and Martin, 1983; Hagerman and Klucher, 1986).

The assay has several advantages in common with previously described precipitation assays (Hagerman and Butler, 1978, 1980a; Martin and Martin, 1983; Asquith and Butler, 1985). For example, the assay is not subject to interference by low-molecular-weight, nontannin phenolics. In addition, the method can be used to determine either condensed or hydrolyzable tannin or mixtures of the two. However, the assay is an improvement over other precipitation assays because it accommodates a wide variety of solvents including acetone; it can be used to assay extracts containing water-insoluble components; and it is especially appropriate for analyzing large numbers of samples.

Acetone does not affect the new assay, which simplifies analysis of extracts. Acetone is one of the most effective solvents for extracting tannin from plant tissue (Fletcher et al., 1977). Most protein precipitation assays for tannin are very sensitive to solvent. For example, as little as 4% acetone in a reaction mixture containing tannin and protein inhibits precipitation by 50%. Thus, acetone must be removed from extracts by evaporation under reduced pressure before attempting precipitation assays. Because acetone does not interfere with the new assay, plant extracts can be analyzed directly, without preliminary workup.

The new assay is more reliable than other assays for some unusual tissues, such as aspen buds or sorghum, which contain water-insoluble materials that interfere with most precipitation assays (Hagerman and Butler, 1978; Asquith and Butler, 1985; Hagerman, unpublished). The water-insoluble components, which are extracted into the aqueous organic solvents with the tannin, interfere with other assays by forming spurious precipitates in the aqueous buffers used in the assays. However, in the new assay, these water-insoluble materials do not enter the gel and thus do not form precipitation rings.

The assay can easily be used to determine tannin in a large number of samples, since extracts can be analyzed directly without any preliminary cleanup steps. Even centrifugation of the tissue extracts is unnecessary, although very

fine tissue samples may block the syringe used to dispense the extract into the wells. Allowing such samples to settle briefly or centrifuging at low speed clarifies the extract enough for radial diffusion analysis.

The assay could be modified to use proteins which are ecologically more significant than BSA. Although using BSA in the assay is analytically convenient, there may be advantages to using various plant or herbivore gut proteins for determining tannin (Martin and Martin, 1983). Soluble proteins such as ribulose-1,5-bisphosphate carboxylase/oxygenase could be incorporated into the agarose gel and used in a radial diffusion assay.

The assay described here provides a convenient, sensitive method for selectively determining tannin in crude plant extracts. The assay can be performed with as little as 100 mg tissue and can be conveniently used with large numbers of samples. Application of this method in studies of herbivory should enable ecologists to establish whether tannin defends plants from insects and other herbivores.

Acknowledgments—Some of the plant samples were kindly donated by Charles Robbins (Washington State University), Walter Jakubas (University of Minnesota), Susan Lunte (The Procter and Gamble Company), and Larry Butler (Purdue University).

(Received November 8, 1985; accepted March 17, 1986)

Abstract—Existence of an aggregation pheromone in *Drosophila hydei* was demonstrated by laboratory bioassay. The pheromone was produced by mature males, but both sexes responded. The nonpolar components consisted of three esters: the methyl, ethyl, and 1-methylethyl (isopropyl) esters of 2-methyl-(*E*)-2 butenoic (tiglic) acid, and two ketones: 2-tridecanone and 2-pentadecanone. The ketones and esters alone were only minimally active in the laboratory bioassay, but 2-tridecanone was highly synergistic with each of the esters, mixtures attracting 3–60 times more flies than the single components. 2-Pentadecanone was less active, but it did cause significant increases in activity when added to synthetic mixtures. The nonpolar portion of an extract of mature males and an equivalent mixture of the synthetic components were not significantly different in bioassay. Neither the esters nor the ketones were detected in sexually immature males or in females of any age. In extracts of mature males, ethyl tiglate was usually the most abundant ester component, with a mean of 8 $\pm$ 5 (SD) ng/male. The absolute and relative levels of the other esters were more variable. The mean level of methyl ketones in the extracts was 122 $\pm$ 106 (SD) ng/male, of which 85–93% was 2-tridecanone.

Key Words—*Drosophila hydei*, Diptera, Drosophilidae, aggregation, pheromone, 2-methyl-(*E*)-2-butenoic acid, ester, 2-tridecanone, 2-pentadecanone.

INTRODUCTION

Aggregation pheromone activity has been previously demonstrated by laboratory bioassay in two species of *Drosophila* (Diptera: Drosophilidae): *D. virilis*

0098-0331/87/0300-0451$05.00/0 © 1987 Plenum Publishing Corporation

and *D. melanogaster*. In each species the pheromone was produced only by mature males, but was attractive to both sexes of any age. The chemical components of the pheromone systems were different. In *D. virilis* the active compounds were (*Z*)-10-heneicosene (Bartelt and Jackson, 1984) and a mixture of five esters: methyl, ethyl, and isopropyl tiglate [2-methyl-(*E*)-2-butenoate] and methyl and ethyl hexanoate (Bartelt et al., 1985a). The hydrocarbon and the ester components were synergistic, the combination showing 4–5 times more activity than either the hydrocarbon alone or the esters. In *D. melanogaster* a major pheromone component was (*Z*)-11-octadecenyl acetate (*cis*-vaccenyl acetate), but it had to be bioassayed in combination with food-related odors for its activity to be observed (Bartelt et al., 1985b).

Aggregation pheromone activity has now been demonstrated in *Drosophila hydei* Sturtevant as well. *D. hydei*, a cosmopolitan species, is a member of the *repleta* group (Wasserman, 1982). *D. hydei* was studied because there were no previous reports of aggregation pheromone activity in this species group, and we wish to sample a wide range of *Drosophila* species for pheromone investigations. We report here the isolation, identification, and bioassay characteristics of five pheromone components.

METHODS AND MATERIALS

Flies. The *D. hydei* culture was obtained from Mrs. M.E. Warren, Department of Genetics, University of Wales, Swansea, U.K. The flies were reared in 1-liter jars (ca. 500 per jar) on Formula 4-24 Instant Drosophila Medium (Carolina Biological Supply Co., Burlington, North Carolina) under existing laboratory temperature and light conditions.

Age of maturity. Based on previous results with *D. virilis* and *D. melanogaster*, only mature males of *D. hydei* were expected to produce pheromone. The age of sexual maturity was determined for *D. hydei* so that the extracts for initial bioassay experiments could be made from flies known to be mature. Also, only flies known to be immature would be used for bioassay tests because these would probably not contain the pheromones being evaluated by the experiments, and the potential for competition would be minimized.

To determine the age of maturity for males, groups of 5 virgin males (0–1 days old) were placed with five mature virgin females (10–16 days old) until the males reached specific ages ranging from 3 to 10 days old, after which the males were removed from the vials. The eventual appearance of larvae in the vials was evidence for the sexual maturity of the males. For females, groups of five virgin females (0–4 hr old) were placed with five mature males (10–16 days old) until the females reached specific ages ranging from 1 to 5 days old. The males were then removed from the vials and the vials observed for the appearance of larvae, indicative of the sexual maturity of the females. Each treatment was replicated four times.

Bioassay. The wind-tunnel olfactometer, paired-test bioassay method, and statistical analysis were described in detail previously (Bartelt and Jackson, 1984). Briefly, the olfactometer contained ca. 1000 flies. Pairs of treated vials were placed into the olfactometer. After each 3-min test, flies which had entered the vials were collected and later counted.

Extraction, Purification, and Identification of Pheromone Components. Flies to be extracted were separated according to sex at 0–5 days of age while immobilized by cold or Fly-Nap (Carolina Biological) and raised in 70-ml vials with ca. 75 flies per vial. At 10–16 days of age, the flies were extracted by soaking in hexane at room temperature for 24 hr. For use as a bioassay standard, 400 fly equivalents of a crude extract of mature males were added to a 9 × 1-cm ID open column of silicic acid (Bio-Sil A, Bio-Rad Laboratories, Richmond, California), and the column was eluted with two void volumes (15 ml) of 10% ether–hexane, to obtain all the less polar constituents in one fraction. Alternatively, for qualitative analysis of pheromone components, ca. 1000 fly equivalents of crude extracts were applied to the silicic acid columns, and the columns were eluted with 15 ml each of a series of solvents of increasing polarity: hexane and 2.5%, 5.0%, 7.5%, and 25% ether–hexane.

The silicic acid fractions which did possess aggregation activity in initial bioassays were further separated by HPLC using a size exclusion column (PLgel 10 μm, 50 Å, 30 cm × 7.7 mm ID, Polymer Laboratories, Shropshire, U.K.). The HPLC fractions which were active in the bioassay were examined by gas–liquid chromatography (GLC) on a Durabond DB-225 or DB-1 capillary column (both columns were 30 m × 0.25 mm ID, from J and W Scientific, Rancho Cordova, California). Details of chromatography were as reported previously (Bartelt et al., 1985a).

Electron impact mass spectra were obtained on a VG MM16 or VG 7070 mass spectrometer, using the DB-225 capillary GLC column for introduction of samples. The ionization energy was 70 eV.

Synthetic Tiglic Esters and Methyl Ketones. After tentative identification of pheromone components by mass spectrometry, synthetic compounds were obtained for comparison of mass spectra and chromatographic retentions and for bioassay tests. Synthetic methyl tiglate, ethyl tiglate, isopropyl tiglate, and propyl tiglate (>98% pure) were on hand from previous work (Bartelt et al., 1985a). Synthetic 2-tridecanone, 2-tetradecanone, and 2-pentadecanone were prepared by converting dodecanal, tridecanal, and tetradecanal to 2-tridecanol, 2-tetradecanol, and 2-pentadecanol, respectively, with methylmagnesium bromide, then oxidizing these alcohols with chromic acid to the corresponding methyl ketones. After silicic acid chromatography and preparative GLC, the methyl ketones were >98% pure. For bioassay, the ketones were diluted with hexane to 5 ng/μl and the esters, to 1 ng/μl. Alternatively, a mixture of ketones and esters was prepared to contain the same concentrations as one extract from mature males (details with Results).

Quantification of Tiglic Esters and Ketones. Six extracts of 1000–1500 mature (10- to 16-day-old) males were analyzed for tiglate content to determine the extent of variability among groups. In another experiment, the levels of both tiglic esters and methyl ketones were measured as a function of age of males. Here, flies were separated by sex within 24 hr of emergence and raised to various ages between 1 and 22 days (ca. 100 flies per sample, exact counts made after extraction). Finally, aliquots of the male-derived nonpolar bioassay standard (eluted from the silica column with 10% ether–hexane) were analyzed for the tiglates and methyl ketones so that an equivalent synthetic mixture could be prepared for bioassay against the fly-derived materials.

The tiglates were quantified for these extracts as described previously (Bartelt et al., 1985a) except that ethyl hexanoate was used as the internal standard. Ketones were quantified on the DB-1 capillary column with dodecanal as the internal standard. Two or three replicates were analyzed for each extract or age treatment.

RESULTS

Age at Maturity. Based on the appearance of progeny in the vials, males reached sexual maturity at 7–9 days of age and females at 2–3 days of age. Utilizing a different method for determining sexual maturity, Markow (1985) reported similar results. Thus aging the flies to 10–16 days ensured that they were mature when extracted, and bioassaying the flies at 0–5 days of age ensured that the males, at least, were immature.

Bioassay Characteristics. When the flies were first put into the olfactometer, they tended to form tight aggregations in the upper corners and flew little. After starvation for 14–16 hr, the flies became dispersed throughout the cage, with a large number on the olfactometer floor, and flight became more frequent. In response to an active preparation, the number of airborn flies increased markedly, and anemotactic behavior was observed. The flies flew slowly upwind, often exhibiting a zigzag motion, until alighting on the pheromone-treated vial. The flies then crawled about on the vial, eventually entering and drinking from the water drop at the bottom. Once inside a vial, flies usually remained for the duration of the test. The flies exhibited the same response behaviors toward both insect-derived and synthetic materials.

The absolute bioassay catches for a given treatment did vary from day to day, due primarily to differences in temperature and in the number and condition of the flies in the olfactometer. Nevertheless, as is apparent in the tables, the ratios of the means between any two treatments were reasonably consistent from day to day.

Isolation of Pheromone Components. As seen previously in the other species, the crude extracts of mature male *D. hydei* were clearly attractive in bioas-

say. For example, the mean catches for the mature male extract, mature virgin female extract, and controls were 20.2, 2.2, and 0.5, respectively ($N = 12$, 1 fly equivalent of extract/test). The male extract was significantly more attractive than the other treatments at the 0.001 level. Although the female extract was also significantly above the control level ($P < 0.05$), it was the more dramatic effect of the male extract which we investigated further. In this bioassay experiment (as well as all other bioassays reported here) both sexes responded in approximately equal numbers.

The crude extract of males contained both polar and nonpolar attractants. After passing a male extract through a silicic acid column with 10% ether–hexane, bioassay catches for this nonpolar fraction, the parent crude extract, and the controls were 17.3, 34.8, and 0.6, respectively ($N = 28$, 1 male equivalent per test, all means significantly different at the 0.01 level). The nonpolar fraction contained compounds with the polarities of hydrocarbons, esters, aldehydes, and ketones, and it accounted for ca. 50% of the activity of the crude extract. Since nonpolar pheromone components had already been identified in *D. virilis* and *D. melanogaster*, initial emphasis was placed on the less polar attractants, for comparative purposes. Work on polar attractants is still in progress.

After fractionation of the crude extract of males by polarity, only the 5.0% ether–hexane fraction and the 7.5% ether–hexane fraction showed activity by bioassay. Based on the elution of standards, the 5.0% and 7.5% ether–hexane fractions contained materials with the polarities of alkyl esters and ketones, respectively, and are referred to below as the "ester" and "ketone" fractions. While the response to either fraction alone was weak, the combination of the two fractions was reliably and dramatically active (Table 1). Unlike *D. virilis*, the hexane (hydrocarbon) fraction showed no hint of activity.

The synergistic activity of the ester and ketone fractions was used to advantage during their subsequent purification on the size-exclusion HPLC column. None of the HPLC fractions was active alone, but by combining each with the appropriate synergistic fraction, clear bioassay results were possible. Two regions of effluent from the ester fraction, 13.0–14.5 and 15.0–16.5 ml after injection, were highly synergistic with the ketone fraction, as the entire original ester fraction had been (Table 2). Similarly, one HPLC region of the ketone fraction, 12.0–13.5 ml after injection, was highly synergistic with the ester fraction in the bioassay (Table 2).

Ester Components. GLC peaks were observed in the active HPLC fractions which were absent from the inactive fractions. In fact, the active 13.5- to 14.0- and 15.5- to 16.0-ml fractions each contained only one detectable peak. Serendipitously, the mass spectra of these peaks corresponded to isopropyl tiglate and ethyl tiglate, respectively, which had been isolated previously from *D. virilis* (Bartelt et al., 1985b). Since *D. virilis* usually contained methyl tiglate and two hexanoic esters as well (methyl and ethyl), later extracts were also exam-

ined for these esters. Methyl tiglate was detected in most extracts of mature male *D. hydei*, but the hexanoates were never found. The GLC retentions (DB-1 and DB-225) and mass spectra of the fly-derived esters and corresponding authentic tiglate standards were identical.

In six mature male extracts (Table 3), ethyl tiglate was always present and was usually the most abundant tiglate. The methyl and isopropyl esters varied greatly, both in absolute amount and relative to the other esters; in some cases one or the other of these was not detectable at all. Propyl tiglate was sometimes present in trace amounts. Replicated analyses indicated that the observed variability among groups of flies was a biological fact rather than an artifact of analytical technique. The biological significance of the variability in ester levels remains unknown, but tiglate production may be influenced by environmental factors such as food quality. For the purpose of evaluating the activity of synthetic compounds, 10 ng was believed a reasonable level for bioassay tests.

With respect to age, tiglates were absent from young males and first began to appear at 7–9 days old, as sexual maturity was attained. The mean level of ethyl tiglate measured in the sexually mature male flies (between 10 and 22 days old) was 8.6 ± 6.8 (SD), in the same range as the earlier results. Again, isopropyl and methyl tiglates were present at lower levels, and the ratios of esters were variable. Once the males reached maturity, neither the amounts nor ratios of esters appeared correlated with age. Tiglates were never detected in females of any age.

Ketone Components. The active HPLC fractions of the ketone material contained three GLC peaks which were absent from the inactive fractions. The mass spectra of these peaks indicated molecular weights of 198, 212, and 226. In all three spectra, the base peak was at m/e 58, and an intense peak at m/e 43 was also present. The data suggested a homologous series of saturated methyl ketones, with 13, 14, and 15 carbons. Comparison with published spectra (Heller and Milne, 1978) supported these structures. Synthetic 2-tridecanone, 2-tetradecanone, and 2-pentadecanone produced mass spectra and GLC retentions (DB-1 and DB-225) which were identical to the respective fly-derived compounds. (If branches had been present in the carbon chains, earlier GLC elution

[b] T = trace (between 0.0 and 0.5 ng/male).

would have been expected, in addition to evidence of branching in the mass spectra).

As with the tiglic esters, these methyl ketones were never detected in females of any age, nor in newly emerged males. The ketones began to appear in males at 6–8 days of age and were always detected in mature males. Extracts of mature males contained 123 ± 106 (SD) ng/male (range: 36–308 ng/male). Although the total amounts of ketones varied considerably, the proportions were fairly constant. 2-Tridecanone was always most abundant, representing 85–93% of the total, while 2-tetradecanone and 2-pentadecanone accounted for 0–2% and 7–15% of the total, respectively.

For initial bioassays, each ketone was used at 50 ng/test. For 2-tridecanone, this was within the range found in mature males. Although the other ketones were less abundant in the flies, these were also tested at the 50-ng level so that relative activities of the ketones could be assessed.

Bioassay of Synthetic Compounds. The bioassay activity of the synthetic esters supported their identification as pheromone components. While the esters alone were only marginally active, all showed dramatic increases in activity when combined with the major ketone, 2-tridecanone (Table 4A). These results paralleled the synergistic effect of the original ester and ketone fractions. Since the experiments in Table 4A were done on different days (hence the means for different esters are not comparable), a further test was conducted to determine the relative activities of the esters on an equal weight basis (Table 4B). Ethyl tiglate and isopropyl tiglate were most active, and methyl tiglate, the least. Propyl tiglate was intermediate in activity, although all four esters clearly synergized the ketone. Since ethyl tiglate was present in all extracts and was usually the most abundant, it is probably the "key" ester under natural conditions. Conversely, propyl tiglate is probably of little importance in nature due to its

[b] Within each column, means followed by the same letter were not significantly different at the 0.05 level. Comparisons of means between columns are not meaningful because the experiments were done on different days, with different groups of flies.

very low level. The importance of methyl and isopropyl tiglates is less clear, but it is evident that even one ester is sufficient to demonstrate activity. The esters may be somewhat "interchangeable."

The previous results (Table 4) already demonstrated that 2-tridecanone had synergistic activity. A more comprehensive investigation with the methyl ketones is summarized in Table 5. None of the ketones was significantly above control levels alone (Table 5A), although in each case the mean catch for the ketone was numerically higher than the control. Only 2-tridecanone caused a clear (ca. eightfold) increase in the response to isopropyl tiglate. For 2-tetradecanone and 2-pentadecanone the increase was less than twofold, and only for the former was the increase significant. Thus the flies appeared far less sensitive to the 14- and 15-carbon ketones than to the 13-carbon homolog.

As with the tiglate experiments, the columns in Table 5A cannot be compared because the experiments were done on different days, but the relative activities of the ketones were determined directly (Table 5B). 2-Tridecanone

was clearly the most active ketone, and neither larger ketone caused a significant increase in the activity of isopropyl tiglate. Due to the minor activity of the higher homologs at 50 ng/test and the small amounts of these compounds actually present in the flies, we anticipated that 2-tetradecanone and 2-pentadecanone would have, at most, subtle effects.

To further test for the effect of 2-pentadecanone (the second most abundant ketone), a mixture of synthetic esters and ketones was prepared in the concentrations found in one extract of mature males (see footnote of Table 6 for details). This was compared in bioassay to a second mixture, which did not contain 2-pentadecanone but was otherwise identical. The means for these mixtures and controls were 32.2, 24.5, and 1.7, respectively (N = 32, mixtures used at one "male equivalent" per test). The two mixtures differed at the 0.10 level, but not at the 0.05 level. We conclude that 2-pentadecanone can cause a subtle increase in response at natural levels and should be considered a pheromone component. Comparable tests for the even less-abundant 2-tetradecanone were not made.

Natural vs. Synthetic Components in Bioassay. In a bioassay experiment

TABLE 6. BIOASSAY COMPARISON OF MALE-DERIVED, NONPOLAR BIOASSAY STANDARD AND COMPARABLE SYNTHETIC MIXTURE[a]

Treatment	Mean bioassay catch[b] (N = 24)
Male-derived material	24.3 b
Synthetic mixture	21.6 b
Control (solvent blank)	2.0 a

[a] Male-derived material contained 1.4 ng of methyl tiglate, 11.5 ng of ethyl tiglate, 94.0 ng of 2-tridecanone, and 24.0 ng of 2-pentadecanone per fly equivalent. The concentrations of these components in the synthetic mixture were equivalent. No isopropyl tiglate was detected in this male-derived sample, and less than 1 ng/fly of 2-tetradecanone was present. Neither compound was added to the synthetic mixture. The materials were bioassayed at 1 male equivalent per test.
[b] Means followed by the same letter not significantly different at the 0.05 level (LSD).

(Table 6), the nonpolar portion of a mature male extract, containing all constituents with the polarities of hydrocarbons, esters, and ketones, was not significantly different ($P > 0.4$) from an equivalent synthetic mixture composed of a mixture of tiglic esters and methyl ketones (see footnote of Table 6). Both treatments were far above control levels in activity. Thus we had no evidence that additional, relatively nonpolar components remained to be discovered; the tiglic esters and ketones together accounted for the observed activity. When 2-pentadecanone was omitted from the synthetic mixture, the means for the natural nonpolar material, synthetic mixture, and controls were 44.6, 31.5, and 0.7, respectively ($N = 36$). Now the natural and synthetic materials differed at the 0.05 level, again indicating that 2-pentadecanone had a measurable effect at natural levels.

DISCUSSION

D. hydei, in possessing an aggregation pheromone produced only by sexually mature males but to which both sexes respond, follows the same pattern observed previously for *D. virilis* and *D. melanogaster*. Aggregation pheromones have now been studied in members of three distinct species groups, and we suspect they exist rather generally in the *Drosophila*.

As in *D. virilis*, the pheromone of *D. hydei* includes a number of components. One class of chemicals, the methyl ketones, has not been reported from *Drosophila* before, although these compounds have been detected in many insect species (for examples see Blum et al., 1983; Francke et al., 1983). The other class of compounds, the tiglic esters, has been detected previously in *D. virilis*. In both species, the tiglic esters exhibit pheromonal activity best when combined with another compound, 2-tridecanone in *D. hydei* but (*Z*)-10-heneicosene in *D. virilis*.

This investigation demonstrated the versatility and sensitivity of the bioassay method. Although no single compound caused clear behavioral responses, it was still possible to screen chromatographic fractions and isolate the active chemicals by bioassaying preparations in combination with appropriate synergistic fractions. Because the test duration was short (3 min), responses toward minute amounts of volatile compounds (e.g., tiglic esters) could be measured before the chemicals dissipated, and a large number of replications of an experiment could be run in a relatively short period of time.

Qualitatively, *D. hydei* responded more consistently and energetically in bioassay than either *D. virilis* or *D. melanogaster*. Instances of 200–300 flies responding to a pheromone source within 1 min did occur. Because these flies responded so strongly in the laboratory bioassay, *D. hydei* might be a good model species for studies on *Drosophila* pheromones in the field.

Acknowledgments—Karin Spindler and Jeane McDonald provided technical assistance. Joe Sears kindly assisted in obtaining the mass spectra. The research was supported by NSF grants PCM-8208393 and DCB-8509976. This is paper No. J-1759 in the Montana Agricultural Experiment Station Journal Series.

(Received December 23, 1985; accepted March 20, 1986)

Abstract—Allelopathic volatiles associated with the weed Palmer amaranth (*Amaranthus palmeri* S. Wats.; AMAPA) were trapped on Tenax GC, thermally desorbed, and identified by gas chromatography-mass spectroscopy. Methyl ketones and alcohols (C_4–C_{11}) were the principal components of the volatiles mixture. Seedheads, stems, or roots were placed in a glass container and incubated at 31°C (10 hr)/21°C (14 hr) for three days prior to trapping the volatiles. Seedheads were rich in 2-heptanone which was consistently found, together with 2-heptanol, in all AMAPA tissues. Vapors of authentic 2-heptanone and (±)-2-heptanol at concentrations of 1 ppm or higher strongly inhibited the germination of onion and carrot and almost completely suppressed the germination of tomato and AMAPA seeds.

Key Words—*Amaranthus palmeri*, Palmer amaranth, allelopathy, seed germination, weed residue, volatiles, ketones, alcohols, 2-heptanone, 2-heptanol.

INTRODUCTION

Amaranthus palmeri S. Wats. (Palmer amaranth, AMAPA) is a hardy, fast-growing weed that commonly infests fields in the southwestern United States. Plants can grow to 9 ft or more and produce a large aerial biomass in the field.

Menges (1985) reported that, in the field, soil-incorporated residues of Palmer amaranth produced allelopathic inhibition in carrot and onion and were

autotoxic. Laboratory seed germination studies of aqueous and organic solvent extracts of harvested AMAPA, as well as isolated and identified compounds from this weed (Bradow, 1985; Bradow and Connick, 1985; Fischer and Quijano, 1985), indicated the presence of both inhibitory and promotive allelochemicals. However, none of these exhibited a sufficiently strong or diverse negative activity to explain the field observations. Subsequently, Bradow and Connick (1985) demonstrated that volatile allelochemicals associated with Palmer amaranth residues were highly inhibitory of the germination of onion, carrot, tomato, and Palmer amaranth itself. It was clear from the magnitude of the inhibitory effects that these volatiles could be a major source of the allelopathic interactions associated with Palmer amaranth.

Our objectives in this study were to identify the major components of the volatiles mixture emitted by harvested Palmer amaranth and to test some of the authentic compounds to see if they inhibited germination of onion, carrot, tomato, and Palmer amaranth seeds.

METHODS AND MATERIALS

Plant Materials. AMAPA was grown at Weslaco, Texas, and harvested on August 16, 1984. Green (young) and mature plants were separated, divided further into seedheads, stems, and roots, and kept frozen until use. Thawed samples were cut into 1 to 2-cm pieces and air dried in the laboratory at 21 ± 2°C for one day, 15 days, or longer for some samples.

Sample Container. Samples were placed in a 1.2-liter glass bottle (Kontes No. K-323255) fitted with Teflon valves, an inlet tube that reached almost to the bottom, and a Teflon joint sleeve. Sample vapors contacted only glass and Teflon.

Tenax GC Trap Tubes. A 0.10-g quantity of Tenax GC (60–80 mesh) was added to glass tubes measuring 84 mm long × 9 mm OD × 1 mm wall thickness (TekLab, Baton Rouge, Louisiana) and held in place near the center with a glass wool plug on each side. Packed tubes were conditioned at 220°C for 24 hr while purging with helium at 15 ml/min. A mark was made near one end of each tube to designate the inlet end for sample volatiles. The tubes were reversed for subsequent thermal desorption so that volatiles would be backflushed from the Tenax GC into the gas chromatograph–mass spectrometer (GC-MS) system.

Volatiles Sampling Procedure. A sample of AMAPA weighing 80 g (if air dried for 1 day) or 20 g (if dried 15 days) was placed in the sample container. Ten milliliters of ultrapurified water (Water-1 apparatus, Barnstead) were added to the plant sample. The container was sealed, wrapped in aluminum foil to exclude light, and placed in an environmental chamber programmed for 10 hr at 31°C and 14 hr at 21°C. After three days, the container was removed and equilibrated at room temperature. A small amount of fungal growth was often

seen on the plant samples after incubation. A Tenax trap tube (sample tube) was placed on the exit port of the sample container with a short length of Tygon tubing. A second Tenax tube was affixed to the inlet port to serve as a final filter for the nitrogen purge gas which had already been passed through a molecular sieve–charcoal cartridge. The valves were opened and the purified nitrogen was swept through the sample container at 100 ± 4 ml/min for 20 min. Not all the volatiles present in the sample container were collected by this procedure, but a sufficient aliquot was trapped for qualitative analysis. Adsorption capacity of the sample tubes was not exceeded using this procedure with a typical plant sample. The Tenax sample tube was sealed with corks pressed through Teflon tape and stored in a freezer until GC-MS analysis. Blank runs gave very small background peaks.

GC-MS Analysis. Volatiles were separated and identified using a Finnigan MAT GC-MS-DS model 4000 instrument. The GC was interfaced with an external, closed inlet system (Scientific Instrument Service, River Ridge, Louisiana) as previously described by Legendre et al. (1979). The GC column was 1/8 in. × 10 ft nickel tubing packed with 60–80 mesh Tenax GC coated with 8% poly-*m*-phenoxylene (poly MPE). With the GC column at room temperature (30°C), the sample liner was secured in the external inlet apparatus and the six-port valve was switched to the inject position. Volatiles were stripped from the sample tube by heat (200°C) and a helium flow of 20 ml/min for 20 min. The valve was then switched to the run position, the mass spectrometer and data system were turned on, and the GC oven temperature was raised to 100°C at 25°/min. Once at 100°C, the column was programmed to 230°C at 5°/min and held at this temperature for 30 min. The mass spectrometer was repetitively scanned from 33 to 450 amu every 2 sec. Data acquistion and analysis were accomplished with a Finnigan-Incos Data System. Compounds were identified by a mass spectra library search in conjunction with a comparison of retention times and mass spectra obtained from authentic compounds (Aldrich Chemical Co.).

Seed Germination Bioassays. Germination of seeds of onion, *Allium cepa* L., cv. Texas Early Grano 502 (Baxter's, Weslaco, Texas); carrot, *Daucus carota* L., cv. Danvers Half-long (Burpee, Warminster, Pennsylvania); tomato, *Lycopersicon esculentum* Mill., cv. Homestead (Carolina Biological, Burlington, North Carolina) and Palmer amaranth grown in Weslaco, Texas, were used to compare the bioactivities of 2-heptanone and 2-heptanol with deionized water controls.

The procedure followed was a slight modification of that used by Bradow and Connick (1985) for the bioassay of volatiles from AMAPA residues. A 10-ml glass beaker was placed on 50 g of pure sand in a crystallizing dish (100 × 50 mm) and the sand was moistened with 10 ml of deionized water. A sample of 2-heptanone or (±)-2-heptanol (1.2, 2.4, 6.0, or 12.3 μl) was added to the beaker. The dish and contents were then placed in the bottom of a 2.5-liter desiccator (160 mm id). The nominal vapor concentrations were 0.5, 1.0, 2.4,

and 4.9 ppm by volume, respectively. These were not exact concentrations because of partitioning and adsorption effects that probably occur within the apparatus.

Seeds of a single species were placed on a porcelain desiccator plate that was covered with two sheets of Whatman No. 1 filter paper saturated with deionized water. Circles (22 mm diameter) had been cut in the center of the paper to facilitate the diffusion of vapors. The filter paper sheets were divided into eight equal segments containing the same number of seeds (20 of carrot, onion, or tomato; 25 of AMAPA), and each segment was treated as a replicate for purposes of statistical analysis (Bradow and Connick, 1985). Controls lacked only the beaker with the volatile sample. Desiccators were sealed and incubated the same as described above for the plant samples in the volatiles sampling procedure, and a germination count was taken after three days. Results of the germination assays of 2-heptanone and 2-heptanol activity (Figures 4 and 5) were compared separately for each seed species by two-way analyses of variance with 16 replicates (Sokal and Rohlf, 1981).

RESULTS AND DISCUSSION

Identification of Allelopathic Volatiles. Volatile organic compounds emitted from harvested AMAPA (green and mature) seedhead, stem, and root pieces were trapped and concentrated using Tenax GC adsorbent. The volatiles were thermally desorbed into a GC-MS instrument and the principal components were identified. Packed-column GC incompletely separated some of the compounds (Figures 1–3), but identifications could usually be made through use of the MS data system and authentic compounds. A list of identified compounds appears in Table 1. Methyl ketones and alcohols, particularly those with an odd number of carbon atoms, were the predominant components of the volatiles associated with AMAPA seedheads, stems, and roots. Although the sampling procedure and GC-MS method are effective for aldehydes (Legendre et al., 1979), the only ones detected were acetaldehyde and hexanal in trace amounts. Because the mechanism(s) and biochemical substrates responsible for the generation of these volatiles have not yet been determined, a satisfactory understanding of the significance of some of the following observations is not possible at this time.

Seedheads were particularly rich in 2-heptanone (Figure 1). Other methyl ketones, such as 2-butanone and 2-pentanone, and the alcohols 2-heptanol and 3-methyl-1-butanol were also found. The same qualitative results were obtained with green and mature seedheads and with samples that were dried one day and 15 days. However, the concentration of the volatiles was generally lower for the 15-day-dried samples. 2-Heptanol was present in low to moderate amounts and eluted on the leading edge of the 2-heptanone peak. Seedheads proved to be the plant tissue most able to release volatiles, particularly 2-heptanone, after

extended air drying. Under the test conditions, 2-heptanone was released from seedheads that had been dried for 99 days.

With stem samples, the strongest peaks were due to 3-methyl-1-butanol, 3-hydroxy-2-butanone (not detected in seedheads), and 2-heptanone (Figure 2). Green and mature stems dried for one day gave almost identical chromatograms. Drying the samples for 15 days led to a large reduction in the concentration of all the volatiles, especially 2-heptanone.

Roots, which constitute a very small portion of the AMAPA biomass, were rich in a variety of volatile compounds after drying for one day. Roots tissue emitted most of the volatiles found in seedheads and stems plus 3-methyl-2-butanone, 2-nonanone and, occasionally, 2-undecanone (Figure 3, Table 1). As was noted for stems, the quantity of volatiles trapped from roots that were dried 15 days was very low.

Volatiles emitted by seedheads (dried for one day) were collected after

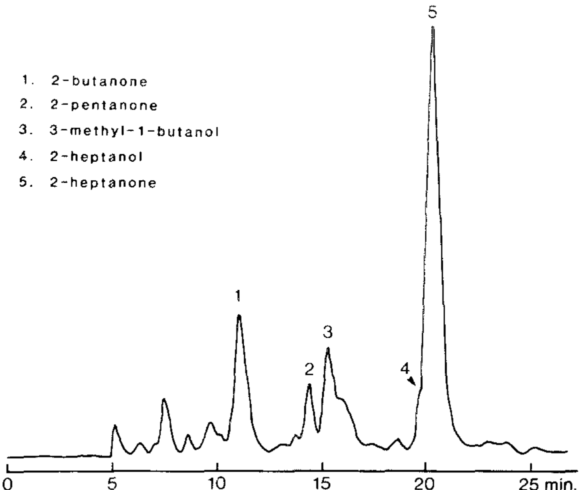

FIG. 1. Gas chromatogram of volatiles emitted by AMAPA seedheads (green, dried 1 day) after a 3-day incubation.

one, two, and three days in the environmental chamber. After just one day, the sample container headspace was already rich in volatiles, particularly 2-heptanol and 2-heptanone. The areas of all the peaks increased each succeeding day but, qualitatively, no new components appeared after the first day.

Water had a dramatic effect on increasing the emission of organic volatiles from AMAPA residues. When 0, 10, or 20 ml of water was added to a seedhead (20%)/stem (80%) mixture that had been air dried for seven days, the respective areas of the 2-heptanone peak were 0, 3.8×10^5, and 6.9×10^5 units, respectively.

Incubation of seedheads (air dried 42 and 99 days) for three days in a

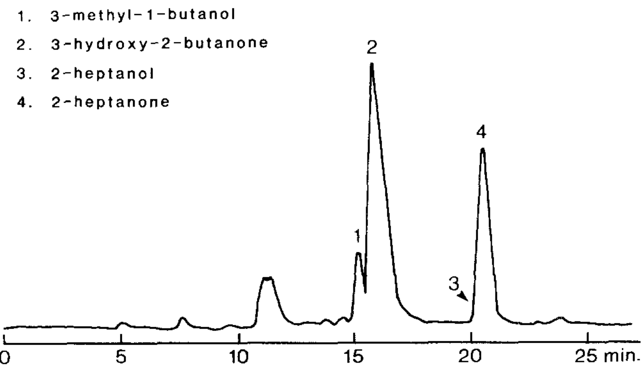

FIG. 2. Gas chromatogram of volatiles emitted by AMAPA stems (green, dried 1 day) after a 3-day incubation.

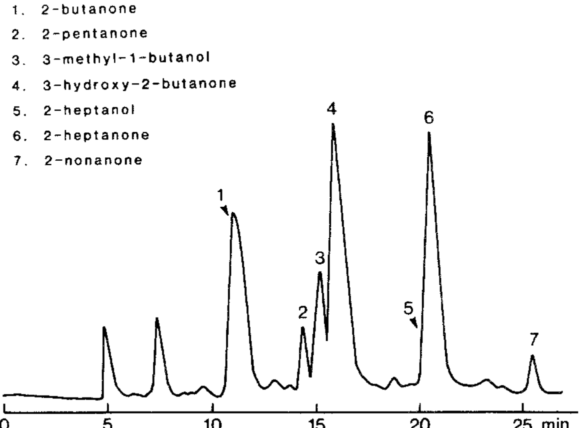

FIG. 3. Gas chromatogram of volatiles emitted by AMAPA roots (green, dried 1 day) after a 3-day incubation.

nitrogen atmosphere greatly increased the concentration of organic headspace volatiles compared with incubation in air. The 2-heptanone concentration (peak area) from the nitrogen atmosphere samples increased an average of 840% compared with the air atmosphere samples. The 2-pentanone and 3-pentanone concentrations increased more than 20 times. Although 2-pentanol increased about 990%, 2-heptanol increased only slightly. Small amounts of 2-hexanone, 2-octanone, and 2-nonanone were detected in the nitrogen headspace, but not in air.

The methyl ketones and alcohols that were identified in the volatiles mixture emitted by AMAPA residues are slightly water-soluble ($> C_4$), oily liquids with boiling points that are in the range 80–232°C. These compounds are widespread in nature and have been found in corn (Buttery and Ling, 1984; Buttery et al., 1978), wheat (Buttery et al., 1985), and in fruits such as strawberry (Schreier, 1980), loquat (Shaw and Wilson, 1982), guava (Idstein and Schreier, 1985), and passion fruit (Chen et al., 1982). Flath et al. (1984) identified numerous volatile compounds released by aqueous suspensions of fresh *Amaranthus retroflexus* plant tissue including 2-heptanol, 3-methyl-1-butanol, 2-butanone, and 3-pentanone. However, we believe that the present study is the first to report C_5–C_{11} 2-alkanones in association with a weed species.

Inhibition of Seed Germination by 2-Heptanone and 2-Heptanol. Reynolds (1977) reported that dilute aqueous solutions of 2-heptanol, 3-methyl-1-butanol, and C_4–C_9 2-alkanones inhibit lettuce fruit germination. French and Leather (1979) found that vapors of 2-heptanone, 2-octanone, and 2-nonanone inhibited the germination of several weeds including redroot pigweed (*Amaranthus retroflexus* L.). Interestingly, these compounds also stimulated germination of curly dock (*Rumex crispus* L.) and/or red sorrel (*Rumex acetosella* L.).

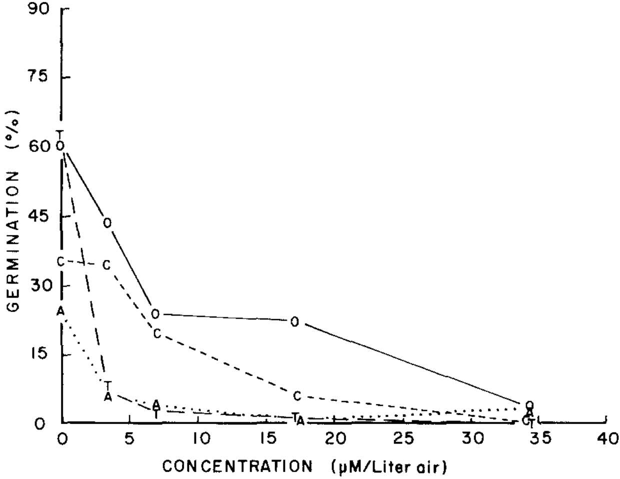

FIG. 4. Effects of 2-heptanone vapors (3-day exposure) on seed germination: (O) onion; (C) carrot; (T) tomato; (A) Palmer amaranth. Germination percentages are means of 16 replicates (standard errors of the means were ≤ 2.0%).

In the present study, 2-heptanone consistently was a principal component of the volatiles mixture and it was always accompanied by 2-heptanol. We decided to bioassay these two compounds as a representative 2-alkanone and a 2-alkanol associated with AMAPA residues.

2-Heptanone and (±)-2-heptanol were highly bioactive in the vapor state, and each was capable of severely inhibiting the germination of carrot, onion, tomato, and AMAPA seeds (Figures 4 and 5). There was a striking similarity in the results of bioassays conducted at several concentrations of the two compounds. Most affected were tomato seeds, which were greatly inhibited by each compound even at 3.4 μM/liter (0.5 ppm), the lowest concentration tested. Little or no germination occurred above 6.9 μM/liter (1 ppm). AMAPA seed in the control experiments germinated only 24.7% in three days. After incubation with 2-heptanone or 2-heptanol at concentrations above 6.9 μM/liter, the germination dropped to 6% or below.

Carrot and onion, the crops that showed the most severe allelopathic effects of AMAPA in the field, were also very sensitive to 2-heptanone and 2-heptanol vapors. Carrot seed germination was strongly inhibited at concentrations of 6.9 μM/liter and higher. The inhibitory effects on onion were evident as low as 3.4 μM/liter, especially with 2-heptanol which was a little more active than 2-heptanone. At 6.9 μM/liter, the germination of onion dropped from 61.1% (control) to 24.1% in 2-heptanone, and to 14.2% in 2-heptanol vapors. The more pronounced inhibition of onion seed by 2-heptanol persisted after the volatile source was removed and the seeds allowed to germinate for four additional

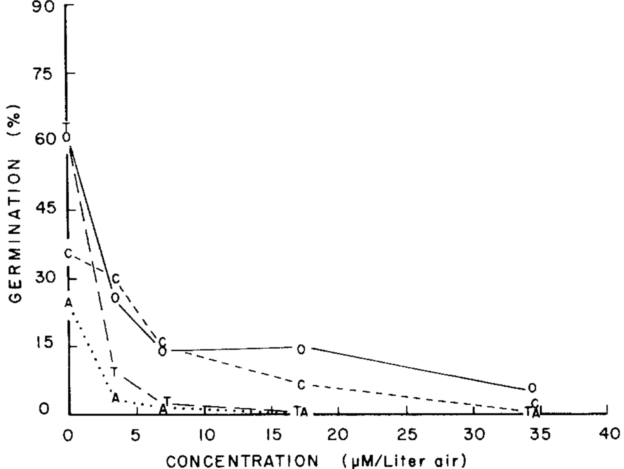

FIG. 5. Effects of 2-heptanol vapors (3-day exposure) on seed germination: (O) onion; (C) carrot; (T) tomato; (A) Palmer amaranth. Germination percentages are means of 16 replicates (standard errors of means were ≤ 2.1%).

days. At 34.4 μM/liter (5 ppm) of either compound, germination of carrot and onion was reduced to 5% or less. The two-way analyses of variance showed highly significant concentration effects in all four assay species exposed to 2-heptanone or 2-heptanol vapors. 2-Heptanol was significantly more inhibitory than 2-heptanone only in onion.

The effects of plant residue volatiles on agricultural crop seed germination have not been widely investigated but could be very important factors in effective weed and crop management. We believe that it is very significant and encouraging that the two compounds we happened to bioassay first were as inhibitory (at low concentrations) as were the volatiles from the most active plant samples (Bradow and Connick, 1985). A more thorough examination of all the volatiles identified in this study is underway. We hope this will lead to a better understanding of their potential as allelochemicals and their role in chemical ecology, as well as explain some fundamental aspects of the allelopathic activity of Palmer amaranth residues in the field.

Acknowledgments—We thank Mary P. Lovisa for her excellent technical assistance.

FLAVONOID PIGMENTS IN CHALKHILL BLUE (*Lysandra coridon* Poda) AND OTHER LYCAENID BUTTERFLIES

ANGELA WILSON

Department of Zoology, University of Oxford
South Parks Road, Oxford, OX1 3PS, U.K.

(Received January 28, 1986; accepted March 25, 1986)

Abstract—Nine flavonoids, namely, kaempferol, kaempferol 7-rhamnoside, kaempferol 3-rhamnoside, kaempferol 3-glucoside, kaempferol 3-glucoside,7-rhamnoside, quercetin 3-glucoside, quercetin 3,7-diglucoside, isorhamnetin 3-glucoside, and isorhamnetin 3,7-diglucoside, have been identified in the body and wings of the chalkhill blue butterfly *Lysandra coridon* Poda. Flavonoids have also been found in 15 of a further 17 lycaenid species examined. Analysis of the two-dimensional paper chromatographic flavonoid patterns and aglycone results has shown that the flavonoid content of *L. coridon* and the other lycaenids is dependent on the flavonoid content of the larval diet. Differences in the flavonoid patterns of *L. coridon* and its leguminous larval food plants *Hippocrepis comosa, Anthyllis vulneraria*, and *Lotus corniculatus*, indicate that the ingested flavonoids are metabolized by *L. coridon* or its gut flora before sequestration. Despite the presence of flavones, glycoflavones, and isoflavones in the larval food plant species, only flavonols are sequestered by the lycaenid species examined. The relationship between lycaenid butterflies and their larval food plants, and the possible role(s) of flavonoids in lycaenids has been discussed. Interactions between ants, plants, flavonoids, and myrmecophilous lycaenids have also been considered.

Key Words—*Lysandra coridon*, Lepidoptera, Lycaenidae, blue butterflies, flavonoids, flavonols, sequestration, two-dimensional chromatography, wing pigmentation, chemical defense, myrmecophily, insect-plant interactions, chemical ecology.

INTRODUCTION

Although the occurrence of flavonoid pigments in plants has been well documented (Harborne and Mabry, 1982), little is known of their existence in animals. Flavonoids have been recognized in insects on a number of occasions

0098-0331/87/0300-0473$05.00/0 © 1987 Plenum Publishing Corporation

(Thomson, 1926; Ford, 1941, 1944; Morris and Thomson, 1963, 1964; Fujimoto et al., 1959; Hayashiya *et al.*, 1959, Feltwell and Valadon, 1970; Wilson, 1985a,b, 1986a,b), but, in most cases identification of these pigments has either not been attempted or is subject to doubt.

Flavonoid pigments in the marbled white butterfly (*Melanargia galathea* L.) have recently been examined in some detail (Wilson, 1985a,b, 1986a). Eighteen flavonoids have been identified in *M. galathea*, and the same flavonoid pattern found in a number of other *Melanargia* species (Wilson, 1985a). In addition the dietary origin of insect flavonoids has been confirmed, and it has been shown that flavonoids are not merely sequestered from the diet but are also partly metabolized (Wilson, 1985b).

Flavonoids have been recognized in the scales on the underside of most British blue butterflies (Ford, 1945); however, only those in the common blue butterfly *Polyommatus icarus* Rott. have been examined further. From the wings of 800 *P. icarus* collected in France feeding on *Anthyllis* species, the free flavonol 3-*O*-methylkaempferol and the flavonol glycoside quercetin 3,4′-diglucoside have been tentatively identified (Feltwell and Valadon, 1970). An unidentified flavone glycoside and an unidentified isoflavone have also been reported.

In this paper, flavonoid pigments in the chalkhill blue butterfly (*Lysandra coridon* Poda) have been identified and the relationship between flavonoids in the butterfly and its leguminous larval food plants *Hippocrepis comosa* L., *Anthyllis vulneraria* L., and *Lotus corniculatus* L. examined. The flavonoids in a number of other lycaenids have also been examined, and the relationship between lycaenid butterflies and their larval food plants discussed.

METHODS AND MATERIALS

Lysandra coridon, *Lysandra bellargus* Rott., *Polyommatus icarus*, and *Cupido minimus* Fuessly were collected as wild individuals from downland at Aston Tirrold in Oxfordshire; *Syntarucus pirithous* L., *Lampides boeticus* L., and *Aricia cramera* Esch., from Grandola, Portugal; *Lycaeides idas* L., *Cyaniris semiargus* Rott., and *Plebicula thersites* Cantener from Ferrières-les-Verrières, Hérault, France; *Aricia agestis* Denis and Schiff. from the Mendips, England; and *Aricia artaxerxes* Fab., from Scotland.

Everes argiades Pallas, *Plebejus argus* L., *Glaucopsyche alexis* Poda, and *Maculinea arion* L., in the entomological collection at Reading Museum, were examined by fuming specimens with ammonia vapor; a reversible yellow coloration indicates the presence of flavonoids.

Leaf, stem, and flower material of *Hippocrepis comosa*, *Anthyllis vulneraria*, and *Lotus corniculatus* collected in May from downland at Aston Tirrold in Oxfordshire was rapidly air-dried and then stored in sealed paper bags until

required for analysis. Voucher specimens of plants have been deposited in the herbarium at Reading University.

The wings and body of each butterfly, including approximately 300 *L. coridon*, were separated, placed in small sample tubes, and the flavonoids extracted by soaking the crushed tissues in 1–2 ml of 70% ethanol at room temperature for 12 hr.

Extracts of the larval food plant species (*H. comosa*, *A. vulneraria*, and *L. corniculatus*) were made by immersing approximately 20 g of dried plant material in about 50 ml of boiling 70% ethanol, and boiling for 3 min. After cooling, the ethanolic plant material was soaked for 12 hr in a stoppered flask at room temperature.

Concentrated aliquots of the plant and insect extracts were applied to ¼ sheets of Whatman No. 1 chromatography paper, and run two dimensionally in BAW (*n*-butanol–acetic acid–water, 4 : 1 : 5, upper phase) and 15% aqueous HOAc (acetic acid) (Harborne, 1973). Dried chromatograms were examined in longwave UV light in the absence and presence of ammonia vapor and the position and color of each spot recorded.

The position of flavonoid spots on the two-dimensional chromatograms is a good indication of the nature of the flavonoids present (Harborne, 1973). Flavonoids occupying different positions on the chromatograms are different; however, flavonoids occupying the same positions are not necessarily the same, since some compounds have similar mobilities in BAW and 15% HOAc. The identification and cochromatography of flavonoids occupying similar positions on the two-dimensional chromatograms is required to confirm that they are the same compound.

Flavone aglycones, most flavone glycosides, and flavonol 3-glycosides appear as dark spots on the papers. After fuming with ammonia, most of these turn yellow or yellow green, but some flavonoids, including 6-hydroxy flavones and flavone 4′-glycosides remain dark. Flavonol aglycones and flavonol 7-glycosides are yellow and remain so when fumed with ammonia. Flavone 5-glycosides are light blue or white and turn fluorescent yellow or yellow green in the presence of ammonia.

A further aliquot of each plant and insect extract was hydrolyzed with 2 N HCl at 100°C for 30–40 min, the cooled hydrolysate extracted twice with ethyl acetate, the extracts combined, evaporated to dryness, and the residues dissolved in a few drops of 90% ethanol. Concentrated spots of each residue were applied to Whatman No. 1 chromatography paper and the aglycones identified by their R_f values in five solvents: BAW (4 : 1 : 5); PhOH (phenol–water, 4 : 1); CAW (chloroform–acetic acid–water, 30 : 15 : 2); FOR (acetic acid–conc. HCl–water, 30 : 3 : 1); and 15% HOAc; their colors in UV light; and by comparison with authentic samples (Harborne, 1967, 1973).

Hydrolysates of *P. icarus*, *L. coridon*, and *L. bellargus* were examined for isoflavones. A few drops of the ethyl acetate residues dissolved in 90%

ethanol were spotted onto fluorescent silica gel TLC plates along with authentic samples of the isoflavones genistein, formononetin, and daidzein, and the plates developed by ascent in 2% methanolic chloroform. Dried plates were examined in UV light; daidzein and formononetin appear as fluorescent blue spots, and genistein as a fluorescent blue-black spot. Spraying the plates with *p*-nitroaniline caused the isoflavones to appear as faint orange spots.

The body and wing extracts of about 300 *L. coridon* which produced similar chromatograms were combined to give one body and one wing extract. These two extracts were treated separately throughout due to the presence of substances in the body fraction that interfere with the chromatographic separation of flavonoids. Further extraction of the wing and body tissues was achieved by soaking them in approximately 500 ml of 70% ethanol at room temperature for 24 hr. After removal of this extract, the tissues were extracted a further five times with warm 70% ethanol, and the series of extracts combined. The flavonoids from 150 g of leaf material of *H. comosa* and *A. vulneraria* were extracted in a similar manner. Each plant and insect extract was then filtered, washed with petroleum ether (bp 40–60°C), and concentrated to a small volume in vacuo on a rotary evaporator.

Standard procedures were used for the separation, purification, and identification of flavonoids (Harborne, 1967, 1973; Markham, 1982). Preparative paper chromatography was used to separate and purify flavonoids. Known pigments were identified on the basis of R_f, UV spectral analysis, acid and enzymic hydrolyses to the aglycone and sugar(s), and by direct comparison with authentic samples where possible.

RESULTS

Nine flavonoids have been identified in the wings and body of *L. coridon*, with the concentration of pigments greatest in the former. The flavonoids in spots 10 and 11 on the two-dimensional chromatograms of this butterfly remain unidentified. The chromatographic and spectral properties, identities, and positions of these flavonoids on the chromatograms are given in Tables 1 and 2 and Figure 1. With the exception of quercetin 3-glucoside, which has been identified in the zebra swallowtail *Eurytides marcellus* (Cr.) (Wilson 1986b), the remaining eight flavonoids, namely, kaempferol, kaempferol 7-rhamnoside, kaempferol 3-rhamnoside, kaempferol 3-glucoside, kaempferol 3-glucoside,7-rhamnoside, isorhamnetin 3-glucoside, isorhamnetin 3,7-diglucoside, and quercetin 3,7-diglucoside have been reported from an insect for the first time. Where the flavonoids identified contain more than one sugar residue, it should be noted that although the number of residues is known, the nature of the glycosidic linkages have still to be determined. No flavones, glycoflavones, or isoflavones were detected in *L. coridon*.

[a]Abbreviations: BAW, *n*-butanol-acetic acid–water, 4:1:5, upper phase; 15% HOAc, 15% aqueous acetic acid; Col, color in UV light in the absence and presence of ammonia vapor; D, dark absorbing; Y, yellow; R, rutin marker (quercetin 3-rutinoside).

The presence or absence of each flavonoid spot on the two-dimensional chromatograms of the wings and bodies of every *L. coridon* butterfly examined was recorded. Although some spots were more difficult to detect on the body chromatograms due to the lower concentration of flavonoids, the flavonoids in spots 1–11 were present in the wings and body of all butterflies. The flavonoid pattern of *L. coridon* at this site may therefore be considered constant.

Due to the difficulty and amount of time involved in the separation and purification of the complex mixtures of closely related flavonoid glycosides present in *H. comosa*, *A. vulneraria*, and *L. corniculatus*, the flavonoids in these plants were not identified. The flavonoid content of *L. coridon* was therefore compared with that of the plant species on the basis of their aglycone results and two-dimensional chromatographic flavonoid patterns.

The flavonols quercetin and kaempferol were identified in the hydrolyzates of all three plant species; isorhamnetin and apigenin were also identified in *A. vulneraria* and *L. corniculatus*, respectively (Table 3). The position and color of flavonoid spots on the two-dimensional chromatograms suggests that *H. comosa* contains a mixture of quercetin and kaempferol 3-, 3,7-, and 3,4′-glycosides; *A. vulneraria* various quercetin, kaempferol, and isorhamnetin 3-, 7-, and 3,7-glycosides; and *L. corniculatus* a mixture of apigenin 7-, and quercetin and kaempferol 3-, 7-, and 3,7-glycosides.

Quercetin and kaempferol were identified in *L. coridon* and the three plant species; however, it is clear from the two-dimensional chromatograms that flavonol glycosylation patterns differ in the plants and insect. Flavonol 3-, 3,4′-, and 3,7-glycosides were found in the plants whereas flavonol 3-, 7-, and 3,7-glycosides were found in the insect. In addition, the number of sugar residues

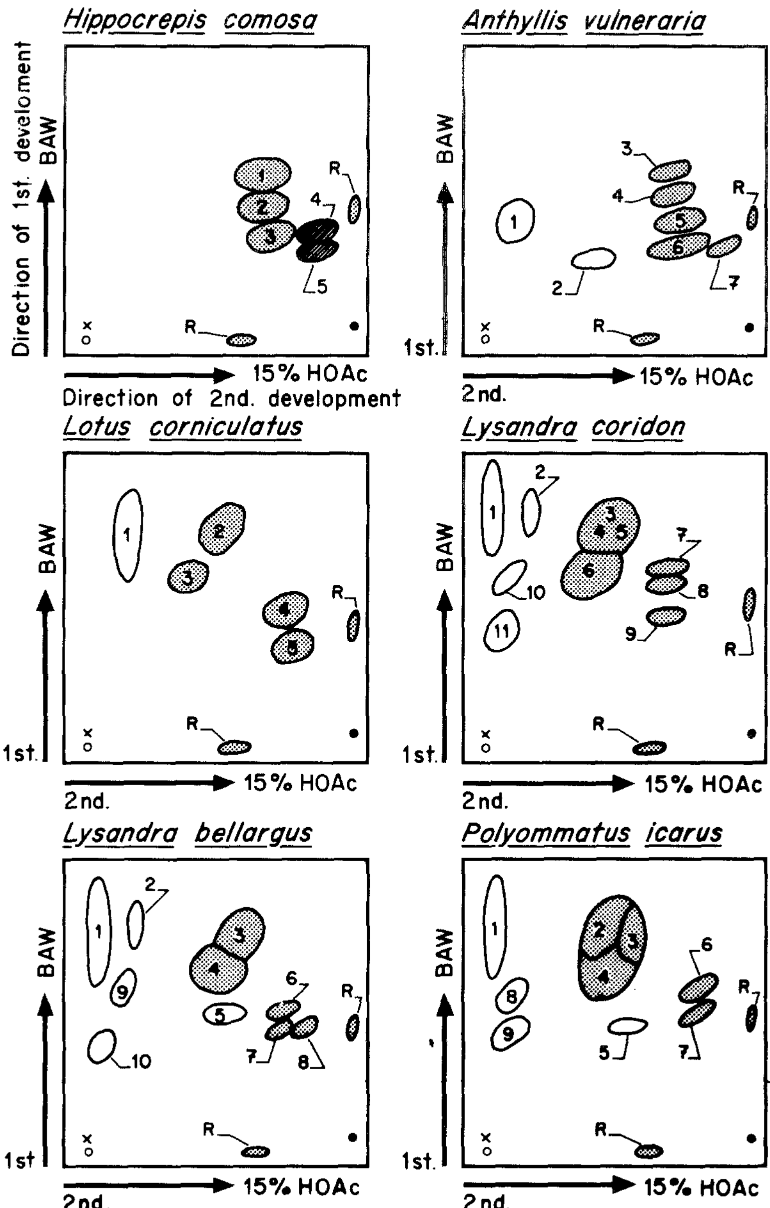

FIG. 1. Two-dimensional paper chromatograms of *H. comosa A. vulneraria*, *L. corniculatus* and the lycaenid butterflies. Chromatograms were developed first in BAW (4 : 1 : 5), then in 15% aqueous HOAc. Spot color characteristics in longwave ultraviolet light are represented as follows: yellow spots remaining so when fumed with ammonia, unstipled; dark absorbing spots changing to yellow in the presence of ammonia, stipled; dark absorbing spots remaining so when fumed with ammonia; hatched. x, represents the origin; •, the position at which the rutin marker was applied for development of the chromatogram in BAW; ○ the position at which rutin was applied for development of the chromatogram in 15% HOAc.

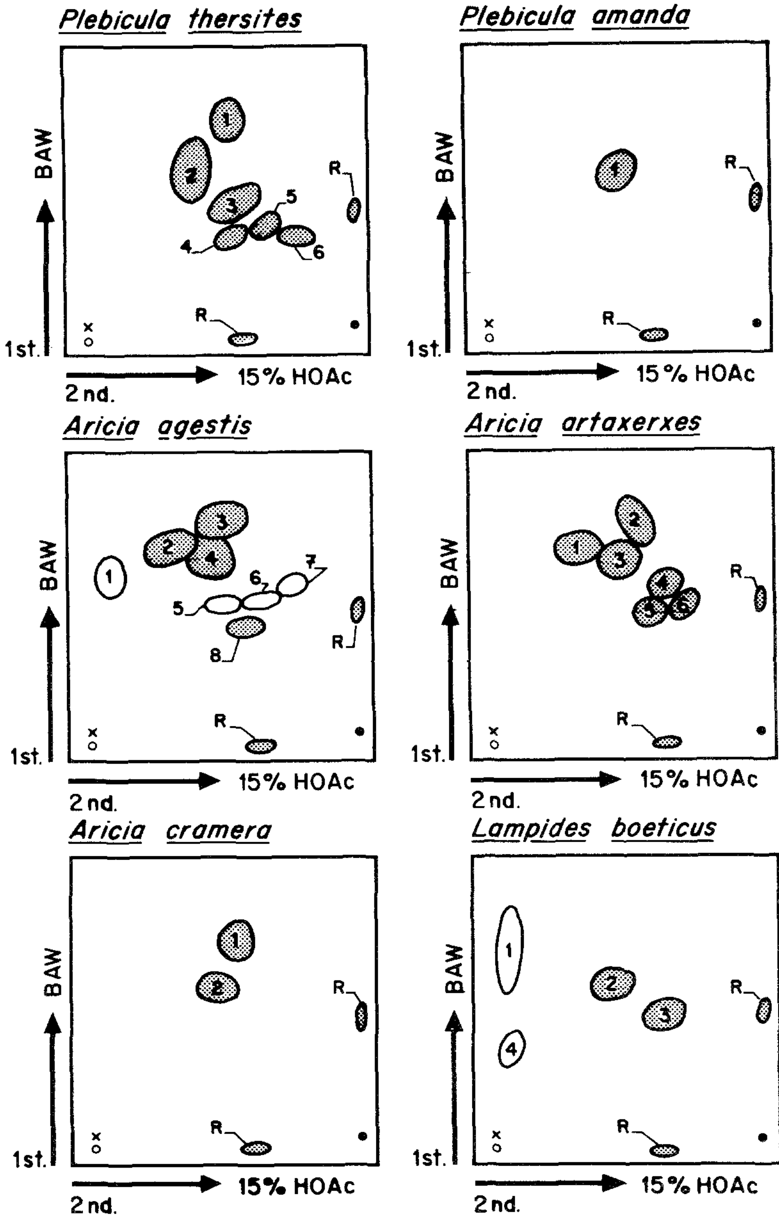

FIG. 1. Continued.

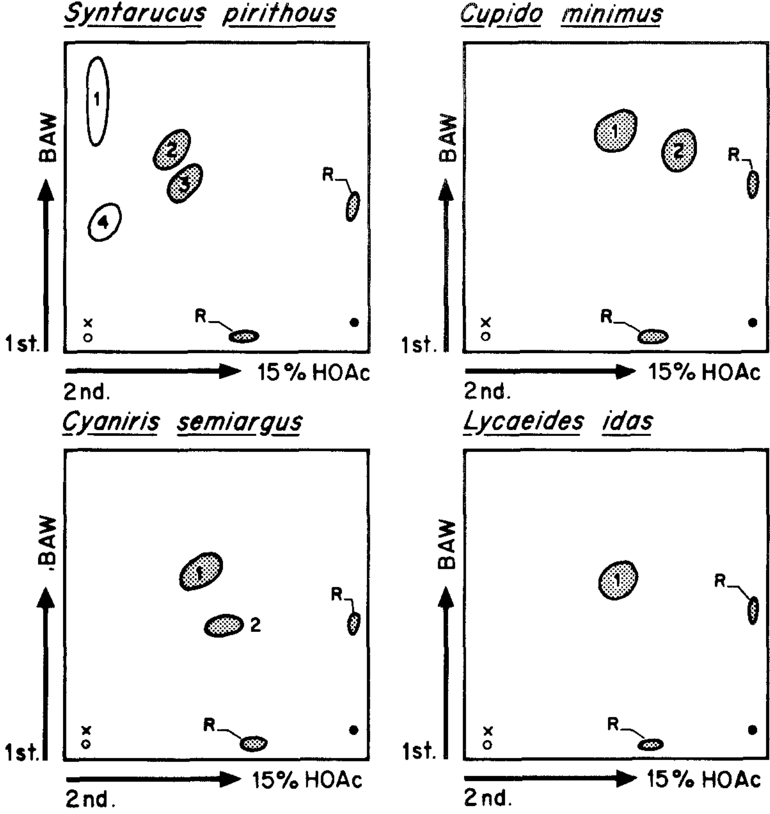

FIG. 1. Continued.

attached to flavonols in the plants is greater than that in *L. coridon*. This is shown by the greater mobility of many of the plant glycosides in 15% HOAc and their correspondingly lower mobility in BAW. Although some flavonoid spots occupy similar positions on the two-dimensional chromatograms of *L. coridon* and the plants, for example, spots 8 and 9 in the insect, spots 1 and 2 in *H. comosa*, and spots 3 and 4 in *A. vulneraria*, it is not possible to say that they contain the same compounds, as many flavonol glycosides have similar mobilities in BAW and 15% HOAc. The purification, identification, and co-chromatography of spot components is necessary to determine that they contain the same flavonoids.

The two-dimensional flavonoid pattern of *L. bellargus* is similar to that of *L. coridon* despite the absence of isorhamnetin from the former species (Figure 1). This difference in the butterflies' aglycone contents is reflected in the flavonoid contents of the larval diets; *H. comosa*, the larval food plant of *L. bellargus*, lacks isorhamnetin, whereas *A. vulneraria*, a recorded larval food plant

of *L. coridon*, contains isorhamnetin (Table 3). The position and color of flavonoid spots on the two-dimensional chromatograms indicates that the quercetin and kaempferol 3-, 7-, and 3,7-glycosides in *L. bellargus* contain fewer sugar residues than the quercetin and kaempferol 3-, 7-, and 3,4′-glycosides in *H. comosa*. No flavones, glycoflavones, or isoflavones were detected in *L. bellargus*.

The two-dimensional chromatogram of *P. icarus* is similar to that of the *Lysandra* species. From the aglycone results and the position and color of flavonoid spots on the two-dimensional chromatogram, it appears that *P. icarus* contains quercetin and kaempferol 3-, 7-, and 3,7-glycosides. No flavonoid spots were visible on the two-dimensional chromatograms that could represent quercetin 3,4′-diglucoside or 3-*O*-methylkaempferol, compounds previously tentatively identified in this butterfly (Feltwell and Valadon, 1970), nor was 3-*O*-methylkaempferol detected in the hydrolysates. Despite the range of flavonol aglycones reported in the larval food plants of this butterfly (Table 3) only quercetin and kaempferol were sequestered by *P. icarus*. Although flavones and isoflavones have previously been reported in *P. icarus*, none were detected in this study.

From the aglycone results and the position and color of flavonoid spots on the two-dimensional chromatograms, it appears that *Plebicula thersites* contains quercetin and kaempferol 3-, and 3,7-glycosides. *Onobrychis*, the larval food plant of *P. thersites*, is reported to contain quercetin and kaempferol (Jay et al., 1971).

Plebicula amanda has a much simpler flavonoid pattern than *P. thersites*. Only one flavonoid spot is present on the two-dimensional chromatogram which, from its chromatographic and color properties and the aglycone results, appears to contain a quercetin 3-glycoside. *Viccia cracca*, the larval food plant of this butterfly, is reported to contain quercetin, kaempferol, and apigenin (Jay et al., 1971).

The flavonoid pattern of *Aricia agestis* appears to consist of quercetin and kaempferol 3-, 7-, and 3,7-glycosides. Despite similarities in the flavonoid patterns of *A. agestis* and *L. coridon*, for example, spots 3, 1, and 4 on the two-dimensional chromatogram of the former species occupy similar positions to spots 3, 10, and 6 on that of the latter species; the larval food plants of *A. agestis* are not members of the Leguminosae but belong to the Geraniaceae and Cistaceae.

The flavonoid pattern of *A. artaxerxes* is similar to that of *A. agestis*. Flavonoid spots 1, 2, and 3 on the two-dimensional chromatogram of *A. artaxerxes* occupy similar positions to those of spots 2, 3, and 4 on the two-dimensional chromatogram of *A. agestis*. Although quercetin and kaempferol 3-, and 3,7-glycosides are found in both species, *A. agestis* also contains a flavonol 7-glycoside (represented by spot 1) (Table 2, Figure 1). The larval food plants of *A. artaxerxes* are reported to be the same as those for *A. agestis*.

[a]Abbreviations: Q, quercetin; K, kaempferol; M, myricetin: R, rhamnetin; I, isorhamnetin; F, fisetin; G, gossypetin; Rc, rhamnocitrin; Mg, 7-*o*-methylgossypetin; Ge, geraldol; Dk, 5-deoxykaempferol; T, tricin; L, luteolin; A, apigenin; C, chrysoeriol; D, daidzein; Gn, genistein; Fo, formononetin; Leg., Leguminosae; Cis., Cistaceae; Ger., Geraniaceae; Plu., Plumbaginaceae; Aqu., Aquifoliaceae; Ara., Araliaceae; +, flavonoids present; –, flavonoids absent; nd, not determined.

[b]Larval food plant aglycone data compiled from Jay et al., 1971; Reynaud et al., 1982; Gonnet 1975; Gonnet and Jay, 1972, and confirmed where possible by the author.

[c]Only these aglycones were detected in *A. vulneraria* collected from the *L. coridon* site.

Aricia cramera has a much simpler flavonoid pattern than both of the former *Aricia* species; only two flavonoid spots which appear to contain quercetin and kaempferol 3-glycosides were present on the two-dimensional chromatograms. Although the larval food plants of *A. cramera* are unknown, one can speculate that they probably include flavonol-containing members of Leguminosae, Geraniaceae, or Cistaceae.

Four flavonoid spots were visible on the two-dimensional chromatogram of *Lampides boeticus*. These appear to contain free quercetin, quercetin or kaempferol 3-, and 7-glycosides and possibly a 3,7-glycoside. *Colutea*, a common larval food plant of this butterfly, also contains flavonols (Table 3).

The aglycone results and position and color of flavonoid spots on the two-dimensional chromatogram suggests that *Syntarucus pirithous* contains free kaempferol and quercetin and kaempferol 3-, and 7-glycosides. It is possible that spot 4 on the two-dimensional chromatograms of *S. pirithous* and *L. boeticus* contains the same flavonoid, probably a flavonol 7-glycoside. The larval food plants of *S. pirithous* are recorded as "small legumes" (Higgins and Riley, 1975) which are also flavonol containing.

Only two flavonoid spots were visible on the two-dimensional chromatogram of *Cupido minimus*. These appear to contain quercetin and kaempferol 3-glycosides. The absence of isorhamnetin from *C. minimus* but its presence in *A. vulneraria*, the larval food plant, may be due to its absence from the seed and seedpod tissues on which the larvae actually feed; the occurrence of isorhamnetin in *A. vulneraria* generally refers to its presence in the leaves.

The two flavonoid spots on the two-dimensional chromatogram of *Cyaniris semiargus* also appear to contain quercetin and kaempferol 3-glycosides. However, as indicated by their different positions on the two-dimensional chromatograms these glycosides are different to those in *C. minimus*.

The single flavonoid spot on the two-dimensional chromatogram of *Lycaeides idas* appears to contain a quercetin 3-glycoside. It is possible that this flavonoid is similar to, if not the same as, that in *P. amanda*. As in the case of *P. amanda*, the larval food plants of *L. idas* are flavonol-containing legumes.

Celastrina argiolus appears to lack flavonoids; none were detected on the two-dimensional chromatogram, nor were any aglycones produced by hydrolysis of the extract. Furthermore, no yellow coloration was detected when the wings were fumed with ammonia vapor. *C. argiolus* does not feed on legumes; alternate generations feed on *Ilex aquilifolium* (Aquifoliaceae) and *Hedera helix* (Araliaceae), respectively. As the date these specimens were collected is not known, it is not known to which generation the specimens belong and hence on which of these food plants they had fed.

Pale-colored scales on the wings of *Plebejus argus*, *Everes argiades*, and *Glaucopsyche alexis* changed reversibly to a yellow color when fumed with ammonia vapor, indicating that they contain flavonoids. The larval food plants of these species include legumes.

The large blue butterfly *Maculinea arion* did not respond to fuming with ammonia vapor; its color remained unchanged. Thus, it appears that this butterfly lacks flavonoids. In contrast to the other lycaenid species examined, *M. arion* does not feed on legumes, but feeds on thyme (*Thymus drucei*), a member of the Labiatae in the early stages, and is later tended by ants and reared on *Myrmica* larvae.

DISCUSSION

The results of this investigation have shown that the flavonoid content of *L. coridon* and the other lycaenids examined is dependent on the flavonoid content of their larval food plants. Flavonoid aglycones identified in the butterflies are always present in the larval food plants; however, flavonoid aglycones reported in the larval food plants do not always occur in the butterflies. Unfortunately, as the precise larval diets of the butterfly specimens examined are not known, it is not possible to say to what extent certain flavonoid aglycones in the recorded larval food plants are not sequestered by the butterflies. For example, where a number of larval food plant species have been recorded for a butterfly, the specimens examined in this study may have fed on only one or two of them containing derivatives of perhaps one or two flavonol aglycones. Consequently, by comparing the range of aglycones reported in the recorded larval food plants with those identified in the butterfly, it would appear that some aglycones are not sequestered by the insect, when in fact, their absence from the butterfly may be due to their absence from the diet. In spite of this, a clear relationship exists between the presence of flavonols and flavonol glycosides in lycaenid butterflies and their larval food plants.

During this investigation, the importance of examining both plants and animals from the same site when studying the relationships between insects and their host plants has been emphasized. Previously, the flavonol aglycones quercetin, kaempferol, isorhamnetin, rhamnetin (7-*O*-methylquercetin), rhamnocitrin (7-*O*-methylkaempferol), fisetin (5-deoxyquercetin), geraldol (fisetin 3′-methyl ether), and 5-deoxykaempferol have been identified in *A. vulneraria* (Gonnet and Jay, 1972). In addition, about 35 flavonol glycosides, the major constituents being quercetin 3-glucoside, quercetin 3-galactoside, quercetin 3-arabinoside, isorhamnetin 3-galactoside, and isorhamnetin 3-arabinoside have been reported in the leaves of *A. vulneraria* (Gonnet, 1975). In this study, the only flavonol aglycones detected in *A. vulneraria* were quercetin, kaempferol, and isorhamnetin, and no flavonoid spots were visible on the two-dimensional chromatograms that could represent the various flavonol 3-glycosides. As these flavonol 3-glycosides were reported as major constituents, it is unlikely that their presence was overlooked in this study, and rather, that flavonol di- and triglycosides are the major flavonoid constituents of *A. vulneraria* at this site.

That differences occur in the proportions of flavonoid mono- and diglycosides in plants from different populations has been demonstrated in *L. corniculatus* (Reynaud et al., 1982). In view of variation in the proportions of flavonoid mono-, di-, and triglycosides in the food plants of some lycaenids, it would be interesting to see if this is reflected in the flavonoid contents of butterflies feeding on plants from different populations.

Differences in glycosylation patterns of flavonols in *L. coridon* and its larval food plant species indicate that this butterfly or its gut flora is capable of metabolizing ingested flavonoids before sequestration. That this involves hydrolysis of at least some of the ingested glycosides to aglycones is suggested by the presence of free kaempferol in *L. coridon* but its absence from the food plants. The metabolism of ingested flavonoids prior to sequestration is not peculiar to *L. coridon*. This phenomenon has been recognized in the sequestration of flavonoids by *M. galathea* (Wilson, 1985a,b), and in the sequestration of other classes of plant secondary compounds, for example, the carotenoids (Harashima et al., 1972, 1976; Kayser, 1982); pyrrolizidine alkaloids (Rothschild and Aplin, 1972; Edgar and Culvenor, 1974; Edgar et al., 1974); and cardenolides (Roeske et al., 1976; Brower et al., 1982) by insects.

Although 3-*O*-methylkaempferol and quercetin 3,4′-diglucoside have been tentatively identified, and an unidentified flavone and isoflavone reported in *P. icarus* (Feltwell and Valadon, 1970), these compounds were not found in specimens examined in this study. However, this does not mean that these flavonoids are not sequestered by *P. icarus*, only that they were not sequestered by the specimens examined by the author. As the butterflies examined in the two studies were from different sites (and from different countries), it is possible that the larvae had fed on different plant species and hence sequestered different flavonoids.

A series of feeding experiments is desirable to determine whether or not lycaenid butterflies are capable of sequestering flavones, glycoflavones, and isoflavones. Although present in many of the larval food plants, these flavonoids were absent from all the lycaenids examined. Rearing batches of lycaenid larvae on diets containing these compounds and examining the flavonoid contents of larval feces and the resulting imagos will yield information on the fate of ingested flavonoids (Wilson, 1985b). The presence of flavones, glycoflavones, and/or isoflavones in imagos would indicate that lycaenids are capable of sequestering these compounds and therefore that their absence from the specimens examined is probably due to their absence from the larval diet; the presence of these flavonoids in the feces but not in the imago would indicate their excretion, while failure to detect them in the feces or in the imago would suggest their metabolism and excretion as nonflavonoid fragments.

The relationship between the *Aricia* species examined and their larval food plants is particularly interesting. These lycaenids do not feed on plants belonging to the Leguminosae, as do most of the other lycaenids examined, but on

species from the Geraniaceae and Cistaceae. Despite this difference in larval food plant families, flavonoid patterns in the *Aricia* species are similar to those in the legume-feeding lycaenids. That similarities exist between the larval food plant families is indicated by the Engler classification scheme in which the Geraniaceae in the Geraniales is placed next to the Leguminosae in the Order Rosales; the Cistaceae is placed slightly further away in the Parietales. The selection of plants from these families as larval food plants by lycaenid butterflies in itself suggests biochemical similarities, since the choice of larval food plants is influenced, at least in part, by their secondary chemistry (Erlich and Raven, 1964; Shapiro and Masuda, 1981). The presence of flavonols in these plants, and their subsequent sequestration by lycaenid butterflies, provides evidence for some similarity in their secondary chemistry.

The absence of flavonoids from *M. arion* is not surprising if one considers that it is only in the very early stages that larvae of this butterfly feed on plant material; for the major part, the larval diet consists of ant larvae. The absence of flavonoids from *C. argiolus* is more difficult to explain. It is possible that this butterfly's choice of larval food plants, species from the Araliaceae and Aquifoliaceae, is partly responsible. However, why this should be so, especially when both of these plant families contain flavonoids is not known.

It has been estimated that about a third of the species in the Lycaenidae associate with ants (Downey, 1962; Cottrell, 1983). As a result of these associations, the range of larval host-plant species is greater in myrmecophilous than in nonmyrmecophilous lycaenids (Pierce and Elgar, 1985). Because the flavonoid content of lycaenid butterflies is dependent on the flavonoid content of the larval diet, one can predict that there will be greater variation in the flavonoid content of myrmecophilous than nonmyrmecophilous phytophagous lycaenids. If lycaenid larvae sequester different flavonoids from different host plants, resulting in different flavonoid patterns in the imagos, then analysis of the flavonoid contents of butterflies belonging to a particular species could provide a means of estimating migrational interchange and gene flow between populations.

Hinton (1951) and others (Malicky, 1969; Eliot, 1973) have argued that ancestral lycaenids were myrmecophilous. Considering the protection from parasitoids and predators gained by lycaenid larvae in ant–butterfly associations (Pierce and Mead, 1981), dissociation of such a relationship would be disadvantageous to the butterfly, unless an alternative defense mechanism evolved. Although the role of flavonoids in butterfly defense has not been established, species containing flavonoids have been reported to be distasteful to a number of vertebrates (Lane, 1957; Pocock, 1911; Wilson 1986a). If the sequestration and storage of flavonoids by adult lycaenids represented a form of chemical defense similar to that encountered with cardenolides in *Danaus plexippus* L. (Brower, 1985), or alternatively, if they provided lycaenid larvae with increased protection against alien microbes rather than vertebrate predators (Wilson,

1986a), this may have reduced the dependence of lycaenids on ants, eventually resulting in the termination of some ant–butterfly associations. In the former case, the decreased mortality rate of adult lycaenids resulting in increased egg production may compensate for the increased mortality of larval and pupal stages concomitant with the loss of ant protection. Since the defense strategy involving ants is costly, in so much as it depends on lycaenid larvae secreting carbohydrate and amino acids (ant-appeasement substances), this may have restricted butterflies to plants rich in nitrogen and protein, for example, to legumes and other nitrogen-fixing or parasitic plants (Mattson, 1980; Pierce, 1985). Reducing the dependence of lycaenids on ants would permit some lycaenids to utilize plants less rich in nitrogen, for example, plants from the Geraniaceae and Cistaceae.

A further possibility in the relationship between ants and butterflies is that flavonoids are present in the secretions of some lycaenid larvae. Although ant attractants are carbohydrate and/or amino acid in nature, the considerable bacteriocidal and antimycetic properties exhibited by many flavonoids (Havsteen, 1983) may be of importance in maintaining infection-free ant colonies.

Flavonoid pigments are thought to be involved in wing coloration in the Lepidoptera (Ford, 1941, 1944; Wilson, 1986a,b). In particular, a relationship has been demonstrated between the flavonoid content and wing background color of *Melanargia galathea*; the greater the flavonoid content, the yellower the wings (Wilson, 1986a). Even in those butterflies with the whitest wing background color, flavonoids represent on average 0.83% by weight of the wing materials and contributed "body" as well as some color to the wings. Hence, it is possible that flavonoids are responsible for the white, cream, and yellow coloring on the underside of the wings of many lycaenids; the blue coloring on the upperside is structural, whereas the brown is melanic. Interestingly *C. argiolus*, which lacks flavonoids, also lacks any cream or white patterning; this butterfly has blue structural color on both the upper and underside.

Acknowledgments—The investigation reported in this paper was performed as part of a PhD study at Reading University. I should like to thank the University of Reading for financial support; my supervisor Professor J.B. Harborne; Dr. R. Tilley for donating lycaenid material from France and Portugal; Reading Museum for allowing me to fume specimens in their collections with ammonia; Kathleen, Stephen, and David Wilson and Martin Dandridge for assistance collecting *L. coridon*; and Mike Amphlett for preparing the figures.

INTERMALE SEXUAL EFFECT ELICITED BY VOLATILE URINARY ETHER EXTRACT IN *Microcebus murinus* (PROSIMIAN, PRIMATES)

MARTINE PERRET and ALAIN SCHILLING

Laboratoire d'Ecologie Générale
Museum National d'Histoire Naturelle
4 avenue du petit Château F-91800 Brunoy, France

(Received December 6, 1985; accepted March 27, 1986)

Abstract—The effect of volatiles of diethyl ether-extracted dominant male mouse lemur urine on conspecific testosterone plasma concentrations was determined in an apparatus permitting olfactory isolation of the experimental subjects. Two experimental groups were exposed to air odorized with either ether or aqueous extracts of dominant male urine, while a third group received nonodorant air. Testosterone concentrations were measured before, during, and after the period of stimulation. The group submitted to the lipid fraction of dominant urine ($N = 15$) showed a significant decrease in testosterone concentrations. In contrast, no difference was observed between the group submitted to the aqueous fraction ($N = 10$) and the controls ($N = 11$). This physiological effect, which occurs in response to conditions of persistent stress, appears to be due to lipophilic components present in the urine of dominant males. The results are discussed in terms of the social structure of this primitive primate species.

Key Words—Primates, *Microcebus murinus*, olfactory signal, urine, organic fraction, dominance, sexual inhibition, testosterone.

INTRODUCTION

Chemical signals mediated through olfactory or vomeronasal endocrine pathways appear to be fundamental to many aspects of mammalian reproductive and social relationships (reviewed in Brown, 1979; Breipohl *et al.*, 1982; Johnston, 1983).

In fact, reproduction and social status are generally linked in mammals since dominant individuals seem to reproduce more often than subordinates (Huck and Banks, 1982; Fedigan, 1983). This correlation is not restricted to a

0098-0331/87/0300-0495$05.00/0 © 1987 Plenum Publishing Corporation

behavioral issue (e.g., priority access to females) but influences the physiological state of all animals within a hierarchical structure (Henry and Stephens, 1977; Keverne *et al.*, 1982; Dantzer, 1984). More precisely, it has been demonstrated in several species, including primates, that in both sexes reproductive functions are inhibited or reduced in subordinate individuals (Christian, 1964; Andrews, 1979; Coe and Levine, 1983; Abbott, 1984; Perret, 1985a).

In some mammals, chemical signals used for social communication, provided by the secretion of specialized odoriferous skin glands, are dispersed passively or actively by "scent marking" behaviors (Mykytowycz and Goodrich, 1974; Schilling, 1979; Epple, 1980; Walro and Svendsen, 1982). Other mammals use secreta of nonspecialized glands and excreta such as urine (reviewed in Adams, 1980) or feces (MacDonald, 1979; Schilling, 1980a). Urine has been shown to be an important mammalian chemosignal system, particularly in species which lack specialized scent-marking glands (Candland *et al.*, 1980; Schilling, 1980b). The voided urine is a complex chemical mixture (Beruter *et al.*, 1973; Preti *et al.*, 1977; Zechman *et al.*, 1984), many components of which are volatiles (reviewed in Albone, 1984). Therefore, it is not surprising that urine is involved in a large number of social functions through either physiological (reviewed in Marchlewska-Koj, 1984) or behavioral responses (Beauchamp, 1973; Nyby *et al.*, 1977; Dunbar and Carmichael, 1981).

As already suggested, these responses can be elicited by the same urinary signal in different reproductive or social contexts. For instance, male dominant urine deters other males but attracts females in mice (Jones and Nowell, 1974) and bank voles (Hoffmeyer, 1982). Moreover, the male mouse androgen-dependent urinary primary pheromone that accelerates sexual development in juvenile females (Bronson and Whitten, 1968) is significantly more active in dominants than in subordinates (Lombardi and Vandenbergh, 1977).

In primates, several studies have suggested a correlation between social rank and either scent deposition (Epple, 1970; Castell and Heinrich, 1971) or endocrine status (Keverne *et al.*, 1982; Coe and Levine, 1983). In the lesser mouse lemur, similar correlations were demonstrated. Indeed, when several males of this prosimian species are kept together, a social hierarchy develops and dominant males in groups mark more frequently than other males and perform almost all mating and sexually associated behaviors (Lebec, 1984). Furthermore, plasma testosterone levels are significantly reduced in all nondominant males (Perret, 1985a). The sensory mechanism of this physiological response has been provided only recently (Schilling *et al.*, 1984). Indeed, a decrease in plasma testosterone concentrations may be induced when males kept in isolation are exposed to the dominant urine odor. This effect, observed even in males which had had no previous contact with the dominant urine donor, was described as resulting from a pheromone-like mechanism (Schilling *et al.*, 1984).

Since chemical investigations concerning urinary material involved in social status or intraspecific agonistic behavior refer to active substances found in the organic (i.e., lipid) fraction of urine (Lee, 1976; Lee *et al.*, 1980; Hoffmeyer, 1982), the present study was conducted in order to determine if the volatile responsible for intermale sexual effect observed in our primate species is present in the lipid or in the aqueous fraction of the dominant urine. As in our previous study, the physiological effect of the odorant factor was measured by the variations of plasma testosterone concentrations of experimental subjects.

METHODS AND MATERIALS

Animals. We used 36 male lesser mouse lemurs (*Microcebus murinus*, Cheirogaleidae, Strepsirrhini), 2–5 years old. The animals were born in the laboratory, from stock originating from the dry forest of south west Madagascar. They were caged singly in experimental conditions described elsewhere (Perret, 1985a) and had no previous contact with the dominant urine donor. The lesser mouse lemur displays a clear photoperiod-dependent cycle of sexual activity (Petter-Rousseaux and Picon, 1981). Sexual activity may be artifically induced by a long photoperiod rhythm and maintained when three- or six-month experimental rhythms are imposed (Petter-Rousseaux, 1975). Our first study showed that the hormonal response to the odorant dominant factor seems to vary according to the seasonal period of the sexual activity cycle (Schilling *et al.*, 1984). Consequently, an artificial photoperiodic schedule consisting of three months of short photoperiod (8 hr light–16 hr dark) followed by five months of long photoperiod (14 hr light–10 hr dark) was used. All the subjects of the present study were tested 60 days after the beginning of the 5-month long-daylight period of reversed lighting cycle.

Urinary Material and Experimental Procedures. The odorant stimulus was obtained from dominant male urine. Dominance status was determined in three heterosexual groups (3 or 4 females with 3 or 4 males) of *M. murinus* according to a method detailed elsewhere (Perret, 1985a). Urine of the dominant males was collected by isolating the animal in special cages placed over a freezing system, thus avoiding bacterial fermentation. Urine was pooled and stored at −25 °C. Separation of whole urine in lipid and aqueous fractions was performed in a Soxhlet apparatus allowing continuous extraction (12–16 hr) of urine to twice its volume of redistilled pure diethylether (peroxide free). The organic and aqueous portions were then separated in 0.5-ml daily samples stored at −25 °C in sealed vials until testing.

Animals are isolated in individual chambers which are composed of a top-closed Perspex cylinder (24 cm in diameter and 42 cm in high) fixed on a wood support. The animals have access to a feeding compartment in a removable

sliding drawer under the chamber. This airtight unit is ventilated by an independent air circuit assuring olfactory isolation. The present experimental device includes six of these units which are separated from each other by wooden partitions ensuring visual isolation. The ventilation is provided by a compressor for intake of external air (pressure regulated to 0.7 bars), through one-way valves and flowmeters (regulated to 50 ml/min) located at the entry of each experimental chamber. An additional exhaust fan expels air outside the experimental room. A digital programmer controls solenoid valves, which direct, alternatively, the air flow through polyethylene or glass tubings to either a nonodorized or an odorized air circuit for each unit. The control animal is only submitted to nonodorized air. In the odorized circuit, air is initially passed through a vial containing the dry residue of 0.5 ml ether extract or aqueous fraction of the dominant urine.

Six animals were tested in each experiment according the following procedure:

1. *Prestimulation Phase (15 Days).* Males, maintained under conditions of visual and olfactory isolation, were submitted to nonodorized air.

2. *Stimulation Phase (30 Days).* Except for controls, males were submitted daily to air odorized by introducing 0.5 ml of the lipid or aqueous fraction of dominant urine in the stimulus vial. The stimulation program was 30 sec of odorized air followed by 4 min of fresh nonodorized air.

3. *Poststimulation Phase (15 Days).* Conditions similar to those of the prestimulation phase. Three series (ether extract group, $N = 15$) of different subjects were submitted to the lipid fraction of the urine of three different dominant male lesser mouse lemurs and two series (aqueous group, $N = 10$) of other subjects to the aqueous fraction of the urine of two of the same dominant males. Since the results for the experimental control group ($N = 5$) showed no statistical difference with six sampled reference animals left in their home cage during the experiment, we summarized the results of the measures as a single control group ($N = 11$).

Blood Collection and Testosterone Radioimmunoassay. Blood samplings began 15 days before the 5-month long-photoperiod cycle and lasted 15 days after. Because the lesser mouse is a very small animal (body weight about 80 g), blood collection ($N = 14$ for each animal) was not made at regular intervals to avoid changes in the packed cell volumes of the animals studied. Thus blood collections (100 μl) were made every two weeks before the stimulation phase, every week during stimulation and post stimulation phases, and then every three weeks (Figure 1).

Animals were sampled during their daily sleeping period without prior anesthesia, at a fixed time (8 hr after onset of the light period), according to studies on circadian testosterone variations (Perret, 1985b). Blood was collected from the saphenous vein within 5 min of removing the animal from its nest box. After centrifugation, plasma was stored at $-20°C$ until assayed. Testosterone

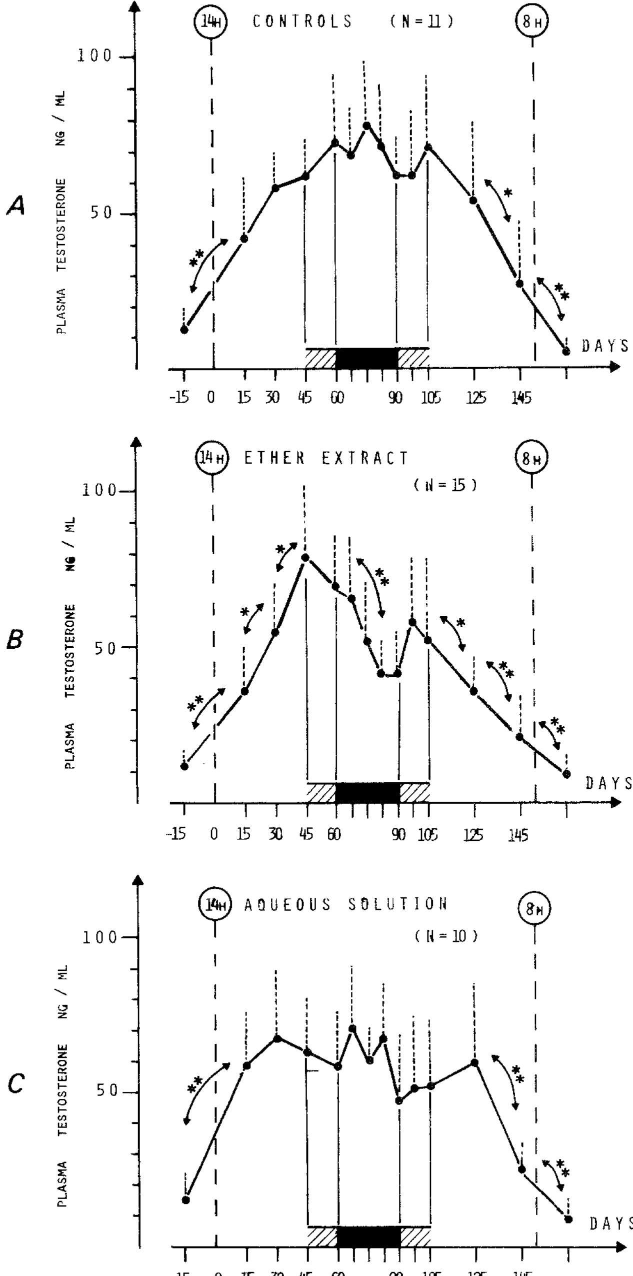

FIG. 1. Mean plasma testosterone concentrations (±SD) throughout the whole experiment for each experimental group. Significant differences between testosterone values within a group are indicated: $*P < 0.05$ and $**P < 0.01$ (F test). The successive experimental phases are indicated: hatched areas: pre- and poststimulation phases; black area: stimulation phase.

concentrations were measured in 20 μl plasma using the radioimmunoassay procedure described in Schilling *et al.* (1984). The antiserum diluted 1/200,000 was raised from 15-carboxymethyl-testosterone coupled to bovine serum albumin (purchased from Pasteur Institute). Radioimmunoassay was performed on extracted aliquots corresponding to 1.6 and 8 μl plasma. The percentages of cross-reactivity were: testosterone, 100%; dihydrotestosterone, 36%; dihydroandrosterone, 3%; Δ^4-androstenedione, 1.5%; other steroids tested, $\leq 1\%$. The intra- and interassay coefficients of variation were less than 14%. The sensitivity of the radioimmunoassay was 10 pg and the minimum detectable level in plasma was 0.6 ng/ml.

[3H]Testosterone was purchased from Amersham Int Plc (Bucks, U.K.) and nonradioactive steroids from Sigma (St. Louis, Missouri).

Statistical Analysis. All data are mean $\pm$ SD, and statistical differences in plasma testosterone concentrations were tested using variance analysis (F test). To compare groups during pre-, post-, and stimulation phases, we used two weeks-mean of testosterone concentrations.

RESULTS

Control Group. Under the experimental photoperiod schedule, testosterone concentration increased rapidly in control animals during the first month of long-daylight stimulation, followed by a spontaneous decrease four months later (Figure 1A). The mean value of testosterone concentration of this control group remained constantly elevated (mean 67 $\pm$ 13.8 ng/ml, N = 11) during the period between 30 and 120 days after the beginning of light stimulation. The apparent variations observed during the different phases of the experiment (Figure 1A) were not significantly different.

Ether Extract Group. As in control subjects, this experimental group responded rapidly to the change in photoperiod conditions by an increase of testosterone concentration which reached a maximum (75 ng/ml) after 1.5 months of long-daylight stimulation, during the beginning of the prestimulation phase of the experiment (Figure 1B). There was no statistical difference with the control group (Figure 2).

During the stimulation phase, animals submitted to dominant male urinary ether extracts demonstrated a significant decrease ($P < 0.01$) in plasma testosterone levels. This decrease was statistically significant within the first two weeks of stimulation and then stabilized after another two weeks (Figure 1B). The increase of values which appeared during the poststimulation phase, probably due to large individual variations of hormonal concentrations, is not statistically significant. This increase in testosterone concentration is followed by a rapid and marked decrease occurring three weeks earlier than the spontaneous decrease observed in control animals. Indeed, at the 125th day of long photo-

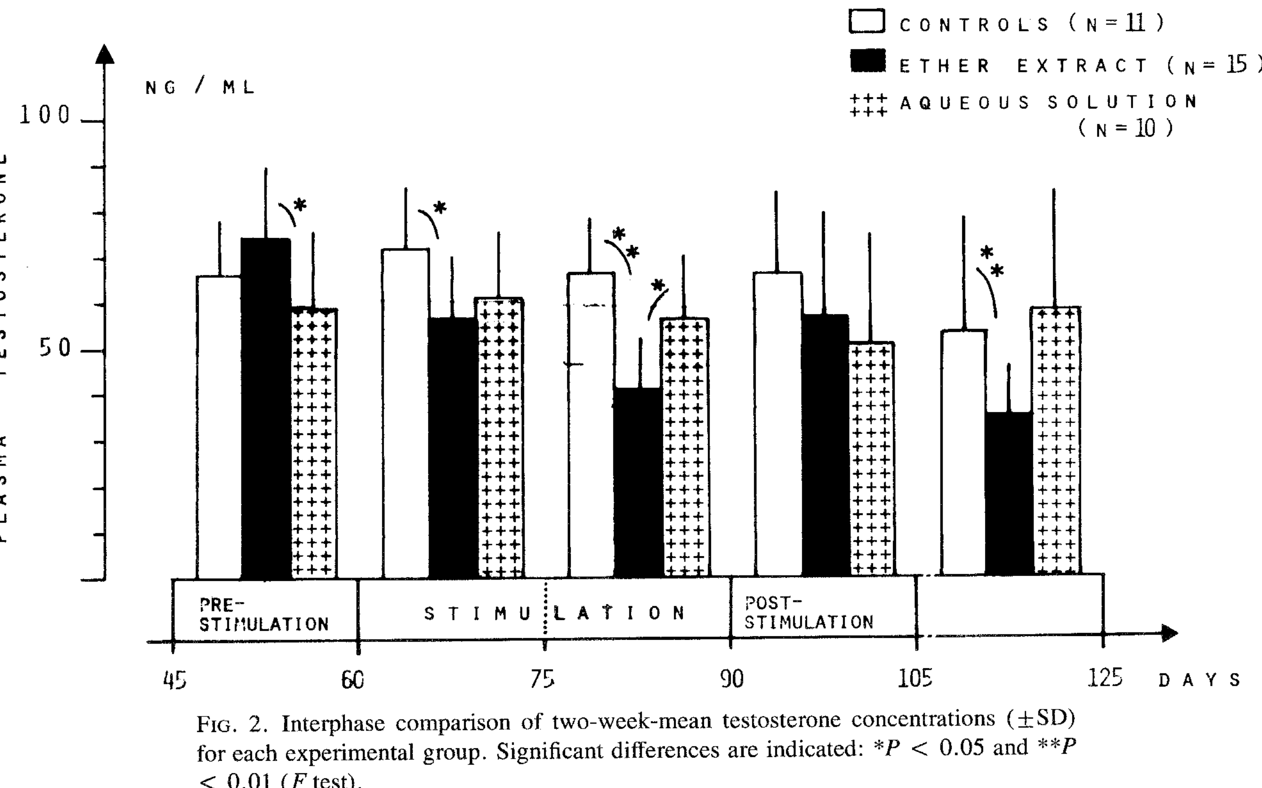

FIG. 2. Interphase comparison of two-week-mean testosterone concentrations (±SD) for each experimental group. Significant differences are indicated: $*P < 0.05$ and $**P < 0.01$ (F test).

period, control animals still showed higher significant testosterone concentrations (i.e., >50 ng/ml) than animals in the ether extract group (i.e., <40 ng/ml).

The interphase comparison of mean plasma testosterone level for each experimental group during 15-day periods (Figure 2) more clearly demonstrates the sexual inhibiting effect of the ether extracts since males exhibited, after 30 days, a significant decrease of the hormone compared with either the control or the aqueous phase group. Twenty days after the poststimulation phase, more than one month after stimulation was stopped, the hormonal level of the ether extract group remained significantly depressed, as if sexual rest had been induced earlier.

Aqueous Fraction Group. In contrast to the effect of ether extracts, the odor of the aqueous fractions of dominant male urine produced no significant changes in plasma testosterone level of conspecifics, although a decrease apparently occurs at the end of the stimulation phase (Figure 1C). In fact, the intergroup (Figure 1) and the interphase (Figure 2) comparisons of mean testosterone concentrations show that the aqueous fraction group reacted similarly to the control group, although at a slightly lower level.

DISCUSSION

The present study supports our previous findings that urine of dominant male *Microcebus murinus* contains a volatile chemosignal which influences testosterone plasma level in male conspecifics (Schilling *et al.*, 1984). This active volatile factor seems to be related to the status of the male, since subordinate male urines fail to induce significant variations of plasma testosterone concentrations in experimental males (Schilling and Perret, unpublished data). The mean value of testosterone decrease is similar in this experiment to previous measures observed in either subordinate males kept in groups (Perret, 1985a) or isolated subjects submitted to the whole dominant urine volatiles (Schilling *et al.*, 1984).

Since the active fraction of this chemosignal is extracted by an organic solvent and is not soluble in the aqueous fraction, it is suggested that the volatiles responsible for the physiological response of the lesser mouse lemur are lipophilic in nature. This result agrees with some other investigations concerning volatile chemicals in mammalian chemoreception. For instance, dichloromethane extracts shorten the estrous cycle of females, whereas the aqueous portions of the male mouse urine have no effect (Monder and Lee, 1978). Nevertheless, studies of urinary mouse pheromones have shown that the question of the volatility of the active chemical is rather complex. On the one hand, even if free urinary odorant active substances are lipophilic in nature, others possessing latent chemosignal properties are conjugated in the aqueous portion

of urine (Ingersoll *et al.*, 1982). On the other hand, volatile active compounds could possibly be bound to large nonvolatile carrier molecules from which they would be progressively released (Vandenbergh *et al.*, 1976; Novotny *et al.*, 1980). This could explain why mouse lemur urine marks, even when dried, retain almost indefinitely a strong characteristic odor.

This chemical complexity is further complicated by the existence of multiple neurosensory pathways involved in the reception of chemosignals. Firstly, depending on the physicochemical state of the material, the chemosignal may stimulate several sensory systems (gustatory, olfactory, vomeronasal, trigeminal, and perhaps terminal). Secondly, a chemical compound, even under the same phase, may, in addition to the main olfactory pathway, trigger different sensory organs. For instance, some of the neurons of the gustatory nucleus of the solitary tract have been shown to respond to various sets of olfactants (VanBuskirk and Erickson, 1977). In particular, the mechanism of stimulation of the vomeronasal system is also not completely resolved. Although several studies have shown that only a liquid-containing compound of high molecular weight (i.e., nonvolatile) activates the system (Johns *et al.*, 1978; Wysocki *et al.*, 1980; Singer *et al.*, 1984), others have shown that the vomeronasal cerebral center (accessory olfactory bulb) is able to respond to an airborne odorant stimulation (Meredith and O'Connell, 1979; O'Connell and Meredith, 1984). Moreover, physiological or behavioral responses to chemical cues may require a process of neuroendocrine integration which simultaneously involves several sensory chanels (Murphy, 1980; Beauchamp *et al.*, 1982; Meredith, 1983; Clancy *et al.*, 1984).

The lipophilic properties of the active urinary extract in male mouse lemurs may suggest a steroid-like nature of the chemosignal. Indeed several steroid components are odoriferous and have been implicated in chemosignals (Gower, 1976; Albone, 1984). Steroid excreted in the voided urine may originate either from the male or female reproductive tract or from the pituitary corticoadrenal system. Many of the sex hormone steroids, being conjugated before kidney filtration, are odorless when excreted. However, some of them, such as 3β-androstenol in pig urine, could be secondarily released by microorganism action and act as a pheromone (Booth and Baldwin, 1980). However, sexual steroids do not appear to be responsible for the effect described in male mouse lemurs since castration of a dominant active male does not reduce its capacity to decrease testosterone levels in conspecifics (Schilling and Perret, in preparation).

It is likely that social chemosignals may act at different physiological levels through different neuroendocrine pathways. Signals eliciting active responses (attraction between conspecifics) are often controlled by genital glands (Michael *et al.*, 1976; Epple, 1979; Dunbar *et al.*, 1980; Yarh, 1981; Macrides *et al.*, 1984). In contrast, some inhibitory signals could be modulated by adrenocortical function (Drickamer *et al.*, 1978; Marchlewska-Koj *et al.*, 1983; Novotny *et al.*, 1986). Indeed, urinary catabolites from corticoadrenals, especially 17-

hydroxycorticosteroids, are important since they reflect how an individual is affected, such as stress and arousal, and copes with psychosocial situations, such as sexual competition and hierarchy (reviewed in Dantzer, 1984), in which olfactory signals and olfactory pathways appeared to play an increasing role (Hoffmeyer, 1982; Feldman and Conforti, 1982; White *et al.*, 1984). Previous experiments have shown that in *Microcebus murinus*, plasma cortisol is increased in animals submitted to long-term social pressure (Perret and Predine, 1984) and that this increase is sustained by exposure to the urine odor of a dominant male (Schilling *et al.*, 1984).

Lastly, considering the importance of chemical signals in nocturnal solitary prosimian primates (Charles-Dominique, 1977a,b; Schilling, 1980a,b), it is assumed that some chemical components dispersed by urinary marking behaviors by dominant male mouse lemurs may possibly serve a double function to enhance the reproductive potential of the species (Perret, 1985a). Although male mouse lemurs with depressed testicular function are not necessarily sexually inhibited (Lebec, 1984), subordinate individuals are actually eliminated from the competition for females, as has been demonstrated for other mammals with similar social structure (Charles-Dominique, 1978). This effect could be achieved, firstly, through a physiological (depressed sexual function) and behavioral (deterent) effect on competitive males and, secondly, through a stimulating effect on the reproductive function of females which in turn would preferentially mate with dominant individuals.

(Received February 19, 1985; accepted March 31, 1986)

Abstract—A consistent pattern of relationships emerges from comparisons of insect electroantennograms, peripheral olfactory receptor neuron responses, and behavioral responses to quantified concentrations of odorants. One consistency is that all of the different response measurements can be described by stimulus–response curves of the same form. Another is that the responses have characteristic groupings when they are plotted against odorant concentration. The pattern of relationships is exemplified in the responses of *Trichoplusia ni* (Hübner), *Heliothis zea* (Boddie), and *Plodia interpunctella* (Hübner) to several pheromone components and analogs. To quantify the relevant stimulus parameters for the response comparisons, the emission rates of the stimulus delivery system were calibrated for several 12 to 17-carbon pheromone components. The stimulus–response relationships determined for *T. ni*, *H. zea*, and *P. interpunctella* are combined with relationships reported for other insects in the literature, and applications are discussed for the interpretation of pheromone trapping and laboratory bioassays.

Key Words—Pheromone, olfaction, electroantennogram, neurophysiology, *Trichoplusia ni*, *Heliothis zea*, *Plodia interpunctella*, Lepidoptera, Noctuidae, Pyralidae.

INTRODUCTION

The ability of insects to detect odors and to distinguish differences in stimulus levels derives from peripheral and central nervous system (CNS) mechanisms

[1] Postdoctoral fellow employed through a cooperative agreement between the Insect Attractants, Behavior, and Basic Biology Research Laboratory, and the Department of Entomology and Nematology, University of Florida, Gainesville, Florida 32611.

0098-0331/87/0300-0509$05.00/0 © 1987 Plenum Publishing Corporation

that may operate similarly in many animals. Consider, for example, that the rate of action potentials elicited in a peripheral olfactory receptor neuron frequently is found to be graded proportionally to the odorant concentration, irrespective of the insect. This proportionality provides a neurophysiological basis whereby the elicited behavioral responses also can be graded with odorant concentration. (We do not imply that all behavior is graded in this way, because CNS integration and other processes may significantly modify the response.) The concept of the graded behavioral response has been a useful interpretive tool in vertebrate physiology, leading to the development of animal and human psychophysics (Stevens, 1975). Our objective is to quantify and compare several behavioral and neurophysiological stimulus–response relationships and then to demonstrate how the concept of graded response can be applied for interpreting laboratory and field bioassays.

A second focus of this report is to address the problem of pheromone quantification by measuring pheromone emission rates and concentrations.

We analyze the dose–emission rate relationship of a glass-tube odorant dispenser and apply the calibration in quantitative comparisons of neurophysiology and behavior for *Trichoplusia ni* (Hübner), *Heliothis zea* (Boddie), and *Plodia interpunctella* (Hübner).

METHODS AND MATERIALS

Insects and Chemicals

Male *T. ni*, *P. interpunctella*, and *H. zea* pupae were obtained from colonies maintained at this laboratory and held at 70–80% relative humidity, 24–27°C, on a 14:10 light–dark cycle. Adults were 48–72 hr old when tested.

Sex pheromone components of *T. ni*, (Z)-7-dodecen-1-ol acetate (Z-7:12Ac); *P. interpunctella*, (*Z,E*)-9,12-tetradecadien-1-ol acetate (*Z,E*-9,12:14Ac); *H. zea*, (Z)-11-hexadecenal (Z-11:16Al); and *Heliothis virescens* (F.), (Z)-9-tetradecenal (Z-9:14Al) and tetradecanal (14Al) were provided by Drs. J.H. Tumlinson and K.W. Vick of this laboratory. They were analyzed by gas–liquid chromatography (GLC) either on a 3% OV-1® 1.8-m packed column or 36-m capillary column and found to be >99% pure. The *Z*7:12Ac also was analyzed on a CPS-2 50-m liquid crystal capillary column by R.R. Heath of this laboratory. To calibrate dispenser release rates at low doses, samples of two of the pheromone components, *Z*-7:12Ac and *Z,E*-9,12:14Ac, were tritiated. The tritiated pheromone components were additionally purified by thin-layer chromatography and then by silicic-acid–column chromatography just before use because their lability increased after tritiation. Their specific activities were 0.804 and 0.951 Ci/mmol, respectively, as determined by GLC and liquid scintillation counting (LSC) using external standards.

Dispensers

Two types of pheromone delivery system were used, a glass-tube and a rubber-septa dispenser. The glass-tube dispensers were assemblies of ground-glass joints described in Mayer (1973) and Mayer et al. (1984). The desired quantity of a pheromone component diluted in 0.5 ml of hexane was pipetted into the assembly. The dispenser was rotated under aeration at 200 cm^3/min for 30 sec to coat the inside uniformly and to evaporate the hexane.

The rubber-septa system was one similar to that developed by Heath and Tumlinson (1986). Prior to loading, the 5-mm-ID × 9-mm-long rubber septa (A.H. Thomas Co.) were Soxhlet extracted in methylene chloride for 24 hr and air dried. The *Z*-7 : 12Ac was applied to the well of a septum in 50-μl aliquots of hexane, and the septum was aired in a hood for two days before use. For testing, the septa were placed in any one of three different delivery assemblies. One was a five-part assembly consisting of a brass Swagelok® 1.587-cm to 0.635-cm reducer, a 1.587-cm to 0.952-cm reducing union, and a 0.952-cm to 0.635-cm reducing port connector, with a 0.635-cm knurled nut at the inlet and a 0.635-cm Teflon® ferrule at the outlet. Another assembly was identical except that the metal was stainless steel. The third delivery system was the glass-tube assembly described above (without an initial pheromone coating).

Prior to pheromone collection or to use in a bioassay, the dispensers were purged for 30 sec with 200 cm^3/min of filtered dry air. The pheromone was delivered by passing filtered dry air through the glass-tube assembly at either 50 or 200 cm^3/min.

Collection and Analysis of Emissions

Three different methods were used in determining the glass-tube dispenser emission rates. Radiolabel analysis of pheromone components collected onto cotton filters was used for emissions at the 50 cm^3/min flow rate. GLC analysis of pheromone components collected in capillaries was used for emissions at 200 cm^3/min with doses between 10 and 1000 μg (0.044–4.4 μmol). The third method used a set of electroantennogram (EAG) bioassays combined with data from the radiolabeled calibration and from a calibration of rubber-septa emission rates by R.R. Heath of this laboratory.

Radiolabeled Pheromone Components. Emission rates of *Z*-7 : 12Ac and *Z*,*E*-9,12 : 14Ac at 50 cm^3/min were determined for doses between 0.08 and 10 μg (3.2×10^{-4}–4×10^{-2} μmol) by LSC analysis of radiolabeled pheromone components collected onto cotton filters. The dispensers were attached with Swagelok connectors to air samplers consisting of 5-mm-ID × 10-cm-long brass tubes stuffed with 35-mg cotton filters at each end. The filtering efficiency of the air samplers ranged from 0.9 to 0.97 as determined by comparing the radioactivity collected on the front and back filters. After the tritiated com-

pounds were collected, the filters were combusted in a Packard model 306® sample oxidizer. The oxidizer distilled the resultant tritiated water vapor into 10 ml of Packard Monophase-40® scintillation fluid cocktail. The efficiency of the oxidizer was monitored by external standards that indicated a negligible loss of radioactivity in this stage of the analysis. (Some of the emissions were collected independently by the capillary trap method described below, in which case the collected pheromone was rinsed with hexane directly into the scintillation cocktail.) The radioactivity of the cocktails was counted for 1 hr in a Packard model 2450® liquid scintillation counter calibrated by external standards.

GLC Analysis of Emissions of Unlabeled Pheromone Components at 200 cm^3/min. For pheromone component doses of 10–1000 μg (0.044–4.4 μmol), the collection device used was that described by Brownlee and Silverstein (1968). The emissions were collected in glass or stainless-steel capillaries connected to the dispenser by glass or Swagelok adaptors. The capillary was inserted into a metal tube heated at the dispenser end and chilled with acetone and Dry Ice at the outlet end. After a 3-min collection interval, the capillary was rinsed with 300 μl of hexane or diethyl ether into a calibrated centrifuge tube. In one series of tests the capillary effluent was passed through 3 ml of hexane to determine the collection efficiency of the capillary (about 80%). In another series of tests emissions from 100-μg doses of *Z*-7 : 12Ac were collected for 15-sec increments from 15- to 180-sec periods to determine a regression of quantity released on time.

The centrifuge tube contents were reduced for quantitative analysis by evaporation under dry nitrogen to remove excess hexane. Evaporative loss was calibrated in several cases by external standards using related compounds of similar volatilities but different GLC retention times. Aliquots from the centrifuge tubes were analyzed on a Varian model 210 GLC system with a flame ionization detector. The 1.8-m × 2-mm-ID glass column was packed with 3% OV-1 on 100–120 mesh Gas-Chrom-Q®, and the flow of nitrogen carrier was 30 cm^3/min. All analyses were isothermal, with the injector and detector at 200°C and the oven at 130–150°C. A Spectra-Physics model 4100 computing integrator was used for recording and quantitating the amounts recovered.

EAG Analysis of Z-7 : 12Ac Emission at 200 cm^3/min. The glass-tube dispenser emission rates at the 200 cm^3/min flow rate for doses of Z-7 : 12Ac between 0.1 and 10 μg (4.4×10^{-4}–4.4×10^{-2} μmol) were estimated by performing a set of three separate EAG bioassays on *T. ni* males. Two of the bioassays were done to determine a regression of EAG on concentration. In the third bioassay, EAGs performed at 200 cm^3/min were correlated with the concentrations predicted from the regression. The expected emission rate from a given dose then was determined by multiplying the predicted concentration by the total air flow in the plume passing over the antenna.

The first bioassay was done primarily at the 50 cm^3/min flow rate using the glass-tube dispenser. Here, the *Z*-7 : 12Ac concentrations delivered to the antenna were calculated from the radiolabeled pheromone calibration. The GLC measurements described above, calibrating *Z*-7 : 12Ac emission rates from the glass-tube dispenser at doses of 10, 31.6 and 100 μg, were used with EAGs of these three doses at the 200 cm^3/min flow rate.

The second EAG bioassay was done using a rubber-septa formulation, calibrated by R.R. Heath of this laboratory. The emission rates were estimated by interpolating between two curves of emission rate against dose, one at a 250 cm^3/min rate of flow through the brass assembly, and one at 100 cm^3/min.

The equation chosen to regress the EAG response magnitude against concentration was a power function (see, e.g., Mayer and Mankin, 1985) of the form:

$$\log(R) = A + B\log(C) \qquad (1)$$

where R is the EAG response in $-$mV, A and B are regression constants, and C is the pheromone concentration in μmol/cm^3. This equation was applied to the uncalibrated, low-dose EAG responses at 200 cm^3/min to estimate what concentrations had been present at the antenna when the responses were elicited. Finally, the release rates were calculated by multiplying the predicted concentration at each dose by the total flow rate.

Bioassays

Neurophysiological. Electroantennogram responses of *T. ni* and *H. zea* to *Z*-7 : 12Ac and *Z*-11 : 16Al, respectively, were measured by procedures similar to those described in Mayer et al. (1984). The concentrations delivered to the antennae for the *T. ni* EAGs were estimated from the 50 cm^3/min emission rate calibration and the rubber-septa calibration described above. The concentrations delivered in the *H. zea* bioassay were determined from the 200 cm^3/min emission rate calibration for doses of *Z*-11 : 16Al above 3 μg. The concentrations for lower doses were estimated by extrapolating from the curve for higher doses and using the same slope as for the *Z*-7 : 12Ac emission rates, as described in the Results section.

Single-sensillum recordings from *T. ni*, and *H. zea* were obtained as in Mayer (1968) using electrodes made from tungsten wire, sharpened electrolytically to less than a 1-μm tip diameter. Adult males were secured with wax, and the recording electrode was placed at the base of the sensillum. Signals were amplified and filtered (bandpass 1–10 kHz) with a Grass P15 AC preamplifier. The signals were monitored with a Tektronix 5113 dual-beam storage oscilloscope. Analysis and storage of data were performed on a Digital Equipment Corporation MINC Declab-23® microcomputer by a procedure similar to that described in O'Connell et al. (1973).

Flight Tunnel. The flight-tunnel bioassays for *T. ni* and *P. interpunctella* are reanalyses of data from two earlier reports by Mayer (1973) and Mankin et al. (1980). In those reports the concentration of pheromone in the tunnel had been estimated by dividing the dispenser output by the total tunnel airflow. However, this estimate of concentration is correct only if complete mixing of pheromone with air occurs. Results from subsequent flight and EAG bioassays had suggested that complete mixing was not occurring, even though $TiCl_4$ smoke released from the dispenser into the tunnel appeared to be well-mixed when the smoke reached the downwind end.

To avoid relying on visual estimates of the completeness of mixing in the tunnel, we determined the downwind pheromone concentration at the insect release point by an EAG bioassay. Electroantennograms were recorded from 10 *T. ni* males in the tunnel with the stimulus airflow through the dispensers set to 50 cm^3/min. Each male was tested with Z-7:12Ac at doses of 3.16, 10, and 31.6 μg (0.014–0.14 μmol). The upwind concentration at the dispenser release point was calculated by dividing the emission rate by the dispenser flow rate. The downwind concentration to which each male had been exposed was calculated from the regression of EAG on concentration described in the previous section. To estimate the mean dilution factor, the upwind concentration was divided by the downwind concentration. The mean dilution factor determined from the three different doses in the EAG bioassay then was applied to all dispenser doses to determine the concentrations in the tunnel.

RESULTS

Although the dispensers were calibrated primarily to relate responses from the behavioral bioassays to responses from the neurophysiological bioassays, the calibrations are interesting in themselves and will be described first. The calibrations then are compared with those of other types of dispensers, and the most significant features of the release pattern are generalized to other release systems.

Two of the findings in this section warrant particular emphasis. First, the emission rate of pheromone from the glass-tube dispenser (and probably from many other types of dispenser as well) is not linearly proportional to dose. The greatest deviations from linearity occurred at the upper and lower ends of the dosage range. Such deviations lead to overestimation of stimulus levels at both high and low doses of pheromone. This can lead to errors of interpretation when a dose–response bioassay is not referenced to the concentration in the airstream. Second, the plume of pheromone in a wind tunnel remains relatively undiluted under most conditions. Measurements by EAG indicate that the mean dilution factor may be no larger than 10–20, even when a visual indicator, e.g., a smoke plume, appears well dispersed. The instantaneous dilution factor varied consid-

erably about the mean in a pattern intermediate to the EAG pattern described for the point source and the continuous cloud source by Baker et al. (1985).

Glass-Tube Dispenser Emission Rates. The relationship between dose and emission rate for the glass-tube dispenser was similar for all of the pheromone components tested at both 50 and 200 cm^3/min flow rates and appeared to follow a general pattern predicted by current theories of molecule-surface dynamics (see Tully and Cardillo 1984). At doses from $1 \times 10^{-3.5}$–1×10^{-1} μmol, the emission rate increased with increasing dose. Above this range the emission rates reached a constant level, independent of dose. Thus we found it necessary to divide the calibration curves for each chemical into multiple segments. The regression equations of best fit for doses of less than 100 μg are listed in Table 1, and the data are shown in Figures 1 and 2.

The inset in Figure 2 shows the *Z*-7 : 12Ac emission rates calculated for the EAG calibration at 200 cm^3/min for doses below 10 μg. The segment of the *Z*-7 : 12Ac line labeled GC is redrawn from the GLC calibration on the main graph, and the segment labeled EAG is the part calibrated by EAG. In the EAG segment, the emission rates are calculated from the concentrations predicted at different EAG levels by the *T. ni* EAG–concentration regression line, TNE, in Figure 3. The top part of the dotted curve in the inset of Figure 2, labeled *Z*-11 : 16Al, also is redrawn from the main graph. The extension of this curve, the segment with larger dots, is an assumption that the curve for *Z*-11 : 16Al is parallel to the curve for *Z*-7 : 12Ac. The *Z*-11 : 16Al emission rate curve was used to estimate the concentrations for the regression of *H. zea* EAG on concentration, HZE, in Figure 3.

The amounts of *Z*-7 : 12Ac release over 15-sec periods from 15 to 180 sec yielded a statistically linear regression over the 3-min period (Table 2). (Note: theoretically, the release rate decreases exponentially, but most of the decrease occurs during the initial 30-sec purge.)

Comparison of Glass Tube with Other Dispensers. Because pheromones are not usually dispensed from glass, it is worthwhile to compare the glass tubes with other substrates and to generalize some of the findings, if possible. The (initial) rate of emission of pheromone from the glass tube is higher than from most slow-release formulations. For example, the half-life of *Z*-7 : 12Ac on rubber septa is 34.8–35.9 days (Butler and McDonough, 1979). Based on this half-life, the initial emission rate from a septum dosed with 1 mg is 6.1×10^{-5} μmol/min. The same initial emission rate of *Z*-7 : 12Ac from the glass tube is achieved by a dose of 3.98×10^{-3} μmol (890 ng), according to the inset in Figure 2. This also can be compared with the measurement by Baker et al. (1981) of a 1.62×10^{-5} μmol/min emission rate from a septum dosed with 1 mg of *Z*-8 : 12Ac.

Comparisons of *Z,E*-9,12 : 14Ac released from different substrates reveal a pattern similar to that shown by *Z*-7 : 12Ac. A polyethylene cap loaded with 33.7 μmol (8.5 mg) of *Z,E*-9,12 : 14Ac emits at the rate of 3.10×10^{-5} μmol/

TABLE 1. REGRESSION EQUATIONS FOR RELEASE RATES OF SEX PHEROMONES AND RELATED CHEMICALS AT DOSES BELOW 100 μg^a

Chemical	Flow rate (cm^3/min)	Regression constant	Estimate	Standard error of estimate	F	R^2

		B	2.05	0.15		

[a]The regression equations have the form: log(emission rate) = $A + B$ log(dose), where A and B are regression constants in the table, the units of emission rate are μmol/min, and the units of dose are μmol.
[b]Statistically significant at the 0.001 probability level.
[c]Statistically significant at the 0.01 probability level.
[d]See inset in Figure 2.

min (Mankin et al., 1980), which compares with a glass tube loaded with 0.18 μmol (45 μg) (Figure 1). A Fiberglas®-coated screen dosed with 0.397 μmol (0.1 mg) of *Z,E*-9,12:14Ac emits 1.33×10^{-6} μmol/min (Mankin et al., 1983), which is slightly less than the emission rate from the glass-tube dispenser.

More important for general comparison, the theory of molecule–surface dynamics (e.g., Tully and Cardillo, 1984) predicts that the emission of pheromone from any dispenser, except an ideal inert matrix, follows a pattern similar to that found for the glass tubes. At some point near the upper end of the dosage range of behavioral relevance, the low vapor pressure of pheromone limits the rate of pheromone release. At low doses the pheromone remains adsorbed to low-energy sites on the substrate. The actual doses where such effects occur

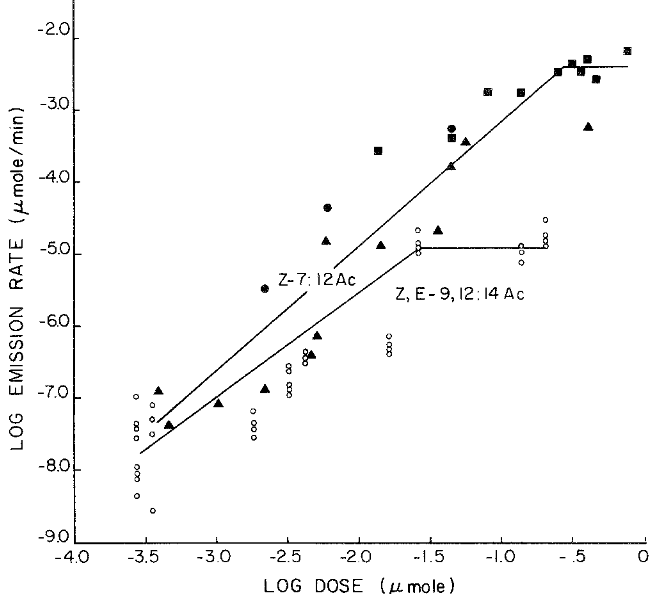

FIG. 1. Release rates of Z-7 : 12Ac and Z,E-9,12 : 14Ac from glass dispensers at a flow rate of 50 cm^3/min: Triangles, means of four to seven replications with ^{3}H-labeled Z-7 : 12Ac collected by the air sampler; closed circles, mean of four replications with ^{3}H-labeled Z-7 : 12Ac collected by cold trap; squares, means of 8–19 replications with unlabeled Z-7 : 12Ac collected by cold trap; open circles, single measurements with ^{3}H-labeled Z,E-9,12 : 14Ac collected by the air sampler.

depend on the substrate, the molecular weight, and the functional groups of the pheromone molecule.

Neurophysiological Bioassays. In the single-neuron study, the responses of pheromone-sensitive receptor neurons in *T. ni* occurred at concentrations only above $1 \times 10^{-4.6}$ μmol/cm^3, which is about the same as the EAG threshold. Similarly, pheromone-sensitive neurons in the long, sexually dimorphic sensilla spaced in rows on the proximal 40–50 subsegments of the male *H. zea* antennae responded to doses of Z-11 : 16Al above about $1 \times 10^{-3.4}$ μmol (0.1 μg). The emission rate of Z-11 : 16Al was not calibrated at this level; however, by extrapolation from the inset of Figure 2, this dose appears to correspond to an emission rate of about 1×10^{-8} μmol/min, and a concentration at the antenna of about $1 \times 10^{-11.1}$ μmol/cm^3 (Figure 3). The *H. zea* and *T. ni* receptor neurons, which are sensitive to their major pheromone components thus appear to have similar sensitivities, and the similarity of the two EAG response curves is in agreement with this finding (Figures 3–5).

The EAG responses of *T. ni* and *H. zea* to Z-7 : 12Ac and Z-11 : 16Al,

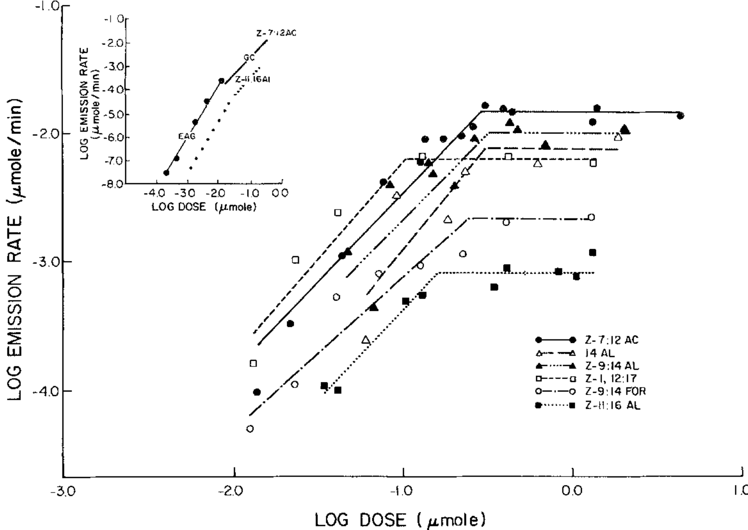

FIG. 2. Release rates of pheromone components from glass dispensers at a flow rate of 200 cm^3/min. All collections were by cold trap and analyses were by GLC. Closed circles, Z-7:12Ac; open triangle, Z-9:14Al; closed triangle, 14Al; open circle, Z-9:14For; closed square, Z-11:16Al; open square, Z-1,12:heptadecadiene. Inset shows EAG calibration of release rates of Z-7:12Ac for doses below 10 μg and the extrapolation of the emission rate of Z-11:16Al for doses below 10 μg.

respectively, are shown in Figure 3. No significant differences in the *T. ni* EAG response were noted in tests with the three different rubber-septa assemblies (brass, stainless steel, or glass). We note also that the *T. ni* EAG levels are somewhat lower than those given in Mayer et al. (1984) because improvements in the mixing chamber of the stimulus delivery system lowered the peak concentrations delivered to the antenna. The regression of *T. ni* EAG response on concentration was used to calculate the emission rate curve in the inset of Figure 2 that estimates emission rates of low doses of Z-7:12Ac at the 200 cm^3/min flow rate. The *T. ni* regression also was used to determine the dilution factor in Table 3 for the wind-tunnel bioassays in Figure 4. The regression equations are listed in Tables 4 and 5.

Wind Tunnel Bioassays. The dilution ratios measured by the wind-tunnel EAGs show that, contrary to earlier assumptions, there was not enough turbulence to cause complete mixing of pheromone in the bioassays of anemotaxis in *T. ni* (Mayer, 1973) and *P. interpunctella* (Mankin et al., 1980). The mean dilution ratio was 23.7 (Table 3). If the Z-7:12Ac plume in the EAG tests had mixed completely with the tunnel air, the mean dilution ratio would have been 51,200, three orders of magnitude higher than the EAG-derived ratio. Conse-

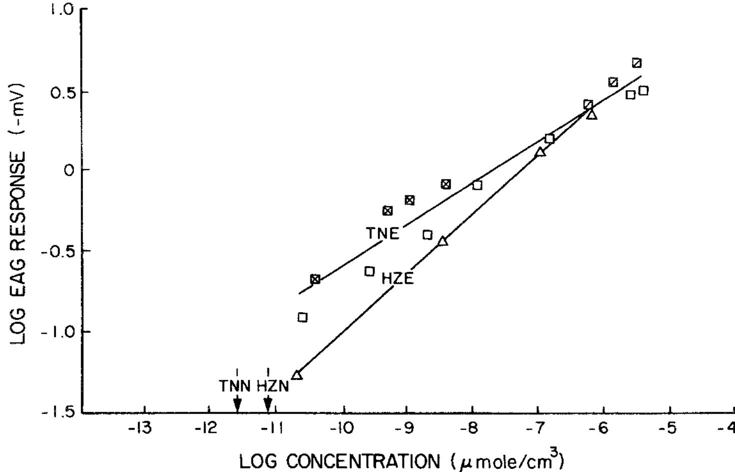

FIG. 3. Concentration–response relationships for *T. ni* and *H. zea* neurophysiological bioassays. TNE: regression of *T. ni* EAG response on Z7–12 : Ac concentration; open squares are means of 10 replications with glass-tube dispenser at 50 cm^3/min flow rate, squares with slash are means of 10 replications with glass-tube dispenser at 200 cm^3/min flow rate, squares with cross are means of 30 replications with rubber septa at 200 cm^3/min flow rate. HZE: regression of *H. zea* EAG response on Z-11 : 16Al concentration; triangles are means of 13 replications with glass-tube dispenser at 200 cm^3/min flow rate. TNN: lowest concentration eliciting detectable response by *T. ni* pheromone receptor neurons sensitive to Z-7 : 12Ac. HZN: lowest concentration eliciting detectable response by *H. zea* pheromone receptor neurons sensitive to Z-11 : 16Al. Regression equations are listed in Table 4.

TABLE 2. REGRESSION EQUATIONS FOR RELEASE RATES FROM DISPENSERS[a]

Flow rate (cm^3/min)	Regression coefficient ($\times 10^{-5}$)	Standard error of estimate ($\times 10^{-5}$)	F	R^2
50	1.10	.08	211.54[b]	0.99
100	3.86	.30	168.29[b]	0.99
200	9.67	.89	119.18[b]	0.98

[a] Dosed with 0.44 μmol (100 μg) Z-7:12Ac at flow rates of 50, 100, and 200 cm^3/min. The regression equations have the form: emission = $K \times$ time, where K is the regression coefficient, emission is given in μmol and time is in seconds.
[b] Statistically significant at the 0.01 probability level.

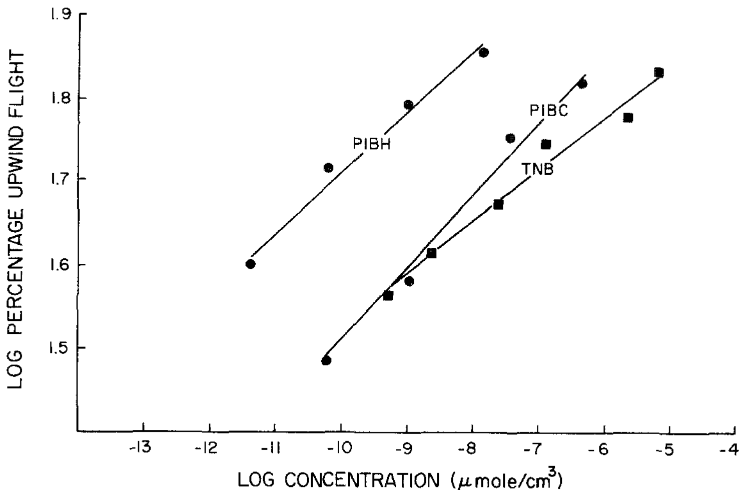

FIG. 4. Concentration–response relationships for wind-tunnel bioassays. The regression equations are given in Table 4. TNB line with squares, anemotactic response to *Z*-7 : 12Ac by *T. ni*; PIBC line with circles, anemotactic response to *Z,E*-9,12 : 14Ac by *P. interpunctella* at 23°C.; PIBH line with circles, anemotactic response to *Z,E*-9,12 : 14Ac by *P. interpunctella* at 34°C.

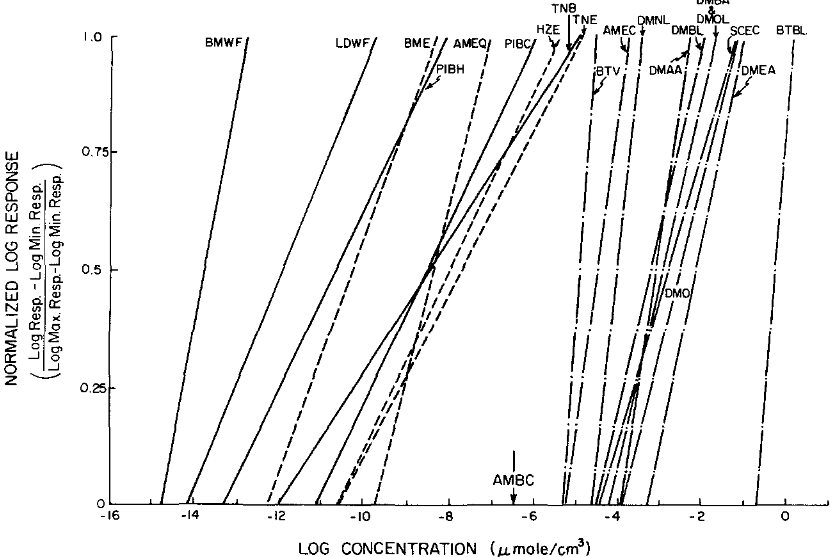

FIG. 5. Comparison of normalized behavioral and neurophysiological responses of several insect species to various odorants. Solid lines indicate behavioral response. Dashed lines indicate EAGs in response to a sex pheromone component. Dot-dashed lines indicate EAGs in response to a non-pheromonal odorant. AMBC is the behavioral threshold of female *A. mellifera* to caproic acid. See Table 5 for key to abbreviations.

TABLE 3. EAG BIOASSAY OF Z-7:12AC DILUTION RATIO IN WIND TUNNEL[a]

Dispenser dose (μg)	log EAG response ($-$mV)	Log concentration (μmol/cm^3) At dispenser outlet	At end of tunnel	Dilution ratio
3.16	-0.056	-6.70	-8.0	20.0
10.0	0.223	-5.95	-7.0	11.2
31.6	0.422	-4.50	-6.1	39.8

[a]The concentration at the end of the tunnel was estimated from Figure 3. The concentration at the dispenser outlet was estimated from the release rates in Figure 1, with the release rate divided by 50 cm^3/min to calculate concentration.

quently, we have revised upward the estimates of pheromone concentration in the two bioassays and recalculated the stimulus–response regression equations.

The pheromone concentration in the wind tunnel was recalculated from the new emission rate curves listed in Table 1 and the mean wind-tunnel dilution factor in Table 3. The regression constants of Eq. 1, based on the revised concentrations, are listed in Table 4, and the new concentration–response regressions are shown in Figure 4. The new estimates indicate that 50% upwind anemotaxis was elicited in *T. ni* at concentrations above about 1×10^{-7} μmol/cm^3 of Z-7:12Ac. Extrapolating the curve to the 25% level, at log percentage upwind flight = 1.4, we find that the threshold occurs near 1×10^{-12} μmol/cm^3. The range of anemotactic response by *P. interpunctella* at 23°C was similar to that for *T. ni.* At 34°C (PIBH), the magnitude of response of *P. interpunctella* was higher than at 23°C (PIBC), but the slopes of the two curves were statistically indistinguishable.

DISCUSSION

The remainder of this report applies a quantitative perspective to problems of behavioral and neurophysiological response. We begin with some comparisons of pheromone emission rates from glass-tube dispensers and natural emitters, and apply the dispenser calibrations to interpretations of behavioral responses in a wind tunnel. Then we discuss how sensation magnitude theory combines the results of this and a number of other studies in the literature into a common framework.

One additional point must be addressed briefly, i.e., the choice of odorant concentration as the common parameter for interrelating the behavioral and neurophysiological responses. It has been noted elsewhere (Elkinton and Cardé,

[a]The regression equations have the form: log(response) = $A + B$ log(concentration), where A and B are regression constants in the table. The concentration is specified in μmol/cm^3. Details of the response measures and references are specified in the bioassay keys in Table 5.

1984; Mankin and Mayer, 1983a) that an odor receptor neuron reacts to the rate of adsorption of odorant onto its receptor sites rather than to the odorant concentration. The rate of adsorption, however, is directly proportional to the concentration because the final approach of odorant molecules to the antenna is controlled by molecular diffusion over a thin boundary layer. The rate of adsorption (μmol/sec) is equal to the overall flux [μmol/(cm^2 sec)] times the collecting surface area for the receptor site (cm^2), which is the sensillum surface. The flux in turn is equal to the concentration (μmol/cm^3) times a parameter called the deposition velocity, which for pheromonal molecular diffusion is about 1 cm/sec (Mankin and Mayer, 1984). Because the receptor surface area and the deposition velocity vary negligibly relative to the concentration, it is convenient to use the more familiar parameter of concentration as the unit of stimulation.

Comparisons between Pheromone Emission Rates of Glass-Tube Dispensers and Natural Emitters. The evaporation of pheromone from a relatively inert surface like glass or from a pheromone gland both occur by similar physical processes; consequently, any differences in the range of release rates between glass dispensers and natural emitters is due primarily to differences in the exposed surface area. There are examples in the literature where the emission rate of pheromone from a female insect is comparable to the maximal emission from a glass-tube dispenser. The emission rate of Z-7 : 12Ac from *T. ni* virgin females has been measured at 3.1×10^{-5} μmol/min by Sower et al. (1971), 5.3×10^{-5}–9.7×10^{-5} μmol/min by Bjöstad et al. (1980), and 1.06×10^{-5} μmol/min by Baker et al. (1981). These rates are about an order of magnitude less than the maximum rates for the glass dispensers in Figures 1 and 2.

Another example where the maximal emission rate from a glass tube and from a female are likely to be similar is the measurement of the emission rate of (+)-*cis*-7,8-epoxy-2-methyloctadecane from *Lymantria dispar* L. females. Charlton and Cardé (1982) reported that the maximal emission rate from a virgin female was 3.8×10^{-3} μmol/min and the mean rate was 1.2×10^{-3} μmol/min. In contrast the pheromone emission rate from *P. interpunctella* females,

1.95×10^{-7} μmol/min (Sower and Fish, 1975), falls near the lower limit of the dispenser release rate calibration in Figure 1 at $10^{-6.7}$ μmol/min.

General Comparisons of Pheromone Concentrations in Plumes Emitted by Dispensers and in Plumes from Natural Emitters. It is somewhat misleading to compare the dispensers with the females solely on the basis of emission rate. Typically, the emitting surface of the dispenser is greater than the area of the pheromone gland, so the dispenser can have a higher overall emission rate than the gland. But the pheromone concentrations in the emitted plumes of the dispenser and the female cannot exceed a limit imposed by the saturated vapor concentration. This concentration limit is often at the upper levels of emission rates of either pheromone glands or pheromone dispensers.

Consider, for example, the case of a hemispherical pheromone gland with a radius between $r = 0.03$ and $r = 0.3$ cm. The maximum physically possible release rate, *ER*, can be estimated from the equation (Hirooka and Suwanai, 1976):

$$ER = 2\pi r D C_v \tag{2}$$

where D is the diffusion coefficient (about 0.04 cm^2/sec), and C_v is the saturated vapor concentration. Values for C_v can be estimated from the literature. Hirooka and Suwanai (1976) list saturated concentrations of 7.0×10^{-5} μmol/cm^3 for 12Ac and 2.8×10^{-5} μmol/cm^3 for 14Ac. Olsson et al. (1983) found the saturated vapor pressure for Z-7 : 12Ac to be 0.562 *Pa*. This can be converted to saturated vapor concentration by applying the Ideal Gas Law, $PV = nRT$: for 1 $Pa = 0.987 \times 10^{-5}$ atm, 1 atm $= 1.01 \times 10^5$ newton/m^2, and $R = 8.31$ newton m/°K/mol, the saturated vapor concentration at $T = 290$°K (= 20°C) is 2.30×10^{-4} μmol/cm^3 ($1 \times 10^{-3.64}$ μmol/cm^3). For 12Ac with $r = 0.3$ cm, this release rate is about $1 \times 10^{-3.0}$ to $1 \times 10^{-3.5}$ μmol/min, and for 14Ac with $r = 0.03$ cm, it is about $1 \times 10^{-4.9}$ μmol/min. The maximum possible release rate for *T. ni* females is near the measured release rate. Based on the above, we conclude that *T. ni*, but not *P. interpunctella*, females release sex pheromone at nearly the highest possible rate.

As with the female *T. ni*, the concentration of Z-7 : 12Ac in the plume from the glass dispensers approaches but does not completely reach saturation. When the release rate is $1 \times 10^{-2.0}$ μmol/min (about the upper limit in Figure 2), the concentration of Z-7 : 12Ac in the dispenser plume is 5×10^{-5} μmol/cm^3 at a dispenser flow rate of 200 cm^3/min, an order of magnitude less than the saturated vapor concentration of about 2.3×10^{-4} μmol/cm^3. The release rates of pheromone from *T. ni* and *L. dispar* females, and from the dispenser, are limited physically as the concentrations approach the saturation vapor concentration.

We expect that similar physical limitations occur for any dispenser operating at physiological temperatures. Thus, when the moth emits pheromone at its highest possible rate, the concentration in its emitted plume will be about

the same as in the plume from the most efficient artificial dispenser. The dispenser can release more pheromone into a larger volume, e.g., by increasing either the surface area or the air flow through the dispenser, but the concentration can be no higher than saturation. It is thus no surprise that calling insects often compete well with field traps.

Comparison of Anemotactic and EAG Response in a Wind Tunnel. The utility of combining dispenser calibration data with stimulus–response data for EAG and behavioral bioassays into a common interpretive framework is illustrated by a reexamination of the anemotactic flight bioassays of *T. ni* and *P. interpunctella* in Mayer (1973) and Mankin et al. (1980). In the original reports, data were presented for pheromone doses up to about 1 μmol (100 μg). This dosage is above the transition point where the emission rate from the dispenser becomes independent of dose (Figure 2). In these assays, the response to increasing doses had seemed anomalous because, in contrast with lower doses, the percentage of upwind flight to the pheromone source failed to increase with dose. On the assumption that the emission rate was proportional to dose, it was hypothesized that a qualitative change in the behavioral response had occurred, i.e., that the moths were induced to switch to a more intensive search pattern in the presence of high pheromone concentrations. Similar hypotheses have been proposed to explain reductions in pheromone trap captures at high pheromone concentrations (e.g., Helland et al., 1985).

Although the original hypothesis indeed may still be valid, the calibration results in this report suggest an alternate explanation for the stimulus–response curves in the *T. ni* and *P. interpunctella* bioassays. Both the behavioral and EAG responses level off when the dose is increased above a critical level. The apparent anomaly disappears when either measure of response is referenced to the actual pheromone concentrations.

General Comparisons of Behavioral and Neurophysiological Responses. To proceed into a more general discussion of interrelationships between insect behavioral and neurophysiological responses requires an assumption that usually has been applied only to vertebrates. The assumption is that a graded olfactory input leads to the production of a graded "sensation" in the CNS that mediates a graded output or behavioral response.

The idea of sensation has considerable importance for the interpretation of insect behavioral and neurophysiological responses because it can be used to generate a number of testable hypotheses. One hypothesis in particular, proposed by Stevens (1975), has been validated many times in vertebrate physiology. Stevens proposed that the magnitude of sensation, and consequently of behavioral response, is a power function of the stimulus intensity. One form of the power function is Eq. 1, which also can be expressed as (Mankin and Mayer, 1983b):

$$R = R_0(C - T)^b \tag{3}$$

where R is the chosen measure of response intensity, R_0, T, and b are regression constants, and C is the odorant concentration. The regression constant, T is analogous to a response threshold, and b is analogous to the conversion factor of an electrical transducer. The parameters T and b are of particular interest in comparisons across bioassays because they are independent of the method of measuring the response, and they may provide a measure of the transduction and central processes that result in behavior.

The power function relationship appears to be valid for all of the insect neurophysiological and behavioral stimulus–response relationships that we have measured or found in the literature, as can be seen in Figure 5. Because a number of different responses were examined, each with a different scale, we transformed the different responses in Figure 5 into a common vertical scale. The transformation procedure makes use of the fact that the concentration, C, and the exponent, b, in the power function (Eq. 3) are independent of the response measure. This permits the different responses to be compared on an equal basis by using a normalizing function (cf. Mankin et al., 1980):

$$\text{normalized log resp.} = \frac{\text{log resp.} - \text{min. log resp.}}{\text{max. log resp.} - \text{min. log resp.}} \tag{4}$$

It should be noted that stimulation must be given over the full range from zero to maximal response to obtain the denominator in Eq. 4. Otherwise the range will be truncated. The regression constants of the stimulus–response relationships in Figure 5 are shown in Table 4.

There are two patterns that appear upon inspection of Figure 5. One is that neurophysiological responses occur at concentrations no more than about two orders of magnitude above the behavioral responses. The second is that responses to the most behaviorally significant pheromone components and responses to other odors, such as host-plant compounds, fall into two distinct groups. Behavioral, EAG, and single-unit responses to sex pheromone components are in the range 1×10^{-9}–1×10^{-15} μmol/cm^3. Responses of EAGs to other chemicals are four or more orders of magnitude less sensitive. An estimate of the threshold can be obtained from the points where the regressions cross the axis. This is the point of 25% response (log = 1.4).

Interpretation of Relationships among Behavioral and Neurophysiological Responses. The two patterns of consistent relationships between behavioral and neurophysiological responses in Figures 3 and 4 may reflect some underlying similarities in the way these different insect olfactory systems operate. A simple model of the olfactory process can be constructed to explain these relationships from concepts of sensation and signal detection theory. The details of such a model are presented in Mankin and Mayer (1983a), Mayer et al. (1984), and Mayer and Mankin (1985).

In brief, the model comprises: (1) a number of detectors that individually

respond at a level that is a power function of the stimulus intensity; (2) a central processor that linearly sums the individual responses to give a sensation; and (3) a behavioral output that is proportional to the intensity of sensation. The summing at a hypothetical central processor explains how a behavioral response can be measured at stimulus levels where a corresponding response cannot be measured at a single receptor neuron, i.e., why the behavioral response can be detected at concentrations up to two orders of magnitude below the single-unit response. This idea is supported by experimental evidence that the pheromone receptor neurons converge into a macroglomerulus from which interneurons emerge that respond to peripheral stimulation at levels below what can be detected in single-unit recordings (Boeckh and Boeckh, 1979).

The EAG fits into the model as a correlative of the summed input to the central processor. The EAG is presumed to be a bulk measure of the summed generator potentials that drive the action potential responses of the receptor neurons; consequently, the EAG is predicted to be a power function of the stimulus intensity (Mayer et al., 1984).

If there were no uncertainties in the detection of the odorant or in the behavioral and neurophysiological measures of the response, the different behavioral and neurophysiological response curves for each insect in Figure 5 would merge; i.e., they would simply be different but equivalent measures of the hypothetical curve for sensation intensity. However, there are many internal uncertainties in the insect's detection of the stimulus, as well as external measurement uncertainties in behavioral and electrophysiological bioassays. According to signal detection theory, increases in the level of uncertainty will shift the response curve to higher stimulus levels (Green and Swets, 1974). Consequently, we can consider each of the response curves in Figure 5 to represent a curve for sensation intensity that has been shifted to the right by an amount that depends on the external and internal uncertainties. The curve for a single olfactory neuron will be shifted, for example, partly because summation occurs at the central processor. The EAG curve will be shifted because of electrical losses in the antenna that decrease the sensitivity of external measurements.

We can apply the model to two sets of data in Figures 3–5 where EAG and behavioral responses to pheromone were measured. For convenience, consider the horizontal intercept of each response curve to be a type of threshold (although this is not strictly equivalent to T in Eq. 3). According to the model, the EAG thresholds for both *T. ni* and *B. mori* are higher than the behavioral thresholds for pheromone because of differences in the (combined) external and internal uncertainties.

Next, suppose that these relationships hold for other insects. If the activation or the flight response of *H. zea* to *Z*-11:16Al correlates with the neurophysiological response in the same way that the behavioral and neurophysiological responses to Z-7:12Ac correlate in *T. ni*, then the behavioral threshold for *H. zea* should be about 1×10^{-12} μmol/cm^3, the apparent threshold for *T.*

ni. The correlation seems plausible because the measurement procedures and uncertainties are similar. The EAG curve for the queen substance, a sex pheromone component of *A. mellifera* (Kaissling, 1971), is similar to the curve for *T. ni*. Thus, it can be expected that the behavioral response occurs at about 1×10^{-12} μmol/cm^3 also.

Finally, we can apply the idea of sensation to interpretation of the EAG responses to non-pheromonal compounds. In Figure 5, EAGs for non-pheromonal compounds do not begin to occur until much higher concentrations than for pheromones, 1×10^{-6}–1×10^{-4} μmol/cm^3. By analogy with the responses for pheromones, behavioral thresholds for these chemicals perhaps occur at concentrations no lower than two orders of magnitude below the EAG threshold, about 1×10^{-6} μmol/cm^3. The measured behavioral threshold of *A. mellifera* to caproic acid (Schwarz, 1955), AMBC in Figure 5, is in general agreement with such a hypothesis.

(Received March 14, 1986; accepted April 4, 1986)

Abstract—The hypothesis that low pH modifies the response of salmonids to certain olfactory stimuli was tested. An interactive video–computer system was used to monitor the behavior of juvenile Atlantic salmon (*Salmo salar*). At a pH of 7.6, animals were attracted to glycine and avoided L-alanine. These effects were dose-dependent, with a threshold of 10^{-7} M. The response of the fish to both amino acids changed when the pH of the test chamber was gradually lowered from 7.6 to 5.1; they became attracted to L-alanine and indifferent to glycine. These effects were reversible with a return to pH 7.6. Our findings suggest that acid rain may contribute to reductions in salmonid populations in acidified rivers by impairing the recognition of olfactory cues by salmon during their spawning migration.

Key Words—Acid rain, salmon, *Salmo salar*, pH, olfaction, computer, video, migration, glycine, L-alanine.

INTRODUCTION

Acidification of rivers and streams throughout Europe and North America has been implicated in the decline of anadromous fish populations (Wright et al., 1975; Leivestad et al., 1976; Schofield, 1980). Population decreases have even been observed in rivers where the pH is above levels considered to be lethal[1] (Haines, 1981; Muniz, 1981; Watt, 1981; Watt et al., 1983). Many factors associated with moderately acidified waters may play a role in reducing or, in some cases, eliminating the recruitment of new animals into the population

[1] The lethal pH level for adult Atlantic salmon is 4.5, parr, 4.0, eggs, 3.5 (Daye and Garside, 1977).

0098-0331/87/0300-0533$05.00/0 © 1987 Plenum Publishing Corporation

(Neville, 1979a,b; Daye and Garside, 1980; McDonald, 1983; McDonald et al., 1983). We have been testing the hypothesis that changes in pH alter salmonids' sense of smell and thus may modify their normal migratory behavior.

It is widely accepted that the freshwater spawning migration of salmonids, like many species of anadromous fishes, is controlled to a great extent by olfactory cues in the environment (Hasler, 1957, 1960a,b; Groves et al., 1968). If the olfactory sense of these animals is altered due to a moderate reduction in the pH of the water (pH 4.5–6.5), migrating fish may not be able to respond appropriately to necessary olfactory cues (Sutterlin, 1974; Fritz, 1980). Although there are some field data available which suggest that adult salmon halt upstream spawning migration and may return downstream when presented with copper and zinc pollution (Saunders and Sprague, 1967), little data are presently available concerning the effect of acidic precipitation on homing behavior or salmonid olfaction (Hara, 1976b; Sutterlin, 1974). We have examined the behavioral response of juvenile Atlantic salmon to amino acids and taurocholic acid, and the modification of their responses by changes in the ambient pH. Our results indicate that pH does have a significant impact on the behavioral response of salmonids to certain olfactory stimuli, and thus it may be a significant factor contributing to the reductions in salmonid populations reported in many moderately acidified rivers.

METHODS AND MATERIALS

Parr-stage Atlantic salmon (*Salmo salar*), approximately 15–20 cm long and 10.0–15.0 g in weight were used in all experiments. Fish were obtained from the Milford State Hatchery in Milford, New Hampshire. They were held in closed-recirculating holding systems at 10°C. Water quality was checked weekly, and the water source was the same as that used in the behavioral experiments.

A two-channel preference–avoidance chamber (Figure 1) that included a common area (Greer and Kasokoski, 1978) was used to monitor the behavioral responses of the juveniles to specific olfactory stimuli. At the beginning of each experiment, four fish were placed in the common area for a 15-min acclimation period. The experiment was initiated by removing the barrier and allowing the animals to explore the chamber (Figure 1). The pH was monitored throughout the experiments with an Orion pH meter equipped with an automatic temperature compensation probe. The response to specific olfactory stimuli was determined by recording movements on videotape and then converting these movements to digital form using an interactive video–computer system designed in our laboratory (Royce-Malmgren and Watson, 1986). To create a digitized track of the fish, the videotaped experiment was viewed on a high-resolution color monitor with computer generated targeting cross hairs overlayed on the image of the chamber by an Ambico special effects generator (ASEG, Figure 1). The

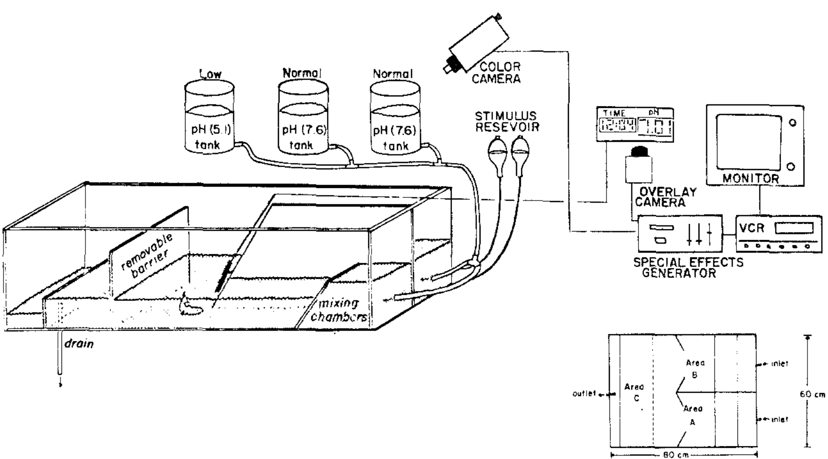

FIG. 1. Test chamber and video–computer data collection system. Fish were introduced into area C of the test chamber, behind the removable barrier. Dechlorinated, aerated tap water (pH 7.6) from overhead storage tanks flowed continuously through the chamber, at a rate of 3 liters/min. Following an acclimation period, the removable screen was lifted to start the experiment. During the control period, no olfactory stimulus was added. During the test period, stimulus was added to area A or B from the stimulus reservoirs. The concentration of stimulus declines as the water from area A and area B mix in area C. This creates a concentration gradient around the tank from the stimulus input to the opposite side. This gradient has been confirmed using dyes with fish present. After 30 min, pH was reduced over a 15-min period, using water from overhead storage tanks whose pH was lowered with a solution of 50% H_2SO_4 and 50% HNO_3 (0.5 M) to simulate the approximate composition of acid rain. Following the acidification, the water in the overhead holding tanks was thoroughly aerated to drive off excess CO_2 and equilibrate O_2 levels between tanks. The pH was maintained for 30 min and then returned to the original level over another 15-min period and held at that level for the remaining 30 min. The pH and temperature of the water were monitored throughout the experiment and stored on videotape by means of an overlay camera. Other physical parameters were determined at the end of the experiment and recorded on the videotape. A Hitachi/Everex model 8A color video camera mounted above the chamber was used to record the experiment, and this video signal along with that of the overlay camera were combined by a special-effects generator and transmitted to a Panasonic NV-8399 video casette recorder (VCR) for permanent storage. Each fish carried a color coded tag for identification.

targeting cross hairs, controlled by the pen of a digitizer tablet, were used to track individual fish in the experiment.

The computer calculated x–y coordinates, based on information from the digitizer tablet and individual test chamber calibration factors. These coordinates were recorded on data disks at time intervals specified by the technician. The pH information for each experiment was entered into a separate data disk

file. Stimulus concentration, channel with stimulus, and other pertinent information[2] about the experiment were added to the end of the tape to ensure that the technician analyzing the experiment was unaware of the presence, location, quality, and quantity of the stimulus. The digitized tracks of individual animals were plotted and the animal's distance from the source of stimuli, time per area of chamber (both measures of attraction or avoidance) and swimming velocity were measured, at user-determined intervals.

Amino acids have been used successfully to study the olfactory system of various fish (Idler et al., 1956, 1961; Sutterlin and Sutterlin, 1971; Hara, 1973, 1976a) and crustacean chemoreception (Mackie and Shelton, 1972; Derby and Atema, 1978). Initially, we tested the following seven amino acids to determine if they would elicit a consistent response from the Atlantic salmon in our test chamber: L-alanine, glycine, L-leucine, L-serine, L-cysteine, L-glutamine, and L-methionine. All amino acid solutions were prepared fresh daily with double-distilled, deionized water in acid-washed glassware. These compounds were chosen for two reasons: (1) when applied to the nares of Atlantic salmon (*Salmo salar*), they produce consistently large responses recorded from the olfactory bulb (Sutterlin and Sutterlin, 1971); and (2) certain of these amino acids are known to elicit behavioral responses in fish (Hoese and Hoese, 1967; Sutterlin and Sutterlin, 1971; Caprio, 1977; Goh et al., 1979; Goh and Tamura, 1980; Atema et al., 1980) and a variety of other animals (McLeese, 1973; Fuzessery and Childress, 1975; Allison and Dorsett, 1977). Taurocholic acid was also screened due to its implication as a naturally occurring olfactory attractant for Arctic char (*Salvelinus alpinus*) and other salmonids (Doving et al., 1980; Stabell, 1984).

Nasal occlusion experiments were conducted to determine the sensory modality involved in the observed behaviors. After running a screening experiment under normal conditions with a stimulus concentration of 10^{-4} M, or 10^{-6} M, the fish were removed and two of the four fish had their nares occluded with Vaseline. The other two fish were sham controls and had distilled water injected into their nares. All four fish were allowed to recover for 1 hr and retested under circumstances identical to the initial testing. This protocol was repeated with five groups of four fish.

The data were analyzed using Student's *t* tests and chi-square tests. Chi-square tests for homogenicity of replicates were performed and accepted for replicates of all tests with the four compounds that elicited reproducible behavioral responses; thus replicates were pooled. Two way analyses of variance (ANOVAs) were performed on the velocity data in order to determine homogenicity of activity levels both between experimental protocols and between fish within a single experiment.

[2]Physical properties of the water. Temperature 10°C ± 1°, Ca^{2+} concentration 6.8 ppm ± 2.3; alkalinity 12.3 ppm ± 3.2.

RESULTS

Eight compounds were screened to determine if they had an effect on the behavior of salmonids. Fish were attracted to glycine ($>10^{-6}$ M). L-alanine, L-glutamine ($>10^{-6}$ M), and taurocholic acid ($>10^{-6}$ M), all evoked significant ($P \leq 0.001$) avoidance responses when compared to controls. Taurocholic acid elicited the strongest avoidance response followed by L-glutamine and then L-alanine. L-Leucine, L-methionine, and L-cysteine elicited no detectable response (neither attraction or avoidance), and L-serine elicited inconsistent behavior.

We conducted most of our experiments with one compound that produced attraction at a normal pH (pH 7.6, glycine, Figure 2A) and one that fish avoided at a normal pH (pH 7.6, L-alanine, Figure 2B). When glycine was added to one of the channels in the test chamber, fish were attracted to the area of the test chamber containing the highest concentration of this amino acid (Figure 2A). The threshold for this effect was 10^{-7} M ($P \leq 0.001$, Figure 2A, bottom). As the concentration of glycine was increased, the preference of the fish for the side of the chamber containing glycine also increased, up to a maximal preference response at a concentration of 10^{-4} M glycine ($P \leq 0.001$, Figure 2A, bottom). In contrast, L-alanine evoked an avoidance response. The threshold for this effect and the concentration that gave maximal avoidance were very similar to the behavioral threshold and maximal preference response obtained with glycine (Figure 2B).

After having their nares occluded with vaseline, fish which had previously been attracted to glycine spent equal amounts of time in all three areas of the test chamber. Therefore, the amino acids required access to the olfactory receptors in the nares in order to elicit behavioral responses (Figure 3).

The behavioral response of the salmon to L-alanine and glycine changed markedly when the pH of the test chamber was gradually lowered from 7.6 to 5.1 (Figure 4). The initial attraction of fish to glycine changed to a neutral response (Figure 4A). Furthermore, fish that avoided L-alanine at a normal pH were attracted to L-alanine at an acidic pH of 5.1 (Figure 4B). The effect of pH was reversible in all experiments.

Behavior was not altered in response to changes in pH alone. The behavioral parameters of fish in near-neutral water (pH 7.6) was comparable to that in acidic water (pH 5.1, Table 1). When acidic water (pH 5.1) was perfused into one side of the test chamber and near-neutral water (pH 7.6) was perfused into the other side, fish displayed area preference behavior comparable to that observed under control conditions, when identical water was entering both channels (Table 2). In both cases, there was no significant difference in the behavioral parameters of the fish in near-neutral (pH 7.6) and acidic (pH 5.1) water.

The fish did not appear to prefer one area of the chamber over another

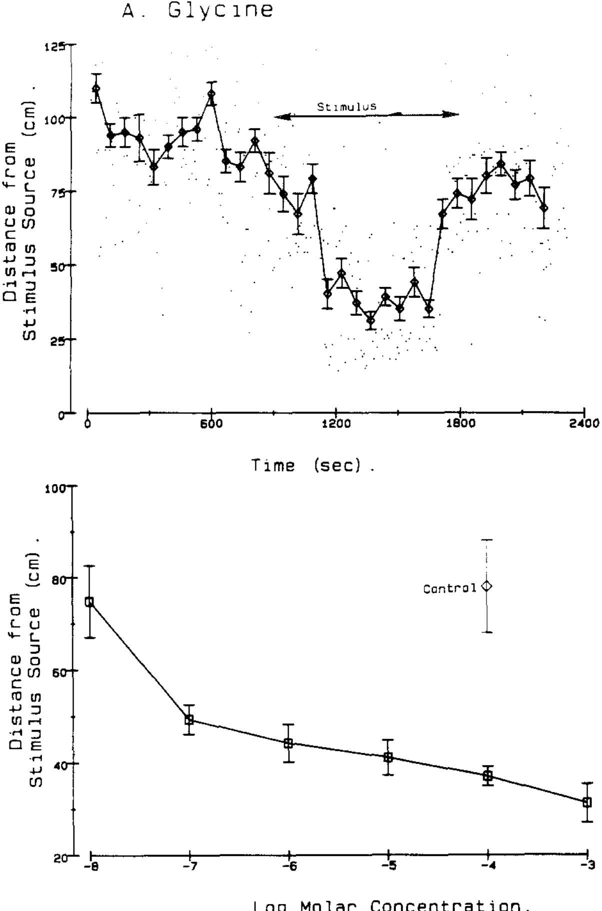

FIG. 2. Response of fish to specific amino acids. (A) Top: Response of eight fish to glycine (10^{-5} M, stimulus bar). Distance from the stimulus is used as an indication of preference for, or avoidance of, a particular olfactory stimulant. Diamonds ($\pm$SEM) are means of eight fish, averaged over 200 sec. Dots are mean values of eight fish, averaged every 9 sec. Prior to stimulant introduction, fish did not show a preference for either side of the chamber, but when glycine was added to one side, the fish tended to move into that area and remain there for longer periods of time. Bottom: The attraction to glycine was dose-dependent, with a threshold of between 10^{-8} M and 10^{-7} M (N = 6–10 fish/concentration). (B) Top: Response of eight fish ($\pm$SEM) to L-alanine (10^{-5} M). The fish showed no preference for either side of the chamber until L-alanine was added. Fish then moved away from the source of the stimulus. Bottom: The avoidance response was dose-dependent (N = 6–10 fish/concentration).

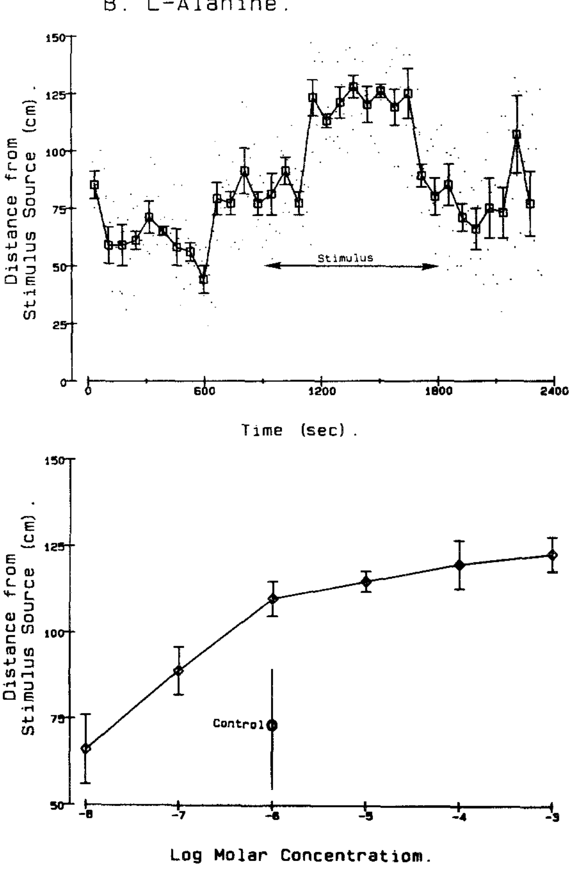

FIG. 2. Continued

under all control conditions, and we randomly introduced stimuli into one of the two input areas (A or B) during our experiments (Figure 1, see stimulus source arrows Figure 4A and 4B, top). In addition, each fish appeared to behave as an individual, rather than as a member of a school. This was apparent from visual inspection of the videotaped experiments, and it was confirmed statistically using a two-way ANOVA analyzing the velocity of all four fish at different pH levels in each pH modulation experiment. While there was no significant variation in velocity for individual fish between pH levels, there were significant ($P \leq 0.05$) differences between velocities of different fish at the same pH level, thus demonstrating that no schooling was occurring.

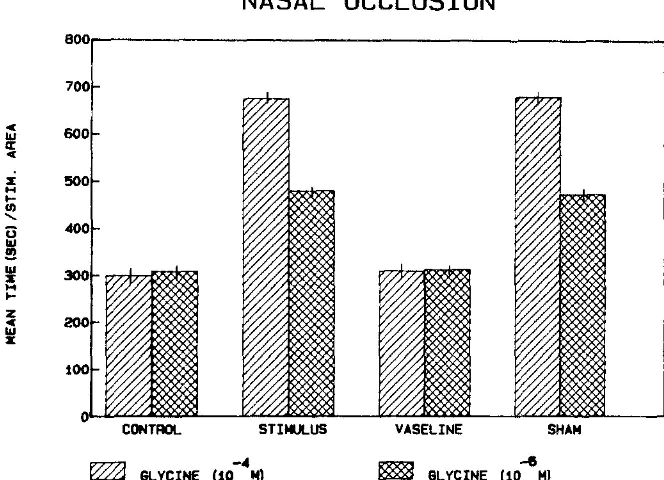

FIG. 3. Response of fish to glycine with and without nares occluded using Vaseline. Under control conditions, with no stimulus present, fish moved randomly about in the test chamber. When glycine was present (stimulus) fish spent more time ($\pm$SEM) in the area of the chamber with the highest concentration of glycine. When those same fish had their nares occluded with Vaseline (Vaseline), they behaved as if no stimulus was present. Sham (sham) control fish, with distilled water injected into their nares rather than vaseline, responded to glycine in a normal manner. At both concentrations of glycine, the responses of the Vaseline occluded and control fish were significantly ($P \leq 0.001$) different from the stimulus and sham control fish ($N = 20$).

DISCUSSION

To our knowledge this is the first demonstration that changes in the pH of surface waters, comparable to those documented in nature, are capable of altering the "normal" behavioral response of fish to olfactory cues. The degree to which our findings pertain to fish migration and behavior in the field remains to be determined. One major problem is that the role of specific substances in fish olfaction and homing is not well understood. Overall, with few exceptions, the specific significance of free amino acids to olfactory-related behavior is not known, and the importance, if any, that amino acids play in salmonid fresh water migration has yet to be demonstrated. The environmental cues which make home stream water unique so that returning adults recognize it and departing smolts imprint to it are at best only vaguely defined. It is considered by many to be heat-labile, volatile, neutral, and dialyzable (Ueda et al., 1967; Hara et al., 1973; Hara, 1976a; Idler et al., 1961; Bodznick, 1978). Others believe a nonvolatile fraction to be important (Atema et al., 1973). Amino acids,

usually in mixtures, can elicit specific behaviors such as exploration and feeding in the goby (*Gobiosoma bosci*) (Hoese and Hoese, 1967) and avoidance by Pacific salmon (Idler et al., 1956, 1961). However, the degree to which amino acids influence the homing behavior of salmonids is not known.

We chose to use amino acids for olfactory stimuli because previous electrophysiological data indicated that the olfactory system responded to certain amino acids in a dose-dependent manner and, in our hands, they gave us reliable, quantitative, avoidance–attraction responses. The dose–response curves that we obtained using our behavioral assay are similar to those determined with the same compounds using electrophysiological techniques (Hara, 1973). Experiments are presently underway to determine how pH affects the behavioral response of salmonids to natural stimuli, such as conspecific odors and home-stream water.

The differential responses of Atlantic salmon to the same compound at two different pH levels is probably the result of a modification of some component of the olfactory system. The level at which this change takes place is not clear, but it may occur at any one, or a combination of levels; receptor site alteration, stimulus molecule charge distribution, or interaction between the two. These receptors are thought to be membrane proteins with anionic and cationic binding sites (Hara, 1982). Hara (1976b) used olfactory bulb recordings to monitor the response of adult rainbow trout (*Salmo gairdneri*) to numerous amino acids at different pHs. He recorded maximal responses to individual amino acids at their isoelectric points (both glycine and L-alanine have isoelectric points of 6.02; Lehninger, 1982), indicating changes in charge may interfere with normal amino acid-receptor interactions. Since the olfactory receptors are exposed to the environment, with limited protection from a permeable mucus layer, they are subject to changes in the external environment (Brown et al., 1982). The fact that our pH effects were reversible suggests that at pH 5.1 the receptors were not permanently damaged. The manner in which one or more of the components of the olfactory system are consistently and reversibly altered by pH, both in electrophysiological (Hara, 1976b) and behavioral studies, remains to be determined.

Our investigations thus far have been limited to juvenile salmonids. We have tested chinook salmon (*Oncorhynchus tshawytscha*) juveniles as well as Atlantic salmon juveniles, and their responses were similar in all cases. Although we do not presently know the extent to which our data on juveniles pertain to adults, it has been shown that salmon parr have the ability to discriminate between odors in much the same way as adult salmon (Stabell, 1982, 1984), and our preliminary data indicate that pH influences the way adult salmon respond to taurocholic acid (Royce-Malmgren and Watson, in preparation). If low pH alters the manner in which adult fish respond to the odor of their home stream water in the same way it modifies the olfactory-related behavior of ju-

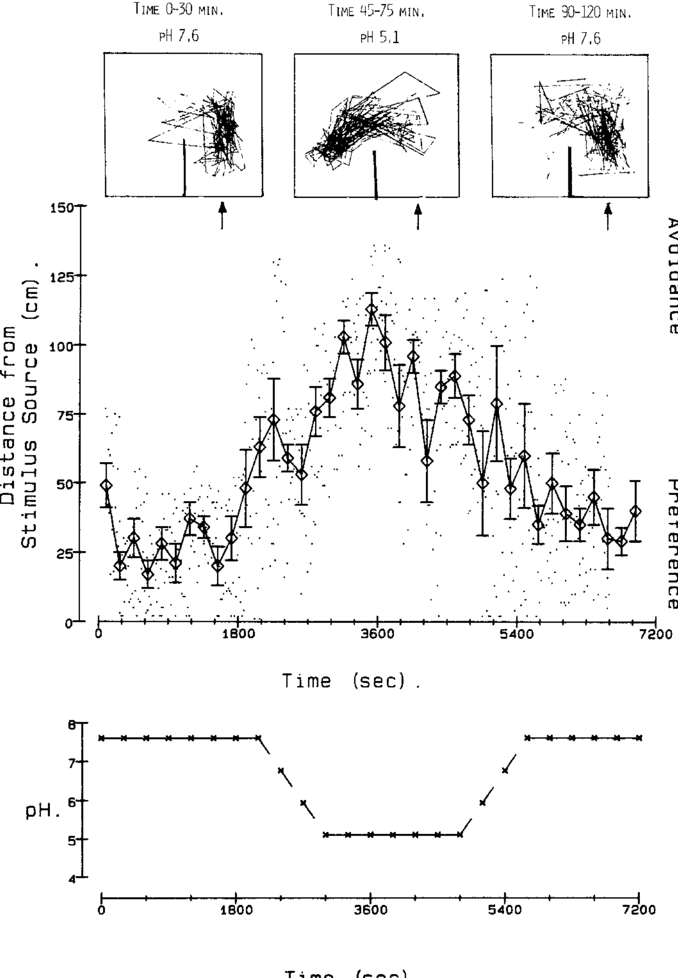

FIG. 4. Modification of the behavioral response of Atlantic salmon to amino acids by pH. (A) Response to 10^{-4} M glycine while the pH of water in the test chamber was changed from 7.6 to 5.1 and then back to 7.6. Top: The track of an individual fish during the course of the experiment. Arrows indicate the source of the glycine. During the initial 30 min of the experiment, the fish spent most of its time in the side of the chamber containing the highest concentration of glycine. However, when the pH was gradually lowered to 5.1 (see bottom graph), the fish moved randomly about the chamber. When the pH was returned to 7.6, the fish was again attracted to the glycine. Center: The aforementioned experiment was repeated with 20 different fish and the results were

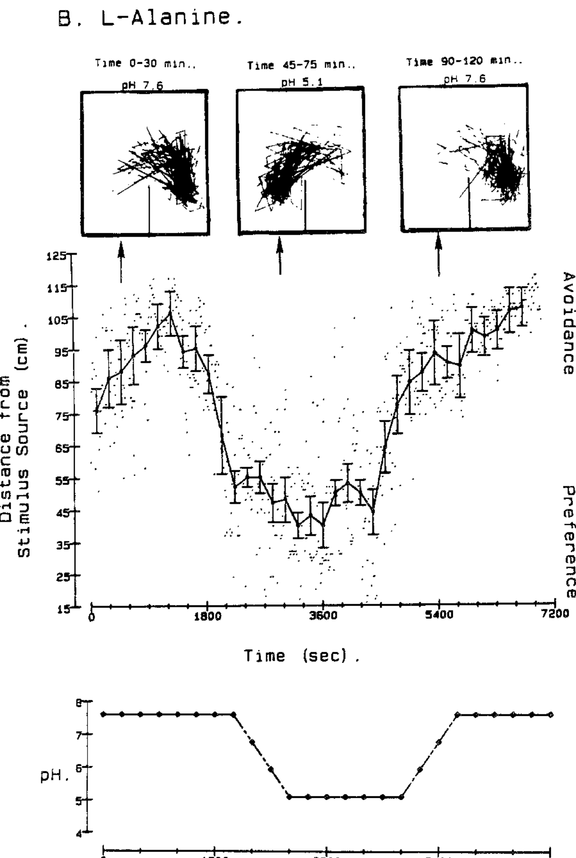

FIG. 4. Continued tabulated and plotted. Diamonds ($\pm$SEM) are means of 20 fish, averaged over 200 sec. Dots are mean values of 20 fish, averaged every 9 sec. (B) The response to L-alanine (10^{-4} M) during pH changes. Center: At a pH of 7.6, the fish avoided the L-alanine, but when the pH (see bottom graph) was lowered to 5.1, they were attracted to the stimulus. Note that in the track of the fish shown, the L-alanine was introduced into the left-hand side of the test chamber (in contrast to the glycine experiment shown in A, top). The side of the chamber used for the stimulus source was varied randomly for each set of experiments. The tracks also show that the activity of the salmon remained fairly constant throughout the course of the experiment.

TABLE 1. COMPARISON OF BEHAVIORAL PARAMETERS OF ATLANTIC SALMON IN ACIDIC (pH 5.1) VS. NEAR-NEUTRAL (pH 7.6) WATER (N = 20)

	pH 5.1	pH 7.6
Mean velocity (cm/sec)	7.5 ± 1.3[a]	7.7 ± 1.1
Mean distance (cm to stimulus source)	75.9 ± 1.5	74.9 ± 1.5
Mean time (sec)/area with stimulus	592.5 ± 13.5	622.0 ± 16.8

[a] Standard error of means.

TABLE 2. RESPONSE OF ATLANTIC SALMON PARR TO ACIDIC (pH 5.1) WATER (N = 20)

Control[a]		Experimental	
Area	Time (sec)/area	Area	Time (sec)/area
A	614 ± 15.8[b]	A (pH 5.1)	592 ± 11.6
B	604 ± 10.4	B (pH 7.6)	589 ± 14.9
Common	580 ± 18.9	Common	619 ± 12.2

[a] The pH was 7.6 throughout the test chamber.
[b] Standard error of means.

venile salmon, then their ability to locate a suitable spawning site may be affected. As a result, fish would become dispersed and spawn in areas unsuitable for the development of eggs, fry, and juveniles. This could eventually lead to a reduction in recruitment and a decline in the salmonid population, even at the nonlethal pH levels now common in many New England and Canadian rivers.

Acknowledgments—We would like to thank Dr. Hunt Howell, Dr. Phil Sawyer, Dr. Marv Freadman, Dr. Jelle Atema, and Dr. David Bodznick for their critical reviews and suggestions on earlier drafts of the manuscript. We would also like to thank the Milford Fish Hatchery in Milford, New Hampshire, for the fish and food, and Dr. Phil Sawyer for his support and advice. Abstract—The synthesis of the enantiomeric 14-methyl-1-octadecenes in >99% EE is described. Enantiomeric 2-methyl-1-hexanols were intermediates in the synthesis. The 1-alkene had been previously identified as the sex pheromone of the peach leafminer moth. Several closely related structures that have Δ12 unsaturation are also described.

Key Words—Chirality, alkenes, synthesis, branched hydrocarbons, diastereomeric amides, resolution, enantiomers, optical purity, olefin inversion.

INTRODUCTION

The peach leafminer, *Lyonetia clerkella* L., is one of Japan's most serious orchard pests (Naruse, 1978). Because larval damage occurs within the leaves, the larvae are not exposed to the usual contact sprays. This results in an emphasis on spray timing, a situation wherein optimal effectiveness of conventional insecticides is compressed into a short time window with attendant un-

[1]Reference to brand or firm name does not constitute endorsement by the U.S. Department of Agriculture over others of a similar nature not mentioned.

certainties. The situation might be relieved if one could monitor the adult moth population. This could be done by use of a pheromone lure trap. The sex pheromone of the female peach leafminer moth then became the subject of an investigation that led to the isolation and identification of 14-methyl-1-octadecene from female rinses (Sugie et al., 1984). About 100 ng of this compound can be obtained per female moth, and traps baited with 100 μg of the synthetic alkene were as attractive as the crude extract of 40 females.

Assignment of absolute configuration of the pheromone by inference using candidate synthetics remained. This report describes synthetic details for the preparation of the enantiomers of 14-methyl-1-octadecene each $>99.6\%$ pure (99.2% EE). The route chosen also allows generation of analogs that have the same stereocenter with a slight structural alteration adjacent to that center to employ as probes for the effect of selected physicochemical variables on the biological activity. In this initial trial, we opted to place unsaturation at the 12,13-position because we were of the opinion that such an alteration of the pheromone structure would constitute minimal perturbation. Since this research was initiated, a synthesis of 14-methyl-1-octadecene has been reported (Mori and Kato, 1985).

METHODS AND MATERIALS

Gas–liquid chromatography (GLC) was performed with a Varian 2400 instrument (flame ionization detection, He carrier) using the following columns: column A, cholesterol *p*-chlorocinnamate (0.25 mm × 11 m) and column B, Durabond I (0.25 mm × 31 m) operated at temperatures as indicated. Infrared (IR) data were obtained with a Perkin Elmer model 467 spectrophotometer (3% solutions in CCl_4), and nuclear magnetic resonance (NMR) data were obtained with a Nicolet 300-MHz FTNMR spectrometer (1% solutions in $CDCl_3$). Mass spectral data were obtained with a Finnigan model 3200 mass spectrometer in either electron impact or chemical ionization (isobutane) operating mode. The mass spectrometer was equipped with a GLC inlet (Varian model 1400) served by an OV-101 column (0.25 mm × 31 m). Melting points were obtained with a Fisher-Johns hot-stage apparatus and are uncorrected.

2-Methylhexanoic Acid. The acid was synthesized by alkylation of the dilithio anion of propanoic acid with *n*-butyl bromide by the general method of Pfeffer and Silbert (1970) (Figure 1). The yield of the racemic acid from 0.20 mol of propanoic acid was 94.4%: bp 70–73°C (0.05 mm); IR (CCl_4) 1706 cm^{-1}; ($CDCl_3$) 0.89 (bt, 3H, CH_3R); 1.18 (d, 3H, CH_3CH); 1.25 (CH_2 envelope); 10.15 (s, 1H, CO_2H) ppm (prior lit. Creger, 1970).

Preparation and Resolution of Diastereomeric Amides, 2. Both (R)- and (S)-α-methylbenzylamines were purified by recrystallization of monotartrate salts from ethanol and analyzed for configurational purity as the first step of a

resolution procedure that has been previously described (Sonnet, 1984). Acid **1** was converted to its acid halide with $SOCl_2$ and DMF catalyst in anhydrous ether. The acid halide was allowed to react with (R)- or (S)-α-methylbenzylamine in CH_2Cl_2 with 1.1 equivalent of triethylamine. The amides were recrystallized four to five times from aqueous ethanol using charcoal treatment during first recrystallization. The yields of purified R^*S^* diastereomers was 40% of theoretical and each diastereomer was 99.6% pure. Analysis by GLC: col A (120°C) α = 1.098, R^*R^* diastereomer eluted first; col B (150°C) = 1.077, R^*R^* diastereomer eluted first also; mp (R^*S^*): 98–99°C; IR (CCl_4) 3460, 1680 cm^{-1}; NMR ($CDCl_3$) δ0.89 (bt, 3H, CH_3R), 1.11 (d, 3H, J = 6.9 Hz, $C\underline{H}_3CHC{=}0$), 1.49 (d, 3H, J = 6.9 Hz, $C\underline{H}_3CHN$), 2.14 (sextuplet, 1H, J = 6.9 Hz, $CH_3C\underline{H}CH_2$), 5.15 (p, 1H, J = 7.1 Hz, CH_3CHNH), 7.2 (5H, aryl H) ppm; CI-MS (m/e) 234 (M+1).

(R)- and (S)-2-Methyl-1-hexanol, 3. Diastereomerically pure amide **2** (7.1 g, 30.5 mmol) was added via Gooch tubing in portions to a reaction mixture consisting of lithium diisopropylamide (LDA) (45 mmol) in tetrahydrofuran (THF) (75 ml) under nitrogen and cooled to 0°C. The resulting mixture was stirred for ca. 0.25 hr without external cooling. The reaction mixture was then cooled to −30°C, and ethylene oxide (3.0 ml, 60 mmol) was injected. Hexamethylphosphoric triamide (HMPT) (16 ml) was injected, and the resulting mixture was stirred at ambient temperature overnight. The reaction mixture was worked up with 2 N HCl (100 ml) and ether in the usual manner. The crude N-2-hydroxyethylated amide was dissolved in THF (40 ml) containing 2 equiv conc. HCl and heated under reflux for 1.5 hr, at which time GLC analysis indicated absence of the starting material, i.e., transacylation to the aminoester was complete. The mixture was stripped of solvent and heated briefly in benzene to drive off residual water. After the benzene had been removed, the residue was dissolved in dry THF (20 ml) and 2–2.5 g of solid LAH were added. The mixture was stirred under reflux for 1 hr and then worked up with aqueous NaOH and ether. The ethereal layer was suction filtered through Celite accompanied by further ether washes of flask and precipitate. The combined ethereal layer was washed with 2 N HCl, H_2O (2×) and dried ($MgSO_4$). Distillation of the crude product gave 3.1 g of **3** (88%): bp 84–101°C/30 mm; IR (CCl_4) 3560 cm^{-1}; NMR ($CDCl_3$) δ0.90 (m's, 6H, CH_3R and $C\underline{H}_3CH$), 1.1–2.0 (m's, ca. 6H), 3.41 and 3.51 (2d of d's, ABX, 2H, $CHC\underline{H}_2OH$)ppm; (R) $[\alpha]_D^{25}$, −9.3° (c, 8.10, $CHCl_3$); (S) $[\alpha]_D^{25}$, +8.7° (C,8.15,$CHCl_3$).

1,12-Dodecanediol Monotetrahydropyranyl Ether, 4. The diol (7.0 g, 34.6 mmol) was dissolved with warming in 1,2-dichloroethane (DCE) (70 ml). A crystal of p-toluenesulfonic acid was added, and then dihydropyran (3.3 ml) was added dropwise. After 0.25 hr, the mixture was stripped and triturated with hexane. The mixture was suctioned filtered, and the recovered solid diol was treated again with DCE and a proportional amount of dihydropyran. The product mixture was again stripped of DCE, slurried with hexane, and filtered. The

combined filtrate from both reactions was freed of solvent and chromatographed on silica gel (60–120 mesh, 30 g) eluting with 200 ml of 5% ether–hexane [bistetrahydropyranyl ether (THP) and some mono-THP] and 300 ml of 10% ether. GLC analysis: col A (200°C) compound (R_t min), diol (1), mono-THP (2.2), bis-THP (9.5). In this fashion **4** (2.7 g, 27.3%) was obtained containing ca. 3% of diol and no bis-THP; the recovered materials may, of course, be recycled, although no effort was made to optimize yields. Thin-layer chromatography (silica gel, 30% ether-hexane): R_f 0.16 mono-THP, 0.5 bis-THP; IR (CCl_4) 3560, 1050 cm^{-1}; NMR ($CDCl_3$) δ 1.25 (CH_2 envelope), 3.5 (m, 6H, CH_2O), 4.09 (m, 1H, OCHO) ppm.

(R)- and (S)-14-Methyl-12-(Z)-octadecen-1-ol, THF Ether, **5**. The diol-mono-THP, **4,** (4.71 g, 16.5 mmol) was added to a stirred mixture of pyridinium chlorochromate (5.3 g, 24.7 mmol) and NaOAc (5.3 g) in CH_2Cl_2 (30 ml) that was cooled in an ice bath. The resulting mixture was stirred at room temperature for 2 hr. Ether (150 ml) was added, and the mixture was passed through Florisil (10 g). The eluant was concentrated and then chromatographed on silica gel (25 g) eluting with 5% ether–hexane. Concentration of the eluant provided crude aldehyde (GLC 90%, col A 200°C, R_t 1.6 min, principal contaminant was the starting alcohol).

The required phosphonium salt (Figure 1) was prepared from (*R*)- and (*S*)-2-methyl-1-hexanol by first converting the alcohol to a bromide. Triphenylphosphine dibromide (25 mmol) was prepared in the usual way in CH_2Cl_2 adding bromine to triphenylphosphine at 0–25°C. The alcohol (3.0 g, 20.8 mmol) was added with 1–2 ml CH_2Cl_2 rinse, and the mixture was stirred at ambient temperature for 16 hr. After a few drops of methanol had been added to consume unreacted dibromide, the mixture was concentrated on a flash evaporator. The residue was triturated with hexane several times, and the hexane solution was concentrated. The crude bromide was then passed through silica gel (20 g) with hexane. The eluant was concentrated, and the bromide thus obtained was treated with triphenylphosphine (5.7 g, 21.8 mmol) and NaI (8.2 g, 54.6 mmol) in acetonitrile (25 ml) under reflux for 64 hr. The solvent was removed, and the crude product was triturated several times with DCE (phosphonium iodide is soluble). The triturate was concentrated and washed with ether. The residual oil was slurried in heptane and the solvent removed by rotary evaporation (to remove traces of DCE). The yield of crude oily salt was near quantitative.

The oil (ca. 20.8 mmol of phosphonium iodide) was dissolved in dry THF (25 ml) under nitrogen. The mixture was cooled (ca. 0°C) and *n*-butyllithium (1 equiv) was injected to generate the ylid. The mixture was cooled (−78°C) and HMPT (2 equiv) was injected. The aldehyde prepared above from **4** (2.6 g, 9.1 mmol) was added and the mixture was stirred at −78°C for 1 hr and for another 1 hr without external cooling. The product was worked up with water and hexane in the usual manner. The crude product was chromatographed on silica gel (30 g) eluting with 100 ml each of hexane, 1% then 2% ethyl acetate–

hexane. The product, **5**, was obtained: 2.23 g (67% yield from alcohol **4**); GLC Col B (250°C) $k' = 2.27$, containing 8% E isomer $k' = 2.40$, $\alpha = 1.057$; TLC (5% ethyl acetate–hexane $R_f = 0.28$); IR (CCl_4) 1050 cm^{-1}; NMR ($CDCl_3$) δ0.88 (m's, 6H, CH_3R and $C\underline{H}_3CH$), 1.25 (CH_2 envelope), 1.6 (m, ca. 3H, allylic CH), 3.5 (m, ca. 4H, CH_2O), 4.1 (m, ca. 1H, OCHO), 5.34 (m, 2H, HC=CH) ppm.

*(*R*)- and (*S*)-14-Methyl-12-(*Z*)-octadecen-1-yl Bromide,* ***6***. The protected alkenol **5** (1.73 g, 4.7 mmol) was added to a solution of triphenylphosphine dibromide (5.7 mmol) in CH_2Cl_2 (15 ml). After 1 hr, the solvent was removed by rotary evaporation, and the crude product was triturated with hexane several times. The hexane solution was concentrated and filtered through silice gel (15 g) with hexane. The solvent was removed providing 0.80 g (50%) of the (Z)-alkenyl bromide **6**: GLC col A (170°C) $R_t = 5.0$ min, E isomer ca. 6% $R_t = 6.2$ min, $\alpha = 1.03$; NMR ($CDCl_3$) 0.89 (m's, ca. 6H, overlapped CH_3R and $C\underline{H}_3CH$), 1.27 (CH_2 envelope), 1.58 (bs, 3H, allylic CH_2, CH), and 3.41 (t, 2H, $J = 7.9$ Hz, $CH_2C\underline{H}_2Br$) ppm; CI-MS (*m/e*) 345, 347 (M+1).

*(*R*)- and (*S*)-14-Methyl-1-(*Z*)-12-octadecadiene,* ***7***. A solution of LDA was prepared with butyllithium (2.5 mmol) and diisopropylamine (4 mmol) in THF (10 ml) under nitrogen at 0–5°C. The (Z)-alkenyl bromide **6** (3 mmol) was added in ca. 1 ml of hexane. After 10 min, the elimination was complete and the product was worked up with hexane and 2 N HCl. The crude diene was purified by argentation column chromatography. A CH_3CN (50 ml) solution of $AgNO_3$ (2 g) was prepared. Silica gel (60–120 mesh, 10 g) was added and swirled gently for 0.25 hr. The silica gel was collected by filtration and washed with dry benzene. The gel was then dried over P_2O_5 in vacuo. A column of this material was made up in hexane and employed repeatedly in this procedure. Retention volumes and GLC retention data for the various compounds are tabulated below (Table 1). More efficient chromatography is possible, but the required separation was affected in this manner.

Pure (R)- and (S)-Z-diene **7** were obtained: IR (CCl_4) 910 cm^{-1}, NMR ($CDCl_3$) δ 0.90 (m, ca. 6H, overlapped CH_3's), 1.27 (CH_2 envelopes) 2.03 (m, 5H, allylic CH), 4.9–5.8 (5H, vinyl H); CI-MS (*m/e*) 265 (M+1).

*(*R*)- and (*S*)-14-Methyl-1-(*E*)-12-Octadecadiene,* ***8***. Diene **7** (140 mg,

0.53 mmol) was added to a solution of metachloroperbenzoic acid (0.25 g, >2 equiv) in CH_2Cl_2 (5 ml). The mixture was allowed to stand at ambient temperature ovenight. The crude bis epoxide was obtained by removing the solvent. A suspension of 3 equiv of triphenylphosphine dibromide in 10 ml of benzene was prepared. The bis epoxide was added thereto with 1–2 ml of benzene, and the resultant mixture was stirred at ambient temperature overnight. The crude tetrabromide was obtained by concentrating the product mixture and triturating the residue with hexane. The hexane was removed, and the product was debrominated by allowing it to react for 2 hr in propanoic acid to which an excess of powdered, activated, zinc had been added (0–5 °C). The mixture was worked up with H_2O and hexane. The organic phase was washed to neutrality with aqueous $NaHCO_3$, and the extract was dried ($MgSO_4$). Removal of the solvent was followed by column chromatography on silica gel (1–2 g) with hexane. The dienes **8** were obtained in ca. 70% yield containing 3–7% *Z* isomer. Passage through the $AgNO_3$ column provided samples containing no more than 3% *Z*: IR (CCl_4) 965, 910 cm^{-1}; CI-MS (*m/e*) 265 (M+1).

(R)- and (S)-14-Methyl-1-Octadecyl Bromide, 9. The (*R*)- and (*S*)-alkenyl bromides **6** were hydrogenated over PtO_2 in propanoic acid and produced the saturated bromdies **9** contaminated with the parent hydrocarbons (ca. 10%). These were not separated at this point: NMR δ 3.40 (t, CH_2Br) ppm and no signals for vinyl H; GLC col A (170°C) for 2.4 min for alkane **11,** 8.0 min for alkyl bromide **9;** CI-MS (*m/e*) 347, 349 (M+1).

(R)- and (S) 14-Methyl-1-Octadecene, 10. The bromides **9** were dehydrobrominated as described above for dienes **7.** The crude product containing the parent alkane was chromatographed on the $AgNO_3$ column to give alkane (eluting first): NMR ($CDCl_3$) δ 0.88 (bt, CH_3R), 1.25 (CH_2 envelope) ppm; EI-MS (*m/e*) 268 (P+1), 267 (P−1), 211 ($C_{15}H_{31}$), and 210 ($C_{15}H_{30}$), and **10:** IR (CCl_4) 910 and 990 (weak) cm^{-1}; NMR ($CDCl_3$) δ 0.89 (m, ca. 6H, overlapped CH_3's), 1.26 (CH_2 envelope), 2.05 (m, ca. 2H, allylic CH_2, and 4.9–5.8 (m's, 3H, vinyl H); CI-MS (*m/e*) 267 (M+1), 266 (P), 265 (M−1).

RESULTS AND DISCUSSION

The asymmetric center was introduced, as shown in Figure 1, by alkylating the dianion of propionic acid with butyl bromide. The original procedure (Creger, 1970) employed the sodium salt of the acid and reported a 54% yield of 2-methylcaproic acid, **1.** We used the general procedure of Pfeffer and Silbert (1970) involving a dilithio anion to obtain a 94% yield. The acid was converted to amide **2** with either (*R*)- or (*S*)-α-methylbenzylamine to produce a mixture of diastereomers that was resolved easily by several-fold recrystallization from ethanol. The process of purification to a nearly pure (>99.6%) diastereomer was monitored by gas chromatography (Methods and Materials). The purified

FIG. 1. Synthesis of configurationally pure phosphonium salts: 1. lithium diisopropylamide, butyl bromide; 2. thionyl chloride, (*R*)- or (*S*)-α-methylbenzyl amine; 3. fractional crystallization, amide reductive cleavage (Sonnet, 1984); 4. triphenylphosphine dibromide, then sodium iodide and triphenylphosphine.

*R*S**- (asterisks indicate relative stereochemistry) diastereomer was then cleaved by (1) *N*-alkylation with ethylene oxide, and (2) transacylation–reduction (Sonnet, 1984) yielding either (*R*)- or (*S*)-2-methyl-1-hexanol, **3**. This procedure has been shown to afford alcohols of configurational purity equal to that of the diastereomeric amide from which it was derived. The alcohols were then transformed to bromides, and these to triphenylphosphonium iodides in preparation for a Wittig condensation reaction.

The other component for this condensation (Figure 2) was obtained by blocking one hydroxyl group of 1,12-dodecanediol and then oxidizing that alcohol, **4**, to the corresponding aldehyde with pyridinium chlorochromate–sodium acetate. The condensation itself was conducted to maximize the *cis*-olefin

FIG. 2. Synthesis of configurationally pure dienes ([a]THP = 2-tetrahydropyranyl): 1. dihydropyran, H^+; 2. pyridinium chlorochromate, sodium acetate; 3. butyllithium (→ ylid), procedure for *cis* (Sonnet, 1974); 4. triphenylphosphine dibromide; 5. lithium diisopropylamide; 6. olefin inversion via bisepoxides (Sonnet and Oliver, 1976).

FIG. 3. Synthesis of the enantiomers of the peach leafminer moth sex pheromone: 1. H_2/platinum oxide; 2. lithium diisopropylamide.

generated by using hexamethylphosphoric triamide as an additive (Sonnet, 1974). Completion of the pheromone synthesis involved conversion of the tetrahydropyranyl ether of the (*R*)- and (*S*)-alkene **5** to a bromide **6** with triphenylphosphine dibromide (Sonnet, 1976). Catalytic hydrogenation of the double bond (Figure 3) was followed by dehydrobromination with lithium diisopropyl amide. The final product, (*R*)- or (*S*)-14-methyl-1-octadecene, **10,** was purified by argentation column chromatography to separate it from the corresponding alkane that had arisen in the catalytic hydrogenation of the alkenyl bromide **6**.

In order to obtain the several stereoisomers of the desired analog, 14-methyl-1,11-octadecadiene, (*R*)- and (*S*)-**6** was dehydrobrominated to the corresponding (*R*)- and (*S*)- *Z*-isomers, **7** (Figure 2). The *E* isomers were prepared by carrying out an inversion via the bisepoxides (Sonnet and Oliver, 1976). The bisepoxides were allowed to react with triphenylphosphine dibromide in benzene producing tetrabromides that are the result of SN-2 inversions on each oxygenated carbon. Reduction with activated zinc–propionic acid, a *trans*-antiplanar elimination of vicinal halogens, causes net inversion of one of the carbons 12/13 to give the inverted alkene. All of these materials were purified by argentation column chromatography monitored by gas chromatography (Methods and Materials).

CONCLUSION

With these materials in hand we were in a position to measure biological activity versus stereostructure and thereby make the final assignment of pheromone structure. Results of field tests showed that the sex pheromone has the *S* configuration and full details of these studies are published elsewhere (Sugie et al. 1985).

Abstract—The noncontingent distribution of *O. nubilalis* Hbn. eggs on various corn varieties has allowed their classification as either "favorable" or "nonfavorable" hybrids. This classification is based on a chemical communication system using volatile compounds active at a distance from the insect or active when in contact with the insect as soluble sugar components. Under this hypothesis, gas chromatography is the best way of investigating for the chemical differences between corn silk extracts from the two types of hybrids. A first experiment, using a "desorption-trapping" system on Tenax coupled to a gas chromatograph showed a quantitative difference between two compounds from the two hybrids. A second experiment showed the advantages and disadvantages of this method and allowed the development of two complementary techniques: (1) direct extraction of corn silk with trichlorofluoromethane and direct injection into a capillary column with an apolar stationary phase using an "on-column" system; and (2) extraction under vacuum of volatile compounds from corn silk and their trapping on Tenax, followed by a second desorption. This allows a direct injection on the same capillary column. The first technique allows identification by mass spectrometry of many alkanes with high molecular weights. The second technique seems to confirm the presence of phenylacetaldehyde. Both techniques show quantitative differences in the composition of corn silk extracts from "favorable" and "nonfavorable" hybrids; however, the biologically active chemicals remain unknown.

Key Words—Pyralidae, *Ostrinia nubilalis*, oviposition preference, corn silk volatile chemicals, extraction, desorption, gas chromatography, mass spectrometry alkanes, phenylacetaldehyde.

INTRODUCTION

Developing a new strategy to protect crops against insect pests by the use of nonpolluting and specific methods requires a basic knowledge of insect–plant relationships. In the sequence of insect reproductive behavior: sex-attraction, mating, insemination, fertilization, and oviposition, the last one is of utmost interest to plant protection specialists because it determines the level of damage. With the European corn borer *Ostrinia nubilalis* Hübn., oviposition behavior and especially the distribution of egg masses in the field were found to differ in various maize varieties. Specific behavioral mechanisms must explain these differences in distribution. Observations under natural conditions (Anglade et al., 1981) enabled us to classify different maize hybrids as "favorable" or "nonfavorable" for the oviposition of *O. nubilalis*. We believe that this choice is mediated by a chemical communication system involving two types of allelochemical substances emitted by the plant and detected by the moth: (1) volatile compounds acting on the insect for long-range identification of plant odors and for locating the host plant, e.g., phenylacetaldehyde by *O. nubilalis* (Cantelo and Jacobson, 1979); and (2) other compounds acting at contact, e.g., soluble sugars (Derridj and Fiala, 1983) which affect the amount of time the insect remains on the plant and stimulate or inhibit oviposition by an unknown mechanism.

This research was designed to identify attractive or repulsive substances and favorable or nonfavorable substances for oviposition of *O. nubilalis*. Similar scientific approaches have been successfully implemented on other models: (1) for attraction of *Delia brassicae* Wied. by natural or synthetic isothiocyanates (Städler, 1978; Finch and Skinner, 1982) or *Acrolepiopsis assectella* Zell. by thiosulfinates and disulfides of leek (Lecomte and Thibout, 1981); and (2) for deterrents or repellents of various species such as *Leptinotarsa decemlineata* Say. or *Mythimna unipuncta* Haw. by the phenylpropanoid extracts from *Bupleurun fructicosum* and *Acaurus calamus* (Muckensturn et al., 1982).

METHODS AND MATERIALS

The purpose of this work was to compare the chromatograms of aromatic extracts of the same organ from two hybrids differing in their effect on *O. nubilalis* and to detect differences which could explain the behavioral choice of females. Fresh corn silk was used because this organ contains many volatile compounds attractive to the European corn borer (Cantelo and Jacobson, 1979). It seemed desirable to use the experimental approach of these authors.

Plant Material. The study was conducted on experimental material developed by Panouillé (Station expérimentale du maïs, St. Martin de Hinx) and recognized as "favorable" or "nonfavorable" to oviposition on the basis of

field and cage trials by Anglade et al., (1981). The experiments were carried out on single hybrids of similar growth habits designated by the following code "favorable" (ABG and AF); "nonfavorable" (LOF and FF). Samples were taken previously during the normal plantings of July 1982 and 1983 and in a greenhouse during April 1983.

To minimize the time between cutting of the corn silk in the field or in the greenhouse and its chromatographic examination in the laboratory (a distance of 3 or 10 km), we transported the whole plant. The plant was removed with about 10 kg of soil, placed in a pail, and transferred to the laboratory in a van to prevent any injury which could influence the natural emission of volatile substances. Under these conditions and with watering, each plant remained apparently normal for at least two weeks in the laboratory and permitted several analyses.

Procedure. The volatile components of the material were analyzed by preliminary concentration in an adsorbent trap before injection and concentration in the column of a gas chromatograph. The plant material was heated in a micro-oven and the volatile compounds were captured by a helium flux and adsorbed in a trap containing Tenax. It could be desorbed later by heat and injected into the column of a gas chromatograph.

For all experiments we used a DCI, Girdel platine (Figure 1). The temperature of the desorption oven can be adjusted from room temperature up to 260°C. The minitrap is a $\frac{1}{8}$-in. inox tube containing about 0.3 ml Tenax. This trap is surrounded by a liquid nitrogen case and a heating device by Joule effect. Valves and transfer lines between oven and trap and between trap and chromatograph are held at 150°C by a heating block regulated by an electronic box.

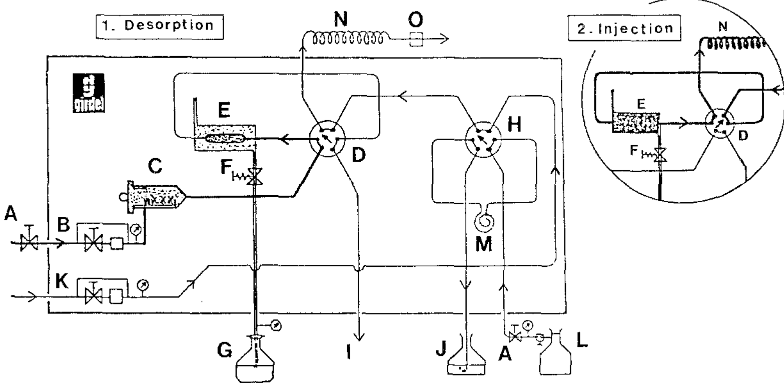

FIG. 1. Gas chromatographic platine DCI Girdel device: A, stopping valve; B, helium scavenging gas; C, desorption oven; D, sampling valve; E, minitrap; F, electrovalve; G, liquid nitrogen; H, valve of standard gas inlet; I, open air; J, ambient pressure system; K, vector gas; L, gaseous standard; M, pattern ring; N, column; O, detector.

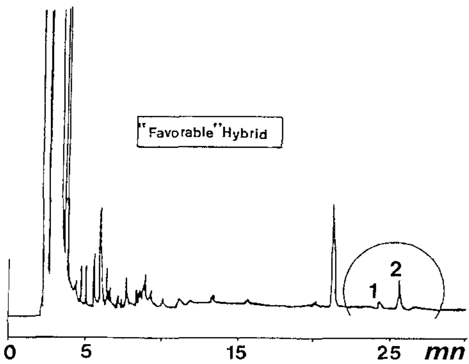
Each step of the analysis is manual. After cooling the trap, the solid sample (corn silk) was placed in a little Pyrex skiff (maximum capacity 1 ml) which was introduced in the micro-oven (oven volume: 7.3 ml). Then, the successive trapping and desorption phases of the volatile chemicals were carried out.

RESULTS AND DISCUSSION

The preliminary 1982 study did not produce spectacular evidence of differences between the two hybrids but a qualitative difference between the two peaks of two unidentified substances (Figure 2). Devising and developing successful improved methods was our main finding; four steps can be distinguished.

Direct Desorption on Corn Silk. In 1982, we used a capillary column (Carbowax 20 M, 50 m) generally suitable for separating aromatic substances which were susceptible to oxidation.

In 1983, the technique was refined to give a better definition of the peaks



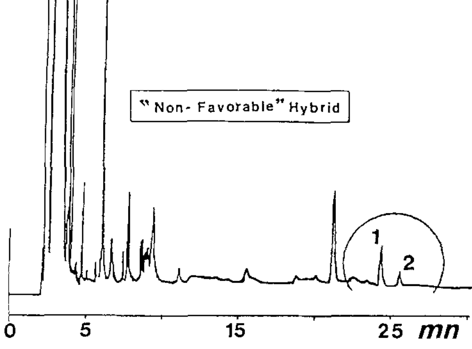


FIG. 2. Corn silk extract chromatograms: preliminary experiment 1982.

as follows: for each experiment, the corn silk mass treated was about 100–300 mg; the desorption oven was heated for 10 min at 50°C under helium scavenging gas (30 ml/mn); during trapping phase, the Tenax trap was not cooled (cooling of the trap at 0°C did not improve the trapping but entailed obstruction of transfer tubes by molding of little blocks of ice); we used a CP cil 5 capillary column (25 m) of 0.31 mm inner diameter. Parameters of analysis were: vector gas pressure 0.6 bar, isotherm 20 min at 80°C, and programming 3°C/min up to 220°C.

The main advantage of this technique is the direct extraction without solvent. According to Visser et al. (1979), the extraction process with organic solvents entails two major disadvantages: (1) impurities from the solvent may accumulate in the aroma concentrate, and (2) nonvolatile components are isolated along with the volatiles. Nevertheless, in our device, the volume of the oven limits the amount of plant material.

The chromatograms obtained were more complicated, but the peaks were well separated. Maximum of retention time reached 70 min. The extractable elements of corn silk seemed to correspond to apolar molecules with high molecular weights.

In the favorable hybrids AF and ABG, we observed the presence of a peak whose retention time might correspond to phenylacetaldehyde. In other respects, the same peaks were found, but the quantitative differences were not consistent and replicability was poor within hybrids. Besides, the blank experiments between each desorption pointed to a recondensation of heavy compounds between the Tenax trap and the column; they were likely to interfere in the following desorptions. These blank experiments were thus necessary and the time of analysis was increased.

Desorption after Extraction by "Coldfinger" Technique. The purpose was to improve the accuracy of the method by indirectly increasing the sample volume. A tube filled with liquid nitrogen (coldfinger) trapped water and some of the aromatic compounds of corn silk treated under vacuum.

By using this procedure, we obtained a very odoriferous watery extract whose organoleptic characteristics were similar to the odors in the open corn field. The Pyrex skiff is filled up with this extract and the desorption is done as previously described. Thus, 10 g of corn silk were extracted instead of 0.3 g by direct desorption, and we expected a significant increase in analytical sensitivity by a factor (10/0.3) = 33.3.

Unfortunately, we did not observe a spectacular increase of the peak size, but rather a decrease. Nevertheless, most of the peaks were recovered. In addition, such watery extracts are extractable by trichlorofluoromethane. After a first desorption during 10 min at 50°C, a strong odor of corn silk remained in the skiff. This odor disappeared after 10 min scavenging by helium vector gas at 150°C. Besides, an increase in chromatogram sensitivity led us to further improve the method using direct extraction of corn silk with trichlorofluoromethane.

Direct Extraction of Corn Silk by Trichlorofluoromethane, Injection on Column, Identification of Compounds. Extractions were done on 20 g of fresh corn silk with 100 ml trichlorofluoromethane for each hybrid. Extracts were concentrated and put in 10 ml hexane before injection on column. Both extracts are very odoriferous. Injections were done as follows: injected volume, 1 μl; vector gas pressure, 0.7 bar; oven temperature, isotherm 40°C during 1 min and programming 4°C/min up to 260°C.

Observation of chromatograms (Figure 3) revealed quantitative rather than qualitative differences between the two hybrids. Thus, peaks 5, 6, and 9 were proportionally more important in hybrid FF than in hybrid ABG, even though peaks 1 and 10 seemed to be constant in both hybrids. Mass spectrometry permitted identification of the first three peaks which were composed of saturated alkanes: 5 corresponds to *N* tricosane, 6 to *N* tetracosane, and 9 to *N* hexacosane. Mass spectra of peaks 7 and 10 presented an analogous structure but were not precisely identified; they might correspond to alcohols (Figure 4). In addi-

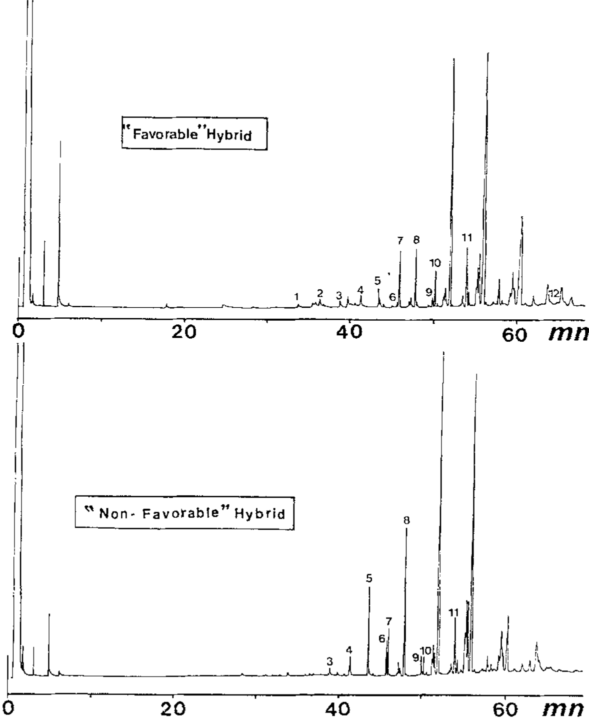

FIG. 3. Gas chromatograms of corn silk extracts with trichlorofluoromethane on-column injection. Peak 1, *N*. nonadecane; 2, *N* eicosane; 3, *N* heneicosane; 4, *N* docosane; 5, *N* tricosane; 6, *N* tetracosane; 7, unidentified; 8, *N* pentacosane; 9, *N* hexacosane; 10, unidentified; 11, *N* octosane; 12, *N* dotriacontane.

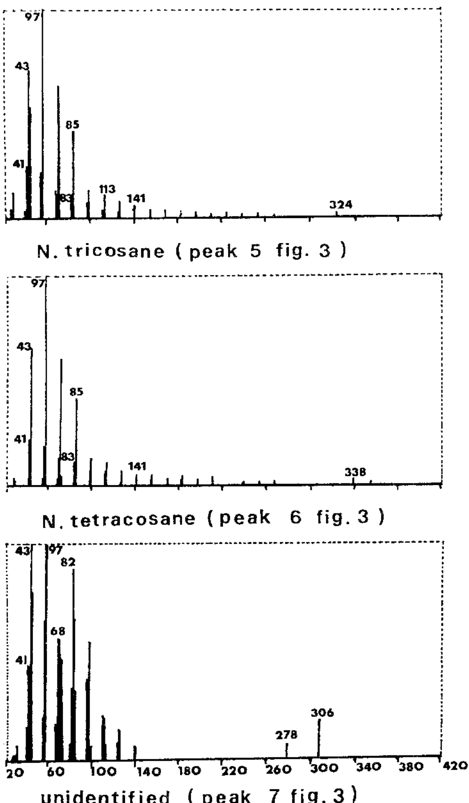

FIG. 4. Mass spectrograms of three compounds obtained by direct extraction of corn silk with trichlorofluoromethane.

tion, there seems to be a relation between the nature of the "favorable" and "nonfavorable" hybrids for insects and the proportions of the peaks which we observed with analogy of structure in mass spectra:

$$\underset{\text{Hybrid FF}}{\frac{\text{height of peak 6 (alkane)}}{\text{height of peak 7 (alcohol ?)}}} > \underset{\text{Hybrid ABG}}{\frac{\text{height of peak 6 (alkane)}}{\text{height of peak 7 (alcohol ?)}}}$$

$$\frac{\text{height of peak 9 (alkane)}}{\text{height of peak 10 (alcohol ?)}} > \frac{\text{height of peak 9 (alkane)}}{\text{height of peak 10 (alcohol ?)}}$$

Addition to FF and ABG hybrid extracts of control alkanes and injection in different polarity columns confirms the above hypothesis. If we hold the mass spectrum on a peak with known molecular weight (mol wt 324 for peak 5, mol wt 338 for peak 6, and mol wt 306 for peak 7), it is possible to record the signal

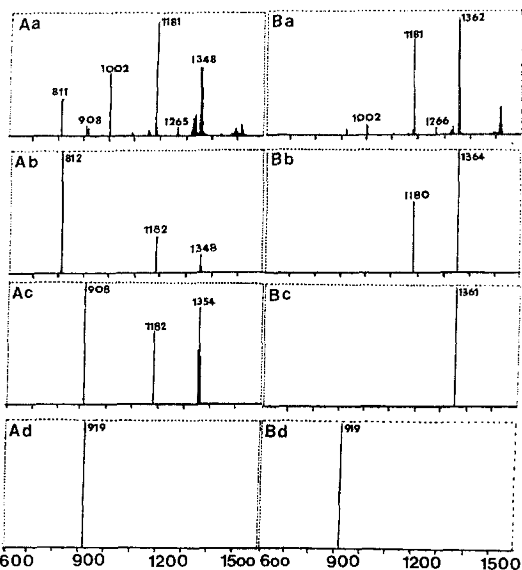

FIG. 5. Mass fragmentometry. Difference between ABG and FF hybrids (A): FF, non-favorable; (B): ABG, favorable. (a) chromatograms; (b) distribution of the mass 324 compound (peak 5); (c) distribution of the mass 338 compound (peak 6); and (d) distribution of the mass 306 compound (peak 7).

given in relation to the time, thus obtaining a "mass fragmentogram." This fragmentogram, similar to a chromatogram, contained only the peaks of compounds having the fragment chosen in their mass spectrum (Figure 5). The preponderance of compounds "5" and "6" in hybrid FF and an identical distribution of compound "7" in both hybrids was then confirmed.

These results should be considered with caution because of the small number of replicates. Also, the concentration phases of trichlorofluoromethane might have induced a loss of the most volatile components. For this reason, we continued our investigations by gathering the volatile compounds.

Extraction under Vacuum and Trapping of Aromatic Compounds with Tenax. As did Buttery and Ling (1984), to identify corn leaf volatiles, we treated corn silk under vacuum and trapped the volatile compounds with Tenax. The advantage of this method was to treat large quantities of corn silk during extended periods of extraction without disturbing the chromatograph examination. Tenax was desorbed in the oven during 30 min at 150°C. Aromatic components which were desorbed from the first Tenax trap were soon readsorbed on the second Tenax trap of the DCI Girdel platine. Otherwise, the other experimental conditions were the same as previously described and the chromatograms obtained were comparable with those obtained after injection on column.

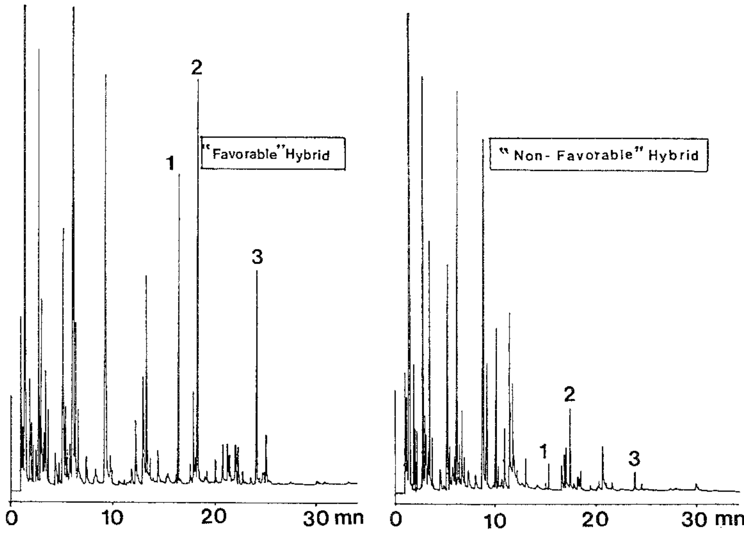

FIG. 6. Gas chromatograms of volatile components: extraction under vacuum and trapping on Tenax. Peaks 1: phenylacetaldehyde?; 2, 3: unidentified.

These chromatograms revealed the presence of numerous light components which did not appear in last method (Figure 6); we could thus observe major differences between the two hybrids studied and especially the greater quantity of three compounds (peaks 1, 2, and 3) in ABG (favorable hybrid) than in FF hybrid. One of these compounds (peak 1) presents a retention time very close to that of the phenylacetaldehyde already observed in the first experimental step.

Flath et al. (1978) did not find phenylacetaldehyde among the volatile components of corn silk by vacuum codistillation with water, followed by ether extraction of the distillate. In contrast, this compound was identified by Cantelo and Jacobson (1979) in the same plant organs by trapping on Porapak-Q and extraction in a Soxhlet apparatus with anhydrous ether.

Most common extraction techniques of chemical insect stimulants entail the use of different organic solvents. Maeshima et al. (1985) thus successively used methanol, *n*-hexane, and a mixture of *n*-hexane–ethyl ether to extract the chemical oviposition stimulants from rice grain for *Sitophilus zeamais*. Woodhead (1983) used two distilled solvents—chloroform and a mixture of *n*-hexane, diethyl ether, and formic acid to identify the components of the surface wax of *Sorghum bicolor*. Last, for isolation and identification of volatiles in the foliage of *Solanum tuberosum*, Visser et al. (1979) only used a mixture of diethyl ether and *n*-pentane in the final extraction phase.

The purpose of this study was to reduce the number and amount of solvent, and this experimental approach enabled us to develop a satisfactory method of

analyzing the aromatic components of fresh maize silk. Comparing the advantages and disadvantages of the techniques will allow future work to progress more quickly. Two complementary methods should be used to analyze the different groups of components: (1) extraction of heavy apolar components with trichlorofluoromethane (third step); and (2) trapping of light components with Tenax (fourth step).

In general, the differences between the two hybrids of maize were quantitative, not qualitative, for both heavy and light aromatic compounds. The heavy components (*N.* tricosane, *N.* tetracosane, *N.* hexacosane) were proportionally more abundant in the silk of FF hybrids (unfavorable) than in the ABG hybrids (favorable). We have not proved that these components diffuse into the atmosphere under natural conditions, but they might play a role either by themselves or as precursors of active components which inhibit oviposition or repel females. This hypothesis agrees with the results of Woodhead (1983). This author also identified in the surface wax of *Sorghum bicolor* the same three alkanes to be deterrent to *Locusta migratoria*. Secondly, the probable presence of phenylacetaldehyde [whose attractive role on *O. nubilalis* was proved by Cantelo and Jacobson (1979)] encourages us to identify the other two compounds which have the same relationship.

CONCLUSION

We have formulated the following hypothesis to explain the oviposition behavior of *O. nubilalis* females: (1) At a remote distance (several meters), the moths would be attracted by the volatile compounds (phenylacetaldehyde type and related compounds) emitted by "favorable" hybrids. (2) On contact, oviposition would be induced preferentially on plants lacking certain heavy components such as alkanes.

To verify this hypothesis, it will be necessary to confirm that the components identified in the two hybrids are responsible for the choice of plants by the females during oviposition. These substances will have to be tested on the insects themselves using olfactometric and neurobiological techniques such as electroantennography in the laboratory and then under natural conditions on plants genetically high or low in these compounds.

Acknowledgments—The authors thank Antoine Panouillé (INRA, Station expérimentale du maïs, Saint Martin de Hinx) for providing the corn hybrids used in this study and Miss Evelyne Ron for her assistance with English.

VARIATION IN METHYLGLUCOSINOLATE AND INSECT DAMAGE TO *Cleome serrulata* (CAPPARACEAE) ALONG A NATURAL SOIL MOISTURE GRADIENT

(Received November 18, 1985; accepted April 14, 1986)

Abstract—We tested the hypothesis that plant loss to insects, and thus the relative fitness of an annual, was inversely related to spatial variation in the concentration of its characteristic secondary compound, methylglucosinolate, a mustard oil precursor. We found that methylyglucosinolate concentrations decreased significantly and linearly from the dry to the wet end along short soil moisture gradients in dry shortgrass prairie. Both leaf damage and capsule predation increased from the dry to the wet end. Thus, the glucosinolate appears to function defensively. Plant growth and flower production were favored at the wet end of the gradient; yet plants in the wet portion of the gradient were also more vulnerable to significant insect damage. The net result was that seed production by individual plants after predation was actually greater in the drier, harsher half of the gradient. The outcome strongly suggests that environmentally related variation in secondary compound concentration along environmental gradients can mediate and influence host-plant population abundance and distribution.

Key Words—Capparaceae, chemical defense, *Cleome serrulata*, glucocapparin, methylglucosinolate, gradient, herbivory, insect-plant interactions, soil moisture gradient, stress.

INTRODUCTION

Four lines of evidence suggest that intraspecific variation in plant natural products may mediate insect herbivore impact on host-plant dynamics. First, damage done by phytophagous insects is common and varies tremendously in intensity. Experimental studies show insect herbivory can influence plant seed reproduction, recruitment, or population dynamics (Cantlon, 1969; Janzen, 1971, 1979; Manley et al., 1975; Waloff and Richards, 1977; Rausher and Feeny, 1980; Parker and Root, 1981; Louda, 1982a,b, 1983, 1984, 1986a).

Second, it is evident that secondary compounds, such as glucosinolates, often play a defensive role in insect–plant interactions (Fraenkel, 1959; Ehrlich and Raven, 1965; Whittaker and Feeny, 1971; Feeny, 1975, 1976; Levin, 1976a,b; Rhoades and Cates, 1976; Rosenthal and Janzen, 1979). Consequently, predictable variation in chemical concentrations could determine systematic patterns of insect feeding and impact.

Third, detailed studies of chemical profiles under natural conditions suggest that extensive chemical variation occurs among individuals within populations of a species and represents the usual situation (Dolinger et al., 1973; Lincoln and Langenheim, 1979; Rodman and Chew, 1980; Feeny and Rosenberry, 1982; Louda and Rodman, 1983a,b; Lincoln and Mooney, 1984). This variation is often correlated with changing environmental conditions along spatial gradients (Lincoln and Langenheim, 1979; Cates and Alexander, 1982; Cates et al., 1983; Louda and Rodman, 1983a,b; Redak and Cates, 1984; Louda, 1982b, 1986b).

Fourth, spatial patterns of seed predation and foliage consumption occur, such as between adjacent sun and shade habitats (Huffaker and Kennett, 1959; Lincoln and Langenheim, 1979; Louda and Rodman, 1983a,b; Lincoln and Mooney, 1984; Louda et al., 1986a,b) and between portions of small, local gradients (Handel, 1976; Redak and Cates, 1984; Louda et al., 1986b) or larger, climatic gradients (Janzen, 1975; Louda, 1982b, 1983). Thus, the utilization patterns are also correlated with the spatial variation in physical environmental conditions and in secondary compounds (Redak and Cates, 1984).

Consequently, an interrelated set of three hypotheses can be proposed to explain systematic patterns of variation in plant susceptibility to attack and damage over environmental gradients. These are: (1) often there is ordered spatial variation in the putative defensive chemicals; (2) this variation in secondary compounds reflects variation in physical parameters along environmental gradients; and (3) the underlying variation in defenses mediates loss to insect consumers and thus the spatial distribution of insect influence on host-plant population dynamics (Louda, 1986b).

The purpose of our study was to examine this set of hypotheses for *Cleome serrulata*, an annual species on which insect damage had been noted along a soil moisture gradient during a recent study of population structure (Farris,

1985). An annual plant species provides a particularly interesting model system for this type of work since any reduction in seed production due to herbivory has immediate, demographic consequences (cf., Harper, 1977). Our study has additional relevance since *Cleome* is a glucosinolate-containing member of the caper family (Capparaceae). Glucosinolates are used as a classical example of the qualitative defense strategy in the predominant theories of chemical defense in plant–herbivore interactions (e.g., Whittaker and Feeny, 1971; Feeny, 1976; Rhoades and Cates, 1976). The theory has been developed with data on the interaction of mustards (Cruciferae) and their adapted insect herbivores. Data in other systems, such as the closely related caper–insect interaction, should provide strong corroborative or contradictory evidence on the functional role of glucosinolates in plant defense.

METHODS AND MATERIALS

Site and Gradient Description. Two populations, 250 m apart, were located in the White Rocks Preservation Area, 11 km east of Boulder, CO. Each population was situated on a south-facing, 5–8° hillside (Figure 1). These mild, dry slopes caused slight but significant gradients in soil moisture availability within each population. Gravimetric determinations in 1984 showed that the soils at the "wet" end of the populations had an average of 6.6 ± 0.48% soil moisture from May to September (both sites combined). During the same period, the soils at the "dry" end of the populations had an average of 4.3 ± 0.37% soil moisture. Predawn plant water potentials, as measured with a Scholander-type pressure chamber, varied along the soil moisture gradients; differences of up to 0.9 MPa were found for plants at opposite ends of the soil moisture gradients (Farris, 1985). Plant growth rates, survival, and reproduction also varied considerably along these gradients (Farris, 1985).

Field Assessment of Insect Damage. Estimates of insect damage to developing capsules and their seeds were made in both 1983 and 1984. In August 1983, the proportion of capsules per inflorescence that were chewed and seriously damaged by insects was categorized and recorded for plants in relation to position along the soil moisture gradient at both sites. Plant location was measured as meters from the dry end of each gradient. This location proved to be a reliable predictor of relative soil moisture availability (Farris, 1985). In addition, in September 1983, foliage area removed or damaged at site 2 was scored as light, moderate, or heavy (i.e., 0–5%, 6–25%, or more leaf removal of tissue by insects). The most common insects observed feeding on the foliage were grasshoppers.

In September 1984, seeds that developed on plants growing along the gradient at site 2 were collected. The collection was made early in the month, after the period of most intense capsule and seed predation by lepidopteran larvae

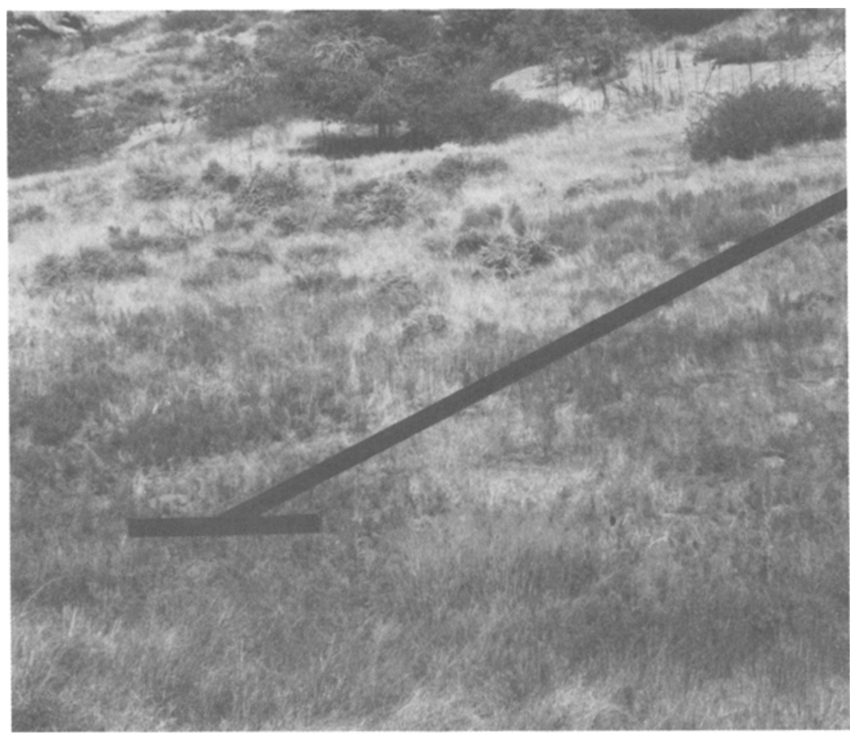

FIG. 1. Location of gradient at site 1 at the White Rocks Preservation Area with the specific microgradient that was sampled marked (transect length-25m).

(Pieridae). Pierids are common herbivores of capers (see Goury and Guignon, 1908). Sixteen plants that spanned the soil moisture gradient had some capsules with viable seeds. Seed production was recorded in the field, and any capsules remaining were collected. Seeds were examined, and the number of viable seeds per plant was determined in relation to plant size and plant position on the gradient.

Collection of Plant Material. On August 14, 1984, leaf material was collected from 22 plants at each site. Capsule and seed material were uncommon. A minimum of 5 g of leaf tissue was removed from each plant, put in a plastic bag, and placed on ice. Plant height, plant diameter, and plant location were recorded. A plant size index was later derived by multiplying height and diameter. The plant samples were returned to the lab and immediately boiled for 10 min in 70% methanol.

Glucosinolate Analysis. Glucosinolate analyses were done according to the methods described by Blua (1984) and Blua and Hanscom (1986). Briefly, the plant tissue in methanol was homogenized at high speed, boiled, condensed to

30 ml, filtered through Whatman No. 2 paper, and condensed to 10 ml by vacuum evaporation. Ten milliliters of 0.05 M sodium phosphate buffer (pH 7.5), 0.10 ml of 4.2% ascorbate in water, 15.0 ml methylene chloride, and 1.0 ml thioglucosidase extract (Rodman, 1978) were added, and the tightly capped Teflon tubes were placed on a shaker for 12 hr at room temperature. The aqueous phase and the methylene chloride phase were then separated by centrifugation (20 min at 1500 rpm).

For chromatographic analysis of nitrogen hydrolytic products, 12 ml of the methylene chloride phase were removed by syringe and concentrated to 1 ml, using an Evapo-Mix vacuum evaporator with an ice-water bath. Undecane was added as an internal standard, making a final concentration of 0.05%. Paper chromatographic analysis for oxazolidinethione-generating glucosinolates was done using published methods (see Rodman, 1978; Louda and Rodman, 1983a). Gas chromatography was done on a Varian Vista 6000 gas chromatograph using a 6-ft, 2 mm ID, glass chromatographic column packed with 10% Carbowax 20 M on 100–120 mesh Chromosorb WAW. Injection and FID temperatures were set at 150°C and 200°C, respectively. Nitrogen flow was 30 ml/min. Oven temperature was maintained at 60°C for 2 min and then raised to a final temperature of 120°C at a rate of 10°C/min. Quantification was done by comparing retention times and area counts to those of known standards (Blua, 1984). Concentrations are given in milligrams methyglucosinolate (glucocapparin) per gram of plant material, dry weight.

RESULTS

Insect Damage. The relative severity of leaf damage increased as soil moisture availability increased. The plants with the heaviest damage were found exclusively in the wettest portion of the site, while those with relatively little damage were generally found toward the drier half of the gradient (Figure 2). The tendency for a relationship between the levels of insect damage and soil moisture was even stronger if plant size was considered as a covariate. Large plants at the wet end of the gradient had lower viable seed production after predation than did much smaller plants at the dry end of the gradient, in spite of having higher flower initiation and potential seed production (Farris, 1985). For example, the largest plant at the wet end of the gradient at site 2 had 900 developing capsules on August 28, 1984, but only four viable seeds by mid-September. At the same time a smaller plant at the dry end of the gradient had one third the number of capsules in August (300) but ten times as many viable seeds (40) in mid-September, after predation by the lepidopteran larvae.

Overall, capsule predation also appeared to increase as soil moisture availability increased. In 1983, the relationship between soil moisture availability and the proportion of capsules damaged was examined on both a per inflores-

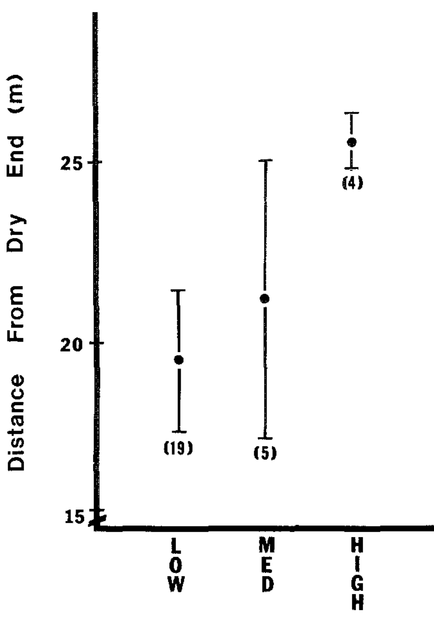

FIG. 2. The relationship between soil moisture availability ($\bar{X} \pm$ SE) and the severity of leaf damage at site 2, September 1983. Plants were scored as having light (0–5%), moderate (6–25%), or heavy (greater than 25%) foliage damage. Sample sizes in parenthesis; groups are not statistically different.

cence and a per plant basis. The Spearman rank-order correlation coefficients (r_s) between distance along the gradient from the dry end and the proportion of capsules damaged per inflorescence were: +0.17 (N = 102) and +0.20 (N = 93) for sites 1 and 2, respectively. The proportion of capsules damaged per plant was also positively associated with increased soil moisture availability [r_s = +0.13 for both sites (N = 11 and 23)]. However, these correlations were not statistically significant. In 1984, the majority of the plants (81.4%, N = 86) had lost all of their viable seeds to the insect predators by early September. However, the number of viable seeds remaining per plant after insect feeding at site 2 was significantly higher at the drier end of the soil moisture gradient (Table 1).

Glucosinolate Concentrations. Most species of *Cleome* that have been studied contain a single isothiocyanate-yielding glucosinolate, methylglucosinolate (glucocapparin), and an oxazolidinethione-generating glucosinolate (2-hydroxy-2-methylbutylglucosinolate, or glucocleomin) (Kjaer and Thomsen, 1963). We found relatively high concentrations of methylglucosinolate in gas chromatographic analysis. In fact, several plants had concentrations which were suprisingly high (46–56 mg/g, dry wt: Blua, personal observation). We found

TABLE 1. SEED PRODUCTION AND METHYLGLUCOSINOLATE CONCENTRATION FOR OPPOSITE SECTIONS OF SOIL MOISTURE GRADIENT AT SITE 2, SEPTEMBER 1984

Distance along gradient	Number of plants	Plants with undamaged capsules (viable seeds/plant)[a,b]				Methylglucosinolate concentration (mg/g, dry wt)[c]		
		N	%	$\bar{X}$	(SE)	N	$\bar{X}$	(SE)
Drier half 0–15 m	37	8	21.6%	22.5	(3.33)	10	41.7	(10.27)
Wetter half 15.1–30	49	8	16.3%	9.0	(2.80)	11	12.0	(3.83)

[a] For $N = 16$ plants with viable seeds, there is a significant negative regression ($r = -0.63$, $P < 0.01$) for the number of viable seeds produced after capsule predation (square-root transformation) and plant position on the gradient [$N = 16$, $Y = 5.5 - 0.105\ X$, where Y = viable seeds per plant for plants with any seeds, X = distance (m) from the dry end of the gradient].

[b] One-way analysis of variance (on square-root transformed number of seeds per plant) shows location effect was highly significant: $F_{1,14} = 12.395$ ($P < 0.01$), with treatment SS = 13.288 (1 df) and error SS = 15.009 (14 df).

[c] One-way analysis of variance (on square-root transformed methylglucosinolate concentration) shows location effect was highly significant: $F_{1,19} = 21.07$ ($P < 0.01$), with treatment SS = 61.606 (1 df) and error SS = 55.562 (19 df).

no indication of the oxazolidinethione-yielding glucocleomin in the paper chromatographic spot test of extracts of *Cleome serrulata.*

Methylglucosinolate concentrations decreased as soil moisture availability increased along the gradient, both at site 1 (Figure 3) and at site 2 (Figure 4). A relatively high proportion of the variance in concentration was explained by position along the gradient: 40% in site 1 and 52% in site 2, semi-log scale.

Concentrations of methylglucosinolate were negatively correlated with both plant height and plant diameter ($r = -0.56$ to -0.77; Table 2). Plant size (as measured by plant height or by plant size index) was also negatively correlated with soil moisture availability, especially in site 2 ($r = -0.71$). A partial correlation analysis showed that when the variation due to plant size was removed, the strong negative relationship between methylglucosinolate concentration and soil moisture availability remained.

DISCUSSION

The results of our study are consistent with the set of hypotheses generated by the converging data from phytochemistry, entomology, and plant ecology. Lower levels of foliage damage (Figure 2), as well as lower levels of capsule damage, with higher production of viable seed after insect predation (Table 1) were associated with higher levels of the characteristic glucosinolate, methylglucosinolate (Figures 3 and 4). The effect of consistent between-year patterns of seed consumption will be cumulative since *Cleome serrulata* is an annual

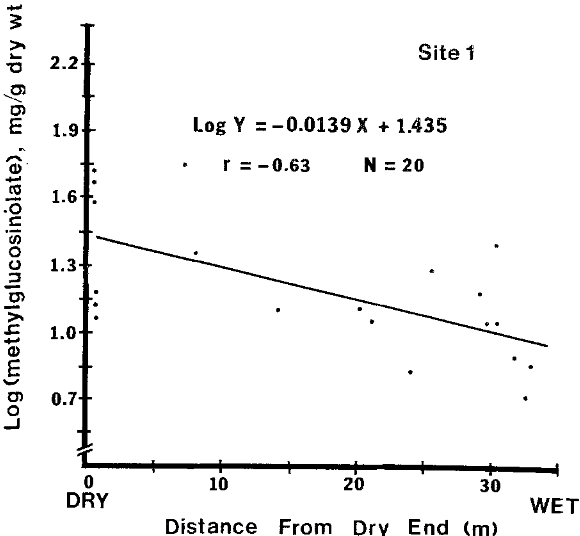

FIG. 3. The relationship between log (methyloglucosinolate) concentration and plant position along the soil moisture gradient at site 1 on August 14, 1984.

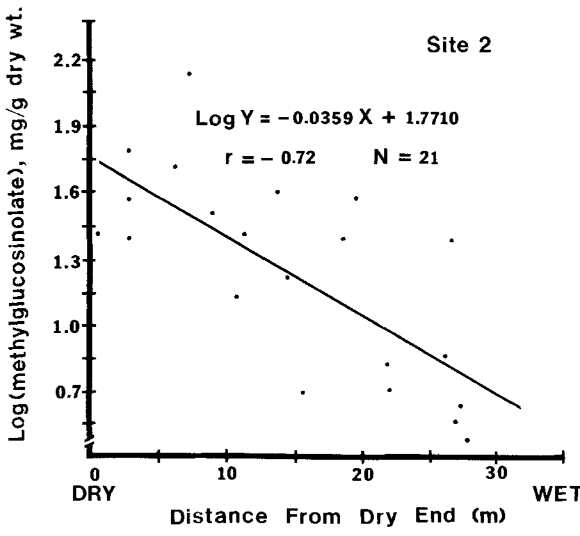

FIG. 4. The relationship between log (methylglucosinolate) concentration and plant position along the soil moisture gradient at site 2 on August 14, 1984.

TABLE 2. PLANT SIZE AND METHYLGLUCOSINOLATE CONCENTRATIONS, $\overline{X}$ (SE), IN RELATION TO PLANT POSITION ALONG SOIL MOISTURE GRADIENT, AUGUST 1984

	Mean distance (m)	N	Plant Size[a]			Methylglucosinolate concentration (mg/g)[c]
			Height (cm)	Diameter (cm)	Index[b] (cm^2)	
Site 1						
Wet	31.0 (0.55)	7	26 (12.8)	44 (7.1)	61 (8.7)	11.8 (2.52)
Mid	22.8 (1.23)	4	91 (15.2)	43 (12.8)	62 (13.6)	12.6 (2.61)
Dry	3.3 (1.75)	6	76 (10.8)	34 (7.4)	46 (8.0)	30.0 (6.20)
Site 2						
Wet	25.6 (0.92)	7	100 (3.5)	52 (6.0)	72 (4.8)	7.6 (2.76)
Mid	15.0 (1.26)	7	80 (9.2)	37 (6.0)	54 (7.3)	23.1 (4.72)
Dry	4.6 (1.21)	7	60 (5.4)	19 (3.1)	33 (4.0)	52.0 (14.77)

[a] Correlations of plant size and soil moisture with $r = -0.42$ to -0.71 ($P < 0.05$ for all cases).
[b] Plant size index = (Ht) × (Diam).

plant. Consequently, we conclude that methylglucosinolate functions as a defensive compound for this annual caper. In addition, there may be a genetic basis for this variation along the gradient. Farris (1985) has, for example, demonstrated that there is a genetic component to the distribution of drought resistance along this gradient.

Also, greater secondary compound concentrations were observed for smaller plants at the harsher (=drier) end of the soil moisture gradient. Low concentrations of the main qualitative chemical defense compound were observed in plants at the wet portion of the gradient (Figures 3 and 4). In this dry habitat, the wet part of the gradient is the physiologically more benign area for plant growth. Interestingly, our observations support Janzen's (1974) prediction and McKey et al.'s (1978) observation that higher defenses are required, or observed, under harsher or more limiting conditions. They are also consistent with Coley et al.'s (1985) hypothesis that slower-growing plants of resource-limited environments should have a greater investment in chemical defense than fast-growing plants in better environments. However, in our case, the defenses

were qualitative ones (glucosinolates) instead of the quantitative ones discussed by Janzen (1974), McKey et al. (1978), and Coley et al. (1985). Also, our variation was intraspecific, rather than the interspecific variation considered in the other studies.

In some cases carbon and nutrient availability may determine defensive strategy and limit plant production of defensive chemcials (Mooney and Chu, 1974; Bryant et al., 1983; Coley et al., 1985). However, in this case, photosynthetic carbon gain does not appear to limit production of glucosinolates. Carbon gain efficiency should be higher at the wet end of our gradients since this was a very dry environment. Yet concentrations of methylglucosinolate were lower at the wet end. These negative findings are similar to those for: (1) another caper–insect interaction (Blua and Hanscom, unpublished data), (2) Douglas fir–spruce budworm interactions (Cates et al., 1983; Cates and Alexander, 1982; Redak and Cates, 1984), and (3) for lepidopteran herbivory on *Diplacus aurantiacus* (Scrophulariaceae) in central California (Lincoln and Mooney, 1984).

The net effect of plant position on the soil moisture gradient for plant reproductive success was the result of two conflicting sets of pressures: physical and biotic. First, physical conditions for plant growth in this dry habitat were better at the wet end; so, greater plant growth and subsequently larger vegetative size and greater reproductive potential were associated with the higher soil moisture levels (Table 2). Plants at the dry end of the soil moisture gradient were under water deficit stress by the end of the growing season (Farris, 1985). Water stress also increases glucosinolate concentrations in related cases, e.g., in black mustard (*Brassica nigra*) (Wolfson, 1980, 1982) and in bittercress (*Cardamine cordifolia*) (Louda and Rodman, 1983a,b; Louda, 1986a,b). However, water stress can increase insect feeding as well as defensive compound concentrations, e.g., on herbaceous plants by generalized insects such as grasshoppers (Lewis, 1979, 1984) and on Douglas fir by spruce budworm (Cates et al., 1983; Cates and Alexander, 1982; Redak and Cates, 1984). Our results are in contrast with those for another small shrub, *Diplacus aurantiacus* (Lincoln and Mooney, 1984), where no correlation occurred between damage and potential water stress differences between plants in sun and in adjacent shade habitats.

Secondly, however, the biotic set of pressures, such as insect herbivore feeding intensity in our case, were also more intense at the wet, more benign end of the gradient (Figure 2, Table 1). And, as noted above, concentrations of the qualitative defensive compound were higher at the harsh end of the gradient (Figures 3 and 4). Thus loss to insects—of foliage, capsules, and seeds—actually decreased as environmental harshness increased (Figure 2; Tables 1 and 2) and, thus, as potential resource limitation increased. The same pattern, of higher loss of flowers and developing seeds in the more benign portion of more extensive (80 km) environmental gradient, was found for one southern

California shrub, *Haplopappus squarrosus* (Louda, 1982b), but not for its overlapping congener, *H. venetus* (Louda, 1983). Unfortunately, no chemical evidence is available from that system.

In sum, the production of the antiherbivore qualitative defense chemical by *Cleome serrulata* was not proportional to the intensity of insect herbivory but, instead, to environmental harshness. Consequently, and contrary to usual expectation, plants that were in the harsher portion of the environment by physiological criteria were the ones that maximized seed reproduction and, other things being equal, plant fitness. This general result has particularly striking demographic consequences, since *Cleome serrulata* is an annual plant and is thus totally dependent upon seed production for population recruitment and persistence between years.

Acknowledgments—This study would not have been initiated or executed without Yan B. Linhart's enthusiastic encouragement and help. Zac Hanscom III was highly instrumental and generous in facilitating the glucosinolate analyses. James E. Rodman stimulated my (S.M.L.) consideration of glucosinolates in an ecological context. Suggestions made by Boyd D. Collier, Sharon K. Collinge, and Daniel H. Janzen improved the manuscript. Support provided by the N.S.F. (BSR-8405625) to S.M.L. and a Noyes Foundation Fellowship to M.A.F. is very gratefully acknowledged.

(Received November 7, 1985; accepted April 15, 1986)

Abstract—When placed in a small observation arena with workers, most young virgin honeybee queens released fecal (hindgut) material during agonistic interactions with workers and with each other. On release of this material, workers moved to the sides of the arena and groomed themselves. Bioassays of virgin queen fecal material demonstrated that it contains pheromone that repels workers and stimulates grooming behavior. Pheromone was present only in the feces of virgin queens that were more than 24 hr old and less than 2 weeks old. Feces of 2- to 4-day-old workers and virgin queens more than 2 weeks old did not elicit an avoidance response by workers. Moreover, the feces of young virgin queens had a strong fragrance, while that of older queens had a rancid odor and that of young workers had no detectable odor.

Key Words—Honeybee, *Apis mellifera*, Hymenoptera, Apidae, feces, queen pheromone, queen acceptance, repellent.

INTRODUCTION

Queen honeybees have long been known to produce a variety of pheromones that are involved in integrating colony behavior. The mandibular glands produce substances (primarily 9-oxodec-*trans*-2-enoic acid) that suppress ovariole development and queen cell construction by workers (see reviews by Butler, 1967; Gary, 1974; Michener, 1974). Secondary queen substances are produced

0098-0331/87/0300-0583$05.00/0 © 1987 Plenum Publishing Corporation

by epidermal glands located on the abdominal tergites (Velthuis, 1970). In addition, pheromone produced by Koschewnikow's glands located near the sting base (Butler, 1967), as well as the mandibular (Gary, 1961; Butler et al., 1973; Simpson, 1979) and tergal glands (Vierling and Renner, 1977), probably have a role in the attraction of workers to queens and in queen recognition. While the existence and function of pheromones in young virgin queens is not well known, little 9-oxodec-*trans*-2-enoic acid is produced by queens less than 3 days old (Butler and Paton, 1962; Velthuis, 1970), and the chemical composition of their mandibular secretion is very similar to that of workers (Crewe, 1982).

Honeybee colonies raise several new virgin queens in response to stimuli that vary with the age and physiological condition of the extant queen and in response to seasonal stimuli associated with the reproductive cycle. When newly emerged virgin queens encounter each other in the hive, they fight until all except one are stung and killed. By observing interactions between 2- to 4-day-old virgin queens in small arenas containing workers, Page and Erickson (1986) frequently found that during agonistic interactions one or both of the queens defecated. On release of the feces, the workers immediately moved away from the queens and clustered near the top of the arena, suggesting that a volatile substance was released. In this paper we describe laboratory studies of interactions between young virgin queens and workers that are confined in small observation arenas. We also present the results of bioassays of the responses of workers to material contained in the hindgut of queens.

METHODS AND MATERIALS

Rearing of Test Bees. Virgin queens and workers used for observations of virgin queen interactions were obtained from eight different colonies, while virgin queens used for the fecal bioassays came from four of the eight colonies. The queen of each colony was in her first season of egg laying during the virgin queen interaction studies (summer of 1984) and in her second season of egg laying during the bioassays of hindgut material (summer of 1985). Each queen of each colony was mated by instrumental insemination to two different unrelated drones. Thus each queen produced worker and virgin queen daughters belonging to two different subfamilies. Queen mothers were supersisters of each other (coefficient of relationship = 0.75).

Virgin queens were produced by grafting young larvae into queen cell cups that were placed in a queenright cell builder colony that was unrelated to the eight source colonies (see Laidlaw, 1979). Once the queen cells were provisioned and sealed by workers, they were placed into individual glass vials (4 dram) and incubated at 34°C until the queens emerged. The wooden base of each queen cell served as a lid for each vial.

Newly emerged queens were subjected to one of the following four treatments:

1. Provided with royal jelly and sugar candy. A small amount of sugar candy was placed in each glass vial, and the queen cells that contained some residual royal jelly were left in place over the tops of the vials. The vials containing queens were returned to the incubator for an additional 2–4 days. In order to determine when the fecal pheromone is produced by queens, some queens were sacrificed at various ages ranging from emergence to less than 48 hr old.

2. Provided with sugar candy only. Queens were treated as described above, except that queen cells were replaced with wooden tops to eliminate the source of royal jelly.

3. Fed by workers for 3–4 days. Queens were removed from the vials immediately after emergence and placed individually in 8-mesh screen cages, which were then inserted into an unrelated colony. The resident queen in the queen-storage colony was separated from the frames holding the young virgin queens by a queen excluder.

4. Fed by workers for 2–3 weeks. Queens were treated as described in (3) above, except they remained in the queen-storage colony for 2–3 weeks. The queens were then placed in individual glass vials, provisioned with sugar candy, and incubated for an additional two days.

Individual workers to be used as a source of feces were collected as they emerged from the brood comb, placed individually into glass vials provisioned with a small amount of sugar candy, and then subjected to one of the following treatments.

1. Provided with sugar candy and royal jelly. The queen cell cups from which queens emerged in treatments 2–4 above were placed over the top of each vial, providing a source of royal jelly for each worker. Each worker was incubated at 35°C for 2–4 days.

2. Provided with sugar candy only. The workers were treated as described in (1) above, except that vials were covered with wooden caps.

All sugar candy used in provisioning the glass vials was made from confectioner's sugar and came from the same batch.

Observations of Queen Interactions. Groups of ten supersister workers (members of subfamilies were phenotypically marked, see Page and Erickson, 1986) were collected at random from individual colonies by vacuuming them from the top bars of the brood chambers into 135-ml cardboard cups (arenas) with wire screen tops. Ten cups of bees were collected at a time and taken directly into the laboratory where behavioral observations began within 15 min after the collection of the last cup of bees. A single virgin queen from treatment 1 was introduced into each arena (cup of 10 bees) by tilting the arena on its side and inverting the vial containing the virgin queen over a hole in the side. Queens were observed individually for 5 min after introduction. Within 30 min to 6 hr after introduction, a virgin queen was removed from one arena and introduced into another that contained a previously introduced queen. Behav-

ioral interactions between the two queens and the workers were then observed for 5 min. Queens and workers were used just once, then discarded.

Procedures for Bioassays of Feces. Groups of 10 workers were collected in 235-ml cups as described above for the observations of queen interactions. Prior to the collection of bees, a 6.0-cm-diameter piece of filter paper with a 1.8-cm-diameter circle marked in the center was taped to the bottom of each cup for use during the bioassays. Cups were taken into the laboratory, and all bioassays with each group of 10 bees were completed within 1 hr.

Prior to each replicate, the feces of a test bee (queen or worker) was collected by immobilizing the bee by crushing its thorax. The terminal abdominal sternite and tergite were spread apart and a micropipet was placed over the anus. The abdomen was gently squeezed until all of the hindgut contents flowed into the pipet.

For each replicate, a test and a control observational arena (cup) were paired. The behavior of the workers was observed for 60 sec before and then for 60 sec after the introduction of feces in the test arena and for similar time periods before and following the introduction of 10–30 μl of distilled water (about equivalent to the volume of feces) in the control arena. The feces and distilled water were introduced into their respective arenas by using a rubber bulb to squeeze each substance out of a micropipet and into the circle on the floor of each arena. Three behavioral patterns of the workers were quantified during each control and test: (1) the number of workers that walked through the 1.8-cm-diameter circle on the bottom of the arena during each 60-sec observation period, (2) the number of bees that groomed their legs or antennae, and (3) the number of workers on the bottom of the arena at the end of each 60-sec observation period.

The responses of the workers to the tests and controls before and after the introduction of feces or distilled water, respectively, were summed for each treatment and analyzed using a χ^2 test of independence. All replicates in which more than five of the worker bees scent fanned were eliminated from the analysis because scent-fanning behavior (with exposure of the Nasonov gland) was interpreted as a consequence of external disturbances and the new surroundings of the bees.

RESULTS

Observations of Queen Interactions. Upon introduction into an arena of workers, 2- to 3-day-old virgin queens typically extended and bowed their bodies, lifted their mesothoracic pair of legs, and expressed a droplet of clear liquid from between open mandibles (N = 312 replicates). Workers usually imbibed the liquid, groomed the queen with their proboscis, and offered the queen a reciprocal droplet of clear liquid. Occasionally, one or more workers behaved

agonistically and grasped a body part of the queen (usually a leg or a wing) with their mandibles. When this occurred, queens often released a volume of liquid hindgut (fecal) material that was light yellowish-brown in color with a strong floral fragrance. Workers usually moved away from this substance to the top and sides of the arena and groomed themselves. Occasionally, queens released a very minute quantity of this hindgut material. Workers appeared to be highly attracted to small amounts.

When two young virgin queens encountered each other, one or both usually released their hindgut content on each other during biting and stinging behavior ($N = 81$ replicates). Workers responded by moving away from the queens and grooming. Many fights between virgin queens lasted for several minutes to several hours with intermittent short periods of biting and attempted stinging followed by longer periods of reduced activity. During periods of reduced activity, workers groomed and fed queens, although frequently queens with feces on their bodies were not cared for by workers or received less care than uncontaminated queens. Occasionally fights resulted in injury and eventual death to both queens.

Fecal Bioassays. At emergence as an adult, virgin queens did not have any hindgut material ($N = 10$). However, queens less than 24 hr old that emerged in glass vials provisioned with royal jelly and sugar candy had approximately 5–20 μl ($\overline{X} = 12.5$; $N = 8$) of material in their hindgut, while queens 24–48 hr old had about 10–30 μl ($\overline{X} = 22.1$; $N = 7$). All fecal material was light yellowish-brown in color and had a strong floral fragrance.

After the hindgut material of a queen from treatments 1 or 2 was introduced into the arena, worker bees moved away from the bottom, clustered on the side and top, and then groomed themselves. Significantly fewer workers walked through the circle and significantly fewer remained on the bottom of the arena after the introduction of feces from treatment 1, yet grooming was significantly more frequent after introduction of fecal material (Table 1). The results of bioassays using the hindgut content of virgin queens from treatment 2 were similar to those of treatment 1, except the decrease in the number of workers remaining on the bottom after 60 sec was not statistically significant. The cessation of walking and frequent grooming were evident 30 sec after the introduction of feces into the arena, and, generally, the workers turned away from the feces and/or clustered for as long as 2–3 min after its introduction.

The feces from 3- to 4-day-old queens fed by workers (treatment 3) elicited responses from workers similar to that of queens reared in glass vials (treatments 1 and 2) (Table 2). However, the feces of 2- to 3-week-old virgin queens fed by workers (treatment 4; Table 2) and 2- to 4-day-old workers (Table 3) did not elicit grooming behavior or repel the bees. There was no significant difference in the number of workers on the bottom of the arena or walking through the circle before and after the introduction of feces.

The feces of all the queens and workers less than 5 days old had a milky

[a] Data are the total numbers of workers walking through a 1.8-cm-diameter circle on the bottom of the arena during 60 sec before and after the presentation of the control (distilled water) and the test (feces), the total numbers of workers on the bottom of the arena, and the numbers grooming at the end of each 60-sec period. Data for the bioassays in treatment 1 and treatment 2 are based on 40 and 25 replicates, respectively, of each control and test.

yellowish-brown color, although the feces from workers had a slight greenish tint. In addition, the feces from young queens had a strong floral scent, while the feces of workers had no detectable odor. Conversely, the feces from 2- to 3-week-old queens fed by workers was clear with chunks of dark solid matter and had a rancid odor.

DISCUSSION

The rectal content of virgin queens less than 2 weeks old contains a pheromone that, under our test conditions, repels workers and stimulates grooming behavior. Production of this material is independent of the food source of virgin

queens. Although feces from young workers is somewhat similar in appearance to that of young queens and very different from that of old queens, our results show clearly that workers do not have the same material in their feces even when fed the same diet as young virgin queens. These results also corroborate the significance of the odor of the feces; only feces of young queens that had a strong floral fragrance elicited avoidance behavior by workers.

Renner and Baumann (1964) found that young virgin queens have a strong floral odor that apparently originates from tergal glands. This odor is found on the abdomens of virgin queens 4–18 days old, but not on newly emerged or very young laying queens (Boch et al., 1975). Although the function of this odor is not known, it does not appear to have a role in drone attraction during mating flights (Boch et al., 1975). Since our results indicate that a similar odor originates from material in the hindgut, it is possible that the odor detected in previous studies actually originated in the hindgut and spread over the abdomen.

The adaptive significance (if any) of the fecal pheromone of young virgin honeybee queens remains to be demonstrated. It may be important in inhibiting rejection of virgin queens by disrupting agonistic behavior of workers. In addition, it may provide a ritualistic element to the dominance fight of virgin queens and help ensure that a queen, and thus the colony, survives. Evenly matched virgin queens may inflict reciprocal damage on each other, reducing the potential for the colony to successfully produce a replacement queen. However, if workers use contamination of a queen with feces as a symbolic determinant of subordination or dominance, then they may aid in the final determination of colony succession by not feeding and grooming contaminated queens and thereby placing the contaminated queen at a disadvantage.

Pheromone in the feces may also provide labels used by workers in kin recognition. Page and Erickson (1986) demonstrated that virgin queens have

genetically determined labels and that workers learn these labels and respond differentially on the basis of genetic relationship. The location and nature of these labels are unknown.

Additional behavioral assays under less artificial test conditions are necessary to determine if queens and workers respond to the pheromone in the same way in a natural context and to determine the adaptive significance of the feces pheromone. Further studies also are needed to determine if the odor described by Renner and Baumann (1964) as emanating from the tergites actually originates from the hindgut, and, if it does not, then to determine the functional relationship of these two sources of pheromone. Identification and testing of specific chemical compounds from the fecal material to determine the active components would greatly facilitate investigations of the possible functional significance of this newly discovered honey bee queen pheromone.

Acknowledgments—We thank Holly A. Downing, Robert L. Jeanne, Harry H. Laidlaw, Jr., and an anonymous reviewer for helpful comments on the manuscript.

(Received January 8, 1986; accepted April 16, 1986)

Abstract—Alpha-terthienyl is toxic to *Aedes aegypti* larvae in the dark, but its activity is much enhanced in the presence of ultraviolet light. The development of first-instar larvae treated with alpha-terthienyl and ultraviolet light was followed until the emergence of adults. The LC_{50} value for first instars was about 0.002 ppm. Practically all the larvae which survived 24 hr reached adulthood. Fourth-instar larvae were also sensitive to photochemical treatment. When their development into adults was followed, the LC_{50} value was 0.45 ppm. Contrary to earlier reports, alpha-terthienyl was also phototoxic in pupae, but not when the adults were about to emerge. The LC_{50} value was ca. 0.06 ppm for pupae which were 1 or 2 days old. This is the first example where the activity of a photoinsecticide has been demonstrated in pupae. Alpha-terthienyl did not affect the hatching of eggs.

Key Words—Alpha-terthienyl, *Aedes aegypti*, Diptera, Culicidae, photosensitization, insecticide.

INTRODUCTION

A recent report described delayed phototoxic effects encountered with three naturally occurring plant products, 8-methoxypsoralen, khellin, and sphondin (Kagan et al., 1986a). In these experiments, first-instar larvae of the mosquito *Aedes aegypti* were treated overnight in the dark with the sensitizer. After a brief irradiation with long-wavelength ultraviolet light, their development in the dark was monitored for the appearance of adults. This approach produced evidence of delayed phototoxic effects by compounds which had shown little or no activ-

0098-0331/87/0300-0593$05.00/0 © 1987 Plenum Publishing Corporation

ity during short-term experiments. To date, highly active photosensitizers have not been investigated for delayed phototoxic effects. We therefore selected alpha-terthienyl for this study.

Alpha-terthienyl occurs naturally in the marigold (*Tagetes erecta*) and in many related plants of the family Compositae (Bohlmann and Zdero, 1985). It has a wide range of biocidal activity, particularly when the target organisms are simultaneously exposed to ultraviolet light.

The pronounced phototoxicity of alpha-terthienyl to immature insects was described by Towers (1980), Wat et al. (1981), Arnason et al. (1981a), Kagan et al. (1983, 1984a), Kagan and Chan (1983), Downum et al. (1984), Towers et al. (1984), Champagne et al. (1984), and Philogene et al. (1985). The potential for commercial applications of this natural product as a photoactive insecticide has become apparent, and one patent on this use has already been issued (Towers et al., 1984). However, alpha-terthienyl is also very phototoxic in nontarget aquatic organisms such as tadpoles and fish (Kagan et al. 1984b, 1986b), and this lack of selectivity may create a major obstacle to the use of this chemical.

Our study defines more carefully the response of immature *A. aegypti* to photochemical treatments with alpha-terthienyl under laboratory conditions, starting with eggs, first- and fourth-instar larvae, as well as with pupae.

Since we observed in our earlier screening experiments that resistance to dieldrin (DLS_1 strain) and to DDT (Trinidad strain) conferred no protection to *Aedes aegypti* larvae treated with alpha-terthienyl and light, compared to the wild type (Rock), all work reported herein was performed with the wild-type organism.

METHODS AND MATERIALS

Alpha-terthienyl was synthesized in the laboratory (Kagan and Arora, 1983). Prof. G. B. Craig, Jr., University of Notre Dame, provided the original eggs of the three strains (Rock, DLS_1, and Trinidad) of *A. aegypti*. Except where noted, all the experiments were conducted at room temperature. Fabric supports containing ca. 20 eggs were placed into 3 ml of sensitizer solution (6.7 and 1.1 ppm), and incubated for 30 min in darkness. One set of eggs was irradiated as described for larvae (see below). Hatching at 24 hr was scored by observation of eggs under a microscope and compared to that in dark controls. In the morning, eggs were placed in aged tap water in an incubator at 28°C. First-instar larvae were collected in the afternoon. For each experiment 10 larvae were transferred into a 6-ml vial, almost all the water was removed, and 3 ml of the appropriate solution (Table 1) were added under very dim incandescent light. The number of replicates at each concentration and illumination var-

ied between three and nine (Table 1). All samples were incubated overnight in the dark.

The next morning, one set of larvae was kept as controls, and the other was irradiated for 30 min under a bank of eight lamps (RPR-3500A from Southern New England Ultraviolet Co, Hamden, Connecticut) mounted 5 cm apart. These lamps emit only between 300 and 400 nm, with a maximum at 350 nm. The light intensity, measured with a Yellow Springs Radiometer model 65, was 15 W/m^2. Each set of larvae was transferred into a Petri dish containing 40 ml of water, to which was added 1 ml of a 16-g/liter aqueous suspension of liver powder (ICN Pharmaceuticals, Cleveland, Ohio). The transfers were performed in a darkroom dimly lit under an amber Kodak OC Safelight filter. Controls and irradiated larvae were then kept in the darkroom for the duration of the experiments. Surviving organisms were counted every day afterwards and were fed in the same manner three and six days after irradiations.

Experiments with fourth-instar larvae were conducted identically, except that the incubation period with sensitizer was only 30 min. Food was provided only once, immediately after irradiation.

Once daily on successive days, all pupae which had appeared from the

same pool of fourth-instar larvae were collected and kept separately. On the third day, samples of 10 pupae from each of the three age groups were placed in vials and incubated in the presence of sensitizer for 30 min, as previously described with larvae (Kagan et al., 1986a). After 30 min of irradiation, all pupae were transferred into Petri dishes containing 40 ml of water. Adult emergence was determined six days after collection of the pupae (Table 2). In order to study the sex dependence of phototoxicity in pupae, a large pool of synchronized first-instar larvae was used. Pupae were collected daily and treated with 1.12 ppm of alpha-terthienyl as described above. Sex determination was made six days later.

In all cases, the fate of organisms irradiated in the presence of sensitizer was compared to that of dark controls which had been treated with equal amounts of sensitizer. The fate of organisms placed in sensitizer solutions which had been previously irradiated for 30 min was also determined using the same procedures. LC_{50} estimates were obtained by visual inspection of mortality curves. Differences in mortality data were analyzed by Mann-Whitney or Kruskal-Wallis tests followed by Dunn a posteriori contrasts (Zar, 1984).

RESULTS AND DISCUSSION

Phototoxicity in Eggs. The hatching of eggs treated with 6.7 ppm alpha-terthienyl [mean 81.9%, standard error of mean (SEM) 6.8%] was not significantly different ($P > 0.5$) from dark controls (87.8%, SEM 6%). Similar results were obtained at 1.1 ppm (irradiated 82%, SEM 5.3%; controls 80.2%, SEM 11%; $P > 0.5$). These results confirm the lack of effect on hatching reported by Arnason et al. (1981a). While the concentrations of alpha-terthienyl did not prevent normal hatching, they were fatal for liberated larvae.

Phototoxicity in Larvae. Alpha-terthienyl is toxic to first-instar larvae of *A. aegypti* in the dark (Figure 1). For example, all larvae died within 24 hr at concentrations of 6.7 and 1.12 ppm. At 0.03 ppm, practically all (94%, SEM 3%) the larvae survived 24 hr, and a large proportion of them developed normally into adults (82%, SEM 6%; Figure 2A). At this concentration, however, all larvae were dead after 30 min under ultraviolet light (Figure 2A). The survival of larvae treated in the dark with a 0.03 ppm sensitizer solution which had been previously irradiated for 30 min produced the same percentage of emerging adults (86%, SEM 5%) as dark controls (not shown).

There was no toxicity without irradiation at 0.005 ppm; 86% of the initial larvae produced adults by the end of the experiments, a level comparable to untreated controls (Kagan et al., 1986a). However, phototoxicity at this concentration was still high, with 23% surviving the irradiation itself and only 12% surviving 24 hr later. Almost all of these survivors, however, developed normally into adults (Figure 2B).

Further dilution of the sensitizer, to 0.0009 ppm, removed all visible toxic

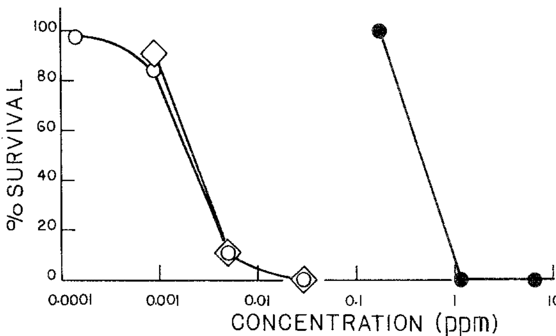

FIG. 1. Survival of *A. aegypti* following the treatment of first-instar larvae as described in text: in the dark (closed circles) and following 30 min of irradiation (open squares: 24-hr survival, open circles: adult survival). The concentration of alpha-terthienyl is shown on a logarithmic scale.

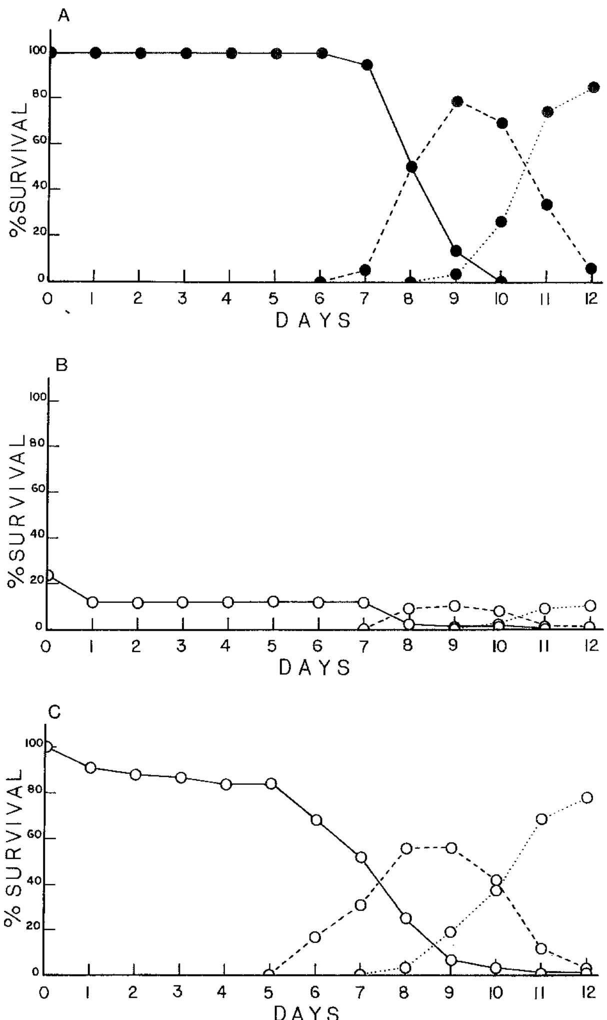

FIG. 2. Surviving larvae (solid lines), pupae (broken lines), and adults (dotted lines) obtained from first-instar larvae in the dark (closed circles) and irradiated (open circles), as a function of time. The alpha-terthienyl concentration was 0.03 ppm (A), 0.005 ppm (B), and 0.0009 ppm (C).

effects, with the same survivorship (78%, SEM 9%) to adults in the irradiated organisms and in the dark controls (78%, SEM 7%; Figure 2C). An LC_{50} value of 0.0018 ppm was measured graphically for the surviving organisms on day 12, the arbitrary end of the experiments determined from survival curves. For comparison, the LC_{50} value determined in the same manner from survival data

determined 24 hr after irradiations was 0.002 ppm (Figure 1). The nearly identical value for survivorship determined 12 days later contrasts with results observed with several phenolic derivatives which displayed significant delayed mortality (Kagan et al., 1986a).

In an earlier work, we demonstrated that the activity of the enzyme acetylcholinesterase was severely reduced in *A. aegypti* larvae during exposure to ultraviolet light in the presence of alpha-terthienyl (Kagan et al., 1984a). Such a change, as well as perhaps the photosensitized inactivation of other enzymes which can be rapidly regenerated by the organisms, could possibly explain the negligible delayed toxicity of alpha-terthienyl following irradiation. If the enzyme(s) activity remains above a critical value and can later be regenerated to optimum level, normal development of the organism is possible. Another reasonable explanation is based on the damage of cell membranes photoinduced by alpha-terthienyl (Downum et al., 1982; Yamamoto et al., 1984). The production of singlet oxygen by alpha-terthienyl has been well characterized by chemical (Bakker et al., 1979; Gommers et al., 1980; Arnason et al., 1981b; Kagan et al., 1984a; McLachlan et al., 1984) and by physical methods (Reyftmann et al., 1985). Damage to membranes by singlet oxygen can possibly disrupt water and ion balance. Anal papillae are delicate structures involved in ion balance in mosquito larvae (Wigglesworth, 1973) and thus may be especially sensitive. Should the damage be limited to parts of the organism which are lost during molting, each surviving larva at its next instar would have shed its damaged components and become able to complete its development unimpaired.

Arnason et al. (1981) reported data for UV-treated first-instar larvae showing 98% survival at 0.1 ppm and 0% at 0.3 ppm. The LC_{50} under these conditions was therefore certainly in excess of 0.1 ppm, perhaps close to 0.2 ppm. We determined the LC_{50} for first-instar larvae to be 0.002 ppm. Differences in light intensity [listed at 6 W/m^2 in an earlier paper by Wat et al. (1981) compared to 15 W/m^2 in ours] and in chemical doses at each concentration level (10 organisms in 3 ml in our work, 25 organisms in 2 ml in theirs, or a 3.75-fold factor) may have contributed to the lack of quantitative agreement between the two studies. Our results for the phototoxicity of alpha-terthienyl in fourth-instar larvae (LC_{50} = 0.5 ppm after 24 hr) are in good agreement with Arnason et al. (1981a), who recorded 52% survival at 1 ppm and 0% at 3 ppm. Their LC_{50} value must therefore have been very close to 1 ppm.

When the development of photosensitized fourth-instar larvae into adults was followed, the LC_{50} value determined visually from the survival curve was 0.45 ppm, compared to 3.5 ppm for the dark controls (Figure 3). The similarity of 24-hr and cumulative-mortality LC_{50}s again underscores the different mode of action of alpha-terthienyl and the phenolic compounds (8-methoxypsoralen, sphondin, and khellin) investigated earlier.

Phototoxicity in Pupae. Arnason et al. (1981a) reported the pupae of *A. aegypti* were not affected 24 hr after a photochemical treatment with alpha-

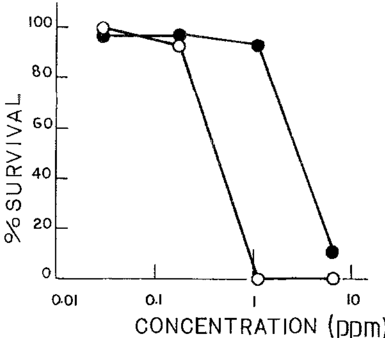

FIG. 3. Surviving organisms following the treatment of fourth-instar larvae with alpha-terthienyl, 24 hr after irradiation (closed circles) and through adult emergence (open circles). The sensitizer concentrations are shown on a logarithmic scale.

terthienyl up to 10 ppm. While we confirmed that no toxicity could be detected over a 24-hr period following irradiations at up to 6.7 ppm, a more careful analysis over the period of time required for adult emergence led to a different conclusion. A systematic study disclosed that the level of phototoxicity for alpha-terthienyl diminished as photochemically treated pupae approached adult emergence.

These experiments indicated that 3-day-old pupae were largely unaffected by the treatment (Figure 4). Adults often emerged during the irradiation of these pupae. Younger pupae were more sensitive to the phototoxic effects of alpha-terthienyl. Practically no difference was found between the survival of 1- and 2-day-old pupae. The survival curves shown in Figure 4 indicate a LC_{50} value of ca. 0.06 ppm for these pupae.

Other experiments were designed to probe whether a sex difference might be responsible for the differential response of pupae according to their age. When series of daily cohorts from a synchronized population were treated with 1.1 ppm of alpha-terthienyl and irradiated, no significant difference in survival was observed for 1-, 2-, or 3-day-old pupae collected over five days (Kruskal-Wallis tests, $Ps > 0.10$). The data from daily collections were pooled and are shown in Table 2. A Kruskal-Wallis test detected a significant difference among the three groups ($P = 0.0001$). It is obvious that the significant difference is due to greater survival of 3-day-old pupae (Table 2), but this could not be statistically demonstrated with a posteriori Dunn contrasts.

Since males emerge slightly ahead of females (Haddow et al., 1959), the age dependence expressed on Figure 4 could have arisen from a depletion of the pool of male organisms during the first two days and be linked to a lesser sensitivity of the remaining females. Actually, a direct analysis of the pupae treated in the experiment described above disclosed that the pupae collected each day essentially had the same sex ratio (range 36.6–54.5% females). The

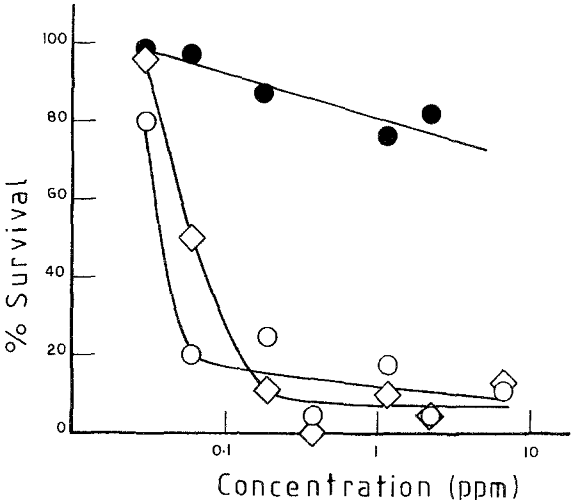

FIG. 4. Survival of pupae through adult emergence following irradiation in the presence of alpha-terthienyl. The age of the pupae at the time of the irradiation was 0–1 day (open circles), 1–2 days (open squares), and 2–3 days (closed circles).

difference in sensitivity to the photosensitized treatment between 3-day-old and younger pupae must therefore be related to developmental changes. For example, decreased sensitivity in 3-day-old pupae is correlated with increased pigmentation of these pupae compared to younger ones: the 3-day-old pupae have complete imaginal pigmentation, and 1- or 2-day-old pupae are mostly unpigmented. It is uncertain whether the amount of pigmentation is directly protective or merely a marker for other coincident phenomena.

CONCLUSION

Alpha-terthienyl was not effective in preventing hatching at the concentration tested. Although some toxicity of alpha-terthienyl to other immature forms of the mosquito *A. aegypti* can be observed in the dark, it is greatly enhanced by exposure to ultraviolet light, even for a short duration. The phototoxicity does not depend on light-mediated synthesis of toxic products, and it is likely to operate because of the extremely favorable photophysical characteristics of the sensitizer, which has a very long-lived triplet excited state, as well as a high quantum yield for energy transfer to oxygen, which produces singlet oxygen (Reyftmann et al., 1985). The detailed mechanism of phototoxicity is still unknown, but the fact that practically all larvae surviving 24 hr emerge as adults suggests that phototoxicity is immediate. Although the sensitizer's potency decreases as larvae mature, it is still appreciable in fourth-instar larvae. Also, the

LC_{50} value for 1- or 2-day-old pupae is one order of magnitude smaller than for fourth-instar larvae.

Our experiments provide the first evidence of phototoxicity to pupae by any sensitizer. Potency appears to be age-dependent since mature pupae (>72 hr) exhibit greatly reduced sensitivity to alpha-terthienyl. Inasmuch as it is not manifested over a 24-hr period, previous investigators (e.g., Arnason et al., 1981a) may have missed the expression of phototoxicity in pupae. Whether the delayed toxicity at this developmental stage indicates a mechanism different from that operating in larvae remains to be established.

Finally, it is instructive to compare the phototoxicity of alpha-terthienyl in *A. aegypti* with that in *A. atropalpus* (Philogene et al., 1985). Sunlight irradiations used in the latter work yielded LC_{50} values between 0.010 and 0.050 ppm, depending on testing conditions. These LC_{50}s are similar to those found in this study. It is clear that, under our experimental conditions, alpha-terthienyl is much more phototoxic to immature *A. aegypti* than the phenolic compounds 8-methoxypsoralen, khellin, and sphondin (see Philogene et al., 1985; Kagan et al., 1986a).

Acknowledgments—We are most grateful to Prof. G.B. Craig, Jr., University of Notre Dame, who generously provided advice and supplied the egg sheets used in starting our laboratory colony of *A. aegypti*, and to Prof. M. Berenbaum, University of Illinois at Urbana, for comments and suggestions. Early investigations, which also benefited from skillful work by I.A. Kagan, were funded by the National Institutes of Health (GM 24144). Financial support by the Research Board of the University of Illinois allowed their completion.

FAILURE OF TANNIC ACID TO INHIBIT DIGESTION OR REDUCE DIGESTIBILITY OF PLANT PROTEIN IN GUT FLUIDS OF INSECT HERBIVORES:
Implications for Theories of Plant Defense

(Received February 3, 1986; accepted April 16, 1986)

Abstract—The rate of hydrolysis of the abundant foliar protein, ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPC), in enzymatically active gut fluid of *Manduca sexta* larvae is very rapid and is unaffected by the presence of tannic acid, even when tannic acid is present in the incubation mixture in amounts in excess of the amount of RuBPC. When this protein is dissolved in the denatured gut fluids of *M. sexta* larvae or *Schistocerca gregaria* nymphs, large amounts of tannic acid must be added to bring about the precipitation of significant quantities of protein. The ability of insect gut fluid to prevent the formation of insoluble tannin–protein complexes is due to the presence of surfactants. On the basis of our results and a review of the findings of other investigators, we argue that there is no evidence that tannins reduce the nutritional value of an insect's food by inhibiting digestive enzymes or by reducing the digestibility of ingested proteins and, further, that the failure of tannins to interfere with digestion is readily explained on the basis of well-documented characteristics of the digestive systems of herbivorous insects. In challenging the currently popular notion that tannins are digestibility-reducing substances, we do not challenge the general utility of either the apparency theory or resource availability theory of plant defense. In debating the merits of these two analyses of plant–herbivore interactions, however, the demise of tannins as all-purpose, dose-dependent, digestibility-reducing defensive substances must be taken into account.

Key Words—Tannins, digestibility-reducing substances, surfactants, detergency, herbivory, chemical defense, allelochemics, *Manduca sexta*, *Lepidoptera*, *Sphingidae*, *Schistocerca gregaria*, Orthoptera, Acrididae.

INTRODUCTION

Ingested tannins interfere with the normal growth and development of many foliage-feeding insects, and this class of allelochemicals has been accorded an important role in protecting vascular plants from herbivory (Feeny, 1976; Rhoades and Cates, 1976; Swain, 1979; Coley et al., 1985). Tannins are known to be protein precipitants (Van Sumere et al., 1975; Hagerman and Butler, 1981; McManus et al., 1983), and it has been proposed that they might interfere with protein digestion in an herbivore's gut by binding proteolytic enzymes or ingested proteins (Feeny, 1976; Rhoades and Cates, 1976). Since the growth of many herbivores is nitrogen limited (Mattson, 1980), any interference with protein digestion could have a severe negative impact on fitness. While there is evidence that tannins act as digestion-inhibiting substances in certain species of vertebrates, possibly by interfering with the growth and metabolism of rumen microorganisms (Waterman et al., 1980, 1984), to date there has been no experimental demonstration that tannins ever act as digestibility-reducing or digestion-inhibiting substances in any herbivorous insect species (Bernays, 1981; Martin and Martin, 1984; Martin et al., 1985). The adverse effects that dietary tannins have on the growth and development of tannin-sensitive insects appear to be due instead to the properties of these polyphenols as feeding deterrents (Klocke and Chan, 1982; Reese et al., 1982; Manuwoto et al., 1985; Manuwoto and Scriber, 1986) and toxins (Berenbaum, 1984; Bernays et al., 1980; Manuwoto et al., 1985; Manuwoto and Scriber, 1986; Steinly and Berenbaum, 1986).

Several characteristics of the digestive systems of insects have been identified which counter the potential anti-digestive properties of tannins. It has been proposed that high gut alkalinity is an antitannin adaptation in lepidopteran larvae (Feeny, 1970; Berenbaum, 1980) and that detergency is a widespread characteristic of insect gut fluids that prevents tannins from precipitating ingested proteins (Martin and Martin, 1984; Martin et al., 1985). In addition, some species of acridids possess digestive β-glucosidases that are able to degrade hydrolyzable tannins and peritrophic membranes that adsorb tannins and remove them from the gut milieu (Bernays, 1981).

In this study we have assessed the capacity of tannic acid to act as a digestion-inhibiting or digestibility-reducing substance in the tobacco hornworm, *Manduca sexta*, and the locust, *Schistocerca gregaria*. *M. sexta* larvae do not normally consume tannin-containing foliage and would not be expected to have evolved specific adaptations to counter the potential adverse effects of tannins, while *S. gregaria* feeds on the foliage of many plant species containing tannins and is quite tolerant of these polyphenols (Bernays, 1981). We have explored the effect of added tannic acid on the rate of hydrolysis of the abundant foliar protein, ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPC), in enzy-

matically active gut fluid of *M. sexta* at pH 10.2–10.6 and have measured the amount of RuBPC precipitated from the denatured gut fluids of *M. sexta* and *S. gregaria* at pH values near neutrality by various amounts of tannic acid. We have conducted these experiments at tannin–protein ratios ranging from zero to values in excess of unity, a range which probably includes the values typical of most natural vegetation. Finally, we have performed experiments to establish which components of the gut fluid are responsible for its ability to prevent the formation of insoluble complexes between tannic acid and RuBPC. Our results do not support the idea that tannins are digestion-inhibiting or digestibility-reducing substances in insects.

METHODS AND MATERIALS

Culturing of Insects. Fifth-instar *M. sexta* larvae were reared from eggs on an artificial agar-based diet (Yamamoto, 1969) supplemented with wheat-germ oil (2.99 g/1000 g diet). Alternatively, larvae were reared on artificial diet through the third instar, at which time they were transferred to tomato plants and allowed to feed through the fifth instar on tomato foliage. Late-instar larvae were also collected from tomato plants growing in a tomato field in Washtenaw County, Michigan. Fifth-instar *S. gregaria* nymphs were raised in crowds on bran and wheat seedlings at The Centre for Overseas Pest Research, London, U.K.

Determination of Minimum Gut Passage Time. Ten fifth-instar larvae, weighing between 3.272 and 5.004 g (the size range used as a source of gut fluid), were placed in Petri dishes containing a cube of artificial diet amended with a small amount of finely divided charcoal. After feeding for 30 min, the larvae were transferred back to diet lacking charcoal. Frass pellets were collected every half hour for the next 10 hr and were inspected visually for the presence of charcoal particles. In separate experiments, it was established that the rates of feeding and pellet production by larvae that had ingested charcoal-amended diet were no different from the rates for larvae that had not fed on the charcoal-amended diet.

Collection of Gut Fluid. Gut fluid was collected from actively feeding fifth-instar *M. sexta* larvae. After making an incision encircling the body, the intact midgut was exposed by gently pulling the two halves of the body apart. The exposed midgut was rinsed with distilled water, blotted dry, and slit longitudinally, allowing the contents to flow into a centrifuge tube chilled in an ice bath. Following centrifugation (12,000*g*, 10 min, 5°C), the supernatant fluid was either frozen and stored at −16°C or denatured by heating at 100°C for 10 min, centrifuged as before, lyophilized, and stored dry at −16°C. There was no significant loss of proteolytic activity in active gut fluid stored in a

frozen state at −16°C even after several months. Gut fluid from 3- to 5-day-old (±12 hr) fifth-instar nymphs of *S. gregaria* was obtained both by inducing regurgitation through handling and by expressing gut contents from a small hole cut at the foregut–midgut junction of the excised gut. Gut fluid was removed with 100-μl capillary tubes and collected in 2-ml portions in chilled vials, denatured by heating at 100°C for 15 min, lyophilized, and air-mailed from London, U.K., to Ann Arbor, Michigan. Upon arrival in Ann Arbor, the lyophilized material in each vial was redissolved by adding water (3 ml). The mixture was centrifuged (12,000*g*, 10 min, 20°C), the supernatant solutions from all of the vials were combined, and the pooled preparation was lyophilized and stored dry at −16°C.

Fractionation of Gut Fluid. Nine volumes of 95% ethanol were added to one volume of gut fluid, and the mixture was allowed to stand for 18 hr at 5°C. Following centrifugation (12,000*g*, 10 min, 20°C), the supernatant solution was concentrated almost to dryness on a rotary concentrator at reduced pressure. The concentrated solution was then lyophilized and stored dry at −16°C. This fraction, which contains all solutes not precipitated by ethanol, was designed fraction A. The precipitate from the ethanol treatment was placed under a gentle stream of nitrogen to remove traces of ethanol, dissolved in water (two times the volume of the original gut fluid), and filtered through a YM-10 membrane (Amicon Corp. Danvers, MA). Both filtrate and residue were lyophilized and stored dry at −16°C. The filtrate, which contained solutes precipitated by ethanol having molecular weights less than 10 kD, was designated fraction B. The residue, which contained solutes precipitated by ethanol having molecular weights greater than 10 kD, was designated fraction C.

pH Measurements. Measurements of pH were made on freshly collected *M. sexta* gut fluid or rehydrated *S. gregaria* gut fluid using a combination pH microelectrode (Microelectrodes, Inc.).

Surface Tension. Surface tension was measured using the horizontal thick-walled capillary apparatus of Ferguson (1943). Surfactant concentration, in multiples of the critical micelle concentration (CMC), was determined by measuring the surface tensions of a series of dilutions of the test sample, and noting the dilution at which there was an abrupt increase in surface tension (Martin and Martin, 1984). The CMC is the concentration at which there is a transition between the surfactant in the free, unassociated state and the micellar state. The diluent was 160 mM KCl–3 mM NaCl, chosen to maintain ionic conditions comparable to those typical in insect midgut fluids (Giordana and Sacchi, 1978).

Precipitation of RuBPC by Tannic Acid. Full-strength denatured gut fluid was reconstituted from lyophilized gut fluid powder by adding water (one third of the volume of the gut fluid from which the powder was originally derived) and an equal volume of 0.3 M PIPES buffer [piperazine-*N*,*N*′-bis-(2-ethanesulfonic acid)], pH 6.8, and adjusting the pH of the mixture to 6.8 by the

dropwise addition of either HCl or KOH. Preparations of gut fluid from larvae from the agar-based artificial diet contained suspended lipid-like particles, which were removed by filtration through Celite. Water was added to the solution or filtrate to bring the final volume to that of the gut fluid from which the powder was derived.

Solutions containing the separate gut fluid fractions were prepared from the lyophilized powders by adding water (one sixth of the volume of the gut fluid from which the powder was originally derived) and an equal volume of 0.3 M PIPES buffer, pH 6.8, adjusting the pH to 6.8 by the dropwise addition of either HCl or KOH, and finally adding water to bring the volume to one half the original volume of the gut fluid from which the fraction was derived. This solution, which was twice as concentrated as gut fluid, was then combined with either an equal volume of 0.1 M PIPES, pH 6.8, or with an equal volume of a solution of a different gut fluid fraction prepared in the same manner. A solution containing all three gut fluid fractions was prepared by combining solutions of fractions A and B with a weighed quantity of lyophilized fraction C.

RuBPC (Sigma R-8000, Lot 82F-7340) was added to reconstituted denatured gut fluid or solutions of the gut fluid fractions (2 mg RuBPC/ml), and the mixture was allowed to stand for 18 hr at 5°C, after which it was shaken for 10 min at room temperature and centrifuged (14,500*g*, 10 min, 20°C). The amount of RuBPC in solution was then determined using the assay procedure described below. Virtually all of the RuBPC dissolved in the *M. sexta* gut fluid, while only about three fourths dissolved in the *S. gregaria* gut fluid, perhaps because of the much higher concentrations of solutes already present in the *S. gregaria* fluid (see Table 3). To 250 μl of this solution was added, with vortexing, 25 μl of a freshly prepared solution of tannic acid (Sigma T-0125, lot 40F-0253) in 0.1 M PIPES, pH 6.8. After 10 min, the mixture was centrifuged (14,500*g*, 10 min, 20°C), the supernatant solution was decanted, and the pellet was rinsed carefully with 0.1 M PIPES, pH 6.8. The pellet was dissolved in 0.60 ml of a solution of 1% SDS in 0.05 M Tris, pH 7.5, and protein was precipitated by adding 0.15 ml of 90% trichloroacetic acid. The amount of protein precipitated was determined using the assay described below.

Proteolysis in Active M. sexta *Gut Fluid.* A mixture, prepared by adding 100 μl of a solution of RuBPC (10.8–14.0 mg/ml) in 1.0 M CAPS [3-(cyclohexylamino)propanesulfonic acid], pH 10.5, to 1 ml of active gut fluid, was incubated at 24°C. Duplicate aliquots (25 μl), removed after 5 and 15 min, were added to 0.15 ml of 90% trichloroacetic acid, and the amount of protein precipitated was determined using the assay procedure described below. When tannic acid was included in an incubation, it was added to the gut fluid immediately prior to the addition of the RuBPC solution. When the amount of tannic acid in the incubation mixture was 1.5 mg/ml, it was added as the dry solid; when it was 0.14 mg/ml, it was added in 10 μl of an aqueous solution. In

separate experiments it was established that proteins present originally in the gut fluid sample were stable and did not undergo autolysis or hydrolysis during incubation. Thus, the decrease in protein content during incubation was due to hydrolysis of the added RuBPC.

Protein Assay. Protein was measured using the method of Schaffner and Weissmann (1973) as adapted by Martin et al. (1985). Protein precipitated from a test solution by the addition of trichloroacetic acid was absorbed on a nitrocellulose membrane (0.45 μm) and stained with Amido black 10B. After removing excess unbound Amido black 10B, protein-bound dye was eluted and absorbance at 630 nm was determined. Absorbance at 630 nm resulting from substances other than RuBPC was determined from RuBPC-free blanks, and this value, which was always small, was subtracted from the observed absorbance of the test sample in order to give the absorbance due to RuBPC. Absorbance at 630 nm due to RuBPC was converted into micrograms of protein by the use of a calibration curve constructed from dilutions of a stock solution of RuBPC.

RESULTS

Rate of Passage of Food through Guts of Fifth-Instar M. sexta *Larvae.* When fifth-instar larvae were allowed to feed for 30 minutes on artificial diet to which finely divided charcoal had been added and then transferred back to charcoal-free diet, the average time interval between the initiation of feeding on the charcoal-containing diet and the appearance of charcoal in a fecal pellet was 2.6 hr (standard error 0.16). The last fecal pellet containing detectable charcoal particles was produced after 8.45 hr (standard error 0.31). Although this experiment does not permit an accurate calculation of the average length of time that a food particle is in contact with midgut digestive enzymes, it does clearly indicate that the time is measured in hours, not minutes.

Digestion of RuBPC in Active M. sexta *Gut Fluid.* The hydrolysis of RuBPC in undiluted enzymatically active *M. sexta* gut fluid at pH 10.2–10.6 is very rapid, whether tannic acid is present or not (Table 1). After only 5 min, digestion was 60–87% complete. Our attempts to assess the effects of added tannic acid on the extent of proteolysis after 5 min, when proteolysis was still in progress, were only partially successful, owing to the variability in our measurements of the amount of unhydrolyzed protein present in a solution in which protein content is changing rapidly. In the runs initially containing 1.08 and 1.18 mg/ml of RuBPC, the inclusion of tannic acid in the incubation mixture did not result in a reduction in the amount of hydrolysis after 5 min, while in the run initially containing 1.36 mg/ml of RuBPC, the inclusion of 1.50 mg/ml of tannic acid resulted in a 30% decrease in the amount of RuBPC hydro-

TABLE 1. EFFECT OF TANNIC ACID (TA) ON HYDROLYSIS OF RuBPC IN ENZYMATICALLY ACTIVE GUT FLUID FROM FIFTH INSTAR *M. sexta* LARVAE FED TOMATO LEAVES DURING LAST TWO INSTARS[a]

Incubation mixture		RuBPC digested [mg/ml (% of original)]	
RuBPC (mg/ml)	TA (mg/ml)	5 min	15 min
1.08	0.00	0.86 (80)	1.07 (99)
1.08	0.14	0.90 (83)	1.11 (103)
1.18	0.00	0.80 (68)	1.22 (103)
1.18	1.50	0.83 (70)	1.16 (98)
1.36	0.00	1.18 (87)	1.30 (96)
1.36	1.50	0.82 (60)	1.30 (96)

[a]The incubation mixture had a volume of 1.1 ml and a pH of 10.2–10.6. Values are the averages of duplicate determinations.

lyzed after 5 min. After 15 min, however, digestion was complete in all cases, even when tannic acid was present in the incubation mixture in excess of the RuBPC present. Since food is in contact with midgut digestive enzymes for a period far in excess of 15 min, it is clear that there is no significant interference with the digestion of RuBPC by tannic acid in the undiluted active gut fluid of *M. sexta* larvae.

Precipitation of RuBPC from Denatured M. sexta *Gut Fluid or Solutions of Gut Fluid Components by Tannic Acid.* Much larger quantities of tannic acid are required to bring about precipitation of an insoluble RuBPC–tannic acid complex from denatured *M. sexta* gut fluid adjusted to a pH of 6.7–6.9 than are required to precipitate this protein from an aqueous salt solution buffered at the same pH (Table 2). While 50 μg of tannic acid precipitates 465 out of 525 μg of RuBPC from a salt solution at pH 6.8, this amount of tannic acid precipitates only 7 out of 500 μg of this protein when it is dissolved in the gut fluid of larvae reared on an artificial diet. The effectiveness of the gut fluid as a solvent for RuBPC in the presence of tannic acid depends upon the dietary history of the larvae. Much more tannic acid is required to precipitate significant amounts of RuBPC from the gut fluids of larvae switched from artificial diet to tomato leaves during their final two instars or larvae which had been collected from tomato plants growing in a cultivated field and which had presumably fed on tomato foliage during their entire larval stage (Table 2).

Using a straightforward procedure involving precipitation with ethanol and ultrafiltration through a membrane with a nominal molecular weight cutoff of 10 kD, the gut fluid was separated into three fractions (Table 3). Fraction A contains all solutes not precipitated by ethanol, fraction B contains solutes pre-

TABLE 2. AMOUNTS OF RuBPC PRECIPITATED BY TANNIC ACID (TA) FROM AQUEOUS BUFFER AND DENATURED GUT FLUIDS FROM FIFTH-INSTAR *M. sexta* LARVAE AND *S. gregaria* NYMPHS[a]

	RuBPC in incubation mixture (μg)	RuBPC precipitated (μg) by			
		50 μg TA	75 μg TA	200 μg TA	300 μg TA
0.1 M PIPES buffer, pH 6.8, 160 mM KCl, 3 mM NaCl	525	465 ± 3 [3]	ND	ND	ND
Gut fluid from *M. sexta* larvae reared entirely on artificial diet	500	7 ± 2 [3]	35 ± 9 [4]	414 ± 4 [3]	480 ± 6 [3]
Gut fluid from *M. sexta* larvae switched from artificial diet to tomato leaves for last two instars	500	ND	ND	11 ± 2 [3]	92 ± 8 [3]
Gut fluid from *M. sexta* larvae collected from a tomato field	500	ND	ND	ND	8 ± 0 [2]
Gut fluid from *S. gregaria* nymphs reared on wheat and bran seedlings	360	ND	ND	11 ± 5 [3]	87 ± 4 [5]

[a]The incubation mixture had a volume of 275 μl and a pH of 6.7–6.9. Values are $\bar{X}$ ± SEM for the number of replicates given in brackets. The small number of replicates precludes the calculation of statistical significance. Values of SEM are included only to provide an indication of the low variance between replicates. ND, not determined.

cipitated by ethanol with molecular weights less than 10 kD, and fraction C contains solutes precipitated by ethanol with molecular weights greater than 10 kD. Experiments testing the effects of fractions A, B, and C on the precipitation of RuBPC by tannic acid implicate surfactants as the components responsible for the effectiveness of gut fluid in preventing the precipitation of protein by tannic acid.

Fraction B contains low-molecular-weight solutes, including inorganic salts, which favor the formation of insoluble tannin–protein complexes (Martin et al., 1985). It is to be expected, therefore, that relatively small quantities of tannic acid would be effective in precipitating protein from a solution of fraction B, and indeed, most of the RuBPC is precipitated by only 50 or 75 μg of tannic acid when the source of fraction B is gut fluid from diet-fed larvae (Table 4). Thus a solution of fraction B from diet-fed animals differs little from a simple buffered salt solution in terms of its properties as a solvent for tannin–protein complexes.

It is interesting to note that more tannic acid is required to precipitate the RuBPC dissolved in a solution containing fraction B from *M. sexta* larvae fed leaves during their last two instars than one containing fraction B from larvae reared exclusively on artificial diet (Table 4), suggesting that the composition of this fraction depends upon the larval diet. Insufficient material was available for a test of the properties of fraction B from field-collected larvae.

TABLE 3. COMPARISON OF pH, SURFACE TENSION (ST), SURFACTANT CONCENTRATION AND SOLUTE COMPOSITION OF GUT FLUIDS OF FIFTH-INSTAR *M. sexta* LARVAE AND *S. gregaria* NYMPHS[a]

Species	Food	pH	ST, dynes/cm (surfactant conc.)	Concentrations of components (mg/ml)			ST, dynes/cm (surfactant conc.)		
				A	B	C	A	B	C
M. sexta	Artificial diet[b]	9.5	33 (10 × CMC)	22.3	12.6	2.8	42 (5 × CMC)	72	69
M. sexta	Diet/tomato leaves[c]	9.7	33 (10 × CMC)	26.1	15.0	2.4	31 (5 × CMC)	71	72
S. gregaria	Wheat/bran seedlings	5.3	37 (10 × CMC)	78.3	57.4	28.4	37 (5 × CMC)	55 (30 × CMC)	53 (20 × CMC)

[a] CMC is critical micelle concentration. Fraction A contains solutes not precipitated by ethanol; B contains solutes precipitated by ethanol with molecular weights less than 10 kD; C contains solutes precipitated by ethanol with molecular weights greater than 10 kD.

[b] Reared through the entire larval stage on artificial diet.

[c] Switched from artificial diet to tomato leaves for the last two instars.

TABLE 4. AMOUNTS OF RuBPC PRECIPITATED BY TANNIC ACID (TA) FROM SOLUTIONS CONTAINING VARIOUS COMPONENTS OF GUT FLUIDS FROM FIFTH-INSTAR *M. sexta* LARVAE AND *S. gregaria* NYMPHS[a]

Species	Food	Components present in incubation mixture			RuBPC precipitated (μg) by			
		A	B	C	50 μg TA	75 μg TA	200 μg TA	300 μg TA

M. sexta	Tomato leaves[c]	+	+	−	ND	ND	ND	8 ± 2
S. gregaria	Wheat/bran seedlings	−	+	−	ND	37 ± 5	293 ± 34	447 ± 55
S. gregaria	Wheat/bran seedlings	+	+	−	ND	12 ± 4	133 ± 6	309 ± 9
S. gregaria	Wheat/bran seedlings	+	+	+	ND	ND	24 ± 5	122 ± 8

[a] The incubation mixture had a volume of 275 μl, a pH of 6.8–7.0, and contained 500 μg of RuBPC (except in the experiment in which all three components from *S. gregaria* gut fluid were recombined, in which case 300 μg of RuBPC were present). Values are $\bar{X} \pm$ SEM for three replicates. The small number of replicates precludes the calculation of statistical significance. Values of SEM are included only to provide an indication of the low variance between replicates. The contents of fractions A, B and C are described in the heading for Table 3. ND, not determined.
[b] Reared through the entire larval stage on artificial diet.
[c] Switched from artificial diet to tomato leaves for the last two instars.
[d] Collected from tomato plants in a tomato field.

Fraction A is the only fraction from either diet- or leaf-fed *M. sexta* larvae which contains surfactants, as indicated by surface-tension measurements (Table 3). Since water has a surface tension of 72 dynes/cm, the values of 69–72 dynes/cm for solutions of fractions B and C indicate that these fractions do not contain significant concentrations of surface-active materials. However, the values of 31 and 42 dynes/cm for solutions of fraction A from diet- and leaf-fed larvae, respectively, indicate the presence of surfactants in those fractions. The amount of RuBPC precipitated by 50 and 75 μg of tannic acid is reduced to 26 and 52 μg, respectively, when the solution contains fraction A, the surface-active fraction, in addition to fraction B. In fact, the combination of fractions A and B is nearly as effective as the original gut fluid or reconstituted gut fluid (fractions A + B + C) from the diet-fed insects in preventing the precipitation of dissolved RuBPC by tannic acid (Tables 2 and 4). Likewise, when RuBPC is dissolved in a solution containing both fractions A and B from the gut fluid and leaf-fed larvae, as much tannic acid must be added to precipitate this protein as is required to effect precipitation from the original gut fluid.

Precipitation of RuBPC from Denatured S. gregaria *Gut Fluid or Solutions of Gut Fluid Components by Tannic Acid.* The gut fluid of *S. gregaria* nymphs reared on bran and wheat seedlings, adjusted to pH 6.7–6.9, is as effective at preventing the precipitation of RuBPC by tannic acid as the gut fluid of *M. sexta* larvae fed tomato leaves during their last two instars (Table 2). However, the results of experiments testing the effects of the individual fractions from the locust gut fluid were somewhat different from those using the fractions from the hornworm gut fluid (Table 4). With materials from both *M. sexta* and *S. gregaria*, the precipitation of RuBPC was brought about by a relatively small amount of tannic acid when it was dissolved in a solution of fraction B, the salt-containing fraction. However, in contrast to the results obtained with the *M. sexta* materials, the combination of fractions A and B from *S. gregaria* did not give a solution as effective at preventing the precipitation of protein by tannic acid as the original gut fluid. Only when all three of the gut fluid fractions from *S. gregaria* were combined was the resulting solution as effective as the original gut fluid.

In marked contrast to the results obtained when *M. sexta* gut fluid was subjected to fractionation, the surface-active components of *S. gregaria* gut fluid were not cleanly separated into a single fraction (Table 3). Solutions of all three fractions had surface tensions well below the value for water, indicating that all three contained surface-active constituents. It is also evident from the concentrations of dissolved solids in the various fractions that locust gut fluid is a much more concentrated solution than hornworm gut fluid. Perhaps the failure of the fractionation procedure to result in a clean separation of surfactants into a single fraction is simply a consequence of the much higher solute content of *S. gregaria* gut fluid (164 mg/ml) than *M. sexta* gut fluid (37 and 44 mg/ml). In any event, the observation that all fractions containing surfactants must be recombined in order to obtain a solution with properties comparable to those of the original gut fluid is consistent with the suggestion that surfactants are responsible for the ability of the gut fluid to prevent the precipitation of RuBPC by tannic acid.

DISCUSSION

Three mechanisms have been proposed by which tannins might interfere with digestion in an insect herbivore: (1) by inhibiting the herbivore's digestive enzymes, (2) by inhibiting the metabolic activities of symbiotic microorganisms that contribute to digestion, and (3) by reducing the digestibility of ingested nutrients.

The suggestion that tannins might inhibit an herbivore's digestive proteinases is a very plausible one, supported by well-documented examples of the inhibition of a variety of enzymes by tannins. Tannins have been shown to

inhibit α-amylase (Gadal and Boudet, 1965), pectinase (Bell et al., 1962), cellulase (Bell et al., 1962; Mandels and Reese, 1965), and β-glucosidase (Goldstein and Swain, 1965; Goldstein and Spencer, 1985). The inhibition of proteolysis by tannins has also been observed, but it has not been possible to determine whether this effect is a consequence of inhibition of the proteinases or of binding to substrates (Feeny, 1969; Rhoades, 1977). It is interesting that Mole and Waterman (1985) have recently demonstrated that under certain conditions tannins can stimulate the tryptic hydrolysis of proteins. In all of the studies in which tannins have been reported to inhibit enzyme-catalyzed processes, very dilute preparations of the enzymes have been used, and conditions have been employed which are very different from those that prevail in an insect's gut. In this study we have shown that in undiluted gut fluid from *M. sexta* larvae, the hydrolysis of RuBPC occurs with extraordinary rapidity and is not inhibited by tannic acid, even when the incubation mixture contains as much or more tannic acid as it contains RuBPC. Of course, it is still possible that tannins might inhibit the proteinases of insect species with less active enzymes, less alkaline midgut, or lower concentrations of detergents in their gut fluids, but to date there is no evidence that they do. Until direct evidence for such inhibition is provided, we maintain that there is no justification for believing that tannins interfere with protein digestion by inhibiting digestive proteinases in any insect herbivore.

Tannins have been observed to inhibit rumen microbes (Waterman et al., 1980, 1984), suggesting the possibility that polyphenols might interfere with digestive processes mediated by symbiotic microorganisms. While this mode of action is a possibility in insects, to date it has not been demonstrated, and there is no basis for believing that it is of widespread importance in herbivorous species. It is most unlikely to be a factor in lepidopteran or acridid herbivores, since gut microbes are not thought to play a significant role in digestion in these groups.

The suggestion that tannins might interfere with protein utilization by forming indigestible complexes with ingested protein is also a very plausible one, considering the extensively documented capacity of tannins to act as protein precipitants. However, in this study we have shown that the abundant leaf protein, RuBPC, is not readily precipitated from the gut fluids of *M. sexta* and *S. gregaria*. We conducted our experiments at pH 6.7–6.9, a pH which is very favorable for the formation of an insoluble complex between tannic acid and this protein (Martin and Martin, 1983). Only when enough tannic acid is added to the mixture to produce a ratio of tannic acid to protein close to unity is a significant portion of the protein precipitated from the gut fluids of hornworm larvae that had been feeding on tomato foliage or locust nymphs that had been feeding on bran and wheat seedlings.

In this study we have shown that the capacity of gut fluid to counter the

effects of tannic acid on the digestion and precipitation of RuBPC manifests itself at tannic acid–RuBPC ratios of 1.3 : 1.0 and 0.4–0.6 : 1.0, respectively. Unfortunately, tannin–protein ratios in foliage are known accurately for very few plant species. In the mature foliage of the pedunculate oak, *Quercus robur*, tannins were quantified accurately by actual isolation, and the tannin–protein ratio was found to be 0.34 (Feeny, 1970). The more common practice in assessing tannin content in foliage is to use functional group assays, such as the Folin-Denis assay, the proanthocyanidin assay, and the catechin assay, and translate the data into "tannin equivalents." The accuracy and utility of such estimates of tannin content are highly suspect (Martin and Martin, 1982). While the proanthocyanidin and catechin assays may provide rough indications of the levels of condensed tannins, the Folin-Denis assay provides no measure whatsoever of total tannin content. Indeed, there is no satisfactory functional group assay for "total tannin," and none of the functional group assays correlate with protein-binding capacity. With these caveats in mind, we note that in only 15 of the 102 species of forest vegetation surveyed by Oates et al. (1980), Waterman et al. (1980), and Coley (1983) did assays for proanthocyanidins or catechins suggest that the condensed tannin–protein ratio might be greater than unity.

In this study and our earlier ones (Martin and Martin, 1984; Martin et al., 1985), we implicated surfactants as the constituents of insect gut fluids that prevent the precipitation of proteins by tannic acid or pin oak tannins. Mole and Waterman (1985) have also demonstrated that surfactants can prevent tannic acid or quebracho tannin from inhibiting the tryptic hydrolysis of bovine serum albumin. In our earlier study (Martin and Martin, 1984), we restricted our attention to a fraction of *M. sexta* gut fluid corresponding to fraction A of this study. Since the preparation of fraction A results in the separation of surface-active substances from the inorganic salts present in the gut fluid, and since inorganic salts enhance the precipitation of proteins by tannins (Martin et al., 1985), it was possible that our earlier study overemphasized the potential for surfactants to interfere with the precipitation of proteins by tannins. The present study has ruled out that possibility. We have found that unfractionated gut fluid is extremely effective in preventing the precipitation of RuBPC by tannic acid and that a solution prepared by recombining gut fluid surfactants and gut fluid salts is as effective in this capacity as the unfractionated gut fluid.

We were surprised to find that the capacity of the gut fluid of *M. sexta* larvae to counter the protein-precipitating capacity of tannins is affected by the nature of the larval diet. The most effective gut fluid was from larvae that had consumed tomato foliage throughout larval life, while the least effective was from larvae that had been reared exclusively on an artificial diet. Gut fluid from larvae that had been switched from an artificial diet to tomato foliage for their last two instars was intermediate in its properties. These differences cannot be attributed to differences in detergency of the gut fluids of larvae with different

dietary histories. Surface-tension measurements of the unfractionated gut fluid and fraction A from diet-fed and leaf-fed larvae indicate no differences in surfactant concentrations (Table 3). Rather, the differences seem to be due to differences in the capacity of fraction B to cause precipitation of RuBPC by tannic acid. Perhaps the gut fluids of diet-fed insects have higher concentrations of inorganic salts, especially alkali metal salts, which are particularly effective in bringing about the precipitation of tannin–protein complexes (Martin et al., 1985).

In *M. sexta* midgut fluid, which normally has a pH of 9.5 or higher, both high alkalinity and detergency interfere with the formation of insoluble tannin–protein complexes. In *S. gregaria*, however, high alkalinity cannot be a factor. Evans and Payne (1964) reported a pH of 5.5 in the crop of this species, where a significant amount of digestion occurs, and a pH range of 6.2–7.0 in the midgut. The *S. gregaria* digestive fluid used in this study, which was primarily crop fluid mixed with some midgut fluid, had a pH of 5.3. RuBPC is readily precipitated from an aqueous salt solution in the pH range 5.5–7.0 (Martin and Martin, 1983). The observation that *S. gregaria* gut fluid interferes with the formation of tannin–protein complexes at pH 6.7–6.9 emphasizes the significance of surfactants in countering the protein-precipitating capacity of tannins in insect herbivores with gut fluids which are neutral or slightly acidic.

This study, in conjunction with other studies which have failed to produce any evidence that dietary tannins reduce digestive efficiency in any insect (Bernays et al., 1980; Klocke and Chan, 1982; Reese et al., 1982; Manuwoto et al., 1985; Manuwoto and Scriber, 1986), adds further support to our contention that tannins do not deserve the status they have been accorded as general, all-purpose, digestibility-reducing substances. It is now abundantly clear that the digestive systems of insects possess a number of attributes that effectively counter the potential protein-precipitating capacity of tannins. At least two of these attributes, alkalinity and detergency, occur widely in insects, in species both with and without an evolutionary history of exposure to tannins, indicating that these characteristics have not necessarily evolved specificially as antitannin adaptations (Martin and Martin, 1984; Martin et al., 1985). In order to ensure that our position not be misinterpreted, we wish to emphasize that we are not proposing that tannins are innocuous chemicals that pose no problems to insect herbivores. There is no question that tannins can act as toxins (Berenbaum, 1984; Bernays et al., 1980; Manuwoto et al., 1985; Manuwoto and Scriber, 1986; Steinly and Berenbaum, 1986) and feeding deterrents (Bernays, 1981; Klocke and Chan, 1982; Reese et al., 1982; Manuwoto et al., 1985) to non-adapted insects. We are only arguing that there is no evidence that tannins reduce the nutritional value of an insect's food by inhibiting digestive enzymes or by reducing the digestibility of ingested proteins, and further that the failure of tannins to interfere with digestion is readily explained on the basis of well-documented characteristics of the digestive systems of herbivorous insects.

Furthermore, we emphasize that in challenging the currently popular notion that tannins are digestibility-reducing substances, we are not challenging the general utility of either the apparency theory (Feeny, 1976; Rhoades and Cates, 1976) or the resource availability theory (Coley et al., 1985) of plant–herbivore interactions. According to both of these theories, low nutrient quality can reduce herbivory by imposing slower growth rates on herbivores, thereby subjecting them to higher mortality from parasitism, predation, and other factors during an extended juvenile period. The only points that we dispute are the assertions that polyphenols make a crucial contribution to low nutritive quality by interfering with digestion and that counteradaptation to the presence of polyphenols is unusually difficult. The demise of tannins as all-purpose digestibility-reducing substances requires that the advocates of these theories of plant defense find other explanations for the reduced nutrient quality of the foliage of "apparent" or inherently slow-growing species.

Acknowledgments—This research was supported by a grant from the National Science Foundation (PCM-8203537). We thank Randy Mercer for determining the minimum gut passage time in *M. sexta* larvae; Barbara Joos and Hugh McGuinness for *M. sexta* larvae; and Judy Bronstein, David Karowe, and Heidi Van't Hof for valuable criticisms.

SEX PHEROMONE DIFFERENCES IN POPULATIONS OF THE BROWNHEADED LEAFROLLER, *Ctenopseustis obliquana*[1]

STEPHEN P. FOSTER and WENDELL L. ROELOFS[2]

DSIR, Entomology Division,
Mt. Albert Research Centre,
Private Bag, Auckland, New Zealand

(Received October 28, 1985; accepted April 22, 1986)

Abstract—*Ctenopseustis obliquana* females collected from Christchurch were found to produce a mixture of (*Z*)-5-tetradecenyl acetate and tetradecyl acetate in their sex pheromone gland, in contrast to *C. obliquana* from Auckland which produce an 80:20 mixture of (*Z*)-8-tetradecenyl acetate and (*Z*)-5-tetradecenyl acetate. This identification has been made on the basis of instrumental and chemical analyses. Antennae of male *C. obliquana* from Christchurch gave a maximal electroantennogram response to (*Z*)-5-tetradecenyl acetate. A field trapping program in Christchurch using combinations of synthetic (*Z*)-5-tetradecenyl acetate and tetradecyl acetate caught *Ctenopseustis* males equally well if the latter chemical was present or absent. No males were caught in traps baited with the Auckland-type pheromone. In Alexandra, *Ctenopseustis* males were caught in traps baited with Auckland-type pheromone and not in traps baited with Christchurch-type pheromone. This phenomenon is ascribed to the existence of sibling species within the described *C. obliquana*.

Key Words—Sex pheromone, Lepidoptera, Tortricidae, (*Z*)-5-tetradecenyl acetate, *Ctenopseustis obliquana*, brownheaded leafroller, sibling species.

INTRODUCTION

The endemic New Zealand leafroller complexes in *Ctenopseustis obliquana* (Walker), *Planotortrix excessana* (Walker), and the Australian immigrant *Epiphyas postvittana* (Walker) form the most significant group of insect pests

[1] Lepidoptera: Tortricidae: Tortricinae.
[2] Visiting scientist from New York State Agricultural Experiment Station, Geneva, New York 14456.

of New Zealand's export fruit crops. In particular, *C. obliquana* is probably the most serious pest of New Zealand's most economically important horticultural crop—kiwifruit—causing typical leafroller damage to the leaves and fruit (Sale, 1982).

We have been studying the sex pheromones of these three leafrollers, with a view to monitoring population levels and hence timing pesticide applications more efficiently. The sex pheromone components of *E. postvittana* (Bellas et al., 1983), *P. excessana* (Galbreath et al., 1985), and *C. obliquana* (Young et al., 1985) have been determined, but the routine use of pheromones throughout orchards in New Zealand has been hindered not only by poor trap catches of the New Zealand native leafrollers (Steven, personal communication) but also by the discovery of sibling species within *P. excessana* (sensu Dugdale, 1966), detected by sex pheromone differences (Galbreath et al., 1985).

The sex pheromone identification of *C. obliquana* (Young et al., 1985) was conducted on a population originally collected from the type locality of *Teras obliquana* Walker (Green and Dugdale, 1982) in Auckland (upper North Island). Two compounds were identified as sex pheromone components, (*Z*)-8- and (*Z*)-5-tetradecenyl acetates (Z8-14:OAc and Z5-14:OAc), in a ratio of approximately 80:20. However, when this blend was used in Christchurch (midcoastal South Island)—a locality of *Cacoecia inana* Butler, regarded by Green and Dugdale as a synonym of *Ctenopseustis obliquana*—it failed to catch *Ctenopseustis* males (Thomas, personal communication). We report here the identification of a single sex pheromone component of *a Ctenopseustis* population collected from Christchurch.

METHODS AND MATERIALS

Insects were collected as larvae from Christchurch and reared on a semi-synthetic diet containing dried *Acmena smithii* (Poiret) leaf (Galbreath et al., 1985). Pupae were sexed, and males separated from females prior to emergence. Adults were maintained on a reverse light-dark cycle (16L:8D).

Crude sex pheromone extract was prepared from stripped glands rather than excised abdominal tips. Pheromone glands of 3- to 4-day-old female moths were stripped with fine forceps under a binocular microscope and allowed to soak in 10 μl of distilled analytical grade *n*-pentane for 3–12 hr prior to gas-liquid chromatographic (GLC) analysis.

Capillary columns (50 m BP20, 50 m CPS-1 and 20 m BP5), packed column (2 m, 2 mm OD, 3% OV-1 on Chromosorb W) and chromatographic procedures are described elsewhere (Foster et al., 1986). Ozonolysis (Beroza and Bierl, 1967) was used to determine the position of unsaturation, comparing capillary GLC retention times of ozonolysis products with those from ozonolysis of synthetic compound and with synthetic aldehyde. The technique as de-

scribed by Foster et al. (1986) involves collection of the natural compounds from the packed column in a 30-cm capillary tube, followed by ozonolysis of the compounds in the tube and the GLC analysis of the products on a capillary column.

The BP20 column resolved positional isomers of long-chain unsaturated acetates more efficiently than the corresponding alcohols; therefore, the collected alcohol fraction was acetylated by allowing it to react with ca. 10 μg of acetyl chloride in 40 μl of pentane for 1–2 hr. The reaction was worked up by allowing a gentle stream of nitrogen to slowly evaporate the mixture to apparent dryness. The residue was dissolved in pentane and the resulting acetates analyzed by capillary GLC.

Synthetic chemicals were assayed by capillary GLC using a 50-m Quadrex Corporation CPS-1 column, and the isomeric purity of Z5–14:OAc was determined to be greater than 97%.

Electroantennograms of responses of excised male antennae were recorded by the method of Roelofs (1984).

Field tests were conducted at and near Christchurch (midcoastal South Island) in home gardens using Sectar 1 traps (3M Co., St Paul, Minnesota) and at Alexandra (central South Island) in an orchard using Pherocon 1C® traps (Zoecon Company, Palo Alto, California), baited with synthetic chemical absorbed on rubber septa (A.H. Thomas Co., Philadelphia, Pennsylvania). Traps were placed on trees 2 m above the ground and at least 10 m away from each other.

Data from field tests were analyzed by the use of log linear models (McCullagh, 1983).

RESULTS

A number of pheromone gland extracts (1–4 FE) were analyzed on the BP20 column, with a consistent pattern for each chromatogram. Unlike gland analyses of *C. obliquana* from the North Island, there was no peak for Z8–14:OAc but two prominent peaks at the retention times of Z5–14:OAc and tetradecyl acetate (14:OAc). Trace components were found at the retention times of dodecyl acetate (3% of Z5–14:OAc), dodecanol (<1%), tetradecanol (14:OH, 2.6%), an unsaturated tetradecenol (3%), and hexadecyl acetate (2%). While baseline separation of the *E* and *Z* isomers of Δ-5–14:OAc could not be achieved using the BP20 column, these chemicals were easily resolved by the CPS-1 column. No (*E*)-5-tetradecenyl acetate (above 1% of the other isomer) was detected in the female gland extracts. Further analysis using the CPS-1 and BP5 columns was consistent with the above identifications.

The 14-carbon acetate and alcohol fractions from crude extract of 30 females were collected from the packed GLC column and the 14-carbon acetate

fraction was ozonized. Capillary GLC analysis showed three major peaks, with retention times corresponding to the ozonolysis products of synthetic *Z*5-14 : OAc (5-acetoxypentanal and *n*-nonanal) and 14 : OAc.

These data confirm the presence of both unsaturated *Z*5-14 : OAc and saturated 14 : OAc in the female pheromone gland. Quantification by addition of 16.4 ng of tridecanyl acetate internal standard to an extract of five female pheromone glands showed that there was an average of 3.3 ng of *Z*5-14 : OAc and 1.7 ng of 14 : OAc per female.

The collected 14-carbon alcohol fraction was shown to consist of 14 : OH and (*Z*)-5-tetradecanol by acetylation and subsequent analysis of the products by GLC on the BP20 column.

EAG profiles of responses of male antennae to series of 12, 14, and 16 monounsaturated acetates and alcohols showed generally a higher response to 14-carbon acetates, with a maximum response within this series to *Z*5-14 : OAc (3.5 $\pm$ 0.3 mV). The response to this isomer was significantly higher than that to *E*5-14 : OAc (2.6 $\pm$ 0.3 mV). The response to *Z*8-14 : OAc (2.0 $\pm$ 0.3 mV) was barely above background. In the 16-carbon acetate series, responses were generally low except to (*Z*)-5-hexadecenyl acetate. Responses to alcohols were low.

A field trapping study testing the effectiveness of *Z*5-14 : OAc and 14 : OAc as attractants showed the attractiveness of *Z*5-14 : OAc to male *Ctenopseustis* moths at Christchurch (Table 1). A comparison of the cross-attractancy of lures baited with *Z*5-14 : OAc and 14 : OAc and with *Z*8-14 : OAc, *Z*5-14 : OAc, and *Z*8-14 : OH (at the time of these trials *Z*8-14 : OH was thought to be synergistic at this level; subsequent work has shown it to give no detectable increase in trap capture of male *C. obliquana*; Clearwater and Foster, unpublished) conducted at Christchurch and Alexandra showed the specificity of the two types of lure to the respective *Ctenopseustis* populations (Table 2).

DISCUSSION

A population of *C. obliquana* in the midcoastal region of the South Island of New Zealand near Christchurch and previously synonymized on morphological criteria with Auckland *C. obliquana* was found to use *Z*5-14 : OAc as its main sex pheromone component. This pheromone is quite distinct from the sex pheromone blend used by *C. obliquana* on the North Island and several other regions on the South Island. Single female gland analyses by capillary GLC easily distinguish the populations, not only by the different components, but also because the Christchurch population generally has a larger quantity of pheromone (particularly *Z*5-14 : OAc) stored in the gland (Young et al., 1985). This is consistent with male trapping tests in which Christchurch males were trapped with much higher release rates of their pheromone than were males from the North Island population with their pheromone (Table 1).

[c]Conducted November 8-December 17, 1984. Three replicates were counted six times, each time rerandomized.

The comparative field catches at two geographically distant locations, Christchurch and Alexandra (Table 2) are clear evidence of attraction of male *Ctenopseustis* moths from the different populations to a specific synthetic pheromone source. The lack of cross-attractancy of the two pheromone sources clearly suggests that there is unlikely to be gene flow between the two pheromone strains, and hence they are probably distinct (sibling) species (Dobzhansky, 1970). Unfortunately, we have no direct evidence to support this as in neither Christchurch nor Alexandra have we found the two pheromone strains

[b]Trial at Christchurch conducted March 2-March 23, 1984, using seven replicates.

in sympatry. It is worth noting that we are (so far) unable to distinguish males of the two populations.

Sex pheromone analyses also have been used in New Zealand to differentiate at least three sibling species in the Tortricinae genus *Planotortrix* (Galbreath et al., 1985; Foster et al., 1986). One of these species, which is host-specific to mangrove (*Avicennia resinifera*), apparently uses the same two chemicals as those produced in the female sex pheromone gland of the *Ctenopseustis* species at Christchurch. The wide geographical separation of these two species, however, precludes speculation on cross attraction. In New Zealand, mangrove bushes are found only in the semitropical upper North Island and not below latitude 38° South (Allan, 1961). Pheromone analyses of female moths within this area (Foster, unpublished) have failed to detect any *Ctenopseustis* individuals without Z8-14:OAc. Additionally, field tests conducted for the mangrove-specific *Planotortrix* species showed that no *Ctenopseutis* males in the mangrove area were captured using the two-component blend (J.R. Clearwater, unpublished).

Our pheromone analysis suggests that it is unlikely that there is cross-attraction between these two populations supporting their distinction as sibling species. Further work will be aimed at more precisely determining this phenomenon.

Further similar sex pheromone studies are underway in New Zealand to detect additional sibling species in the genera *Ctenopseustis* and *Planotortrix*. In-depth analyses of pheromone biosynthetic pathways, morphological characters, and genetics should help to clarify species status of these populations and to formulate evolutionary relationships.

Acknowledgments—The authors wish to particularly thank Dr. D.M. Suckling and Mr. D. Rogers and their associates at Lincoln Research Station D.S.I.R. for collecting larvae and conducting field tests in the Christchurch area, and Dr. G.F. McLaren for conducting field tests at Alexandra. We also thank Mr. J.S. Dugdale for taxonomic discussion and Val Holt for maintaining the insects. We are grateful to Dr. J.R. Clearwater and Sue Muggleston for running some electroantennograms and to Dr. C. Triggs for the statistical analysis. We thank the NRAC for the award of a Senior Postdoctoral Research Fellowship (to W.L.R.).

SEX PHEROMONE OF *Planotortrix*[1] SPECIES FOUND ON MANGROVE

STEPHEN P. FOSTER, J.R. CLEARWATER, and WENDELL L. ROELOFS[2]

D.S.I.R., Entomology Division,
Mt. Albert Research Centre,
Private Bag, Auckland, New Zealand

(Received October 28, 1985; accepted April 22, 1986)

Abstract—(*Z*)-5-Tetradecenyl acetate and tetradecyl acetate were identified as sex pheromone components of an unnamed *Planotortrix* leafroller moth species found on *Avicennia resinifera* (mangrove). An equal mixture of the two compounds used as bait gave field trap catches at least as good as those baited with caged virgin females. Traps baited with the two chemicals caught male *Planotortrix* moths in a mangrove swamp not previously found to host the unnamed *Planotortrix* species. Adults of the unnamed *Planotortrix* species and of the greenheaded leafroller, *Planotortrix excessana* are morphologically indistinguishable. The sex pheromone of *P. excessana* has been found previously to be a mixture of (*Z*)-8-tetradecenyl acetate and tetradecyl acetate, and this means that the two species may now be distinguished by sex pheromone differences.

Key Words—Sex pheromone, Lepidoptera, Tortricidae, (*Z*)-5-tetradecenyl acetate, *Planotortrix*, mangrove, sibling species.

INTRODUCTION

Dugdale (1966) described the genus *Planotortrix* since certain New Zealand Tortricidae appeared to have been incorrectly classified in the genus *Tortrix* Linnaeus. Eleven species were assigned to the new genus, although it was noted that more remain to be described. Two species of this genus are major pests; *P. excessana* (Walker) the greenheaded leafroller, is a pest of most fruit crops while *P. notophaea* (Turner) can cause considerable damage to young conifers.

[1] Lepidoptera: Tortricidae: Tortricinae.

The sex pheromone of *P. excessana* (collected from Christchurch in the South Island) was found to be a mixture of (*Z*)-8-tetradecenyl acetate (*Z*8–14 : OAc) and tetradecyl acetate (14 : OAc) (Galbreath et al., 1985). Galbreath et al. (1985) also reported that a population of this species collected in the central North Island utilized a different pheromone, possibly involving a mixture of (*Z*)-5- and (*Z*)-7-tetradecenyl acetates (*Z*5–14 : OAc and *Z*7–14 : OAc). These data underscored the importance of defining pheromone blends for various *Planotortrix* populations throughout New Zealand. The results would be of value in reexamining the systematics of the genus and in determining the pheromone to be used in monitoring traps in each geographic area.

We initiated our study with a population of *Planotortrix* that was known to exist in the Firth of Thames (North Island) and whose larvae feed on foliage of mangrove (*Avicennia resinifera* Forst.f.) (Dugdale, personal communication). While the larvae can be distinguished from the larvae of *P. excessana*, the adults are morphologically indistinguishable from *P. excessana* populations that feed on other plants (Dugdale, personal communication). Although adults from the mangrove species are generally darker than those of *P. excessana*, they cannot be definitively distinguished due to the large variation in color of *P. excessana* adults (Dugdale, personal communication). This paper details the identification of two sex pheromone components of the unnamed *Planotortrix* species that feeds on mangrove.

METHODS AND MATERIALS

Insects were initially collected from mangrove bushes as larvae and reared on a semisynthetic diet containing dried acmena leaf (Galbreath et al., 1985). Further larval generations were reared on the semisynthetic diet containing approximately 17% (by weight) ground mangrove leaf.

Adults were maintained on a reverse light–dark cycle (16L : 8D).

Gland extracts were taken by the following method. One hour into the scotophase, the ovipositor of a 3- to 4-day-old female moth was extruded under a binocular microscope and the pheromone gland excised using fine forceps. The gland was placed in 10 μl of distilled analytical grade *n*-pentane in a flamed 4-mm-OD glass tube drawn to a point. This was stored 3–12 hr in a 4-ml glass vial prior to gas–liquid chromatographic (GLC) analysis.

Capillary GLC analysis of gland extracts was performed with splitless injection and flame ionization detection. Capillary columns were a 50-m SGE BP20 (stabilized Carbowax 20 M), capable of resolving most straight-chain 14-carbon acetate isomers, a 50-m Quadrex Corporation CPS-1 (bonded SP2340 equivalent), capable of resolving not only most straight-chain but also most geometric 14-carbon acetate isomers, and a 20-m BP5 (SE54 equivalent). A

program of 100–200°C at 4°C/min, following an initial delay of 1 min was generally used. For analysis of the ozonolysis products, the initial temperature was changed to 40°C. For the CPS-1 column, a program of 100–180°C at 3°C/min was used. Carrier gas was nitrogen at a linear velocity of 35 cm/sec. Samples were quantified by electronic integration of peak areas, relative to 16.4 ng of added tridecanyl acetate (13:OAc) internal standard.

A 2-m 3% OV-1 on Chromosorb W packed column was used for fraction separations prior to collection. Fractions were collected in 30-cm glass capillaries cooled by an aluminium block partially immersed in liquid nitrogen. Following collections of the separated fractions, positional isomers were determined by ozonolysis (Beroza and Bierl, 1967) and capillary GLC identification of the products.

Ozonolysis was performed by allowing a steady stream of ozone (ca. 2–3 ml/min) to pass through the capillary tube for 30 sec at ambient temperature. The tube was rinsed with 30–40 μl of pentane: to the solution was added ca. 1 μg of solid triphenylphosphine. The retention times of the resultant acetoxy aldehyde and aldehyde were determined by capillary GLC and compared with those of the corresponding products obtained from ozonolysis of synthetic compound and with synthethic aldehyde.

Synthetic chemicals used were assayed by capillary GLC, and their isomeric purity was determined to be greater than 97%.

Electroantennograms (EAGs) from excised male antennae were recorded by the method of Roelofs (1984).

Four field trials were conducted in the mangrove swamp from which the larvae were collected, and in an Auckland mangrove swamp using Pherocon 1C® traps (Zoecon Company, Palo Alto, California) and Sectar 1 traps (3M Company, St. Paul, Minnesota), baited with synthetic chemicals absorbed on rubber septa (A.H. Thomas Co., Philadelphia, Pennsylvania). Virgin females (used in trial 2) were from the laboratory-reared colony originally collected from the mangrove swamp in Thames. Three females were enclosed in each wire-mesh cage (5 × 5 × 5 cm), suspended in Pherocon 1C® traps. Traps were randomized each time they were counted.

Data from the field tests were analyzed by the use of log linear models (McCullagh, 1983).

RESULTS

Capillary GLC analysis of a single female pheromone gland extract revealed two major components, which had retention times identical to 14:OAc and *Z*5–14:OAc on the polar BP20 and CPS-1 and the nonpolar BP5 columns. The retention time of *Z*5–14:OAc on the BP20 column (38.08 min) was not

separable from that of the $Z6$ isomer (38.11 min), but was separable from the $Z7$ (38.37 min) and $Z8$ (38.63 min) isomers. Baseline separation of the two geometric isomers of $\Delta5$–14:OAc could easily be achieved, using the CPS-1 column. No (E)-5-tetradecenyl acetate was detected in the female pheromone gland extracts.

Ozonolysis of the two compounds collected from an OV-1 column confirmed their identification as 14:OAc and a $\Delta5$–14:OAc. The compound with a retention time corresponding to 14:OAc had the same retention time after ozonolysis, and the other compound was ozonized to give peaks at the same retention times as 5-acetoxypentanal and *n*-nonanal (16.23 min and 21.41 min, respectively) on the BP20 column (revised temperature program).

EAG profiles showed a consistent maximum response to $Z5$–14:OAc. The average response of 17 antennae (22 replicates) to $Z5$–14:OAc was 5.5 ± 0.6 mV compared to 3.8 ± 0.6 mV for $E5$–14:OAc.

Quantification using pheromone extracted from five females and added internal standard (13:OAc) gave an average of 1.3 ng of $Z5$–14:OAc and 0.6 ng 14:OAc per female. Analysis of further female extracts showed the ratio of $Z5$–14:OAc to 14:OAc to vary from this 2.2:1 ratio to 0.45:1, with an average of approximately 1:1.

Field trials were carried out to determine the attractiveness of these chemicals to male moths. Traps baited with lures known to be attractive to *P. excessana* (Galbreath et al., 1985) were also used. The results (Table 1) clearly show the attractiveness of equal quantities of 14:OAc and $Z5$–14:OAc to male moths of this species, even though catches of males generally were low. In trial 1, the catch to 100 μg of both chemicals was significantly higher than that to a lower concentration of each or to the *P. excessana* lure ($Z8$–14:OAc and 14:OAc). Some 96% of males in the traps were caught in the final two weeks of the trial. This is due probably to an initiation of a moth flight period rather than to the decay of pheromone components in the lures to a more optimal concentration, since a similar phenomenon was observed in the lower concentration in the trial.

Trial 2 confirmed the efficacy of the synthetic lure in comparison with virgin females and trial 3 the necessity for the two-component mix for attraction. Trial 4 was conducted at a site where the moth has not previously been found and confirms the lure's efficacy in what is probably a low-density population (previous searches for this moth in this area failed to detect its presence, Dugdale, personal communication). The traps baited with *P. excessana* lures caught few moths. The morphological similarity between *P. excessana* and the mangrove-feeding *Planotortrix* males precluded absolute identification of the moths in the trap, and so it could not be determined if any *P. excessana* were captured in these tests.

DISCUSSION

The sex pheromone, Z5-14:OAc + 14:OAc, of the mangrove-feeding species of *Planotortrix* was found to be quite different from the populations of *P. excessana* which had previously been reported to be Z8-14:OAc + 14:OAc in one location and possibly Z5-14:OAc + Z7-14:OAc in another location (Galbreath et al., 1985). Although all three populations are morphologically indistinguishable, the significant difference in mate recognition systems should be sufficient to classify these populations as sibling species. Sibling or cryptic species have been defined as "species that morphologically resemble each other so closely that they can be recognized only after careful study of biochemical, cytological, or behavioral traits." (Diehl and Bush, 1984). The host preference of the mangrove-feeding *Planotortrix* species is also very different from the polyphagous *P. excessana* (Dugdale, 1966).

In Tortricidae, Z5-14 : OAc has been found as a sex pheromone component only twice—both times in New Zealand species. *Ctenopseustis obliquana* (Walker), the brownheaded leafroller, was found to use a combination of Z5-14:OAc and Z8-14:OAc (Young et al., 1985), and the *P. excessana* "species" from the central North Island apparently uses a combination of Z5-14:OAc and Z7-14:OAc (Galbreath et al., 1985). Z5-14:OAc also has been reported to be a sex pheromone component of a cossid moth (Capizzi et al., 1983) and a noctuid moth (Bestmann et al., 1980), and as part of an attractant blend for several other noctuid moth species (Steck et al., 1982). Since the compounds found in the New Zealand leafroller species are uncommon in other Tortricidae (Roelofs and Brown, 1982), further studies on the sex pheromone of other related New Zealand leafroller populations and the biosynthetic pathways used in these primitive species should provide valuable information on evolutionary relationships within the genus *Planotortrix* and between other genera in the tribe Archipini.

Acknowledgments—We especially thank Mr. J.S. Dugdale for directing our attention toward this species. We also thank Dr. C. Green for collection of the larvae from the field and Val Holt for rearing the insects. We are grateful to Dr. C. Triggs for statistical analysis of the data. We thank the N.R.A.C. for the award of a Senior Postdoctoral Research Fellowship to one of us (W.L.R.), permitting this cooperation.

Abstract—The airborne sex pheromone components (*Z,E*)-9,12-tetradecadien-1-yl acetate and (*Z*)-9-tetradecen-1-yl acetate from single calling females of *Ephestia cautella* (Walker) were trapped within glass capillary tubes and were measured by gas chromatography–mass spectrometry. Broad and similar distributions of relative quantities were found for a laboratory strain and three Australian field strains, and means differed strongly from those reported previously for this species. The overall mean proportion of the two components found for Australian females was 88 : 12. The composition in individuals ranged from 63 : 27 to 97 : 3. The proportions for individuals appeared to vary slightly in a random fashion from day to day, and proportions for first-generation progeny were influenced by the maternal blend.

Key Words—Effluvium, variation, *Ephestia cautella*, Lepidoptera, Pyralidae, single insect, pheromone composition, behaviour, GC-MS, (*Z,E*)-9,12-tetradecadien-1-yl acetate, (*Z*)-9-tetradecen-1-yl acetate.

INTRODUCTION

The relative quantities of the components of airborne sex pheromone blends are likely to be important at a number of evolutionary levels: in sexual selection, stabilizing selection, allopatric speciation, and reproductive isolation between species (Cardé and Baker, 1984). In spite of this pervasive influence, however, information on variation in proportions of emitted pheromone components is

[4] Author order in this paper is alphabetical.

0098-0331/87/0300-0639$05.00 © 1987 Plenum Publishing Corporation

available for only a few species such as *Spodoptera littoralis* (Campion et al., 1980), *Heliothis virescens* (Pope et al., 1982) and *Pectinophora gossypiella* (Haynes et al., 1984).

This dearth of information is partly because techniques for collecting and measuring the effluvia of single insects have become available only recently. Thus, Baker et al. (1981) and subsequently Pope et al. (1982) showed how to collect and quantify the pheromone blend released aerially from the forcibly extruded ovipositor of a female moth. Shani and Lacey (1984) later described an efficient procedure for collecting and measuring airborne sex pheromones from naturally calling female moths. The present paper reports results of a study of the sex pheromone blend of the moth *Ephestia cautella* (Walker) using the latter method.

E. cautella is one of several closely related phyticine pests of stored products. Two sex pheromone components have been identified from the effluvia of calling females, namely, (*Z,E*)-9,12-tetradecadien-1-yl acetate (*Z,E*9,12–14:Ac) (Brady et al., 1971b; Kuwahara et al., 1971b) and (*Z*)-9-tetradecen-1-yl acetate (*Z*9–14:Ac) (Brady, 1973) and have been shown to be active in attracting the male to the calling female (Brady, 1973; Read and Haines, 1976, 1979). These two compounds have been reported in somewhat differing ratios (Table 1), and total quantities recovered in various ways from the pheromone gland have been estimated as between 1.5 and 50 ng per female (Sower et al., 1973; Kuwahara and Casida, 1973; Read and Beevor, 1976; Coffelt et al., 1978).

(*Z,E*)-9,12-Tetradecadien-1-ol (*Z,E*9, 12–14:OH) has been reported from extracts of the sex pheromone gland of *E. cautella* (Kuwahara and Casida, 1973; Read and Beevor, 1976). Although looked for in effluvia, the compound was not found in the present study. Sower et al. (1974) similarly were unable to find *Z,E*9,12–14:OH in the effluvia of calling females and showed that this com-

TABLE 1. MEAN RATIOS OF (*Z,E*)-9,12-TETRADECADIEN-1-YL ACETATE (*Z,E*9,12–14:Ac) TO (*Z*)-9-TETRADECEN-1-YL ACETATE (*Z*9–14:Ac) OBSERVED IN DIFFERENT STUDIES OF *Ephestia cautella*

Ratio of *Z,E*9,12–14:Ac to *Z*9–14:Ac	Source	Study

4.9:1	rinsed glands (photophase)	
7.5:1	effluvium	present study

pound significantly inhibited male responses to the female's sex pheromone blend. Thus, in this paper we report only the relative contributions of *Z,E*9,12–14 : Ac and *Z*9–14 : Ac to the effluvia of individual calling *E. cautella* females. For preliminary reports, see Barrer et al. (1984) and Shani et al. (1985).

METHODS AND MATERIALS

Ephestia cautella (Walker) was reared as described by Barrer (1976). Pharate adults were collected as they emerged from the culture and were held individually until required for experiments.

Four strains were investigated. The laboratory strain (L) had been in culture for 11 years and had been combined periodically with other strains, the last time three years previously. Each of three field strains had been started from the eggs of between 10 and 20 field-collected females. Field strains were used in the present study when they had passed two or three generations under culture. Strains were collected from Pinkenba Grain Export Terminal, Brisbane, Queensland (P strain); the Peanut Marketing Board premises, Tolga, Queensland (T strain); and Scott Creek, a pastoral and farming property near Katherine, Northern Territory (S strain).

Apparatus for making collections of airborne pheromones from individual free-moving insects is described in full by Shani and Lacey (1984). Briefly, a gentle air stream passes over each unrestrained insect in its own glass cage and the effluent flows through the capillary section of a clean Pasteur pipet. Typical pheromone molecules adhere to the walls of the capillary and are readily recovered at the end of the collection period with microliter quantities of solvent. The sealed capillary sections containing the trapped pheromone solutions are then stored at $-5°C$ until required for measurement.

The efficiency of the collection device is difficult to assess for a free-moving moth, but it may be high for the following reasons. There is no breakthrough of the pheromones released from synthetic sources for low nanogram/subnanogram quantities (Shani and Lacey, 1984). The cage design and the airflow rate were selected to minimize entrainment of emitted pheromone by the cage walls. Any pheromone entrained by the cage walls would be fixed irreversibly (Shani and Lacey, 1984) and would not contribute further to the blend in the trap. Because the mean quantities of C-14 acetates in the pheromone gland are no more than one order of magnitude greater than our yields of trapped pheromone, measured quantities of emitted pheromone are not unexpected and are probably close to the natural rates of emission.

To detect the possible presence of *Z,E*9,12–14 : OH in the effluvia from *E. cautella*, the contents of capillaries collected from 14 females during the same collection period (2 hr) were amalgamated. This was effected by washing the capillaries sequentially with the same limited volume of solvent, using cen-

trifugation to facilitate recovery of the pooled solution. Since the alcohol was not detectable in this experiment ($<0.2\%$ of the amount of Z,E9,12–14 : Ac), nor in individual aerial collections, comparative analyses of the effluvia were directed to the known pheromone components Z9–14 : Ac and Z,E9,12–14 : Ac. It seems that cuticular enzymes that hydrolyze *Choristoneura pinus* pheromone acetates to alcohols (Silk et al., 1985) are not a problem for effluvia collected from individual *E. cautella* by the current method.

In earlier experiments, Dry Ice was used to cool the pipet traps as a precaution against possible breakthrough of pheromone components. However, cooling of the glass walls proved to be unnecessary to trap such small quantities (less than 2 ng/hr) released from calling female *E. cautella*, and later experiments were performed with the traps at ambient temperature ($22 \pm 1\,°C$). Pheromone was collected from calling virgin females (0, 1, or 2 days old) in the 1–2 hr following scotophase. Subdued lighting (approximately 1.5 lux) was used for the period of collection and the calling behavior (Barrer and Hill, 1977) of females was monitored at 15- to 20-min intervals.

Standard solutions of Z9–14 : Ac and Z,E9,12–14 : Ac were prepared from HPLC purified material ($>99\%$) in hexane (HPLC grade, Waters Associates) and kept at $-5\,°C$ when not in use. Mixtures of Z,E9,12–14 : Ac and Z9–14 : Ac in blend proportions of 85 : 15, 91 : 9, and 96 : 4 were prepared in duplicate. Separate syringes were used for standards and unknowns to obviate any possibility of cross-contamination.

Blend proportions and quantities of the trapped effluvia from individual female moths were assessed by gas chromatography–mass spectrometry (GC-MS). The gas chromatograph was a Varian 1400 Series interfaced to a VG Micromass 70-70 mass spectrometer through a single-stage glass jet separator. The conductance of the vacuum jacket of the separator was increased to improve the efficiency of molecular transfer to the mass spectrometer. Injections were made on-column to a packed glass column (10% Silar 10C, 1.8 m length $\times$ 3 mm ID) under conditions indicated previously (Shani and Lacey, 1984). The column was conditioned immediately before use with nanogram injections of Z9–14 : Ac and Z,E9,12–14 : Ac and was used exclusively for aerial collections.

Most of the MS measurements were carried out under electron ionization conditions at 70 eV, but some later measurements were made at 20 eV to improve the signal-to-noise ratio. The selected $(M - HOAc)^{+\bullet}$ ions for Z9–14 : Ac and Z,E9,12–14 : Ac were monitored using a VG multiple ion detection (MID) module in its electric field switching mode, using the column bleed peak of m/z 207 for mass locking. The analog output from the MID was directed to a Servogor 460 multichannel analyzer, and results were assessed from peak heights.

The GC-MS strategy for quantitation capitalized upon the constancy of

response of the mass spectrometer to small quantities over a short time interval. For instance, seven successive injections at 5-min intervals from a standard pheromone blend containing quantities similar to aliquots from individual moths (35–55 pg Z9–14 : Ac and 190–300 pg *Z,E*9,12–14 : Ac) gave a coefficient of variation of 3.9% for the mean ratio of mass channel responses. The responses of the selected mass channels were essentially linear with quantity over the range 40–210 pg Z9–14 : Ac ($r = 0.990$) and 230–1150 pg *Z,E*9,12–14 : Ac ($r = 0.994$), for 13 successive injections at 5-min intervals.

The solution of the trapped effluvium from each individual moth was divided to allow duplicate measurement of its relative quantities of components by GC-MS. The two injections of the unknown were interposed by one for a standard solution, and blend proportions and quantities for the duplicates were assessed by interpolation. The blend proportion of the particular standard for each assessment was chosen to be close to the apparent blend proportion for the first of the duplicates to increase the reliability of the interpolation. Successive injections of unknowns and standards could be carried out at 5-min intervals because the selectivity of the GC-MS procedure nullified interference from any coeluting impurities from the effluvia.

Typically, the measured difference between the duplicate blend proportions was <2% of the total blend for the aerial collection from a strongly calling female, and duplicate measurements for individual *E. cautella* were rejected if they differed by more than an arbitrary 3.5%. Not all females called, and not all calling females released sufficient quantities of pheromone for accurate measurement. About 50% of all females released sufficient pheromone during their bouts of calling to meet criteria for acceptance of the duplicates. Of the 122 aerial collections that were accepted, duplicate blend proportions varied by 0–0.5% in 27%; 0.5–1.5% in 47%; 1.5–2.5% in 18%; and 2.5–3.5% in 8%.

With a multicomponent system, relative quantities can be expressed either as ratios or as proportions. Ratios and proportions are each transformations of the raw data, each with their own particular properties. Where the relative quantities of components are very different, the use of proportions compresses distributions and the use of ratios expands them. Because of this and because our results show relative quantities far removed from equimolar, we report values both as proportions and as ratios. Calculations were performed on arcsine transformed proportions (Zar, 1974). Mean quantities are reported here with the standard error (i.e., ±SE).

RESULTS

Relationship between Calling Behavior and Pheromone Production. There was an approximate relationship between the calling behavior of a female and

the amount of pheromone later detected. When an insect exhibited no overt calling behavior, the pheromone produced and trapped was either barely detectable or, more often, undetectable. Conversely, pheromone was usually trapped and readily detected from insects that were observed to call. Moreover, a sample of 28 females (L strain, no cooling of traps) that called strongly (Barrer and Hill, 1977) and continuously for 2 hr produced a measured 1285 ± (SE) 193 pg per female, whereas a sample of 24 otherwise similar females calling less strongly and/or less frequently produced only 563 ± 102 pg over the same period. Nevertheless, calling strength and frequency did not provide accurate predictions of pheromone yield, where a range from 78 to 4503 pg was detected among strongly and continuously calling females, and an overlapping range from undetectable to 1890 pg was obtained among females that called less readily.

Relative Quantities of Acetates among L Strain Females. A sample of 38 calling females produced the distribution of pheromone proportions summarized in Figure 1A. The mean value for this population was 89.1 ± 0.8% *Z,E*9,12-14:Ac, equivalent to 8.2 parts *Z,E*9,12-14:Ac to 1 part Z9-14:Ac (8.2:1). The range for the sample population was 75.9-95.7% *Z,E*9,12-14:Ac (3.1:1-29:1, almost an order of magnitude).

Both the mean value and the total range of the individual aerial collections were unexpected. The mean differed markedly from previously published data (Table 1) for this species, while the distribution of blend ratios was two or more times broader than the differing blend ratios reported, for example, for the pher-

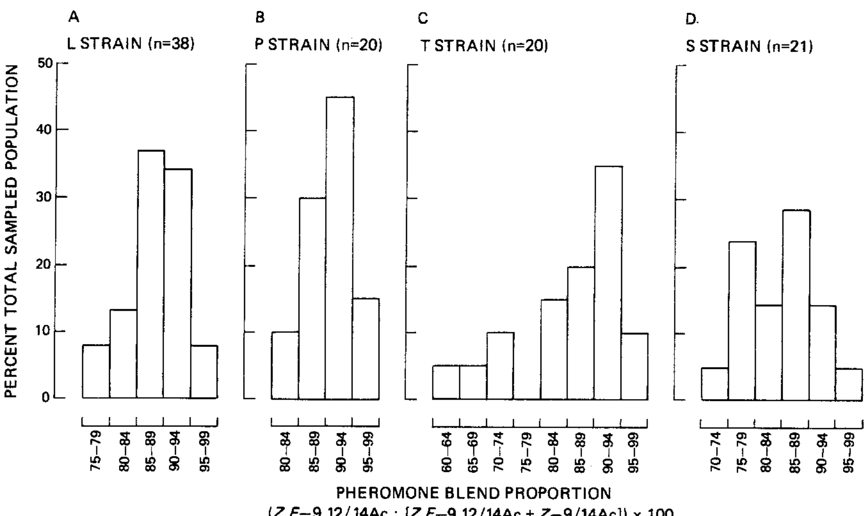

FIG. 1. Distributions of pheromone blend proportions in samples from each of one laboratory strain and three field strains of *Ephestia cautella*.

omone blend components of *Argyrotaenia velutinana* (Miller and Roelofs, 1980) or *Pectinophora gossypiella* (Collins and Cardé, 1985).

The laboratory history of the L strain may have rendered it atypical of *E. cautella* in the field. To assess this possibility, samples were taken from the three field strains (P, T, and S) obtained from widely separate sources in Australia.

Relative Quantities of Acetates among Field-Strain Females. Samples of 20 (P), 20 (T), and 21 (S) females produced the distribution of pheromone proportions summarized in Figure 1B–D. The mean of the P strain was 91.0 ± 1.0% *Z,E*9,12–14:Ac (10.1:1), that of the T strain was 86.8 ± 1.7% *Z,E*9,12–14:Ac (6.2:1), and that of the S strain was 85.7 ± 1.6% *Z,E*9,12–14:Ac (6.0:1). The three ranges were 80.8–97.3% (4.2:1–36:1), 62.7–96.2% (1.7:1–31:1), and 71.7–95.7% (3.2:1–22:1), respectively. Within these samples, 13 (P), 10 (T), and 10 (S) females called strongly and continuously during the 2-hr period of collection. These females produced 1202 ± 162 pg, 831 ± 60 pg, and 636 ± 83 pg, respectively.

Given the considerable variation in relative quantities within the samples, the means and ranges of pheromone proportions for laboratory and field strains appear quite similar. A Kruskal-Wallis test with tied ranks (Zar, 1974) gave a χ^2 of 7.62 with 3 df and $P > 0.05$, suggesting similarly that the four strains should not be considered samples from pheromonally distinct populations.

Results from the laboratory population were representative of those from the sampled field strains, so that results from all four strains could be amalgamated. Figure 2 shows the distribution arising from amalgamation of individual pheromone blends from all four strains. The mean of the amalgamated population was 88.3 ± 0.7% *Z,E*9,12–14:Ac (7.5:1) and the range, 62.7–97.3% *Z,E*9,12–14:Ac (1.7:1–36:1).

Pheromone Blend of Same Individual from Day to Day. To determine whether the pheromone blend of an individual varied from day to day, pheromone was collected from 10 L strain females over the first 2 hr of scotophase on the day of emergence and on the two days following.

Two females produced pheromone sufficient to be reliably assessed on only two of the three days. The remaining results are summarized in Figure 3. Pheromone blends appeared to change by small amounts and in an apparently random fashion from one day to the next. The mean change per day for a female was plus or minus 3.2 ± 0.5% *Z,E*9,12–14:Ac. The change was considerably greater than the measuring error, where the mean difference between duplicate measurements was 1.3 ± 0.2% *Z,E*9,12–14:Ac. It is not clear whether or how much other small errors could have contributed to this apparent change. In any case, there was little or no evidence of a constant trend in any one direction, where the mean change over two days was plus or minus 3.8 ± 1.0% *Z,E*9,12–14:Ac, hardly different from the change observed over one day only. Evidently, the measured pheromone blend of an individual changed relatively little

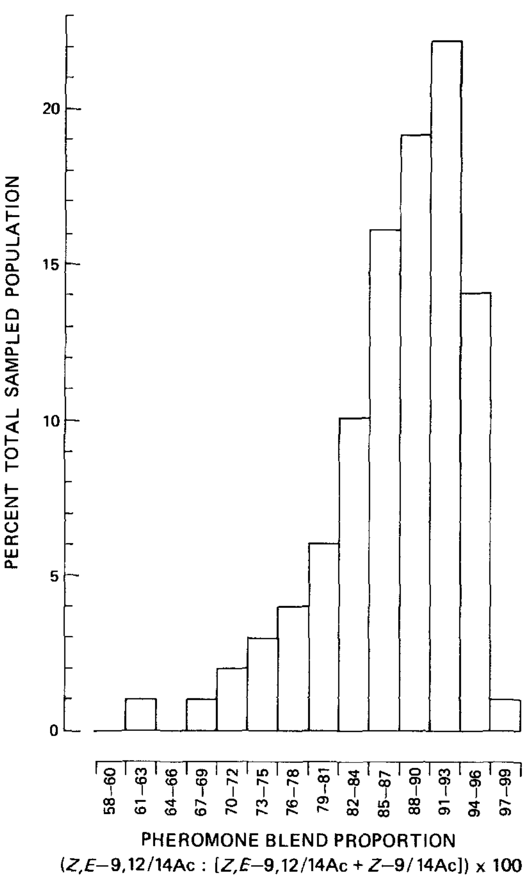

FIG. 2. Distribution of pheromone blend proportions in combined samples from one laboratory strain and three field strains of *Ephestia cautella*.

or not at all, and where it did vary, it tended to do so randomly from day to day around a mean value.

Relationships between Pheromone Blends of Two Consecutive Generations. As has been shown, relative quantities of *Z*,*E*9, 12–14 : Ac and *Z*9–14 : Ac varied within a population but individual females tended to maintain approximately the same pheromone blend composition from day to day. A preliminary experiment was set up, therefore, to determine whether there was evidence of an inherited component to an individual's pheromone blend composition.

Pheromone was collected from each of four virgin L strain females which were then mated with siblings, allowed to oviposit, and their progeny reared to

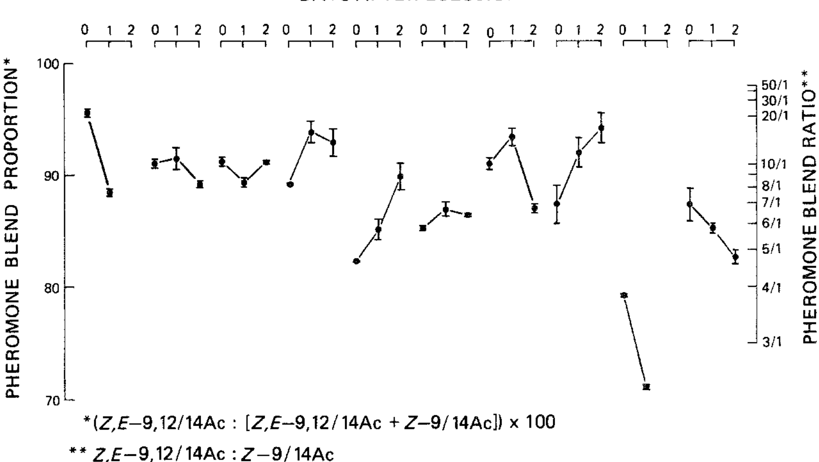

FIG. 3. Pheromone blend ratios and proportions of ten individual *Ephestia cautella* females over two or three days (bars represent differences between duplicated measurements).

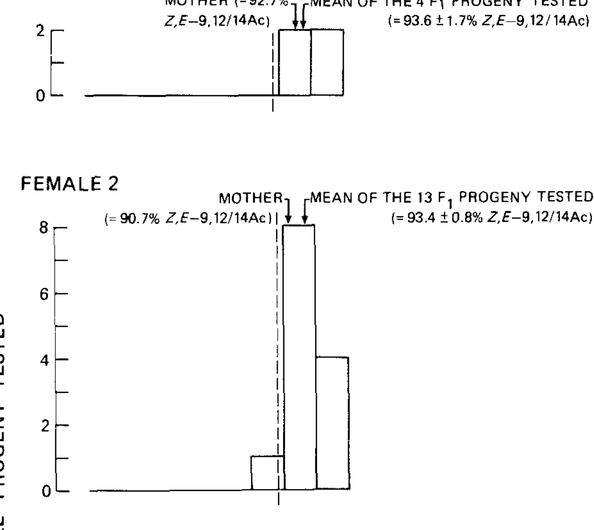
F_1 adults. Pheromone samples were collected in turn from several randomly selected F_1 female progeny of each of the original females.

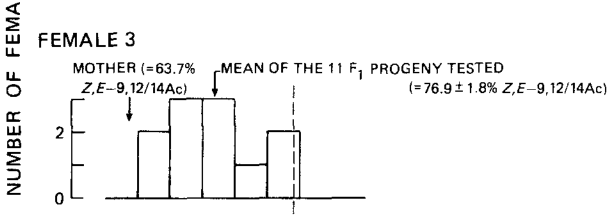
Results are summarized in Figure 4. The mean blend composition and range of each F_1 population sample were influenced by the mother's blend composition, although a moderate range of F_1 blends was evident even for small population samples. More detailed study is required to clarify the genetic mechanisms involved and to determine whether populations selected for extreme pheromone blends will "breed true" over a number of generations.

DISCUSSION

The mean composition of the sex pheromone blend of Australian strains of *E. cautella* (Figure 2) differs from compositions reported previously for strains from outside Australia (Table 1), and the reported compositions differ also between themselves. However, the range of the reported blend proportions falls within the range of individual values obtained in the present study of Australian strains (Figure 2). There is evidence, therefore, of an unexpectedly wide and more or less continuous range of blend proportions within and between populations of this species.

The differences between blend proportions for *E. cautella* are less than those reported between the so-called *Z* and *E* strains of *Ostrinia nubilalis* (Klun et al., 1973; Klun and cooperators, 1975), but the two *O. nubilalis* strains are





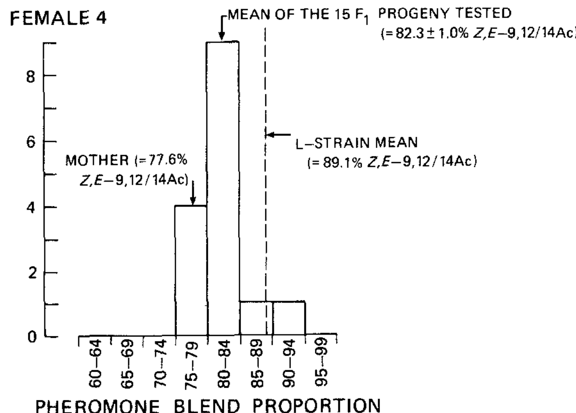


FIG. 4. Pheromone blend proportions of four *Ephestia cautella* females and samples of their female progeny.

genetically differentiated to an extent that may indicate semi- or sibling species status (Cardé et al., 1978). There is no reason to believe that *E. cautella* populations from different parts of the world are genetically differentiated to a similar extent, although it is perhaps surprising that the means of the four sampled Australian strains (Figure 1) are all so similar to each other but unlike those reported from North America and Europe. It is appropriate to consider what factors could account for this apparent pattern of similarities and differences in pheromone blend proportions.

Blend proportions obtained from pheromone gland extracts need not reflect the composition of the effluvium, but Brady (1973) measured both the gland contents and the effluvium from *E. cautella* and found similar blend ratios (Table 1). Thus the different methodologies are unlikely to have contributed much to the dissimilarities in mean blend composition.

Evidence of the relationships between the pheromone blend of parents and progeny (Figure 4) suggests that environmental factors in the laboratory, such as variation of the quality of larval rearing medium, could not account for the large differences between individuals in Australian strains of *E. cautella*, nor between mean blend proportions of strains around the world. Furthermore, the pheromone blend of an individual tends to remain relatively constant from day to day (Figure 3). It does seem necessary, therefore, to assume moderately precise genetic control over pheromone blend.

Do strains of *E. cautella* from various parts of the world differ in mean blend composition as a result of selection pressure or genetic drift? The similarity between the four sampled Australian strains of presumably heterogeneous origin suggests the former, although it is not immediately apparent what external factors can mediate a population mean typical of Australia, with its wide range of conditions, and atypical of North America and Europe. It is possible that selection pressures are active in some parts of the world only, pushing pheromone blend proportions towards some extreme that is not maintained in the absence of such pressures.

Competition for sex communication channels between *E. cautella* and other cosmopolitan phyticine moth pests of stored produce is likely to be limited, since *Plodia interpunctella* (Hübner) is the only species with broadly similar temperature and food preferences. Other species are likely to compete less frequently with *E. cautella*, either because of different temperature requirements (*E. kuehniella*, *E. elutella*) or because of more specific food requirements (*E. figulilella*, *E. calidella*). Although most of these species are known to share $Z,E9,12$–14 : Ac as the sole or major identified component of their sex pheromone blends, *E. cautella* and *P. interpunctella* possess qualitatively different blends (Table 2) and appear not to rely on different ratios of common components to distinguish between the species.

Behavioral evidence confirms that *E. cautella* readily distinguishes be-

tween its own and *P. interpunctella* sex pheromone (Ganyard and Brady, 1971; Sower et al., 1974) and that the converse is true, although to a lesser extent. Under these conditions, there would be little selective pressure for *E. cautella* to maintain precise control over the relative quantities of *Z*9–14 : Ac to *Z*,*E*9, 12–14 : Ac, and the mean and variance would be limited only by other, possibly intraspecific, factors. If, however, *E. cautella* was sometimes sympatric with other species that shared the same two blend components, then such populations of *E. cautella* could be expected to maintain blend proportions much more precisely and possibly centered on a different mean. In Australia, *P. interpunctella* is the only phyticine species to compete at all commonly with *E. cautella*. However, *E. cautella* does occur together with *E. figulilella* in the dried-fruit growing areas of Australia, and samples of *E. cautella* from these localities could be instructive. A similar situation appears to influence the responsiveness of male *Archips argyrospilus* from different parts of North America (Roelofs et al., 1974; Cardé et al., 1977).

We have not studied the responses of males to the range of pheromone blend ratios found within Australian populations of *E. cautella*. Because of the wide and continuous distribution of ratios found within all tested populations, however, it seems quite possible that the majority of males will prove to be broadly tuned, responding almost equally to the different proportions. In a population where this was not so, relatively large numbers of females from each generation would attract finely tuned males too infrequently for significant reproductive success. In the absence of other selective pressures against wide distributions of blend proportions in the population, extreme ratio females that did mate would tend to propagate or transmit those genes that made it possible for them to reproduce. An effective way of doing this would be to produce male progeny with a broad, rather than a narrow, responsiveness to blend proportions.

Also requiring comment is the wide range of pheromone quantities obtained from otherwise similar strongly calling females. Some of this variation could have been methodological (e.g., in airflow rates around pheromone glands), but some may be a reflection of basically different release rates. Greenfield (1981) points out that sexual selection by female moths would be facilitated where the female emitted a very weak signal and selected "superior" males with better searching abilities. Given that release rates above and below the norm represent two quite distinct reproductive strategies, then it seems possible that variation in release rates might characterize populations where sexual selection is mediated in this way. Moreover, in the crowded conditions of laboratory cultures of *E. cautella*, background pheromone levels tend to be high and sexually excited males attempt to mate indiscriminately with any insect they encounter. As a consequence, the occasional receptive female that releases little

or no pheromone should be able to "parasitize" her siblings' pheromone production with no reproductive penalty.

PARTIAL CHEMICAL CHARACTERIZATION OF URINARY SIGNALING PHEROMONE IN TREE SHREWS (*Tupaia belangeri*)

F.v. STRALENDORFF

Department of Animal Physiology
University of Bayreuth
Universitätsstr. 30, D-8580 Bayreuth, F.R.G.

(Received January 26, 1986; accepted April 22, 1986)

Abstract—Tree shrews of both sexes exhibit marking behavior ("chinning") in response to scent marks made by the urine of fertile male conspecifics. To isolate the effective odor components, the urine was fractionated by liquid–liquid extraction and TLC, and the fractions were tested by bioassay. The results show that chinning is elicited by several lipophilic urine fractions, which are more effective in combination than alone. To characterize the complex scent signal, the lipophilic extracts from urine of the two sexes were analyzed by GC-MS and compared. The GC profile of the males is distinguished by pyrazine compounds not detected in the profile of the females. The profiles of the sexes also differ with regard to several volatile monocarboxylic acids, which are present at higher concentrations in male than in female urine. More than 30 urine components have been identified. Synthetic equivalents of these urine components were bioassayed for effectiveness in eliciting chinning and compared with one another as well as with scent substances not normally present in tree-shrew urine. Strong chinning responses were elicited by (1) certain pyrazine compounds and (2) some monocarboxylic acids, when presented at the high concentrations specific to male urine. Marking behavior is usually not elicited by scent substances not contained in tree-shrew urine or by urine components common to mammals in general. The data so far available indicate that the male-specific scent signal of tree shrews is based less on a single unique component than on the qualitative and quantitative characteristics of a multicomponent mixture. In the bioassay, tree shrews of both sexes respond equally to the male specific substances by chinning. As the scent signal represented by these substances has a different meaning to males and females (rival or potential mate, respectively), chinning probably serves several different functions.

Key Words—Chinning response, pyrazines, scent marking, signaling pheromone, tree shrew, *Tupaia belangeri*, urinary chemosignal, volatile carboxylic acids.

INTRODUCTION

Tree shrews mark the area in which they live with urine (Martin, 1968), as many other mammals do (Coblentz, 1976; Hopp and Timberlake, 1983; Johnson, 1973; Whitten et al., 1980). When an adult tree shrew of either sex encounters the urine mark left by a strange, fertile, adult male conspecific, it immediately overmarks it with secretion from its sternal glands (Holst, 1985) by a movement called "chinning." The urine of juvenile or castrated male conspecifics does not elicit chinning, nor does that of male mice (Stralendorff, 1986). The implication is that the urine of male tree shrew contains a characteristic, androgen-dependent signal that produces a specific behavioral reaction. In the experiments described here, this signal was characterized chemically by a bioassay procedure.

METHODS AND MATERIALS

Animals. A total of 30 adult tree shrews (15 male and 15 female *Tupaia belangeri*) were used, some as urine donors and some as test animals in the bioassay. The animals were kept singly in cages; their living conditions and food and the method by which urine was obtained are described elsewhere (Stralendorff, 1986). The concentration of the urine samples was estimated prior to chemical analysis by creatinine measurement (Haeckel, 1980), and only samples approximately equal in concentration were used in the experiments.

Bioassay. Ten animals of each sex were used for bioassay. In each trial, 25 μl of a test solution (urine, a particular urine fraction, or a solution of a synthetic substance) was applied to the front (wire mesh) of the animal's home cage (for details see Stralendorff, 1986), and the number of times the sample was overmarked with sternal-gland secretion within 2 min after sample application was recorded as the "chinning score." At 30 min before or after this test, the same animal was presented with a control solution—for example, the corresponding fraction of female urine or another fraction of male urine. The chinning score in response to the control solution was also recorded. Each combination of sample and control solution was tested on all of the animals, five times (on different days) in each case.

From the results of the five tests on a single animal (and the control responses), the median was found and recorded as the individual chinning score. As prior experiments have shown (Stralendorff, 1986), the individual chinning scores of the experimental animals in response to a given test solution differ considerably. In order to reduce the individual values to a common denominator, an additional term has been introduced: the average chinning score. The average chinning score for a given sample (whole urine, a particular urine frac-

tion, or a synthetic scent substance) was obtained by taking the median of the 20 individual chinning scores.

Since responses of males and females to the urine of fertile male conspecifics cannot be distinguished, the data obtained from the two sexes are not treated separately.

Statistical Analysis. The individual chinning scores served as the basic data for statistical evaluation. Responses to samples to be compared were first tested for difference by the Friedman two-way analysis of variance by ranks (Siegel, 1959). The significance of the differences between the responses to sample and control solutions was evaluated with the Wilcoxon matched-pairs signed-ranks test. Differences were considered significant when the two-tailed test gave $P < 0.05$.

Urine Fractionation. Urine from male and female tree shrews was treated separately. The first step was liquid–liquid extraction to give three fractions: lipophilic acidic extract, lipophilic basic extract, and aqueous residue. Fractionation was done by the method of Wimmer et al. (1978); 20 ml of urine was buffered, acidified, and applied to a ready-to-use Extrelut® column (Merck, Darmstadt). After separation, the lipophilic acidic and neutral components were extracted with 40 ml diethyl ether. The eluate was washed three times with 5 ml of 1 N hydrochloric acid and dried over anhydrous sodium sulfate. The dried extract was concentrated to 20 ml under nitrogen, to return the components to the concentration they had had in the original urine sample. Of this extract, 5 ml was divided into 25-μl samples and deep-frozen ($-40°C$) for later use in bioassay. The remaining 15 ml of acidic lipophilic urine extract was concentrated further and analyzed by thin-layer chromatography (TLC) and gas chromatography (GC).

The residue on the Extrelut column was basified by ammonia-saturated air and extracted with 40 ml methylene chloride. The eluate was washed three times with 5 ml of 1 N potassium hydroxide, dried, and concentrated to 20 ml. As above, 5 ml of this lipophilic basic extract was used for the bioassay and the rest concentrated further for chemical analysis.

After extraction of the lipophilic components of the urine, the solvent remaining on the column was removed in a weak vacuum, and the remaining hydrophilic components were eluted by application of 40 ml saturated sodium chloride solution. This aqueous urine residue (ca. 20 ml) was neutralized, divided into samples for bioassay, and deep-frozen ($-40°C$).

Thin-Layer Chromatography (TLC). TLC was performed using precoated plates of silica gel 60 F (Merck, Darmstadt). Chromatograms were run with chloroform–methanol (9 : 1) and visualized by exposure to UV light and staining with vanillic–sulfuric acid (LeRosen et al., 1952) or Tillman's reagent (Passera et al., 1964).

Subfractions for bioassay were obtained with the same precoated plates

and the same carrier solvent used for analytical TLC. The chromatograms were developed and dried three times and subsequently divided into four sections; the adsorbed material in each section was scraped from the plate. Each of these four fractions was extracted with diethyl ether for 3 hr in the Soxhlet; the extracts were concentrated to 20 ml and divided into samples for bioassay.

Gas Chromatography (GC). A Siemens gas chromatograph (Sicromat 1) with flame ionization detector (FID) was used. It was equipped with glass capillaries (length 25 m, inside diameter 0.32 mm) lined with Carbowax 20 M, OV-101, or OV-17 (Machery and Nagel, Düren). The carrier-gas flow rate was about 1 ml nitrogen per minute. The analysis was temperature programmed from 60°C to 220°C with 5°C/min. The gas chromatograms were evaluated by means of a Hewlett Packard 3380 A Integrator.

The concentrated lipophilic basic extracts were gas-chromatographed directly, with no additional treatment. Because the components were present in such low concentrations, the splitless injection technique (Grob and Grob, 1978) was used.

The free carboxylic acids in the lipophilic acidic extracts were converted to methyl esters by treatment with boron fluoride–methanol (Morrison and Smith, 1964; Edwards et al., 1975). The carboxylic acid methyl esters were applied to the GC capillary by inlet splitter (split ratio 1 : 100).

Coupled Gas Chromatography–Mass Spectrometry (GC-MS). An LKB-2091 device equipped with a Pye-Unicam gas chromatograph was used; the carrier gas was helium. The columns and the operating conditions were as described above; the temperature between this device and the mass spectrometer was 250°C, electron energy 70 eV.

The scent substances were identified by comparing the mass spectra of the samples with those of authentic substances (where available) and with various published mass spectra (Bondarovich et al., 1967; Buttery et al., 1971; Maga and Sizer, 1973; Stenhagen et al., 1974).

Reagents. All the solvents used were of analytical grade; they were obtained from EGA-Chemie (Steinheim), Fluka (Neu-Ulm), Merck (Darmstadt), Serva (Heidelberg), and Woelm-Pharma (Eschwege). Diethyl ether was further purified on a column with basic aluminum oxide and active silica gel.

RESULTS AND DISCUSSION

Prior to analysis, untreated samples of the urine from males and females were tested by bioassay (Table 1). Male urine was overmarked by both males and females; the average chinning score was 12. As observed in previous experiments (Stralendorff, 1986), female urine did not elicit chinning in most animals. The urine samples from the two sexes did not differ appreciably in concentration (creatinine: males 9.6 μmol/ml, females 9.7 μmol/ml) or in pH.

TABLE 1. COMPARISON OF AVERAGE CHINNING SCORES[a] OF 20 TREE SHREWS IN RESPONSE TO DIFFERENT FRACTIONS OF URINE[b] FROM MALE AND FEMALE CONSPECIFICS

	Test series		Male urine		Female urine		Significance of difference	
			Median	[25–75%]	Median	[25–75%]	T^c	N^d
1	Untreated whole urine		12	4–13	0	0–0	0	20

9		fractions I–IV, recombined	6.5	4–8	1.5	0–3	13.5	17

[a] Each value is the median of the individual chinning scores of all animals tested; 25–75 percentiles in brackets; the individual chinning score is the median of the scores obtained in five tests of a given sample.

[b] In each bioassay 25-μl aliquots were presented; the concentration of each fraction was adjusted to approximate the natural concentration of the components in the urine.

[c] Wilcoxon matched-pairs signed rank test; all differences are significant except as marked with asterisk.

[d] N = number of matched pairs with $d \neq 0$.

Hence the difference in chinning scores probably results from differences in composition of the urine.

Response of Animals to Various Urine Fractions. Male and female urine samples were each separated into two lipophilic fractions (acidic and basic extract) and one hydrophilic fraction (aqueous residue).

The aqueous residue of male urine does not elicit chinning in the bioassay (Table 1) and was therefore discarded. The lipophilic acidic extract of male urine was overmarked five times on average, and the lipophilic basic extract was overmarked 10–12 times. The responses to the two lipophilic extracts differ significantly from one another ($P < 0.005$). From these results we conclude that chinning is elicited by various lipid components in the male urine, and that the lipids in the basic extract are the most effective.

As a control, both lipophilic extracts were tested against the corresponding extracts from female urine (Table 1: test series 3 and 4). Surprisingly, both the basic and the acidic extracts from females elicited chinning in most animals tested. The average chinning scores are considerably lower than those in response to the corresponding extracts from males; the differences between them are significant ($P < 0.005$).

The responses to lipophilic extracts from female urine raise the question: Why, when less than a quarter of the animals respond to whole female urine, do extracts from it elicit chinning in more than half of those tested (see medians and percentiles, Table 1)?

Probably the whole urine of females contains a female-specific component that the animals can detect. Its presence is indicated by the following response of two males in the bioassay. Both males were clearly sexually excited, sniffing and licking the female urine and giving "rhythmic clicking" calls. The latter are produced only by males in pursuit of an estrous female (Sprankel, 1961; Martin, 1968). Samples obtained by fractionation of the urine no longer caused either male to give rhythmic clicking calls. Evidently the female-specific material was either not present or not detectable in these samples. In whole urine, this characteristic substance could act antagonistically to the substances that elicit chinning and thus inhibit the marking response to female urine. This "inhibition" could be eliminated by fractionation of the urine.

On the other hand, the different responses to whole urine and the lipophilic extracts may be due to a solvent-dependent concentration effect. In aqueous solutions, as whole urine is, physical and/or chemical interactions between volatile components and nonvolatile material such as salts and proteins may result in retention of volatile components (Maier, 1970). The lipophilic organic extracts of the urine lack these proteins and may therefore retain volatile components to a lesser degree. Consequently the headspace over the untreated female urine and those over their organic extracts may differ in their content of chinning-eliciting components. This would result in different chinning responses

even though these components are contained in nearly equal concentrations in both whole urine and the organic extract.

The lipophilic extracts of both sexes were analyzed by thin-layer chromatography to find out whether the chinning response to the extracts from females is elicited by the same components that are responsible for the response to the extracts from males. The basic extracts, because their concentration in the original urine is so low, had to be brought to a concentration ten times that of the acidic extracts for this purpose.

Comparative TLC of Lipophilic Extracts from Male and Female Urine. The thin-layer chromatograms characterize the lipophilic extracts from tree-shrew urine as complex lipid mixtures (Figures 1 and 2). No qualitative differences between the acidic extracts of the two sexes could be detected (Figure 1), although the staining intensities of comparable zones (dotted areas) indicate quantitative differences. One's subjective impression of the smell of the extracts corroborates these quantitative differences; that is, the acidic extract from males smells more strongly of meat broth than does that from females.

The differences between the chromatograms of the two basic urine extracts are more pronounced (Figure 2) and are qualitative as well as quantitative. That is, there are several zones in which spraying with vanillic-sulfuric acid produces a yellow spot in the chromatogram for male urine (hatched areas) but does not stain that for female urine. This qualitative difference between the basic extracts from the two sexes can also be detected by the human nose: the extract from

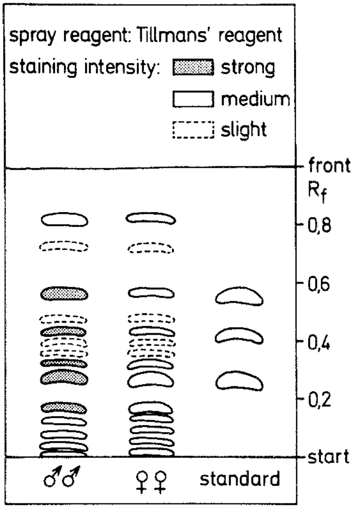

FIG. 1. Thin-layer chromatogram of lipophilic acidic extracts from the urine of male and female tree shrews. Standard: a mixture of 2-methyl-butyric acid (top), phenylacetic acid (middle), and 3-methyl-2-oxo-valeric acid (bottom).

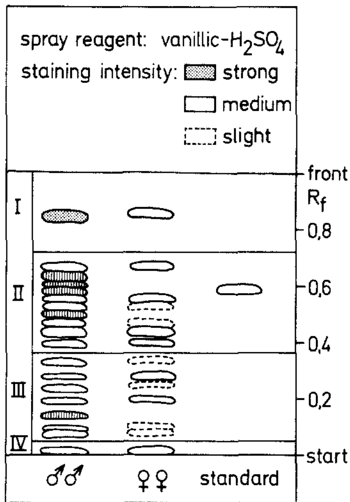

FIG. 2. Thin-layer chromatogram of lipophilic basic extracts from the urine of male and female tree shrews. Standard: a mixture of three isomeric dimethylpyrazines. The hatched areas are demonstrable only with male urine. The numbers I–IV designate subfractions that were analyzed further by bioassay.

males has a strong smell of roasted nuts, and that from females has only a weak mousy odor.

In order to isolate the characteristic male components, the lipophilic basic extracts from both sexes were separated into four subfractions by preparative TLC (Figure 2).

Behavioral Effect and Odor Characteristics of Subfractions of Basic Extracts. The boundaries of the subfractions were positioned so as to separate the male-specific components (in fractions II and III) from some of the components common to both sexes (fractions I and IV).

Fraction IV, whether of male or female urine, did not elicit chinning in most animals tested (Table 1) and was therefore discarded.

Fraction I of male urine is overmarked by nearly three quarters of the animals, whereas the corresponding fraction of female urine usually does not elicit chinning. The TLC analysis (Figure 2) and the subjective impression of odor intensity both indicate that the difference between the two fractions is quantitative; that is, presumably the concentration of the component(s) in fraction I from females is too low to elicit chinning in most animals.

Fractions II and III also include some components common to both sexes, but only in fraction II is the concentration of these components in female urine high enough to elicit chinning in most animals tested. Fractions II and III from males contain additional, male-specific substances, which make both fractions

smell different (to humans) from the corresponding fractions of female urine. In fraction II from males, after the solvent has evaporated, one can detect the roasted-nut odor that characterized the basic lipophilic extract before TLC fractionation. A few seconds later, however, this roasted smell disappears and is replaced by an intense pyrazine odor, which also characterized fraction III from males. Fractions II and III from females have neither a roasted nor a pyrazine smell; they tend more to smell mousy to urinous, like the basic extract from female urine before fractionation. As would be expected from the results of TLC analysis and of organoleptic evaluation, fractions II and III from males are overmarked by nearly all animals. The strongest chinning response is elicited by fraction II (average chinning score 4.5). This reaction is significantly different ($P < 0.005$) from that to fraction II from females.

The bioassay results show that several different fractions of the basic urine extract are effective in eliciting chinning. No differences have been observed between the chinning responses of both sexes. The various fractions of male urine are nearly additive in effectiveness; that is, the mixture of given amounts of all components elicits more chinning than does the same amount of any of the components alone (Table 1, test series 9).

The basic extract before fractionation gives a higher chinning score than does a mixture of fractions I to IV (test series 3 and 9 in Table 1). This loss of biological activity (or behavioral effectiveness) is accompanied by a subjectively discernible reduction in the intensity of the roasted odor. It may be that during fractionation, the male odor substances are partially lost by evaporation, oxidation, and so on.

Comparative GC-MS Analysis of Volatile Components of Lipophilic Acidic Urine Extracts. The GC-MS analysis was undertaken in order to identify the odor substances present in male but not in female urine. The GC profiles also provide a means of characterizing sex-specific proportions of the various components in the mixture.

The acid profiles of the urine samples from males and females differ sharply in quantitative composition (Figure 3), but reveal no qualitative differences. (Some peaks in the acid profile for females are not labeled by capital letters although they were identified by GC-MS.) Some peaks (e.g., X, Y, and Z) are of almost equal height in both profiles, while others (e.g., G, H, and L) are considerably higher in the profile for males; that is, these components are present in higher concentration in male than in female urine.

On the basis of mass spectrometry, the main components of these profiles can be divided into three groups (Table 2): aliphatic monocarboxylic acids (peaks A–K, V, and Z), aromatic monocarboxylic acids (peaks N, R, and U), and aliphatic dicarboxylic acids (the other peaks labeled with letters).

Component G, identified as 3-methyl-2-oxo-valeric acid, is responsible for the meat-broth odor of the lipophilic acidic extracts, and the difference in height

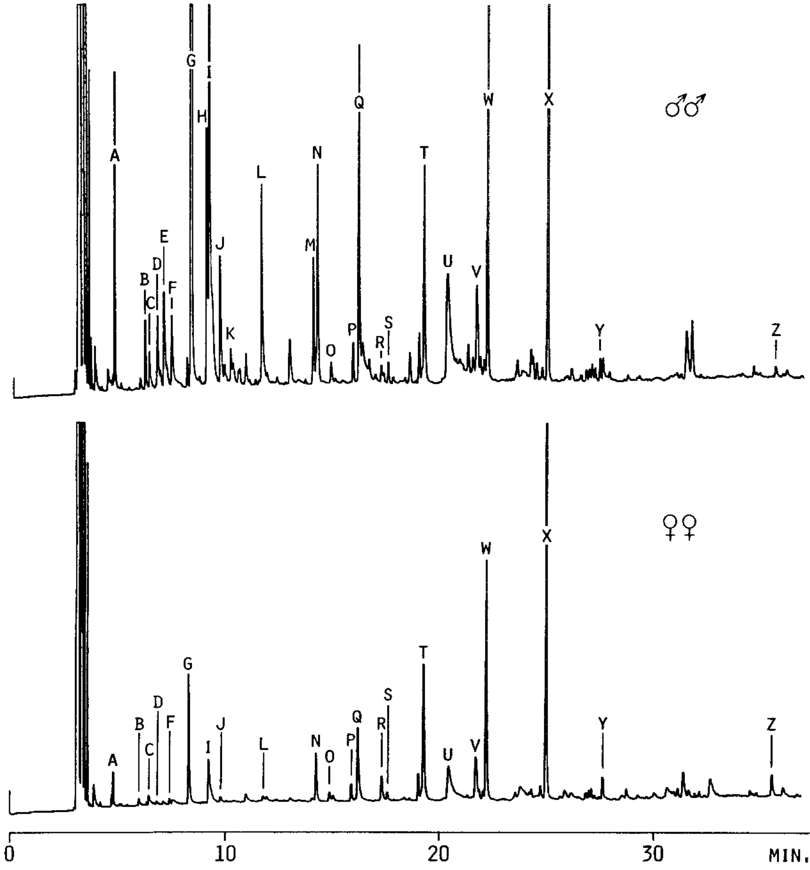

FIG. 3. Comparison of the carboxylic acid profiles obtained by gas chromatography of the urine of male and female *Tupaia belangeri*. The free carboxylic acids were methylated prior to analysis. The capital letters above the peaks label compounds analyzed by mass spectrometry; not all of the peaks so identified in the female profile are labeled. Analysis conditions for GC: 2.0-μl sample injected; split ratio 1:100; phase OV-101.

of this peak in the profiles corresponds to the difference in odor of the male and female extracts. (Male urine, depending on its concentration and the individual producing it, contains 40–250 μg of 3-methyl-2-oxo-valeric acid per milliliter; female urine on average contains only 1/20 as much.) Probably the lower concentration of this component in female urine is one reason for the relatively low chinning scores obtained with the acidic extracts from female urine.

Some of the identified carboxylic acids have been found also in the urine or glandular secretions of other mammals (Albone et al., 1974; Bakke and Figenschou, 1983; Berüter et al., 1974; Brundin et al., 1978; Holland et al.,

TABLE 2. CARBOXYLIC ACIDS[a] FROM PROFILES OF LIPOPHILIC ACID EXTRACTS FROM URINE OF *Tupaia belangeri*

Peak[b]	Mol. weight	Elemental formula	Chemical name	Identification criteria[c]
A	116	$C_6H_{12}O_2$	2-Methyl-butyric acid methyl ester (m.e.)	II

1983; Kaji and Saito, 1983; Lefebvre et al., 1982; Martin, 1973; Mueller-Schwarze et al., 1974; Spiteller and Spiteller, 1979; Suemitsu et al., 1968; Thiessen et al., 1974; Yasuhara and Fuwa, 1979). It is, nevertheless, possible that the particular mixture of carboxylic acids found in tree-shrew urine gives a profile characteristic for *Tupaia belangeri*. To test this hypothesis, we compared the urine profiles of our tree shrews with those of Mongolian gerbils. (To exclude the possibility of diet-related differences, the gerbils were given the same food as the tree shrews for several months before their urine was sampled.) As expected, the acid profiles of tree shrews and gerbils differ by the qualitative and quantitative composition of their components. For example, no keto acids were detectable, and phenylacetic acid was the main component of the acid profile of the gerbils (unpublished results).

Comparative GC-MS Analysis of Volatile Components of Lipophilic Basic Urine Extracts. The profiles of the basic urine extracts of the two sexes (Figure 4) differ primarily in the peaks H, J, K, M, N, O and U. The urine components corresponding to these peaks were identified by their mass spectra as alkylpyrazines (Table 3); none of them are traceable in the urine from females. These findings are consistent with the result of TLC analysis (R_f values and staining of reference substances).

To evaluate the odor properties of components H–U, the GC analysis was repeated without FID (flame extinguished) and the column effluent was evaluated organoleptically. About 10 min after injection of the sample (i.e., at the time when peak H appears in the chromatogram when the FID is in operation), the male-specific roasted odor can be detected in the column effluent, closely followed by the typical odors of 2,5-dimethylpyrazine, mentioned above in the context of TLC analysis. Hence peak H includes two different components, which are not separated from one another under these conditions of analysis. The two components can be separated by using another capillary (phase OV-101 instead of CW-20 M), which gives the profile shown in Figure 5. Here the roasted odor (peak W) does not appear until about 2 min after the pyrazine odor (peak H). The mass spectrum of peak W with the fragments *m/e*: 42 (100), 69 (65), 108 (54), 41 (40), 110 (27), 54 (14), 109 (11), 81 (8), 68 (7), 95 (5) closely resembles the spectrum of 5,6-dihydro-2,3-dimethylpyrazine (Flament and Stoll, 1967).

According to Bondarovich et al. (1967), certain dihydropyrazines have an intense roasted odor. Some of these are unstable and difficult to isolate; for example, when 3,6-dihydro-2,5-dimethylpyrazine is heated, it readily oxidizes to 2,5-dimethylpyrazine, giving the same mass spectrum as the latter (Wilen, 1970). Accordingly, the characteristic male odor substances could be dihydropyrazine compounds which, at least in part, are oxidized to the identified pyrazines during collection or analysis of the urine. This possibility will be tested in future studies.

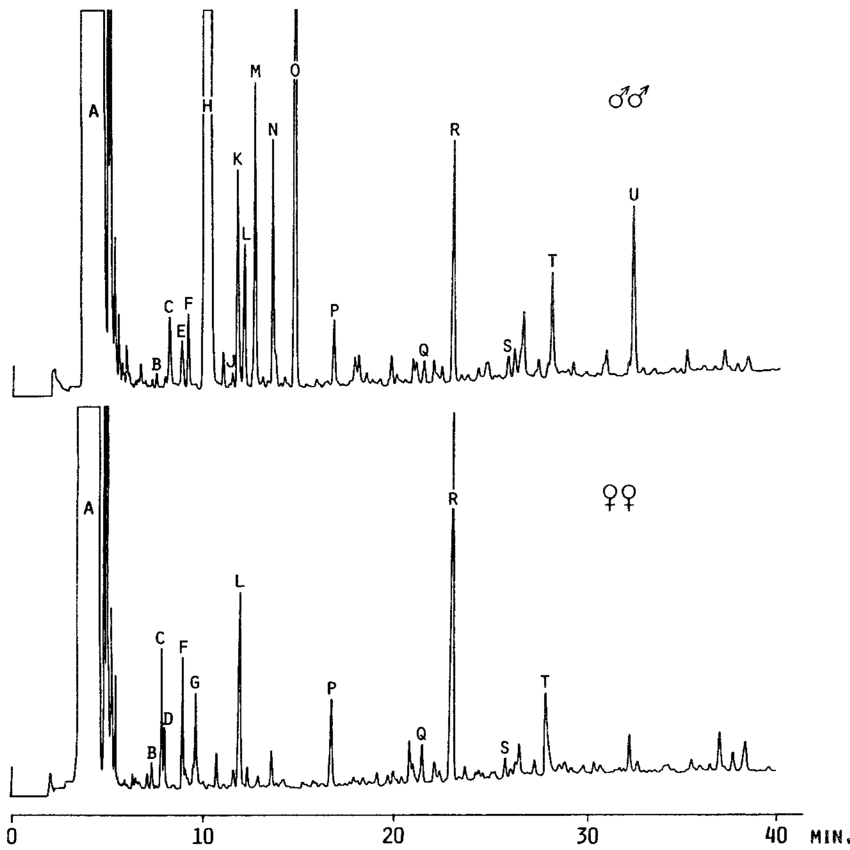

FIG. 4. Comparison of the profiles of the lipophilic basic extract from urine of male and female *Tupaia belangeri*. The capital letters over the peaks label compounds analyzed by mass spectrometry. Analysis conditions for GC: 3.0-μl sample injected; splitless injection; phase CW-20 M.

Regardless of whether the pryrazine compounds or their metabolites are the signal substances, they are male-specific urine components not previously found at this concentration (50–400 μg 2,5-dimethylpyrazine per milliliter urine from a male in the intermediate weight class) and in this combination in any other mammalian species (Table 4). Pyrazines are naturally produced by the metabolism of various bacteria (Hayward et al., 1977; Labows et al., 1980). In insects, they play a number of important roles; to list only a few examples; they serve as marking substances (Borg-Karlson and Tengö, 1980), alarm pheromones (Wheeler and Blum, 1973), trail pheromones (Evershed et al. 1981), and warning odor components (Rothschild et al., 1984).

[a] Peaks labeled as in the profiles of Figures 4 and 5.
[b] Identification criteria: I, mass spectra comparison; II, reference spectra comparison with authentic substances and their coinjection on three different capillaries; III, not identified.

Pyrazines have also been identified as volatile constituents of various foods (Goldman et al., 1967; van Praag et al., 1968; Mason et al., 1966; Buttery et al., 1971) and are used in the food industry as food flavorings (Maga and Sizer, 1973). They are naturally formed during the roasting process from amino acids and carbohydrates by a Maillard reaction (Koehler et. al., 1969; Rizzi, 1972).

Therefore the tree-shrew pyrazines could, in principle, also be artificially produced from urine components during heating (e.g., in the injector of the gas chromatograph). Evidence that they are not is provided by the following findings: (1) The male-specific roasted odor is detectable in the headspace of urine samples taken directly from the urinary bladder of fertile males. (2) The pres-

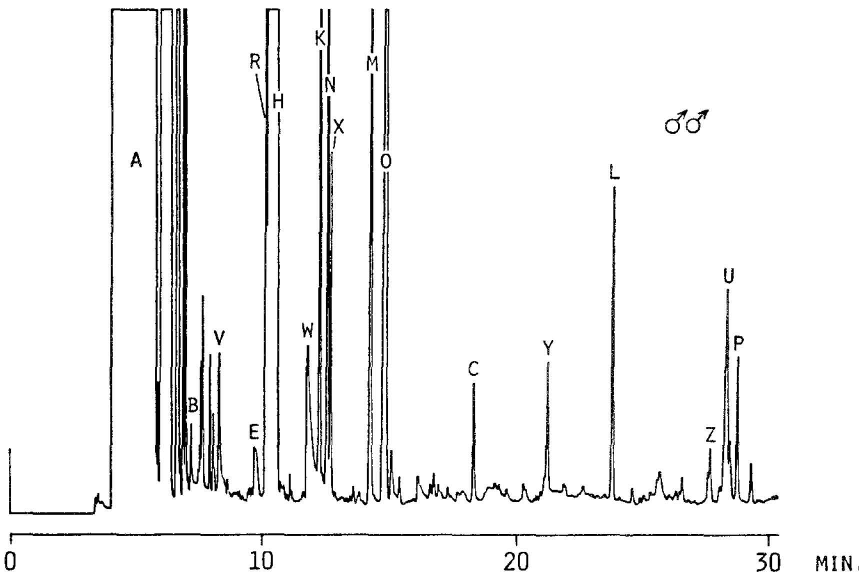

FIG. 5. Profile of the basic extract from urine of male *Tupaia belangeri*, obtained with a different GC capillary (phase OV-101). The capital letters above the peaks label compounds, the mass spectra of which are identical to those of the corresponding peaks in the profile of Figure 4. Peak W does not appear in the profile obtained with phase CW-20 M.

TABLE 4. OCCURRENCE OF TREE-SHREW URINARY SULFUR COMPOUNDS (B AND R) AND PYRAZINES (H–U)[a] IN SCENT PRODUCTS OF OTHER MAMMALS

Animal	Substrate or scent product	Sulfur compounds and pyrazines identified in tree-shrew urine										Reported by
		B	R	H	J	K	L	M	N	O	U	
Hamster	gland secretion	x										Singer et al., 1976

Pig	urine	x										Lunn and van de Vyver, 1977
Rabbit	feces/gland secretion	x				x						Goodrich et al., 1981
Red deer	gland secretion		x									Bakke and Figenschou, 1983

[a]The letters B–U refer to the components so labeled in the profiles of basic urine extract (Figures 4 and 5 and Table 4).

ence of dimethylpyrazines in the basic urine extract from males has been demonstrated by comparison with reference substances in thin-layer chromatography (Figure 2).

The possibility must be considered that male mammals fed on diets like that of the tree shrews might generally excrete pyrazines in the urine as species-unspecific, androgen-dependent metabolites. The comparison of tree-shrew urine with that of fertile male Mongolian gerbils fed for several months on tree-shrew diet contradicts such interpretation. Analysis of the gerbil urine samples revealed no pyrazine compounds; hence pyrazines are probably not a general androgen-dependent urine constituent.

Reaction of Animals to Synthetic Scent Substances. Bioassays with synthetic scent substances were carried out to establish whether odors in general elicit chinning and, if not, what properties (chemical composition, nature of the odor, distribution among mammals) characterize those substances that are effective (Table 5). All scent substances were tested as a 0.1% solution in diethyl ether. They are expected to be perceptible at this concentration, since it is above those measured in normal tree-shrew urine.

The first test series compared the effectiveness of a scent substance that is one of the characteristic components of tree-shrew urine (3-methylthiopropionic acid) with that of amyl acetate, which was not detected in tree-shrew urine. 3-Methylthiopropionic acid is particularly interesting because it is present in higher concentrations in male than in female urine (Figure 3, peak J). Amyl acetate was chosen because it is attractive to tree shrews, presumably because it smells like bananas. In the bioassay, 3-methylthiopropionic acid was overmarked by 19 of 20 animals (average chinning score = 3), but amyl acetate did not elicit chinning at all in half the animals tested. The results suggest that, in general, samples of scent substances typical of the species are overmarked more frequently, and by more animals, than samples of scent substances not produced by these animals ($P < 0.005$); the latter elicit little or no chinning.

In the second series, another odor component of higher concentration in male than in female urine was tested, 2-methylbutyric acid (Figure 3, peak A). In contrast to 3-methylthiopropionic acid, this substance occurs commonly in mammals. 2-Methylbutyric acid was compared with pyrazine-2-carboxylic acid, a pyrazine compound that might be contained in the urine of male tree shrews as a product of the oxidation of alkylpyrazines, although it has not yet been demonstrated in urine samples. Both carboxylic acids fail to elicit chinning in most animals tested. It follows that not all urine components present in different amounts in male and female urine elicit chinning when presented at the high concentration typical of male urine. It appears that for a urine component to be behaviorally effective in isolation, it must have greater species specificity than does 2-methylbutyric acid.

In the third test series, two different dilutions (0.1% and 0.01% in diethyl

TABLE 5. AVERAGE CHINNING SCORES[a] OF TREE SHREWS IN RESPONSE TO SYNTHETIC URINE COMPONENTS AND OTHER SYNTHETIC SCENT SUBSTANCES[b]

Test series	Synthetic scent substances	Median	[25–75%]	R_j[c]	T[d]	N
1	amyl acetate	0.5	0–1	116	7	15
	3-methylthiopropionic acid	3	1–5	164		
2	2-methylbutyric acid	0	0–2	101	15.5*	8
	pyrazine-2-carboxylic acid	0	0–1	109

	3-methyl-2-oxovaleric acid 0.01%	0	0–3	121		
4	2,3-dimethylpyrazine (A)	6	2–9	221	A:B = 4.5	17
	2,5-dimethylpyrazine (B)	0	0–2	161	B:C = 32*	13
	2,6-dimethylpyrazine (C)	2	0–3	155	C:A = 2	18
5	pyrazine-2-carboxylic acid m.e. (D)	4.5	1–10	178	D:E = 2.5	15
	2,3,5-trimethylpyrazine (E)	0.5	0–2	113	E:F = 17*	9
	3-ethyl-2,5-dimethylpyrazine (F)	0	0–2	110	F:D = 7.5	14

[a] Each value is the median of the individual chinning scores of all animals tested, 25–75 percentiles in brackets.
[b] Presented as 25-μl aliquots of a 0.1% solution in diethyl ether.
[c] R_j = sum of ranks in Friedman two-way analysis.
[d] Wilcoxon matched-pairs signed rank test; * = not significant, all other differences are significant.

ether) of the typical tree-shrew scent substance 3-methyl-2-oxovaleric acid were compared. The concentration of this component, which smells of meat broth, is about 20 times as high in male as in female urine. In the bioassay the more concentrated samples (0.1%) elicited chinning in 19 of 20 animals (average chinning score = 3), while samples containing only one tenth as much of the substance were nearly ineffective. This result corroborates the above inference that samples containing typical tree-shrew scent substances are overmarked only if the substances are present in the high concentration characteristic of males. Most animals fail to respond to samples with low concentrations, corresponding to those in urine from females.

In the fourth series, the main component of the basic extract from male urine (2,5-dimethylpyrazine) was tested against the isomers 2,3-dimethylpyrazine and 2,6-dimethylpyrazine. 2,6-Dimethylpyrazine is also present in the urine, but in much smaller amounts than 2,5-dimethylpyrazine (ca. 1 : 1000); 2,3-dimethylpyrazine is not detectable. Surprisingly, in the bioassay, 2,3-dimethylpyrazine elicits an intense chinning response in nearly all animals (average chinning score = 6), whereas 2,5-dimethylpyrazine does not stimulate most animals. The average chinning score for 2,6-dimethylpyrazine is 2, larger than that for 2,5-dimethylpyrazine, although the difference is not significant. These

results of bioassay seem inconsistent with those of GC-MS analysis. Perhaps the behavioral responses can be explained by the difference in odor of the dimethylpyrazines; to the human nose, 2,3-dimethylpyrazine has a slight roasted odor like that characteristic of male tree shrews. The other dimethylpyrazines do not smell like this. It may be that 2,3-dimethylpyrazine elicits such a strong chinning response because the tree shrews also detect the resemblance to the sex-specific male scent substance.

The fifth series was designed to test whether what we experience as a roasted odor is a characteristic property of the pyrazines that are overmarked by the tree shrews. Pyrazine-2-carboxylic acid methyl ester has such an odor and is not present in the profile of the basic urine extract; it was compared in the bioassay with 2,3,5-trimethylpyrazine and 3-ethyl-2,5-dimethylpyrazine, both of which are characteristic components in the GC profile of male urine (Figures 4 and 5, peaks K and M). To humans, 2,3,5-trimethylpyrazine has the typical pyrazine odor and 3-ethyl-2,5-dimethylpyrazine smells like chocolate. In the bioassay, pyrazine-2-carboxylic acid methyl ester elicits intense chinning in most animals (average chinning score = 4.5), whereas half of the animals give no response to the other two alkylpyrazines.

This result supports the hypothesis that a roasted odor could be the criterion for effectiveness of a pyrazine compound in eliciting chinning. This roasted odor, as mentioned above, also characterizes peak W of the GC profile and the TLC fraction II of basic extract of male urine, which elicits a stronger behavioral response than any of the other fractions.

The results of these bioassays of synthetic odor substances can be summarized as follows. When tested at the same concentration, the various urine components elicit marking at different rates (Friedman two-way analysis: $x_2^2 = 83$; $P < 0.001$). The marking responses of males and females to a given sample do not differ. Intense chinning is elicited by odor substances that distinguish tree-shrew urine from the urine of other mammals and which, to the human sense of smell, are representative of the typical odor of male tree shrews (certain pyrazine compounds, 3-methyl-2-oxovaleric acid, 3-methyl-thiopropionic acid). On the other hand, odor substances commonly produced by mammals in general (e.g., 2-methylbutyric acid) and substances not produced by tree shrews or other mammals (e.g., amyl acetate) elicit little or no chinning. Substances need not belong to different chemical classes to elicit differential responses; tree shrews also respond quite differently to isomers of a given compound—for example, to 2,3-dimethylpyrazine and 2,5-dimethylpyrazine.

Although various substances at a given concentration are differently effective, the efficacy of a given substance can also depend on its concentration, as the tests of 3-methyl-2-oxovaleric acid demonstrated. Therefore additional experiments are being undertaken to establish threshold curves for the relevant urine components.

These results suggest a number of problems for further study, but for the present it is clear that chinning can be elicited by several urine components, which are also excreted by other mammals. It seems likely that the most pronounced chinning is elicited by a mixture of these components that has a particular quantitative composition.

GENERAL DISCUSSION

Many mammals can distinguish the scent marks produced by conspecifics of different sexes and in different physiological states (Johnston, 1983). In principle, such a discrimination could be based either on single characteristic odor components or on particular mixtures of components. Single-component signals would require mammals to have at their disposal a great variety of scent substances; in the alternative case, a small set of scent substances could be combined to produce many different multicomponent mixtures. As few as 300 substances, combined in groups of 15 components each, would give more than 10^{27} qualitatively different mixtures. The number of different mixtures would be even greater if quantitative differences also counted. This number of odor mixtures would probably suffice to characterize all the mammals now in existence, with regard to species, sex, individual identity, and physiological state.

Of course, no matter how diverse the chemical information mammals can produce, it functions in communication only if an adequate system for detecting and processing the information is available. That the necessary abilities can exist has been demonstrated in training experiments on dogs (Neuhaus, 1956) and mongooses, *Herpestes auropunctatus* (Gorman, 1976), which have learned to distinguish mixtures of several odor components differing in both qualitative and quantitative composition.

The scent substances excreted in mammalian urine are sufficiently numerous to signal all the species and individual characteristics mentioned above (Albone, 1984). It has been shown for the laboratory mouse (Novotny et al., 1980) and the red fox (Jorgenson et al., 1978; Bailey et al., 1980) that various breeds, the two sexes, and different physiological states of an individual can all be characterized by volatile urine components. Similar results have been obtained by the analysis of cutaneous gland secretion (Brinck et al., 1983; Smith et al., 1985).

Male tree shrews also excrete urine that differs from that of females with respect to several volatile components. These components are responsible for the differences in chinning responses of the tree shrews to urine from conspecifics of different sexes. We conclude that these identified pyrazine compounds and monocarboxylic acids are in fact used by the animals to identify the sex of an individual. Male tree shrews can also distinguish their own urine from that

of other male conspecifics, inasmuch as they fail to overmark samples of their own urine (Stralendorff, 1986).

It seems plausible that the quantitative and the qualitative composition of the urine sample contributes to discrimination among individual urine samples, so that the relative proportions of the various components in the urine would be an important feature with regard to identification of the sample. In view of this, it may seem surprising that tree shrews will overmark such crude imitations of the male scent signal as the pure chemicals 3-methyl-2-oxovaleric acid or pyrazine-2-carboxylic acid methyl ester. However, the average chinning score in response to these single components is considerably lower than that to whole urine. Presumably the pyrazine compounds and the monocarboxylic acids are just barely sufficient for an approximate characterization of the male signal—sufficient to distinguish it from the scent signals of female conspecifics. That is to say, odor samples conveying only the general information "fertile male tree shrew" trigger the fixed behavioral response "chinning," whereas urine samples from an identifiable individual may elicit more flexible or graded responses.

But why is the scent signal of an individual overmarked by its conspecifics at all? At first glance, it appears that overmarking would obscure the scent left by the other animal. The sternal-gland secretion deposited during chinning is a complex lipid mixture produced by males at the rate of 10–20 mg/day (Stralendorff, 1977). By spreading it over alien scent marks encountered in his own living space, a male can either eliminate the strange odor or at least change the odor at that spot in such a way that the identity of the animal that produced the original scent mark is no longer discernible.

Unlike the males, female tree shrews produce very small amounts of sternal-gland secretion, less than 1 mg/day. Therefore it is unlikely that chinning by a female would eliminate or disguise the scent left by a male. By adding female-specific scent components, she could modify a male scent mark sufficiently to document her presence. But this goal is probably achievable with urine, so why overmark with sternal-gland secretion? One answer to this question could be provided by a form of behavior observed by chance during the bioassays. That is, if male urine is applied not to the front of a female's cage but rather to the floor, some females rub their entire ventral surface over the spot rather than just the sternal region. They may even roll over on the urine mark, so that the dorsal fur also comes into contact with it. To all appearances, they become sexually excited while doing this. Such behavior gives an observer the impression that the female intends less to eliminate the scent mark than to pick up the male scent in her own fur. Males have never been observed to respond in this way to male urine. We suppose, therefore, that overmarking has a different function for the two sexes.

Studies of animals in large enclosures (Holst, 1985) have shown that both

male and female tree shrews, when in familiar surroundings, vigorously attack strange conspecifics of the same sex. Before, during, and after such fights the males mark the boundaries of their territory or enclosure copiously with urine and sternal-gland secretion. These findings have been confirmed by field observations (Kawamichi and Kawamichi, 1979). In an enclosure, the male that emerges from the conflict as subordinate henceforth ceases marking behavior. Marking at the boundaries of the enclosure accounts for 80% of the marking behavior of male tree shrews. The remaining 20% is done within the remainder of the enclosure and occasionally on the sexual partner. That is, male tree shrews perform chinning predominantly in the territorial context. Assuming that overmarking makes a strange scent mark unrecognizable, this behavior could prevent the strange male from establishing familiarity with the area and thus reduce his chances of winning a new territory. When the occupant of a territory distributes his own scent marks, they could enhance his familiarity with the territory and increase his self-confidence in defending it. These functions of scent-marking have previously been postulated by other authors (Ewer, 1968; Adams, 1976).

Although females overmark the scent marks of strange males with their sternal-gland secretion, they do not attack such males in the territorial context. On the other hand, as mentioned above, a female will violently attack strange females but not overmark their urine marks.

The absolute marking frequency of females in large enclosures is only about $\frac{1}{10}$ that of males (Holst, 1985). Moreover, females do not preferentially mark the boundaries, but rather distribute their marks throughout the area. In doing so, presumably they are overmarking the urine marks of the territorial male. Paired females perform chinning on the head and back of the partner, moving their bodies over the male in the same way as over a male urine sample in the bioassay. This behavior is often observed during mating.

Evidently, then, chinning is done by females not in the context of territorial behavior but in the context of pair formation and pair bonding. If overmarking of male urine marks by a female has the effect of mixing female-specific components with the male scent, the result could be to indicate the presence of a female to strange males. When a female rubs male scent substances into her own fur, the effect could be that when the originator of the male scent later encounters the "perfumed" female she seems olfactorily familiar to him, which might facilitate pair formation or reinforce an existing bond.

If these hypotheses should prove correct, it would follow that identical scent substances (pyrazine compounds and monocarboxylic acids) encode an item of information (fertile male conspecific) that, as a scent signal, elicits a given, fixed behavioral response (chinning). Nevertheless, the "significance" of the scent signal would be different for the two sexes; for males it would mean "rival" and for females, "potential sexual partner."

Acknowledgments—I am grateful to Prof. Dr. D. Schneider, Prof. Dr. D. v. Holst, and Dr. M. Kaib for critically reading this paper and for their valuable advice. Thanks also to Dr. M.B. Thorson for translating the manuscript and to Mrs. W. Deinlein for her excellent technical assistance. The GC-MS analysis was carried out at the Center of GC-MS Analysis of the University of Bayreuth. Thanks to Mr. M. Glaessner for preparing the mass spectra. The work was supported by the Deutsche Forschungsgemeinschaft.

FACTORS INFLUENCING DISTRIBUTION OF *Diabrotica* SPP.[1] IN BLOSSOMS OF CULTIVATED *Cucurbita* SPP.

J.F. ANDERSEN[2] and R.L. METCALF

Department of Entomology, University of Illinois
Urbana, Illinois 61801

(Received August 16, 1985; accepted April 23, 1986)

Abstract—Cultivars representing three species of *Cucurbita* were examined for blossom preference by *Diabrotica* spp. *C. maxima* cultivars were found to be preferred by *D. undecimpunctata howardi* over those of *C. pepo* and *C. moschata*. *D. virgifera virgifera* preferred *C. maxima* and the "Connecticut Field" cultivar of *C. pepo*. *C. moschata* and other cultivars of *C. pepo* were not preferred. Cultivars were examined for differences in floral volatile release, blossom cucurbitacin content, and pollen content of male blossoms. *C. maxima* male blossoms released a larger quantity of volatiles than *C. pepo* or *C. moschata*. Also, only *C. maxima* male blossoms contained cucurbitacins. Cultivars of *C. moschata* contained the largest quantities of pollen, but all three species contained relatively large quantities. The data indicate a correspondence of *D. u. howardi* distribution in the field with high volatile release rates and high cucurbitacin levels that are found in *C. maxima* blossoms. *D. v. virgifera* distribution appears to be somewhat independent of these factors since this species was abundant in blossoms of a *C. pepo* cultivar as well as cultivars of *C. maxima*.

Key Words—*Cucurbita, Diabrotica undecimpunctata howardi, Diabrotica virgifera virgifera,* floral volatiles, cucurbitacins, Cucurbitaceae, Coleoptera, Chrysomelidae, host selection.

INTRODUCTION

Previous studies have shown that *Diabrotica* spp. prefer the blossoms of certain species and cultivars of *Cucurbita* (Fronk and Slater, 1956; Bach, 1977; Fisher et al., 1984). Fronk and Slater (1956) found that the northern corn rootworm

[1] Coleoptera: Chyrsomelidae.
[2] Present Address: Department of Entomology, University of Wisconsin, Madison, Wisconsin 53706.

0098-0331/87/0400-0681$05.00/0 © 1987 Plenum Publishing Corporation

(*Diabrotica barberi* Smith and Lawrence), the southern corn rootworm (*D. undecimpunctata howardi* Barber), and the related striped cucumber beetle [*Acalymma vittatum* (F.)] prefer the blossoms of *Cucurbita maxima* Duchesne over those of *C. pepo* L. Bach (1977) reported that the "Buttercup" cultivar of *C. moschata* Poir. were preferred by *A. vittatum*. In addition, the "Hubbard" cultivar of *C. maxima* and the "Pumpkin" cultivar of *C. moschata* were preferred by the western corn rootworm (*D. virgifera virgifera* LeConte). Recently, Fisher et al. (1984) found that *D. v. virgifera, D. barberi,* and *D. u. howardi* all preferred the cultivars of *C. maxima* over those of other cultivated species. *D. v. virgifera* differed from the other beetle species in that substantial numbers were also found in certain *C. pepo* cultivars.

The blossom characteristics responsible for preference are not known. It has been demonstrated, however, that the blossoms of *C. maxima* cultivars release indole, an attractant for *D. v. virgifera* adults (Andersen and Metcalf, 1986). Other examples of *Diabrotica* attraction to compounds commonly found in floral odors have recently been reported (Ladd, 1984; Lampman, personal communication). This suggests that differences in odor may be important in determining preference.

Gustatory stimulants may also play a role in blossom selection. Cucurbitacins, a group of oxygenated triterpenoids, occur in the leaves and fruits of wild *Cucurbita* species. These act as nonvolatile feeding stimulants, and have proven to be of importance in host selection by *Diabrotica* spp. (Metcalf et al., 1980). Cucurbitacins do not occur in the fruits and true leaves of cultivated *Cucurbita* (Metcalf et al., 1980). However, their possible occurrence in blossoms has not been investigated. In this report, nutritional and secondary chemical characteristics of blossoms from cultivated *Cucurbita* are examined in relation to beetle preference.

METHODS AND MATERIALS

Field Preference Measurements. Eight cultivars representing *C. moschata, C. pepo,* and *C. maxima* were planted in three rows. The cultivars were arranged in small plots containing six plants each, and the position of each cultivar within a row was randomly assigned. Each row contained one plot of each cultivar, and the distance between the plots was 3 m, preventing any overlap of plants from different plots. Due to severe drought conditions in the summer of 1983, an entire plot (cultivar) was lost in the center row. Consequently, samples were taken from only the two outside rows.

The sampling procedure consisted of selecting two blossoms from each cultivar in each of the outside rows. A small plastic bag was placed over each blossom. The bag was closed, and placed on ice to limit the activity of the insects. In the laboratory, the adults of *Diabrotica* spp. in each bag were

anesthetized with carbon dioxide, identified to species, and counted. Since male blossoms are far more abundant than females, only male blossoms were selected for sampling. Five collections were made during the months of August and September 1983, and these were carried out between the hours of 9:00 and 10:30 AM.

For statistical analysis, the two blossom counts for each row on a given date were averaged, and each mean was treated as a replicate. Data were analyzed by a two-factor ANOVA to test the influence of sampling date and cultivar on beetle distribution. For paired comparisons of means, data were analyzed by one-way ANOVA coupled with the Student-Newman-Keuls test for multiple comparisons. All tests were performed with the Statistical Package for the Social Sciences (SPSS; Nie et al., 1975).

Analysis of Cucurbita *Floral Volatiles.* Floral volatiles from field collected blossoms were obtained by trapping on Porapak-Q using a tubular glass collection chamber described previously (Andersen and Metcalf, 1986). An airstream (2 liters/min) was passed through a column of activated charcoal, through the chamber containing the blossoms, and finally through a short column containing 5 g of Porapak-Q. Volatiles were collected from 20 cut male blossoms in a single batch. The flowers were obtained from field-grown plants on the morning of anthesis and transported to the laboratory on ice. All blossom collections were made in late July and early August, 1983. During this period, infestations of *Diabrotica* spp. were relatively light, so damage to blossoms was minimal.

Volatiles were collected for a period of 4 hr, at the end of which the Porapak-Q was removed from the column and extracted for several hours with diethyl ether in a Soxhlet apparatus. The dilute extract was dried over anhydrous sodium sulfate and concentrated to a volume of 15 ml by slowly removing the ether in a rotary evaporator. Final concentration to 0.5 ml was accomplished under a gentle stream of nitrogen.

For more detailed studies of the qualitative and quantitative composition of floral odors, plants were grown in a greenhouse in large pots. Natural lighting was supplemented by artificial fluorescent and incandescent lighting (16 hr–8 hr light–dark). Applications of resmethrin were made periodically to suppress whiteflies, and no fertilization was provided. Volatiles were obtained from groups of 3–14 blossoms collected from six different plants of each cultivar. The procedure was repeated four times on four separate days. The collection chamber was a 3000-ml three-neck flask having two 24/40 joints and one 45/50 joint. Nitrogen (1.0 liter/min) was filtered through activated charcoal and entered the flask through one of the 24/40 jointed necks. Attached to the second 24/40 neck was a short column containing 2.5 g Tenax TA (60/80). At the end of a 5-hr collection period, the column containing the Tenax TA was backflushed with 150 ml anhydrous diethyl ether. The extract was then concentrated to a volume of ca. 12 ml by slow removal of the solvent through a Vigreux

column. Final concentration to 200–300 μl was performed under a gentle stream of nitrogen.

Gas–liquid chromatography (GLC) of volatile samples from field collected blossoms was performed on a Varian 2700 instrument equipped with a hydrogen flame ionization detector (FID) and a 3.7-m × 2-mm ID glass column packed with 3% OV-17 on Gas Chrom Q (100/120). The temperature was programmed from 110 to 180° C at 4°/min with an initial hold of min at 110° C and a final hold of 15 min at 180°C. Quantitative work was performed using a Varian 3700 instrument equipped with an FID and a 25-m × 0.32-mm fused silica WCOT column having a bonded phase of DB-1701. The temperature was programmed from 40 to 200°C at 6°/min with a 5-min hold at 40°C and a 15-min hold at 200°C.

Electron impact gas chromatography–mass spectrometry (GC-MS) (70 eV) was performed on Hewlett Packard 5985, Finnigan 1020, and Finnigan TSQ quadrupole instruments equipped with fused silica capillary columns of DB-1 or DB-1701 (J&W Scientific). When standards were available, compound identities were verified by retention comparisons with authentic standards on the DB-1701 column. Retention indices were calculated using the homologous *n*-alkane series (Van den Dool and Kratz, 1963).

To quantify individual components, areas of sample capillary GLC peaks were measured by electronic integration and compared to values obtained with known quantities of authentic standards.

Indole was detected in volatile samples from field- and greenhouse-collected blossoms by TLC on silica gel (0.1- and 0.25-mm plates) using a mobile phase of chloroform–benzene–ethanol (83 : 8.5 : 1; v/v/v). The developed plates were sprayed with Ehrlich's reagent (*p*-dimethylaminobenzaldehyde) which reacts to form a pink spot (Durkee and Sirois, 1964). Quantification of indole from field-collected samples was made by HPLC. A silica gel radial compression-type column (Waters Assoc.) was employed with a mobile phase of 10% tetrahydrofuran in hexane (2.0 ml/min) (Andersen and Metcalf, 1986). The eluent was monitored at 254 nm using a UV absorbance detector, and the retention time of indole was determined by comparison with an authentic standard. Quantification of indole was made by electronic integration of sample and standard peak areas.

Cucurbitacin Analysis. Blossoms from all cultivars utilized in field measurements of beetle preference were subjected to analysis for cucurbitacins. Ten to fifteen male blossoms were collected from each cultivar on single dates in August and September, 1983, and returned to the laboratory on ice. The blossoms (without stems) were homogenized in a blender with 50 ml distilled water. The homogenate was added to a flask with 250 ml chloroform and stirred vigorously for 2 hr. The mixture was then filtered through cheesecloth into a separatory funnel. The chloroform layer was collected, dried over anhydrous so-

dium sulfate, and rotary evaporated to dryness. The residue was dissolved in chloroform at a concentration of 10.0 g plant material (wet weight)/ml.

A bioassay developed by Metcalf et al. (1980) was used for the detection of cucurbitacins. Twenty microliters of each extract was applied to 0.1-mm silica gel TLC plates which were developed in a mobile phase of chloroform–methanol (95:5; v/v). Cucurbitacins were detected by placing the developed plate in a cage with 100 adult *D. u. howardi* and a source of 5% sucrose solution. Over a period of several days, the insects ingested silica gel from the area of the plate containing cucurbitacins.

Separate extraction of the corolla, nectary, and anther–filament region from five male blossoms of "Pink Banana Jumbo" showed cucurbitacins to be localized in the anther–filament structure of the male blossom. This greatly facilitated isolation for quantitative studies, since the heavily pigmented corolla could be discarded prior to extraction.

The isolation of blossom cucurbitacins was accomplished by preparative TLC of anther–filament extracts on 0.25-mm silica gel plates containing fluorescent indicator. These were developed in diethyl ether–hexane–methanol (70:30:5; Metcalf et al., 1980). Bands were located by observing the quenching of fluorecence under short wave UV light and subsequently were removed from the plate. The bands were extracted with chloroform, and a small portion was chromatographed along with authentic cucurbitacin standards using the same solvent system as above. Cucurbitacins were identified by comparison of R_f values with authentic standards using the beetle feeding assay for detection.

Small quantities of interfering pigments were present after the first preparative chromatography. Consequently, the material was rechromatographed in the same solvent system, and again the UV absorbing bands were recovered. At this point, cucurbitacin levels could be quantified by measuring percent transmittance at 210 nm in absolute methanol with a Hitachi-Perkin Elmer 124 double-beam spectrophotometer. The values obtained were compared with those from a curve generated with authentic standards.

Individual variation in cucurbitacin levels was measured in greenhouse-grown plants (grown under the conditions described above) by the analysis of anther–filament extracts from single male blossoms. Immediately after picking, the anther–filament structures were dissected from both mature (postanthesis) blossoms and immature buds ($>$ 1 day preanthesis). They were then placed in a 150-ml flask with 1 ml methanol and chopped with a spatula. Fifty milliliters of chloroform were added and the mixture was shaken for 4 hr. After filtration through anhydrous sodium sulfate, the extract was evaporated to dryness and taken up in 0.25 ml chloroform.

Analyses were made by TLC on 0.25-mm silica gel plates (ether–hexane–methanol; 70:30:5) and by HPLC with a C_{18} column (Whatman; methanol–water; 60:40; 1 ml/min). The HPLC eluent was monitored at 230 nm with a

UV detector. Compound identity was verified by comparison of HPLC retention time and TLC R_f value with authentic standards. Cucurbitacins were visualized on TLC plates by observing the quenching of fluorescence under short wave UV radiation. Quantification was accomplished by comparison of HPLC peak areas with a curve generated from authentic standards.

Quantification of Pollen Weights. On the evening prior to anthesis, four to five male blossoms on field-grown plants were enclosed in plastic pollination bags to exclude insects. The following morning, the blossoms were harvested and returned to the laboratory. The corollas were removed, and the pollen was rinsed with distilled water from the anther and nectary areas onto a single pre-weighed piece of filter paper. The samples were air-dried for 24 hr, at which time the weight was determined.

Blossoms from greenhouse-grown plants (grown under the conditions described above) were treated in the same manner with two exceptions: The blossoms were not shielded by pollination bags, since no pollen feeding insects were present, and the pollen contents of individual blossoms were kept separate and weighed individually.

RESULTS

Field Preference Measurements. Two *Diabrotica* species. *D. virgifera virgifera* and *D. undecimpunctata howardi*, were common in the study area. *D. v. virgifera* was more abundant on the early sampling dates, while *D. u. howardi* was the most abundant species later (Figure 1). Results of a two-factor analysis of variance revealed a significant preference by *D. v virgifera* for certain cultivars ($P < 0.001$). No significant interaction between cultivar and sampling date effects was seen ($P > 0.05$), indicating that preference was consistent throughout the growing season (Figure 1). Comparisons of *D. v. virgifera* counts combined over the entire sampling period showed that three cultivars, "Blue Hubbard," "Pink Banana Jumbo," and "Connecticut Field," were significantly preferred over all others (Table 1). The former two are *C. maxima* cultivars, and the latter is a *C. pepo* cultivar.

D. u. howardi also showed significant preference for certain cultivars ($P < 0.001$), but unlike *D. v. virgifera*, a significant interaction between cultivar and sampling date was seen ($P < 0.001$). In Figure 1, it is apparent that the numbers of *D. u. howardi* found in *C. maxima* blossoms increased dramatically over the course of the sampling period, while the numbers found in *C. pepo* and *C. moschata* blossoms were similarly low on all sampling dates. Data given in Table 1 demonstrate that both cultivars of *C. maxima* were strongly preferred by this species.

Analysis of Cucurbita *Floral Volatiles.* GLC was performed to compare the volatile compositions or "profiles" from field-collected blossoms of each

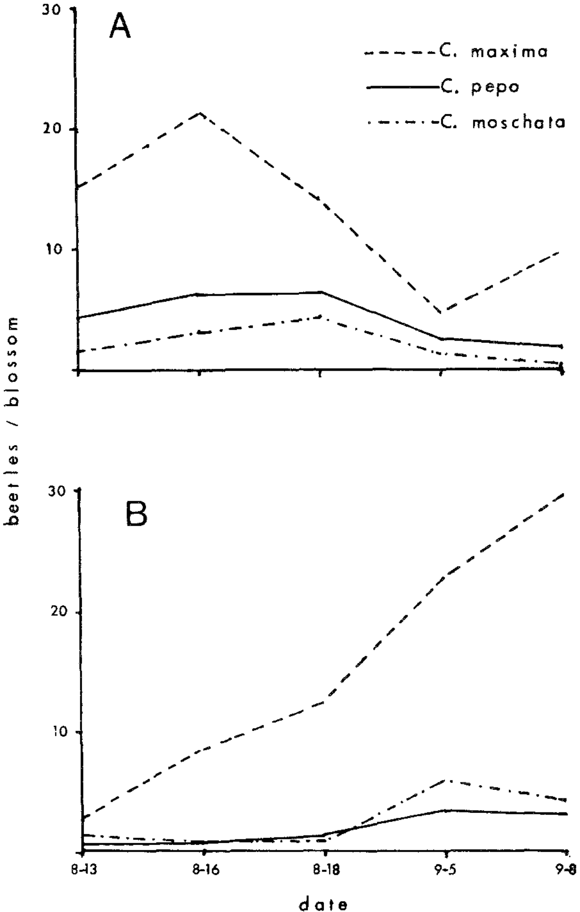

FIG. 1. Seasonal distribution of *D. v. virgifera* (A) and *D. u. howardi* (B) in blossoms of three species of cultivated *Cucurbita* in 1983. *C. maxima* = 2 cultivars; *C. pepo* = 4 cultivars (including *C. pepo* × *C. texana* hybrid); *C. moschata* = 2 cultivars.

Cucurbita species sampled in field preference measurements. Injection quantities representing equal periods of volatile collection were analyzed to detect differences in the qualitative or quantitative composition of the floral volatile mixtures.

It was obvious from these analyses that *C. maxima* cultivars produced a much larger quantity of an apparently more complex mixture. The differences are illustrated in Figure 2 by a comparison of gas chromatograms of "Blue Hubbard" (*C. maxima*), "Connecticut Field" (*C. pepo*), and "Waltham Butternut" (*C. moschata*), representing equal durations of volatile collection.

TABLE 1. MEAN DISTRIBUTIONS (± SE) OF *D. v. virgifera* AND *D. u. howardi* IN BLOSSOMS OF CULTIVATED *Cucurbita* SPP. ON FIVE SAMPLING DATES IN AUGUST AND SEPTEMBER, 1983

Species and cultivar	*D. v. virgifera*[a]	*D. u. howardi*
C. maxima		
"Blue Hubbard"	14.2 ± 2.7a	17.3 ± 2.6
"Pink Banana Jumbo"	11.5 ± 1.8a	13.4 ± 3.1
C. pepo		
"Connecticut Field"	9.0 ± 1.5a	1.9 ± 0.6
"Early White Bush Scallop"	2.7 ± 0.6b	1.6 ± 0.3
"Yellow Summer Crookneck"	3.0 ± 0.5b	2.2 ± 0.4
C. pepo × *C. texana*	3.9 ± 0.9b	1.8 ± 0.5
C. moschata		
"Dickinson Field"	3.4 ± 0.8b	2.7 ± 0.9
"Waltham Butternut"	1.7 ± 0.3b	2.9 ± 0.5

[a]Means followed by different letters are significantly different at the 5% level when analyzed by ANOVA and the Student-Newman-Keuls test for multiple comparisons.

The qualitative composition of *C. maxima* floral volatiles was examined by GC-MS. Samples of the volatile material from field-collected blossoms of "Blue Hubbard" and greenhouse-grown "True Hubbard" were compared. "True Hubbard" was not included in the field-sampling experiment described above, but was found to be highly preferred over "Waltham Butternut" by *D. v. virgifera* and *D. u. howardi* in small field plantings during 1985 (Andersen, unpublished observation).

Volatiles from both cultivars were qualitatively and quantitatively similar, despite differences in growth conditions and sample preparation. The predominant components of both were simple aromatics and sesquiterpene hydrocarbons (Table 2). In separate studies with floral steam distillates (Andersen, unpublished), the diversity of sesquiterpenoids seen in headspace samples was not encountered. These compounds are apparently somewhat labile, and degradation occurs even under the relatively mild conditions of reduced pressure distillation.

The volatile mixture released by greenhouse-grown "Connecticut Field" male blossoms was compared chromatographically to the *C. maxima* volatile mixtures and was found to be similar in composition (Table 2). As with the field-collected samples, however, much smaller quantities of volatile material were released, and consequently fewer components were detected.

In greenhouse studies with "True Hubbard" and "Connecticut Field,"

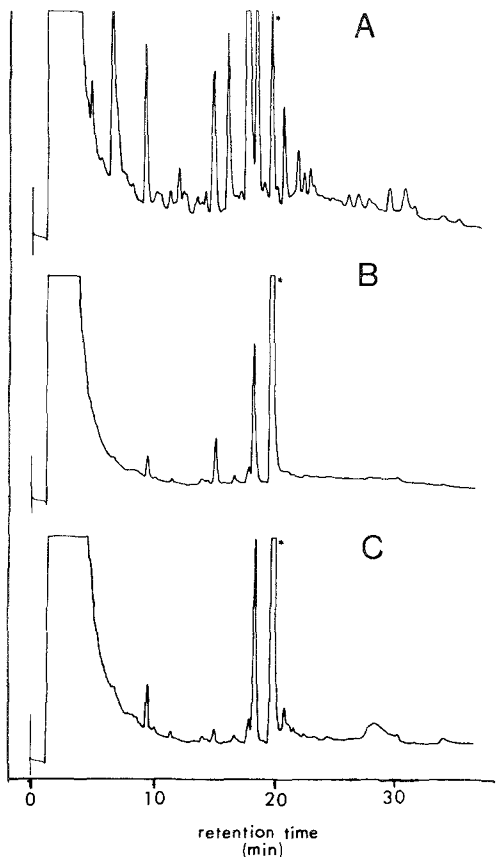

FIG. 2. Gas chromatograms of "Blue Hubbard" (A), "Connecticut Field" (B), and "Waltham Butternut" (C) on 3% OV-17. Each chromatogram represents the equivalent release of one blossom in 0.2 hr. Asterisk indicates butylated hydroxytoluene added as a preservative.

the relative quantities of odor components were not perfectly consistent from sample to sample. With both cultivars, there appeared to be a general increase in the quantities of sesquiterpene hydrocarbons released with time. This variation is shown by the ranges of relative composition given in Table 2. "Connecticut Field" was sampled four times over a period of seven days and "True Hubbard" was sampled four times on four consecutive days. Although these changes were significant, the levels of volatiles released by "Connecticut Field" never approached those exhibited by "True Hubbard."

As an absolute measure of the differences between cultivars, the release rates of the major components from greenhouse-grown plants of "True Hub-

bard'' and ''Connecticut Field'' were determined by GLC. Peak areas from samples were compared to those of authentic standards for each identified compound. Since none of the sesquiterpene hydrocarbons were fully characterized, release rates were estimated by comparison of peak area with an authentic standard of β-caryophyllene. In these tests, ''True Hubbard'' was found to release far more volatile material than ''Connecticut Field.'' With ''True Hubbard,'' four components occurred in measurable quantities in all samples. These made up 90–95% of the total mixture and showed a combined mean release rate of 11.8 μg/blossom/hr (Table 3). ''Connecticut Field'' released only one consistently measurable component, *p*-dimethoxybenzene, which comprised 72–100% of the volatile mixture. The average release rate of this compound was 2.4 μg/blossom/hr (Table 3).

Indole has previously been isolated from the floral volatiles of *C. maxima* and found to be attractive to *D. v. virgifera* when tested in field sticky traps (Andersen and Metcalf, 1986). Qualitative measurements by TLC with detection by Ehrlich's reagent showed that this compound was present in field-collected blossoms of all three species tested for beetle preference. Quantification of indole in headspace samples of blossoms taken from the field showed that more indole was released by cultivars of *C. maxima* than by *C. pepo* or *C. moschata* cultivars (Table 4). The ''Connecticut Field'' and ''Early White Bush Scallop'' cultivars of *C. pepo* did not release levels of indole detectable by TLC or HPLC.

Indole was also detected in greenhouse-grown blossoms of ''True Hubbard'' and ''Connecticut Field'' by TLC and capillary GLC (Table 2). However, the levels released were very small (<50 ng/blossom/hr) in both cases

TABLE 3. RELEASE RATES OF MAJOR VOLATILE COMPONENTS FROM BLOSSOMS OF ''TRUE HUBBARD'' AND ''CONNECTICUT FIELD''[a]

	Release rate (μg/blossom/hr ± SE)	
	''True Hubbard''	''Connecticut Field''

and did not differ greatly between cultivars. Note the difference between the relative quantities of indole contained in head space samples of field-collected "Blue Hubbard" and greenhouse-grown "True Hubbard" (Table 2). Other studies with floral steam distillates have shown these two cultivars to contain similar levels of indole (Andersen, unpublished data).

Cucurbitacin Analysis. Chloroform extraction of single batches of whole field-collected male blossoms followed by the TLC feeding bioassay indicated that cucurbitacins were present only in the two *C. maxima* cultivars. Both "Pink Banana Jumbo" and "Blue Hubbard" portions of the plate showed two obvious feeding spots, while no traces of feeding were apparent on areas of the plate containing other extracts.

Dissection experiments with 13 blossoms showed that cucurbitacins were contained only in the anther–filament structure of male *C. maxima* blossoms. These were identified as cucurbitacins *B* and *D* by comparison of TLC R_f values with those of authentic standards. In both cultivars, cucurbitacin B occurred in considerably larger quantities than D (Table 5).

In greenhouse studies, cucurbitacin levels of individual blossoms of "Connecticut Field," "Waltham Butternut," and "True Hubbard" were compared. Again, only the *C. maxima* cultivar "True Hubbard" was found to contain cucurbitacins, and these were identified as cucurbitacins B and D by TLC. Quantification was accomplished by HPLC with UV detection. The molar absorptivities of cucurbitacins B and D at 230 nm are reported to be 10,500 and

TABLE 5. CURCURBITACIN LEVELS IN ANTHER–FILAMENT STRUCTURES FROM FIELD-GROWN AND GREENHOUSE-GROWN *C. maxima* MALE BLOSSOMS (μg/blossom)[a]

	Cucurbitacin

[c]Trace quantity present.

10,000 respectively (Lavie and Glotter, 1971). This allowed relatively accurate quantification of cucurbitacin B using a cucurbitacin D standard which was available in large quantities.

As expected from the results with field-collected material, five mature blossoms from four plants of "Waltham Butternut" and eight blossoms from four plants of "Connecticut Field" contained no detectable cucurbitacins. Also in agreement with field results was the fact that 12 blossoms from 12 plants of "True Hubbard" showed detectable levels of cucurbitacins B and D (Table 5).

In single blossom extracts, levels of cucurbaticin D were too low to quantify, and levels of cucurbitacin B were quite variable (Table 5). The mean cucurbitacin B content, however, was similar to that seen for the "Blue Hubbard" cultivar in the field (Table 5).

Buds from the same 12 "True Hubbard" plants were extracted individually and cucurbitacins B and D were detected in 11 of 12 individuals. Cucurbitacin B was again dominant, and the levels were somewhat lower than in mature blossoms (Table 5). Bud levels of cucurbitacin B were also variable, but showed a strong correlation with the levels found in mature blossoms from the same plants (Figure 3).

Quantification of Pollen Weights. In the field, cultivars of *C. moschata* contained the largest quantities of pollen (mean of 25.8 mg/blossom, Table 6), while *C. pepo* including (*C. pepo* × *C. texana* hybrid) contained the least (mean of 15.5 mg/blossom; Table 6). *C. maxima* was intermediate in pollen content, with a mean value of 19.5 mg/blossom (Table 6).

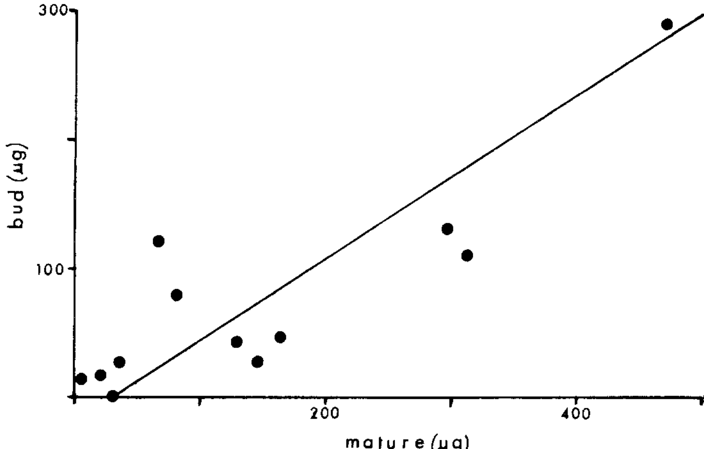

FIG. 3. Relationship of cucurbitacin B levels in postanthesis blossoms of "True Hubbard" (mature) with levels found in immature buds from the same plants ($Y = 0.64x - 20.92$, $r = 0.85$).

TABLE 6. POLLEN CONTENTS OF FIELD-COLLECTED (SINGLE LUMPED MEASUREMENT) AND GREENHOUSE-GROWN MALE BLOSSOMS OF CULTIVATED *Cucurbita* SPP (mg/blossom).

Species and cultivar	Pollen: Field	Pollen: Greenhouse[a]
C. maxima		
"Blue Hubbard"	18.1	—
"Pink Banana Jumbo"	20.9	—
"True Hubbard"	—	21.6 ± 1.9b
C. pepo		
"Connecticut Field"	15.7	21.1 ± 1.8b
"Early White Bush Scallop"	8.9	23.5 ± 1.5b
"Yellow Summer Crookneck"	16.4	18.4 ± 0.8b
C. pepo × *C. texana*	20.9	—
C. moschata		
"Waltham Butternut"	27.1	30.6 ± 1.6a
"Dickinson Field"	24.5	—

[a] Means (± SE) followed by a different letter are significantly different at the 5% level using Student-Newman-Keuls test for multiple comparisons.

In greenhouse measurements, the *C. moschata* cultivar "Waltham Butternut" produced significantly more pollen than *C. pepo* or *C. maxima* cultivars (Table 6). The only large discrepancy between field and greenhouse data involved the *C. pepo* cultivar "Early White Bush Scallop," which produced a very small quantity of pollen in the field. Low pollen weights were also observed on occasion in the greenhouse. For example, the range of values obtained for "Connecticut Field" was 8.9–29.1 mg/blossom. The reason for this occasional drop in pollen production is not known.

DISCUSSION

The species of *Diabrotica* sampled in the field show clear preference for certain cultivars of *Cucurbita* spp. (Table 1). *D. u. howardi* was found almost exclusively in the blossoms of *C. maxima* cultivars, while *D. v. virgifera* preferred the cultivars of *C. maxima* as well as a single cultivar of *C. pepo* ("Connecticut Field"). These data are similar to those of Fisher et al. (1984) who found that *D. u. howardi* and *D. barberi* showed strong preference for *C. maxima* cultivars. *D. v. virgifera* also significantly preferred *C. maxima* over all *C. pepo, C. moschata*, and *C. mixta* cultivars, but blossoms of certain *C. pepo* cultivars did contain significantly more *D. v. virgifera* than *C. moschata* and *C. mixta* (Fisher et al., 1984). In the study of Fisher et al. (1984), *D. v. virgifera* and *D. barberi* were the dominant species numerically. *D. v. virgifera* occurred in much larger numbers than *D. barberi* in blossoms of certain *C. pepo* cultivars, but the two beetle species occurred in similar numbers in *C. maxima* blossoms (Fisher et al., 1984). It appears, then, that *D. barberi* and *D. u. howardi* are similar in their host preferences, each strongly favoring *C. maxima*. *D. v. virgifera*, on the other hand, appears to find a broader range of cultivars acceptable.

Reasons for the strong displays of preference observed here must be related either to higher availability of a food resource in preferred blossoms or to the quality and quantity of sensory stimuli associated with preferred blossoms. An important food resource for *Diabrotica* adults is pollen, which can be obtained from a variety of host plants (Ludwig and Hill, 1975). The quantity of pollen found in field and greenhouse studies did not vary in any discernible way with preference (Table 6). In fact, the least preferred *Cucurbita* species (*C. moschata*) contained the largest quantities of pollen. This suggests that pollen content is not a major factor in the discrimination of preferred and nonpreferred blossoms by *D. v. virgifera* or *D. u. howardi*.

Sensory stimuli involved with host selection can act on the olfactory, gustatory, and visual senses. The importance of olfactory stimuli in host selection by *Diabrotica* spp. has been established indirectly through field trapping ex-

periments. Andersen and Metcalf (1986) isolated indole from headspace samples from *C. maxima* blossoms and found it to be a potent attractant for *D. v. virgifera* and the related *Acalymma vittatum* (F.). Morgan and Crumb (1928) found that cinnamaldehyde and cinnamyl alcohol attracted *D. u. howardi* to field traps. (*E*)-Cinnamyl alcohol was found as a component of *C. maxima* headspace samples, and both of these compounds occurred in steam distillates of *C. maxima* blossoms (Andersen, unpublished data). In field trapping tests, Lampman (personal communication) has found several simple aromatic compounds, including the floral components benzyl alcohol and 2-phenylethanol, to be attractive to *D. u. howardi*. Ladd (1984) has found eugenol, isoeugenol, and 2-methoxy-4-propylphenol to be potent attractants of *D. barberi*. Interestingly, none of the latter were found in *Cucurbita* headspace samples.

In both the field and greenhouse, cultivars of *C. maxima* were found to release larger quantities of volatile material than other cultivated species, even when accounting for variation in the release rates of single components (e.g., indole). This observation corresponds well with preference data for *D. u. howardi* given here, and with published data for *D. barberi* (Fisher et al., 1984). It is impossible at this time, however, to determine the effect on beetle behavior of any single volatile component or group of components. The variety of compounds found to be active in the behavioral studies listed above suggests that multiple floral components may be acting in attraction to blossoms. The efficacy of multicomponent plant-derived attractants has been demonstrated for other phytophagous species (Fein et al., 1982) and, recently, synergistic effects have been observed with three-component attractants of *D. u. howardi* (Metcalf and Lampman, unpublished data). More study of the effects on beetle behavior of single components, multiple components, and variation in multiple-component mixtures needs to be performed in order to determine the nature of the volatile stimulus from *Cucurbita* blossoms.

It is clear from field preference data and quantitative volatile release measurements that floral odor is not of sole importance in blossom selection by *D. v. virgifera*. The "Connecticut Field" cultivar of *C. pepo* is highly preferred by this species, but releases little volatile material (Table 3, Figure 2), while "Waltham Butternut" has a similar volatile profile to "Connecticut Field" (Figure 2), but is almost completely ignored by *D. v. virgifera*.

More clearly understood than the effects of floral odors are the effects of cucurbitacins as specific gustatory cues. Adults of *D. v. virgifera*, *D. u. howardi*, and *D. barberi* respond to these substances by the cessation of locomotion followed by compulsive feeding (Metcalf et al., 1980, 1982). This occurs even when the substrate is an inert material such as silica gel (Metcalf et al., 1980, 1982). In both greenhouse and field tests, only *C. maxima* cultivars contained detectable cucurbitacins. Mature foliage and fruits of this species are reported not to contain these compounds (Metcalf et al., 1980), but the coty-

ledons are a rich source of cucurbitacins B and D (Ferguson et al., 1983). When herbivorous insects were excluded (greenhouse studies), cucurbitacins were found at levels comparable to those in field-collected *C. maxima* (Table 5) and were absent from *C. moschata* and *C. pepo*. This indicates that the presence of cucurbitacins in *C. maxima* blossoms is not due to induced synthesis or translocation caused by feeding damage.

As with floral odor, the distribution of *D. u. howardi* and the reported distribution of *D. barberi* (Fisher et al., 1984) correspond very well to the cucurbitacin levels of male blossoms, suggesting that cucurbitacins may be a determining factor in blossom selection by these species. Also, the preference of *D. v. virgifera* does not correspond to cucurbitacin levels detected in field and greenhouse experiments, since ''Connecticut Field'' contained no detectable cucurbitacins and was preferred along with the *C. maxima* cultivars. A notable field observation with regard to these results was that *C. maxima* male blossoms incurred much higher levels of tissue damage than ''Connecticut Field.'' This was true even when *D. u. howardi* were nearly absent from the sampling area on early collection dates. Feeding by *D. v. virgifera* was concentrated in the anther area and was apparently due to the presence of cucurbitacins. *D. v. virgifera* found on ''Connecticut Field'' blossoms did not feed as actively as those on *C. maxima* and were dispersed about the surface of the corolla.

While gustatory and olfactory cues may act individually, they may also act in concert to produce the pattern of preference exhibited by *D. u. howardi*. High levels of volatile release may increase arrival rates at blossoms, while after arrival, the nonvolatile cucurbitacins would decrease the departure rate by stimulating feeding and arresting locomotion (Howe et al., 1976; Metcalf et al., 1982). Over time, this would lead to the large aggregations of *D. u. howardi* normally found in *C. maxima* male blossoms.

Apparently, neither olfactory or gustatory stimuli serve as the sole blossom selection cues for *D. v. virgifera*. In this instance, visual qualities of blossoms may be most important. *Diabrotica* species are known to orient to yellow-colored surfaces (Hein and Tollefson, 1984), and yellow is the color of *Cucurbita* blossoms. Also, the spectral sensitivity of *D. v. virgifera* has been determined to lie in the yellow-green and near-ultraviolet regions (Agee et al., 1983).

Chemical factors may still play a role in blossom selection by *D. v. virgifera* since Fisher et al. (1984) found a significant preference for *C. maxima* cultivars. The degree of preference, however, was much smaller than that seen with *D. barberi* and *D. u. howardi*. In this study, both *C. maxima* cultivars contained more *D. v. virgifera* than the ''Connecticut Field'' cultivar of *C. pepo*, but the differences were not significant (Table 1). This trend of a small preference for *C. maxima* cultivars over the most preferred *C. pepo* suggests that visual cues may be of primary importance and that these may be augmented

by chemical factors. Specifically, the blossoms of *C. maxima* and "Connecticut Field" may have similar visual characteristics, but the high levels of volatile release or the presence of cucurbitacins would increase insect arrival rates, decrease departure rates, or both.

In addition to spectral qualities, visual characteristics important in blossom selection of *D. v. virgifera* may include differences in blossom size or differences in blossom visibility due to plant growth form. These differences do exist and should be examined more closely, if a complete explanation of blossom selection by *D. v. virgifera* is to be gained.

(Received November 27, 1985; accepted April 23, 1986)

Abstract—Six compounds previously identified from hindguts of unmated male *Ips typographus* (L.) during host colonization: 2-methyl-3-buten-2-ol (MB), *cis*-verbenol (cV), *trans*-verbenol (tV), myrtenol (Mt), *trans*-myrtanol (tM), and 2-phenylethanol (PE), were tested for their attractivity in the field with a subtractive method. The amounts of MB and cV released from a pipe trap were similar to those given off from the commercial bait Ipslure as well as that from a Norway spruce tree, *Picea abies* (L.) Karst., under mass attack. The blend of the compounds became nonattractive when either MB or cV was subtracted, while subtraction of any of the other four compounds had no effect. Addition of ipsdienol (Id) to the blend did not significantly increase the attraction. In a second comparative test, the addition of three compounds as a group (tV + Mt + PE) to MB + cV again had no effect on the attraction, but the addition of Id increased the catch somewhat. Addition of host logs to a bait releasing MB + cV at a rate lower than in previous experiments did not influence the attraction to pipe traps. Sticky traps containing natural pheromone sources (50 males in a log), which released 1–5 mg/day of MB as determined by aerations with deuterated MB as internal standard, were less attractive than a synthetic source releasing similar amounts of MB.

Key Words—2-Methyl-3-buten-2-ol, *cis*-verbenol, *trans*-verbenol, myrtenol, *trans*-myrtanol, 2-phenylethanol, ipsdienol, subtractive assay, *Ips typographus*, Coleoptera, Scolytidae, *Picea abies*, host volatiles.

INTRODUCTION

The aggregation pheromone system by which the spruce bark beetle of Eurasia, *Ips typographus* (L.), colonizes a patch, such as a tree or a part of a tree, consists of two major signals. One is an attractive signal initiating the attack, and a second is a density-regulating signal that also functions in terminating the attraction (Schlyter et al., 1986). The chemical nature of the first attractive signal is the subject of this study.

The existence of a male-produced aggregation pheromone in the spruce bark beetle has been shown in the field by Bakke (1970) and Rudinsky et al. (1971). In the laboratory, it was later shown that the pheromone was released soon after host contact, with maximum attraction reached after 4–6 hr, followed by a rapid decline after the admission of females (Schlyter and Löfqvist, 1986).

Chemical analysis by gas chromatography of *I. typographus* males indicated the presence of *cis*-verbenol (cV), *trans*-verbenol (tV), ipsenol (Ie), and ipsdienol (Id), which were also found in other *Ips* species (Vité et al., 1972). However, different combinations of these substances had rather weak attractivity in the field (Bakke, 1976). The identification of 2-methyl-3-buten-2-ol (MB) with gas chromatography–mass spectrometry (GC-MS) by Bakke et al. (1977), together with the determination of (−)-(4*S*) as the active isomer of cV (Krawielitzki et al., 1977) formed the basis for the design of lures competitive with natural pheromone sources. Ipslure® (Bakke and Riege, 1982) and Typolure II (Sauerwein and Vité, 1978) both contain MB, cV, and Id, but in different ratios, while Typolure I (Vaupel et al., 1981) and Pheroprax® (Adlung, 1979) contain only MB + cV. However, rigorous tests to determine the attractivity of the individual components MB, cV, and Id are still lacking. These lures have also been tested with α-pinene and host volatiles (resin) to increase attraction, but with less clear results (Vaupel et al., 1981; Bombosch et al., 1982).

A detailed chemical analysis of beetles in different attack phases has showed that unpaired males with a completed nuptial chamber (phase 3) had a blend of at least six major components in their hindguts (Birgersson et al., 1984): MB, cV, tV, myrtenol (Mt), *trans*-myrtanol (tM), and 2-phenylethanol (PE). A seventh compound, verbenone, was only found in trace amounts. After mating and the beginning of egg-laying, some males also had Id and Ie, while the seven other components had decreased. It is possible that all of these natural compounds of related chemical structure have behavioral activity.

In this field study we have analyzed the attractivity of the components of the natural blend by a subtractive assay (Byers et al., 1985), compared the natural blend with three lures, tested synergism between host and synthetic pheromone, and compared natural and synthetic pheromone sources.

METHODS AND MATERIALS

Substances and Release Rates

The substances tested were those of the natural blend identified from male hindguts by Birgersson et al. (1984); see Table 1 for sources, purity, and release rates. Attempts were made to adjust the release rates to represent the ratios found in male hindguts. For comparison, the absolute and relative release rates of cV and MB were measured from commercial Ipslure® dispensers.

An airflow of 100 ml/min was passed over 0.1-m sections of the laminated Borregaard/Hercon® Ipslure bands in a cuvette (diameter 5 cm), and the resulting volatiles were trapped on a plug of 325 mg Porapak®-Q. The adsorbed volatiles were extracted with 2 ml pentane, and an internal standard (100 g C_7Ac) was added. The extracts were then subjected to GC for quantification and GC–MS for identification, conditions as in Birgersson et al. (1984). The release rates were calculated to be 50, 1, and 0.3 mg/day of MB, cV, and Id, respectively, for a 1-m strip (standard length) of Ipslure dispenser after one week of aging.

Field Tests

Subtractive Assay. Dispensers with test chemicals were placed in the lower part of black drainpipe traps with white exterior funnels ("N79 with funnel" type, Regnander and Solbreck, 1981). Traps were placed about 50 m apart on clear-cuts and randomized after each replicate period which lasted a few hours to more than two days, depending on flight activity. The test was carried out at two different sites in 1982: site A (Aborrtjärnsberget), a fresh clear-cut with a very high local beetle density (> 100 trees killed the previous year), and site L (Lilltjärnsberget), an old clear-cut with a low population density (no trees killed within 1 km the previous year), close to Torsby, province of Värmland, middle Sweden, 1982.

Comparative Study. Four different clear-cut areas in 1982 near Torsby were used for the comparison between the "phase-3" (natural) and the three "commercial" compositions. Two were fresh clear-cuts with high beetle densities: site A (as above) and site T (Torkbäcken, > 10 trees killed the previous year), and two were old with lower densities: site B (Boseberget) and site G (Gäddtjärnsberget). Both sites B and G had no trees killed the previous year. The later site had an elevation difference of about 50 m, while the other had less than 20 m. Traps and positioning were as in the subtractive assay.

Host Synergism. Pipe traps without funnel ("N79" type, Bakke et al., 1983) were baited with screened logs (6 cm diameter, 30 cm long, with ten 2- to 3-cm axe cuts) freshly cut from a Norway spruce (*Picea abies* (L.) Karst.) with or without a "medium" dose of MB + cV (Table 1). Together with traps

Comparison of natural and synthetic pheromone, Gribskov, Denmark, 1984				
2-Methyl-3-buten-2-ol (MB)	97	Aldrich	5.8 ± 0.3	"730" with 50-μl capillary
			0.5 ± 0.05	"730" closed
			0.2 ± 0.02	0.25-mm-diam capillary
(4*S*)-*cis*-Verbenol (cV)	99	Borregaard/KTH	0.05 ± 0.001	"730" with 150-μl capillary
			0.01 ± 0.001	"7570," 1.1 mg of cV
			0.002 ± 0.001	"7560," 0.5 mg of cV

[a] Chemical purity estimated by capillary GC. Optical purity for cV > 94% (−)-(4*S*), Id was racemic.

[b] The release rates from polyethylene vials were estimated in the laboratory by measuring the weight loss of the vials, placed in a wind tunnel at 0.7 m/sec and 20°C, during a month's period. The rate of release was calculated as the slope, with its 95% confidence interval, from the regression of weight on time.

[c] Dispensers were polyethylene vials (Kartell, Italy) of two types: "730," a 1-ml vial of soft polyethylene; and "hard," a 2-ml vial of hard polyethylene, with capillaries or drilled holes in their lids. For the two lowest rates of cV we used polyethylene tubes, 3 cm long, heat sealed in both ends, with 0.40 mm (7570) or 0.55 mm (7560) wall thickness.

with only MB + cV, these formed an equilateral triangle, a trap group, with 10 m to a side, randomized within the group after each replicate. A total of four groups were used in an old clear-cut, north of Skien, Lardal, southern Norway in May–June 1983.

Comparison of Natural and Synthetic Pheromone. Logs (diameter 12 cm, 30 cm long) infested with 50 males or 30-cm sections of pipe traps with dispensers for synthetic pheromone (Table 1) were enclosed by a sticky trap (hardware cloth No. 4 coated with Stickem Special, Byers and Wood, 1980). Logs and pipe-trap sections were both screened with brass net (No. 60) to exclude arriving beetles and to give a similar appearance. The logs were cut from three Norway spruce [*Picea abies* (L.) Karst.] trees that represented different stages of vigor and resin content (Table 4). The trees were all cut in the evening on May 17, 1984. Male beetles were introduced, after sex separation (Schlyter and Cederholm, 1981), the day after. The males (50/log) were introduced into predrilled holes on the evening before May 18, but had a free choice to start excavating the nuptial chamber or to leave, in which case they were replaced after a few hours. Both beetles from our laboratory stock (from Lardal, southern Norway) and wild, Danish beetles (caught in pipe traps baited with synthetic pheromone in the area the days before) were used (Table 4). In all cases, each set had one log from each of the three trees infested with 50 males. The traps in a set were placed in two lines with a minimum of 10 m between traps. The two trap sets were at least at 25 m away from each other and other pheromone sources such as trees under attack. Trap positions were randomized after each replicate. Trapping sites were in clear-cuts, cleared of logging residues, near groups of trees killed the previous year in Esrum forest district, Grib Skov, north of Hillerød, Denmark, 1984.

Aerations of Natural and Synthetic Pheromone Sources. Male-infested logs and sections of pipe traps (containing dispensers with synthetic compounds) were aerated after each day of trapping. Logs and pipe-trap sections were placed individually in glass jars (ID 15 cm, 30 cm high) through which 150 ml air/min (charcoal filtered, ID 2 cm × 20 cm) was passed with a pneumatic suction ejector (AGA). The volatiles in the effluent were trapped on Porapak-Q (mesh 80–100, 170 mg). As internal standards, trideuterated-MB and α-isophorone were evaporated from fused silica capillaries (ID 0.20 mm), one end sealed with beewax, attached to the side of logs or pipe-trap sections. After 3 hr of aeration, the Porapak-Q plugs were extracted with 2 ml of diethyl ether, 500 ng C_7Ac was added as a standard for the concentration, and the extracts stored at −20°C. The extracts were concentrated and subsequently analyzed by GC −MS; conditions as in Birgersson et al. (1984).

Sample Handling and Statistics

Sample Handling. Beetles were preserved in ethanol and identified to sex by pronotal bristle density (Schlyter and Cederholm, 1981). In the subtractive

assay, at least 260 beetles (or the total catch if less than 260) from each site and bait were identified to sex. Beetles from the comparative study were not identified to sex, and, for samples of >100 individuals, their numbers were estimated by measuring the volume of *I. typographus* (42 beetles/ml).

Statistics. Raw catch data (y) were subjected to a series of transformations y^{-1}, $y^{0.5}$, $\log(y + \text{constant})$, p^{-1} to make them suitable for ANOVA by achieving homogeneous variances (Cochran's C and Barlett box tests, $P > 5\%$) and approximately normal distributions. The transformation $\log(y + \text{constant})$ was chosen for the first two tests as it made the data homoscedastic and gave high F ratios in ANOVA. The high number of zero catches in the two later tests caused significant heteroscedacity to remain after transformations, which made it more appropriate to perform a nonparametric test [Wilcoxon matched-pairs with significance levels adjusted for number of comparisons (Kirk, 1969)] of the untransformed data in lieu of ANOVA.

RESULTS

Subtractive Assay

Subtraction of either MB or (−)-(4*S*)-cV from the natural phase-3 blend dramatically reduced the catch of *I. typographus* (Figure 1), indicating that both MB and cV are equally essential for attraction. The relative response in the two sites was very similar, in spite of a 10-fold difference in total catch (Figure 1). Thus, (+)-(4*S*)-tV or Mt could not substitute for cV (or MB). The inclusion of tM, a component of the natural phase-3 blend, in the later replicates also did not increase the attractivity. The addition of (*R/S*)-Id to the phase-3 blend seemed to increase the catch of *I. typographus* slightly, although the difference was not statistically significant. The sex ratio was little affected by subtraction or addition of compounds. Exceptions were the removal of PE or MB, which resulted in a somewhat higher percentage of males in the catch (Table 2).

I. duplicatus Sahlb. was attracted only to the bait with Id added to the phase-3 blend. Several other scolytid species were caught in low numbers in the pipe traps with funnel, but none showed a clear pattern of attraction like the two *Ips* species. *Pityogenes chalcographus* (L.) was caught on all baits with an increase on phase 3 plus Id but the numbers were low (Table 2).

Comparison between Lures

The two baits containing Id (Ipslure, Typolure II) generally caught more beetles, although the differences were small and not statistically significant at the site with the highest number of replicates (Figure 2). The bait with the highest catches, Typolure II, had both a higher dose of Id and of cV, while Ipslure was almost identical to phase 3 at the best site. This means that it is difficult to assign a clear synergistic function of Id based on these data. When

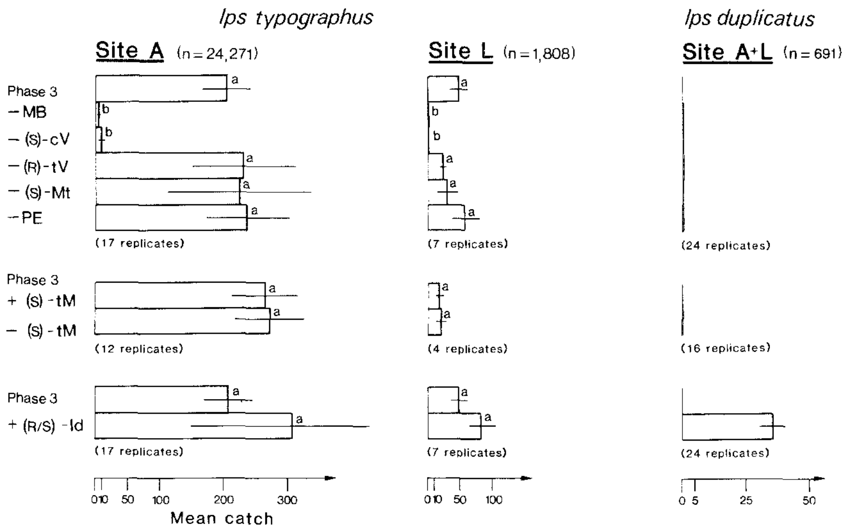

FIG. 1. Mean catches (±SE) per replicate in pipe traps with the subtractive assay of *Ips typographus* pheromone components. Subtraction or addition of a component of the phase-3 blend is indicated by + and −, respectively. Phase 3 is a bait representing the pheromone content in hindguts of unmated *I. typographus* males, which included the components MB, cV, tV, Mt, and PE during the first five replicates. For the remaining replicates, an additional trap was added which had a sixth compound, tM, which is also found in males from phase 3. One bait had the phase-3 blend plus Id, which is found in mated males. Total catch is given by (n). Release rates and names of chemicals and sex ratios of catch are shown in Table 1. Chirality of compounds with optical activity is given by *R* and *S*. Bars with the same letter are not significantly different within a site ($P > 5\%$) by ANOVA of log (catch + $\frac{1}{4}$) followed by Duncan's multiple-range test.

comparing phase 3 with Typolure I, it is evident that the addition of tV, Mt, and PE to our standard MB + cV bait (=Typolure I) did not increase the attraction, as the catches of the two baits were virtually identical in all sites (Figure 2).

Host Synergism

Volatiles from a spruce log did not enhance the attractivity of a lower, "medium" dose of MB and cV, as shown by the nearly identical mean catches (Table 3). The bait consisting of a log alone in the pipe traps without funnel did not catch a single beetle during the entire experiment, while 705 beetles were caught by the two pheromone baits. The sex ratio was not altered significantly by the addition of the log to the pheromone source. Few other scolytids were collected, probably due to the low pheromone release and the use of pipe traps without an exterior funnel.

TABLE 2. SUBTRACTIVE ASSAY OF AGGREGATION PHEROMONE CANDIDATES IN *Ips typographus*: BAITS, SEX RATIOS, AND CATCHES OF OTHER SPECIES IN PIPE TRAPS, VÄRMLAND, SWEDEN, MAY 17, TO JUNE 8

Total catch			705			

[a]Tree cut June 1, logs 6–8 cm diam. × 28 cm (with 2- to 3-cm long axe cuts, 10 per log).
[b]Values followed by the same letter are not significantly different by Wilcoxon matched-pairs signed ranks test ($P > 5\%$) for totals, males, or females.
[c]95% Binomial confidence intervals (Byers and Wood, 1980).

Natural and Synthetic Pheromone: Attraction and Release Rates

The strongest bait in this test, the "medium" MB + cV synthetic pheromone source consistently caught more beetles than did the male-infested logs (Table 4). There was no consistent difference in the catch between logs infested with laboratory-reared males originating from Norway and logs with wild males of local origin, and the data are pooled in Table 4. The sex ratio was about 40% males on most traps but, of the synthetic baits, only the catches of the two stronger baits were significantly different from an equal sex ratio. If the catches from all three traps with male-infested logs are pooled, the proportion of males (35%) is also significantly different from an equal sex ratio (95% binomial confidence interval, Byers & Wood 1980).

The release of MB could be accurately estimated by the deuterated MB internal standard and showed that the release of MB from the logs was high and close to the "medium" synthetic bait, which was the strongest in this test. The release rates estimated by weight loss and by entrainment were in good agreement for the MB in both the "medium" and "low" baits (Table 4). The standard for the monoterpene alcohols, α-isopherone, was not released in sufficient quantities to obtain an estimate of their absolute release rates. However, the ratios between the monoterpene alcohols could be measured with precision and accuracy and were used to show that verbenone, together with readily detectable amounts of cV and tV, was released from the logs at some times in approximately equal ratios to the verbenols (Table 4).

DISCUSSION

Tests of Synthetic Compounds

MB and cV could be identified as essential for the attraction of *I. typographus*, while subtraction from the phase-3 blend of tV, Mt, or PE, or addition of tM had no apparent effect on the catch. Thus, the released amounts of (+)-tV, (−)-Mt, PE, and (−)-tM could not substitute for or increase the attraction to MB and cV. We could not substantiate the report by Dickens (1981) that (+)-(4*S*)-tV could substitute for cV and was as attractive as (−)-(4*S*)-cV when tested in sleeve olfactometers. The addition of Id increased the catch somewhat, but not significantly, as was earlier indicated by Dickens (1981) and Bakke et al. (1983). Thus Id plays, at most, a minor role in the aggregation pheromone, as tested here. However, a small, but significant, increase in catch when small amounts of Id were added to MB + cV was demonstrated by Schlyter et al. (1987).

Only combinations including ipsdienol (Id) were attractive to *I. duplicatus*, in agreement with the results of Bakke (1975). The comparative test of baits

TABLE 4. RELEASE RATES OF AND ATTRACTION TO NATURAL AND SYNTHETIC PHEROMONE SOURCES OF *Ips typographus* GRIB SKOV, DENMARK, MAY 19–JUNE 5 1984, STICKY TRAPS, 12 REPLICATES

	Release rate by weight loss (mg/day)		Release rates by entrainment per day				Catch (number of beetles)

Control (blank)	—	—	0	0	0	0	1.7	5–0	(24)

[a] MB release estimated by GC-MS via the m/z 71:74 relative to the release of d_3-MB in the aeration vial. Values given for release by entrainment are means of three or more aerations of the same bait. For release by weight loss and abbreviations of compounds see Table 1.

[b] cV, tV, Vn calculated relative to the 500 μg C_7Ac added after extraction of the adsorbent.

[c] Two sets of traps were used, with five and seven replicates each, and results pooled as no difference between the sets could be detected. In one of the two sets the laboratory-beetle-infested logs were replaced with local, wild beetles caught in pheromone traps after the second replicate. No differences in relative or absolute catches could be noted between wild and laboratory beetles.

[d] Significantly different from "Medium" at $P < 5\%$ by Wilcoxon matched-pairs signed ranks test, significance level (α) corrected for number of planned comparisons (Kirk, 1969).

[e] Significantly different from 50% males (95% binomial C.I.), values within ( ) indicate less than 20 beetles caught.

[f] Tree N of low apparent vigor (crown narrow with low needle density, "transparent") with a mean annual increment for the last five years of 3.3 mm/year, while MI and MII were of high apparent vigor with dense, dark green crowns with 6.8 and 6.7 mm increments, respectively.

representing commercial lures showed that even the addition of tV, Mt, and PE as a group did not enhance the attractivity of the MB + cV combination. The addition of a small amount of Id, in combination with a doubled dose of cV (Typolure II), produced the bait with the highest catch, but significantly so in only one of four test sites. As the known attractant cV also was increased, the effects of Id might be confounded, so we cannot, in this case, confirm a benefit of Id in the attractant blend. However, the bait representing Ipslure also caused high catches, which, in one of four sites, was significantly different from one of two possible controls. One reason that none of the hindgut components other than MB and cV (and possibly Id) were found active in this study could be that the tV, Mt, tM, and PE tested had impurities of an inhibitory nature or they were not of the appropriate enantiomeric composition. However, the tV tested was the same enatiomer, (+)-(4*S*)-tV, as tested by Dickens (1981), and the (4*S*)-enantiomer is probably the one naturally produced (Klimetzek and Francke, 1980; Birgersson et al., unpublished). The natural enantiomeric composition of Mt and tM produced by the beetles is not known, and we used only one enantiomer. Thus, the possibility remains that a full, enantiomerically correct blend of phase 3 might be more active than MB + cV alone.

Host Synergism and Natural/Synthetic Comparison

Examples exist in several bark beetle genera of an aggregation pheromone synergized by volatiles from living host material: *Scolytus multistriatus* and elm logs (Peacock et al., 1984), and *Tomicus minor* and pine logs (Lanne et al., 1987), or by identified host compounds: *Dendroctonus brevicomis* and myrcene (Bedard et al., 1969), *D. ponderosae* or *D. frontalis* and α-pinene (Pitman, 1971; Renwick and Vité, 1969), and *Gnathotrichus* spp. and α-pinene (Borden et al., 1980). Tests with *I. typographus* in Germany have indicated that α-pinene or spruce resin added to traps with synthetic pheromone did not increase trap catches (Vaupel et al., 1981). However, spruce logs in one experiment increased catch considerably (Bombosch et al., 1982), although proper controls and replication appear to be lacking. Our test showed no increase in catch in pipe traps with spruce logs added. Comparisons between experiments using logs are made difficult by the fact that, as in our experiment, the release rates of the host compounds are usually not known, but only the size of logs used. In our test the logs were rather small and volatile release may have declined too soon to show possible weak pheromone synergism effects. However, the lack of any strong host attraction or synergism found in this study is not surprising, as other *Ips* species have not conclusively been shown to have a long-range host attraction behavior or synergism between pheromone and host odors (Wood, 1982).

The poor attractivity of the natural pheromone sources (50 males in log) is more surprising, especially as the chemical analysis of aerations showed that the release of MB from the logs was similar to "medium," the strongest syn-

thetic bait in this test. MB is believed to be produced de novo by the beetle in the appropriate biological phase. The high production of MB, similar to that of beetles mass-attacking trees (Birgersson, unpublished), indicates that the beetles in the test logs were in the appropriate physiological and behavioral condition for maximal pheromone production. The period of the test (18 days for one set of logs) is not unreasonably long, as walking beetles in a Y-tube bioassay were attracted to male-infested logs for 16 days (Schlyter and Löfqvist, 1986). However, a low and declining release of cV (produced from the host monoterpene α-pinene) may well explain the low attractivity of the logs. Byers (1981) showed for *I. paraconfusus* Lanier males that the pheromone components, ipsenol and ipsdienol (produced from host myrcene), began to decline after about six days and were undetectable (GLC) after two weeks. Furthermore, verbenone (Vn) decreases trap catches (Bakke, 1981), and although its release rate was low, it could also have contributed to the low catches. The release of Vn from infested logs is probably due to the activity of microorganisms in the host tissue as they convert pinene and verbenols to Vn (Brand et al., 1975; Leufvén et al., 1984), while male hindguts contain very little Vn (Birgersson et al., 1984).

If the pheromone system in *I. typographus* in fact consists of only two components (MB + cV), one might ask if such a simple system is specific enough to ensure species specificty of the pheromone signal. The monoterpene alcohol cV is found in several related and/or sympatric species (Vité et al., 1972; Wood, 1982). However, the enantiomeric ratios and behavioral roles of cV are not well characterized in these species. As yet, the very large amount of the isoprene alcohol MB in the two-component system appears unique to *I. typographus* among *Ips* species and probably plays the major role to ensure the species specificity of the pheromone.

Acknowledgments—Chemical compounds were generously supplied by Borregaard, Sarpsborg, Norway (L. Riege) and by KTH, Stockholm, Sweden (T. Norin). Deuterated MB was kindly synthesized by Dr. F. Björkling, KTH. Information on field sites, provision of facilities, and permission to work on forest land was provided by I. Olsson (Skogsvårdsstyrelsen, Torsby), M. Sjölander (Billerud, Torsby), T.C. Corneliusen (Treschow-Fritzøe A.S., Skien), L. Tobsvig (Statsskovvaesenet, Esrum Skovdistrikt), H.P. Ravn (Royal Veterinary and Agricultural University, Copenhagen), T. Dabelsteen and H. Lind (Institute of Population Biology, Strødam and Copenhagen). Technical assistance was given by E. Jirle, O. Anderbrant, M. Appelgren, E. Marling, B. Bartosch, J. Börnfors, E. Wijk, and K. Persson. T. Liljefors and R. Isaksson at the Department of Organic Chemistry 3, Lund, analyzed tV for optical purity. We thank them all for their professional help in gathering and analyzing the large material.

Funding was provided by Swedish Research Councils (NFR, FRN, SJFR, STU).

[2]*Department of Obstetrics and Gynecology, School of Medicine Hospital of the University of Pennsylvania 3400 Spruce Street, Philadelphia, PA 19104*

(Received January 13, 1986; accepted April 23, 1986)

Abstract—Previous studies have shown that menstrual cycle length and fertility are affected by a regular pattern of either: (1) intimate contact with men; or (2) contact with extracts from male axillary secretions; and (3) the axillary extracts of women. Experiments utilizing axillary extracts employed a controlled, double-blind research design using either extract or placebo. The study reported here employed quantitative gas chromatography–mass spectrometry (GC-MS) techniques to determine the concentration of several steroids in the male and female axillary secretion extracts. The steroids examined were: androsterone sulfate, dehydroepiandrosterone sulfate, and the volatile steroid androstenol. The results suggest the following: (1) The concentration of androstenol produced by secretion donors varied during the collection period. Males appear to produce more androstenol at certain times; women's secretions show a menstrual variation in androstenol; the highest concentrations of this compound appear to be produced in the midfollicular phase, prior to ovulation. (2) The concentration of dehydroepiandrosterone sulfate is significantly greater in men than in women. (3) In addition to the steroids, a series of aliphatic acids which range from C_2 to C_{18} in chain length were found. The more volatile members of this series may contribute to the odor of the secretions.

Key Words—Primer pheromones, human steroids, androstenol, axillary secretions, menstrual synchrony, menstrual cycle regularization.

INTRODUCTION

The possibility that human odors can affect reproductive biology has been discussed at some length in both the scientific and the popular press. Much of this discussion has centered upon the possible existence of releaser pheromones (i.e., substances which release a behavioral response in a conspecific). Although specific data to support the existence of a releaser pheromone in humans has not been forthcoming, data from several studies suggest the possibility of another more subtle pheromonal effect, i.e., a primer pheromone. Such a substance would cause a slow changing or priming of the endocrine system (see Albone, 1984; Freeman, 1978, for a discussion of primer and releaser pheromones). Several studies reveal that interpersonal relations between women may result in menstrual synchrony (McClintock, 1971; Graham and McGrew, 1980; Quadagno et al., 1981), while sexual interactions between men and women can influence cycle length (Cutler et al., 1979, 1980, 1985; Russell et al., 1980). These data therefore imply that humans may exert a primer pheromone influence on human reproductive endocrinology.

Studies recently completed in our laboratories employed axillary extracts obtained from men and women to influence the menstrual cycle length of nulliparous women (Cutler et al., 1986; Preti et al., 1986). Female subjects who reported having a history of aberrant length cycles (<26 days and >33 days) received extract from male donors while those who reported having normal length cycles received extract from female donors. Women who received the male extracts for 13.5 ± 1 weeks experienced more regular (i.e., less aberrant) cycles than the controls who received placebo applications. The women who received female extracts showed a significant shift towards a synchronization of their menstrual cycle onset with menstrual onset of the donor females. These two studies demonstrated that axillary constituents can shift the length and onset of the menstrual cycle when subjects are chronically exposed to them and that this effect can occur in the absence of direct social contact. In addition, the studies confirmed olfactory–reproductive system relationships in humans that had been previously demonstrated among several nonhuman mammals.

The stimuli used in our studies were derived from the axillary region, a body area with unique odor-producing characteristics. In the axillae, apocrine, sebaceous, and eccrine glands provide an excellent substrate for a large permanent population of microorganisms (Labows et al., 1982). The apocrine secretion as collected at the skin surface is odorless. However, incubation with the resident bacteria results in the production of a characteristic odor which appears to be unique to the organism used (Leyden et al., 1981; Labows et al., 1982). The micrococci bacteria present in the axillae give an acidic odor to the secretion that has been characterized by headspace analysis as isovaleric acid (Labows, 1979; Labows et al., 1982). The diphtheroid bacteria give similar

chromatographic headspace profiles with isovaleric acid being present; however, the odor is more distinct and pungent and suggests the presence of other unidentified volatiles (Labows et al., 1982).

Previous analyses of both the apocrine secretion and the total axillary sweat have shown the presence of a variety of both volatile and nonvolatile steroids (Brooksbank, 1970; Brooksbank et al., 1974; Claus and Alsing, 1976; Labows et al., 1979; Bird and Gower, 1980). In addition, the axillary bacteria are also thought to produce volatile aliphatic acids (Labows, 1979; Labows et al., 1982).

Analysis of freshly collected apocrine secretions in our laboratory has shown the presence of two androgen steroid sulfates: 17-oxo-5α-androstan-3α-yl (androsterone) sulfate and 17-oxo-5α-androsten-3β-yl (dehydroepiandrosterone) sulfate (Labows et al., 1979). Both dehydroepiandrosterone sulfate and androsterone sulfate are present in high concentrations and may serve as precursors for the volatile, odiferous androst-16-enes. The androst-16-enes, 5α-androst-16-en-one (androstenone) and 5α-androst-16-en-3α-ol, (androstenol) act as releaser pheromones in the mating behavior of the pig (Gower et al., 1981). Several studies have examined, with limited success, the potential behavioral effect of androstenol and androstenone in human subjects (Cowley et al., 1977; Kirk-Smith and Booth, 1978; Benton, 1982; Black and Biron, 1982).

GC-MS techniques were employed to analyze the female and male axillary extracts which, as described above, had affected the length and onset timing of recipient's menstrual cycles. Several steroids were examined in a quantitative fashion. These were dehydroepiandrosterone sulfate (DHEAS), androsterone sulfate (AS), and 5α-androst-16-en-3α-ol (androstenol). In addition, a series of aliphatic acids were identified in several of the male extracts.

METHODS AND MATERIALS

Collection of Axillary Secretions. The axillary secretions used to prepare the axillary extracts employed in this study were collected from both male and female volunteer donors. Four females (ages 25, 26, 29, and 35) and three males (ages 41, 35, and 32) provided the samples and were recruited from among coworkers and members of the university community during the autumn of 1982. Each was engaged in a stable, ongoing heterosexual relationship and had large numbers of lipophilic diptheroids in the axillary regions. As noted above, lipophilic diphtheroids are associated with a more pungent axillary odor (Leyden et al., 1981). This pungent odor is similar to that of C_{19}-androst-Δ^{16}-enes such as androstenol and androstenone. Our secretion donors were selected for their ability to produce a complete spectrum of axillary odorants (Labows et al., 1982).

Each female donor had a history of normal length (29.5 $\pm$ 3 day) men-

strual cycles. None of the donors shaved their axillary regions. During the 14–16 weeks in which donors collected secretions, all were required to (1) not use deodorant, deodorant soap, or perfumes in the axillary region; (2) wash once each morning with Ivory soap; and (3) not shave their underarms. Secretions were collected on 4 × 4-in. cotton pads which had been previously extracted, autoclaved, dried, and wrapped in solvent-extracted foil (Preti and Huggins, 1975). Each donor wore one pad in each axilla three times a week for a 6- to 9-hr span which was most convenient for him or her. Each day after removal, the pads from any one donor were placed in an individual acid-cleaned-glass-jar and frozen at −60°C until extraction.

Preparation of Axillary Extracts—Female Samples. Each female donor collected secretions for three complete menstrual cycles. However, the axillary pads included in the preparation of the stimulus came from only five of the donated cycles which met the following more rigorous criteria: (1) each was 29 ± 2 days in length; (2) the basal body temperature charts were clearly biphasic and presumably ovulatory with basal body thermal rises which lasted 12 or more days, a characteristic of a fertile cycle (Cutler et al., 1979, 1985; Treloar et al., 1967; Vollman, 1977); and (3) menstruation occurred within 7 days of a full moon (Cutler, 1980; Friedman, 1981). We have previously shown that women who cycle as often as the moon cycles tend to be the most fertile: These women have an increased propensity for menstruation at the time of the full moon. This timing of donor cycle selection did yield significant effects not directly related to this report (Preti et al., 1986; Cutler, et al., unpublished data).

Because of the similarity in cycle lengths employed, it was assumed that each of the three-day sequences from each donor (i.e., cycle days 1, 2, and 3) would be endocrinologically similar, and consequently the pads from these days were combined. To prepare the sample, pads were grouped in three-day segments: e.g., all pads from cycle days 1–3 were combined and called "combined donor day 2" (the first day of menstruation = day 1 of a menstrual cycle); all pads in days 4–6 were combined and called "combined donor day 5"; all pads in days 7–9 were combined to form "combined donor day 8"; and so on. In this fashion, 10 separate extracts were prepared, each containing odors from different portions of the menstrual cycle to form the "donor cycle" of combined donor days 2, 5, 8, 11, 14, 17, 20, 23, 26, and 29.

All pads from each three-day group were placed in a glass column and allowed to soak in doubly distilled ethanol for 1 hr at room temperature. Fifteen milliliters of ethanol were used for each pad in the column. After 1 hr, the ethanol-extracted materials were allowed to run out of the bottom of the column through a Teflon stopcock as the pads were squeezed with a Teflon disk. Approximately $\frac{2}{3}$ of all ethanol put on the pads was recovered. The ethanol extracted axillary secretions were subsequently stored at −60°C until used for behavior testing or chemical analysis.

Preparation of Axillary Extracts—Male Samples. To prepare the male extracts, batches of glass jars containing the pads were grouped consecutively according to the date received. Each batch of pooled extract was prepared from six consecutively collected jars and contained pads from all three individuals. A total of 14 separate extracts were prepared in this manner. All pads from each sample were extracted in the same manner as described above for females.

Analysis of Extracts and Standard Samples by Gas Chromatography and Mass Spectrometry. A Finnigan 4510 GC-MS data system equipped with a split-splitless injector, a fused silica capillary column, and with capabilities for operation in both electron impact and chemical ionization modes was used for analysis. The column employed for chromatography was a methylsilicone permanently bonded phase, CP SIL-8, 25 m × 0.32 mm with a 1.2-μm coating (Chrompack, Inc., Bridgewater, New Jersey). Analyses of both male and female donor extracts as well as extracts containing the standard mixture extracted from pads were performed by concentrating to a low volume, generally 20–80 μl and diluting with an equal volume of the injection standard, androstane, to give 100 ng of androstane for each injection. The chromatographic program used for the analysis was as follows: 150°C for 8 min and then 3°/min to 300°C with a hold for 20 min. The mass spectrometer is interfaced with a Nova 3 computer which utilizes the Incos software for data acquisition, analysis, and quantitation. The mass range employed during these analyses was m/z 50–450. This mass range was scanned once each second and a typical run included 3600 scans.

The data system also includes the NBS library of 31,000 compounds. Identifications were based on comparison of unknown spectra with both the NBS library and interpretation of the resulting comparison with mass spectra generated from commercially available standard compounds. In addition, the relative chromatographic retention times of unknowns and known standards were compared. A mixture of both fatty acid ethylesters as well as hydrocarbons was used to determine relative retention times. In the case of the compounds being quantitated, commercially available, authentic compounds were used for comparison of retention times, mass spectra, and generation of standard curves.

Determination of Extraction Efficiency of Target Compounds from Pads. Because the extracts of the axillary pads were to be placed on humans (with associated requirements for human subject experimentation), no internal standards were added to the pads. Thus, the efficiency of extraction could not be judged directly. Subsequently, post hoc tests were performed. A standard solution was made which contained the following steroidal compounds: DHEAS, 103 ng/μl; AS, 18 ng/μl; and androstenol, 0.3 ng/μl. Pads were prepared in the same way as those pads that had been worn by the donors.

Pads were put together in several different sized batches reflecting the original experimental conditions in order to evaluate whether the number of pads affected the extraction efficiency. For example, the number of pads in each

female extract, as noted above, varied depending on the yield received: e.g., combined donor day 2 contained 10 pads; combined donor day 5, 16 pads; combined donor day 8, 16 pads. Six repetitive measures were performed on the smallest batch (6 pads) and the largest batch (16 pads). For the men, a greater consistency was possible because each batch contained 12 pads. In order to test for extraction efficiency from the male samples, ten separate batches of 12 pads each simulated the actual extraction protocol.

Each pad had 100 μl of the standard solution added to it. Each batch of pads was then placed in the column used previously to extract the donor derived pads. Next, the pads were put through the same soaking, extracting, and solvent concentration protocol as had been performed on the actual donor pads. The resulting mixture was analyzed on our Finnigan 4510 system as described above.

Quantitation of Compounds Extracted from Pads of Human Donors and Standard Pads. The Incos software (supplied by the Finnigan Corporation) was used to quantitate the desired compounds by using the Targeted Compound Analysis (TCA) package. This software package locates and quantitates individual compounds by employing retention times and the intensities of key ions designated by the user. For each of the steroids, we used quantitation based principally on the molecular ion and the most intense ion fragment in the mass spectrum. The standard curves for androstenol, DHEAS, and AS consisted of the absolute computer-generated intensities of key ions for each steroid at different concentrations vs. the ratio of that intensity divided by the intensity of the molecular ion of androstane generated by 100 ng of that compound. The concentrations of androstenol, DHEAS, and AS used for each standard curve were 1 ng, 5 ng, and 10 ng. A representative of standard curve for DHEAS may be seen in Figure 1.

RESULTS

Extraction efficiency from standard mixtures was higher for androstenol (67% $\pm$ 22.1%; mean $\pm$ standard deviation) than for DHEAS (22% $\pm$ 11%) or AS (21.4% $\pm$ 10.5%). Thus for the two sulfates, approximately five times the concentration extracted was initially present on the donor pads. For androstenol, about 1.5 times the concentration extracted was initially present in the donor pads. No variation in efficiency emerged as a function of the number of pads in a batch.

The data shown in Figures 2 and 3 display the actual concentrations of the three steroids isolated from the sequentially collected donor pads of men and women in Autumn, 1982. In Tables 1, 2 and 3, the respective concentrations for androstenol, DHEAS, and AS are listed. In these tables we have also provided the 95% confidence level (1.96 $\times$ standard deviation) around each data point. This confidence level was calculated from the data set used to determine

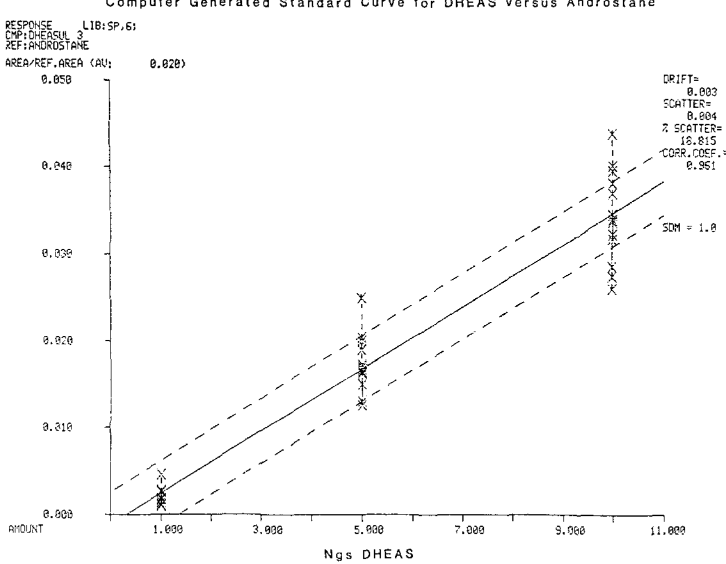

FIG. 1. The standard curve generated for dehydroepiandrosterone sulfate (DHEAS). The standard calibration curve is generated by the Target Compound Analysis package of the Incos software supplied by the Finnigan/MAT Corporation, San Jose, California. The curve was generated by injecting three different concentrations of DHEAS sulfate in conjunction with a fixed amount of injection standard, androstane. The three separate concentrations employed for DHEAS were 1, 5, and 10 ng of DHEAS with 100 ng of androstane. Each of the Xs at the three separate concentrations in the graph represent a separate injection. Fifteen injections were done at each of the three concentrations. The percent variation shown in the graph is the standard deviation assigned to the injection technique.

efficiency by the following procedure: (1) multiplying the standard deviation obtained from the standard extraction by 1.96; and (2) adding (as well as subtracting) this derived confidence interval to the value obtained in the actual samples. Because internal standardization and multiple measurements at each time interval were not obtained, this was the best 95% confidence limit available and served to estimate statistical variation around each data point. Data points whose confidence intervals do not overlap may be interpreted as being generated by biological or physiological variation rather than by variation due to extraction and analysis methods.

When one examines the data points and compares them to their 95% confidence intervals, one may see that several of the combined female donor days and male batches of pads appear to be significantly more concentrated in androstenol than the rest. Figure 4 shows the menstrual variation in androstenol concentration for the women. The data suggest that women produce signifi-

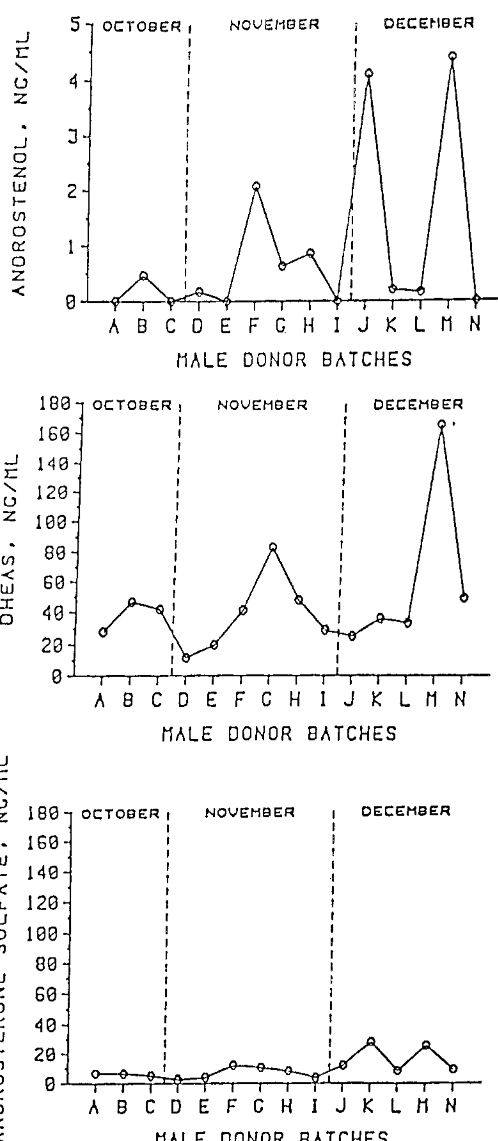

FIG. 2. The concentration of the three steroids measured from the male donor axillary secretions. The concentrations listed are in nanograms per milliliter of axillary secretion extract. These show the actual concentrations of material which were applied to the subjects as part of our previous studies. The compounds listed from top to bottom are androstenol, DHEAS, and AS. The graph also shows the month in which the pads for each extract were collected.

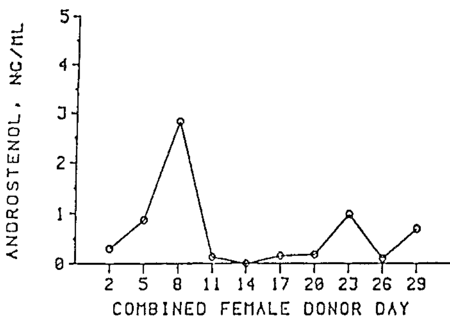
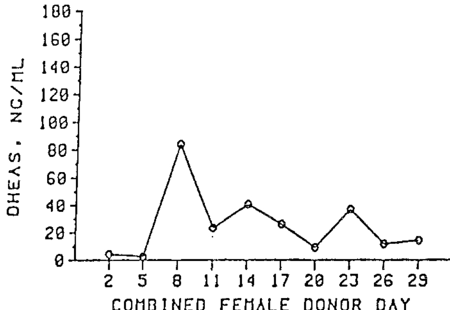
Variation in Female Axillary Secretion Constituents





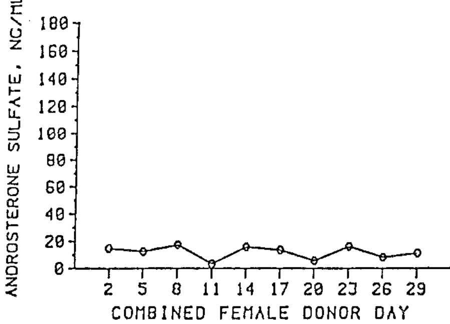


FIG. 3. The concentrations of the three steroids measured from the female donor axillary secretion extracts. The concentrations are nanograms per milliliter of secretion extract. The compounds listed from top to bottom are androstenol, DHEAS, and AS. The concentrations are the actual concentrations isolated from the pads.

cantly more androstenol during the preovulatory period, i.e., donor day 8 ± 1 of the 29-day, normal menstrual cycle. The five menstrual cycles used to generate the pads for this study all showed a definitive normal ovulatory type basal body temperature chart (Vollman, 1978) in which ovulation appeared to occur during days 13–16. The preovulatory blood estrogen rise in a typical 29-day cycle with midcycle ovulation generally commences on or about day 8. Concentrations of male axillary androstenol show several maxima in concentrations (e.g., batches F, J, and M).

The data from Tables 2 and 3 show that the overlap for each of the data points for the steroid sulfates was too large to suggest a significant variation due to physiological causes. This occurs despite the suggestion of such a variation in women (Figure 3). Although the concentration appears to maximize during combined donor day 8, corresponding to the androstenol peak, the variation due to experimental procedure for isolation of this compound was too great. We must await further experimental data before concluding the presence of a menstrual variation for DHEAS.

Inspection of the data in Table 2 and Figures 2 and 3 did suggest that the differences in levels of DHEAS between males and females might be significant. To test this, the Mann-Whitney U test was used. The results revealed that men do secrete more DHEAS ($U = 33, p = 0.025$). Figure 5 shows the median value and interquartile range of DHEAS concentrations for men and women.

Several of the male samples were also surveyed for the presence of ali-

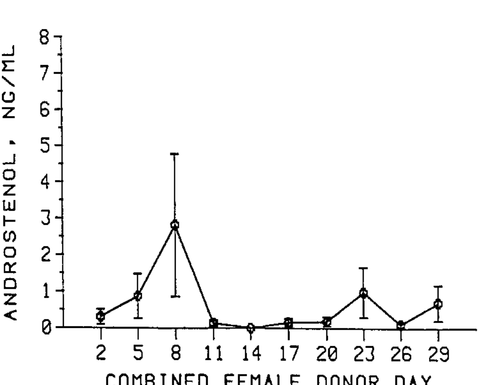

FIG. 4. This figure represents the variation in androstenol concentration across the combined female donor secretions. For each data point we have plotted 1.96 × standard deviation of the isolation technique. Androstenol appears to be produced in greater amounts in the pads comprising combined donor day 8. This is the midfollicular phase for the subjects.

phatic acids. Acids which range from C_2 to C_{18} chain length were found. Both the chromatographic retention times and mass spectral data of lower-molecular-weight acids from two of the male batches suggest the presence of acetic, propionic, isobutyric, butyric, isovaleric, valeric, and isohexanoic acids. Although C_8 and C_{10} acids are present, we cannot say which members of this series are represented.

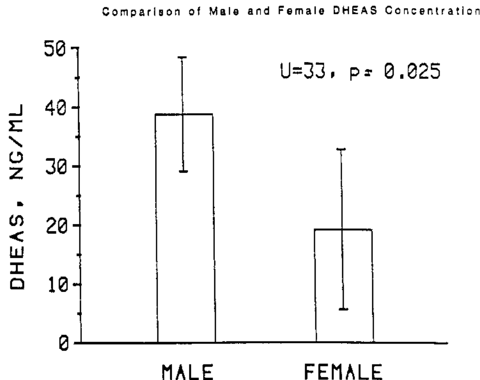

FIG. 5. A comparison of the concentration of DHEAS in male and female subjects. The data show the median value for this compound in each of the subject groups and the interquartile range. The Mann-Whitney U test performed on these data reveals significant differences.

DISCUSSION

The results of these experiments suggest that men secrete more DHEAS in their axillary region than do women. They also suggest that there are different rates of production of androstenol in the axillary region of women at different times of the menstrual cycle and perhaps at different times for men. In women, there has already been revealed a cycle variation in menses onset with respect to the lunar cycle. We have previously reported that women who menstruate every 29.5 $\pm$ 1 days (the same cycle length as the moon's repeating cycle), tend to menstruate in the full moon part of the lunar cycle (Cutler, 1980; Friedman, 1981). The presence of a seasonal variation in plasma androgens of men and their related implications for a pheromonal influence has been recently reviewed (Cutler and Garcia, 1984). It is therefore reasonable, although not yet studied, that men also will show a seasonal variation in reproductive endocrine rhythm that may be reflected in the constituents of the axillary secretions.

While these results do not definitively show which axillary constituents influence women's cycles (e.g., menstrual synchrony and/or menstrual cycle regularization), they do suggest that there are different patterns of production for at least two of the steroids. Moreover, the extracts do contain a number of other odoriferous compounds which should be quantitatively measured to see if there is a concerted increase in the entire odor profile at the key times in the female menstrual cycle (i.e., combined donor day 8) and during the fall season in males.

The use of ethanol as the solvent for the extraction of the original pads was not ideal, given our expectation of large amounts of lipophilic substances in the axillary secretions. However, the choice of the solvent was dictated by safety requirements for human testing and, thus, all the analyses of axillary products had to employ ethanol. Despite its low lipophilicity, ethanol still managed to remove a great number of lipid-like substances, as indicated by the GC-MS analysis. In addition, the most important consideration was the fact that the extracts did alter the menstrual cycle (Cutler et al., 1986; Preti et al., 1986), and therefore, ethanol does remove sufficient active components to elicit a biological effect.

Several other investigators have examined the steroid substances of axillary secretions in a quantitative fashion. Bird and Gower (1980) made quantitative measurements of androstenone in male and female axillary secretions using radioimmunoassay techniques. An earlier study done by Brooksbank et al. (1974) estimated the amount of androstenol taken from the combined extract of seven male donors who wore pads under their arms for a number of days in succession. The amounts obtained from this study suggested that each male produced approximately 50–100 ng per day in his axillae. This number, when corrected for the extraction efficiencies which we found, agrees very well with our results. Our male donors show amounts in their extracts which range be-

tween 0.1 ng and 5 ng. In addition, although other studies (Labows, 1986) have suggested the presence of isovaleric acid in the axillary secretions, our data suggests that an entire series of aliphatic acids is present in male samples.

As axillary extracts alter female menstrual cycles, further studies of the components of this extract continue in our laboratory with the goal of determining which individual constituents and/or groups of constituents alter this important physiological function.

Acknowledgments—This research was supported in part by a grant from the National Science Foundation, BNS 82-03018. We thank Dr. James Leyden, Ken McGinley, and Joseph Nicholson of the Duhring Laboratories, Department of Dermatology, University of Pennsylvania, for their screening of axillary secretion donors for the correct microflora and odor production; in addition we thank Mrs. Janice Blescia for processing the manuscript.

MALE-PRODUCED AGGREGATION PHEROMONE IN PEA AND BEAN WEEVIL, *Sitona lineatus* (L.)[1]

MARGARET M. BLIGHT and LESTER J. WADHAMS

Rothamsted Experimental Station
Harpenden, Herts., AL5 2JQ, U.K.

(Received February 12, 1986; accepted April 25, 1986)

Abstract—The attraction of *S. lineatus* to live baits comprising *S. lineatus* feeding on *Vicia faba* (L.) was studied in a field experiment in the early spring. There was clear evidence that male *S. lineatus* produced an aggregation pheromone which attracted approximately equal numbers of both sexes from overwintering sites. No evidence was obtained for the production, in the spring, of any semiochemical by female weevils.

Key Words—*Sitona lineatus*, pea and bean weevil, pea leaf weevil, Coleoptera, Curculionidae, aggregation pheromone.

INTRODUCTION

The pea and bean weevil, *Sitona lineatus* (L.), a pest of leguminous crops (Bardner et al., 1983; El-Lafi, 1977), is widely distributed throughout Western Europe, the Middle East and the northwest region of North America. It has recently been found also in eastern North America (Hoebeke and Wheeler, 1985). The biology of this insect was first documented in detail in Britain by Jackson (1920), and it has since been studied intensively by several workers, including Andersen (1931) and Hans (1959) in Germany.

Adult weevils overwinter in sheltered situations in long grass, clover, lucerne, or the stubble of pea and bean fields. They migrate to the preferred food plants, peas, beans, and vetches (Jackson, 1920; Hans, 1959), in the following spring when mating occurs and egg laying commences. Adult feeding damage, consisting of characteristic semicircular notches in the margins of leaves is most obvious, but more serious damage is caused by the larvae which live in the soil and feed on the root nodules.

The production of aggregation pheromones by several weevils, including *Anthonomus grandis,* three *Sitophilus* spp., and three *Pissodes* spp., is well-documented (Hardee et al., 1969; Tumlinson et al., 1969; Walgenbach et al., 1983; Fontaine and Foltz, 1982; Booth et al., 1983). We are therefore investigating the production by *S. lineatus* of pheromones which might be used to detect, monitor, and mass trap these insects or to time insecticide application. In this paper we present evidence for the presence of a male-produced aggregation pheromone in *S. lineatus*. The identification of and initial field studies on some components of this pheromone have been published elsewhere (Blight et al., 1984).

METHODS AND MATERIALS

Insects. S. lineatus used in the experiments were adults which had overwintered in the field. Weevils were collected in early spring from cultured broad bean (*Vicia faba*) plants which had been placed out on Rothamsted farm in areas where field beans had grown in the preceding year. They were sexed by examination of the ventral posterior abdominal segments (Jackson, 1920). Males and females were maintained separately, until use, on broad bean plants, under a controlled 16:8 (light–dark) photoperiod with a temperature of 15–16°C in the light and 9–10°C in the dark period.

Traps. The nonsticky cone traps (Figure 1) were similar in design to the Leggett trap (Leggett et al., 1975) used for capturing the cotton boll weevil, *Anthonomus grandis*. The base, A, consisted of an inverted yellow polythene bucket (26 cm diameter at lower edge, narrowing to 16 cm diameter × 25 cm high) from which the bottom had been removed. Surmounting the base was a cone, B, (24 cm diameter at lower edge, narrowing to ca. 5 cm diameter at upper edge × 27 cm high) made of woven stainless-steel square mesh wire cloth, aperture size 0.40 mm. The cone was held away from the base by three plastic spacers, G. A transparent polystyrene circular collecting pot, C, (7.5 cm diameter, narrowing to 6 cm diameter × 11 cm high) was held on the top of the cone with nylon shock cord. It contained a small (5 cm diameter × 8 cm high) wire cloth cone, D, which hindered the escape of live weevils. The assembled trap was held down on the soil by nylon shock cord guys, E, attached to tent pegs, F. Insects were able to gain access to the trap either by walking over the outside of the base and entering under the bottom edge of the large cone or by walking straight up the inside of the base from the ground. As the latter appeared to be the preferred route, six semicircular holes (3 cm radius) were cut out at the lower edge of the base to allow easier access.

Live Baits. Each bait consisted of a 13-cm pot of five broad bean (Sutton variety) shoots enclosed in a fine mesh terylene bag. The bag was taped tightly to the pot, the weevils were added, and the bag was closed securely with a

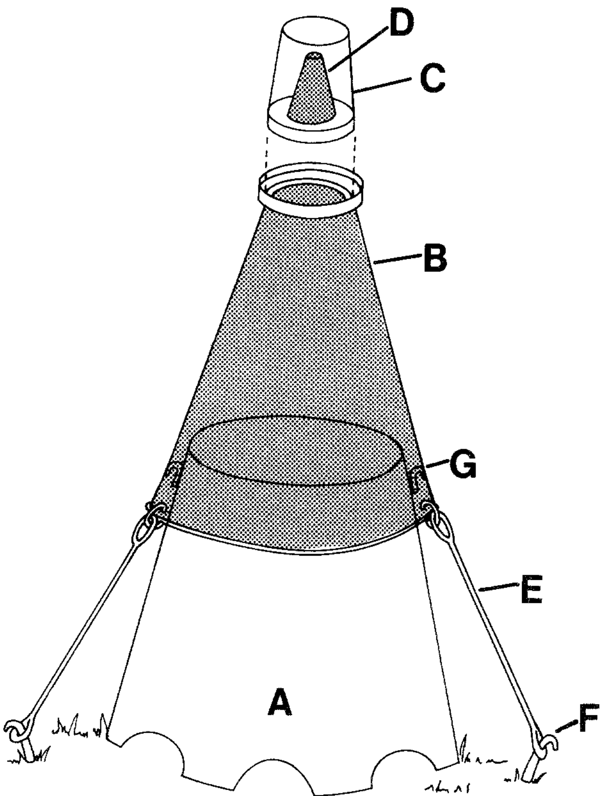

FIG. 1. Diagram of cone trap. A, base; B, cone; C, collecting pot; D, small cone; E, shock cord guy; F, tent peg; G, spacer.

rubber band. The five treatments (baits) were a blank control (pot containing soil only, enclosed in a bag), broad bean plant, and plants with, respectively, 40 females, 40 males, and 40 males plus 40 females. When the treatments were set out in the experiment, each pot was sunk into the ground so that the top of the pot was level with the soil surface, and a cone trap was then placed over the top. The plants were watered every day. When the experiment was terminated the numbers of live weevils of each sex present on the baits were recorded.

Experimental Design. The experiment was carried out on Rothamsted Farm, Harpenden, Hertfordshire, April 12–26, 1984. Three blocks were set up, two of which were towards the edges of fields where field beans had grown in 1983, and the third was on a field approx. 4 m from a wood. On each site, the treatments, 8 m apart, were placed in a row, parallel with the hedgeline. On two of the sites, the treatments were approx. 4 m out from the hedgerow and

wood, respectively, but on the third, because of farming operations, they were 1 m in from the hedge.

A randomized complete block design, with periodic rerandomization within the blocks, was used. Each treatment occurred once in each block, and each block was rerandomized when a minimum of 50 weevils had been caught. Weevils were removed from the traps each day and were stored alive at 6°C until sexed and counted.

Total catch data were subjected to the transformation $x = \log_e (t + 1.0)$ where x and t were the transformed and untransformed counts, respectively. Factorial analyses of variance were performed on these data and on the ratio of males to males-plus-females caught by each treatment.

RESULTS AND DISCUSSION

The catch data, derived from 12 replicates, are shown in Table 1. Because of uneven weevil distribution among the three sites, eight of the replications were performed on one site, with the other two sites yielding two replicates each.

Only low numbers of weevils were caught by either the blank control or the bean plant alone (5.4% and 5.6%, respectively, of the total catch). Although a few more weevils (7.3% of the total caught) were trapped by treatment 2 containing females, the "female effect" was not significant (Table 2). However, treatments 1 and 3, containing males, were highly attractive to both sexes, which were trapped in approximately equal numbers ("male effect" significant at $P < 0.001$, Table 2). The presence of females with males had no effect on

TABLE 1. FIELD RESPONSE OF *S. lineatus* TO TRAPS BAITED WITH MALE AND/OR FEMALE *S. lineatus* FEEDING ON BEAN PLANTS[a]

Treatment	Mean no. of weevils caught per replicate (range)	Sex Ratio (♂ : ♀)[b]
1. Bean plant + 40 ♂♂	31.3 (13–78)	1.0:1
2. Bean plant + 40 ♀♀	5.4 (0–14)	0.9:1
3. Bean plant + 40 ♂♂ + 40 ♀♀	29.3 (8–72)	0.9:1
4. Bean plant	4.2 (0–13)	0.9:1
5. Blank control	4.0 (0–10)	0.6:1

[a]The total number of weevils caught in 12 replicates was 891. At the end of the experiment, at least 85% of each sex of the *S. lineatus* comprising the baits remained alive.

[b]Factorial analysis of variance of the ratio of males to males plus females showed no significant differences between the five treatments.

this attraction (Table 2), and there were no significant differences between the sex ratios of weevils trapped by the five treatments.

These results indicate clearly that *S. lineatus* produces an aggregation pheromone in the spring. In common with most curculionids, it is male-produced (see references cited in the Introduction). However, in the experiment reported here, the possibility that some of the bean volatiles synergized the activity of the male-produced pheromone cannot be excluded. Indeed, we have independent evidence that the three synthetic bean volatiles, (*Z*)-3-hexen-l-ol, (*Z*)-3-hexen-l-yl acetate, and linalool, synergize the male-produced attractant, 4-methyl-3,5-heptanedione (Blight et al., 1984).

There was no evidence that female *S. lineatus* produced any semiochemical, although they may do so at other times of the year. Females of some curculionids, viz., *A. grandis* and *Cylas formicarius elegantulus* (Coffelt et al., 1978) produce a sex pheromone. In the case of *A. grandis,* it has weak attractancy compared to the male-produced aggregation pheromone (McKibben et al., 1977). However, the aggregation pheromone apparently functions mainly as a sex attractant after the insects are established on the host plants (Lloyd et al., 1983). A similar situation could exist with *S. lineatus* (Blight and Wadhams, unpublished).

The adaptive significance of an aggregation pheromone in these weevils is not clear. It has been suggested (Shorey, 1973) that coleopteran aggregation pheromones arose initially as mechanisms by which insects could cause others of the same species to aggregate at a suitable food source. The male-produced

Sitona pheromone presumably does assist the aggregation of the weevils in legume fields for the purposes of both feeding and mating. However, in this artificial monoculture it must be of far less importance to survival than in an environment comprising widely scattered food resources.

Acknowledgments—We thank J. McEwen and R. Moffitt for their help and cooperation with the field experiment, T. Dixon for statistical analyses, and J. Steinmann and M.C. Smith for technical assistance.

(Received February 13, 1986; accepted April 25, 1986)

Abstract—Contrary to constitutive resistance, inducible resistance to Mexican bean beetle (MBB) (*Epilachna varivestis*) herbivory in PI 227687 soybean leaves was positively correlated with total phenolic content and temporally unique, increased L-phenylalanine ammonia-lyase (PAL) and L-tyrosine ammonia-lyase (TAL) activities. Initial expression of the induced resistance was localized at or near the site of herbivory. Systemic parameters of the induced resistance also were observed. Inducible MBB resistance in PI 227687 soybeans apparently involves increased phenylpropanoid metabolism.

Key Words—Plant resistance, constitutive, inducible, soybean, Mexican bean beetle, *Epilachna varivestis*, Coleoptera, Coccinellidae, PI 227687, phenylpropanoid metabolism, PAL, TAL, total phenols.

INTRODUCTION

Plant resistance to insect pests involves at least two (i.e., constitutive and inducible) categories of parameters (Kogan and Paxton, 1983; Chiang and Norris, 1985). Constitutive parameters are expressed by the plant independent of environmental stresses. Such chemical parameters which are effective against Mexican bean beetle (MBB), *Epilachna varivestis* Mulsant, feeding have been studied partially in *Glycine max* (L.) Merr. PI 227687 soybeans by Chiang et

0098-0331/87/0400-0741$05.00/0 © 1987 Plenum Publishing Corporation

al. (1986). In this work, L-phenylalanine ammonia-lyase (PAL) and L-tyrosine ammonia-lyase (TAL) activities in given-age leaves of nonstressed PI 227687 plants showed characteristic temporal patterns which were distinct from those of such leaves on nonstressed, insect-susceptible "Davis" soybeans. Activities of these enzymes have previously been positively correlated with the biosynthesis of phytoalexins and other flavonoids which include antifeedants for insects (Ebel et al., 1984).

Inducible versus constitutive (i.e., stress-dependent versus stress-independent) chemical parameters of PI 227687 resistance to MBB feeding have now been compared. This study contributes new understanding toward an ultimate holistic comprehension of PI 227687 soybean resistance to *E. varivestis* and other herbivores.

METHODS AND MATERIALS

Rearing of E. varivestis. Egg masses of the Mexican bean beetle (MBB) were removed from snapbean (*Phaseolus vulgaris* L.) plants on disks cut from leaves with a No. 8 cork borer. Masses on disks were sterilized for 10 min in Clorox® bleach–distilled H_2O (1:50), and then rinsed for 10 min in distilled H_2O. Egg masses on leaf disks were then placed on a dry filter paper in the bottom of a Petri dish which contained a water-wetted filter paper attached to the inside of the lid. Such eggs were held for three to four days at 25°C for hatching. Larvae were returned to vigorous snapbean plants growing within cages in 16-hr photoperiod, 27°C, and 65% relative humidity in a greenhouse. Feeding larvae and adults were provided daily with vigorous snapbean plants.

Growing of Soybean Plants. Relatively insect-resistant *G. max* PI 227687 plants were grown and studied. Seeds were germinated in moistened vermiculite in flats under the same environmental conditions as were used for the experimentation. Such conditions were: (1) 15-hr photophase, using Metalarc® high-intensity (1000-W), full-spectrum metal halide lighting, 27°C, and 65% relative humidity in a greenhouse or (2) 14-hr photophase with 12 hr of full light intensity, i.e., 300–500 $\mu E/m^2/sec$; day temperature, 27 ± 1°C, and night temperature, 20 ± 1°C; and relative humidity, 65 ± 5%, in the University of Wisconsin Biotron.

Germinated plants were transplanted at the first-leaf stage into individual plastic pots. In greenhouse experiments, plants were watered two times per day in a sterilized potting mixture (i.e., compost–soil–sand–vermiculite, 5:5:2:1). Plants in biotron studies were potted in a support medium and were provided with 30–40 ml of one-half-strength Hogland's nutrient solution (Hammer et al., 1978) four times per day (i.e., every 6 hr). All experiments involved plants between the V2 and V3 stages of development (Fehr and Caviness, 1977).

Mexican Bean Beetle Feeding Assays. The substrate utilized in feeding bioassays was an 18-mm-diameter leaf disk. Each disk was positioned with its abaxial side up. Assay insects were given a choice between two PI 227687 disks, each from a plant which had received a specific "stress" treatment, presented in an opposed arrangement in a Petri disk arena adapted from Norris and Baker (1967).

Only adult female *E. varivestis* beetles that were 2 weeks old and had been starved 24 hr, but were water-satiated, were used in bioassays. Two MBB females were released in each Petri dish arena. Assays were run for 22 hr in complete darkness at 24 ± 1°C and 60 ± 5% relative humidity.

Evaluation of beetle feeding in the bioassays involved measuring area (cm^2) of leaf disk eaten using a model LI-3100 Area Meter (LICOR, Inc., Lincoln, NE).

Estimation of Phenols. The used analytical method was based on techniques of Price and Butler (1977). Single fresh leaves, just removed from the plant, were weighed and then homogenized in 5 ml 60% methanol in a 10-ml ground-glass hand homogenizer. Homogenate plus 1 ml 60% methanol rinse was filtered through Whatman No. 1 paper in a glass funnel using vacuum. The approximate 6 ml of filtrate were added to 50 ml double-distilled (dd) H_2O in a 250-ml flask. Three milliliters of each of two reagents (i.e., A and B) were next added to the flask. Reagent A was 0.1 M $FeCl_3$ in 0.1 N HCl and reagent B was 0.008 M $K_3Fe(CN)_6$. The mixture was allowed to react for 10 min for color development. After 10 min, the optical density of samples was determined with a B&L Spectronic 20 at 720 nm. A blank of identical composition except for omission of the homogenate was analyzed and its reading at 720 nm was subtracted from all other sample readings.

Results were expressed as catechin equivalents (CEs), using a standard curve prepared daily from fresh solutions of commercial D-catechin. A catechin equivalent is the milligrams of catechin/100 mg of soybean leaf tissue that would be required to give the observed absorbance.

Assays for L-Phenylalanine Ammonia-Lyase (PAL) and L-Tyrosine Ammonia-Lyase (TAL). Extraction and assay of PAL from soybean tissue employed the method of Zucker (1965) as modified by Ciepiela (1984). A 1.5-g aliquot of dried acetone extractables from PI 227687 soybean leaves was homogenized in 10 ml of 0.1 M borate buffer, pH 8.8, using a glass homogenizer. The homogenate was centrifuged at 14,000 *g* for 15 min at 4°C. An aliquot (0.7 ml) of the resultant supernatant was mixed directly with 1 ml 0.03 M L-phenylalanine, 1 ml 0.1 M borate buffer, pH 8.8, and enough dd H_2O to bring the total volume to 3 ml. Incubation was 60 min in a 37°C water bath, and enzyme activity in such aliquot mixtures was then determined spectrophotometrically as the increase in absorbance at 290 nm. The enzymatic reaction in samples was killed by addition of 1 ml 1 N HCl. Specific enzyme activity was

expressed as units per milligram protein in the enzyme extract. One unit of enzyme activity equals the amount of PAL required to produce 1 μmol of *t*-cinnamic acid in 1 hr under specific conditions. Soluble protein content of samples was determined using the reagent and methods of Bradford (1976).

Extraction and assay of TAL were conducted similarly to the methods used for PAL, except that the substrate, L-tyrosine, is not dissolved completely in 0.1 M borate buffer, pH 8.8, so the reaction mixture must be continuously shaken at 37°C. At the completion of incubation, 1 ml 1 N HCl was added to kill the reaction and to clear the otherwise cloudy solution so required spectrophotometry could be readily performed. Activity of TAL was measured as the change in absorption at 333 nm.

RESULTS

Comparative Antiherbivory to Mexican Bean Beetle. Experimentally inflicted MBB herbivory on the middle leaflet of the second leaf (i.e., first trifoliolate leaf) of PI 227687 soybeans resulted in a significant ($P < 0.01$ or 0.05) reduction in subsequent MBB feeding on other leaflets of this second leaf at both 12 and 24 hr after the stress (i.e., MBB herbivory) treatment (Table 1). Systemic MBB antiherbivory effects of the experimentally inflicted MBB herbivory on PI 227687 second leaves were observed on the first (i.e., unifoliate) leaves ($P < 0.05$) at 48 hr after the stress treatment (Table 1). Other antiherbivory comparisons of first or second leaves between MBB herbivory-stressed

TABLE 1. COMPARATIVE MEXICAN BEAN BEETLE (MBB) FEEDING ON LEAF DISKS FROM LEAVES (OR LEAFLETS) ON PI 227687 PLANTS EXPERIENCING PRIOR MBB HERBIVORY OR NO HERBIVORY IN STANDARDIZED BIOASSAY

Hours after treatment	Leaf No.	Mean ± SD cm^2 eaten per leaf disk[a]	
		Herbivory stressed	No herbivory
12	2[b]	0.30 ± 0.1[c]	0.53 ± 0.2
24	2[b]	0.22 ± 0.04[d]	0.32 ± 0.02
48	1	0.21 ± 0.03[e]	0.33 ± 0.01

[a] Results from all other bioassays of leaves 1–3 at various times after treatment were not significantly different, $P < 0.10$, *t* test, $N = 4$.
[b] Significantly different feeding on "other" leaflets, *t* test, $N = 4$.

versus -unstressed PI 227687 at 12, 24, 48, or 72 hr gave no significant difference ($P < 0.10$) attributable to treatment.

Total Phenolic Content of Leaves. At 4 or 8 hr after MBB herbivory, no leaves of the stressed PI 227687 soybeans showed a significantly ($P < 0.05$) greater total phenolic content than corresponding leaves on nonstressed plants. However, by 12 hr after this stress treatment, the herbivory-wounded (i.e., fed on) middle leaflet of the first trifoliolate leaf contained a significantly ($P < 0.05$) larger amount of total phenolics (Table 2). At 24 hr after the stress treatment, this wounded (middle) leaflet of the first trifoliolate leaf still contained a significantly larger ($P < 0.05$) amount than was in such leaflets from unwounded PI 227687 plants (Table 2). By 48 hr after the stress treatment, the greater average CEs ($P < 0.05$) were found in the nonwounded (other) leaflets of the wounded second trifoliolate leaf and in the unwounded first (unifoliate) leaf. By 72 hr after the MBB herbivory, none of the leaves (i.e., 1–3) on the wounded (stressed) plants had significantly ($P < 0.05$) more total phenols than did corresponding leaflets or leaves from nonstressed PI 227687 soybean plants.

L-Phenylalanine Ammonia-Lyase (PAL) and L-Tyrosine Ammonia-Lyase (TAL) Activities. MBB herbivory on the middle leaflet [Leaf 2(M), Figures 2 and 4] of the first trifoliolate leaf of PI 227687 soybeans significantly ($P < 0.05$ or 0.01) increased levels (i.e., units per milligram protein) of both PAL and TAL in plants (Figures 1–4). The temporal pattern of activity for each enzyme also differed distinctly from that in the nonstressed plants. Major in-

TABLE 2. COMPARATIVE TOTAL PHENOL CONTENT IN PI 227687 SOYBEAN LEAVES AT INDICATED INTERVAL AFTER MBB HERBIVORY (TREATMENT) ON MIDDLE LEAFLET OF FIRST TRIFOLIOLATE LEAF OR IN LEAVES OF NONSTRESSED (CONTROL) PLANTS

Hours after treatment	Leaf No.	CE[a] (Mean ± SD per leaf)	
		Herbivory stressed	No herbivory

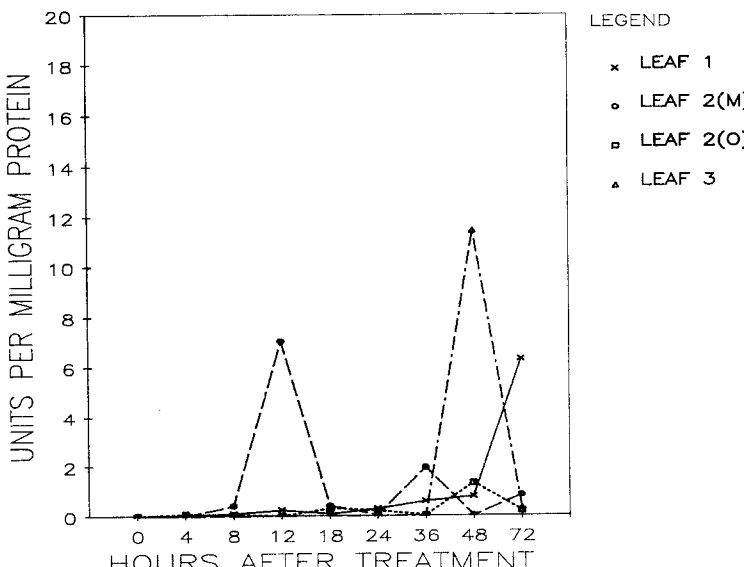

FIG. 2. L-Phenylalanine ammonia-lyase (PAL) activity in the indicated leaf, or leaflet, of experimentally stressed PI 227687 soybean plants, at the given time after the herbivory (stress) treatment, growing in a biotron room. LEAF 2(M) refers to the middle leaflet of the first trifoliolate leaf; and LEAF 2(O), to the outside (lateral) leaflet(s) of such a leaf.

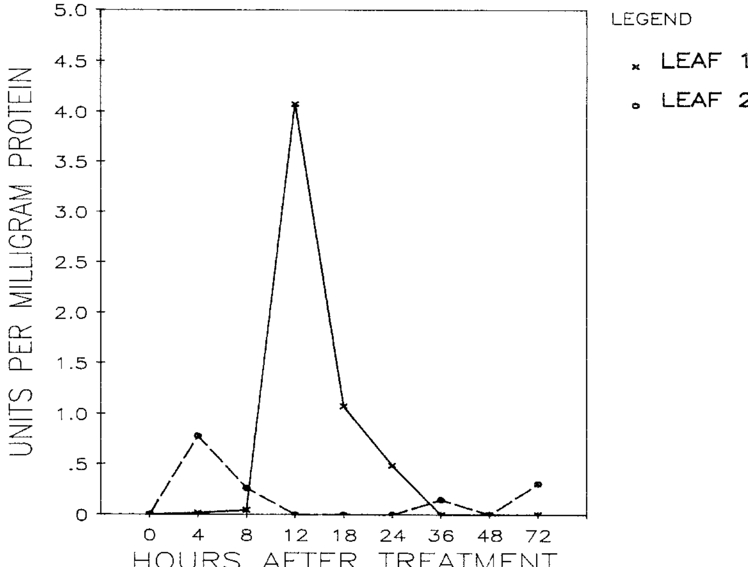

FIG. 3. L-Tyrosine ammonia-lyase (TAL) activity in the indicated leaf of healthy (nonstressed) PI 227687 soybean plants, at the given time after treatment, growing in a biotron room.

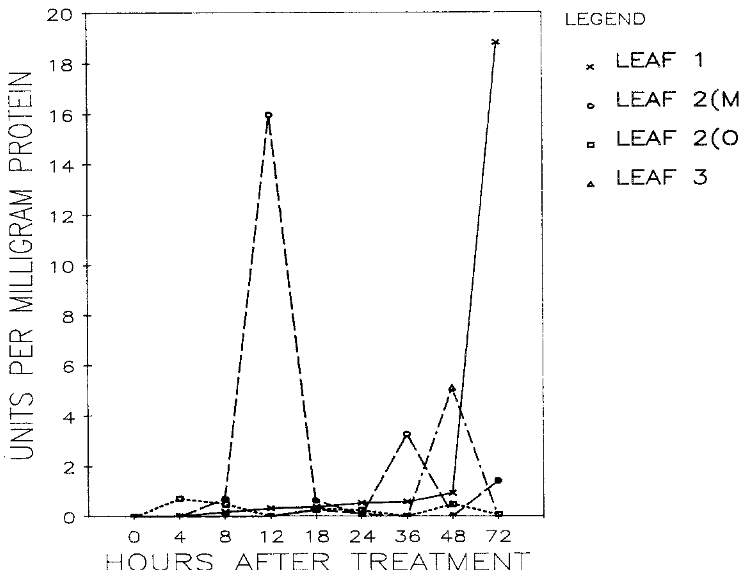

FIG. 4. L-Tyrosine ammonia-lyase (TAL) activity in the indicated leaf, or leaflet, of experimentally stressed PI 227687 soybean plants, at the given time after the herbivory (stress) treatment, growing in a biotron room. LEAF 2(M) and LEAF 2(O) have the same meanings as in Figure 2.

duced activity ($P < 0.01$) for each enzyme was limited to the "attacked" middle leaflet [Leaf 2(M), Figures 2 and 4] until 48 hr after the herbivory treatment. In each case, induced activity ($P < 0.01$) next appeared in leaf 3 (i.e., the youngest leaf present) (Figures 2 and 4). Activity of both enzymes increased ($P < 0.01$) markedly in the unifoliate leaf (i.e., the oldest leaf present) by 72 hr after treatment.

DISCUSSION

Stress (MBB herbivory) -induced higher levels of PI 227687 resistance to subsequent MBB feeding occurred first locally at or near the site of the initial stress (i.e., herbivory), which was the middle leaflet of the first trifoliolate leaf. This increased antiherbivory was positively correlated with an elevated level of total phenolics and temporally and quantitatively altered patterns of active PAL and TAL enzymes in such tissues. Such altered phenolic and enzyme levels occurred within 12 hr after the MBB herbivory. Systemic effects from the herbivory were evidenced as significant increases in PAL and TAL activities in leaf 3 by 48 hr after treatment. Increased antiherbivory activity and altered levels of total phenolics and active PAL and TAL enzymes in leaf 1 by 48 hr after the initial treatment provided further evidence of systemic effects.

Temporal aspects of the observed induced greater MBB resistance, including increases in the total phenolics and PAL and TAL activities, are compatible with the reported timetables of similar events associated with microorganismal induction of phytoalexins in soybeans (Sequeira, 1983; Darvill and Albersheim, 1984; Ebel et al., 1984).

Abstract—Factors contributing to resistance of maize to infestation by the corn weevil *Sitophilus zeamais* were investigated in four populations of indigenous and improved maize from Belize. Resistance was related to the antifeedant properties of grain as well as sugar content and mechanical hardness. Grain extracts of all populations of maize significantly reduced insect feeding on treated artificial diets when compared to control diets. Consumption of treated diets was negatively correlated with phenolic content of the grain extract. An analysis by GC-MS indicated that ferulic acid and *p*-coumaric acid were the principal phenolics present in the extracts, and insect feeding was strongly deterred when pure substances were added to insect diets. Fluorescence associated with ferulic acid and related compounds in grain sections was located in the pericarp and aleurone layer and was especially intense in the most resistant grain variety.

Key Words—*Sitophilus zeamais*, Coleoptera, Curculionidae, maize weevil, maize, resistance, antifeedant, sugar content, hardness, phenolic content, ferulic acid, *p*-coumaric acid.

INTRODUCTION

Postharvest losses of grain to stored product insects remain among the most serious problems faced by small farmers throughout the tropics, accounting for

[1]Contribution No. 838.

0098-0331/87/0400-0751$05.00/0 © 1987 Plenum Publishing Corporation

substantial losses in less-developed countries (CIMMYT, 1970–1971). In attempts to reduce losses it must be remembered that small farm conditions for storage are often very poor, and, because grain is intended for human or animal consumption, pesticide use should be avoided. For this reason, selection of lines that are resistant to stored product insects is one practical way to deal with these pests (Dobie, 1977).

Unfortunately, breeding programs have been concerned mainly with increased yield and resistance of vegetative growth tissues to insect pests and fungal pathogens. Resistance in storage has received less attention, resulting in an increase in the severity of storage problems as traditionally used varieties are replaced by improved ones (Fortier et al., 1982).

In order to reduce gain losses of the small farmer at the postharvest level, it is important to identify resistant lines in the maize gene pool, pinpoint the mechanisms of resistance, and focus on stable heritable characters for breeding programs.

It has long been known that resistance to insect attack is strongly correlated with physical factors such as kernel hardness, husk protection (Singh and McCain, 1963), and low moisture content (Rivnay, 1972). Feeding stimulants correlated with susceptibility are sugar (Singh and McCain, 1963), and tryptophan (Betanzos, 1980), but do not include protein content or fat in seeds (Singh and McCain, 1963). Attractants are also known to occur in seeds. Yamamoto et al. (1975) have isolated a number of volatiles (e.g., hexanoic acid) that are attractants to *Sitophilus* spp.

No studies have been made of secondary metabolites and their relationships to the resistance of corn seeds to maize weevil.

The present study examines factors correlated with exceptional resistance in lowland tropical races of maize from Belize (Fortier et al., 1982), with special emphasis on the presence of phenolics in the grain.

METHODS AND MATERIALS

Maize Seed. Maize grain *Zea mays* L. collected in Belize, C.A., as described in Fortier et al. (1982), was used. Two populations had exceptional resistance to corn weevil (designated as Belize local yellow and Belize local white) and one population, Belize local black, was moderately susceptible. One improved double-cross hybrid variety, Pioneer 230 which was highly susceptible to weevils, was also included. Ordination and cluster analysis of 16 taxonomic characters, derived from measurements on the local populations indicated that all had affinities to the ancient indigenous group of maize races (Fortier et al., 1982). A very close relationship between Belize local yellow and the land race Nal-Tel amarillo was evident. Belize local black was linked to land race Negro de Tierra Caliente and Belize local white linked with land race Dzit-

Bacal. The hybrid had greatest affinity with upland races of the exotic group of races of maize.

Insect Culture. Corn weevils (*Sitophilus zeamais* Motsch.) from a stock maintained in our laboratory were cultured and kept in screened Mason jars with locally produced maize grain. Jars were placed in a controlled environment chamber at 27°C and 70% relative humidity. Photoperiod was 16:8 hours light–dark.

Choice Tests. For relative consumption of maize populations, 20 unsexed, 14-day-old adults from the stock culture were offered 10 g of each population of grain in a feeding arena. Grain was equilibrated to constant humidity for six weeks before the test and weighed weekly for three weeks after the introduction of the insects.

For emergence tests, 120 insects were offered 20 g of each variety in a feeding arena. After one week of exposure, the number of live adults in each variety were counted and removed, and percentage of seeds with oviposition sites determined by counting under a microscope. Each maize population was then transferred to an individual screened jar and new emergence assessed at 22 days.

Extraction Procedures. Extraction of 10 g milled grain was performed using the hydrolytic procedure of Krygier et al. (1982) for total phenolic acids and dissolved in a final volume and 1 ml ethanol. Acetone extractions for total soluble phenolics and phenolic glycosides were performed as follows: 10 g of corn seeds were placed in liquid nitrogen, ground in a ball mill, and put into 35 ml acetone. After centrifugation (15 min 1000 *g*), the supernatant was reduced to dryness in vacuo, dissolved in 10 ml of 95% ethanol, microfuged, and the supernatant retained. Four replicates of each extraction were assayed in the feeding tests.

Preparation of Diets and Antifeedant Assay. A diet based on wheat flour was prepared as follows: 1 g white wheat flour, 1 ml of extract from corn in ethanol (the equivalent of 1 g corn grain), and 5 mg sorbic acid were placed in a 5-g mortar. The ethanol was evaporated and 0.5 ml water added to make a paste. The paste was rolled to a sheet 2 mm thick and seven 1-cm disks were cut. Control diets were made with addition of only ethanol. Diets treated with pure substances were made in a similar manner from stock solutions of the compounds in ethanol.

For the feeding assay, four weighed disks of each diet type were placed in a 9-cm Petri dish with five unsexed corn weevil adults and kept at 27°C, 70% relative humidity, 16:8 light–dark in an incubator. The disks were later weighed at two-day intervals to day 10. Three disks were kept under similar conditions to monitor weight changes not associated with insect feeding. Calculations of consumption were made from weight changes corrected for nonfeeding changes. Wheat flour was chosen as the artifical diet because of its exceptionally low phenolic content as compared to corn (Krygier et al., 1982).

Chemical Analysis. Total sugar content of grain was assessed by the method of Dubois et al. (1956) and total phenolics of extracts by the method of Swain and Hillis (1959). Extracts were analyzed on a Beckman HPLC using a reverse phase 5 μm ODS column and isocratic elution with 1 : 1 MeOH–1% HOAc in H_2O. GC-MS analysis was performed on TMS derivatized extracts using a VG7070-E spectrometer with a 3% OV-1 column programmed at 150°C and 10°C/min. Two-dimensional TLC of extracts was performed on TLC micro-polyamide foils (F1700, Schleicher and Schüll) using aqueous developing solvent: butanol–acetone–glacial acetic acid, 10 : 5 : 5; and organic developing solvent: chloroform–methanol–butanol–water, 55 : 22 : 20 : 3.

Hardness Tests. Mechanical hardness of seeds was tested with an Instron model 4201 instrument fitted with an electronic force transducer. Hardness was measured as the force to peak (N) in a compression test between two flat steel plates (Timbers et al., unpublished).

Fluorescence Microscopy. Autofluorescene associated with ferulic acid was detected by fluorescence microscopy described previously (Fulcher et al., 1972, 1981). Briefly, individual corn kernels were sectioned 20–30 μm thick on a freezing microtome, the sections fixed to glass microscope slides, and mounted in immersion oil under a cover glass for detection of phenolic autofluorescence. Phenolic fluorescence was also enhanced in the outer tissues by staining sections with boronate (Fulcher and Wong, 1980). With or without boronate staining, all sections were examined with a Zeiss Universal microscope equipped with III RS epi-illuminating condenser and HBO 200-W illuminator. Fluorescence filters included a 365-nm exciter filter and long-pass 420-nm barrier filter. Boronate has been used as a fluorescent indicator for flavonoid compounds (Fulcher and Wong, 1980), and it also markedly enhances the *in situ* fluorescence of known deposits of ferulic acid and related cinnamates in sections of wheat, oats, and barley. Parallel sections were also treated with dimethylaminocinamaldehyde for demonstration of possible aromatic amines (Fulcher et al., 1981).

RESULTS AND DISCUSSION

The exceptional resistance of two populations of maize (local white and local yellow) is evident in the choice test (Table 1) when the consumption of grain by adults and new emergence at 22 days for these populations is compared to the data for a susceptible land race (local black) and a highly susceptible improved variety (Pioneer 230). An examination of two factors (correlated with resistance or susceptibility), mechanical hardness and sugar content, shows (Table 2) that the least susceptible populations (local yellow and local white) had the greatest hardness and lowest sugar content. The more susceptible maizes (Pioneer 230 and local black) had higher sugar content and less hardness.

The presence of extractable antifeedants in the grain is demonstrated in

TABLE 1. VARIATION IN CONSUMPTION, SURVIVAL, AND REPRODUCTIVE CAPACITY OF *S. zeamais* WITH RESPECT TO FOUR MAIZE POPULATIONS

Population of maize	Consumption by adults (mg/week)	No. of live adults found after 1 wk exposure	Seeds with oviposition sites (%)	Total new emergence at 22 days
Pioneer 230	15.1	70	100	77
Local black	3.9	32	100	31
Local white	1.8	9	40	10
Local yellow	1.7	3	26	0

Table 3. Treatment of artificial insect diets with hydrolyzed total phenolic extracts of each grain population led to significantly lower consumption of diets as compared to consumption of untreated controls ($P \leq 0.05$). The antifeedant properties of the hydrolyzed extracts of the three land races were significantly higher than Pioneer 230, and the order of increasing antifeedant activity is the same as the order of resistance in Table 1.

As the total phenolic extracts were hydrolyzed, a second extraction was undertaken of grain in acetone at liquid nitrogen temperatures to extract the soluble glycosides. The consumption of diets treated with these extracts at concentrations found in corn grain was also significantly different from controls ($P \leq 0.05$) but not significantly different among varieties.

Consumption as percent of control was reduced more by the hydrolyzed than unhydrolyzed extracts (except for Pioneer 230). This finding is presumably related to a greater total amount of phenolics and is similar to the observations of Woodhead and Cooper-Driver (1979), who examined the effect of phenolics

TABLE 2. HARDNESS AND SUGAR CONTENT CHARACTERISTICS OF MAIZE POPULATIONS USED

	Total sugars[1] (%)[a]	Instron hardness (mean force at peak compression, *N*)[b]
Pioneer 230	4.0	408

Local black	3.89c	3.43b
Local white	3.67c	3.57b
Local yellow	3.66c	3.25b

[a]For ANOVA with total phenolic data: $F = 3.76$; $P = 0.001$; $df = 51$; and with acetone extract data: $F = 4.62$; $P = 0.0001$; $df = 51$. Means followed by the same letter are not significantly different ($P = 0.05$) in Duncan's multiple-range test. Phenolic contents of the extracts are reported in Figure 1.

from sorghum on feeding of *Locusta*. They also emphasized the possibility of synergism, as mixtures of compounds were markedly inhibitory.

The antifeedant properties of the total phenolic grain extracts as measured by consumption (data from Table 3) were negatively correlated ($r = -0.84$) with the phenolic content of the extracts (Figure 1A). For the acetone extracts the correlation was -0.96 (Figure 1B). These results suggest that phenolics are the major substance contributing to reduced feeding.

An analysis of the total phenolic extracts by GC-MS and HPLC indicated that more than 80% of the phenolic material in all varieties was present as ferulic acid (Figure 2), with *p*-coumaric acid being the second most abundant substance (up to 20%). Other phenolic substances such as syringic, caffeic, protocatechuic, and vanillic acids, as have been reported by Sosulski et al. (1982), were evident at much lower concentration in two-dimensional chromatography of the extracts on polyamide.

A preliminary phytochemical investigation of the acetone extracts showed that they contained a variety of phenolic substances including free and esterified phenolic acids, as described by Sosulski et al. (1982). We also investigated the possibility that glycosides of hydroxamates, which are correlated with resistance of maize leaves to *Ostrinia nubilalis* (Klun and Robinson, 1968), were present in these extracts. A GC-MS analysis of the acetone extracts, before or after hydrolysis, indicated that none of the major peaks were hydroxamates, although these substances were readily detected by the same GC-MS procedure after germination, as described by Woodward et al. (1979).

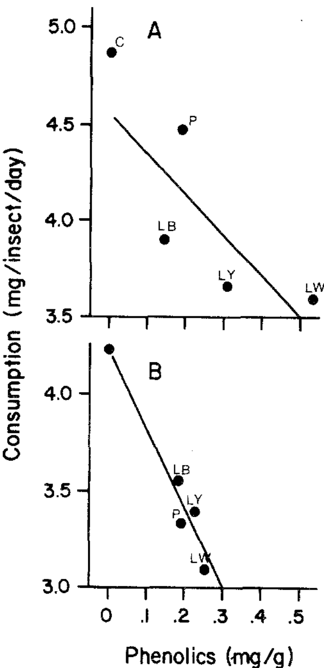

FIG. 1. Consumption by maize weevil of artificial diets treated with extracts from the four maize populations investigated plotted aganist the phenolic content of the extract. (A) Total phenolic extracts (hydrolyzed); (B) acetone extracts (unhydrolyzed).

The feeding response of *Sitophilus* to a number of pure phenolic substances (Table 4) indicates clearly that these substances have significant antifeedant properties ($P \leq 0.05$) at a concentration of 0.3 mg/g, close to the phenolic content of grain. Ferulic acid was a highly effective antifeedant at concentrations as low as 0.05 mg/g (data not shown). Ferulic acid is present in maize grain as a free acid in small quantities, but soluble glycosides and polysaccharide-bound ferulic acid are probably released as the free acid during digestion in the insect. Free ferulic acid release could make a substantial contribution to reduction of feeding by *Sitophilus* on grain. Undoubtedly, the real situation in grain is considerably more complicated due to presence of phenolics such as glycosides, synergism, etc.

Fluorescence microscopy was used to locate phenolics in sections of maize seeds. All varieties showed strong blue autofluorescence in the outer tissues, much of which has been associated with the presence of ferulic acid in other cereals (Fulcher et al., 1972). The exceptional fluorescence was enhanced by boronate staining (Figure 3) and was particularly intense in the pericarp of local

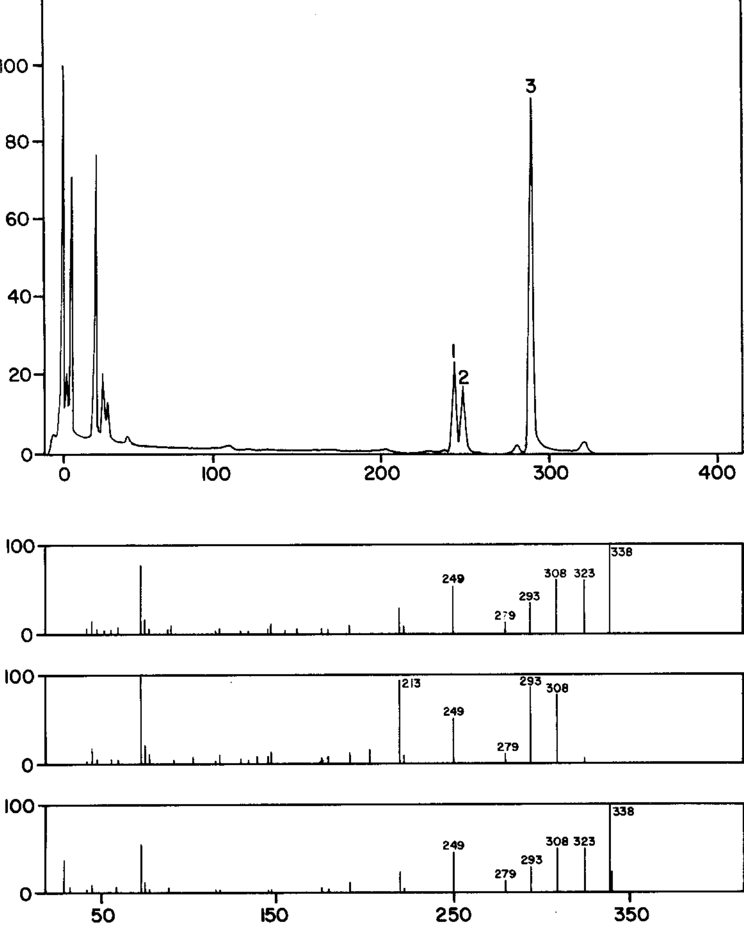

FIG. 2. GC chromatogram and normalized spectra of TMS-derivatized total phenolic extracts from local yellow corn: (1) *cis*-ferulic, (2) *p*-coumaric, and (3) *trans*-ferulic.

white and to a lesser extent in local yellow. Both local white and local yellow were highly resistant to attack by *Sitophilus*, and such resistance appears to be correlated with a higher proportion of phenolics bound to the cell wall, since the susceptible Pioneer and local black had feeding deterrent properties comparable to that of the resistant population in the soluble acetone extracts but not the total phenolic extracts which includes bound material. In the local white pericarp (Figure 3a), the distribution of fluorescent compounds was relatively homogeneous, while in that of the local yellow, the fluorescence was notably more intense in the outer regions of the pericarp (Figure 3b). The local black

TABLE 4. CONSUMPTION OF DIETS TREATED WITH PURE PHENOLIC SUBSTANCES BY *Sitophilus zeamais*[a]

Treatment	Consumption (mg/insect/day)
Control	3.49a
BOA	2.70b

6-MBOA	2.24c
Ferulic acid	2.04c

[a]Concentration was 0.3 mg/g diet. Means followed by the same letter are not significantly different ($P \leq 0.05$) in Duncan's multiple-range test. (ANOVA values $F = 15.48$; $P = 0.0001$; $df = 51$).

pericarp showed a somewhat lower level of fluorescence (Figure 3c), while the Pioneer pericarp showed an exceptionally low level of fluorescence (Figure 3d).

In addition, the cytoplasm of the aleurone cells stained pink to red with dimethylaminocinnamaldehyde, suggesting the presence of aromatic amines (Fulcher et al., 1981). Intensity of staining was greater in the three local populations than the hydrid (not shown). The presence of these substances in the outer tissues of maize seeds is consistent with their proposed defensive role. In addition, their discontinuous distribution suggests that their concentration in these tissues is probably higher than that used in the feeding deterrence assays. The secondary chemistry of maize is complex, especially if spatial organization of substances in tissues and the full range of phenolics in free esterified and bound forms in maize is to be considered. Besides their contribution to reduced feeding, phenolics may also contribute to physical factors such as hardness. For this reason, more detailed phytochemical-biological activity investigations are in progress.

There are few other reports of chemical deterrents to *Sitophilus* spp. Maize flour is known to contain inhibitors of the digestive proteases of *Sitophilus* (Baker, 1982). These are proteins themselves and would not likely be present in any of the extracts used in the present study. A group of secondary metabolites, the sesquiterpene lactones, isolated from species of the Apiaceae (Nawrot et al., 1983) and Asteraceae (Nawrot et al., 1982) have antifeedant activity to *Sitophilus granarius*.

Deterrent effects of phenolics to other maize feeding insects are well documented. Recently, a new flavanoid glycoside, maysin, isolated from corn silk of the land race, "Zapalote chico" has been shown to have exceptional growth-reducing properties to *Heliothis zea* (Waiss et al., 1979).

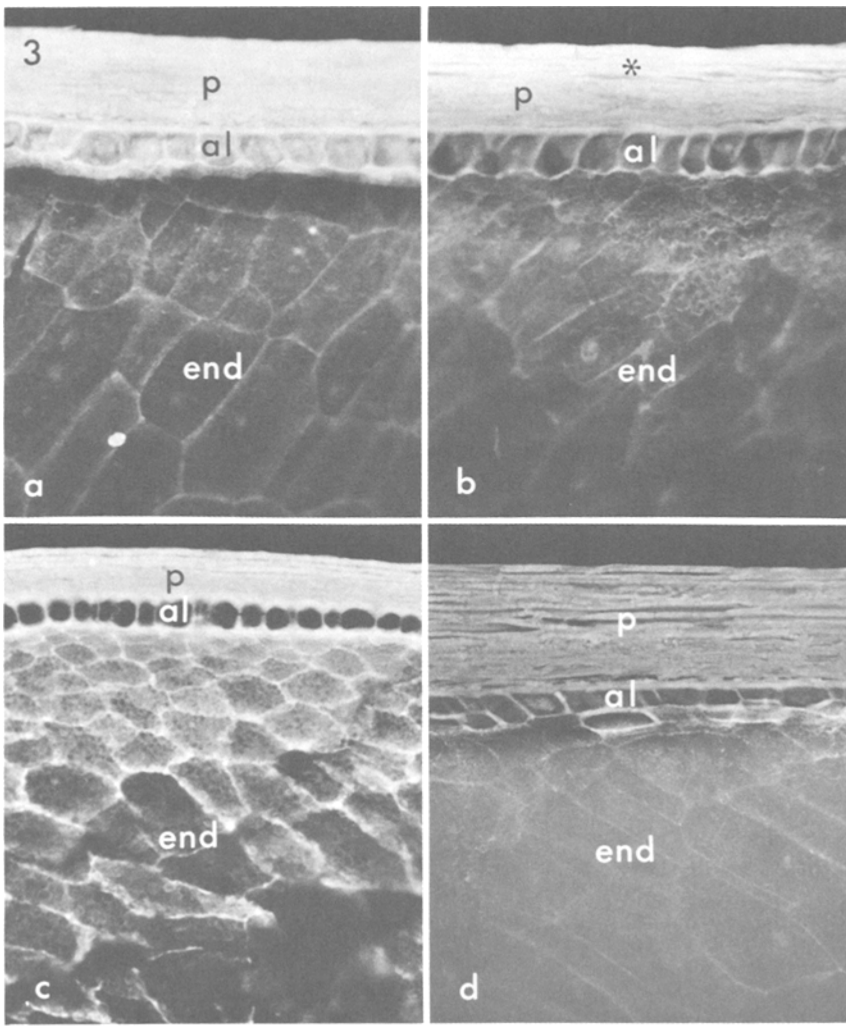

FIG. 3. Fluorescence micrographs of sections of corn kernels showing pericarp (p), aleurone layer (al), and endosperm (endo) tissues after staining with diphenyl boronate. Fluorescence intensity is highest in the pericarp of the local white variety [LW (3a)], while in the local yellow [LY (3b)], a similar intensity is concentrated primarily in the outer layers of the pericarp (*). The local black [LB (3c)] sample showed noticeably lower intensity in the pericarp than either the white or yellow kernels, while the Pioneer line [P (3d)] showed very low intensity.

The exploitation of phenolics as part of a complex of factors for *Sitophilus* control is possible but must be approached with caution. Heritability of phenolics (Styles and Ceska, 1977; Dunn, 1981) in corn is well studied, and the increase in levels of these substances in improved varieties in a conventional breeding program is envisaged. The obvious danger of this approach is that the grain may also become toxic to humans and animals or influence palatability. To avoid this danger, we are examining the existing land races of maize. As these traditional varieties have been used for human consumption for thousands of years without any apparent detrimental effects, their analysis may yield information on acceptable levels of phenolics which will contribute to the resistance to stored grain pests.

Acknowledgments—Funding for the project was provided by NSERC and IDRC. We are grateful to David Jewell and John Mihm (CIMMYT) for helpful discussions. L.P. was the recipient of a University of Ottawa summer scholarship. We thank G. Timbers for assistance with the hardness tests.

(Received February 11, 1986; accepted April 30, 1986)

Abstract—Nymphs of the rhododendron lace bug produce from specialized setae a liquid secretion from which a number of related acetogenins have been identified. Two (2,6-dihydroxyphenyl)-1,3-diketones are the principal components and are accompanied by the corresponding chromones as well as by chromones bearing an additional phenolic oxygen.

Key Words—Hemiptera, Tingidae, *Stephanitis rhododendri*, lace bug, setal exudate, chromones, acetogenins.

INTRODUCTION

Nymphs of many genera of lace bugs exude clear fluids that collect as microdroplets on secretory setae on the abdomen, abdominal protruberances, and antennae segments (Livingstone, 1978). We recently reported the identification of several components of secretions produced by nymphs of the azalea lace bug, *Stephanitis pyrioides* (Scott) (Oliver et al., 1985), one of three *Stephanitis* species known to occur in North America. This unusual insect secretion included decanal, undecan-2-one, the novel phenolic acetogenin 2,6-dihydroxyacetophenone, and some derivatives including the diketone **2b** and chromone **3b.** We have since turned our attention to a congeneric species, the rhododendron lace bug, *S. rhododendri* (Horvath). This species is thought to have originated in

eastern North America (Bailey, 1951; Johnson, 1936), but taxonomic relationships to other congeneric species are not firmly established. The other two species in North America, *S. pyrioides* and *S. takeyai* Drake and Maa are known to be introductions from Japan (Drake and Ruhoff, 1965).

The rhododendron lace bug is morphologically distinct from other species by the presence of an irregular biseriate hypocosatal ridge that is uniseriate in other species (Bailey, 1951), and the presence of only four nymphal instars (Crosby and Hadley, 1915; Johnson, 1936) is unusual in the genus and the Family. Thus, in addition to questions concerning the functions of lace bug secretions, a chemical comparison of the secretions of the azalea and rhododendron lace bugs seemed of interest because it might contribute to an understanding of the relationship between these species.

METHODS AND MATERIALS

Gas chromatography (GC) was performed on a Shimadzu model GC-9A instrument equipped with a flame ionization detector, a split–splitless injector operated at a ca. 50:1 split ratio, and a 15-m DB-1 fused silica column with helium as a carrier. A frequently employed temperature program (injection block temperature 300°) consisted of a 2-min interval at 160° followed by a 5°/min increase to 260° which was maintained an additional 10 min. High-performance liquid chromatography (HPLC) was carried out on a Spectra Physics model 8700 system with a variable wavelength UV detector operated at 254 or 220 nm, fitted with a 150 or 250 × 4.1-mm Hamilton PRP-1 "resin" column; various gradient elution systems were performed using water and either methanol or acetonitrile as the primary and secondary solvents, respectively. One such program began with 65% methanol at 1.5 ml/min. for 2 min, then increased the methanol content to 80% between 2 and 6 min. At this point the flow was increased to 2 ml/min, solvent programming from 80 to 100% methanol was continued from 6 to 10 min then the composition was maintained at 100% methanol for an additional 8 min.

Mass spectra were obtained from a Finnigan model 4510 gas chromatograph–mass spectrometer fitted with a 30-m × 0.32-mm-id DB-1 fused silica column. The instrument was scanned from *m/z* 50 to 650 with a total scan cycle time of 1.0 sec. Electron ionization spectra were collected at 70 eV and a source block temperature of 150°C. Data were analyzed via an Incos data system.

Lace bugs were reared on cuttings of mountain laurel, *Kalmia latifloria* L., in a Sherer Environment Rearing Chamber at 26 ± 1°C and 16:8 (light–dark) photoperiod. As was the case with *S. pyrioides*, the cleanest samples of exudate were collected by carefully blotting the material from the surfaces of late instar nymphs with small pieces of filter paper, then extracting the filter paper with dichloromethane. Alternately, nymphs, or their cast moult skins, could be dipped directly in dichloromethane.

Synthesis of Trihydroxydiketone **4c** *and Dihydroxychromone* **5c.** A mixture of 2,4,6-trihydroxyacetophenone (0.34 g, 2 mmol) and *t*-butylchlorodimethylsilane (0.90 g, 6 mmol) in dichloromethane (10 ml) was slowly treated with triethylamine (0.8 ml, 5.7 mmol) at room temperature. After 1 hr, the reaction mixture solution was washed with water and with 1 N $NaHCO_3$, then was dried, concentrated in vacuo, and the residue was further dried in a vacuum desiccator. The resulting oil was dissolved, along with 0.50 g (2.2 mmol) of ethyl dodecanoate, in 3 ml dry pyridine, and this solution was added dropwise to a stirred suspension of sodium hydride (0.4 g) in 5 ml pyridine under nitrogen. After the initial gas evolution, the mixture was refluxed 2 hr, cooled, and added to ice. The solution was rinsed twice with ether, then was neutralized with a mixture of ice and aqueous HCl.

Extraction with ether, followed by water and bicarbonate washes, drying, and evaporation of solvent gave a tan oil that was chromatographed on 20 g of silica gel with benzene containing increasing amounts of ethyl acetate. Fractions 3 (0.17 g, 12% EtOAc) and 4 (0.29 g, 16% EtOAc) contained most of the material of interest. Crystallization of fraction 4 from benzene gave pure diketone **4c,** mp 128.5–129.5°C. Mass spectrum (70 eV) *m/z* (relative intensity): 350 (M^+, 3%); 333 ($M^+ - OH$, 1.9%); 332 ($M^+ - H_2O$, 2.5%); 205 (14.6%); 196 (11.8%); 195 (100%); 153 (38.4%); 69 (3.2%); 57 (3.4%). Chromatographic fraction 3 (a mixture of **4c** and **5c**) was boiled about 3 min in methanol containing a few drops of conc. HCl; this converted all the diketone **4c** to chromone **5c** whereupon cooling and filtration gave pure **5c** as a white solid, mp 96–97°C. Mass spectrum (70 eV) *m/z* (relative intensity): 332 (M^+, 19.8%); 261 (4.0%); 205 (100%); 192 (28.2%); 153 (17.1%); 69 (3.1%); 55 (3.6%).

Diketone **4b** *and Chromone* **5b.** These were similarly obtained when ethyl decanoate was used in place of ethyl dodecanoate: **4b,** mp 131–132°C; **5b,** mp 102–102.5°C. Their mass spectra were analogous to those of **5c** and **6c,** respectively.

Dihydroxydiketones **2c** and **2d,** and hydroxychromones **3c** and **3d,** respectively, were synthesized by the methods previously described (Oliver et al., 1985) for the preparation of **2b** and **3b; 2c,** mp 74.5–75.5°C; **2d,** mp 73–74°C; **3c,** mp 54–54.5°C; **3d,** mp 60–60.5°C. Mass spectra of these compounds were analogous to those of **2b** and **3b** described earlier (Oliver et al., 1985).

RESULTS

GC and HPLC analyses of *S. rhododendri* secretions revealed a more complex mixture than that encountered from *S. pyrioides*. GC-MS (Figure 1) suggested, however, that most of the volatile components were closely related to those previously described and that the two most abundant components were the C_{11} and C_{13} dihydroxydiketones (**2c** and **2d,** respectively) homologous to

the C_9 analog **2b** which had been the major component identified from *S. pyrioides*. Diketone **2b** was also present in the *S. rhododendri* sample along with small amounts of C_7- and C_{15}-alkyl derivatives **2a** and **2e**, respectively.

Cyclodehydration (thermal or acid-catalyzed) of dihydroxydiketones **2a–2e** readily gives 2-alkyl-5 hydroxychromones **3a–3e**, and indeed **3a–3e** were all detectable by GC-MS in the *S. rhododendri* sample. It has been our experience that some cyclization of dihydroxydiketones **2** to hydroxychromones **3** frequently occurs during gas chromatography, and although small peaks consistent with **3d** and **3e** were detectable by HPLC, it is possible that at least portions of the 5-hydroxychromones encountered here may have been formed during analysis. In any event, it is evident that the dihydroxydiketones are the principal components of the exudate. This contrasts to the *S. pyrioides* secretion in which chromone **3b** constituted a substantial portion of the exudate. The C_{11}- and C_{13}-alkyl diketones **2c** and **2d**, and the corresponding chromones **3c** and **3d** were

synthesized as described earlier for **2b** and **3b** (Oliver et al., 1985); the authentic samples matched (GC, HPLC, mass spectra) those identified in the exudate. The C_7- and C_{15}-alkyl analogs were not synthesized; their structures are assigned on the basis of their mass spectra [the C_7-alkyl analogs **2a** and **3a** had also been tentatively identified as very minor components of the *S. pyrioides* exudate (Oliver et al., 1985)].

Among the less abundant components of the *S. rhododendri* mixture were three members of a third series **5b–5d** not encountered in the *S. pyrioides* exudate. Mass spectra of these compounds closely paralleled those of hydroxychromones **3a–3e** except that major ions of **5b–d** were shifted by 16 amu; in fact, these spectra closely resembled a published mass spectrum of 5,7-dihydroxy-2-nonadecylchromone (Tringali and Piattelli, 1982). The n-C_9- and C_{11}-substituted 5,7-dihydroxychromones **5b** and **5c,** respectively, were synthesized and matched the respective components of the secretion. The assignment of the structure of **5d** followed from its analogous mass spectrum. While synthesizing **5b** and **5c,** we observed that the precursor trihydroxydiketones **4b** and **4c** seemed somewhat more prone to cyclodehydration than had been the dihydroxydiketones **2b, c.** Thus the absence of diketones **4** in the gas chromatograms or reconstructed ion chromatogram (Figure 1) might have reflected thermal instability rather than the true composition of the insect exudate. HPLC showed, however, that in contrast to the less highly oxygenated analogs, the chromones were in fact the more abundant components of the **4–5** pairs, at least by the time the samples were collected and analyzed (solutions were stored at $-10°C$ after collections were made, but the viscous microdroplets had in most cases been accumulating on the surfaces of the nymphs for several days prior to collection).

The compositions of these exudates remained quite reproducible over a number of samples. All samples consisted of exudates of a number of nymphs because of the small size of the latter, so individual varieties would not have been recognized. Because of severe limited availability of material, all initial structural assignments were made on the bases of GC-MS; no individual components were available for NMR or IR spectra. Syntheses by standard procedures from defined intermediates completed the structural assignments.

Synthesis of Authentic Samples. Syntheses of dihydroxydiketones **2c** and **2d,** and of 5-hydroxychromones **3c** and **3d,** were achieved as reported for the preparations of **2b** and **3b,** by condensing the monobenzylether of 2,6-dihydroxyacetophenone with appropriate esters in the presence of sodium hydride (Oliver et al., 1985). Our first thought was to carry out analogous condensations between a dibenzylether of 2,4,6-trihydroxyacetophenone **7** and the same esters; however, although **7** has appeared in the literature, it has been observed that O-alkylation of 2,4,6-trihydroxyacetophenone with benzyl chloride tends to be accompanied by considerable C-alkylation (Jain et al., 1972), and we

experienced difficulties obtaining pure samples of the desired dibenzyl ether **7.** We found, however, that **6** reacted smoothly at room temperature with a slight excess (i.e., 2.2 equiv.) of *t*-butylchlorodimethylsilane to give the diether **8** and that **8** satisfactorily underwent condensation with esters under the same conditions employed earlier (Figure 2). Deprotection (and some cyclization) of the initial condensation product occurred during the neutralization step of the workup, and mixtures of **4b** + **5b** or of **4c** + **5c** were obtained that were separated by column chromatography.

DISCUSSION

Although *S. rhododendri* secretes a larger number, and somewhat greater diversity, of components than does *S. pyrioides*, the compounds secreted by the two species are closely related and, in fact, at least two, and probably four (**2b, 3b;** and probably **2a** and **3a**), components are common to the two insects. The implications of the similarity will not be certain until other species in other genera are examined.

(Received January 8, 1986; accepted May 6, 1986)

Abstract—Crude extracts of the root of the resistant legume, *Lupinus angustifolius*, showed feeding deterrent activity to *Costelytra zealandica* and *Heteronychus arator* larvae. Nine 5-hydroxyisoflavones were isolated from an active fraction and their feeding deterrent activity and antifungal activity was measured. High feeding-deterrent activity was associated with high antifungal activity with some exceptions.

Key Words—*Costelytra zealandica, Heteronychus arator, Lupinus angustifolius*, insect resistance, feeding deterrent, antifungal activity, 5-hydroxyisoflavones.

INTRODUCTION

The isoflavan vestitol was isolated from the root of the resistant pasture legume *Lotus pedunculatus* Cav. and shown to be a potent feeding deterrent for third-instar larvae of the two pasture scarabs *Costelytra zealandica* (White) and *Heteronychus arator* Fabr. (Russell et al., 1978, 1979). Vestitol was already known as an antifungal phytoalexin from *Lotus corniculatus* L. (Bonde et al., 1973). An investigation of the effect on insect feeding of a range of isoflavonoids including other recognized phytoalexins (Russell et al., 1979; Sutherland et al., 1980) showed that antifungal activity and insect feeding-deterrent activity were closely associated, suggesting a dual defensive role for isoflavonoids in legumes against both insects and fungi.

0098-0331/87/0400-0771$05.00/0 © 1987 Plenum Publishing Corporation

Lupin (*Lupinus*) species have been shown to be resistant to both *C. zealandica* and *H. arator* larvae (Farrell and Sweney, 1974; Farrell and Stufkens, 1977; Wallace, 1945), and we have investigated the possible role of plant-derived feeding deterrents in this phenomenon. Crude root extracts of *Lupinus angustifolius* cv. "Borre" significantly reduced feeding of *H. arator* larvae (Sutherland and Greenfield, 1978). We have found feeding of *C. zealandica* larvae as well as *H. arator* larvae to be significantly reduced by an extract of *L. angustifolius* cv. 'Uniharvest' root. This feeding deterrent activity has been investigated, a series of structurally related isoflavones isolated from active fractions, and their effects on insect feeding and fungal growth determined. The isolation of angustone A (VI) as a feeding deterrent has been briefly reported in a preliminary communication (Russell et al., 1979).

METHODS AND MATERIALS

Insect Feeding Assays. These were performed as described previously (Russell et al., 1978). Field-collected third-instar larvae of *C. zealandica* and *H. arator*, which had been starved for 24 hr, were enclosed individually in 5.2-cm-diameter Petri dishes with a 4% agar–4% cellulose powder disk (1.5 cm) containing a standard feeding stimulant (0.1 M sucrose and 0.01 M ascorbic acid for *C. zealandica*, and 0.1 M maltose for *H. arator*) plus the test fraction or compound. Feeding-deterrent activity was assessed by comparing 24-hr fecal pellet counts of larvae offered disks containing the test compound (TC) with similar counts of larvae offered disks containing feeding stimulants only (control = C) and of a third group offered blank disks (B) prepared with distilled water. Twenty larvae were tested with each medium. The results are presented as percentage feeding response defined as: $100 \times (TC - B)/(C - B)$ (May 1976). Crude extracts and fractions were incorporated in the feeding disks at a concentration equivalent to 10 g dry wt/50 ml medium, with the exception that chromatography fractions (Scheme 1) were tested with *H. arator* at 25 g dry wt equivalent/50 ml medium. Pure compounds, some of which were isolated in only limited quantities, were tested over a range of concentrations up to 200 μg/ml if possible. In all cases, the test material was added to the cellulose powder in solution, and the solvent removed by evaporation. Cellulose powder in control discs was pretreated with solvent.

Antifungal Assays. Antifungal activity in crude fractions was monitored by fungal spore germination assays on TLC plates. Eluted plates were sprayed with a suspension of conidia of the pigmented fungus *Cladosporium cladosporioides* (Fresen.) de Vries in a nutrient solution (Bailey and Burden, 1973) and examined after three days.

The antifungal activity of purified compounds was determined by sporeling growth assays (Skipp and Bailey, 1976) with *C. cladosporioides*, and *Colleto-*

trichum gloeosporioides (Penz.) Sacc. as an additional suitable test organism. These assays have been found to be useful for discriminating the relative antifungal activities of isoflavonoids, showing little variation in inhibitory concentration for a range of test fungi (Skipp and Bailey, 1977). Assays were performed using germinated spores of the test fungi as inoculum, supported on sterile, 4-mm-diameter disks of cellophane film. Disks were placed on the surface of a sucrose–acid casein hydrolysate medium (SCH, containing: sucrose 1.5%, Difco Casamino Acids 0.46%, KH_2PO_4 0.1%, $MgSO_4 \cdot 7H_2O$ 0.5%, agar 20%) in Petri dishes and were inoculated with 2-μl drops of test fungus spore suspension (50–100 spores per drop), and incubated for 20 hr at 20°C.

A range of concentrations of each test compound was prepared by placing appropriate volumes of an ethanolic solution of each (2000 μg/ml) in duplicate in the wells of Boerner Micro Test Slides using a micrometer syringe. Drops were air dried and the residues in the well redissolved in 2-μl drops of dimethyl sulfoxide (DMSO). Drops (0.1 ml) of liquid SCH medium (without agar) were added to the wells. The final concentration of DMSO in the medium was 2.0%, and the concentration ranges of the test compounds were: 0, 10, 20, 30, 40, and 50 μg/ml and 0, 40, 60, 80, and 100 μg/ml. Disks bearing sporeling inoculum were placed in the drops of test solution. Four disks were also mounted in lactophenol, and the lengths of 10 sporeling germ tubes on each disk were measured with an eyepiece micrometer. Sporelings were incubated at 20°C in test solutions for 24 hr; then 100 on each disk were examined to determine the percentage of sporelings which had grown (i.e., had germ tubes of greater length than the largest of the sporelings used as inoculum). The lowest concentration of each compound which prevented the growth of over 95% of sporelings (ED_{95}) was determined.

Extraction of Roots and Feeding-Deterrent Activity of Extract. Roots (3.1 kg dry wt) of 3-month-old field grown *Lupinus angustifolius* L. cv. "Uniharvest" (Barnard, 1972) were air dried (80°C), ground, and extracted with 95% EtOH in a Soxhlet for 48 hr, and the solvent was evaporated under reduced pressure. The crude extract was tested for insect feeding deterrent activity (Table 1). Feeding of *H. arator* larvae was significantly reduced by the extract, as found for *L. angustifolius* cv. "Borre" (Sutherland and Greenfield, 1978). Feeding of *C. zealandica* larvae was also significantly reduced.

Fractionation of Feeding-Deterrent Activity. The extract was fractionated by solvent partitioning and column chromatography, and the feeding-deterrent activity of each fraction monitored in the feeding assay. In preliminary testing, a partitioning scheme for lupin alkaloids (Ruiz, 1978) was used to separate an organic base fraction. Most of the activity did not partition into this fraction, but under neutral conditions partitioned into solvents of medium polarity. The partitioning scheme adopted is shown in Scheme 1 and fractions exhibiting feeding deterrent activity are indicated.

TABLE 1. EFFECT OF CRUDE EXTRACTS OF *Lupinus angustifolius* CV. "UNIHARVEST" ROOT ON FEEDING BY 3RD INSTAR *C. zealandica* AND *H. arator* LARVAE (TOTAL FECAL PELLETS PER 20 TEST INSECTS)

	Blank	Control	Control + extract	Feeding response (%)
C. zealandica	230	582	206	−6.8[a]
H. arator	160	669	284	24.2[a]

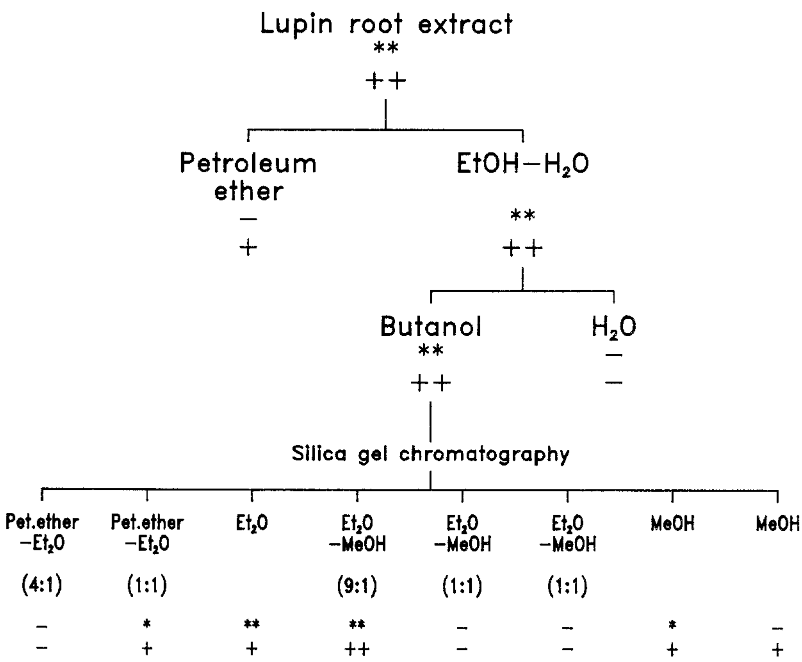
[a] Significant reduction in feeding: $P < 0.05$, Wilcoxon's rank sum test applied to untransformed counts.

The aqueous ethanol and subsequent butanol fractions showed high activity to *C. zealandica*. A similar pattern was observed for *H. arator*, with the petroleum ether fraction also showing some activity. The active butanol fraction was evaporated and eluted through silica gel (2 kg) with a sequence of solvents and fractions collected and tested as shown (Scheme 1). Major insect feeding-deterrent activity appeared to be concentrated in the Et_2O and Et_2O–MeOH (9 : 1) eluates, and these were investigated further.

Isolation of Compounds from Active Fractions. Separations were monitored by TLC on silica gel 60 F_{254} aluminum sheets (Merck) with $CHCl_3$–MeOH (19 : 1), pentane–Et_2O–HOAc (75 : 25 : 3), and petroleum ether–EtOAc (1 : 1); on cellulose sheets (Macherey-Nagel) with H_2O–HOAc (2 : 1), and polyamide (Wang) with acetone. Spots were visualized with UV light (254 nm and 366 nm) and by spraying with fast blue B salt solution, and antifungal components detected with the TLC fungal bioassay. HPLC was performed on Whatman 10-μm Partisil-ODS columns with MeOH–H_2O and UV detection at 254 nm.

A series of compounds (Fig. 1) was isolated for identification and bioassay from the Et_2O–MeOH (9 : 1) eluate and the Et_2O eluate of the initial silica gel column chromatography (Scheme 1). The Et_2O–MeOH (9 : 1) eluate was evaporated to dryness (8.38 g) and a portion (2.8 g) was chromatographed on silica gel with a $CHCl_3$–EtOH gradient. The EtOH fraction was rechromatographed on Sephadex LH-20 with $CHCl_3$–EtOH (1 : 1) to give III (151 mg).

The Et_2O eluate from the initial silica gel chromatography (Scheme 1) was evaporated to dryness (10 g) and rechromatographed on silica gel (5% H_2O) with a series of solvents (petroleum ether–Et_2O, 4 : 1, 3 : 1, and 1 : 1; Et_2O; Et_2O–MeOH, 9 : 1) to give several fractions from which pure compounds were isolated by rechromatography on silica gel and Sephadex LH-20. A petroleum ether–Et_2O (3 : 1) fraction (182 mg) was rechromatographed on silica gel with



SCHEME 1.

$CHCl_3$ and on Sephadex LH-20 with petroleum ether–CH_2Cl_2 (1 : 1) to give IX (28 mg). A further petroleum ether–Et_2O (3 : 1) fraction (431 mg) was rechromatographed on silica gel with $CHCl_3$ and with petroleum ether–Et_2O (3 : 1) to give VIII (71 mg).

Chromatography of the petroleum ether–Et_2O (1 : 1) fraction (3.85 g) on silica gel with $CHCl_3$–MeOH (19 : 1) and with petroleum ether–Et_2O (4 : 1) and on Sephadex LH-20 with petroleum ether–$CHCl_3$–EtOH (10 : 10 : 1) gave VII (114 mg) and VI as a gum (728 mg), a portion (50 mg) of which was further purified by HPLC and crystallized (12 mg) from petroleum ether–Et_2O.

The Et_2O fraction (3.36 g) was rechromatographed on silica gel with $CHCl_3$–Et_2OH (19 : 1) and on Sephadex LH-20 with petroleum ether–$CHCl_3$–EtOAc–EtOH (4 : 4 : 1 : 1) to give V (331 mg) and II (23 mg). The Et_2O–MeOH (9 : 1) fraction (1.12 g) was rechromatographed on silica gel with petroleum ether–Et_2O (1 : 1) and on Sephadex LH-20 with petroleum ether–$CHCl_3$–EtOH

Fig. 1. Lupin isoflavones.

(9:4:2) to give a solid (51 mg). Crystallization from EtOH-H_2O gave I (33 mg) and HPLC of the mother liquor gave IV (6 mg).

RESULTS

Identification of Isoflavones. Isoflavones were identified by comparison of the mp and spectroscopic properties with published data, and by TLC comparison with authentic samples where these were available. The determination of the structures of angustone A (VI), angustone B (VIII), and angustone (IX) is the subject of a separate report (Lane and Newman, 1986). Yields, shown as percent dry weight, are estimated total yields from TLC and HPLC of mixed fractions.

Genistein (I). Yield 0.03%; mp 304–306°C (decomp.) (lit. 300–301°C) (Bradbury and White, 1951); UV and EI-MS data in agreement with reported values (Ollis, 1962; Biggs, 1975). Coelutes with authentic sample (ICN Pharmaceuticals).

Wighteone (II). Yield 0.002%; mp 216–217°C (lit. 220–221°C) (Deshpande et al., 1977); UV, EI-MS, and [^{1}H]NMR data in agreement with reported values (Ingham et al., 1977; Deshpande et al., 1977).

2'-Hydroxygenistein (III). Yield 0.04%; mp 273–275°C (decomp.) (lit.

272 °C) (Whalley, 1957); UV and EI-MS in agreement with data reported by Biggs (1975). Coelutes with authentic sample (Dr. D. R. Biggs).

Luteone (IV). Yield 0.0005%; mp 222–223 °C (lit. 225–227 °C) (Fukui et al., 1973); UV and EI-MS data in agreement with these reported by Fukui et al. (1973). Coelutes with authentic samples (Professor H. Fukui, Dr. J. Ingham).

Licoisoflavone A (V). Yield 0.02%; mp 111–114 °C (lit. 111–113 °C) (Kinoshita et al., 1978); UV and EI-MS data in accord with reported values (Kinoshita et al., 1978; Woodward, 1979). Coelutes with authentic sample (Professor S. Shibata).

Angustone A (VI). Yield 0.06%; mp 159–160 °C; (Lane and Newman, 1986) (lit. 155–157 °C) (Tahara et al., 1984a).

Licoisoflavone B (VII). Yield 0.008%; UV, EI-MS and [^{1}H]NMR data in agreement with reported values (Ingham et al., 1983; Kinoshita et al., 1978). The mp (185–186 °C) differed from that reported by Kinoshita et al. (1978) (245–248 °C) for material prepared from V. However, acetylation (Ac_2O-pyr) gave a triacetate with mp 188–190 °C (lit. 186–188 °C) (Kinoshita et al., 1978), and UV, EI-MS MS, and [^{1}H]NMR data in agreement with these authors.

Angustone B (VIII). Yield 0.003%; mp 160–161 °C (Lane and Newman, 1986).

Angustone C (IX). Yield 0.001%; mp 170–180 °C (Lane and Newman, 1986).

Isolation of Wighteone (II) and Luteone (IV) from Lupinus luteus *Pods.* To provide additional material for biological testing, wighteone (II) and luteone (IV) were isolated from immature seed pods of *Lupinus luteus* cv. "Weiko" (Fukui et al., 1973; Ingham et al., 1977). Freeze dried pods and seeds (1.5 kg) were ground and extracted with MeOH in a Soxhlet for 60 hr. The extract was concentrated and partitioned (3×) between petroleum ether and 80% MeOH. The combined MeOH fraction was evaporated and partitioned (3×) between Et_2O and H_2O, and the combined Et_2O fraction evaporated and chromatographed on silica gel. Elution with petroleum ether–Et_2O (4 : 1) and rechromatography on silica gel (CH_2Cl_2–EtOH, 19 : 1) and Sephadex LH-20 (CH_2Cl_2–petroleum ether–EtOAc–EtOH, 3 : 4 : 2 : 1) gave wighteone (II) (19 mg). Elution with petroleum ether–Et_2O (1 : 1) and rechromatography on Sephadex LH-20 ($CHCl_3$–petroleum ether–EtOH, 2 : 2 : 1) gave luteone (IV) (38 mg).

Feeding-Deterrent and Antifungal Activity of Isolated Compounds. All nine isoflavones isolated were assayed for feeding-deterrent activity with *C. zealandica*, and six reduced feeding significantly at one or more concentrations (Table 2). Four of these, licoisoflavone B (VII), luteone (IV), 2-hydroxygenistein (III), and licoisoflavone A (V) reduced feeding significantly at a concentration of only 2 μg/ml (ppm). In the case of VII, IV, and III, higher concentrations reduced *C. zealandica* feeding very substantially.

Six of the isoflavones for which sufficient purified material was available

[b] Complete inhibition of some sporelings and progressive inhibition of sporeling growth at concentrations >40 μg/ml.

were tested with *H. arator* (Table 2), and five of these showed significant feeding-deterrent activity. Each of these compounds was also active with *C. zealandica*. Only licoisoflavone B (VII) caused a significant reduction in feeding at concentration below 100 μg/ml, and in no case was the reduction in *H. arator* feeding with purified compounds comparable to that observed with the crude extract (Table 1).

All nine isoflavones were tested for antifungal activity against both *Colletotrichum gloeosporioides* and *Cladosporium cladosporioides* in the sporeling growth assay (Table 3) and showed a similar pattern of activity towards both fungi (Skipp and Bailey, 1977). Of the four compounds most active in the insect feeding-deterrent assays, three, licosoflavone B (VII), licosoflavone A (V), and luteone (IV), prevented growth of 95% of sporelings at 20, 30, and 30 μg/ml, respectively. No effect on sporeling growth was observed for 2′-hydroxygenistein (III) up to 100 μg/ml. Of the remaining five compounds, only wighteone (II) displayed distinct antifungal activity (ED_{95} 30 μg/ml), although some inhibition of the growth of *C. gloeosporioides* was observed with angustone A (VI).

DISCUSSION

The results show that, as in the case of *Lotus pedunculatus* (Russell et al., 1978), isoflavonoids with high insect feeding deterrent activity are present in crude root extracts of *Lupinus angustifolius* and suggest these compounds may play a role in the resistance of this plant to *C. zealandica* and *H. arator*.

The resistance of *Lupinus* spp. to foliar-feeding insects has, in several cases, been linked to the alkaloid complement (Bentley et al., 1984; Cantot and Papineau, 1983; Wink et al., 1982; and references cited). However, alkaloids do not appear to be implicated in the resistance of *L. angustifolius* to these root-feeding insects. Low-alkaloid cultivars such as "Uniharvest" (Barnard, 1972; Ruiz, 1978) as well as high-alkaloid cultivars such as "Borre" have been found to be resistant to *C. zealandica* (Farrell and Sweney, 1974; Farrell and Stufkens, 1977) and to show feeding-deterrent activity to *H. arator* (Sutherland and Greenfield, 1978, and this study), and this is reflected in the partitioning of the feeding-deterrent activity.

This study also provides further evidence for a dual defensive role for isoflavonoids in legume roots. Prenyl isoflavones are well-established antifungal components in *Lupinus* spp. Wighteone (II) and luteone (IV) have been reported as constitutive antifungal components from both the aerial parts and roots of a number of *Lupinus* spp., including *L. angustifolius* cv. "Beliak" (Fukui et al., 1973; Harborne et al., 1976; Ingham et al., 1977, 1983), often cooccurring with the parent isoflavones genistein (I) and 2′-hydroxygenistein

(III). In detailed studies of *L. albus* root extracts, licoisoflavone A (V), angustone A (VI) (= 2′-hydroxylupalbigenin), licoisoflavone B (VII), the chromenylisoflavones parvisoflavone B and alpinumisoflavone, the diprenylisoflavone lupalbigenin, and six related dihydrofuranoisoflavones have been isolated as antifungal components in addition to I–IV (Ingham et al., 1983; Tahara et al., 1984a). While all these compounds have been reported to show antifungal activity in TLC plate bioassays with *Cladosporium herbarum* (Ingham et al., 1983; Tahara et al., 1984a), the quantitative sporeling growth bioassay reported here was more discriminatory. Of the nine isoflavones tested, high activity (ED_{95} below 100 μg/ml) was limited to four (II, IV, V, and VII; Table 3). These compounds were also highly active in the TLC bioassay, although not with the same relative order of activities (Tahara et al., 1984a).

The isoflavonoid complement of *Lupinus* spp. roots thus appears to be implicated in resistance to both insects and fungi, and three isoflavones (IV, V, and VII) show the association of high antifungal activity with insect feeding deterrent activity we have observed with other isoflavonoids (Sutherland et al., 1980). However, for some compounds, the biological activity is more specific. Wighteone (II) shows high antifungal activity, but lacks significant feeding-deterrent activity at the concentrations tested, while 2′-hydroxygenistein (III) is an active feeding deterrent but is inactive in the sporeling growth bioassay. These results show the structural requirements for activity against insects and fungi are not identical, despite the strong association.

High antifungal activity of the lupin isoflavones is restricted to the monoprenylated compounds. The parent isoflavones show low activity, as do the polar dihydrofuranoisoflavones with hydroxylated side chains found in *L. albus* (Tahara et al., 1984a) and other products of prenyl side-chain oxidation formed as fungal detoxification products from luteone (IV) (Tahara et al., 1984b) and licoisoflavone A (V) (Tahara et al., 1985). The higher antifungal activity of the prenylated compounds has been attributed to their higher lipophilicity (Harborne et al., 1976; Ingham et al., 1977). However, the diprenyl isoflavones, although more lipophilic than the active monoprenyl compounds, show low antifungal activity (Tahara et al., 1984a, and this study). While the bioassay conditions may not adequately reflect the in vivo activity of the water-insoluble diprenyl compounds, or include the relevant test organisms, these findings do suggest there is an optimum lipophilicity for antifungal activity. It is also worth noting that the active compounds all possess an amphiphilic structure with distinct lipophilic and polar regions.

Insect feeding-deterrent activity in these isoflavones is associated with a 2′-hydroxygenistein (III) nucleus. Licoisoflavone B (VII), which showed activity towards both insects at low concentrations (Table 2), possesses a ring B-fused dimethylpyranyl ring as found in the highly active isoflavonoid feeding deterrents phaseollin and phaseollinisoflavan from bean roots (Sutherland et al.,

1980). While the parent compound (III) and the monoprenyl derivatives (IV, V, and VII) showed feeding-deterrent activity to *C. zealandica* at low concentrations, the additional prenylation found in angustones A (VI) and B (VIII) is association with reduced feeding-deterrent activity, as observed with antifungal activity. The relationship between isoflavonoid structure and feeding-deterrent activity towards *H. arator* is not clearly defined. The activity of isoflavonoids as *C. zealandica* feeding deterrents has been shown to be very dependent on their molecular shape and the arrangement of polar and lipophilic groups in the molecule (Lane et al., 1985).

From these considerations it may be seen that while the structural features for antifungal activity and feeding activity may not be identical, they coincide in IV, V, and VII. Although these compounds show activity against both types of test organism, this does not define a dual defensive role. A full assessment of the role of lupin isoflavonoids in the defense of the plant root system would require that the isoflavonoid complement be considered as a whole, taking into account the scope and level of biological activity of each component, its abundance and location in the plant (Barz and Hoesel, 1979), and possible induction by disease organisms (Ingham and Dewick, 1980) or insect feeding. As a first approximation, considering the concentrations at which insect feeding was reduced (Table 2), and the estimated total yields (Results), licoisoflavone B (VII) and, for *C. zealandica*, 2′-hydroxygenistein (III) and licoisoflavone A (VI) appear to be the most significant insect feeding deterrents isolated. On a similar basis, licoisoflavone A (VI) appears to be the most significant antifungal compound.

(Received March 17, 1986; accepted May 6, 1986)

Abstract—A large amount of 20-hydroxyecdysone was orally administered to larvae of the tobacco budworm, *Heliothis virescens*, in order to investigate its detoxification mechanisms. Four major relatively nonpolar metabolites were isolated from their frass. These compounds were identified as the 22-linoleate, 22-palmitate, 22-oleate, and 22-stearate of 20-hydroxyecdysone using various forms of spectroscopy, including NMR. This is the first report of this type of metabolite from an insect.

Key Words—20-Hydroxyecdysone, feeding, insect, metabolites, conjugates, *Heliothis virescens*, feces.

INTRODUCTION

Current research in our laboratory is centered around the chemical basis of insect–plant relationships and particularly the physiological effects of phytoecdysteroids. We have isolated several phytoecdysteroids from various tropical plant species which are known to be resistant to insect attack (Kubo et al., 1983a, 1984). One of the most abundant and widespread phytoecdysteroids is 20-hydroxyecdysone (Bergamasco and Horn, 1983), which is also the moulting hormone in insects themselves. Recent studies in our laboratory demonstrated that small amounts of this ecdysteroid consumed with diet can inhibit growth and ecdysis in larvae of the lepidopterous species *Pectinophora gossypiella* (pink bollworm), *Spodoptera frugiperda* (fall armyworm), and *Bombyx mori* (silkworm) (Kubo et al., 1983b). The inhibition of ecdysis, which can occur through

0098-0331/87/0400-0785$05.00/0 © 1987 Plenum Publishing Corporation

disruption of the normal titer of 20-hydroxecdysone, results in failure to complete ecdysis after normal apolysis and confines the insect in the pharate condition (Kubo and Klocke, 1986). This abnormal pharate condition prevents feeding, excretion, and locomotion and eventually results in death of the affected insect.

In contrast, certain insect species are apparently able to survive on plants containing large amounts of phytoecdysteroids, such as the moth *Milonia vasalis* which feeds on leaves of *Podocarpus macrophyllis* (Hikino and Takemoto, 1974). Kubo et al. (1981) found that larvae of the bollworm complex, *Heliothis zea* and *H. virescens*, are not affected by high concentrations of 20-hydroxyecdysone in their diet. Clearly, these insects must have a defensive mechanism which operates against disruption of the hormonal coordination. Therefore, we examined the physiological basis of this phytoecdysteroid resistance in one such insect, the tobacco budworm, *H. virescens*, by studying the metabolic fate of the ingested phytoecdysteroid.

We describe here the isolation and structural elucidation of several relatively nonpolar metabolites of ingested 20-hydroxyecdysone from frass of tobacco budworm larvae.

METHODS AND MATERIALS

Insects. Larvae of the tobacco budworm, *Heliothis virescens* (Fabricius) (Lepidoptera, Noctuidae) were reared from eggs obtained from a culture maintained at the U.S.D.A. at Stoneville, Mississippi. Upon hatching, larvae were reared individually on an artificial diet (Chan et al., 1978) in plastic containers at 28°C and at 16:8 light–dark cycle. The phytoecdysteroid-containing diet is prepared by adding a solution of a known concentration of ecdysteroid to the cellulose part of the diet. After evaporation of the solvent, the cellulose laced with the ecdysteroid is mixed with the other ingredients of the diet to form the test diet. Control diet is made similarly except for the addition of the ecdysteroid.

Newly hatched larvae ($N = 50$) were reared on an artificial diet containing 1000 ppm 20-hydroxyecdysone through the fifth instar. Fecal material of larvae fed on test and control diet was collected regularly and stored in methanol at 0°C. The fecal material of these larvae, as well as the diets themselves, were analyzed for the presence of metabolites of 20-hydroxyecdysone. These samples were homogenized in methanol, and the filtrate was evaporated to dryness and partitioned between *n*-hexane and water. The aqueous layer was extracted with ethyl ether. The ethyl ether layer was dried over Mg_2SO_4, filtered, and evaporated to dryness. This fraction was purified by C_{18} reversed-phase medium-pressure liquid chromatography on a Pharmacia SR10/50 column packed with hand-made 40 μm ODS. The mobile phase used was methanol–water (9:1),

delivered with a Pharmacia P-3 peristalic pump at a flow rate of 1 ml/min. Fractions (5 ml) were collected, and an aliquot of each fraction was injected into the HPLC system to check their purity.

Chemicals. 20-Hydroxyecdysone had previously been isolated from various tropical medicinal plants (Kubo et al., 1983a, 1984). Solvents used were of reagent or HPLC grade. A Sep-pak C_{18} cartridge (Waters Assoc., Milford, Massachusetts) was used for the preliminary purification of the HPLC samples.

Analysis. Analyses were carried out with an Eyela PLC-5 liquid chromatograph system (Tokyo Rikakikai, Tokyo, Japan). A YMC pack ODS column (15 cm × 6 mm) (Yamamura Chemical, Kyoto, Japan), equipped with Uptight precolumn (2 cm × 2 mm) (Upchurch Scientific, Oak Harbor, Washington) and packed with pellicular ODS (Pell, Whatman Co.), was used. The mobile phase used was methanol–water (9:1) at a flow rate of 1.25 ml/min. The effluent was monitored by built-in UV detector at 254 nm.

Identification. Isolated compounds were analyzed by several spectroscopic techniques. Ultraviolet (UV) spectra were recorded on a Hitachi 100-80 spectrophotometer. Infrared (IR) spectra were recorded on a Perkin-Elmer 1310 IR spectrophotometer. Secondary ionization mass spectra (SI-MS) were obtained on a Hitachi RMU-6MG apparatus. Proton nuclear magnetic resonance ([^{1}H]NMR) spectra were determined on a Nicolet NT-300 spectrometer.

RESULTS AND DISCUSSION

To examine the metabolic fate of ingested phytoecdysteroids in larvae of *H. virescens*, fecal material was collected from larvae reared on artificial diet containing 1000 ppm 20-hydroxyecdysone. The following four samples were chromatographically analyzed; I, control diet; II, test diet (containing 1000 ppm of 20-hydroxyecdysone); III, control feces (obtained from insects feeding on the control diet); and IV, test feces (obtained from insects feeding on the test diet). The resulting chromatograms are illustrated in Figure 1. Four compounds appearing in chromatogram IV, M-1, M-2, M-3, and M-4, were not found in the other three samples. 20-Hydroxyecdysone appeared in the chromatogram of II (retention time: 3.0 min). Chromatogram IV also showed 20-hydroxyecdysone. These results suggest that the four major components of sample IV, M-1, M-2, M-3 and M-4, are metabolites of 20-hydroxyecdysone. All four metabolites, M-1 (7.3 mg), M-2 (10.5 mg), M-3 (8.5 mg), and M-4 (3.4 mg), were obtained in large enough quantities to perform various spectroscopic studies.

Spectroscopic data of M-1: UV (EtOH) λ_{max} 242 nm; IR ($CHCl_3$) 1715, 1654 cm^{-1}; SI-MS *m/z* 743 $(M + 1)^+$, 725 (743-H_2O), 707 (743-2H_2O), 689 (743-3H_2O), 463 (743-fatty acid), 445 (463-H_2O), 427 (463-2H_2O), 409 (463-3H_2O), 353 (409-C_4H_8), and 301 (ecdysone nucleus); [^{1}H]NMR ($CDCl_3$) δ 0.85

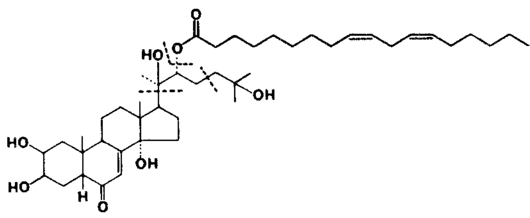
J = 7.0, terminal-CH_3), 0.98 (3H, s, 19-CH_3) 1.24–1.25 (6H, 2s, 26, 27-CH_3), 2.37 (2H, t, J = 7.1, —O—CO—CH_2), 2.43 (1H, m, 5β-H), 3.00 (1H, m, 9-H), 3.88 (1H, m, 2-H_{ax}), 4.04 (1H, m, 3-H_{eq}), 4.89 (1H, d, J = 9.4, 22-H), 5.85 (1H, d, J = 1.7, 7-H).

M-3: UV (EtOH) λ_{max} 242 nm; IR ($CHCl_3$) 1715, 1654 cm^{-1}; SI-MS m/z 745 $(M + 1)^+$, 727 (745-H_2O), 709 (745-2H_2O), 691 (745-3H_2O), 463 (745-fatty acid), 445 (463-H_2O), 427 (463-2H_2O), 353 (409-C_4H_8), and 301 (ecdysone nucleus); [^{1}H]NMR ($CDCl_3$) δ 0.86 (3H, s, 18-CH_3), 0.88 (3H, t, J = 7.0, terminal-CH_3), 1.21 (3H, s, 21-CH_3), 1.24 (6H, s, 26, 27-CH_3), 2.37 (2H, t, J = 7.1, —O—CO—CH_2), 2.43 (1H, m, 5β-H), 3.00 (1H, m, 9-H), 3.88 (1H, m, 2-H_{ax}), 4.04 (1H, m, 3-H_{eq}), 4.89 (1H, d, J = 9.4, 22-H), 5.34 (2H, m, 9′, 10′ olefinic Hs), 5.85 (1H, d, J = 1.7, 7-H).

M-4: UV (EtOH) λ_{max} 242 nm; IR ($CHCl_3$) 1715, 1654 cm^{-1}; SI-MS m/z 747 $(M + 1)^+$, 729 (747-H_2O), 711 (747-2H_2O), 693 (747-3H_2O), 463 (747-fatty acid), 445 (463-H_2O), 427 (463-2H_2O), 409 (463-3H_2O), 353 (463-C_4H_8), and 301 (ecdysone nucleus); [^{1}H]NMR ($CDCl_3$) δ 0.86 (3H, s, 18-CH_3), 0.88 (3H, t, J = 6.7, terminal-CH_3), 0.99 (3H, s, 19-CH_3), 1.21 (3H, s, 21-CH_3), 1.23 (6H, s, 26, 27-CH_3), 2.37 (2H, t, J = 7.2, O—CO—CH_2—), 2.44 (1H, m, 5β-H), 3.00 (1H, m, 9-H), 3.89 (1H, m, 2-H_{ax}), 4.05 (1H, m, 3-H_{eq}), 4.88 (1H, d, J = 9.4, 22-H), 5.85 (1H, d, J = 1.6, 7-H). Typical SI-MS and [^{1}H]NMR spectra are illustrated in Figures 2 and 3.

The UV and IR spectra of all four compounds were quite similar. The presence of ester was suggested by the IR absorption at 1715 cm^{-1}. The SI-



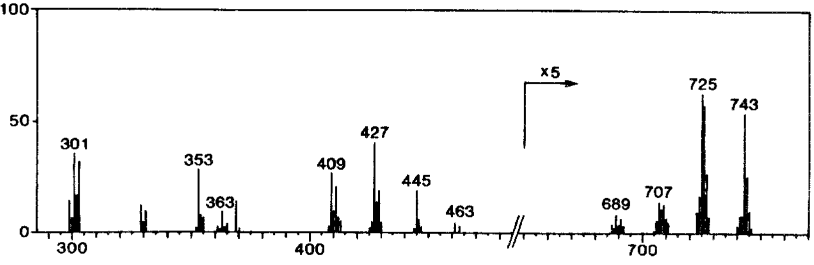


FIG. 2. Secondary ionization mass spectrum of M-1

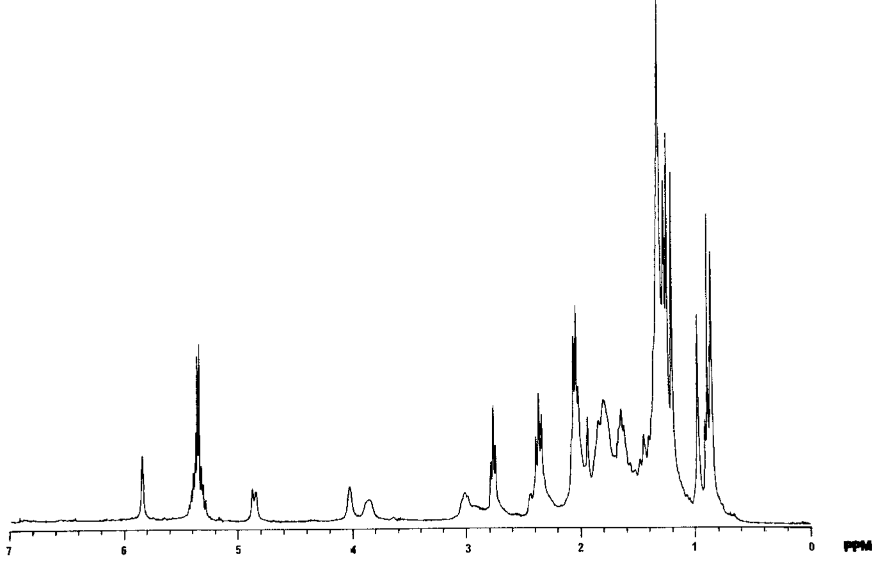

FIG. 3. 300-MHz [^{1}H]NMR spectrum of M-1 in $CDCl_3$.

MS fragment patterns for all four compounds were almost the same below *m/z* 463. The main fragmentations of 20-hydroxyecdysone usually occur at C-17/20 (*m/z* 301) and C-20/22 (*m/z* 363)(Nakanishi, 1971). An intense peak at *m/z* 301 could also be seen in the SI-MS of all four compounds. However, all SI-MS had a peak at *m/z* 363 of quite low intensity. It appeared to be replaced by an intense peak at *m/z* 353, which is not found in the SI-MS of 20-hydroxyecdysone. Since the retained *m/z* 301 peak is believed to result from cleavage of the C-17 to C-20 bond, we believe its presence suggested any ester group present must be on the side chain. The absence of the *m/z* 363, representing cleavage of the C-20 to C-22 bond, suggests that the ester group could be placed on the hydroxyl at C-22 in all four compounds. Each acyl group: M-1, $C_{18:2}$, M-2, C_{16}, M-3, $C_{18:1}$ and M-4, C_{18} fatty acids, could be conjectured due to each $(M + 1)^{+}$-463.

A comparison of the [^{1}H]NMR spectra of M-1, M-2, M-3, and M-4 with the previously assigned [^{1}H]NMR spectrum of 20-hydroxyecdysone showed strong similarities between the spectra (Kubo et al., 1985). However, there was a shift of the H-22 signal from the value in 20-hydroxyecdysone of δ 3.32 to a new value of δ 4.86 in all four compounds. The order of magnitude of this shift is consistent with an esterification of the hydroxyl group at C-22. Also, an HPLC analysis of metabolites hydrolyzed with 0.006% NaOH in ethanol coincided with 20-hydroxyecdysone. A long-range coupling between H-7 (δ 5.85) and H-9 (δ 3.00) was seen in the two-dimensional contour plot.

Typical proton signals of fatty acids, δ 0.88 and δ 2.37, appeared in all four [^{1}H]NMR spectra. These resonances were assigned to terminal methyl and 2′-methylene in their fatty acid ester side chains. The resonances at δ 2.77 and δ 5.35 in the spectra of M-1 and at δ 5.34 in the spectra of M-2 coincided with previously reported [^{1}H]NMR shifts and coupling patterns of the olefinic proton signals of methyl linoleate and methyl oleate respectively (Hashimoto et al., 1965).

Hence the structure of the metabolites were determined to be the 20-hydroxyecdysone-22-fatty acid esters; M-1: linoleate, M-2: palmitate, M-3: oleate, and M-4: stearate (Scheme 1).

Much of the metabolism of ecdysteroids in insects is well documented (Koolman, 1982). Several metabolic pathways have been reported in several

M-1

M-2

M-3

M-4

SCHEME 1. Structures of metabolites in the feces of *H. virescens*.

species of Lepidoptera including: *Antheraea polyphemus* (Cherbas and Cherbas, 1970), *Bombyx mori* (Moriyama et al., 1970; Hikino et al., 1975), *Hyalophora cecropia* (Gorell et al., 1972), *Prodenia eridania* (Yang and Wilkinson, 1972), *Manduca sexta* (King, 1972), *Choristoneura fumiferana* (Lagueux et al., 1976), and *Pieris brassicae* (Lafont et al., 1983). According to these investigations, the metabolism of ecdysteroids usually occurs by hydroxylation at C-20; epimerization at C-3; dehydration at C-3; acetylation at 3-OH; conjugation to sulfate esters, phosphate esters, glucosides, and glucuronides; and conversion to 26-oic acids. Recently, apolar metabolites of 20-hydroxyecdysone were found using ^{3}H-labeled 20-hydroxyecdysone in feeding experiments with ticks (Connat et al., 1984; Wigglesworth et al., 1985). The structures of apolar metabolites from tick whole-body extracts were identified by hydrolyzed fatty acid analysis, mass spectrometry, and by comparison to a synthetic 20-hydroxyecdysone-22-palmitate (Diehl et al., 1985). Apolar metabolites have been investigated from the cockroach *Periplaneta americana* (Slinger et al., 1986) and other arthropods (Connat and Diehl, 1986). However, their structures remain unidentified at this time.

The compounds isolated in the present study were the same as those previously reported in whole-body extracts of ticks (Diehl et al., 1985). However, this is the first report of this type of metabolite from an insect. These metabolites are found in fecal material at relatively high concentrations: approximately 16% of ingested 20-hydroxyecdysone.

Several metabolic studies of ecdysteroid metabolism in lepidopterous larvae have been carried out by injecting ^{3}H-labeled ecdysteroids into the insect body. However, the oral administration of ecdysteroids must be considered when examining phytoecdysteroids in insect–plant relationships. It has been pointed out that the hydroxy function at C-22 in ecdysteroids is essential for hormonal activity (Sorm, 1974). Synthetic 22-deoxy-20-hydroxyecdysone (Galbraith et al., 1969) and 2,22-dideoxy-20-hydroxyecdysone (Ikekawa et al., 1980) are about 10–100 times less active than 20-hydroxyecdysone. The presence of phosphate or adenosinemonophosphate esters on the 22-hydroxy of ecdysteroids also reduces the biological activity (Sall et al., 1983). This suggests the esterification at the 22-hydroxy group with fatty acids to be a detoxification mechanism in *H. virescens* against ingested 20-hydroxyecdysone. Research is in progress to examine the mode of action of this defensive mechanism.

Acknowledgments—We are grateful to Dr. H. Naoki, Suntory Institute for Bioorganic Research, for [^{1}H]NMR and SI-MS measurements and Dr. R. H. Dadd for critical reading of the manuscript.

(Received February 20, 1986; accepted May 8, 1986)

Abstract—We conducted a comparative study of volatiles produced by whole *Crataegus* hawthorn fruit and four cultivars of apple (Royal Red Delicious, Red Astrachan, McIntosh, and Wealthy) and determined quantitative and qualitative changes of volatiles associated with fruit ripening. Within the approximate range of the GLC fraction known to elicit behavioral activity in the apple maggot fly, *Rhagoletis pomonella* (Walsh) (Diptera: Tephritidae), 52 esters were identified.

Key Words—Apple volatiles, apple maggot fly, *Rhagoletis pomonella*, Red Astrachan, Royal Red Delicious, Wealthy, McIntosh, hawthorn, *Crataegus*.

INTRODUCTION

Control of the apple maggot fly, *Rhagoletis pomonella* (Walsh), is currently accomplished by organophosphate applications three to five times a season (Neilson et al., 1976; Reissig et al., 1982). This is purely a preventive method, with no regard for the presence of flies in the orchard. Although insecticide applications keep indigenous populations low, commercial fruit often can be infested by flies that have immigrated from external sources, such as abandoned orchards, wild apple, or hawthorn (*Crataegus* spp.).

Development of a sensitive trap that allows detection of low numbers of immigrating flies could ultimately reduce the number of insecticide applications as well as enhance the timing of such applications. Additionally, because of the apple maggot's recent invasion of western states, especially California (Joos et al., 1984), sensitive traps may be crucial for detection of the fly's spread into uninfested and quarantine regions.

0098-0331/87/0400-0795$05.00/0 © 1987 Plenum Publishing Corporation

To date, the most effective trap for detecting immigrating flies incorporates visual and olfactory stimuli from the fly's host fruit and is a sticky-coated red sphere combined with six esters characterized in volatiles collected from stored Red Delicious apples. The esters are hexyl acetate, butyl 2-methylbutyrate, propyl hexanoate, hexyl propionate, butyl hexanoate, and hexyl butyrate (Fein et al., 1982; Reissig et al., 1982). Field studies showed that there is an optimum range of release rates for these volatiles (Reissig et al., 1982).

Using these traps, Reissig et al. (1982) found in preliminary tests that the relative effectiveness of volatile-baited traps to unbaited traps varied not only among different orchards containing different cultivars, but also within orchards throughout the season as fruit matured. These results suggest that natural apple odor may compete with the synthetic blend due to greater attractiveness, concentration, or both. Indeed, early-ripening, sweet cultivars are frequently more heavily infested by *R. pomonella* than other cultivars, and for years researchers and orchardists have suggested that the type or amount of odor emitted by these apples is particularly attractive to the flies (O'Kane, 1914; Brittain and Good, 1917; Porter, 1928; Bush 1966; Prokopy et al., 1973).

Prompted by these anecdotal and experimental observations, we conducted a comparative study of volatiles produced by early (Red Astrachan), early-intermediate (Wealthy), intermediate (McIntosh), and late-ripening (Royal Red Delicious) apple cultivars. We also collected volatiles from a species of *Crataegus* because hawthorns are the native host fruit of *R. pomonella* and are very readily attacked by the fly (Prokopy et al., 1982). For each fruit type, we determined quantitative and qualitative changes of volatiles associated with fruit ripening. This work may provide a foundation for the development of more attractive blends for monitoring traps and, possibly, for development of optimum blends for use at different stages of fruit maturation.

METHODS AND MATERIALS

Collection of Fruit Volatiles. We collected apple volatiles in the manner described by Fein et al. (1982). For each sample, we picked 20–40 apples just prior to volatile collection, removed stems and leaves, and dried wet apples with a paper towel. Apples were placed in a foil-lined desiccator, which was washed and rinsed with acetone between collections. Using a vacuum pump, air was pulled through a purifying column of Porapak Q, then through the desiccator and onto a column (18 cm long, 0.7 cm diameter) of Ambersorb XE-348 beads (Rohm and Haas). Prior to use, the beads were washed in a Soxhlet extractor for 24 hr with a 3 : 1 chloroform–methanol wash, and then oven-dried.

Collections were made for 3 hr from June 11 to September 2, and for 24 hr from September 5 until November 19, 1983. Methyl decanoate was used as

an internal standard by injecting 35 μg in 2 μl of Skelly B onto the glass wool at the inlet of the column of beads. Air was pulled through the system for an additional 10 min. After this time, the column was attached to a 10-ml syringe and washed by pulling 8 ml of redistilled Skelly B back and forth, ten times, over the beads. The extracts were kept in Teflon-lined, screw-capped glass vials until analyzed. For volatile collections, we picked fruit from four apple cultivars that mature at different times: Red Astrachan (early), Wealthy (early-intermediate), McIntosh (intermediate), and Royal Red Delicious (late), and also from hawthorn (*Crataegus coccinea* L.). All fruit of like type were picked from a single tree. Hawthorn volatiles were collected and treated in the same manner as were the apple volatiles, except the mass of fruit was determined in grams and collections were made for 48 hr.

Sampling began on June 11, 1983, and continued every week until no apples remained on the trees. Hawthorns were collected from the middle of August 1984, again until no fruit remained on the tree. Fruit were randomly picked from all sections of the trees.

A separate test was made to determine if there were any qualitative or quantitative differences in volatile production by picked versus unpicked apples. To accomplish unpicked apple collections, the entire volatile collection apparatus was carried to the field. For both picked and unpicked apples, a glass funnel large enough to completely surround the apple was placed beneath the fruit and was attached to a pump and column of beads as described above. Volatile samples from picked apples were collected immediately following harvest. Within the examined range of volatiles, the samples collected did not vary substantially in volatile composition or concentration.

Analysis of Samples. From all of the samples collected and analyzed by GLC, we chose three time points from each fruit type for further analysis: a time well before fruit ripeness, an intermediate time, and when the fruit were ripe.

Two to three microliters of each sample were injected (splitless) onto a fused silica cross-linked methyl silicone capillary column that was programmed after a 1-min hold at 80°C to 180°C at 10°/min. At the beginning of each day, a hydrocarbon standard series (7–18 carbons) and a standard apple ester blend were run. In order to correct for day-to-day variations, all retention times were converted to Kovats' retention indices. A preliminary identity of each component was made by comparing the retention indices of the analyzed sample with those of the standard. Mass spectra were also obtained on each component with an HP-5985 GC-MS interfaced with a 20-m OV-101 glass capillary column.

Most synthetic samples were obtained from commercial sources, but if not available, were synthesized via established methods (Vogel, 1961) and purified by distillation. Mass spectral and GLC retention time data were collected on all synthetic esters.

Data Analyses. The absolute quantity of each component of a particular collection was obtained by dividing the peak area of the component with that of the internal standard and multiplying by the amount of the external standard (35 μg). For apple collections, each sum was standardized by converting all values to represent the amount released by 30 apples in 24 hr. For hawthorn, values represent the amount released by 500 g of fruit in 24 hr. The data were graphed as a simulated GLC tracing. If components came off as one peak, they were separated in the simulated tracing to show the relative amounts as determined by the GC-MS analyses.

RESULTS

Analysis was limited to the approximate range of esters found in the active GLC fraction of Fein et al. (1982) (approximately 5–12 carbon esters) because of the great number of volatiles present in the samples. The combined GLC and mass spectral data were used to identify 31 esters in the hawthorn extract and 48 in the apple extracts. Most identifications were straight-chain or 2-methyl esters that ranged from methyl to hexyl for the alcohol portion and propyl through octyl for the acid portion (Table 1).

Because few (Red Delicious) or no (all other cultivars) compounds were detected in the first volatile collections of the apple cultivars (taken well before fruit ripening), only analyses of the latter two collections are presented. Analyses of volatile collections taken one to two months prior to apple ripening are shown in Figure 1; analyses of collections from ripe apples are shown in Figures 2 and 3. For hawthorn, because no compounds were detected until the fruit were ripe in September, only analysis of the final collection is presented (Figure 3).

Except for the hexyl acetate peak in Wealthy, the ethyl hexanoate peak in Red Astrachan, and several minor peaks, the esters identified from unripe apple extracts were very similar (Figure 1). Each contained butyl hexanoate, hexyl butyrate, hexyl 2-methylbutyrate, and hexyl hexanoate. All but the Red Delicious extract contained butyl 2-methylbutyrate and butyl octanoate.

Regarding volatile composition of the extracts collected when the apples were ripe (Figures 2 and 3), all contained a butyrate and 2-methylbutyrate series. In comparison to the Wealthy extract, which contained a single dominant (60%) component (hexyl 2-methylbutyrate), or McIntosh, which contained only several major components, the Red Astrachan and Red Delicious extracts were more complex with an important series of hexanoates as well as a few octanoates.

In ripe hawthorn extracts, straight-chain hexanoates and octanoates were the major components (Figure 3). Hexyl hexanoate was the dominate (40%) ester. Unlike apples, 2-methyl esters were unimportant, but like most of the

[b] Tentative identification.

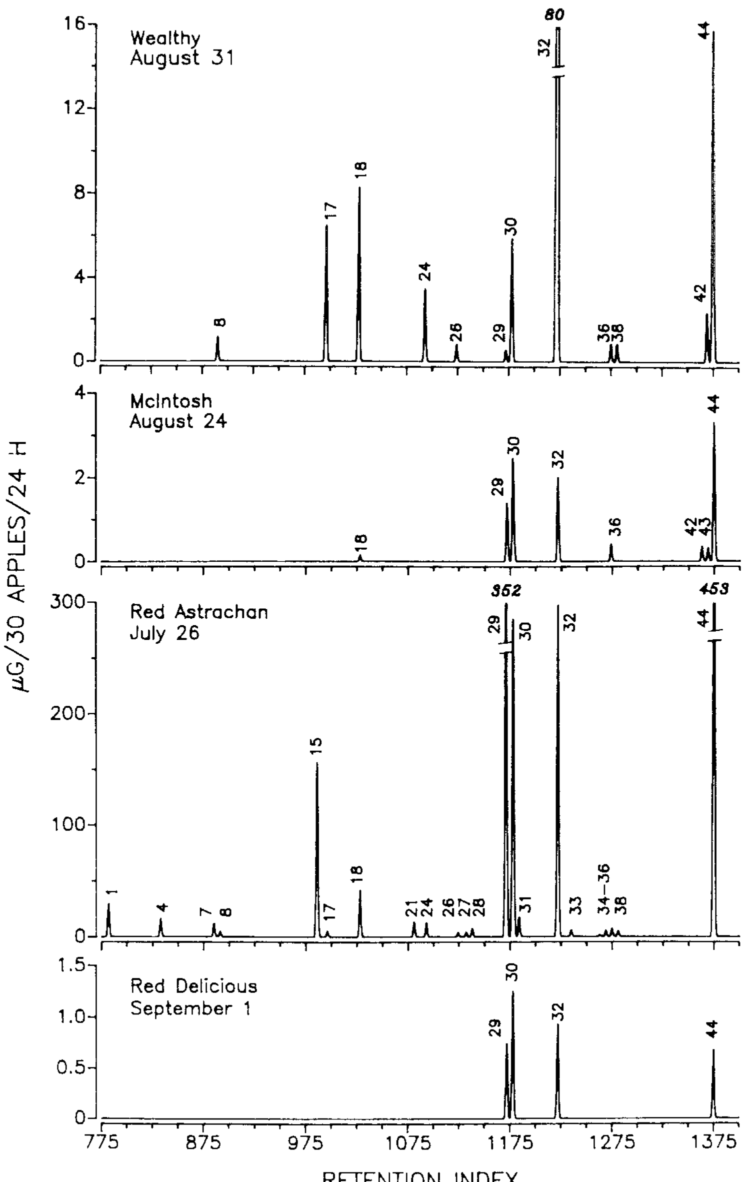

FIG. 1. Simulated GC traces of volatiles produced by Red Astrachan, McIntosh, Wealthy, and Red Delicious apples 1–2 months prior to fruit ripening. Vertical numbers near peaks refer to compound identifications, which are listed in Table 1. If compounds came off as one peak, they were separated in the tracing to show relative amounts. Horizontal numbers designate peak amounts that were off-scale.

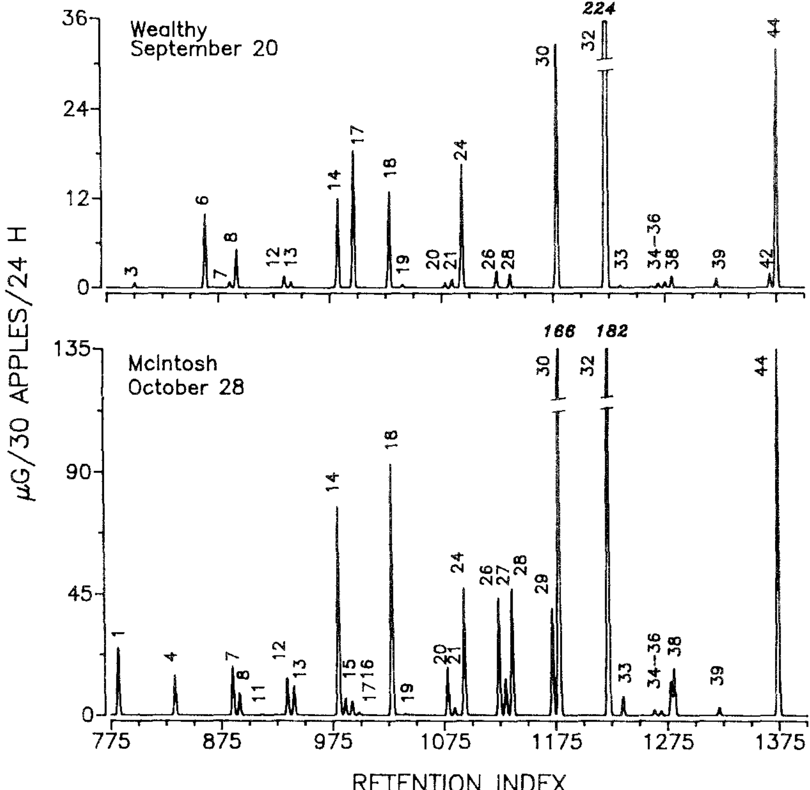

FIG. 2. Simulated GC traces of volatiles produced by ripe Wealthy and McIntosh apples. See Figure 1 for additional notes.

apples, especially unripe apples, the hawthorn extract contained butyl hexanoate, hexyl butyrate, and hexyl hexanoate. Greatest similarity appeared between Red Astrachan and hawthorn. In addition to the above compounds, large ethyl and butyl octanoate peaks appeared in both extracts.

For all apple cultivars, the number and quantity of esters was higher in ripe than in unripe apples. In McIntosh and Red Delicious extracts, where two months separated the volatile collections, appearance of new esters (especially short-chain esters) in the ripe apple collection was pronounced. When ripe, both produced a ''flush'' of esters that was hundreds of times more concentrated than that of unripe apples. In Red Astrachan and Wealthy extracts, where one month separated volatile collections, compounds already present in unripe apples appeared in greater concentration following fruit ripening. In Wealthy, ratios of the various compounds did not change much following ripening, but in Red

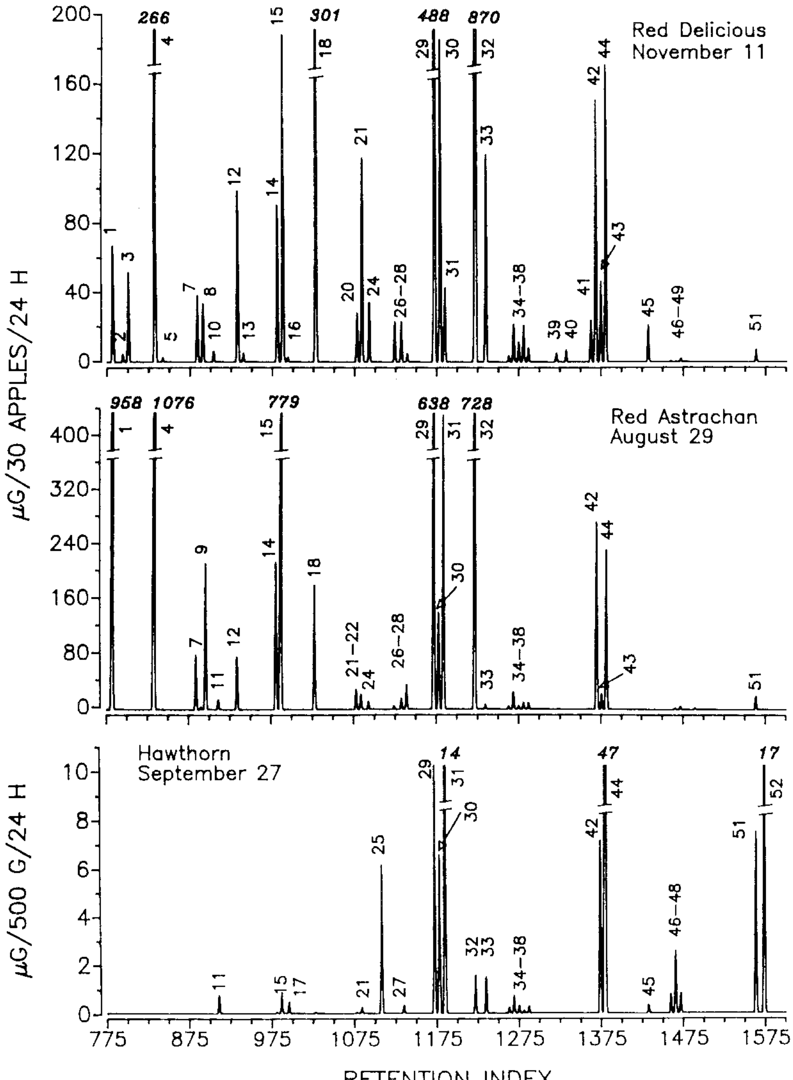

FIG. 3. Simulated GC traces of volatiles produced by ripe Red Astrachan and Red Delicious apples and *C. coccinea* hawthorns. See Figure 1 for additional notes.

Astrachan, the major peak in unripe extracts (hexyl hexanoate) was swamped by an increase of short-chain esters (ethyl butyrate, ethyl 2-methylbutyrate, and ethyl hexanoate) produced by ripe apples.

Because the time of greatest *R. pomonella* host-seeking and oviposition behavior occurs from late July to September, foraging flies would likely en-

counter ripe Red Astrachan fruit, almost-ripe Wealthy and hawthorn fruit, and unripe McIntosh and Red Delicious fruit. During this interval of peak fly activity, only Red Astrachan and, to a lesser extent, Wealthy were producing a sizable quantity of volatiles. Comparison among the apple extracts collected at this time revealed that the total volatile production by Red Astrachan was ca. 60 times greater than Wealthy, 600 times greater than McIntosh, and 1000 times greater than Red Delicious.

DISCUSSION

Volatiles produced by many apple cultivars have been thoroughly investigated numerous times (Dimick and Hoskin, 1983). Similar to our findings, these studies have often shown similarity in the compounds identified, but differences in the ratio of these compounds from cultivar to cultivar (Flath et al., 1969; Dimick and Hoskin, 1983). Further, all of the major apple components identified in our study have previously been reported. However, these studies seldom report analyses of volatiles produced by whole fruit immediately following harvest and do not allow comparison of volatiles produced by the particular fruit types of interest to us.

During the interval when apple maggot fly activity occurs (July–September) and within the volatile region found to be most attractive to the apple maggot (Fein et al., 1982), there was surprising similarity among the apple cultivars as well as between apple and *C. coccinea* hawthorns. This latter finding was of particular interest because *R. pomonella* originally infested hawthorn and has only recently expanded its host range to include apple as well as several other introduced and domesticated fruits, such as cherry and pear. Because olfactory cues appear to play a role in initial orientation to the host plant by *R. pomonella* and also influence oviposition-site selection (Bush, 1966; Prokopy et al., 1973, unpublished data), perhaps this similarity in volatile composition has facilitated the apparently easy shift of *R. pomonella* from hawthorn to apple.

Among the apple cultivars, similarity in ester composition and ratio was most apparent in Red Delicious and Red Astrachan. Such a similarity was previously reported by Fein et al. (1982), but in their study, the largest peak reported for both cultivars was hexyl acetate. Although our collection and analysis techniques were consistent with those used by Fein and coworkers, we did not isolate any hexyl acetate from either cultivar. The previous study, however, was conducted with apples kept in storage. Studies of Red Delicious and other cultivars have shown that changes in volatile profile occur rapidly following even short storage intervals and fluctuate throughout the storage period (Brown et al., 1966; Guadagni et al., 1971). In general, but depending on apple ripeness and storage conditions, certain short-chain esters build up to a maximum within

a few weeks after harvest (Hatfield and Patterson, 1977; Dimick and Hoskin, 1983).

All of the apple cultivars we examined are moderately to highly susceptible to attack by *R. pomonella*, but if ranked, Red Astrachan and, to a lesser extent, Wealthy, would likely be considered most susceptible. While numerous factors, such as changes in fruit acidity and skin toughness, would be associated with the early ripening of these cultivars (Dean and Chapman, 1973) and probably would contribute to the susceptibility of these cultivars, the higher level of volatiles produced may also be important. On the other hand, the apple maggot fly may be selectively tuned to reception of hawthorn volatiles. Perhaps the remarkable similarity between the volatile profiles of Red Astrachan and hawthorn, combined with Red Astrachan's exceptionally high rate of volatile release, may in part account for the extreme susceptibility of this particular cultivar. In the future, comparative studies of volatiles produced by cultivars that are seldom attacked by *R. pomonella* might prove interesting.

Although there is little evidence to support such a contention (Reissig et al., 1985), we question whether the increasing concentration of natural odor from ripening apples may compete with the synthetic blend. Indeed, within the range of volatiles that we analyzed, we calculated that a ripe Red Astrachan apple produces over 8 μg of esters per hour. At this rate, it would take only 60 apples to produce an amount comparable to the release rate of synthetic blend (500 μg/hr). For the other cultivars we investigated, it would require ca. 950, 330, or 95 ripe Wealthy, McIntosh, or Red Delicious apples, respectively, to equal the volatile release of a trap. Prior to fruit ripening, it would require 200 Red Astrachan apples to equal the volatile release of a trap or 2000, 35,000, or 100,000 Wealthy, McIntosh, or Red Delicious apples, respectively, to equal trap release. However, whether trap efficacy declines over the season, or if this occurs as a result of competition with ripe apple aroma, remain to be tested. No doubt, numerous other factors associated with fruit ripening may influence trap efficacy. For example, changes may occur in the physiological state of the flies. It is very likely that early in the season, fruit are hard and acidic, and thus, unsuitable to a *R. pomonella* female foraging for oviposition sites. Under such circumstances, the probability that a female would respond to the synthetic blend may be much higher than later in the season, when abundant, suitable fruit are available.

We are currently testing apple maggot fly response (throughout the growing season) to synthetic blends based on the volatile profiles determined from hawthorn and the four apple cultivars. Because dissimilarity in the profiles was due to differences in ratio of the various components rather than to the appearance of any one or a series of novel components, at the superrelease rates of volatiles normally utilized in field tests, differences in the level of attractiveness among the blends may not be apparent. For this reason, and because variation in overall concentration of volatiles produced was the most salient difference

observed among the cultivars, controlled release rates of the volatile blends will be a key focus in future studies.

QUANTITATIVE AND QUALITATIVE VARIATION IN MALE PHEROMONES OF *Phragmatobia fuliginosa* and *Pyrrharctia isabella* (LEPIDOPTERA: ARCTIIDAE)

STUART B. KRASNOFF, LOUIS B. BJOSTAD,[1] and WENDELL L. ROELOFS

(Received February 19, 1986; accepted May 19, 1986)

Abstract—The dihydropyrrolizine pheromones, hydroxydanaidal and danaidal, were identified from the scent organs of male *Phragmatobia fuliginosa* (L.) and *Pyrrharctia isabella* (J.E. Smith). Qualitative and quantitative GLC analyses were conducted on ca. 80 field-collected males of each species. The total pheromone titer was distributed bimodally in each species with most males having either a small amount (< 10 ng) of pheromone or a large amount (1–10 μg in *Pyrrharctia* and 0.3–3 μg in *Phragmatobia*). *Pyrrharctia* males in the 1- to 10-μg range had a predominance of hydroxydanaidal, with little if any danaidal. Most *Phragmatobia* males in the 0.3- to 3-μg range had danaidal with little if any hydroxydanaidal. These compounds elicited a courtship response in sexually receptive females of both species. A bioassay based on this response was used to measure the thresholds of female response to these compounds. *Pyrrharctia* females were more sensitive to (*R*)-(−)-hydroxydanaidal than to danaidal. *Phragmatobia* females were more sensitive to danaidal then to (*R*)-(−)-hydroxydanaidal.

Key Words—*Phragmatobia fuliginosa, Pyrrharctia isabella,* male pheromones, sex pheromones, Lepidoptera, Arctiidae, pyrrolizidine alkaloids, hydroxydanaidal, danaidal.

INTRODUCTION

Dihydropyrrolizines have been identified from the scent organs of males of numerous danaine butterfly species (Meinwald and Meinwald, 1966; Meinwald et

[1] Present address: Department of Entomology, Colorado State University, Fort Collins, Colorado 80523.

al., 1971, 1974; Edgar et al., 1971, 1973; Edgar, 1982; Komae et al., 1983). In several cases these compounds were shown to be derived from pyrrolizidine alkaloids (PAs) contained in plants that were fed upon by adult males (Edgar et al., 1973; Schneider et al., 1975). The pheromonal function of one of these compounds, danaidone, has been established for only one of these butterflies (Pliske and Eisner, 1969; Schneider and Seibt, 1969).

The male scent organs (coremata) of arctiid moths of the genus *Utetheisa* are inflatable sacs covered with scent scales that emerge from slits in the sides of the genital valves. The dihydropyrrolizine hydroxydanaidal (Figure 1: II) was identified from *Utetheisa pulchelloides* (Hamps.) and *U. lotrix* (Cram.), and the related compound, danaidal (Figure 1: I), was identifed from the latter species only (Culvenor and Edgar, 1972). Conner et al. (1981) identified hydroxydanaidal from *U. ornatrix* (L.), showed that it is derived from PA precursors obtained during larval feeding, and established the role of the compound as a close-range courtship pheromone in that species.

Moths of the Asian arctiid genus *Creatonotos* also have coremata, but these are tubular structures arising from the 7th abdominal sternite and so are not homologous to those found in *Utetheisa*. Schneider et al. (1982) showed that larval ingestion of PAs is necessary for both the presence of hydroxydanaidal in adult male coremata as well as the full development of the organs themselves in *Creatonotos gangis* L. and *C. transiens* (Walker). The behavioral role of hydroxydanaidal as an attractant of females, and possibly males, to mating aggregations in these two species has been referred to in several reports (Wunderer et al., unpublished, cited in the following: Schneider, 1983; Boppré and Schneider, 1985; Boppré, 1986).

We studied the pheromone biology and mating behavior of two north temperate arctiids, *Phragmatobia fuliginosa* (L.) (hereinafter referred to as *Phragmatobia*) and *Pyrrharctia isabella* J.E. Smith (hereinafter referred to as *Pyrrharctia*). Like *Creatonotos*, males of these species have eversible tubular

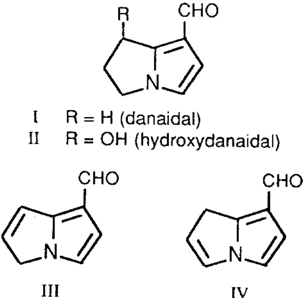

FIG. 1. I, II: dihydropyrrolizine pheromones of arctiid moths; III, IV: GLC degradation products of II.

coremata (Nielsen, 1979, 1982). However, in contrast to the protracted static display of the coremata exhibited by *Estigmene acrea* (Drury) (Willis and Birch, 1982) and *Creatonotos* spp. (Schneider et al., 1982), *Phragmatobia* and *Pyrrharctia* males evert their coremata only briefly during the courtship flight while approaching a calling female (Nielsen, 1982; Krasnoff, 1987). In this paper we document the presence of hydroxydanaidal and danaidal in the coremata of both of these species, as well as the behavioral activity of the two compounds. We show that pheromone quantity of individual wild males varies widely and in a characteristic way within each species. We also show that pheromone composition differs between the two species and that this difference is reflected in differences in female response.

METHODS AND MATERIALS

Insects. All of the male moths used in this study were captured in the field at sites in Ontario, Schuyler, Seneca, and Tompkins counties, New York State, between June and November, 1984. Most of the males were collected at lights, but some were collected as mature larvae and allowed to pupate and eclose in the laboratory following a modification of the methods of Goettel and Philogène (1978).

Colonies of each species were derived from eggs of field-collected females. Larvae were reared in the laboratory on either leaf cuttings of wild plants (*Plantago* spp., *Taraxacum* spp.) or on an artificial diet (Shorey and Hale, 1965). Larvae were held at 25° ± 2°C under a 16:8 light-dark photoperiod. Females used in bioassays were either exposed to a reversed light cycle as pupae and used during working hours or were exposed to natural light and used during the natural mating activity period (ca. 0.5–2.0 hr after dark for *Pyrrharctia* and ca. 2.0–4.0 hr after dark for *Phragmatobia*).

Bioassay. During courtship, a *Phragmatobia* or *Pyrrharctia* female often responds to the corematal display of an approaching conspecific male with a characteristic wing-fluttering and clicking behavior (Krasnoff, 1987). Preliminary experiments showed that male coremata artificially extruded by squeezing, solvent extracts of male coremata, or synthetic hydroxydanaidal held close to the antennae of calling *Pyrrharctia* or *Phragmatobia* females elicited this response, whereas solvent blanks presented in this manner never did. This response provided the basis for a pheromone bioassay.

During the mating period, calling females were coaxed to perch on wooden dowels. Materials to be tested were applied to the tip of a glass or metal rod in a measured amount of solvent. The solvent was allowed to evaporate, the tip of the rod was held ca. 2 mm from the tips of a female's antennae for 3 sec and the female's response noted. The rod was never allowed to make physical contact with the antennae of the test subject (cf. Conner et al., 1981). This method

of presentation was designed to approximate the exposure of a calling female to the pheromone of an aproaching male and to assure that only olfactory stimuli were affecting the female. Although responses ranged from short bursts of wing-fluttering and clicking lasting less than 1 sec to sustained responses lasting more than 5 sec, any response involving wing-fluttering and/or clicking was scored as positive in these experiments. If neither of these behaviors was observed a negative score was recorded.

Chemical Identifications. Coremata of individual males were manually everted by gently squeezing the abdomen. They were then gripped with forceps, removed with a razor blade, placed in ca. 0.5 ml redistilled dichloromethane in a tightly capped 4-ml vial, and allowed to stand for at least 1 hr at ca. 22°C. Samples were stored at −20°C until they were analyzed.

Preparative GLC was carried out at 150°C on a 2-m glass column (ID 4 mm) packed with 1% (w/w) OV-101 (methyl silicone) on 100- to 120-mesh Gas-Chrom Q. Fractions were collected from this column by cold-trapping in 30-cm glass capillary tubes. Capillary GLC was conducted with a 25-m cross-linked methyl silicone column (ID 0.31 mm) and a 5% phenylmethyl silicone column (ID 0.20 mm) used with splitless injection and programmed from 80° to 200°C at 10°/min after an initial hold of 1 min, or a 30-m Supelcowax 10 column (ID 0.25 mm) programmed from 80° to 230° at 15°/min after an initial hold of 1 min. Quantification was achieved by comparing electronically integrated pheromone peak areas with that of a known amount of an internal standard (hexadecane). As little as 10 pg of material could be detected by this method. Electron ionization and chemical ionization (isobutane) mass spectra were obtained with a Hewlett-Packard 5985 GC-MS system using methyl silicone, 5% phenylmethyl silicone, and Supelcowax columns identical to those described above.

Preliminary analyses and bioassays indicated that some males of both species appeared to have relatively large amounts of pheromone, whereas others appeared to have little or none at all. Therefore a screening procedure was developed to permit a refinement in the quantification system. Before quantitative analysis of a large number of field samples, ca. 1–2 μl out of 200–500 μl of each sample was tested for behavioral activity. Samples producing a positive response were given 500 ng of the internal standard (hexadecane), whereas only 5 ng were added to samples that produced no response. Samples in the positive category were analyzed by injecting 1–2 μl out of a total of 300–500 μl. Samples in the negative category were concentrated under a stream of dry nitrogen to ca. 20 μl volume and 3–4 μl were injected.

Synthetic Sources. Synthetic (*R*)-(−)-hydroxydanaidal, obtained from Dr. J. Meinwald for use in bioassays and in chromatographic and spectroscopic standards, was shown by GLC to be >99% pure. Synthetic danaidal, obtained from Dr. J.A. Edgar and used similarly, was determined by GLC to be >99%

pure. Serial dilutions for bioassays were made in redistilled dichloromethane. The control for bioassays was a 1% solution of hexadecane in dichloromethane.

Threshold Studies. With the bioassay described above, the threshold of response of *Pyrrharctia* and *Phragmatobia* females to both danaidal and (*R*)-(−)-hydroxydanaidal was measured for ca. 20 insects in each of four separate experiments. Only the (*R*)-(−) enantiomer of hydroxydanaidal was used because preliminary tests showed that it had much greater activity than is antipode. Moreover (*R*)-(−)-hydroxydanaidal was identified, by a behavioral bioassay, as the pheromone in *Utetheisa ornatrix* (Conner et al., 1981) and as the predominant constituent of the corematal secretions of *Creatonotos gangis* and *C. transiens* (Bell et al., 1984; Bell and Meinwald, 1986).

Calling females, never previously exposed to synthetic or male-derived odors, were presented with a control and then a series of doses of pheromone increasing in potency in logarithmic steps. Preliminary trials established a starting dose that could be assured of getting no positive response. Making certain that a female would not respond to the first dose in a series eliminated doubt as to whether she would have responded to a lower dose. The first dose (i.e., the lowest) in the series that elicited a response for each individual female was noted. After a female's threshold of response was established in this way, she was not tested with higher doses. Testing continued until all females had responded.

A single application was never used for more than six females in succession, so no more than 30 sec elapsed from the first presentation to the last for any dose. Illumination in all four experiments was provided by a 6-V lantern with red acetate covering the lens. *Pyrrharctia* female response to danaidal was assayed during the natural activity period. Temperatures during this experiment ranged from 16 to 18°C. Also metal rods (7-cm finishing nails) were used in place of glass in this experiment only. All of the other tests were conducted with clock-shifted insects at 20–25° C. In the test of *Pyrrharctia* female response to hydroxydanaidal, doses were delivered in either 1 μl or 10 μl of solvent, and some of the females used were derived from the laboratory colony while some were from field-collected larvae. In all other tests, all doses were delivered in 10 μl of solvent, and all females used were from laboratory colonies.

RESULTS

Chemistry. Preliminary packed-column GLC analyses on OV-101 showed that synthetic hydroxydanaidal chromatographed poorly, producing a broad peak with considerable tailing. Fractionation of behaviorally active extracts of *Pyrrharctia* males gave activity in all fractions collected after the retention time of hydroxydanaidal. Subsequently, both hydroxydanaidal and danaidal were iden-

tified from individual field-collected *Phragmatobia* and *Pyrrharctia* males by comparisons of GLC retention times on polar and nonpolar capillary columns and mass spectra with those of authentic samples of synthetic material.

We encountered a peak that always appeared with hydroxydanaidal and eluted at the same time as danaidal on methyl silicone and 5% phenyl methyl silicone (Figure 2). This compound was present as ca. 10% of total hydroxy-

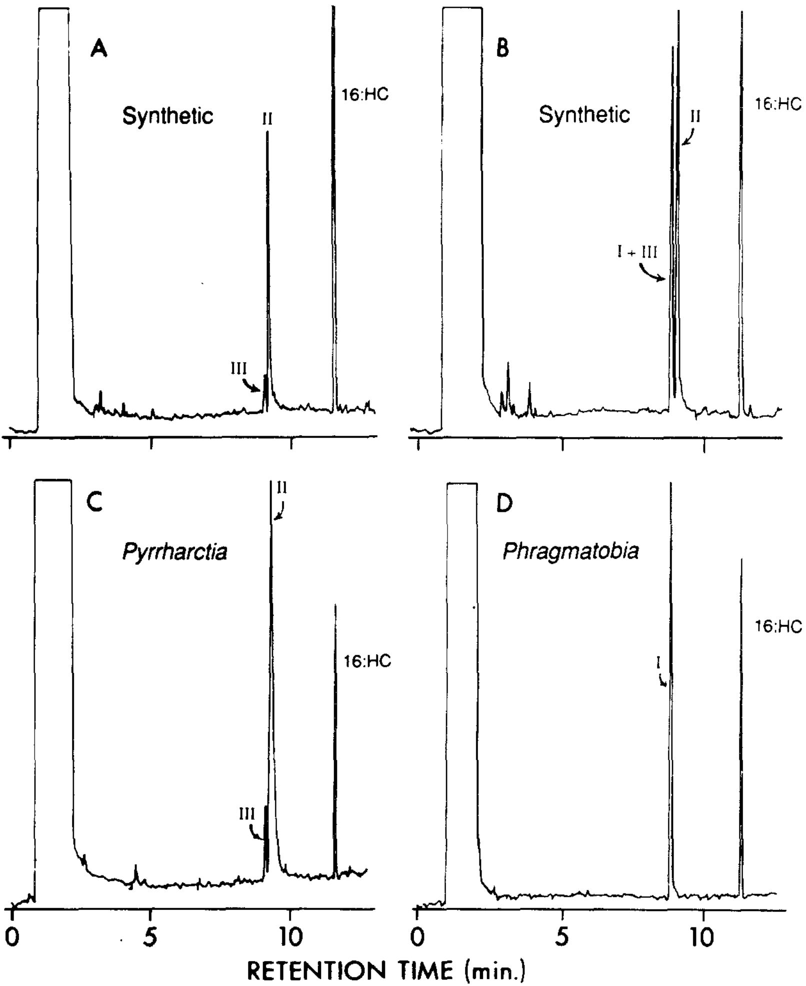

FIG. 2. Chromatograms of (A) synthetic hydroxydanaidal, (B) synthetic hydroxydanaidal + synthetic danaidal, (C) a *Pyrrharctia* male corematal extract, and (D) a *Phragmatobia* male corematal extract. Compound numbers correspond to those in Figure 1. 16:HC is hexadecane, the internal standard.

danaidal in chromatographic analyses (N = 15) of synthetic hydroxydanaidal. The CI mass spectrum of this peak indicated a molecular weight of 133, 18 mass units lower than hydroxydanaidal. The EI mass spectrum showed peaks two mass units lower than danaidal throughout the spectrum (Figure 3). These spectra are consistent with expectations for a dehydration product (Figure 1: III) that might arise readily from hydroxydanaidal.

A virtually identical EI mass spectrum was obtained for a peak with a retention time of 0.90 relative to the later peak on methyl silicone and 5% phenylmethyl silicone. This earlier peak was always smaller than the later peak (range: 8–15%). On this basis we suggest that it is rearrangement of the dehydration product of hydroxydanaidal (Figure 1: IV). Because these compounds appear in chromatograms of synthetic hydroxydanaidal shown to be >95% pure on the basis of [^{1}H] NMR analysis (G. Zarilli and J. Meinwald, personal communication), it is most likely that they are being generated under the severe conditions (250°C) encountered in the GLC injector.

Samples showing microgram quantities of compound III on methyl silicone were analyzed on Supelcowax. A mass spectral survey indicated that compound III did not elute from Supelcowax. Although Supelcowax separated danaidal and hydroxydanaidal, it gave lower quantitative estimates than methyl silicone for both compounds, suggesting that active sites were not allowing substantial amounts of these compounds to elute. Consequently, quantitative data were derived from analyses performed on methyl silicone. By adding together the

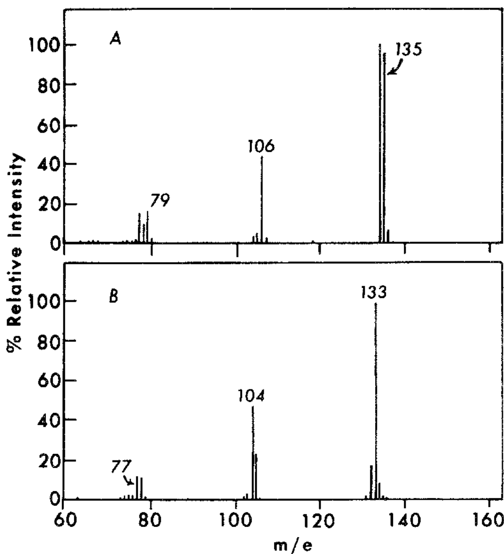

FIG. 3. Mass spectra of (A) danaidal from a *Phragmatobia* male corematal extract and (B) compound III from an analysis of synthetic hydroxydanaidal.

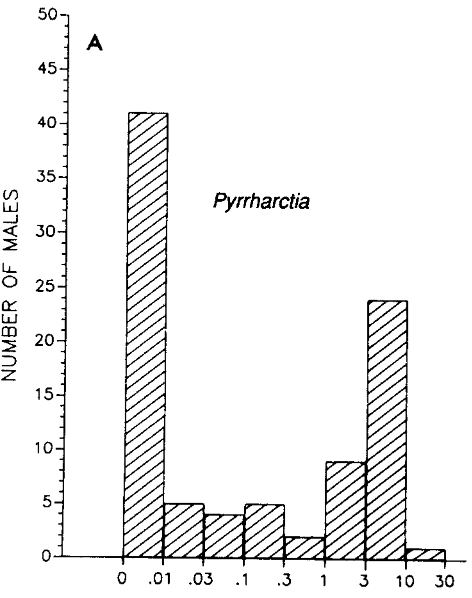

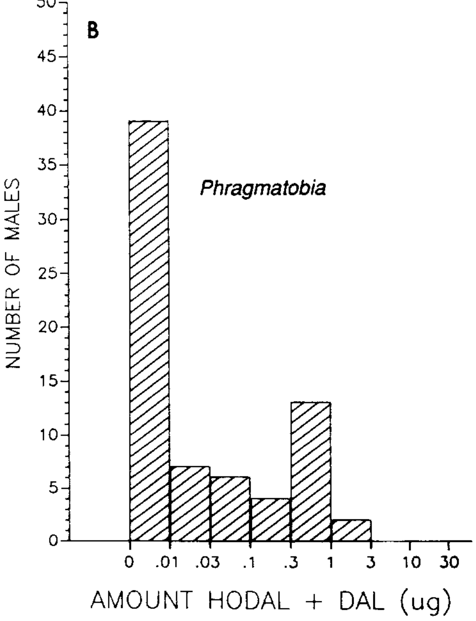

FIG. 4. Frequency distributions of total male pheromone content (hydroxydanaidal + danaidal). A. *Pyrrharctia* ($N = 91$). B. *Phragmatobia* ($N = 71$). Bars represent number of males within the indicated range.

estimates of danaidal and hydroxydanaidal for each individual male, and using the totals to provide an overall picture of the variability of the amount of PA-derived pheromone for males of each species, the confounding effect of compound III on the quantification system was avoided.

Pyrrharctia males had from < 10 pg to 12.3 μg of total pheromone. In *Phragmatobia* males, the measurements ranged from < 10 pg to 1.5 μg. Figure 4A shows a distinct bimodality in the amount of PA-derived pheromone found in *Pyrrharctia* males, with most males in either the 0–10 ng range (45%) or the 1–10 μg range (35%). There is a similar bimodality in *Phragmatobia* (Figure 4B) but with the higher mode ca. one order of magnitude lower than that found in *Pyrrharctia*. Here we found 55% of all males in the sample in the 0 to 10-ng range and 21% in the 300- to 1500-ng range.

Of the 15 *Phragmatobia* males with >0.3 μg of total pheromone, most had >99% danaidal, although one had as little as 12% (Figure 5). On the other hand, although three *Pyrrharctia* males had more danaidal than hydroxydanaidal (260 ng danaidal: 1 ng hydroxydanaidal, 170 ng danaidal: 50 ng hydroxydanaidal, and 68 ng danaidal: 4 ng hydroxydanaidal), all of the 33 *Pyrrharctia* males with > 1 μg of total pheromone showed > 85% hydroxydanaidal (Figure 5). The breakdown product of hydroxydanaidal (III) accounts for some or all of the "danaidal" in the samples showing microgram quantities of hydroxydanaidal. Therefore, ratios of hydroxydanaidal to danaidal represent minima. GLC analysis on Supelcowax firmly established the presence of danaidal in

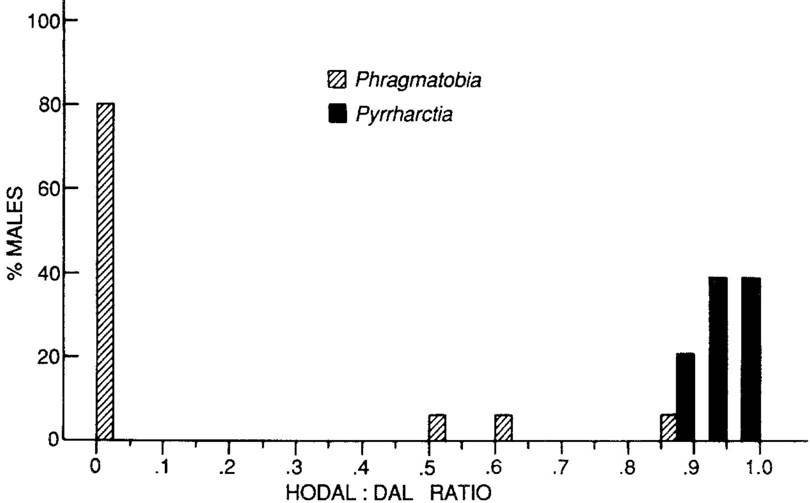

FIG. 5. Frequency distributions of hydroxydanaidal-danaidal ratio for *Pyrrharctia* males with > 1 μg of total pheromone (N = 33) and *Phragmatobia* males with >0.3 μg total pheromone (N = 15). Bars represent number of males within the indicated range.

several of these higher mode *Pyrrharctia* males, and, as expected, the estimate of the proportion of danaidal in the total pheromone blend was always smaller than the estimate obtained from methyl silicone. However, underestimating the percentage of hydroxydanaidal in the total blend for *Pyrrharctia* males only minimizes the difference between the ''typical'' blends of the two species, which is still highly significant ($P < 0.0001$, Mann-Whitney U test).

Threshold Studies. Some female *Pyrrharctia* responded to as little as 50 fg of (*R*)-(−)-hydroxydanaidal, most responded to 5 pg or less, and in no case were more than 50 pg required to elicit a response (Figure 6A). The response profile moves up two orders of magnitude in this species when danaidal is substituted for hydroxydanaidal (Figure 6B). To be certain that the apparent lower sensitivity of *Pyrrharctia* females to danaidal relative to hydroxydanaidal was not due to the lower temperatures obtaining during the danaidal test, we assayed several of the subjects in the danaidal test with hydroxydanaidal and found that they did indeed respond to lower doses of hydroxydanaidal than danaidal under the same conditions.

We observed the reverse situation in *Phragmatobia*, with most females responding to less than 50 pg of danaidal and all responding to 5 ng or less (Figure 7A). Up to 50 ng of hydroxydanaidal were required for many of the *Phragmatobia* females to respond (Figure 7B) and one female (not respresented in Figure 7B) failed to respond to 500 ng, the highest dose tested.

DISCUSSION

The samples analyzed in this study exposed a pattern of quantitative variation among individual wild males of both species that is, as far as we know, unique in the pheromone literature. Boppré et al. (1978) reported greater absolute variation in danaidone titers of 19 field-collected *Danaus chrysippus* (31–420 μg), but proportionally the differences are much greater in *Phragmatobia* and *Pyrrharctia*, with differences of three to four orders of magnitude between the lowest and the highest measurements compared to the 15-fold difference seen in *D. chrysippus*. Boppré and Schneider (in press, referred to in Boppré and Schneider, 1985) also refer to a ''drastic'' variation in hydroxydanaidal titers in field-collected *Creatonotos* males. In light of the differences in hydroxydanaidal titers between *Creatonotos* males reared in the laboratory on PA-deficient plants (<5 ng) and those reared on PA-containing plants (up to 450 μg) (Schneider et al., 1982), and the polyphagous nature of *Creatonotos* in the field (Boppré and Schneider, 1985), it seems possible that the extent of variation could be greater than that seen here by one to two orders of magnitude. However, the distinct bimodal distribution of pheromone titer observed in *Phragmatobia* and *Pyrrharctia* was reported in neither *Danaus* nor *Creatonotos*.

From laboratory feeding experiments, we have evidence that the pher-

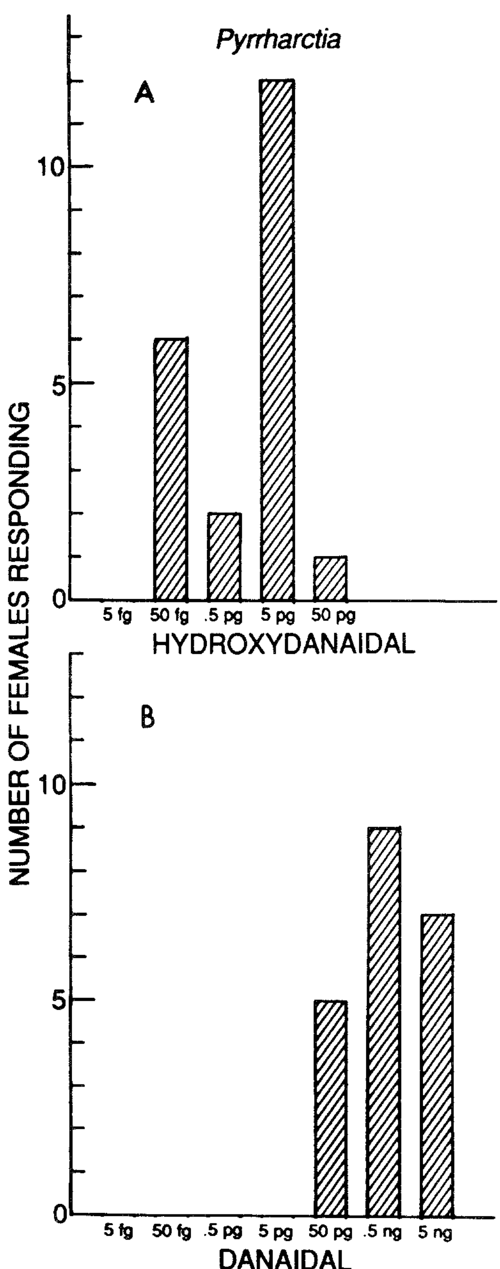

FIG. 6. Number of *Pyrrharctia* females responding first to given dose of (A) (*R*)-(−)-hydroxydanaidal (N = 21 females) and (B) danaidal (N = 21 females). Dosage series were present sequentially from lowest to highest. Highest dose labeled was highest necessary to elicit a response in any female in test.

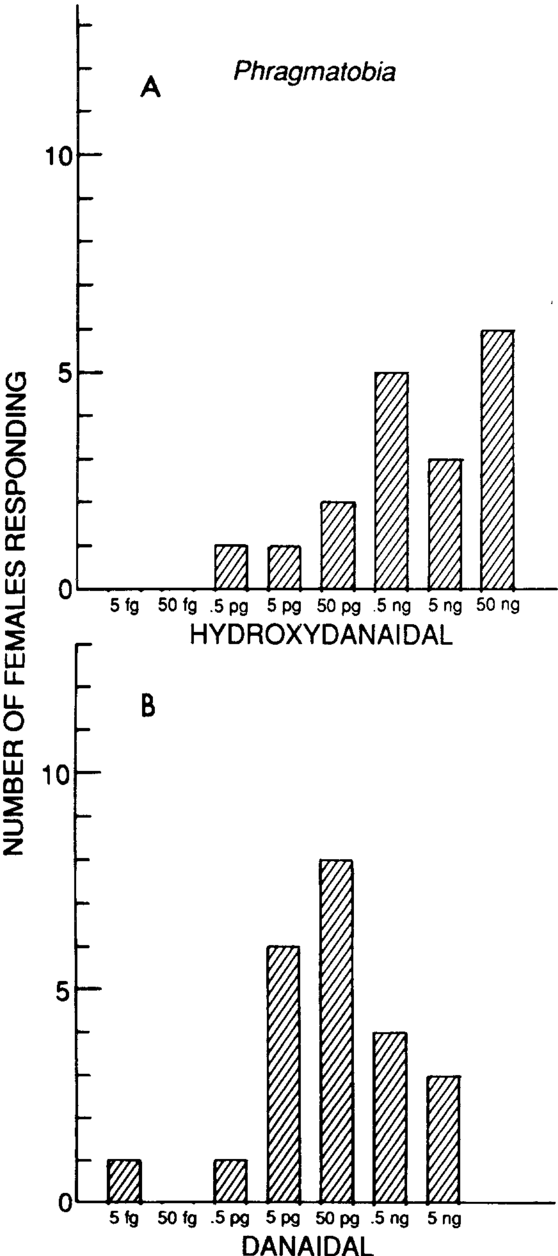

FIG. 7. Number of *Phragmatobia* females responding first to given dose of (A) (*R*)-(−)-hydroxydanaidal (N = 18 females) and (B) danaidal (N = 23 females). Dosage series were presented sequentially from lowest to highest. Highest dose labeled was highest necessary to elicit a response in any female in test.

omones identified here are derived from PA-precursors in the larval diet, and although *Phragmatobia* and *Pyrrharctia* are polyphagous as larvae, we have observed them feeding on PA-containing plants in the field (Krasnoff, 1987). In this light, the variation in pheromone content in field-collected *Phragmatobia* and *Pyrrharctia* males reported here can be seen as indicative of variation in larval feeding history in the field. Males with the higher amounts of pheromone are, we believe, those that gained access, as larvae, to some source of PAs. Those with no pheromone at all clearly did not feed on any PA plants during larval development. Inasmuch as female arctiids are capable of passing PAs into their eggs (Benn et al., 1979; Dussourd et al., 1984; Boppré, unpublished data cited in Boppré and Schneider, 1985), it is possible that *Phragmatobia* and *Pyrrharctia* males with small amounts of dihydropyrrolizines inherited the precursors for them from their mothers without themselves feeding on any PA-containing plants as larvae. Males with intermediate amounts of pheromone, say 50–100 ng, may have either inherited a lot of precursor or fed only minimally on PA-laden food.

Some notable exceptions notwithstanding, a "typical" *Pyrrharctia* male in the higher categories for the species had hydroxydanaidal with little if any danaidal, while a "typical" *Phragmatobia* male had danaidal with little if any hydroxydanaidal. The few *Pyrrharctia* males with more danaidal than hydroxydanaidal and *Phragmatobia* males with more hydroxydanaidal than danaidal, recall the case reported by Culvenor and Edgar (1972), in which *Utetheisa lotrix* males collected at different sites yielded different ratios of hydroxydanaidal and danaidal. We were intrigued by the fact that two of the three *Pyrrharctia* males in our sample with more danaidal than hydroxydanaidal came from the same site. In accordance with the speculations of Culvenor and Edgar, we propose that any atypical pheromone profiles in *Phragmatobia* and *Pyrrharctia* males are due either to genetic differences or to differences in the PA plants, and hence the alkaloids themselves, ingested by the larvae in different regions. We are currently investigating these possibilities.

Overall, our qualititative pheromone data depict an association of *Pyrrharctia* males with hydroxydanaidal and *Phragmatobia* males with danaidal that is supported by the data on the behavioral response profiles of the females of each species. We do not interpret these differences as having evolved in a context of reproductive isolation between these two species because they are neither seasonally cosynchronous nor cross-attractive due to major differences in the female sex attractants (Roleofs and Cardé, 1971; Descoins and Frerot, 1984; Meyer, 1984; Krasnoff and Roelofs, unpublished).

Although numerous compounds have been identified from male lepidopteran scent organs, reports of overt female behavioral responses to male pheromones are still relatively few (Nishida et al., 1982 and references cited; Krasnoff and Vick, 1984, and references cited). Fewer still are quantitative behavioral data on the level of female sensitivity to male pheromones (Jacobson et

al., 1976). Preliminary tests showing that nanogram quantities of hydroxydanaidal elicited virtually 100% response from *Pyrrharctia* females suggested that the response thresholds could be very low and this, indeed, proved to be the case. Females proved sensitive enough to male pheromone that even a male in the lower mode of the distribution, with as little as 1 ng of total pheromone, could possibly evoke a response in almost any female, assuming that a male's coremata release pheromone as efficiently as a glass rod.

The quantitative relationship between male pheromone titer and female sensitivity has broader implications for understanding the significance of these pheromones in the mating behavior of *Phragmatobia* and *Pyrrharctia*, as well as the arctiids that have been under investigation by other workers. In *Utetheisa ornatrix*, the absence of the PA-derived male pheromone has been shown experimentally to reduce a male's mating success (Conner et al., 1981). However, *U. ornatrix* has a larval host-range limited to plants of the genus *Crotalaria*, all of which contain PAs. Consequently, it is unlikely that females in nature will encounter a male without the pheromone. In contrast, *Phragmatobia* and *Pyrrharctia*, as well as the *Creatonotos* spp. referred to above (Boppré and Schneider, 1985; Boppré, 1986), apparently have a looser relationship to PA-containing plants, i.e., they are essentially polyphagous as larvae, but will feed on PAs if the opportunity arises. The resulting variation in male pheromone titer raises questions: What effect, if any, does the amount of male pheromone have on mating success of males in these polyphagous species? In the case of *Phragmatobia* and *Pyrrharctia*, do more than half of all the males in the field suffer a disadvantage due to their failure to feed on PA-containing plants during larval development? We anticipate that current investigations of the courtship of these species and the effects of pheromone dose on the intensity and duration of the female response, as well as the distance at which it can be elicited, will provide insights into the relationship between variation in male pheromone titer and variation in male mating success.

Acknowledgments—We thank Dr. J.A. Edgar (CSIRO, Australia) for providing synthetic danaidal; and Drs. D. Dussourd, G. Zarrilli, and J. Meinwald (Cornell University) for providing synthetic hydroxydanaidal and helpful comments. We thank R. Butts for assistance with mass spectrometry; and L. Budgar, M. Cambell, L. Child, and K. Poole for help in rearing insects. We also thank the Benford, Carson, and Gilbert families for allowing us access to excellent collecting sites; Dr. G.C. Eickwort for helpful comments; and Dr. J.G. Franclemont for providing specimens for extraction.

(Received February 26, 1986; accepted May 19, 1986)

Abstract—The most prominent beetle-produced volatiles identified in the abdominal extracts of male *Dryocoetes confusus* Swaine after they had bored for 24 hr in logs of subalpine fir, *Abies lasiocarpa* (Hook.) Nutt. were: *exo*- and *endo*-brevicomin, *trans*-verbenol, verbenone, myrtenol, *trans*-pinocarveol, *cis*- and *trans*-*p*-menthen-7-ol, 3-caren-10-ol, and several monoterpenes and sesquiterpenes. Myrtenol was the only conspicuous compound in extracts from males that had been exposed to *A. lasiocarpa* resin volatiles for 24 hr. Laboratory bioassays indicated that both (±)- and (+)-*exo*-brevicomin were attractive to female *D. confusus*, and that the (−) enantiomer did not inhibit response to its antipode. Results from field trapping experiments indicated that both *exo*-brevicomin and myrtenol are aggregation pheromones for *D. confusus*. *exo*-Brevicomin baits were effective in causing attack by *D. confusus* on baited and surrounding trees, suggesting that this pheromone may have utility in manipulating populations of the beetle.

Key Words—Semiochemicals, pheromones, enantiomers, western balsam bark beetle, *Dryocoetes confusus*, Coleoptera, Scolytidae, *exo*- and *endo*-brevicomin, *trans*-verbenol, verbenone, myrtenol, *trans*-pinocarveol, *cis*- and *trans*-*p*-menthen-7-ol, 3-caren-10-ol.

INTRODUCTION

The western balsam bark beetle, *Dryocoetes confusus* Swaine, is a major pest of mature subalpine fir, *Abies lasiocarpa* (Hook.) Nutt., in North America (Furniss and Carolin, 1977). It acts in association with a pathogenic fungus, *Ceratocystis dryocoetoides* Kendrick and Molnar (Kendrick and Molnar, 1965), which it introduces into living trees. This symbiotic invasion of beetles and fungus is ultimately lethal to the trees. From 1948 to 1975 the volume of trees killed in British Columbia comprised a reported 15 million cubic meters of wood (Stock, 1981) enough to build 375,475 houses.

Stock and Borden (1983) found that *D. confusus* males produce a pheromone-based secondary attraction. Abdominal extracts of males allowed to bore into fresh host logs or exposed to the vapors of subalpine fir blister resin for 24 hr were attractive in laboratory bioassays. These discoveries suggest that, as for other scolytids (Borden, 1984a), attractive semiochemicals could be used to manipulate *D. confusus* if the identity of the chemicals were known.

A preliminary analysis (Schurig et al., 1983) has disclosed that male *D. confusus* excised from subalpine fir logs after 24 hr contained *exo*- and *endo*-brevicomin in approximately an 18:1 ratio, and that *exo*-brevicomin was present as 99.2% (+)-enantiomer, while the *endo*-brevicomin was 81.6% (+)-enantiomer. Males of a European species, *D. autographus* Ratz., produce *exo*- and *endo*-brevicomin, which have proven to be attractive in field tests although the role of *exo*-brevicomin is unclear (Kohnle and Vité, 1984).

Our objectives were: (1) to isolate and identify the major volatiles found in abdominal extracts of *D. confusus* males that were allowed to bore into host logs, and females that were allowed to feed or join males in nuptial chambers, (2) to isolate and identify the volatiles in abdominal extracts of *D. confusus* males that were exposed to *A. lasiocarpa* blister resin, and (3) to test the major male-produced volatiles and host monoterpenes for their ability to attract beetles in the field to baited traps and to induce attack on baited trees.

METHODS AND MATERIALS

Collection and Maintenance of Beetles. A. lasiocarpa logs infested with *D. confusus* were obtained from trees felled at various locations in the B.C. interior and held at 0–5°C until used. When beetles were required, the logs were placed in screened cages held at approximately 28°C. The emergent beetles were collected daily, their sex was determined by the presence (females) or absence (males) of the setal brush on the frons (Bright, 1976), and the beetles were stored at 4°C on moistened paper.

Preparation of Extracts. Male beetles were placed in preformed entrance holes in the bark of fresh *A. lasiocarpa* logs, restrained by gelatin capsules

affixed outside the holes, allowed to bore into the phloem tissue for 24 hr, and then removed from the bark. Their abdomens were excised and extracted immediately in double-distilled pentane held over Dry Ice. Approximately 1200 male abdomens were extracted in this manner, and the extracts were stored at −40°C.

Female beetles were allowed to either feed on host bark or to join male beetles by placing them singly inside the gelatin capsules over the holes into which the males had bored. After 24 hr, they were excised from the bark and their abdomens extracted in the same manner as for males.

In two experiments, groups of 11 and 24 emerged male *D. confusus* were placed on moistened filter paper in individual 1.85-ml shell vials in sealed glass jars in which was placed an open, 2-ml vial containing 1.8 g (experiment. 1) or 0.8 g (experiment 2) of fresh blister resin from *A. lasiocarpa*. After 24 hr in the dark in an atmosphere saturated with the resin vapors, the beetles were removed, and their abdomens individually extracted as above. There were groups of 10 and 24 control males, respectively, for the two experiments. They were treated in the same manner as experimental beetles, except that they were not exposed to *A. lasiocarpa* resin volatiles.

Analysis of Extracts. Hewlett-Packard 5830A and 5880A gas chromatographs equipped with capillary inlet systems and flame-ionization detectors (FID) were employed for analyses by gas chromatography (GC). Samples were analyzed on open-tubular glass columns coated with SP-1000 (Supelco, Bellefonte, Pennsylvania). The temperature program for analytical GC was 70°C for 2 min, then 4°C/min to 180°C, holding for 20 min. A Varian 1200 gas chromatograph equipped with a 10:1 effluent splitter, FID, and thermal gradient collector (Brownlee and Silverstein, 1968) was used for micropreparative separation of volatiles. The column used was a 3.05-m × 3.18-mm-OD stainless-steel tube packed with 10% SP-1000 on Supelcoport (100-120 mesh). The temperature program was 70°C for 2 min, then 4°C/min to 210°C, holding for 5 min. For the micropreparative separation, the crude pentane extracts from the abdomens of 1200 males were combined and concentrated to 3 ml by evaporation under a gentle stream of N_2 at −10°C. After removal of 0.5 ml for analysis as an unfractionated control, the remaining 2.5 ml was further concentrated to ~70 μl. For both chromatographs, helium was the carrier gas, and the injection port and detector temperatures were 260°C and 270°C, respectively.

Mass spectra were determined on a Hewlett-Packard 5895A GC-MS-DS fitted with a 30-m × 0.32-mm-ID fused silica column coated with SP-1000 (J & W Scientific, Inc., Rancho Cordoba, California) using helium as the carrier gas. Peak identities were established by comparison of their mass spectra to those of authentic samples.

Chemicals for Laboratory and Field Tests. The sources and purities of

(+)-3-carene, myrcene, (−)-β-phellandrene, (±)-α-pinene, (−)-β-pinene and (±)-*exo*-brevicomin have been reported elsewhere (Conn et al., 1983). (±)-*endo*-Brevicomin (99.7%) and (±)-limonene (95.0%) were obtained from Albany International Co. (Columbus, Ohio) and Matheson, Coleman & Bell (East Rutherford, New Jersey), respectively. (±)-Myrtenol was prepared by selenium dioxide oxidation of (±)-α-pinene, and after purification via the *p*-nitrobenzoate derivative was 99.7% pure. The (+)- and (−)-*exo*-brevicomin were synthesized by Johnston and Oehlschlager (1982). Compounds synthesized by us as authentic samples for mass spectral analysis were *trans*-verbenol, verbenone *cis*- and *trans*-*p*-methen-7-ol, and 3-caren-10-ol. *trans*-Pinocarveol was a gift from L.C. Ryker, Oregon State University, Corvallis, Oregon.

Laboratory Bioassays. Tests for response to the fractions of the abdominal extracts (experiment 1) as well as (±)-*exo*-brevicomin and its enantiomers (experiment 2) (Table 1) were done with a walking bioassay in an arena olfactometer, using Stock and Borden's (1983) modifications of the basic design and procedures used by Wood and Bushing (1963). Each stimulus was tested with 5 groups of 15 beetles each. In each experiment, pentane solvent controls were used, as were attractive controls comprising the crude abdominal extracts.

Field Trapping Experiments. Two randomized-block trapping experiments were conducted in 1984 in an overmature stand of spruce and subalpine fir at Prospect Creek, approximately 40 km northwest of Merritt, B.C. Both experiments utilized eight-funnel multiple-funnel traps (Lindgren, 1983) placed at least 30 m apart on isolated lines through the forest. The first experiment tested (±)-*exo*-brevicomin alone, in combination with one of the six major monoterpenes in *A. lasiocarpa* (Zavarin et al., 1971) (myrcene, 3-carene, α-pinene, β-pinene, β-phellandrene, or limonene), or in combination with an equal part mixture of all six monoterpenes. The second tested myrtenol alone, in combination with two monoterpenes (myrcene and 3-carene), or in combination with *exo*-brevicomin and the two monoterpenes. Numbers of replicates, dates, types of bait receptacles and release rates are given in Table 2.

Field Tests with Baited Trees. On June 12, 1983, a 10-replicate experiment was set up in an overmature stand of white spruce, *Picea glauca* (Moench) Voss, and subalpine fir at McKendrick Pass, approximately 30 km northwest of Smithers, B.C. Ten *A. lasiocarpa* [$\bar{X}$ diameter at breast height (dbh) ± SE = 42.1 ± 2.7 cm] were baited with *exo*-brevicomin (Table 3) and 10 trees ($\bar{X}$ dbh ± SE = 44.3 ± 3.0 cm) were marked as controls. The trees were on a line, with a minimum distance of 50 m between trees. The treatments for each two-tree block (one baited and one control tree) were assigned randomly.

On October 6, 1983, each baited tree was checked for attack by *D. confusus*. Trees with loose, granular frass in the bark crevices or around the base of the bole were judged to be successfully mass-attacked. Those with no gran-

trapping experiment (experiment 1, Table 2). Twelve trees were left unbaited as controls. On September 11, 1984, the trees were assessed as in 1983 for attack by *D. confusus*.

RESULTS

Chemical Identification and Laboratory Bioassays. The most prominent potential pheromone in the abdominal extract of males that had bored into *A. lasiocarpa* logs for 24 hr was the bicyclic ketal, *exo*-brevicomin (Figure 1). Other compounds present in these male abdominal extracts were: *endo*-brevicomin, *trans*-verbenol, verbenone, myrtenol, *trans*-pinocarveol, *cis*- and *trans*-

p-menthen-7-ol, 3-caren-10-ol, plus several monoterpenes and sesquiterpenes (Figure 1). *exo*-Brevicomin was present in highest levels in unmated males in host bark, and declined in amount after they were joined by females. There was no *exo*-brevicomin in emergent males (Figure 2), but all males (emergent, fed, or fed and mated) contained *trans*-verbenol. Only *trans*-verbenol was detectable in females that were either fed on *A. lasiocarpa* bark or allowed to join males in new galleries.

Bioassay results indicated that male abdominal extracts were attractive to females, as was the gas chromatographic fraction containing *exo*- and *endo*-brevicomin (Table 1). Significant responses were obtained to racemic *exo*-brevicomin, and both of its enantiomers (Table 1). However, the observed attraction to (−)-*exo*-brevicomin was probably due to the presence of a small amount (approx. 2%) of the (+)-enantiomer. This result also indicates that the (−)-enantiomer does not inhibit the response of the females to naturally occurring (+)-*exo*-brevicomin.

There was no significant response to any fraction other than that containing *exo*-brevicomin (Table 1). Moreover, there was no increase in response over that to the *exo*-brevicomin fraction when all fractions were combined. To investigate the possibility that, as in other scolytids, there was a terpene alcohol pheromone that was disclosed in males allowed to bore into logs, the resin exposure experiments were conducted.

Abdominal extracts of males that had been exposed to *A. lasiocarpa* blister resin contained very few compounds. However, the terpene alcohol, myrtenol, a derivative of α-pinene, was detectable in male abdominal extracts in both experiments (Figure 2).

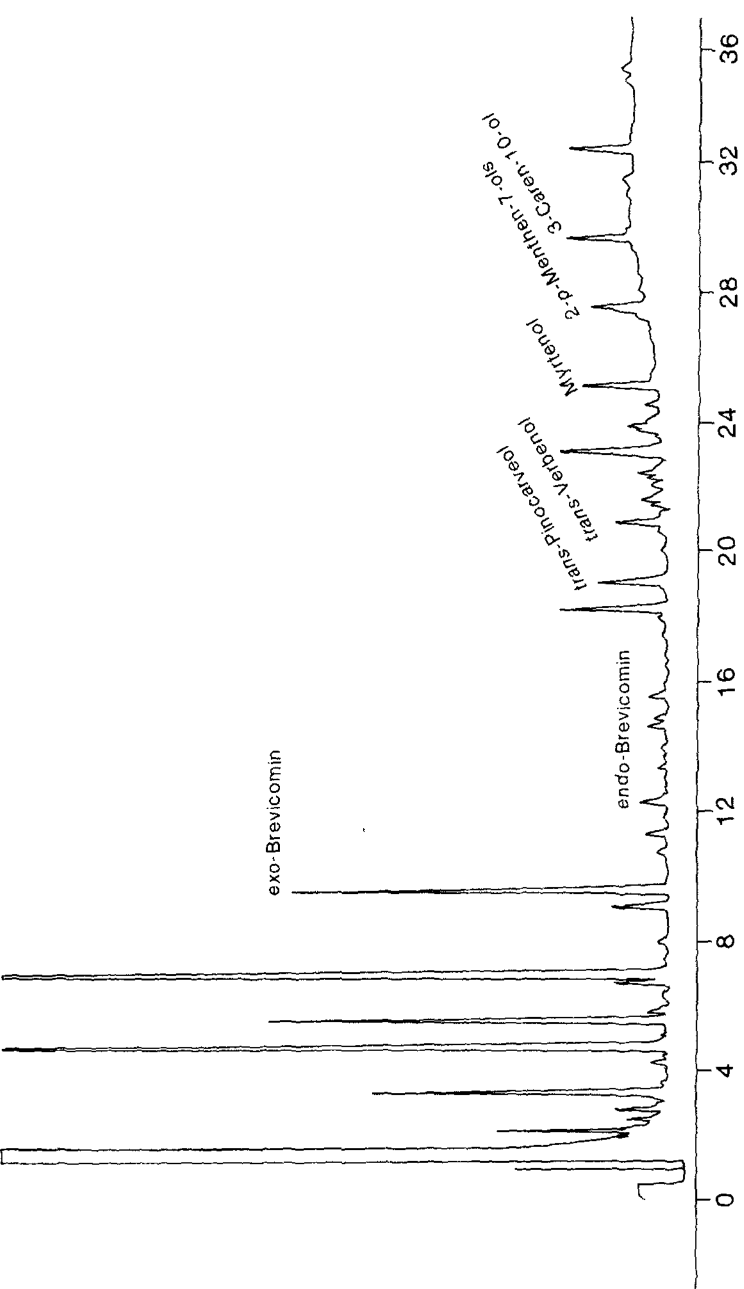

FIG. 1. Gas–liquid chromatogram of volatiles from male *D. confusus* allowed to bore into *A. lasiocarpa* logs for 24 hr. Volatiles were isolated from crushed abdomens by steam distillation (Godefroot et al., 1981). Peaks eluting earlier than *exo*-brevicomin are monoterpenes. Peaks with retention times of 18, 23, and 32.3 min are unknown sesquiterpenes. A 28-m × 0.66-mm-ID glass column coated with SP-1000 was employed for analysis.

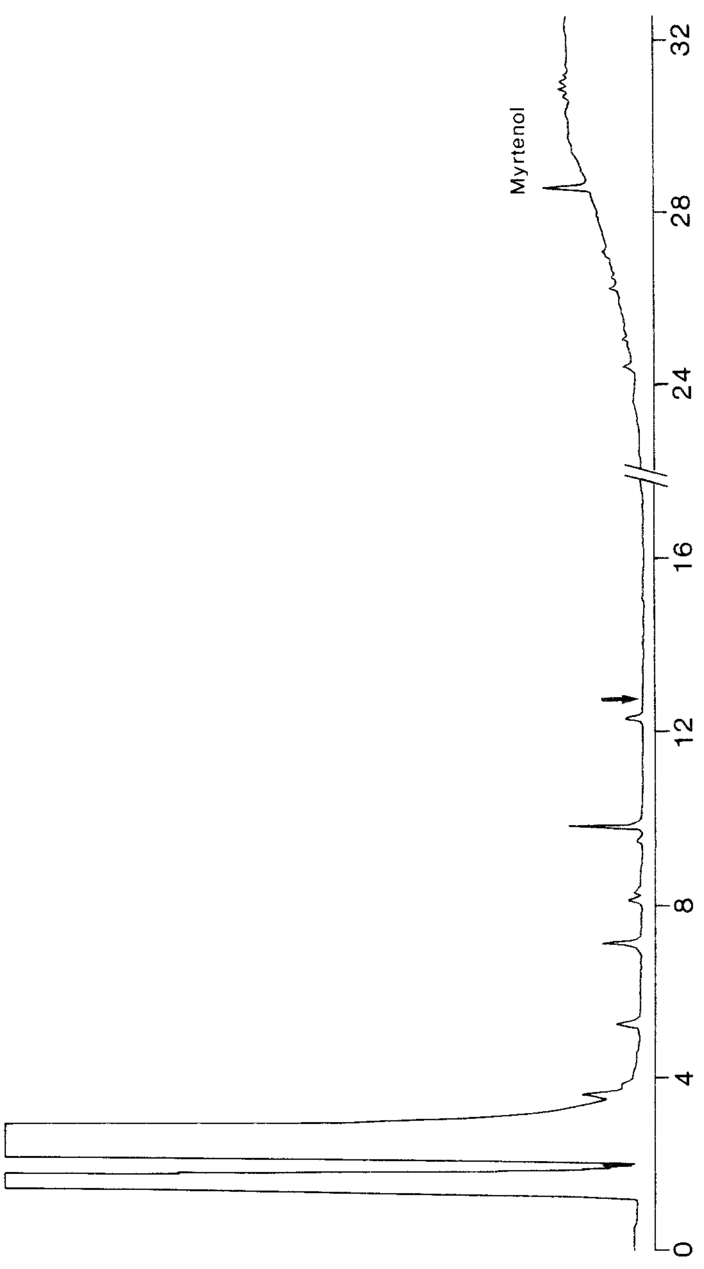

FIG. 2. Gas–liquid chromatogram of the pentane abdominal extract of a representative male *D. confusus* exposed to the volatiles of *A. lasiocarpa* blister resin for 24 hr. Arrow denotes retention time of *exo*-brevicomin. A 30-m × 0.5-mm-ID glass column coated with SP-1000 was employed for analysis.

Field Trapping Experiments. Male beetles were attracted to racemic *exo*-brevicomin alone or in combination with selected monoterpenes (experiment 1, Table 2). The monoterpenes caused neither a significant increase nor a decrease in response. However, as responses to *exo*-brevicomin mixed with myrcene or 3-carene were consistently high, the two nonoterpenes were included as baits in subsequent experiments.

The experiment with myrtenol was done late in the season when so few beetles were present that the responses to *exo*-brevicomin with the two monoterpenes were not significantly higher than to the unbaited control traps (experiment 2, Table 2). However, when myrtenol was added to the baits, the total response was over five times higher than to *exo*-brevicomin and monoterpenes, and the responses by both sexes were the only ones to stand alone as significantly higher than those to the unbaited control traps (experiment 2, Table 2).

Field Tests with Baited Trees. All 10 trees baited with *exo*-brevicomin in 1983 were attacked by *D. confusus*, and six of these were successfully mass attacked (Table 3). Moreover, there was a significantly higher number of attacked trees surrounding the baited trees than the unbaited control trees. As there were 4.3 and 4.7 attacked trees/plot surrounding unsuccessfully and successfully attacked baited trees, respectively, a successful attack does not appear to be necessary to induce attacks on trees around a baited tree. In comparison to the control plots, the baited trees caused an unnatural shift in the diameter distribution of surrounding trees attacked (Figure 3). Many trees in the 20 to 25-cm-dbh class were attacked around the baited trees, probably because they were simply in the path of beetles orienting upwind in the odor plume. No trees

>45 cm dbh were attacked. In contrast, only one of the 12 attacked trees in the control plots were in this diameter class, and three attacked trees (25%) were >45 cm dbh.

Addition of monoterpenes to the *exo*-brevicomin baits, at an approximate rate of 20 mg/24 hr release, had no evident effect on attack by *D. confusus* (Table 4). Almost all of the baited trees were attacked. From 50 to 75% were successfully attacked, and there were no significant differences in attack frequencies. The 25% variation in attack frequency was probably due more to local availability of beetles than to the attractiveness of the baits.

Response by Red-Bellied Clerid. Significant numbers of red-bellied clerids, *Enoclerus sphegeus* (F.), responded to traps baited with *exo*-brevicomin alone (Table 2). Their response was not significantly increased by addition of single monoterpenes or the monoterpene mixture to *exo*-brevicomin.

DISCUSSION

Until the discovery of *exo*-brevicomin in *D. confusus* (Schurig et al., 1983) and the demonstration that it is attractive to both sexes (Tables 1 and 2), it had been

reported as an aggregation pheromone exclusively in *Dendroctonus* spp. (Borden, 1984b). It has also been detected in male *Leperisinus varius* (F.) for which it, in combination with two other male-produced volatiles, had an antiaggregative effect (Francke et al., 1979). Thus, as investigations proceed in the Scolytidae, it is likely that restriction of certain pheromones to only a few taxa will prove to be unfounded, supporting Blum's (1970) concept of pheromonal parsimony between diverse taxa.

The report by Kohnle and Vité (1984) that *exo*- and *endo*-brevicomin were equally attractive to *D. autographus* in field tests is unusual, as this is the first report of attraction to both isomers in the Scolytidae. As (+)-, (−)-, and (±)-*endo*-brevicomin are now available in our laboratory and as (+)-*endo*-brevicomin has also proven to be a potent aggregation pheromone for the Southern pine beetle *Dendroctonus frontalis* Zimmerman (Vité et al., 1985), we plan to test these materials in combination with *exo*-brevicomin as potential attractants for *D. confusus.*

The disclosure of myrtenol in extracts of males exposed to *A. lasiocarpa* blister resin for 24 hr (Figure 2) suggests that it is a major derivative of α-pinene inhaled by the beetles. Both sexes of *Ips paraconfusus* (Lanier) and *Dendroctonus brevicomis* LeConte produced (−)-myrtenol following exposure to vapors of (−)-α-pinene (Byers, 1983). Myrtenol is also a common constituent of volatiles produced by other scolytids, such as the Douglas fir beetle, *Dendroctonus psendotsugae* Hopkins (Rudinsky, 1976) and *Ips typographus* (Birgersson et al., 1984), and has been identified as a multifunctional pheromone in the southern pine beetle, *Dendroctonus frontalis* Zimmermann (Rudinsky et al., 1974). It is probable that allowing males to bore into host logs in the laboratory does not accurately duplicate conditions present in a living host attacked by aggessive bark beetles. Therefore, a practice of exposing beetles of the pheromone-producing sex to host volatiles as well as allowing them to bore into host logs should probably be followed in order to reconstitute conditions that occur in living host trees in the field.

The finding that *exo*-brevicomin and myrtenol are attractive to *D. confusus* in the field (Table 2) suggests that they are the principal aggregation pheromones in this species. However, additional research should test *endo*-brevicomin and the other terpene alcohols found in male beetles for attraction in the field and should evaluate myrtenol as a bait on trees.

Although several clerids are known to use bark beetle pheromones as host-finding kairomones (Borden, 1982), the response by *E. sphegeus* to *exo*-brevicomin is the first recorded instance of such a phenomenon for this species.

The reliability with which *exo*-brevicomin induced attack on baited trees with or without monoterpenes (Tables 3 and 4) and concentrated attack on adjacent trees (Figure 3) suggests that it may have utility in manipulating populations of *D. confusus.*

(Received February 28, 1986; accepted May 19, 1986)

Abstract—Several major chemicals in the glandular heads of type VI trichomes of *Lycopersicon* species were identified and quantified by gas chromatography and mass spectrometry. Two normal odd-chained ketones, 2-undecanone (47 ng) and 2-tridecanone (146 ng), and one unknown sesquiterpene (5 ng), comprised approximately 95% of the contents of a gland of *L. hirsutum* f. *glabratum* Mull. In a closely related plant, *L. hirsutum* Humb. & Bonpl. (LA 361), two unknown insecticidal sesquiterpenes accounted for 6% of the gland contents. Additionally, small amounts of one unknown monoterpene and another unknown sesquiterpene were found in type VI glands of a commercial tomato variety, *L. esculentum* Mill. Bioassays comparing the gland exudate (by direct contact) and isooctane extracts of glands to neonate larvae of *Keiferia lycopersicella* (Walsingham) (Lepidoptera: Gelechiidae) and *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae) indicated that: (1) 2-tridecanone and 2-undecanone were the major insecticidal compounds in *L. hirsutum* f. *glabratum*, (2) the two unknown sesquiterpenes in *L. hirsutum* were acutely toxic to both species, and (3) gland contents in the commercial tomato variety provided only a physical barrier to *K. lycopersicella*, and were not detrimental to *S. exigua*. In topical bioassay trials, synthetic mixtures of 2-tridecanone and 2-undecanone (3 : 1) demonstrated potentiation. Concentrations of these chemicals decreased as trichomes aged. Quantities of insecticidal chemicals and density of type VI trichomes varied with plant age and location within plants.

Key Words—*Lycopersicon*, *Keiferia lycopersicella*, *Spodoptera exigua*, Lepidoptera, Gelechiidae, Noctuidae, leaf trichomes, 2-tridecanone, 2-undecanone, terpenoids, toxicity.

INTRODUCTION

Glandular trichomes of wild tomatoes in the genus *Lypersicon* have recently become the subject of considerable study because of their effectiveness in protecting tomato plants from insect damage (Rodriguez et al., 1972; Schuster, 1977; Dimock and Kennedy, 1983; Schwartz and Snyder, 1983; Snyder and Carter, 1984; Kennedy and Sorenson, 1985) and the possibility of breeding this character into the commercial tomato *L. esculentum* (Kennedy and Henderson, 1978; Fery and Kennedy, 1983; Fery et al., 1984). The secretion of glandular trichomes from one tomato accession, *L. hirsutum* Humb. & Bonpl. (PL 251301), has also proven toxic to the spider mite *Tetranychus urticae* Koch (Aina et al., 1972), suggesting that trichome-based resistance could be an effective tool in a pest management program against a wide variety of arthropod pests.

Relatively few chemical analyses of trichome contents or exudates in tomato species have been reported. Studies by Beckman et al. (1972) found phenolics in capitate cells of four-lobed trichomes of *L. esculentum*, and Duffey and Isman (1981) determined that rutin (a flavonoid glycoside) was a major constituent of the trichomes in commercial tomatoes. More recently, Kennedy and Dimock (1983) reported that 2-tridecanone (a methyl ketone) was the dominant compound in the type VI glands (characterized by Luckwill, 1943) of *L. hirustum* f. *glabratum* (PL 134417) which was acutely toxic to *Manduca sexta* (L.), *Heliothis zea* (Boddie), and *Leptinotarsa decemlineata* (Say).

Our previous studies on resistance in wild and commercial tomatoes to a specialist herbivore, the tomato pinworm (TPW), *Keiferia lycopersicella*, demonstrated that type VI glandular trichomes were the primary cause of larval mortality (Lin and Trumble, 1986). In this paper we: (1) quantify the constituents of glandular heads of type VI trichomes from selected wild and commercial tomato accessions, (2) document effects of trichome age and location within plants on chemical composition of type VI trichomes, and (3) report a bioassay procedure designed to quantify the insecticidal activity of these compounds for both *K. lycopersicella*, and a generalist herbivore, the beet armyworm (BAW), *Spodoptera exigua*.

METHODS AND MATERIALS

All plants used in the following tests were grown from seed in a glasshouse in 15-cm pots containing UC soil mix (Matkin and Chandler, 1957) and a slow-release fertilizer. Day length was maintained at 16 hr using artificial illumination. Seeds of *L. hirsutum* (LA 361) were obtained from Dr. C. Rick (University of California, Davis) and *L. hirsutum* f. *glabratum* (PL 134417) were obtained from Dr. G. Kennedy (North Carolina State University). Commercial *L.*

esculentum cv. VFN 7718 were purchased from Champion Seed Co. (529 Mercury Lane, Brea, California 92621).

Identification and Quantification of Chemicals in Type VI Glands. All gland samples were analyzed for chemical content using a capillary gas chromatograph (GC) and GC-mass spectrometer. The GC was a Packard gas chromatograph equipped with hydrogen flame ionization detector and a DB-5 60-m × 0.25-mm-ID capillary column. Temperature was programmed from 45 to 210°C at 1°C/min. The head pressure for helium was 20 pounds per square inch. The flow rates for hydrogen and compressed air were 30 and 200 ml/min, respectively. Internal standards for quantitative analyses were 2-decanone and 2-pentadecanone peak areas and retention time(s) were calculated using a Spectra-Physics Autolab System I program integrator (333 N. First St., San Jose, California). Electron-impact mass spectra were recorded from samples at 70 eV with a VG ZAB-HF mass spectrometer. Comparisons of chemical quantities in glandular trichomes were evaluated with the Student's t test.

Identification of the chemical contents in glandular heads of type VI trichomes was based on three samples of 100 intact mature glands which were collected from the adaxial, interveinal areas of three leaflets per plant (8th–9th leaves from the bottom) for five plants of each variety ($N = 45$ samples of 100 glands/variety; plants were 123 days postgermination). With the aid of a dissecting microscope, a glass probe was used to rupture the glands and transfer their contents directly into isooctane. The probe was rinsed in ethanol and isooctane after collecting each 100-gland sample to avoid any contamination of subsequent samples. Additional samples of 200–4500 glands were also collected for identification of other possible minor constituents. All glands were collected between 11 AM and 2 PM to minimize potential diel variation in chemical production (Turner et al., 1980).

Effect of Trichome Age and Location within Plants on Chemical Composition of Type VI Glands. Fully developed type VI trichomes exhibited two stages which were clearly discernible using a dissecting microscope. In the initial mature stage, the trichomes possessed glandular heads with a clear liquid content. The subsequent stage, referred to as aged, had yellow-orange glandular heads which appeared to have a more viscous content. In order to determine if gland age affected the chemical content, three 200 gland samples of each maturity stage were collected from four plants each of *L. hirsutum* and *L. hirsutum* f. *glabratum*, and prepared for analysis as described previously ($N = 12$ samples of 200 glands/maturity stage). Mature and aged trichomes were collected from the same leaves.

The influence of location within plants on chemical content of type VI trichomes was evaluated by collecting 200 gland samples from three locations per plant on five plants each of *L. hirsutum* and *L. hirsutum* f. *glabratum*. To standardize the test material, glands were collected weekly from 2–5-week post-emergence-old plants on: (1) the terminal leaflet of the third leaf from the bot-

tom, (2) the stem between the second and third lowest nodes, and (3) terminal leaflet of 1-week-old leaf at the plant apex. This plant stage was chosen because the tomatoes were in the critical developmental period following germination, and the specific leaves tested began to senesce at five weeks. In addition, number of type VI glands per unit leaf area was determined using a micrometer grid reticule and a dissecting microscope.

Bioassays of Gland Exudate, Gland Extracts, and Pure Compounds. TPW and BAW used in these trials were obtained from cultures initiated with larvae collected in Orange County, California and maintained on tomato plants (VFN 7718) and artificial diet (Patana, 1969), respectively. Insects were maintained at 27 ± 1°C and a photoperiod of 12:12 light–dark. Mature type VI glands were collected from terminal leaflets (*N* = 12 leaflets/variety) of the eighth and ninth leaves from the base of 2-month-old *L. hirsutum*, *L. hirsutum* f. *glabratum*, and *L. esculentum*. Additional type VI glands (*N* = 12 samples of 200/leaflet) were collected for GC quantitative analysis in order to document concentrations of key compounds in fresh plant material for comparison of isooctane gland extracts with pure compounds. Data on the toxicity resulting from topical applications of gland exudate, isooctane extracts of glands, and pure compounds to BAW and TPW were standardized by transforming all data to nanograms of chemicals per larva to allow direct comparisons between treatments. Data were then analyzed by probit analysis with the Proc Probit procedure of the Statistical Analysis System (Helwig and Council, 1979) after correction for control mortality with Abbott's (1925) formula.

First-instar larvae of BAW and TPW were exposed directly to gland exudate on fresh plant material by adhering individuals to a water-moistened 000 paint brush, and with the aid of a dissecting microscope, breaking type VI glands against the dorsal thorax. Four replicates of 15 larvae of TPW were treated at the following gland "dosage" (*N* = 60 larvae/dose) for the two wild tomato accessions tested: *L. hirsutum* = 1, 2, 4, 6, 8 glands/larva, and control (moistened brush treatment only); *L. hirsutum* f. *glabratum* = 1, 2, 3, 4, 5, and control. Similarly, BAW were exposed as follows: *L. hirsutum* = 20, 30, 40, 50, 60, and control; *L. hirsutum* f. *glabratum* = 12, 15, 18, 21, 24, and control. Mortality was also observed in trials with *L. esculentum*, where TPW or BAW were exposed to 20 or 60 glands, respectively, the maximum possible for the size of the larvae. Larvae were held at 26 ± 1°C, and mortality was evaluated at 24 hr. Larvae were considered dead if they were unable to move within 30 sec of being prodded.

In a related experiment, neonate larvae of both insect species were exposed to an extract of glands dissolved in isooctane. Isooctane was selected as a carrier because this solvent was used for all GC analyses. Gland contents were collected with a glass probe as described earlier, and serial dilutions of concentrate were topically applied to neonate larvae using a 0.5-μl Hamilton syringe. Be-

cause of the small size of the larvae, dosages were applied to the dorsum of the thorax in a 0.01-μl droplet for TPW, and in a 0.2-μl droplet for BAW. Larvae were treated on a glass surface instead of filter paper, since our preliminary trials indicated that efficacy was artificially reduced on filter paper as some test material was lost to absorption into the substrate. Four replicates of 15 larvae of each species were exposed to the extract of each of the five dosages and isooctane controls evaluated, and mortality was assessed at 24 hr. Dosages tested for TPW were 60, 70, 80, 90, and 100 glands of *L. hirsutum* f. *glabratum*/μl of isooctane and 30, 40, 50, 60, and 70 glands of *L. hirsutum*/μl of isooctane. Dosages evaluated for BAW were 60, 70, 80, 90, and 100 glands of *L. hirsutum* f. *glabratum*/μl of isooctane and 10, 20, 30, 40, and 50 glands of *L. hirsutum*/μl of isooctane.

The contact toxicities of the two commercially available pure chemicals, 2-undecanone and 2-tridecanone (purity 97.0%, Pfaltz & Bauer, Inc., Waterbury, Connecticut), were also evaluated. Each compound was dissolved in isooctane to a concentration of 50 mg/ml, as was a 3 : 1 mixture of 2-tridecanone and 2-undecanone. Neonate larvae of TPW and BAW were treated with five concentrations (dosages) of the test chemicals and a control (isooctane). Dosages tested for TPW were 3.6, 4.0, 4.8, 5.6, and 6.4 mg of 2-tridecanone/ml of isooctane; 2.0, 2.4, 3.2, 4.0, and 4.8 mg of 2-undecanone/ml of isooctane; and 0.1, 0.3, 0.5, 0.7, and 0.8 mg of mixture/ml of isooctane. Dosages evaluated for BAW were 12, 14, 16, 18, and 20 mg of 2-tridecanone/ml of isooctane; 12, 14, 16, 18, and 20 mg of 2-undecanone/ml of isooctane; and 6, 8, 10, 12, and 14 mg of mixture/ml of isooctane. Data were analyzed for potentiation after Finney (1971). All topical applications were made with a 0.5-μl Hamilton syringe, using the same equipment and procedures as previously described.

RESULTS AND DISCUSSION

Identification and Quantification of Chemicals in Individual Glands. GC analyses of isooctane extracts of the type VI glands of *L. hirsutum* f. *glabratum* detected three major components: 2-tridecanone, 2-undecanone, and one unknown compound in the relative proportion of 30 : 10 : 1, respectively, (Figure 1). The predominance of 2-tridecanone was consistent with previous reports documenting the presence of this chemical in foliage of *L. hirsutum* f. *glabratum* (Soost et al., 1968; Dimock and Kennedy, 1983). The relatively high proportion of 2-undecanone was unexpected. Mass spectrometric analysis of the unknown compounds produced different fragmentation patterns with identical molecular ions at *m/e* 204 (Table 1), which are consistent with the assignment of the molecular formula of a sesquiterpene (SES) ($C_{15}H_{24}$) (Silverstein et al., 1974).

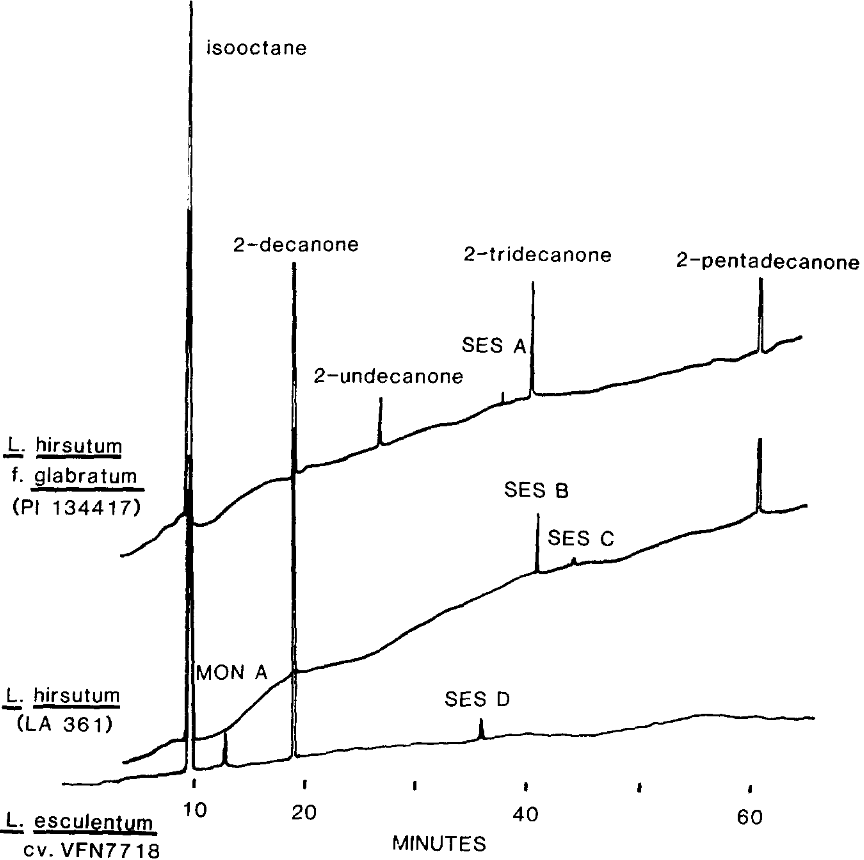

FIG. 1. Chromatograms of isooctane extracts of glandular heads of type VI trichomes from *L. hirsutum* (LA 361), *L. hirsutum* f. *glabratum* (PI 134417), and *L. esculentum* (VFN 7718) using a DB-5 0.25-mm-ID × 60-m long capillary column on a Packard gas chromatograph.

In *L. hirsutum* (LA 361), two unknown sesquiterpenes (SES B and SES C) were detected by GC-MS analysis (Table 1, Figure 1). The retention time of the unknown SES B was very similar to 2-tridecanone, but augmentation with 2-tridecanone confirmed that SES B was different. In *L. esculentum*, one unknown monoterpene and one unknown sesquiterpene (SES D, which was different from SES A, B, and C; Figure 1) were found to be the major volatile components. Although Soost et al. (1968) reported several ketone groups as the major volatile compounds in whole foliage of *L. hirsutum* and *L. esculentum* cv. Ace, our experiments demonstrated that there were neither 2-tridecanone nor other methyl ketones in the glandular heads of type VI trichomes of *L hir-*

[b] Tentative compound identification based on GC and MS data.

sutum (LA 361) and *L. esculentum* cv. VFN 7718. Even though the GC retention time of the major unknown monoterpene in *L. esculentum* cv. VFN 7718 was close to limonene, which was reported as the major volatile on cv. Ace (Soost et al., 1968), the mass spectrum demonstrated that these compounds were different. The identification of these unknown terpenoids in *L. hirsutum* and *L. esculentum* is currently under investigation. To date, the quantities of glandular material have not been sufficient for qualitative analysis.

Gas chromatography revealed an average of 146 ng of 2-tridecanone, 49 ng of 2-undecanone, and 5 ng of sesquiterpene A per type VI gland of *L. hirsutum* f. *glabratum*, constituting approximately 93% of the estimated volume (Table 2). These results are in contrast to those obtained earlier by Kennedy and Dimock (1983), who reported only ca. 6.3 ng of 2-tridecanone in a glandular head of *L. hirsutum* f. *glabratum*. Such differences might occur in response to method of extraction, the GC sensitivity level, photoperiod during plant growth or, as noted in the following section, gland age, plant developmental status, or location within pl?

The relative concentrations ca .ne volatile compounds in the other *Lycopersicon* accessions tested were considerably less than for *L. hirsutum* f. *glabratum*. The quantity of the two unknown sesquiterpenes in *L. hirsutum* was

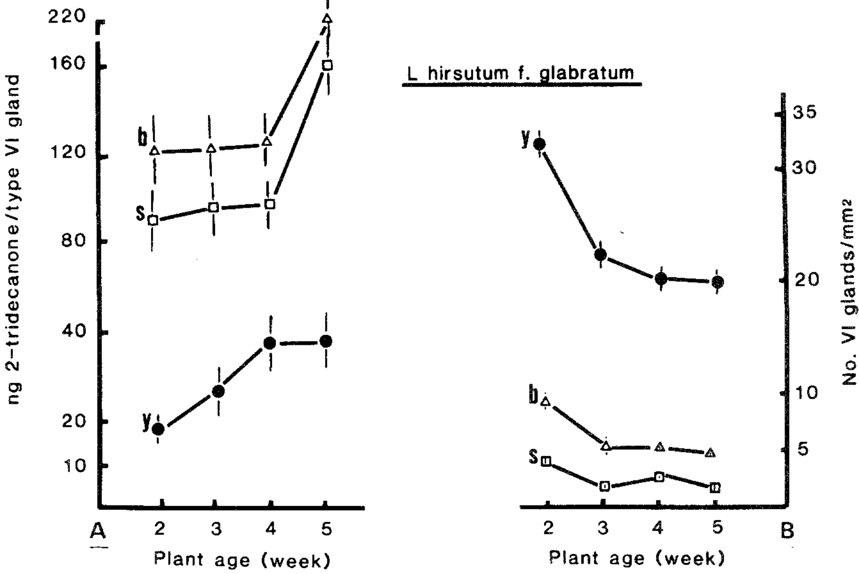
L. esculentum	Monoterpene A	3.0 ± 1.2[d]	2.1–2.6
	Sesquiterpene D	0.5 ± 0.1[d]	0.4–0.5

[a] Unless noted, 200 glands per sample, 6 samples/plant, 5 plants/variety, all plants were 123 days old; radius of type VI glands was 0.04 mm in *L. hirsutum* f. *glabratum*, 0.035 mm in *L. hirsutum*, and 0.05 mm in *L. esculentum* [density assumed to range between 0.8 g/cm^3 (Buckingham, 1982, for high tridecanone content) to 1.0 g/cm^3 for water].
[b] 3000 glands per sample.
[c] 1000 glands per sample.
[d] 4500 glands per sample.

only 8 ng/gland, while the two unknown terpenoids in *L. esculentum* accounted for only 3.5 ng of the contents of a type VI glandular head.

Effect of Trichome Age and Location within Plants on Chemical Composition of Type VI Glands. The chemical contents of type VI glands varied with trichome age in *L. hirsutum* and *L. hirsutum* f. *glabratum*: all chemical concentrations decreased significantly as the glands aged ($P \leq 0.05$, t test). In mature glands from *L. hirsutum* f. *glabratum*, 149.2 ng/gland of 2-tridecanone was detected versus 31.9 ng in an aged gland. In mature glands, the ratio of 2-tridecanone to 2-undecanone in glands of *L. hirsutum* f. *glabratum* was constant (ca. 3.4). However, neither 2-undecanone in *L. hirsutum* f. *glabratum* nor SES C in *L. hirsutum* could be detected in samples of 200 aged glands. Thus, contents of glands vary with the age of the gland as well as accession.

Chemical content of glandular heads in the type VI trichomes of *L. hirsutum* and *L. hirsutum* f. *glabratum* also varied with plant age and location within plants (Figure 2). In the glands of *L. hirsutum* f. *glabratum*, 2-tridecanone concentration remained relatively constant for leaves reaching maturity, then increased sharply when leaves became senescent (Figure 2A). A similar trend was evident for aging stems. Concentration of 2-tridecanone in glands on 1-week-old foliage increased with plant age, but was four to six times lower than in glands on mature leaves or stems. However, since the density of type



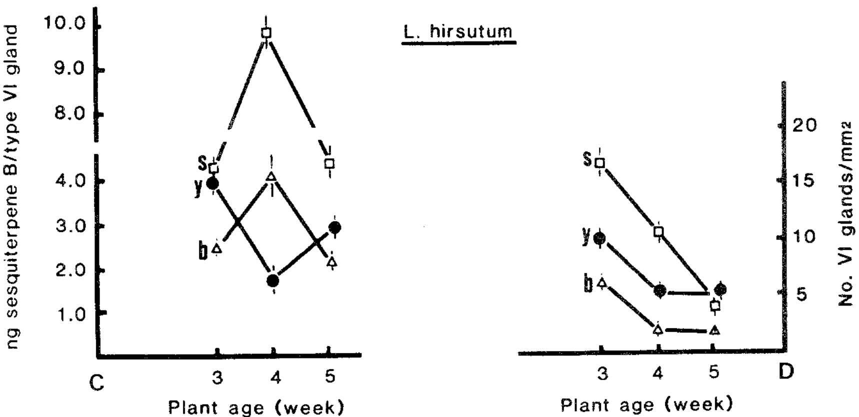


FIG. 2. Chemical contents of glandular heads of type VI trichomes as affected by age and location within plants: y = 1-week-old leaves, b = third true leaves from the bottom, and s = internodal stem between second and third nodes in *L. hirsutum* f. *glabratum* (PI 134417) and *L. hirsutum* (LA 361). Brackets on data points delineate standard errors.

VI trichomes on the young leaves was approximately four times that of the older foilage (Figure 2B), the young leaves were similarly protected.

In the mature glands of *L. hirsutum*, SES B content varied regardless of location within plants (Figure 2C). Concentrations of SES B in glands from both stems and mature leaves fluctuated in a similar pattern: SES B increased until decreasing sharply as the leaves became senescent and stems grew tougher. This pattern is consistent with studies by Croteau and Loomis (1972) documenting that terpenoid synthesis was promoted by the availability of sucrose and other photosynthates, although this pattern could also occur as a result of increased catabolism without any change in the rate of synthesis. The function of sesquiterpenes as insecticides, repellents, and insect feeding deterrents has been previously reported (Kelsey et al., 1984). Sesquiterpene content in trichome heads from immature leaves was highest when plants were youngest. Since density of type VI trichomes was highest at this time as well (Figure 2D), the youngest leaves of young plants were also well protected. The importance of this protection was demonstrated in our previous experiments, where TPW survival was greatly improved by removal of the glandular heads of type VI trichomes (Lin and Trumble, 1986).

Bioassays of Gland Exudate, Gland Extracts, and Pure Compounds. Chemicals in the glandular heads of type VI trichomes from either wild tomato accession were toxic to larvae of both herbivore species. However, BAW was approximately 20 times less susceptible than TPW, despite weighing only three times more than TPW (23.6 μg/BAW; 7.6 μg/TPW). Such differences might occur in response to either differential detoxification systems or variations in cuticular penetrability.

No acute toxicity was observed at 24 hr for either TPW or BAW exposed to glandular heads from *L. esculentum*. However, a previous study reported that TPW would ultimately starve as a result of entrapment, whereas BAW was not affected (Lin and Trumble, 1986). Thus, chemical contents in glandular heads of type VI trichomes on this commercial variety provide only a physical barrier to TPW and are not detrimental to BAW.

Toxicities of equivalent concentrations of the two volatiles from gland exudate or isooctane extracts of glandular heads of *L. hirsutum* f. *glabratum* were not significantly different within each species of herbivore (Table 3). This suggests that not only did the isooctane successfully extract key volatiles, but that the estimates of 2-tridecanone and 2-undecanone concentration determined by GC analyses of isooctane extracts were close to the actual chemical content in type VI glandular heads.

Even with the relatively small amounts found in glandular heads, the two unknown sesquiterpenes provided considerable insecticidal activity. However, the isooctane extract from glandular heads of *L. hirsutum* was more toxic than glandular exudate to both TPW and BAW. If increased toxicity of the extract is due to the isooctane acting as a more efficient carrier, this suggests that a

[a] LD_{50} values and 95% confidence (Helwig and Council, 1979); larvae were directly contacted with glandular heads containing 149.5 ng of 2-tridecanone and 37.4 ng of 2-undecanone per gland of *L. hirsutum* f. *glabratum* (PI 134417), and 7.3 ng of unknown sesquiterpene B per gland of *L. hirsutum* (LA 361) (from concurrent GC analyses). Four replicates of 15 larvae were tested per dose, with five doses per treatment.
[b] A single gland caused in excess of 50% mortality.
[c] Significantly more toxic than expected from an additive effect ($P < 0.05$, chi-square test).

large portion of the unidentified content of the type VI glandular heads on *L. hirsutum* might be water or some other isooctane-insoluble materials.

In bioassays with pure compounds, 2-undecanone was at least as toxic to TPW and BAW as 2-tridecanone ($P > 0.05$, chi-square) (Table 3). In a study comparing the relative toxicity of analogs of 2-tridecanone, Dimock et al. (1982) found 2-undecanone to be less acutely toxic than 2-tridecanone to *H. zea*. A comparison of their results with our own suggests that the toxicity of the two chemicals varies with insect species. The LD_{50} values for the chemical reagents were consistent with the LD_{50} values produced by gland exudates and isooctane extracts for BAW. Similar comparisons were not possible for TPW, because even a single gland caused 100% mortality. Gland extracts were less toxic than the chemical reagents to TPW. This difference may be due, in part, to the ratio of 2-tridecanone and 2-undecanone. There was more 2-tridecanone (4:1) in the extract than in the pure compounds (3:1), which might have influenced penetration of the cuticle.

Mortalities resulting from combinations of both chemicals in a ratio ap-

proximating that found in mature glands (e.g., 3:1) demonstrated significant potentiation [expected additive effect for TPW, LD_{50} = 20.0 ng/larva, observed LD_{50} = 4.0 ng/larva, $P < 0.01$; expected additive effect for BAW = 2800.0 ng/larva, observed LD_{50} = 2080 ng/larva, $P < 0.05$ (chi-square tests)]. This potentiation provides a clear advantage for those plants with glandular heads of type VI trichomes synthesizing or sequestering both chemicals. Additionally, since in a natural state 2-tridecanone is a solid (Dean, 1979), and since 2-undecanone is a liquid which evaporates readily (Dean, 1979), we suspect that the 2-undecanone serves to keep 2-tridecanone dissolved in a liquid form (and therefore more suitable for contact toxicity), while the mixture helps retard evaporation of 2-undecanone from the glands. This hypothesis is supported, in part, by our earlier observation that 2-undecanone could not be detected in aged type VI glands. This combination of chemicals probably plays a key role in physical defense (entrapment) as well. Following release of the liquid content, the rapid evaporation of 2-undecanone would leave an increasingly viscid residue attached to the insect.

CONCLUSION

The major volatile chemicals produced and/or stored in glandular heads of type VI trichomes produce acute insecticidal activities against the specialist and generalist herbivores tested. Although these chemicals proved to be more toxic to the specialist, TPW feeds for the first two instars as a leafminer (Lin and Trumble, 1985) and may thereby behaviorally avoid contact with trichome exudates. In contrast, the generalist BAW feeds on whole foliage and is therefore forced to contact and consume the glandular heads. Thus, the potential defense offered by the glandular heads of type VI trichomes may be greater for the early instars of BAW than for TPW. However, additional studies on the effects of chemicals in glandular heads on oviposition behavior are needed before the importance of chemical activities against larvae can be determined.

Since the concentrations of these volatiles and density of type VI trichomes varied with gland age, plant age, and location within plants, variations in "investment" in specific tissues may occur. Information on such chemical variation could not only offer new avenues of research for plant systematists interpreting relationships difficult to clarify by strictly morphological means, but may assist plant breeders in selecting accessions exhibiting specific chemical traits as well as morphological characteristics which impact TPW and BAW populations. Additional research on the chemical content of type VI glands will be necessary, since the onset and rate of chemical production appears to be dependent on a variety of environmental factors (Langenheim et al., 1984).

(Received March 7, 1986; accepted May 22, 1986)

Abstract—Male Mongolian gerbils scent mark during a standardized open-field test on an individually different but more-or-less constant level in the absence of females. The presence of females in the same room but without direct contact to the males increases the marking frequencies of the males to an individually different higher level. A similar increase in marking frequency is obtained by application of female urine directly to the nostrils of the males, but not by male gerbil urine or female laboratory mouse urine. This indicates that substances present in female gerbil urine are responsible for the increase in male marking behavior. Using this bioassay, various fractions of female urine were tested for their influence on marking behavior. Our results to date show that the component increasing male scent-marking behavior is hydrophilic and nonvolatile and is contained in the nondialyzable, high-molecular-weight polypeptide fraction of female gerbil urine.

Key Words—Mongolian gerbil, *Meriones unguiculatus*, scent marking behavior, urinary polypeptides, primer pheromones.

INTRODUCTION

Mongolian gerbils (*Meriones unguiculatus*) scent mark their environment with the secretions of a specialized ventral scent gland. The hormonal regulation of this scent-marking behavior is quite well known in males. Castration almost eliminates scent marking (Thiessen et al., 1968), while testosterone treatment of castrates can prevent and even reverse these changes (Blum and Thiessen, 1971; Probst, 1985a).

The effects of chemical signals on scent-marking behavior in gerbils are little known to date. Similar to castration, bilateral olfactory bulb ablation re-

0098-0331/87/0400-0851$05.00/0 © 1987 Plenum Publishing Corporation

duces scent marking (Baran and Glickman, 1970; Lumia et al., 1975). However, direct effects of olfactory signals from scent-gland secretions and urine of males could not be demonstrated using open-field tests (Baran, 1973; Blum and Thiessen, 1970; Blum et al., 1975; Fullenkamp et al., 1985).

The observation that, when females are present, males scent mark at an increased level compared with that in the absence of females (Probst and von Holst, 1982) led to the identification of female urine as the source of chemical signals increasing scent marking to the individual's maximum levels (Probst, 1985b). The experiments reported here constitute the analysis of the active fraction of female urine capable of stimulating scent marking in male Mongolian gerbils.

METHODS AND MATERIALS

Animals and Housing. Mongolian gerbils (*Meriones unguiculatus*) were obtained from our breeding colony. After weaning at 28 days of age, males were housed singly in macrolon cages with wire mesh tops, while females were grouped two to three per cage (cage size: 37 × 20 × 15 cm). All gerbils were exposed to a 12:12-hr light–dark cycle (lights on from 12 AM to 12 PM) with constant room temperature of 22 ± 1°C and relative humidity of 55%. The air inside the room (volume 50 m^3) was exchanged 16 times per hour. All animals had free access to gerbil food pellets (Altromin, Lage, FRG) and water. Males and females were at least 6 months of age at the beginning of the experiments.

Behavioral Observation. The experimental males were kept in single cages in a separate room where only males were held, unless not otherwise required during the experiments. The scent-marking behavior was observed inside this room in an open-field apparatus (Thiessen et al., 1968), modified as described previously (Probst, 1985a). For the marking tests, the males were placed individually inside this open-field and during 5 min the occurrences of scent marking were counted. All observations were made during the third hour of the dark phase of the light cycle with a dimmed fluorescent bulb providing sufficient illumination for observation of the animals.

The experimental procedure consisted of three phases for every test situation. During the first phase, the basal marking activity for each male was determined (5–8 tests/animal). The average marking activity of each individual was then used as its basal marking activity. During the second phase, the conditions were changed according to the required test situation while scent-marking tests were carried on. Provided adequate stimulus is present, at least three days of stimulation are required to increase the males' marking activities from the basal level to the higher, stimulated level (Probst, 1985b.) Therefore, for calculation of the test situation marking activity, only the values from the day 5 to 12 of stimulation were used. To prevent interactions between different tests using the same individuals, a control phase was included, during which the

decline of marking activities to the original basal level was monitored after the stimulus had been withdrawn (7–14 tests/animal).

For statistical analysis, the individuals' average scent-marking response during the basal period was compared with the respective response during the different tests using Wilcoxon's matched-pairs signed-rank test. A treatment was considered to cause a significant influence on scent-marking activity when $P < 0.05$ (two-tailed).

Urine Preparations. Urine was collected from 20 female gerbils, 10 male gerbils, and 10 female laboratory mice. The animals were individually placed for 5 min, or less if they urinated earlier, in a beaker. The urine was pooled without considering the estrous state of the females and stored frozen at −25°C. For the bioassay, 10 μl of urine and urine fractions were pipetted directly into each nostril of the males twice per day, resulting in a total of 40 μl applied per day. Since pervious studies had shown that application of demineralized water as a control stimulus does not affect scent marking (Probst, 1985b), this test was not repeated during the present study.

Head-Space Distillation. Head-space distillation (Lee et al., 1980) of female urine was performed to examine the influence of volatile and nonvolatile chemical cues on scent marking. Briefly, about 2 ml nitrogen per minute were passed over urine at 37°C and the head space was trapped on a charcoal filter (von Stralendorff, 1982). The distillation was finished when phenylacetic acid broke through the filter and could be identified by its characteristic smell. The trapped volatiles were then extracted from the filter by small volumes of chilled physiological saline. This "volatile fraction" was stored frozen at −25°C until used.

The residue of the head-space distillation was dialyzed against distilled water at 10°C for 12 hr with two exchanges of water (Spectapor, Spectrum Medical Industries, Los Angeles, California; molecular weight cutoff at 8000 daltons). The "nondialyzable fraction" was freeze dried and reconstituted to the original volume with physiological saline.

Separation of Lipids. The separation of lipids contained in female urine was performed by liquid–liquid extraction of urine using Extrelut® columns (Merck, Darmstadt, FRG). Acidified urine (pH 2.0) was first extracted with diethylether, which yields the acidic lipophilic fraction. Subsequently, the column was alkalized to pH 10.0 by passing ammonia gas through the column, then extracted with dichlormethane to yield the basic lipophilic fraction. The aqueous residue was then eluted with saturated saline. (Wimmer et al., 1978).

For the biotest, the solvents of the acidic and basic lipophilic fractions were evaporated in the cold, and the residue was dissolved in physiological saline to the original volume. The aqueous fraction was dialyzed for 24 hr against distilled water at 10°C with four interchanges of water to remove the saline. The nondialyzable fraction was freeze dried and reconstituted to the original volume with physiological saline.

Polypeptide Fraction. To determine the effects of polypeptide fraction of female urine, polypeptides were reversibly precipitated with ammonium sulfate (Vandenberg et al., 1975). The precipitate was prepared by adding ammonium sulfate to chilled urine to give a final saturation of 80% at 4°C. After centrifugation, the precipitate was dialyzed against water and redissolved in the original volume of physiological saline.

RESULTS

During the presence of females in the experimental room—but without direct contact to the males—the scent-marking activity (number of scent marks per 5 min as determined in a standardized open-field test) is significantly increased by about 100% (Figure 1). This increase is mediated by chemical cues contained in the urine of females. Application of 40 μl urine per day to the nostrils of the males caused an increase in scent-marking activity comparable to that obtained by the presence of females inside the room (Figure 1). In contrast to female gerbil urine, male gerbil and female laboratory mouse urine did not significantly influence the marking activity of males when applied to their nostrils (Figure 1).

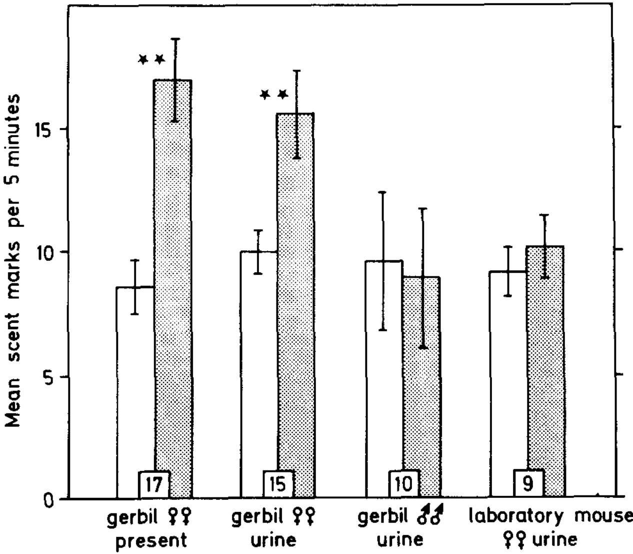

FIG. 1 Influence of the presence of female gerbils and application of female gerbil urine, male gerbil urine, and female laboratory mouse urine on open-field marking behavior of male gerbils. Mean ± SEM; given are the basal values (□) and the respective stimulated values (▩); number of males as indicated at the bottom of the bars; *: $P < 0.01$; **: $P < 0.001$.

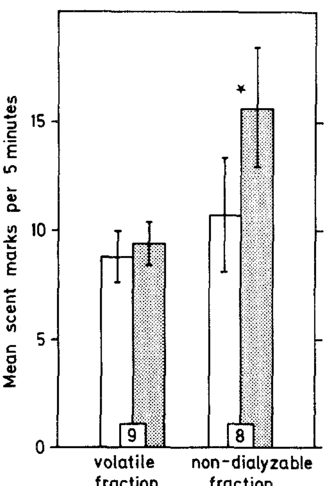

FIG. 2. Mean number of ventral scent gland marks before (□) and after application of the volatile and nondialyzable fractions (▩) of head-space distilled female urine. Mean ± SEM, number of males as indicated at the bottom of the bars; *: $P< 0.01$; **: $P < 0.001$.

For discrimination between volatile and nonvolatile stimuli, female urine was processed by head-space distillation. The volatile fraction was immediately redissolved in water (adjusted to the original volume) and applied to the males' nostrils. Although smelling intensely of phenylacetic acid, this volatile fraction proved to be inactive during the behavior tests (Figure 2), even when applied three times per day. The residue of the head-space distillation was dialyzed before application to remove low-moleulcar-weight substances and the remaining volatiles. This preparation still retained its scent-mark stimulating potency (Figure 2) and significantly increased scent-marking activity above prestimulation levels.

The separation of lipophilic and hydrophilic substances was achieved by liquid–liquid extraction of urine. Only the dialyzed aqueous extract of female urine significantly increased the males' scent-marking activity above the prestimulation level, while both the acidic and basic lipophilic extract were ineffective (Figure 3).

These tests excluded almost all substance classes except polypeptides. Therefore, urinary polypeptides were reversibly precipitated with 80% ammonium sulfate. The dialyzed precipitate then significantly stimulated scent marking (Figure 4). Surprisingly, the dialyzed supernatant significantly inhibited scent marking (Figure 4). A possible explanation could be that the marking activity was still increased from the preceding experiment and continued to decrease during these tests. Since the urinary protein concentration was higher

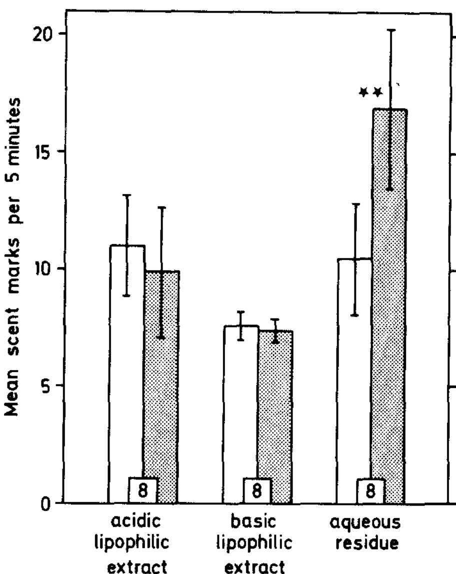

FIG. 3. Mean number of ventral scent gland marks before (▭) and after application of acidic and basic lipophilic extracts and the aqueous residue of female urine (▭). Mean $\pm$ SEM, number of males as indicated at the bottom of the bars; *: $P < 0.01$, **: $P < 0.001$.

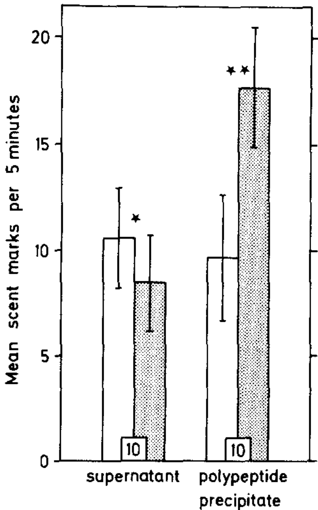

FIG. 4. Mean number of ventral scent gland marks before (▭) and after (▦) application of the supernatant and the ammonium sulfate-precipitated urinary polypeptides, respectively. Mean $\pm$ SEM, number of males as indicated at the bottom of the bars; *: $P < 0.01$; **: $P < 0.001$.

TABLE 1. MEAN MARKING ACTIVITIES OF MALE MONGOLIAN GERBILS AFTER EXPOSURE TO FEMALES AND FRACTIONS OF URINE

Condition	Number of males	Marking activity (mean ± SEM)
Females present	17	17.00 ± 1.56[b]
Female urine	15	15.05 ± 1.81[b]
Female lab. mouse urine	9	10.38 ± 1.39
Male gerbil urine	10	9.05 ± 2.83
Head-space volatiles	9	9.90 ± 1.00
Dialyzed residue	8	15.66 ± 2.64[b]
Acidic lipophilic extract	8	9.97 ± 2.19
Basic lipophilic extract	7	7.53 ± 0.52
Aqueous residue	8	16.93 ± 3.48[b]
Peptide precipitate	10	17.68 ± 2.34[b]
Supernatant	10	8.51 ± 2.34
Controls (females present)	17	8.66 ± 1.10
Controls (female urine)	16	10.08 ± 0.95
ANOVA[a]		$P < 0.001$

[a] Within experiment analysis of variance based on $\log_{10}$ transformed data.
[b] Significantly different from either baseline control at $P < 0.05$; determined using Duncan's multiple-range procedure.

in the male urine pool than in the female urine pool (male: 0.23 mg/ml; female: 0.20 mg/ml; determined using Coomassie blue and bovine serum albumin as standard), sex differences in protein concentration cannot account for the differential action of male and female urine in the bioassay.

The overall analysis of variance across all treatments comparing the controls of females present and female urine application with the various extracted fractions confirmed the significant effects found by using nonparametric statistics [$F(12,131) = 4.6$; $P < 0.001$; Table 1].

DISCUSSION

Urinary chemosignals exert a wide range of influences on reproduction in mammals (for summaries see: Whitten and Bronson, 1970; Milligan, 1980; Vandenberg, 1983). Best investigated are the effects of so-called "primer pheromones" on reproductive development and function in mice (reviewed by Marchlewska-Koj, 1983). Vandenberg et al. (1975) partially isolated from male mouse urine a compound accelerating puberty in juvenile females. In addition to sexual maturation, estrous cycles of adult females become more regular and can be synchronous in a group of females following the exposure to male urine

(Whitten, 1959; McClintock, 1983). Also, pregnancy in a newly mated female can be blocked by exposure to urine from a strange male (Bruce, 1959).

While the chemical nature of some signaling pheromones has been identified (e.g., von Stralendorff, 1982; Jemiolo et al., 1985), comparatively little is known about the chemical constitution of primer pheromones. Vandenberg et al. (1976) isolated a low-molecular-weight fraction from male urine accelerating puberty in female mice, which was further purified by Novotny et al. (1980). The failure to identify the biologically active chemical components may largely be due to the lack of sufficiently discriminating bioassays to compare the biological activity of different urinary fractions.

The bioassay presented here for the scent-mark-stimulating effect in male gerbils represents a relatively fast and very sensitive test. Similar to mouse primer pheromones, the scent marking increase requires continuous stimulation for at least three days until the higher marking level is achieved and, after withdrawing the stimulus, it takes several days until the males mark at their respective lower level. The female urinary chemosignal selectively influences male scent-marking behavior. Neither locomotor activity (number of open-field squares entered) nor serum testosterone concentrations were significantly different comparing basal and female-stimulated test phases (Probst, 1985b). Other open-field behaviors were apparently not changed, although no further quantitative evaluation was performed. Since the scent-marking increase is reversible and the procedure is noninvasive, one animal can be tested with different urinary fractions. The response obtained during stimulation can then be compared with the respective unstimulated marking activity of the same individual, thus largely increasing the precision of this bioassay.

The chemical signals responsible for this increased marking effect in male Mongolian gerbils is probably sex- and species-specific, since neither male gerbil urine nor female mouse urine stimulated scent-marking activity compared with female gerbil urine. The head-space distillation experiment demonstrated that the scent-mark-stimulating effect is not mediated by volatile substances. It is contained in the higher molecular weight fraction of female urine, since dialysis removes most lower-molecular-weight substances. Earlier results from Thiessen et al. (1974) showed that phenylacetic acid was the main chemical cue emitted from the scent gland of gerbils. The present results, however, indicate that phenylacetic acid might primarily be a behaviorally ineffective urinary component that is transfered to the scent gland during marking on urinated substrate rather than a component produced by the scent gland itself. Moreover, Thiessen et al. (1974) did not demonstrate the influence of phenylacetic acid on scent-marking behavior, but showed that gerbils can discriminate between phenylacetic acid and a control stimulus. During our experiments, no influence of phenylacetic acid on scent marking in the open field tests was found. Neither chronic stimulation for eight days with the phenylacetic acid containing acidic

lipophilic extract of female urine (Figure 3) nor direct application of phenylacetic acid (1% solution, 50 μl per marking peg) into the open field during the marking tests (control: 13.7 ± 3.6; phenylacetic acid: 11.7 ± 3.1; $n = 9$) caused a significant change in scent-marking behavior.

The stimulation of scent marking in male gerbils by chemical signals from females also provides an explanation for contrary results on the effect of testosterone on scent marking in castrated males. While Thiessen et al. (1968) observed an increase in scent marking of more than 100% above the respective precastration level during postcastration testosterone treatment, Swanson (1980) could not confirm this "supermarking." One reason for this might be that Thiessen et al. (1968) used males held without females present. These would scent mark at a reduced level prior to castration. However, there are no details of holding conditions given in this respect. During testosterone treatment, scent marking would then increase to the individual maximum level (Probst, 1985a) that female stimulated males show before castration, as in the experiments by Swanson (1980). As the present results show, testosterone-induced "supermarking" in castrated male gerbils (Thiessen et al., 1968) might be caused by comparing submaximal marking levels before castration with testosterone-induced maximally stimulated scent marking after castration, but not by a specific action of testosterone. This submaximal scent marking before castration can be prevented by the presence of sociochemical cues contained in the polypeptide fraction of female urine. After castration, testosterone treatment increases scent-marking activity above this submaximal level; however, even very high testosterone concentrations will not increase scent marking above the individual's maximum marking activity (Probst, 1985a).

Further research is necessary to investigate the influence of the gonadal state of females on their capability to increase male scent marking as well as the role of the dual olfactory pathways (Estes, 1972; Keverne, 1979; O'Connell and Meredith, 1984) involved in the perception of chemical signals in gerbils.

Acknowledgments—We would like to thank Drs. von Holst and von Stralendorff for critical discussions of this paper.

Abstract—A series of structural analogs of (+)-*cis*-(1*R*)-3-isopropenyl-2,2-dimethylcyclobutanemethanol acetate, sex pheromone of the citrus mealybug, *Planococcus citri* (Risso), was synthesized. The analogs were tested in a field bioassay in order to determine the structure–activity relationships of the pheromone. All changes in structure reduced the activity of the test compounds, to various degrees. The most active analog tested was the homolog (+)-*cis*-(1*R*)-3-isopropenyl-2,2-dimethylcyclobutaneethanol acetate (IV), whose activity, at a higher dosage, was comparable to that of the pheromone. The alcohol (+)-*cis*-(1*R*)-3-isopropenyl-2,2-dimethylcyclobutanemethanol was tested in mixtures with the pheromone and found to be neither an inhibitor nor a synergist. The results show that all functional groups of the pheromone molecule are essential for optimal biological activity.

Key Words—Citrus mealybug, *Planococcus citri*, Homoptera, Pseudococcidae, sex pheromone, synthetic analogs, structure–activity relationship, field bioassay.

INTRODUCTION

The citrus mealybug, *Planococcus citri* (Risso), is a cosmopolitan pest of numerous crops. It is, in particular, a serious economic problem in citrus groves (Bartlett, 1978; Bodenheimer, 1951).

[1]Homoptera: Coccoidea: Pseudococcidae.
[2]Contribution from the Agricultural Research Organization (ARO), The Volcani Center, Bet Dagan, Israel, No. 1667-E, 1986 series.

The female sex pheromone of this pest was identified (Bierl-Leonhardt et al., 1981) as (+)-(1*R*)-3-isopropenyl-2,2-dimethylcyclobutanemethanol acetate (I). The pheromone has been synthesized by several groups (Bierl-Leonhardt et al., 1981; Gaoni, 1982; Carlsen and Odden, 1984; Odinkov et al., 1984; Wolk et al., 1986) and shown to be highly attractive to males in field tests (Bierl-Leonhardt et al., 1981; Ortu and Delrio, 1982; Rotundo and Tremblay, 1982; Dunkelblum et al., 1983; Moreno et al., 1984; Tauber et al., 1985). These results demonstrate the potential of the synthetic pheromone for use in monitoring and possibly for control of the citrus mealybug.

This paper describes the synthesis of some structural pheromone analogs, shown in Figure 1, and reports on the biological activity of these compounds in field tests. The aim of the present study was to probe the structure–activity relationship in the *P. citri* sex pheromone and to find potential attractive analogs for practical use.

METHODS AND MATERIALS

Chemicals. The pheromone (I), $[\alpha]_D^{19}$: +20.7° (c 0.93, $CHCl_3$), and the keto analog (III), $[\alpha]_D^{22}$: +103.2° (c 6.20, $CHCl_3$), were prepared from (+)-α-pinene by a short synthesis developed recently by our group (Wolk et al., 1986). The alcohol (II), $[\alpha]_D^{22}$: +16.2° (c 3.64, $CHCl_3$), free of contaminating pheromone I, was obtained from the latter by alkaline hydrolysis. The trifluoroacetate (VII), $[\alpha]_D^{26}$: 12.1° (c 0.78, $CHCl_3$), formate (VIII), $[\alpha]_D^{26}$: +19.6° (c 0.52, $CHCl_3$), and propionate (IX), $[\alpha]_D^{26}$: +14.2° (c 1.96, $CHCl_3$), were prepared from the alcohol with trifluoroacetic anhydride, formic acid–acetic anhydride, and propionic anhydride, respectively.

Selective reduction of the aldehyde group of (+)-*cis*-pinonaldehyde, $[\alpha]_D^{19}$: +79.5° (c 1.33, $CHCl_3$), with sodium borohydride in acetic acid (Saksena and Mangiaracina, 1983) gave the corresponding ketoalcohol, $[\alpha]_D^{22}$: +73.3° (c 1.16, $CHCl_3$) (Gora et al., 1982), which was acetylated to the respective ketoacetate, $[\alpha]_D^{22}$: +58.1° (c 1.16, $CHCl_3$). Wittig methylenation of the latter afforded the homolog (IV), $[\alpha]_D^{22}$: −22.5° (c 1.00, $CHCl_3$), along with some of the corresponding alcohol.

The acyclic analog V was prepared by the following route (Scheme 1). Michael addition of dimethyl malonate to mesityl oxide gave the diester X, decarbomethoxylation of which in moist dimethyl sulfoxide (Krapcho, 1982) gave methyl 3,3-dimethyl-5-oxohexanoate (XI) (Andersen et al., 1981). Wittig methylenation of XI to the unsaturated ester XII (Jellal and Santelli, 1980), followed by lithium aluminum hydride reduction gave the alcohol XIII (Blume et al., 1965). Acetylation of XIII gave the desired analog V.

Hydrogenation of the pheromone I over the catalyst prepared from nickel acetate and sodium borohydride (Brown and Brown, 1963) gave exclusively the

SCHEME 1. Synthesis of acyclic analog V. a. NaH b. NaCl, H_2O/DMSO c. $Ph_3P{=}CH_2$ d. $LiAlH_4$ e. Ac_2O/Pyr.

cis-dihydro analog (VI), $[\alpha]_D^{26}$: +3.8° (c 0.84, $CHCl_3$), along with some of the isopropylidene isomer of the pheromone. The two products were easily separated by preparative gas-liquid chromatography. When the hydrogenation was performed over 5% palladium on carbon, considerable amounts of the *trans* isomer of VI were also obtained.

All synthetic analogs were purified by column chromatography and/or bulb-to-bulb distillation and were homogeneous, as verified by capillary GLC (DB225, 30 m × 0.25 mm). Satisfactory NMR and mass spectra were obtained for all analogs. The purity of all compounds was 95–98%.

Field Tests. The attractancy of the analogs (II–IX) was compared with that of the synthetic pheromone (I) in field bioassays. Most of the tests were performed in a grapefruit orchard in the experimental farm at Zerifin (coastal plain), Israel, during 1985. Triangular plastic traps (10 × 10 × 10 × 15 cm), equipped with a replaceable sticky board at the bottom, were hung in the canopy of two adjacent rows of trees at intervals of about 10 m. Rubber septa, impregnated with a hexane solution of the test chemicals, were used as baits. Some tests were conducted at the Biological Control Institute in Rehovot (coastal plain) Israel, in a shaded hut (15 × 4 m), where squashes infested with the citrus mealybug were stored. Traps were hung above the shelves, at a distance of 2–3 m between traps. The sticky boards were exchanged every 4–8 days and the trapped males were counted in the laboratory using a stereoscope microscope. Traps were rotated by one position on every check.

RESULTS AND DISCUSSION

In the pioneering paper on the identification and synthesis of the sex pheromone of *P. citri* (Bierl-Leonhardt et al., 1981), it was reported that only the (*cis*)-(+) enantiomer of 3-isopropenyl-2,2-dimethylcyclobutanemethanol acetate was significantly active as sex attractant to males. In view of this finding,

we decided to preserve the same relative configuration in all the cyclobutyl analogs, with the sole exception of the acyclic analog (V).

A series of analogs (Figure 1) was prepared and field bioassayed in groups with the synthetic pheromone (I) as standard for comparison. A control trap baited with a septum impregnated with pure hexane, was included in all the tests. The control traps caught no *P. citri* males, except for a few isolated instances of single males.

The first group of chemicals included the alcohol (II) alone and mixtures containing 2, 5, 10, 20, and 100% of II with the pheromone (I). The alcohol (II) is a side product in our recently developed synthesis of the pheromone (I) (Wolk et al., 1986); therefore it was of practical importance to assess the activity of II. The field tests indicated that the alcohol (II) was ineffective as a sex attractant. Only the addition of the equal amount of II to the pheromone (I) led

to a significant reduction of the activity of the latter. Addition of smaller amounts of II had no statistically significant effect on the attractiveness of I, although the addition of 10% of II enhanced slightly the activity of the pheromone (Table 1). A very similar effect of the corresponding alcohol on the activity of an acetate pheromone was found in field tests with the sex pheromone of the Comstock mealybug, *Pseudococcus comstocki* (Bierl-Leonhardt et al., 1982).

The second group of compounds included the keto analog (III), the homolog (IV), the acyclic analog (V), and the dihydro analog (VI) (Table 2). These compounds incorporate various alterations in the pheromone skeleton, including the opening of the cyclobutyl ring in V. Compounds III, V, and VI gave negligible trap catches. The homolog (IV) had significant activity, and therefore it was decided to test this compound at several concentrations. Periodical trap catches of IV at three concentrations are recorded in Table 3. Increase of the amount of IV from 500 μg to 2000 μg enhanced the attractiveness substantially, in particular in the first four weeks, almost equaling the activity of the pheromone at the concentration of 500 μg.

The last group of analogs included three esters: the trifluoroacetate (VII), formate (VIII), and propionate (IX), which differ from the pheromone only in the ester function. These esters had low activity, in particular the trifluoroacetate which performed similarly to a control bait (Table 2).

So far all attempts to design analog compounds which would be as active as the corresponding pheromones failed, although useful analogs have been

prepared in a few cases of Lepidoptera (Beevor et al., 1977; Carlson and McLaughlin, 1982; Mitchell et al., 1975; Silk et al., 1985; Tatsuki and Kanno, 1981). Studies of analogs of a coccoid sex pheromone have been reported only for that of the Comstock mealybug, *P. comstocki.* All compounds tested had significantly lower activity than the respective pheromone (Bierl-Leonhardt et al., 1982; Uchida et al., 1981). The results of EAG studies and field tests carried out in all these studies on analogs indicated that all active sites in a pheromone are essential for optimal substrate–receptor interaction. Although various models of this interaction have been proposed (Bestmann and Vostrovsky, 1982; Kafka and Neuwirth, 1975; Roelofs and Comeau, 1971), the basic phenomenon is still not completely understood.

The pheromone of the citrus mealybug (I) has a unique structure with a relatively large number of active sites: a polar acetate group, a cyclobutyl ring, a double bond, a specific chain length, and two chiral centers which constrain the total stereochemistry of the molecule. With the exception of the achiral acyclic analog V, the two chiral centers were preserved in all the compounds in this study. The acetate group was hydrolyzed to the alcohol or replaced by a trifluoroacetate, formate, and propionate ester. The carbon–carbon double bond was either reduced or replaced by a carbon–oxygen double bond, and the chain length was increased by one carbon. All changes in the molecular structure of I (Figure 2) reduced the activity of the corresponding analogs. Reduction of the double bond, replacing it by a carbonyl function and opening of the cyclobutyl ring eliminated almost all activity (Table 2). These results establish the essential role of the ring and the olefinic function in the pheromone. Manipulation of the methanol acetate group led to interesting results. Hydrolysis of the acetate function or its replacement by another ester group reduced activity drastically. However, there was a considerable difference between the trifluoroacetate and the propionate esters (Table 2). The former had no activity at all, whereas the latter retained some attractiveness to the males. This result reflects the difference in the polarity between these two groups. The propionate has almost the same polarity as the acetate, while that of the trifluoroacetate is much greater (Liljefors et al., 1984). Addition of one carbon to the methanol side chain to form homolog IV gave the most active, nonpheromone compound tested (Table 3).

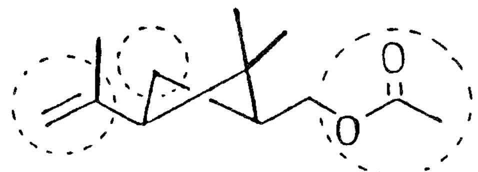

FIG. 2. Pheromone molecule with sites of alterations.

CONCLUSIONS

All changes (II–IX) in the shape and electron distribution of the sex pheromone molecule of *P. citri* (I) resulted in a significant reduction of its biological activity. All functional groups seem to be essential for full activity in the field. Lengthening of the cyclobutanemethanol moiety to cyclobutaneethanol, in the homolog IV, was the only modification which yielded an analog with a relatively high attractiveness to *P. citri* males. This analog retained all functional groups having the same polarity as the pheromone, with only a slight change in the molecular shape.

(Received April 23, 1986; accepted May 23, 1986)

Abstract—A computer tracking system was used to quantify the responses of infective second-stage juveniles of the plant-parasitic nematode *Meloidogyne incognita* to carbon dioxide. A sudden increase in concentration caused an increase in the rate of locomotion and a decrease in the frequency of changes of direction. The threshold was about 0.01% vol CO_2/vol gas when the baseline concentration was very low and 0.05% CO_2 when the baseline concentration was 1% CO_2. The latter value represents a relative change of 5%. Concentrations above 10% CO_2 caused a general decrease in movement. In a second type of experiment, a constant concentration gradient of CO_2 was established, and the net movement of the nematodes along the gradient was determined. At low concentrations, the threshold was about 0.02% CO_2/cm. At higher concentrations, the threshold gradient was below 0.01% CO_2/cm or a relative gradient of less than 1% change/cm. At all concentrations to which nematodes responded they were attracted. The degree of orientation was estimated to be approximately 10% under most conditions. The rate of migration under the most favorable conditions was about 0.7 cm/hr. Three possible functions of the response are discussed: attraction to roots, movement toward optimal depth in soil, and as a collimating stimulus.

Key Words—*Meloidogyne incognita*, nematode, carbon dioxide, chemotaxis, video camera, microcomputer, tracking, soil.

INTRODUCTION

An important question in soil ecology is how animals orient in this complex environment. A specific question of particular importance to agriculture is how

0098-0331/87/0400-0873$05.00/0 © 1987 Plenum Publishing Corporation

plant-parasitic nematodes locate their hosts. Carbon dioxide is a known attractant for several phytoparasitic nematodes (Prot, 1980). While CO_2 is the most abundant root exudate, its relative importance as an attractant under natural conditions is debatable. Prot (1980) concluded that CO_2 may be one of the attractants for nematodes toward host roots, but that its influence probably does not extend further than 1 or 2 cm from the roots.

A major problem in determining the influence of CO_2 in situ has been the lack of quantitative data for minimum concentrations and gradients required to elicit attraction and for the strength of the response. Using a computer–video tracking system, we have measured these parameters for the root-knot nematode *Meloidogyne incognita*.

METHODS AND MATERIALS

The computer tracking system was similar to that previously described (Dusenbery, 1985a,b), except that an IBM XT computer with an Imaging Technology camera interface was used. Several other modifications were made to accommodate the plant-parasitic nematodes which are smaller, slower (Goode and Dusenbery, 1985), and more sensitive to thermal gradients (J.A. Diez, M.J. Pline, and D.B. Dusenbery, unpublished data) than the free-living nematodes studied previously. The tracking interval was increased from 1 to 5 sec. The illumination source was switched from an incandescent bulb to a 14-W U-shaped fluorescent bulb to reduce the heat produced. To reduce thermal gradients, air was recirculated through a heat exchanger coupled to a water bath and over the chamber which contained the nematodes. A Computar® enlarging lens (f1.9, 55 mm) provided a fast lens with a flat field at close focus. Increased magnification produced a field of 20 × 17 mm. Since the video image is digitized into an array of 512 × 480 pixels, the pixel spacing was 39 μm along the flow and 35 μm across the flow.

Meloidogyne incognita were grown on tomato plants (Goode and Dusenbery, 1985). Several hundred 1- to 2-day-old juveniles (J2) from egg masses acclimated to 23°C for several days were placed on a thin sheet (30 × 50 mm) of 2% agar poured on a glass plate (75 × 150 × 5.5 mm). This plate was inverted onto a similar glass plate to which rubber tubes had been cemented to form an open-ended chamber (35 × 130 × 5 mm) with an input tube at one end (Figure 1).

Hydrated air was a carrier for the CO_2 stimulus. To compare the sensitivity of the nematodes to CO_2 under different baseline CO_2 concentrations, we used a carrier of either low hydrocarbon compressed air containing 0.003% CO_2 or compressed air containing 1.04% CO_2. The compressed air was blown through a flowmeter and activated charcoal trap into a gas washing bottle submerged in a thermostatically controlled water bath. The hydrated air then flowed into the

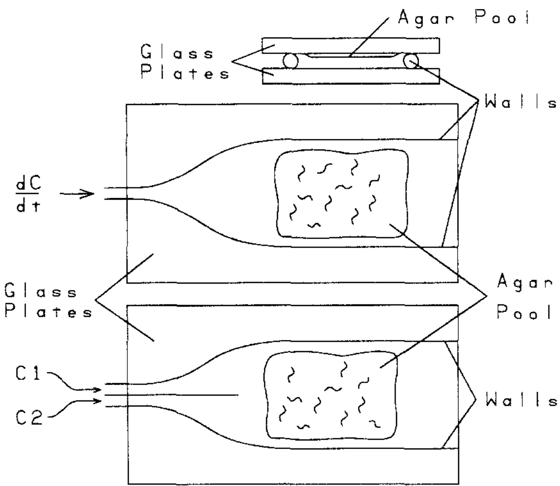

FIG. 1. Diagram of the two flow chambers used. The top figure is a cross-section of either chamber. The middle figure is the chamber used to generate a temporal, spatially uniform stimulus. The lower figure is of the chamber used to generate a steady spatial gradient. "C1" and "C2" stand for two different concentrations of CO_2 in air flowing through the chambers; "*dC/dt*" indicates a temporal change in concentration.

chamber and over the agar sheet. Air flow within the chamber was laminar. Various concentrations of CO_2 (0.25–100%) were premixed with hydrated air in a syringe pump and injected at various flow rates (0.01–0.04 ml/sec) into the constantly flowing (0.25, 0.5, or 1.0 ml/sec) hydrated air for 2 min. Mixing occurred in 35 cm of small-diameter Teflon tubing before entering the chamber. This procedure increased the concentration delivered to the nematodes by 0.0025% to 16% CO_2. Sufficient time (3–6 min) was allowed between exposures for behavior to return to a stable baseline for at least 1 min. Concentrations of CO_2 were confirmed by gas chromatography. Each concentration was tested with 4–10 replicates.

To measure the response of the nematodes to gradients of CO_2, the chamber was modified by cementing two input tubes at one end of the chamber and separating them by a thin vertical partition of plastic extending 3 cm into the chamber (Figure 1). The stream of hydrated air (containing 0.003% or 1.04% CO_2) was split before entering the chamber, and CO_2 of various concentrations was injected by syringe pump into one of the two air flows. A switching valve controlled which side of the chamber received added CO_2. When two gases with different CO_2 concentrations were used with this chamber, diffusion occurred between them as they flowed through the chamber. This established a concentration gradient across the direction of flow. Concentrations of CO_2 in the gradients were determined by gas chromatography. This procedure was ef-

fective in creating near-linear gradients of CO_2 across the width of the chamber in the area of the agar sheet.

In the first series of experiments, involving temporal step changes in CO_2 concentration, the position of each of 150–300 nematodes was determined every 5 sec and the absolute value of locomotion in two orthogonal directions was determined and summed. Reversals (a change in direction of locomotion of >90°; Dusenbery, 1985a) were also determined every 5 sec and summed. In the second series of experiments, involving CO_2 gradients, the amount and direction of locomotion in each of two orthogonal directions (i.e., parallel and perpendicular to the direction of flow) was determined every 5 sec and separately summed to indicate the net movement of the average position of 200–300 nematodes along the flow and along the gradient of CO_2 created in the chamber. The absolute amount of locomotion as described above was also measured.

RESULTS

Low CO_2 Baseline. Figure 2 illustrates the response of *M. incognita* to sudden small increases in CO_2 concentration under conditions of low (0.003%) CO_2 baseline concentration. Figures 2–5 show responses for only a sample of the concentrations tested. The nematodes reacted quickly to changes in concentration $\geq 0.01\%$ CO_2 by increasing their rate of locomotion and decreasing their frequency of reversals. At a carrier flow rate of 1.0 ml/sec, the CO_2–air mixture reached the nematodes in 10 sec, and their initial response began about 5–10 sec later. Peak response occurred within 1 min. Some adaptation was usually observed during the second minute of the stimulus with a slight decrease in locomotion and increase in reversals. At concentrations $\leq 0.04\%$ CO_2, movements returned to prestimulus levels usually within 60 sec after the CO_2 was turned off.

Figure 3 presents similar data for large changes in concentration. At concentrations $\geq 6\%$ CO_2, the response was depressed and acquired a biphasic character. The initial changes in movement lasted less than a minute before decreasing. After the stimulus was removed, there was a second response, similar to the first. In all cases, the rate of locomotion and reversal frequency changed in opposite directions.

High CO_2 Baseline. Figure 4 illustrates the response of *M. incognita* to sudden small increases in CO_2 concentration under the condition of high CO_2 baseline concentration (1.04%). As with low CO_2 baseline concentration, the nematodes responded quickly to CO_2, but the pattern of response was different. For concentration changes $\leq 0.03\%$ CO_2, no response was detected. For a change of 0.06% CO_2, the rate of locomotion increased and reversal frequency

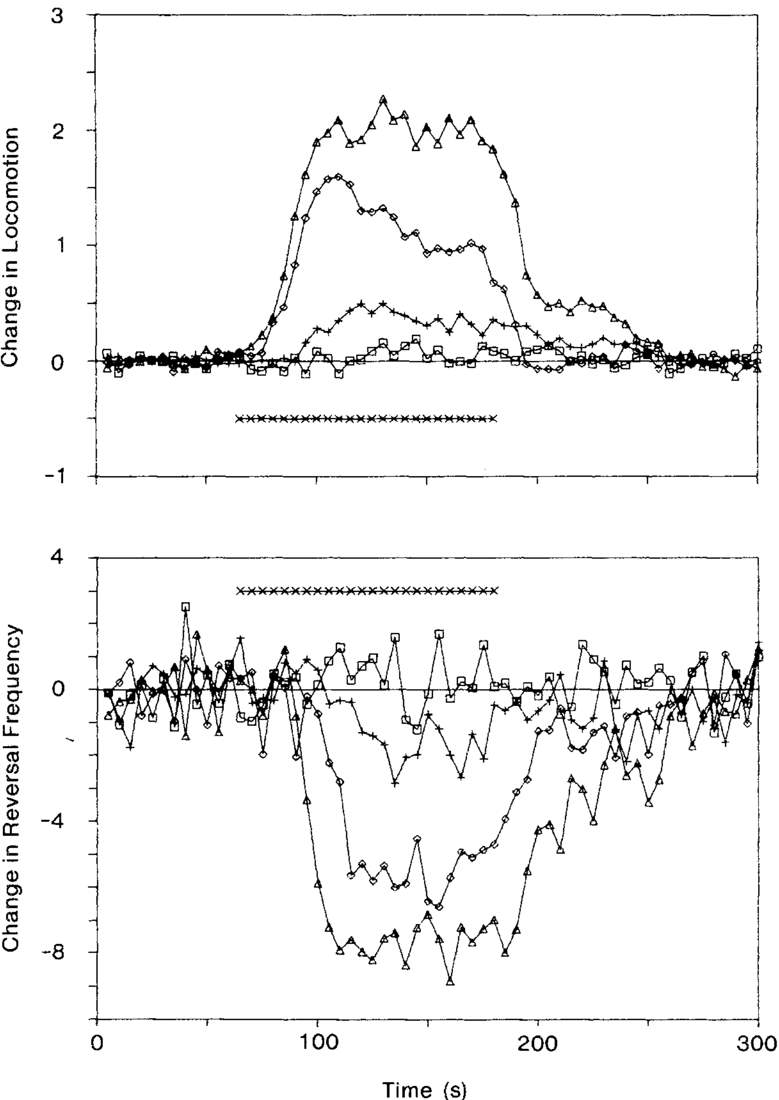

FIG. 2. Time course of changes in movements in response to small, temporal step changes in CO_2 concentration with low (0.003%) CO_2 baseline concentration. Locomotion, presented as the change from the prestimulation value, is the average distance in pixels the nematodes have moved between successive determinations of their position (trackings). Reversal frequency, presented as the change from the prestimulus value, is the average number of reversals detected per 100 nematodes per tracking. During the times indicated (X), CO_2 was added to the air flow to increase concentration by (□) 0.0075, (+) 0.01, (◇) 0.02, or (△) 0.04% volume CO_2/volume gas.

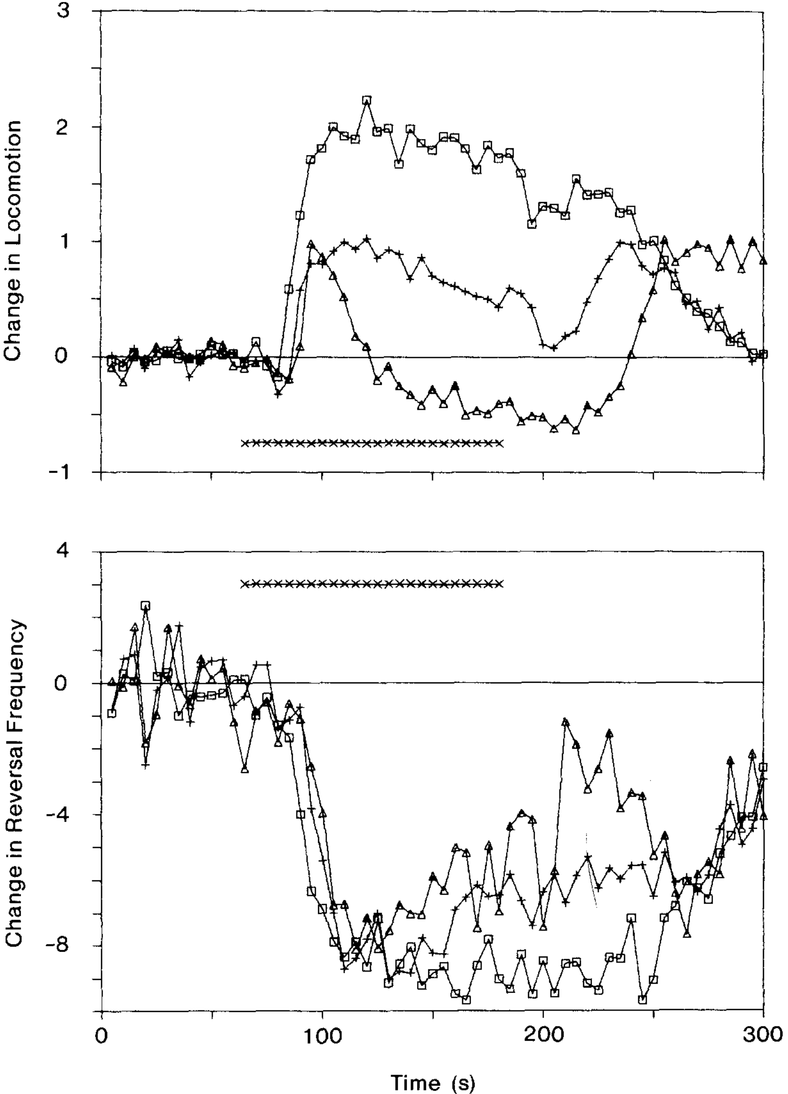

FIG. 3. Time course of changes in movements in response to large, temporal step changes in CO_2 concentration. Same as Figure 2, except the concentration increases are larger: (□) 4% CO_2, (+) 8% CO_2, or (△) 16% CO_2.

decreased. These movements returned to prestimulus levels in about 30 sec. When the stimulus was turned off, there was an abrupt decrease in the rate of locomotion and increase in reversal frequency. This pattern of response was discernible but weak at 0.04% CO_2. Not until the stimulus concentration reached

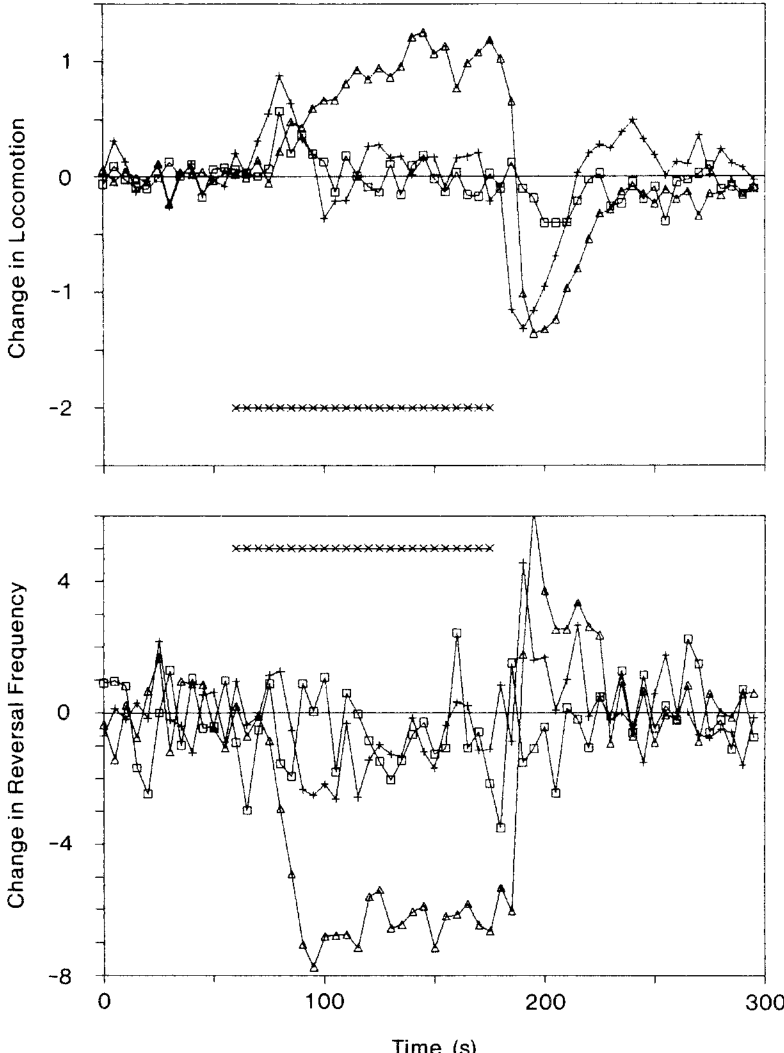

FIG. 4. Time course of changes in movements in response to small, temporal step changes in CO_2 concentration with high (1.04%) CO_2 baseline concentration (see Figure 2). During the times indicated (X), CO_2 was added to the air flow to increase concentration (volume CO_2/volume gas) by (□) 0.04% CO_2, (+) 0.06% CO_2, or (△) 2% CO_2.

2.0% CO_2 did the rate of locomotion remain elevated and the frequency of reversals remain depressed throughout the stimulus application. The characteristic response to the removal of the stimulus occcurred at all concentrations $\geq$0.06%.

Figure 5 presents data for large changes in concentration with high CO_2 baseline air. Results were similar to Figure 3 in showing the depression of response within 1 min of initial stimulus application.

To more precisely define the effect of concentration on the strength of the response, the average change in locomotion (or reversal frequency) per tracking for the second minute of the 2-min stimulus application was calculated for 75 experiments using low CO_2 baseline air and 75 experiments using high CO_2 baseline air (Figure 6). Change was measured with respect to a prestimulus value calculated for each experiment from the average locomotion (or reversal frequency) per 5 sec tracking for 1 min immediately preceding application of the stimulus.

With low CO_2 baseline air, prestimulus values ranged from 1.4 to 1.9 pixels displacement per nematode, and from 11 to 14 reversals per 100 nematodes. The smallest stimulus to which the nematodes responded was a concentration change of 0.01% CO_2. The strength of the response changed little between 0.04% and 4% CO_2. In this range, the rate of locomotion doubled and the reversal frequency was half its prestimulus value. The response was significantly depressed over 6% CO_2. The rate of locomotion actually fell below prestimulus levels with the application of 12% and 16% CO_2.

High CO_2 baseline air elicited prestimulus movements of 2.2–3.8 pixels displacement per nematode, and 7–12 reversals per 100 nematodes. Because the nematodes acclimated so quickly to small step changes in CO_2 concentration with high CO_2 baseline air, Figure 6 does not illustrate the response of the nematodes to threshold concentrations as clearly as with low CO_2 baseline air. While Figure 4 clearly indicates that the nematodes reacted both to the application and removal of a 0.06% CO_2 stimulus, there is a barely detectable rise in locomotion in Figure 6. As with low CO_2 baseline air, CO_2 concentrations $\geq 6\%$ caused general depression of movement, and the rate of locomotion fell below prestimulus levels with the application of 12% and 16% CO_2.

In other experiments, nematodes were subjected to 20% CO_2 for 3 min followed by 100% CO_2 for 3 min. The rate of locomotion was depressed by 70% with 20% CO_2 and by 93% with 100% CO_2. Following the removal of 100% CO_2, the rate of locomotion slowly increased to prestimulus levels.

Gradients. To determine clearly whether these responses lead to effective migration of the nematodes in a gradient of CO_2, a concentration gradient was established across the direction of flow in the gradient flow chamber (Figure 1). Often, the nematodes showed a significant net migration with the same gas flowing through both sides. This was presumably due to shallow thermal gradients to which these animals are extremely sensitive (J.A. Diez, M.J. Pline, and D.B. Dusenbery, unpublished data). Thermal gradients were minimized, and a background rate of migration was established. Stimulus was added to one side of the flow and then switched to the other side. If the net migration changed

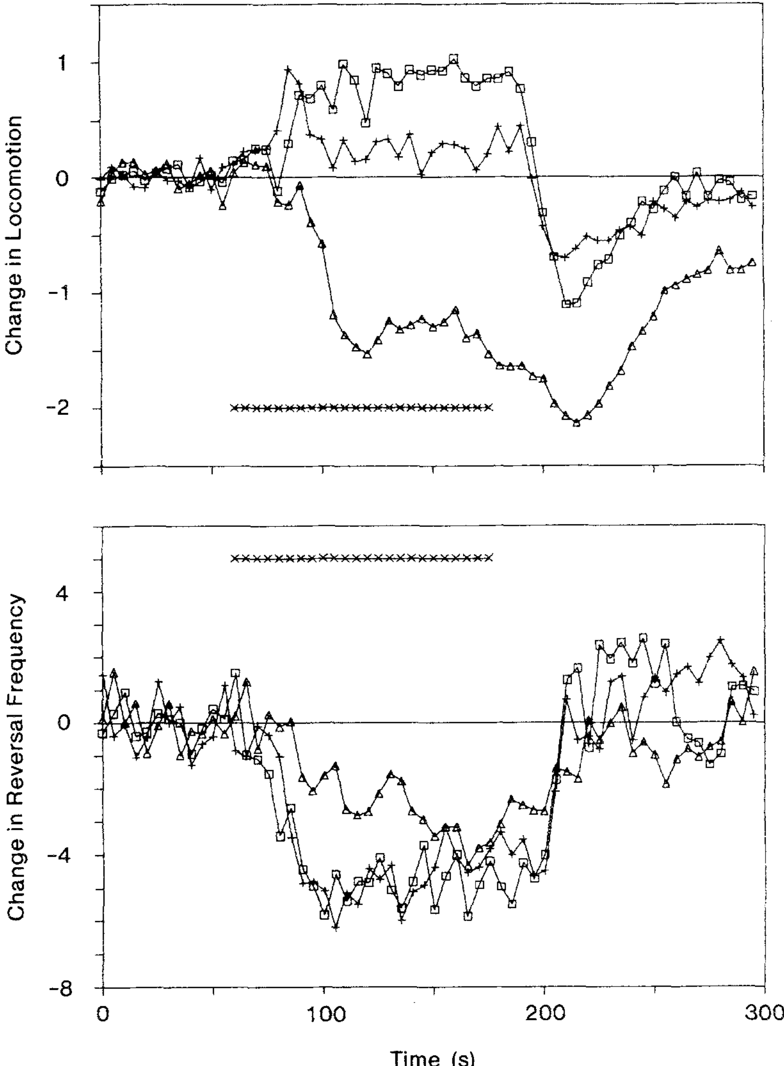

FIG. 5. Time course of changes in movements in response to large, temporal step changes in CO_2 concentration. Same as Figure 4, except the concentration increases are larger: (□) 4% CO_2, (+) 8% CO_2, or (△) 16% CO_2.

consistently either toward or away from the side with the stimulus, an effective migration to the chemical stimulus was established. Figure 7 shows that the nematodes migrated toward the CO_2. Migration away from CO_2 was not found with any tested concentration.

Table 1 summarizes results from 40 experiments that measured the re-

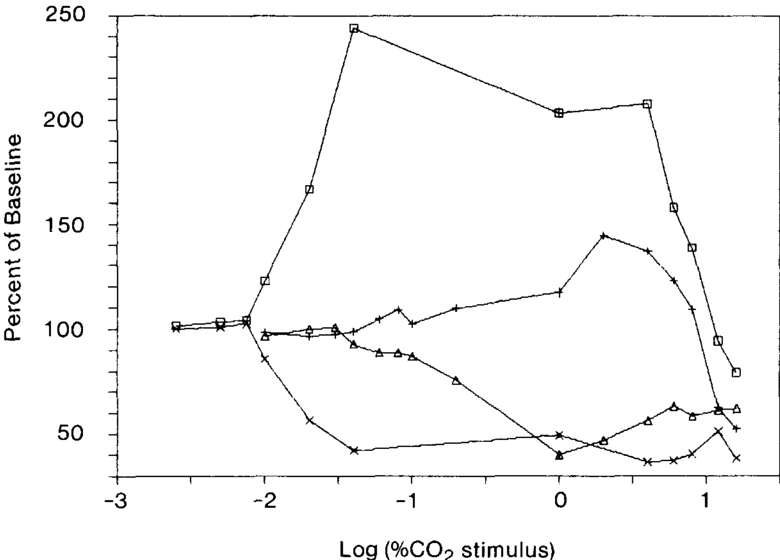

FIG. 6. Relative changes in locomotion and reversals as a function of concentration. Each data point represents the average locomotion or reversal frequency during the application of a stimulus concentration as a percent of the average prestimulus value. The stimulus is the change in concentration from the baseline value. Locomotion (□) and reversal frequency (×) with low CO_2 (0.003%) baseline concentration. Locomotion (+) and reversal frequency (△) with high CO_2 (1.04%) baseline concentration.

sponse of the nematodes to gradients of CO_2 containing low concentrations ranging from 0.02% to 0.24% CO_2. Relative gradient steepness was calculated as the percent change in CO_2 concentration per centimeter at the center of the field of camera view. The assumption that gradients were linear was supported by periodic measurements of CO_2 concentration at regular intervals along typical CO_2 gradients. The reported response is for locomotion perpendicular to the flow of air. The response for each experiment was the average rate of locomotion per nematode toward higher CO_2 concentrations (up the gradient) for the last 4 min of a 6-min gradient duration minus the average rate of locomotion per nematode for the last 4 min of a 6-min period either immediately preceding or immediately following the gradient application.

For each range of gradient strengths reported in Table 1, the response was the average of *N* experiments converted to cm/hr. Initial analysis of responses, grouped by relative gradient steepness, revealed little correlation between response strength and relative gradient steepness. When responses were grouped by absolute gradient steepness (and mean CO_2 concentration within the gradients), the rank sum test revealed that the nematodes detected and responded

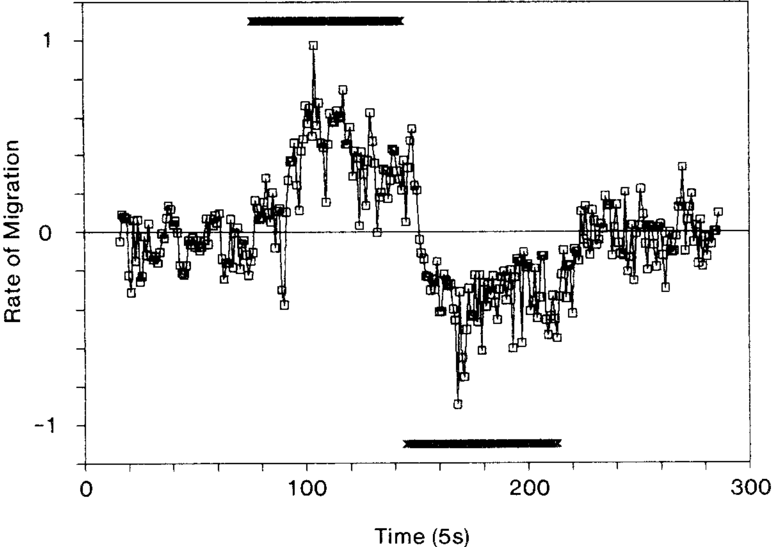

FIG. 7. Record of rate of migration in a steady gradient. The rate of migration across the flow is presented in units of pixels per nematode per tracking. Positive values indicate net movement to the left and negative to the right. The bar at the top indicates times during which 0.16% CO_2 was added to the left-hand side of the flow (containing 0.003% CO_2), creating a concentration gradient of 30% change/cm. The bar at the bottom indicates addition to the right side, creating a concentration gradient of 38% change/cm. At other times, no CO_2 was added.

TABLE 1. EFFECT OF GRADIENT STEEPNESS ON RATE OF MIGRATION AT LOW CONCENTRATIONS

Gradient type	Concentrations Mean (% CO_2)	Gradients: Relative (% change/cm)	Gradients: Absolute (% CO_2/cm)	Response (cm/hr): Mean	SD	*N*	P^a
Control	0.003	0	0	0.08	0.16	12	
Measured	0.026–0.028	16–12	0.004–0.006	0.07	0.06	4	>0.2

Measured	1.69–2.02	12–20	0.22–0.41	0.24	0.37	16	<0.04

[a] P is the probability that rate of migration measurements came from the same population as the control measurements as determined by the rank sum test.

to absolute gradients of $\geq 0.024\%$ CO_2/cm at a mean CO_2 concentration of $\geq 0.082\%$. Their response to gradients with lower concentrations of CO_2 was not significantly different from the control experiments, even though relative gradient steepness was comparable or higher.

Table 2 summarizes results from 52 experiments using gradients of CO_2 with moderate concentrations ranging from 1.04% to 2.37% CO_2. All calculations were performed as in Table 1. Very shallow gradients were not accurately measurable using gas chromatography and were estimated conservatively by extrapolating from the relationship of injected CO_2 concentrations to measurable, steeper gradients. An analysis of grouped responses by the rank sum test indicated that the nematodes detected and responded to relative gradients of $\geq 1.0\%$ change/cm, which corresponded to absolute gradients of $\geq 0.01\%$ CO_2/cm.

DISCUSSION

Sensitivity. This research determined minimal concentrations and gradients for behavioral responses of root-knot nematodes to carbon dioxide. Experiments using sudden jumps in concentration and measuring individual rates of movement indicated that the minimal concentration for a response was about 0.01 volume percent (Figures 2 and 6). Experiments measuring response to gradients demonstrated that the minimal concentration was about 0.05% CO_2 (Table 1). These values are well below the concentrations usually found in the soil atmosphere (Boynton, 1941; Nye, 1981). Thus, the minimal sensitivity does not normally limit the response in soil. Rather, the response is likely limited by the minimal detectable change in concentration.

This aspect of the response was tested by exposing the nematodes to a

baseline concentration of 1.04% and increasing the concentration by small amounts. Measurement of individual movements in response to sudden changes indicated a threshold change of about 0.05% CO_2 (Figure 4) or a relative change of 5%. Experiments measuring the response to gradients demonstrated a threshold less than 0.01% CO_2/cm (Table 2). These values are significantly lower than the limit of 0.1% CO_2/cm established by Klingler (1963) for directed responses of *Ditylenchus dipsaci*. In terms of the relative steepness of the gradient, the limit for *M. incognita* is less than 1% change/cm (Table 2). The corresponding value calculated from Klingler's graph (1963, Figure 9) is about 50% change/cm. Thus, these experiments demonstrate a much higher degree of sensitivity to carbon dioxide than has previously been demonstrated for any nematode.

The juveniles continued to be attracted to carbon dioxide at higher concentrations. The only limit was a decrease in all movements at concentrations above 10% CO_2. This is probably due to the anesthetic effects of carbon dioxide known in other nematodes (Davis et al., 1986).

Mechanism. Klingler (1963) observed that *D. dipsaci* were capable of direct orientation (klinotaxis) to gradients. Our observed decreases in rate of change of direction with increases in CO_2 concentration (Figures 2–6) suggest that indirect orientation via klinokinesis may also occur. Similar observations were made with the response of *Caenorhabditis elegans* to CO_2 (Dusenbery, 1985b) and, using the tether technique, with the response of both *M. incognita* (Goode and Dusenbery, 1985) and *C. elegans* (Dusenbery, 1980) to NaCl. The major difference is that in most previous cases the response adapted in less than a minute. This type of response was observed at the high baseline concentration (Figure 4), but not at the low concentration (Figure 2). Adaptation makes indirect orientation much more efficient. Thus, the sensory–response system may function optimally at higher concentrations. However, higher rates of migration were observed at lower concentrations.

Both direct and indirect mechanisms may be used by nematodes in responding to other stimuli, with indirect orientation occurring at low concentrations and direct orientation taking place near the source at higher concentrations (Dusenberry, 1980). If this is true for *M. incognita* and *D. dipsaci*, the sensitivity observed by Klingler may differ from that observed here simply because different aspects of the response were measured.

The data allow estimation of the degree of orientation achieved by the nematodes. We simply divide the net distance moved per nematode (= the displacement of average position of all nematodes) in a given time interval by the total distance moved per nematode. The net distance moved is the square root of the sum of the squares of net movement in the x and y directions, after first compensating for the difference in pixel lengths. Because total distance moved was measured by the computer program as the sum of the absolute dis-

tance traveled in the x and y directions, it must first be multiplied by a factor of 0.79 (the average ratio of the true distance moved to the sum of the two orthogonal distances moved, assuming movement in random directions). If all nematodes were moving in the same direction for the entire time interval, the result would be 100%. If all were moving in random directions, the result would be 0%.

In 91 experiments where no CO_2 gradient existed, the mean degree of orientation was 7.2% ± 5.2% SD. In 56 experiments where gradient intensities were at or above threshold, the mean was 9.9% ± 5.7% SD. While this suggests a 38% increase in directed locomotion in the presence of CO_2 gradients, the degree of variation in results, the lack of complete independence of measurements, and the unknown effects of ubiquitous thermal gradients precludes stating that CO_2 gradients alone caused the increased orientation. We conclude that the nematodes can achieve a degree of orientation of about 10% in a gradient of stimuli. This can be interpreted as meaning that in a typical situation about 10% of the nematodes are moving in a particular direction, while the rest move at random.

Rate of Migration. An important question in understanding host location by plant-parasitic nematodes concerns the rate at which they can move along a stimulus gradient. An estimate can be made by using the computer tracking system to measure the movement of the average position of a group of nematodes in the x and y directions, compensating for the difference in pixel lengths, and taking the square root of the sum of the squares of the two values. Under baseline conditions when no CO_2 gradients existed, the average rate of migration was about 0.4 cm/hr. Under conditions when CO_2 gradients were above threshold, the average rate of migration was about 0.7 cm/hr.

Function. A variety of other plant-parasitic nematodes have been reported to be attracted to carbon dioxide (Prot, 1980). This has naturally led to the suggestion that this response allows them to find plant roots by moving up the concentration gradient created by rhizosphere production of carbon dioxide. However, some have suggested that it could only act within 1 or 2 cm of the root (Prot, 1980). Since we have determined the sensitivity with more precision, it is worth investigating this question quantitatively.

Nye (1981, Appendix) provides a theoretical basis for determining concentrations of carbon dioxide in the rhizosphere. Using his symbols and typical values,

$$Cg_r = Cg_a - aF \ln (r/a)/D$$

where Cg is the concentration of CO_2 in the gas phase; $a = 0.037$ cm, the radius of a typical root; $F = 1.59 \times 10^{-6}$ ml/cm^2/sec, rate of CO_2 production; $D = 0.065$ cm^2/sec the diffusion constant of CO_2 in soil.

The gradient is obtained

$$dCg_r/dr = aF/Dr$$

The maximum value, at the root surface, is 0.0025% CO_2/cm. This is much smaller than the 0.02% CO_2/cm threshold found at low baseline concentrations (Table 1). But the experiments at higher concentrations (Table 2) are more relevant, and in this case we could not establish gradients that were lower than 0.006% CO_2/cm. Thus, although attraction to roots requires an extraordinary sensitivity to shallow gradients, it remains a possibility (Dusenbery, 1987).

Another potential function of the response is to lead the nematode to the optimal depth in the soil profile. Boynton (1941) provides many measurements of carbon dioxide concentration at various levels in apple orchards. Analysis of data from his Table 9 for approximately 500 samples taken at 1-, 2-, and 3-ft depths shows that mean concentrations at the three depths were 2.2, 3.6, and 5.0% CO_2, and 90% of the differences between adjacent levels were in the range 0.4–5% CO_2. This range corresponds to gradients of 0.01–0.16% CO_2/cm. Theoretical analysis of CO_2 profiles in soil (Wesseling, 1962) suggests a range of 0.003–0.2% CO_2/cm in the upper 40 cm. Since nematodes showed a clear response to gradients less than 0.01% CO_2/cm (Table 2), sufficiently strong gradients should exist under most conditions. Since carbon dioxide generally increases with depth, the nematodes should move downward, away from the surface.

A third possibility is that this response serves simply to maintain a straight path. All organisms have limits on how accurately they can move along a straight line without reference to an external stimulus. In the absence of any cues as to the location of a target, the best strategy for an organism may be to move in a straight path in order to sample as large an environment as possible in a given time. Circling is inefficient and invariably happens when an animal has no directional references. Stimuli that serve such a function might well be termed "collimating stimuli." It is possible that carbon dioxide is such a stimulus. If so, carbon dioxide gradients do not lead the nematode to plant roots or even to a particular level in the soil but simply provide a directional reference. To fulfill this function, the only requirement is that the gradients be above threshold and extend over distances that are large compared to the size of the nematode. The rapid diffusion of carbon dioxide, which makes gradients around roots shallow, ensures that what gradients do exist extend over relatively large distances.

The quantitative effect of a collimating stimulus can be analyzed using a random walk with step size L at a frequency f for a time period t. Let $L = 0.01$ cm, roughly the size of soil particles and accessible spaces. A reasonable value for f is 0.1 Hz. Let $t = 86{,}400$ sec or a day. The root-mean-square distance moved, x, in three dimensions is

$$x = L(ft/3)^{1/2} = 0.54 \text{ cm}$$

On the other hand, if the walk is all in one direction

$$x = Lft = 86 \text{ cm}$$

In other words, the nematode travels 160 times further in a straight path. Our observations indicate that the nematodes typically achieve only about 10% orientation. This would suggest 10 cm/day as a more realistic estimate, which is still superior to completely random searching.

Abstract—Two phytotoxic compounds [2,4-dihydroxy-1,4(2*H*)-benzoxazin-3-one (DIBOA) and 2(3*H*)-benzoxazolinone (BOA)] were previously isolated and identified in 35-day-old greenhouse-grown rye shoot tissue. Both compounds were also detected by TLC in greenhouse-grown root and field-grown shoot tissue. The concentration of DIBOA varied in the tissues, with the greatest quantity detected in greenhouse-grown shoots. DIBOA and BOA were compared with β-phenyllactic acid (PLA) and β-hydroxybutyric acid (HBA) for activity on seed germination and seedling growth and were consistently more toxic than either compound. Dicot species tested, including lettuce (*Lactuca sativa* L.), tomato (*Lycopersicon esculentum* Mill.), and redroot pigweed (*Amaranthus retroflexus* L.), were 30% more sensitive than the monocots tested. Of the two benzoxazinone compounds, DIBOA was most toxic to seedling growth. DIBOA and BOA reduced chlorophyll production in *Chlamydomonas rheinhardtii* Dangeard, by 50% at 7.5×10^{-5} M and 1.0×10^{-3} M, respectively. Both DIBOA and BOA inhibited emergence of barnyardgrass (*Echinochloa crusgalli* L. Beauv.), cress (*Lepidium sativum* L.), and lettuce when applied to soil, indicating their potential for allelopathic activity.

Key Words—Hydroxamic acids, benzoxaquinone DIBOA, BOA, allelochemicals, allelopathy.

INTRODUCTION

Allelopathy, where one plant chemically interferes with the germination, growth, or development of another plant, has been implicated in many aspects

of higher plant interactions (Muller, 1966; Whittaker and Feeny, 1971; Rice, 1974; Swain, 1977; Lovett, 1982). Difficulties in separating allelopathy from competition and detection of small quantities of biologically active compounds have hindered past research. As a result, there are few instances which clearly implicate a particular chemical in the observed interference between two plants. Even where chemicals have been identified, their significance and role in higher plant interactions under field conditions remain unclear (Harborne, 1977).

Winter rye (*Secale cereale* L.) is an annual grass that has proven useful as a rotational species in a variety of cropping systems (Overland, 1966; Benoit et al., 1962) and has been found to contribute organic matter, reduce soil erosion, and enhance water penetration and retention (Benoit et al., 1962; Blevins et al., 1971). An increased use of reduced-tillage systems employing cover crops such as winter rye will undoubtedly be important to agriculture in the future. Residues at the soil surface are inherent to reduced tillage systems. This residue may interact with weeds and/or crops to inhibit growth of plants. The interference is believed to arise from chemicals released into the environment via both root exudates and plant residues.

Although there are numerous reports of toxicity by rye and its residues (Cubbon, 1925; Hill, 1926; Osvald, 1953; Patrick and Koch, 1958; Patrick, 1971; Kimber, 1973; Chou and Patrick, 1976; Putnam and DeFrank, 1982; Barnes and Putnam, 1983; Shilling et al., 1985), none have conclusively explained the interference. Fuerst and Putnam (1983) proposed a set of criteria to be met for proof of allelopathic interference. Through a series of experiments leading up to and including the present work, we have attempted to meet these criteria when evaluating the allelopathic activity in rye residues.

Initially, the symptoms of interference must be identified in the natural state with experiments designed to eliminate competitive and indirect forms of interference (Fuerst and Putnam, 1983). In no-till field studies designed to separate physical from chemical mulch influences, ''Wheeler'' rye residues significantly reduced weed density and biomass over both no-residue and poplar (*Populus*) excelsior (PE) controls (Putnam et al., 1983). Greenhouse studies which simulated the no-till system confirmed field experiments (Barnes and Putnam, 1983; 1985). Indicator species emerging through the rye residue in greenhouse bioassays were chlorotic and stunted, although nutrient supplies were superoptimal.

Bioassays testing the effects of greenhouse-grown residues in soil on early stages of seed germination and seedling growth produced the greatest toxicity when seed was placed in close proximity to the residue (Barnes and Putnam, 1985). The soil diminished the activity, although growth reduction still occurred when residues were placed 15 mm away. Radicle elongation was a more sensitive measure of toxicity than germination, per se. Shoot tissue was about twice as active as root tissue on the species tested with 0.8 g/150 g soil placed
