umn and eluted after the void volume; thus its molecular weight could not be estimated. With the fathead minnow, the major constituent was estimated to have a molecular weight of approximately 519,000 daltons and the minor constituent 27,000 daltons. The estimates of the earthworm and fathead minnow high-molecular-weight materials along with their K_{av} values are shown in Table 10.

The low-molecular-weight materials obtained from the CM extraction from both prey were not estimated for molecular weight due to the lack of an accurate

Since Bio-Gel P-2 resin fractionates globular proteins of molecular weight 100–1800 daltons (Gordon and Richard, 1972), it is assumed that the upper limit of fractionation for the resin under these separation conditions is 1800 daltons and the estimated molecular weight range for the low-molecular-weight materials from both prey is between 1350 and 1800 daltons.

Amino Acid Analysis. Amino acid analysis was conducted on the high- and low-molecular-weight materials from the water layer of the chloroform–methanol extractions of the earthworm and fathead minnow. The results of the analyses are shown in Table 12 along with the amino acid composition of glycopeptides and collagen obtained from the earthworm cuticle determined by Muir and Lee (1970).

The methods of determining the amino acid composition in our study did not provide a measure of the hydroxyproline content. Hence, the concentration of other amino acids will be artificially high since it is undoubtedly present in at least the earthworm samples, given the previous analyses of earthworm surface-derived substances. We have concentrated on establishing the presence of both high- and low-molecular-weight materials and defining methods for the high-yield isolation of the interesting low-molecular-weight substance. The composition reported here refers to fractions that are still mixtures and may only be useful as indicators of similarity rather than indicators of identity to previously isolated fractions. Nevertheless, qualitative comparisons of the amino acid composition of the high- and low-molecular-weight earthworm fractions isolated in this study to similar data available for earthworm cuticle, earthworm collagen, and the earthworm F2 fraction (e.g., Halpern et al., 1986) are in order.

The most significant observation is the similarity of the major amino acids in all five materials. Thus, alanine, glycine, serine, glutamate, and threonine are major components in all. Presumably hydroxyproline is also an important component in our extracts but that remains to be determined. The principal differences are in the relative amounts of the amino acids. In the high-molecular-weight F2 and in the glycopeptide and collagen analyzed by Muir and Lee (1969, 1970), glycine is the major amino acid by far. The differences in glycine content are too great to be explained by our lack of hydroxyproline analysis and must reflect either a serious difference in the materials being studied or the presence of an unindicated impurity in the previously studied materials.

There are other apparently significant differences in composition. For example, EW-HMW has more than twice the amount of leucine found in any other fraction and EW-LMW has similarly high amounts of serine. Since we know that we are dealing with fractions that have more than one component, it is not possible to state definitively that these elevated amounts are due specifically to active material. On the other hand, the high serine content is quite provocative in view of the probable glycopeptide nature of these substances.

Several of the amino acids most common in both earthworm fractions also

appear to be important components of the high-molecular-weight fathead minnow fraction (e.g., glycine, alanine, leucine, glutamate, threonine, and serine). In addition, this fraction and the high-molecular-weight earthworm fraction share a high lysine concentration, significantly higher than in the other materials analyzed.

The low-molecular-weight fathead minnow fraction was found to have an extremely high concentation of arginine or a substance that mimics its behavior in the automated amino acid analysis. The significance of this obervation is not clear, but it could account for the difficulty experienced in attempted chromatography on silica gel-based absorbents. (Although it appears likely from our NMR analysis that this value is an artifact, the chromatographic similarity demonstrated in the amino acid analysis would also be reflected in other chromatographic systems.) Due to this apparently high arginine content, all other amino acids appear to be at much lower concentration than in the other fractions in Table 12. However, if the relative concentrations of the other amino acids are compared without considering the high arginine content, many of those occurring in high concentrations in other extracts are again found to be important. As in the high-molecular-weight fraction from the fish, lysine is relatively more important than in most other materials.

Carbohydrate Analysis. Silica thin-layer chromatography conducted with 3:2 methanol–chloroform on the high- and low-molecular-weight materials from the CM extractions indicated the presence of sugars when the plates were developed using alpha-naphthol–sulfuric acid spray. Hydrolysis of the individual materials followed by acetylation provided mixtures that could be analyzed by gas chromatography. Comparison of retention times of these hydrolysis mixtures with known acetylated sugars allowed identification. The identities of the sugars allowed identification. The identities of the sugars were also confirmed by mass spectrometry (Jansson et al., 1976).

The percent composition of sugars was estimated by comparing peak areas in the gas chromatograms to those of available standards of known concentrations separated under the same conditions. Since known concentrations of derivatized fucose and arabinose were not obtained for concentration data, an integration constant was calculated from the average of the peak area responses per mg of each known acetylated sugar. This averaging was implemented since it was assumed that all acetylated sugars should result in a similar relative response by the GC detector. Two inositol isomers were found in the low-molecular-weight materials of the earthworm. Both isomers resulted in the same mass spectrometric data but different GC retention times (Sherman et al. 1970). One isomer was determined to be myoinositol from GC retention time data. The integration constant was assumed to be the same for both isomers.

The percent composition of sugars (Table 13) for the high- and low-molec-

[a] From Muir and Lee (1970).
[b] The standard mass spectra for the acetalated ribose does not match this compound's mass specta but results in a peak at the same GC retention time as other ribose derivatives.

ular-weight materials from both prey demonstrated relatively high glucose, fucose, galactose, and mannose contents in all four samples. Myoinositol was found in each sample. The low-molecular-weight materials of the earthworm had two isomers of inositol, which comprised a large portion of the sugar components.

The specific carbohydrate composition associated with the earthworm surface extracts has not been as extensively documented as the amino acid composition. Muir and Lee (1970) demonstrated a high galactose content and documented the presence of galactosyl di- and trisaccharides in purified cuticle collagen. In unpurified extracts they also found significant quantities (2–10% of neutral sugars) of fucose and xylose along with mannose and amino sugars in lower concentrations.

Both the high- and low-molecular-weight earthworm fractions identified in this study as attack stimuli differ significantly in the neutral carbohydrate analysis after hydrolysis of lyophilized materials compared to the previously studied materials. Galactose still appears to be the major monosaccharide unit in the high-molecular-weight sample but is a minor constituent of the low-molecular-weight fraction.

While the diminished galactose content of the high-molecular-weight fraction is in conflict with the Muir and Lee (1970) findings with crude cuticle collagen extracts, finding fucose and xylose in an approximately 2 : 1 ratio is in accord with their study. However, we find significantly greater quantities of both and a surprisingly large amount of mannose along with previously unreported glucose. Purification of the collagen by Muir and Lee resulted in a substance almost free of aldohexoses other than galactose. Thus, it appears that we have isolated a fraction rich in one or more components that Muir and Lee (1970) ultimately removed during the purification process.

The low-molecular-weight earthworm attack-eliciting material provides a completely different carbohydrate profile. Instead of a substantial amount of galactose, we find it as a minor component. Moreover, the major component appears to be myoinositol, a substance unreported in earlier studies of earthworm surface substances. This is accompanied by an unidentified inositol and relatively low amounts of simple aldohexoses.

Comparison of the materials isolated from the earthworm and those from fathead minnows shows some surprising similarities. Galactose and fucose are the predominant hexoses in both of the high-molecular-weight fractions. The principal difference is the increased glucose content and the reduced xylose content of the fish extract. The two low-molecular-weight fractions are less similar. While both show diminished galactose and fucose content relative to the respective high-molecular-weight fractions, the glucose, myoinositol, and ribose concentrations differ significantly.

Since many other sugars are present in the CMw extraction of the earth-

worm than are found in the earthworm cuticle, it might be that the materials obtained from the CM extraction are different than those obtained solely from earthworm cuticle.

Nuclear Magnetic Resonance. Carbon and proton NMR spectra were obtained for the low-molecular-weight fractions from the CM extraction of both earthworms and fathead minnows. Although the materials examined were crude mixtures and serious spectral interpretation awaits purer samples and more careful attention to pH effects, the spectra reflect the general carbohydrate and peptide nature of the materials. Thus, even with the low-signal-to-noise ratio imposed by the sample size, the carbon spectra of both samples displayed multiple resonances in the 50–80 ppm range, as expected for the saccharide oxygenated carbons. Likewise, signals typical of peptide linkages were apparent in the 170–185 ppm range. Furthermore, the low concentration of aromatic amino acids is reflected in both proton and carbon spectra in which there are essentially no aromatic carbon or hydrogen signals.

Perhaps the most significant feature of the spectra was the absence of a strong guanidino carbon resonance in the fathead minnow carbon spectrum. Although it is a nonprotonated carbon that can be difficult to observe, if the high percentage of arginine indicated by the amino acid analysis is real, one would have expected a clearly assignable resonance of significant intensity. Such is not the case, and we must conclude that the value measured for arginine is largely (or totally) an artifact.

DISCUSSION

Biologically active materials from the earthworm (*Lumbricus terrestris*) and fathead minnow (*Pimephales promelas*) have been isolated with two extraction procedures. These materials generally exhibit similar chemical properties as demonstrated by gel filtration data, amino acid analysis, sugar analysis, and comparison of NMR spectra.

Both high- and low-molecular-weight fractions were obtained. There are similarities in the solubility properties of these prey extracts, that is, the amount of material obtained per liter of extract is similar for both, and the majority of the material from the AQmc extracts was extractable from the methanol–chloroform solutions. These similarities are noteworthy since the earthworm and fish were of similar size and had comparable surface area-to-weight ratios.

As observed with the aqueous extracts, the CM extraction resulted in similar observations between the fathead minnow and the earthworm. The active components from both were found primarily in the water layer of the CM extraction. Much weaker activity was found in the organic layer. The high- and low-molecular-weight materials from the water layer from both the earthworm

and fathead minnow elicited prey attacks. The low-molecular-weight materials from each extract consisted of six times more material by mass than the high-molecular-weight materials for both prey.

The compounds isolated from the earthworm using the CM extraction method exhibited similar chemical and physical properties to active earthworm material isolated in the Sheffield et al. (1968) study and in Halpern's laboratory (e.g., Reformato et al., 1983). Although the molecular weights estimated in the present work differ from previous estimates, the overall properties indicate that our high-molecular-weight earthworm component is similar but not identical to previously isolated materials.

An important difference between this work and previous studies on *Thamnophis* is the identification of low-molecular-weight materials with prey identification activity. The activity of a low-molecular-weight fraction was noted by Sheffield et al. (1968) but has not been reported in recent publications (e.g., Kirschenbaum et al., 1985, 1986). These workers may not have found this active low-molecular-weight fraction since the bioassay method they utilized differed from our own (see p. 856). Perhaps the bioassay procedure used may lead to different conclusions as to what materials are active, since different chemicals may be involved in different phases of feeding or the methods differ in sensitivity. Our low molecular weight material may, ultimately, derive from the high molecular weight compounds. It should be noted that by using methylene chloride extracts of snake skins, Weldon and Schell (1984) were able to elicit prey attacks from ophiophagous snakes. These chemicals may have also been of relatively low molecular weight.

Reformato et al. (1983) reported that activity of the earthworm material seemed to diminish with the decrease of the carbohydrate content of the material. Interestingly, both active fractions of CMw-EW-HMW_{P10} and of CMw-EW-LMW_{P10} had very high carbohydrate contents. This supports these authors' view that carbohydrates may be related to the activity of the material. In the same paper they reported that the active material resulted in a positive assay for proteins. The studies reported here showed that both active fractions obtained from the CM extraction of the earthworm indicate the presence of proteins or peptides by the amino acid analysis.

The complete purification and identification of the active material from the earthworm (*Lumbricus terrestris*) and fathead minnow (*Pimephales promelas*) had not yet been achieved. However, new methods have been discovered that extract the active material from the prey through direct chloroform–methanol extraction and the methanol extraction of the lyophilized water extract. We have also found, in preliminary studies, that the mosquito fish, *Gumbusia affinis*, contains components chemically similar to the fathead minnow. Likewise, *Thamnophis butleri* seems to react to the same active fractions of both fish and earthworm as does *Thamnophis sirtalis*. Thus, these procedures may lead to the

determination of whether different species of snakes that will eat the same prey species are utilizing similar or different chemical cues in identifying it.

Acknowledgments—This work was supported in part by NSF grant BNS-8217569 (awarded to GMB) and the UTK Science Alliance, and it is based in part on a MS thesis submitted by Scot Goss in partial fulfillment of the requirements for the MS degree in Chemistry at the University of Tennessee, Knoxville. We thank Mike Beckham for assisting in some of the experiments, Dr. Velupillai Puvanesarajah for his expert advice and technical assistance with the carbohydrate analysis, and the NSF for contributing toward purchase of the Nicolet NT 200 NMR. Parts of this paper were presented at the Snake Ecology Symposium at the American Society of Ichthyologists and Herpetologists meeting in Vancouver, British Columbia, June 1986. We thank Paul Weldon and an anonymous reviewer for their comment on an earlier version.

(Received March 17, 1987; accepted May 20, 1987)

Abstract—The responses of *Microplitis croceipes* (Cresson) and *Microplitis demolitor* Wilkinson to the *R* and *S* stereoisomers of the kairomone 13-methylhentriacontane were evaluated. Singly and in combination at 5, 50-, and 500-ng dosage levels each were tested. There was a linear dosage response by both species to the three dosages. Furthermore, there was no difference between responses to the two stereoisomers or their combination by either species at any dosage level. The effects of the two stereoisomers were fully interchangeable and additive. This is the first report of parasitoid responses to stereoisomers of a kairomone.

Key Words—*Microplitis croceipes*, *Microplitis demolitor*, Hymenoptera, Braconidae, parasitoids, semiochemicals, kairomones, 13-methylhentriacontane, stereoisomers, enantiomers, *Heliothis zea*, Lepidoptera, Noctuidae.

INTRODUCTION

The relationship of biological activity to stereostructure of insect pheromones has been a subject of considerable research. Insects generally respond to one stereoisomer of a pair (or a set, if more than one asymmetric center is present

[1] Present address: Chemical Modifications Research, ARS, USDA, East 600 Mermaid Lane, Wyndmoor, Pennsylvania 19118.
[2] Present address: Cotton Insects Research Unit, ARS, USDA, P.O. Drawer DG, College Station, Texas 77814.

in the pheromone's chemical structure) and to a lesser extent, if at all, to the other or others of the set (Silverstein, 1979; Brand et al., 1979). In some cases the optimal response is to a specific ratio of stereoisomers (Lanier et al., 1980). In other situations, however, the biological response is to one of the enantiomers, and the presence of the other enantiomer is inhibitory (Tumlinson et al., 1977; Birch et al., 1977).

Although a number of hydrocarbon pheromones and other semiochemicals have been identified from insects, only a few have been synthesized in high configurational purity. Consequently, the relationship of stereostructure to the biological activity of these compounds has not been studied. No known study of stereostructure of any class of kairomones or the resulting influence on biological activity of entomophagous insects has been reported.

We report here the biological testing of the stereoisomers of 13-methylhentriacontane, a kairomone from the frass of corn earworm larvae, *Heliothis zea* (Boddie), that influences the host location behavior of the larval parasitoid, *Microplitis croceipes* (Cresson) (Lewis and Jones, 1971; Jones et al., 1971). This hydrocarbon also elicited the host-seeking response in *M. demolitor* Wilkinson, a closely related braconid recently imported into the United States from Australia (Nordlund and Lewis, 1985). Comparative evaluations of the level of responses elicited by the *R* and *S* stereoisomers singly or in combination (1 : 1) for each parasitoid species was the objective of this study.

METHODS AND MATERIALS

The synthesis of (*R*)- and (*S*)-13-methylhentriacontane in >99.6% configurational purity has been reported (Sonnet, 1984). Samples for this study were >95% pure chemically, containing 5% hydrocarbons such as docosane that were not expected to influence behavioral response.

The host insects were reared according to Burton (1970), and the parasitoids of both species were reared according to Lewis and Burton (1970) at ca. 26°C and 70% relative humidity. The age of the parasitoids used ranged from four to eight days, with equal numbers of replications (27 for *M. croceipes* and 10 for *M. demolitor*) for each treatment category and each group of parasitoids.

The bioassay procedure of Jones et al. (1971) was used. Samples of the materials were placed on filter paper in the bottom of a 150 × 15-mm Petri dish. A female parasitoid was placed in the dish and her response observed as she walked across the sample. These parasitoids are negatively geotactic and positively phototactic, so the direction of movement could be guided by rotating the dish in a vertical plane with the sample side (bottom) toward the light. Individual parasitoids were each allowed three passes over the sample and scored according to antennal examination of the material. A score of 3, 2, 1, or 0 was

assigned based on whether the individual responded on the first, second, third, or none of the passes.

Three dosages, 500, 50, and 5 ng, of each treatment were evaluated by applying 5-μl samples of the materials to filter paper at concentrations of 0.1, 0.01, and 0.001 mg/ml of the respective dosages.

The responses of 81 *M. croceipes* individuals (from three separate rearing dates) were tested for each treatment category. The responses of 30 *M. demolitor* individuals were tested, again involving individuals from three different rearing dates.

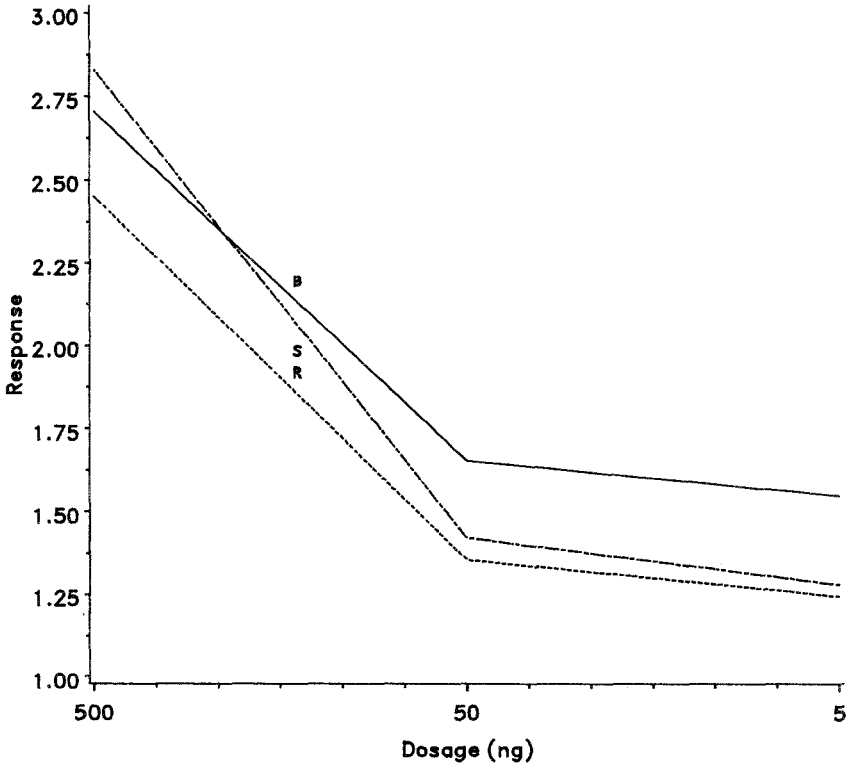

FIG. 1. Responses of *M. croceipes* to varying dosages (500, 50, and 5 ng) of stereoisomers of 13-methylhentriacontane, R, response to the *R* isomer; S, response to the *S* isomer; B, response to a mixture of equal amounts of the two isomers with the indicated dosage being the total amount of both. All treatments behaved linearly ($P < 0.0001$), and there were no treatment differences ($P < 0.05$) or treatment × dosage interactions ($P < 0.05$). Equations generated for responses were B: $Y = 1.5358 + 11.6902X$; R: $Y = 1.2325 + 12.1788X$; S: $Y = 1.2641 + 15.6638X$.

Linear regression techniques were used to test for treatment differences and interactions between treatments and dosage levels.

RESULTS AND DISCUSSION

The linear regression tests for *M. croceipes* and *M. demolitor* (Figures 1 and 2) showed: (1) no significant differences in the responses to the *R*, *S*, or combination of stereoisomers ($P < 0.05$); (2) dosage levels were all related linearly ($P < 0.0001$); and (3) there were no interactions between dosage levels and

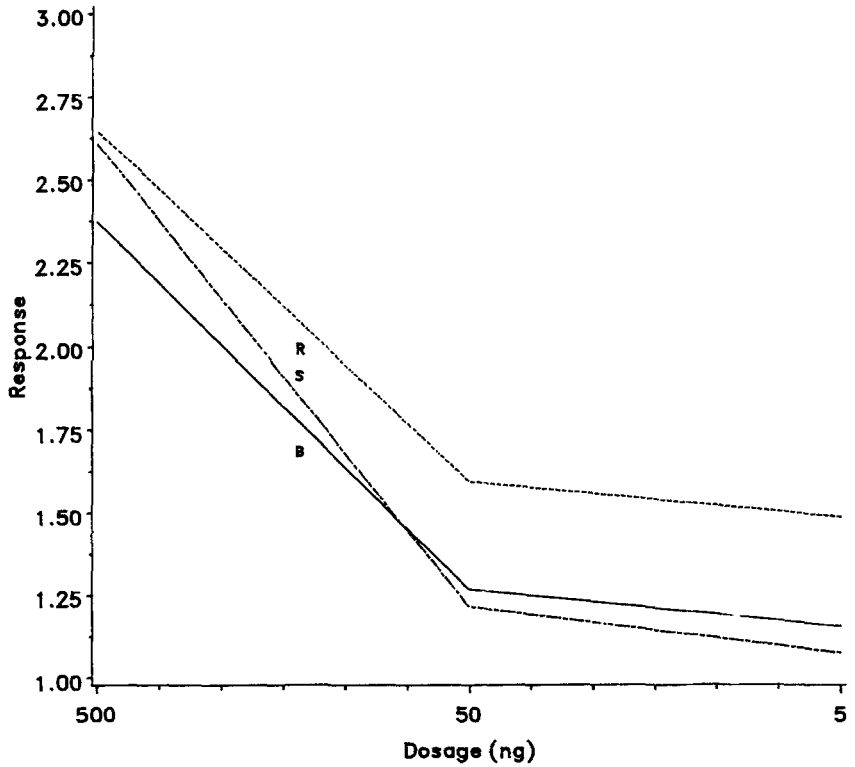

FIG. 2. Responses of *M. demolitor* to varying dosages (500, 50, and 5 ng) of stereoisomers of 13-methylhentriacontane, R, response to the *R* isomer; S, response to the *S* isomer; B, response to a mixture of equal amounts of the two isomers with the indicated dosage being the total amount of both. All treatments behaved linearly ($P < 0.0001$), and there were no treatment differences ($P < 0.05$) or treatment × dosage interactions ($P < 0.05$). Equations generated for responses were B: $Y = 1.1463 + 12.2623X$; R: $Y = 1.4796 + 11.6617X$; S: $Y = 1.0611 + 15.4655X$.

the *R*, *S*, and combination treatments. (The equations describing the responses are presented in the figure legends.)

Microplitis croceipes and *M. demolitor* both respond to 13-methylhentriacontane even though they occur in areas widely different geographically, and *M. demolitor* has a wider host range than *M. croceipes* (Nordlund and Lewis, 1985). Our results show that they have similar dose responses to each stereoisomer and the combination. The possibility of the comparisons being confounded due to impurities is unlikely, since the responses to each stereoisomer and the mixture were all similar.

This is the first report of evaluations of a parasitoid response to stereoisomers of a kairomone. The fact that there was no measurable difference in the response to the two stereoisomers by either species is interesting. Furthermore, the effect of the stereoisomers appears fully interchangeable and additive, as shown in the responses to their combinations as compared to each of the stereoisomers alone. It is important to note that the results of Jones et al. (1971) showed that the position of the methyl group up or down the carbon chain influenced the response strongly, in that dramatically lower responses were found for 11- and 15-methylhentriacontane as compared to 13-methylhentriacontane. Moreover, most studies of stereoisomers of materials mediating intraspecific responses demonstrate a bias for one stereoisomer over the other.

It is not known at this time whether the host and its frass possess both isomers. Such information would assist in determining the biological significance of the results.

Acknowledgments—The authors are grateful to Amy Heidt, Lisa Hill, and Sheila Norris for assistance in rearing the parasitoids and conducting the bioassays for this study; and to Richard Layton for help in analyzing the data.

(Received January 21, 1987; accepted May 21, 1987)

Abstract—In studies of the lysis of rabbit erythrocytes, red beet cells, and *Penicillium notatum* protoplasts by the potato glycoalkaloids α-solanine and α-chaconine, the latter was consistently the more membrane-disruptive compound and erythrocytes the more susceptible cell type. A 1:1 mixture of solanine and chaconine produced pronounced synergistic effects in all three test systems. In beet cells, such effects were apparent from an early stage of treatment and persisted over a period of several hours. With erythrocytes and fungal protoplasts, the synergism was maximal with mixtures containing approximately 70% chaconine, whereas with beet cells it peaked at approximately 40% chaconine. Synergistic interactions between solanine and chaconine also occurred with regard to cholesterol binding in vitro, with a maximum response corresponding to the 50% mixture. The implications of these findings for the nature and efficacy of chemical defense systems in plants are discussed.

Key Words—Potato, *Solanum tuberosum*, glycoalkaloids, α-solanine, α-chaconine, cell membrane disruption, in vitro sterol binding, synergistic interactions.

INTRODUCTION

It is now generally accepted that plants are able to withstand herbivores and microbial pathogens largely because they have evolved effective chemical

0098-0331/88/0300-0889$06.00/0

defense systems (Wallace and Mansell, 1976; Harborne, 1978; Rosenthal and Janzen, 1979; Cooper-Driver et al., 1985). However, relatively few detailed biochemical investigations of such defenses have been carried out compared with the vast range of secondary compounds elaborated by plants (Bell and Charlwood, 1980). Of the studies that have been reported, the majority have been concerned with single compounds or single classes of compounds. This approach has yielded interesting and valuable information but suffers from two major limitations: (1) it fails to acknowledge that the behavior and physiology of feeding herbivores or invading microorganisms are often based on contact with a wide diversity of plant chemicals rather than a single compound, and (2) within such a "multichemical" defense system, certain compounds may interact to produce effects qualitatively or quantitatively different from those predictable from the effects of individual compounds.

Much work on chemical defense in the potato plant (*Solanum tuberosum* L.) has centered on the two major steroidal glycoalkaloids, α-solanine and α-chaconine (Figure 1). These compounds, which share a common aglycone (solanidine) and differ only in their carbohydrate moiety, have powerful physiological and pharmacological activity (Roddick, 1986) that has resulted in numerous human and livestock poisonings and fatalities (Morris and Lee, 1984). In addition, there is evidence that these glycoalkaloids, due to their toxicity and/or bitterness, play some role as resistance factors against insects (Tingey, 1984) and, possibly to a lesser extent, as antifungal compounds (Roddick, 1987). In such organisms, deterrence by glycoalkaloids is attributable in large measure to the membrane destabilizing properties of these compounds (Mitchell and

Harrison, 1985; Roddick, 1987). A number of studies in which single glycoalkaloids were tested on a wide variety of organisms from viruses to mammals (e.g., Thorne et al., 1985; Sharma et al., 1979) consistently showed chaconine to be the more potent of the two compounds. We observed similar differential activity with regard to lysis of phosphatidylcholine–sterol liposomes (Roddick and Rijnenberg, 1986) and, more recently, have demonstrated that, in combination, solanine and chaconine produce a pronounced and highly reproducible synergistic effect (Roddick and Rijnenberg, 1987). The synergism was quite specific and did not occur if one of the glycoalkaloids was substituted by related compounds, e.g., tomatine, digitonin, or β_2-chaconine. However, because this study employed synthetic lipid membranes, the biological (and particularly ecological) implications of the synergism cannot be properly assessed. Work in this field has therefore been extended to include the responses of membranes of living cells, and in this communication we report the effects of solanine and chaconine, both singly and in combination, on the integrity of representative cells from animals, plants, and fungi.

METHODS AND MATERIALS

Source of Glycoalkaloids. Solanine and chaconine were extracted from *S. tuberosum* cv. Wauseon and purified by the method of Swain et al. (1978). Authentic samples were also purchased from Sigma Chemical Company, Poole, U.K.

Preparation and Treatment of Erythrocytes. Rabbit blood was collected into heparinized tubes and used either fresh or after storage at 4°C for up to two days. The cells were washed twice with 9× the blood volume of phosphate-buffered saline, pH 7.4, with centrifugation at 400*g* for 10 min after each wash. The final erythrocyte pellet was resuspended in its original volume of buffered saline, and a portion of this suspension removed and diluted to 2% with buffered saline. A 3-ml aliquot of the 2% suspension was incubated with 1 ml of glycoalkaloid solution in buffered saline at 37°C for 2 hr. Glycoalkaloid solutions were prepared by dissolving in the minimum volume of 0.1 M HCl and making up to volume with buffered saline. Erythrocytes were counted using a hemacytometer and the percentage of lysed cells calculated by comparing with counts in the control containing buffered saline only. In solanine–chaconine interaction experiments, the two glycoalkaloids were prepared as 50 μM solutions and mixed in the ratios indicated. The total alkaloid concentration in all test mixtures was 12.5 μM.

Preparation and Treatment of Beet Disks. Cylinders (1 cm diam.) of the swollen tap root of red beet (*Beta vulgaris* L.) were removed with a cork borer and cut into disks 2 mm thick. These were washed in running tap water for 16

hr and lightly blotted to remove excess water. Ten disks were placed in a 50-ml conical flask along with 10 ml of test solution. Glycoalkaloid solutions were prepared by dissolving in acid as above and making up to volume with phosphate–citrate buffer, pH 7.2. Flasks were closed with cotton wool plugs and placed on a reciprocating shaker at 100 rpm. Mixtures were incubated at 25°C, and at various times the test solutions were decanted and their absorbance at 535 nm measured to quantify betanin loss and, where appropriate, returned to the flask. In interaction experiments, 50 μM solutions of solanine and chaconine were used and mixed in the ratios indicated. The total alkaloid concentration in flasks was 50 μM.

Preparation and Treatment of Fungal Protoplasts. The fungal culture used was *Penicillium notatum* Westling, IMI 17968, maintained on a 2% agar-solidified medium containing 2% malt agar at 20°C. Protoplasts were prepared by a method based on that of Hamlyn et al. (1981). Liquid cultures were initiated by inoculating a medium consisting of 2% sucrose, 0.6% $NaNO_3$, 0.15% KH_2PO_4, 0.05% $MgSO_4 \cdot 7H_2O$, and 0.5% trace element solution (42 mg/liter $CuCl_2 \cdot 2H_2O$, 317 mg/liter $ZnSO_4 \cdot 7H_2O$, 15 mg/liter $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 32 mg/liter $MnSO_4 \cdot 4H_2O$, 398 mg/liter $FeSO_4 \cdot 7H_2O$, and 400 mg/liter EDTA) with a spore suspension in sterile distilled water to give a final spore load of 10^6/ml of medium. The culture was incubated at 25°C for 63 hr, after which the fermenter (21) contents were vacuum-filtered through fine nylon (mesh size approx. 100 μm) which retained mycelium but not spores or small mycelial fragments. The mycelial mat was washed with 20 ml 100 mM MES–NaOH buffer, pH 5.8, containing 0.8 M KCl, after which 5 g of mycelium was removed and resuspended in 50 ml of the same buffer. To 7.5 ml of this suspension in a beaker was added 2.5 ml of a 2.4% (w/v) solution of Novozym 234 (Novo Bio Labs, Bagsvaerd, Denmark) in 100 mM MES–NaOH buffer. The yield of protoplasts was adjusted by altering the amounts of mycelium and Novozym used, but the ratio of the two components was maintained as given above. The mixture was stirred gently at 25°C, and the extent of protoplast formation was monitored by hourly microscopic examinations. After 3 hr of incubation, the digest was gravity-filtered through single muslin and the protoplasts concentrated by centrifugation of the filtrate at 3000*g* for 5 min. The pellet was resuspended in 20 ml of 20 mM MES–NaOH buffer containing 0.8 M KCl and then filtered through double muslin. The filtrate was centrifuged at 1200*g* for 5 min and the supernatant discarded. The protoplast pellet was resuspended in 7.5 ml of 50 mM potassium hydrogen phthalate containing 1.2 M sorbitol with the pH adjusted to 7.2 with tetramethylammonium hydroxide. This suspension was subjected to a final filtration through single muslin before use. Protoplasts were treated with glycoalkaloids by adding 462.5 μl of suspension to 37.5 μl of alkaloid solution in 0.002 M HCl in a 5-ml specimen tube. Reaction mixtures were left at 25°C for 1 hr, after which an aliquot was removed and protoplast

number determined using a hemacytometer. The percentage of protoplasts lysed was calculated by comparing numbers in test samples and controls containing acid only. In interaction experiments, stock solutions of 0.67 mM alkaloid were used to prepare solanine–chaconine mixtures. The total alkaloid concentration in all treatments was 50 μM.

Glycoalkaloid–Sterol Complex Formation In Vitro. The extent of complex formation was determined by measuring the amount of unbound sterol remaining in solution. Glycoalkaloids and cholesterol were dissolved in 96% (v/v) ethanol at strengths of 1 mM and 20 mM, respectively. Solutions were mixed in the ratio of 2.0 ml : 0.1 ml in 15 ml polypropylene tubes, heated at 90°C for 5 min and cooled at room temperature for 1 hr and at 4°C overnight (16 hr). Tubes were centrifuged at 27,000*g* for 30 min at 4°C and the supernatant decanted. A 0.5-ml aliquot was transferred to a 5-ml vial and the solvent evaporated in a nitrogen stream at room temperature. The residue was dissolved in 0.25 ml of ethyl acetate containing 0.04% (w/v) 5α-cholestane. The cholesterol concentration of this solution was determined by GLC for which 5α-cholestane acted as internal standard. A 1-μl sample was injected into a 2-m × 6-mm glass column packed with 3% OV-101 on Gas Chrom Q. The nitrogen flow rate was 50 ml/min and the column and detector (flame ionization) temperatures 275 and 325°C, respectively. Cholesterol was quantified using a precalibrated peak integrator.

Experimental Procedure. All treatments were replicated as indicated in the text, and each experiment was carried out at least twice. Data were analysed using a *t* test and by calculation of least significant differences (LSD) at $P = 0.05$.

RESULTS

As a prerequisite to investigating the interaction between solanine and chaconine, the lytic action of the individual glycoalkaloids against mammalian erythrocytes, red beet cells, and *P. notatum* protoplasts was examined. Dose–response curves are shown in Figure 2.

The greater membrane-lytic effect of chaconine was confirmed in all three systems. Rabbit erythrocytes proved the most susceptible to chaconine, showing lysis at around 1 μM (Figure 2a), whereas beet and protoplasts were unaffected by concentrations less than 10 μM (Figures 2b and c). Similarly, a maximal effect on blood was achieved with 25 μM chaconine (Figure 2a), whereas beet and protoplasts required around 60 μM and 100 μM, respectively (Figures 2b and c). Erythrocytes and beet showed a similar reduced sensitivity to solanine, lysis being first observed at 15–20 μM (Figures 2a and b). However, whereas 100 μM solanine caused almost 100% hemolysis, it elicited only

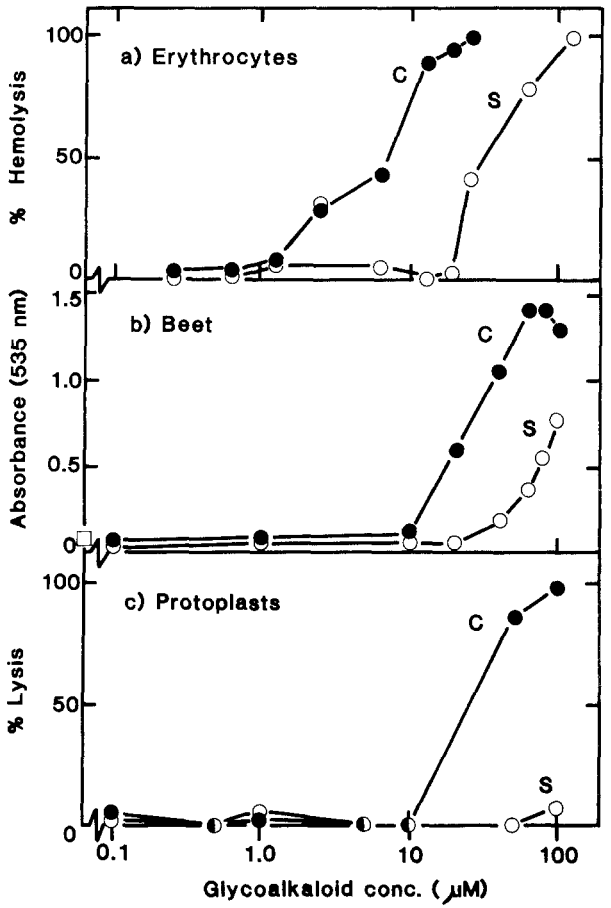

FIG. 2. Semilog plot showing effects of solanine and chaconine on disruption of (a) erythrocytes, (b) beet root cells, and (c) *P. notatum* protoplasts. Cells were treated in buffered solutions, pH 7.2–7.4, for 2, 4, and 1 hr, respectively. Lysis was assessed in erythrocytes and protoplasts by hemacytometer counts relative to controls and in beet cells by measuring the absorbance of the bathing solution at 535 nm. Each point is the mean of three replicates (five counts per replicate) for erythrocytes and five replicates for beet and protoplasts. S = solanine; C = chaconine.

40% loss of betanin from beet cells (Figures 2a and b). In contrast, fungal protoplasts were virtually unaffected by solanine concentrations up to 100 μM (Figure 2c).

From these data, we decided to explore the combined effects of solanine and chaconine in a 1 : 1 ratio using each compound at 6.25 μM against eryth-

rocytes and 25 μM against beet and protoplasts. At these levels, solanine did not lyse any of the cells and chaconine effects (where present) were less than maximal, thus facilitating the detection of any additive or synergistic responses. In all three test materials, the solanine–chaconine combination gave rise to pronounced synergisms (Table 1). In fact, with beet, the glycoalkaloid mixture was more disruptive than full-strength chaconine. With erythrocytes and *Penicillium* protoplasts, however, the mixture, while synergistic, was less so and approximately the same as full-strength chaconine. A time-course study on beet indicated that the synergism occurred from the outset of the experiment and persisted over a period of several hours (Figure 3). The actual magnitude of the synergism increased for the first 3 hr, after which it remained relatively constant.

The fact that potato tissues do not always accumulate solanine and chaconine in a 1:1 ratio (chaconine is usually more abundant than solanine) prompted us to examine the effects of other glycoalkaloid combinations ranging from 100% solanine to 100% chaconine in steps of 10% (Figure 4). The most hemolytic glycoalkaloid mixture comprised approximately 70% chaconine and 30% solanine, with some indication of a slight supraoptimal effect at higher chaconine levels (Figure 4a). The curve joining the values corresponding to zero, half-strength (6.25 μM), and full-strength (12.5 μM) chaconine only, confirms that the data in Figure 4a represent a series of real synergistic effects and not a dose–response curve for chaconine. Consistent with the results in Table 1, the 50% alkaloid mixture was less hemolytic than 100% chaconine (Figure 4a). In beet tissue, stronger synergisms were observed than in erythrocytes,

TABLE 1. EFFECT OF SOLANINE AND CHACONINE AND THEIR INTERACTION ON DISRUPTION OF ERYTHROCYTES, BEET ROOT CELLS, AND *P. notatum* PROTOPLASTS

Treatment[a]	Hemolysis (%)	A_{535}	Protoplast lysis (%)
Control	—	0.03 ± 0.007	—
Solanine (FS)	11.4 ± 5.59	0.11 ± 0.009	17.9 ± 7.31
Chaconine (FS)	89.0 ± 0.32	0.38 ± 0.080	70.9 ± 4.75
Solanine (HS)	3.2 ± 1.64	0.03 ± 0.005	2.3 ± 1.41
Chaconine (HS)	51.6 ± 3.56	0.15 ± 0.019	4.5 ± 1.03
Solanine (HS) + chaconine (HS)	70.6 ± 2.60*	0.88 ± 0.061***	73.8 ± 1.53***

[a]FS = full strength = 12.5 μM for erythrocytes, 50 μM for beet and protoplasts; HS = half strength. Cells were treated in buffered solutions, pH 7.2–7.4, for 2, 4, and 1 hr, respectively. Lysis was assessed in erythrocytes and protoplasts by hemacytometer counts relative to controls and in beet cells by measuring the absorbance of the bathing solution at 535 nm. Each value represents the mean of five replicate determinations ± standard error. *, *** = Significantly different from Σ solanine (HS) + chaconine (HS) (all combinations) at 5%, 0.1% level.

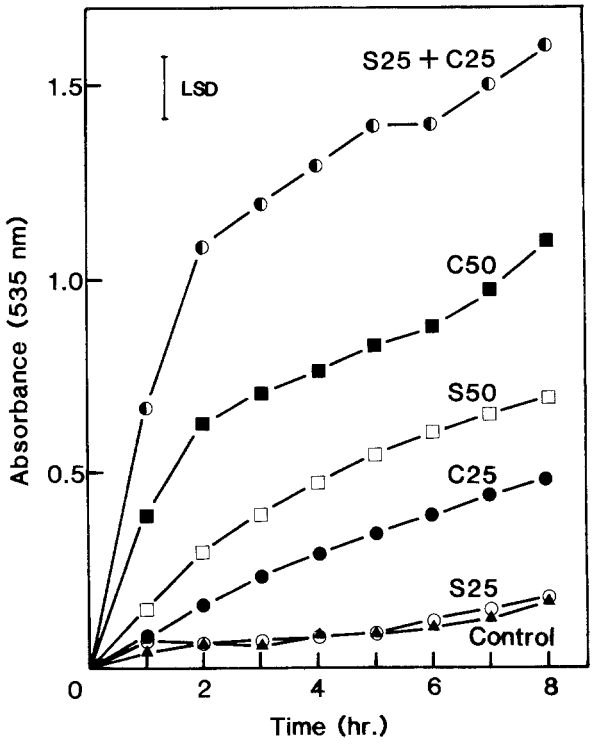

FIG. 3. Effects of solanine and chaconine and their interaction on leakage of betanin from root cells of red beet over a period of time. At various intervals, incubation solutions were decanted, their absorbance at 535 nm measured and returned to flasks. Each point is the mean of five replicates. S = solanine; C = chaconine. Values following abbreviations represent concentration in μM.

with a marked peak response corresponding to approximately 40% chaconine (Figure 4b). The earlier observation that a 50% glycoalkaloid mixture was significantly more disruptive than 100% chaconine (Table 1) was again borne out in this experiment (Figure 4b). The synergistic effects of the solanine–chaconine mixtures on *Penicillium* protoplasts (Figure 4c) bore more resemblance to those on erythrocytes than on beet, with a maximal response again at around 70% chaconine. However, in this case, the 50% mixture and 100% chaconine were of similar efficacy, an observation in keeping with the data in Table 1.

Since membrane destabilization by glycoalkaloids is thought to result from their complexing with membrane sterols (Arneson and Durbin, 1968; Roddick and Drysdale, 1984), experiments were conducted to determine whether solan-

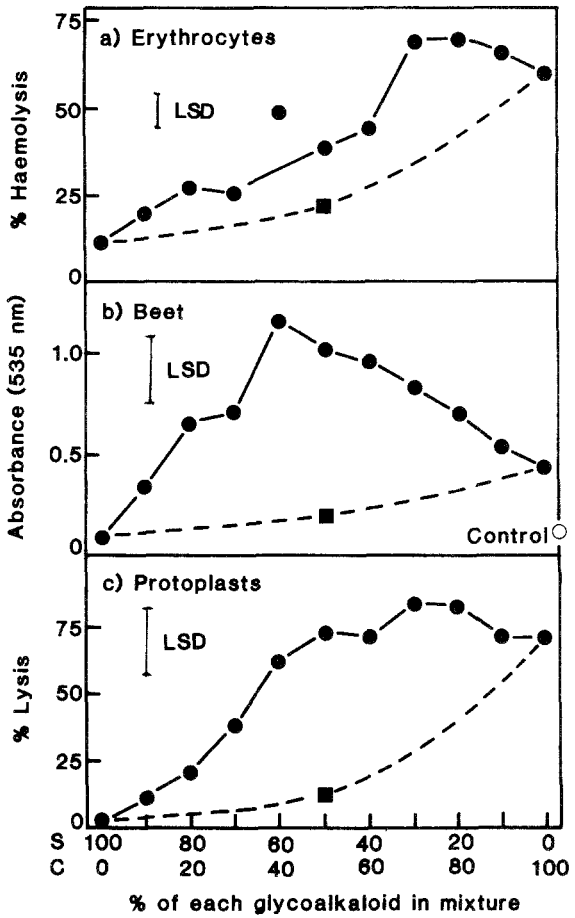

FIG. 4. Effect of relative amounts of solanine and chaconine on disruption of (a) erythrocytes, (b) beet root cells, and (c) *P. notatum* protoplasts. The total glycoalkaloid concentration was 12.5 μM for erythrocytes and 50 μM for beet and protoplasts distributed between solanine and chaconine as shown. Treatments, assessment of cell disruption, and replication were as in Figure 2. ■ = 6.25 μM chaconine only in (a), 25 μM chaconine only in (b) and (c); S = solanine; C = chaconine.

ine and chaconine also interacted synergistically in relation to cholesterol binding in vitro. Using similar glycoalkaloid mixtures, synergistic responses were observed which peaked with the 50% solanine–chaconine mixture (Figure 5). As previously (Figure 4), synergisms are particularly apparent when data are compared with those for single alkaloids (Figure 5, broken lines). In contrast

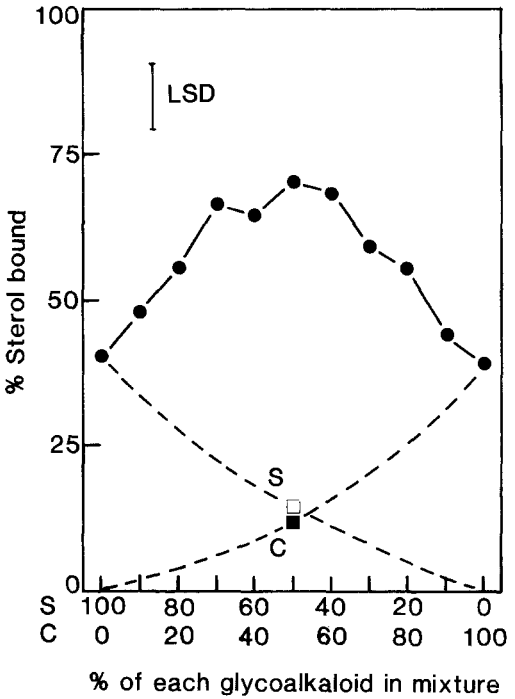

FIG. 5. Effect of relative amounts of solanine and chaconine on glycoalkaloid binding to cholesterol in vitro. The total glycoalkaloid concentration was 1 mM distributed between solanine and chaconine as shown. Reactants were prepared in 96% ethanol and incubated for 1 hr. Cholesterol binding was determined by measuring unbound sterol by GLC relative to the control. Each point is the mean of five replicates. ■ = 500 μM chaconine only; □ = 500 μM solanine only; S = solanine; C = chaconine.

to their differential lytic effects, both solanine and chaconine showed a similar affinity for cholesterol in vitro, an observation which is consistent with earlier reports (Roddick and Rijnenberg, 1986).

DISCUSSION

The greater lytic effect of chaconine than solanine on erythrocytes, beet cells, and *Penicillium* protoplasts is in keeping with numerous reports of similar differential activity against *Herpes simplex* (Thorne et al., 1985), *Alternaria solani* (Sinden et al., 1973), *Fusarium caeruleum* (McKee, 1959), erythrocytes (Tschesche and Wulff, 1964), nematodes (Allen and Feldmesser, 1971), Colorado potato beetle (Mitchell and Harrison, 1985), mice (Sharma et al., 1979) and liposomes (Roddick and Rijnenberg, 1986) and also in taste tests (Zitnak

and Filadelfi, 1985). Total lack of activity of solanine, as found here against *Penicillium* protoplasts, has also been observed with *Herpes* virus (Thorne et al., 1985) and liposomes (Roddick and Rijnenberg, 1986). The carbohydrate moiety is thus an important determining factor in the biological activity of these compounds, although no biochemical explanation of this phenomenon yet exists. The possibility that this effect might be explained by solanine and chaconine differing in their response to degradative enzymes and/or in their ability to reach binding sites in membranes cannot be ruled out.

The synergism between solanine and chaconine previously observed in relation to destabilization of synthetic phosphatidylcholine–sterol liposomes (Roddick and Rijnenberg, 1987) is now also shown to hold for membranes of living cells from taxonomically diverse groups. Further, the synergisms caused by different solanine–chaconine mixtures are not a simple reflection of the differential lytic ability of the two compounds but show an optimum response at particular ratios. The reasons for this remain obscure, but it is probably significant that the mixtures of solanine and chaconine usually found in potato tissues (60–70% chaconine in tubers; Fitzpatrick et al., 1977; Bushway et al., 1980; 70–80% chaconine in shoots; Ahmed and Müller, 1979; Gregory et al., 1981) are those apparently most effective against animal and fungal membranes. However, whether solanine and chaconine interact synergistically against animals and fungi is not yet known.

Data for in vitro cholesterol binding by different solanine–chaconine mixtures correlate well with those for lysis of beet cells (correlation coefficient $r = 0.77$, $P < 0.01$). On the other hand, with erythrocytes and *Penicillium* protoplasts, cell disruption remained high at higher levels of chaconine, while sterol binding fell away, and no significant correlations were observed between sterol binding and cell disruption ($r = 0.008$ and 0.35, respectively). Although cholesterol is a minor sterol in plants and fungi, the major sterols of these organisms, i.e., sitosterol and ergosterol, complex with potato glycoalkaloids in vitro to a similar extent (Roddick and Rijnenberg, 1986). Consequently, it remains open to question whether the solanine–chaconine synergism is due to sterol binding, whether it is achieved through some other mechanism (e.g., penetration into the membrane), or whether different mechanisms operate in different types of membranes. We have previously expressed reservations concerning the relevance of in vitro sterol binding data to in vivo cell toxicity (Roddick and Drysdale, 1984; Roddick and Rijnenberg, 1986), and similar caution probably needs to be exercised in this case.

Although under natural conditions potato glycoalkaloids encounter erythrocytes only rarely (Nishie et al., 1971) and *Penicillium* protoplasts and beet cells not at all, the responsiveness of these cells suggests that the synergism between solanine and chaconine in relation to membrane disruption is a general biological phenomenon rather than a rare event restricted to particular types of

cells. In addition to their lytic properties, solanine and chaconine may protect plants through other effects, e.g., taste (Zitnak and Filadelfi, 1985) and anticholinesterase activity (Orgell, 1963; Alozie et al., 1978), but whether these parameters are affected synergistically by the two compounds remains to be established.

To date, most studies on the biological activity of potato glycoalkaloids have employed single, pure compounds, but our demonstration of a synergistic interaction between solanine and chaconine questions the validity of extrapolating from single compound effects to in situ interactions between potato tissues and other living systems. In addition, the possibility that solanine and chaconine might further interact with other potato compounds cannot be ruled out. Our findings also raise the question of the extent to which synergisms might occur between other glycoalkaloids, e.g., between solasonine and solamargine, which share a common aglycone (solasodine) and possess the same carbohydrate moieties as solanine (solatriose) and chaconine (chacotriose), respectively, as well as between other quite different secondary plant compounds.

The idea that plant allelochemicals may function in an interactive capacity is a relatively recent one. Commercial insecticide synergists have been known for some time (Metcalf, 1967) but few biochemical/ecological studies of naturally occurring compounds have been conducted in this area. Berenbaum (1985) demonstrated a synergistic interaction between myristicin and xanthotoxin with regard to their deleterious effect on larvae of *Heliothis zea*, while Miyakado et al. (1983) found that two amides of *Piper nigrum*, pellitorine and piperine, although individually nontoxic to *Callosobruchus chinensis*, were highly so in a 1 : 1 combination. Piperine and myristicin (also nontoxic) apparently enhance toxicity by interfering with the activity of detoxifying multifunction oxidase enzymes and are therefore referred to as "quasi" synergists (Berenbaum, 1985). Saponins may also function in a quasisynergistic capacity by affecting the penetration, transport, etc., of biologically active molecules (Freeland et al., 1985). In contrast, the synergism between solanine and chaconine is more an "analog" type (Berenbaum, 1985) where two chemically related compounds of differing biological activity interact such that the efficacy of one or both is increased. However, it is not known if chaconine increases the activity of solanine, or vice versa, or both. Structural analogs are widespread within many groups of secondary plant compounds and may have been selected for partly because chemical defense systems incorporating synergistically interacting components could be energetically less expensive, and partly because resistance to such a "multichemical" defense system would probably not arise so readily (Dolinger et al., 1973). Certainly, such arguments help rationalize the apparent dilemma of considerable material and energy resources being channeled into the synthesis of solanine even though this compound is biologically less effective than chaconine.

There is currently a growing realization that the outcome of plant–herbivore and plant–pathogen conflicts may be determined by the total biochemical profile of plant tissues rather than by single allelochemicals. The additional, and related, possibility that the biological/ecological impact of a particular biochemical environment may derive to a significant extent from interactions between component chemicals finds further support in the data presented here.

SEX PHEROMONE BIOSYNTHESIS OF (*E,E*)-8,10-DODECADIENOL IN CODLING MOTH *Cydia pomonella* INVOLVES *E*9 DESATURATION

(Received March 30, 1987; accepted May 22, 1987)

Abstract—Sex pheromone biosynthesis in the codling moth *Cydia pomonella* (Lepidoptera; Tortricidae) was studied by topical application of deuterated fatty acids in DMSO to pheromone glands. The incorporation of deuterium label into fatty acids and alcohols in the pheromone gland was monitored by gas chromatography with flame ionization detection and mass spectrometry in the selected ion monitoring mode. Dodecanol, (*E*)-9-dodecenol, (*E,E*)-8,10-dodecadienol, tetradecanol, and hexadecanol were found in gland extracts. The application of [12,12,12-$^2H_3$]dodecanoic acid resulted in labeled dodecanol, (*E*)-9-dodecenol, and (*E,E*)-8,10-dodecadienol, as well as the corresponding labeled acids. No label was incorporated into tetradecanol or hexadecanol or any acid with more than 12 carbon atoms. The application of labeled tetradecanoic or hexadecanoic acid introduced label not only into the 12-carbon alcohols, but also into tetradecanol, or tetradecanol and hexadecanol, respectively. The application of (*E*)-[11,11,12,12,12,-$^2H_5$]9-dodecenoic acid, whose facile synthesis is described, resulted in labeled (*E*)-9-dodecenol and (*E,E*)-8,10-dodecadienol. The (*E,E*)-8,10-dodecadienol so produced was characterized by an ion at *m/z* 186, equivalent to $[M]^+$ of a dienol labeled with four deuterons. Thus, one deuterium label is lost when the labeled (*E*)-9-monoene is converted to the (*E,E*)-8,10-diene. We conclude that (*E,E*)-8,10-dodecadienol is synthesized by chain shortening (β-oxidation) of palmitic acid to dodecanoic acid, followed by an unusual *E*9 desaturation and subsequent conversion of this intermediate into the conjugated precursor, which is finally reduced to the pheromone alcohol. The evolutionary significance of *E*9 desaturation being responsible for pheromone production in an Olethreutinae species is discussed.

INTRODUCTION

Available information concerning pheromones in many lepidopteran families indicates that most of the pheromone components can be biosynthetically derived from hexadecanoic (palmitic) acid, by chain shortening through β-oxidation and desaturation, involving a Δ 11-desaturase (Roelofs and Bjostad, 1981, 1984). Z11 desaturation of hexadecanoic acid followed by chain shortening and subsequent reduction and acetylation can produce the whole homologous series (Z)-11-hexadecenyl, (Z)-9-tetradecenyl, (Z)-7-dodecenyl, and (Z)-5-decenyl acetate, as was shown in the turnip moth (Löfstedt et al., 1986a). If chain shortening precedes desaturation, Δ11-unsaturated 14-carbon compounds and their homologous chain shortened Δ 9-unsaturated 12-carbon compounds can be produced. Such compounds are the predominant pheromone components within the Tortricidae (Roelofs and Brown, 1982).

Interestingly, many tortricids within the Olethreutinae subfamily have Δ 8- and Δ 10-unsaturated, or Δ 8,10 doubly unsaturated pheromone components. Analysis of pheromone precursors in two primitive New Zealand tortricids supported the idea of Δ 10 desaturation being responsible for the production of Δ 8- and Δ 10-unsaturated compounds (Löfstedt and Roelofs, 1985). Roelofs and Brown (1982) suggested that the Δ 8,10 doubly unsaturated pheromone components could be produced by Δ 10 desaturation, followed by chain shortening and a new Δ 10 desaturation. Alternatively, they suggested that the production of these pheromone components could be accounted for by a Δ 11-desaturase producing 11-tetradecenoate moieties. The Δ 11-tetradecenoate could then be biosynthetically converted into a Δ 10,12 conjugated system and subsequently chain shortened to the Δ 8,10-12 carbon compounds. Such a pathway was confirmed in the silkworm moth *Bombyx mori*, which stores large amounts of (Z)-11-hexadecenoate (Z11–16:acyl) (Bjostad and Roelofs, 1984) that are converted to (*E*, Z)-10,12-hexadecenoate (*E*,Z10,12–16:acyl), the immediate fatty acid precursor of bombykol (*E*,Z)-10,12-hexadecadienol (Yamaoka et al., 1984).

The major pheromone component of the codling moth was identified as (*E*,*E*)-8,10-dodecadienol (*E*,*E*8,10–12:OH) (Roelofs et al., 1971). In addition to other geometric isomers and the corresponding aldehyde and acetate, the codling moth pheromone gland was also found to contain dodecanol (12:OH), tetradecanol (14:OH), hexadecanol (16:OH), and (*E*)-9-dodecanol (*E*9–12:OH) (Arn et al., 1985; Einhorn et al., 1984). The occurrence of *E*9–12:OH

led Arn et al. (1985) to suggest that (*E*)-9-dodecenoate (*E*9–12 : acyl) could be a monounsaturated intermediate in biosynthesis of the pheromone. In fact *E*9–12 : acyl was the only unusual monounsaturated fatty acyl moiety found by us in a preliminary precursor analysis, indicating its potential role in pheromone biosynthesis.

In an earlier study on pheromone biosynthesis in the turnip moth, we showed that deuterium-labeled fatty acids, as well as their corresponding acetates, could be separated from unlabeled analogs by gas chromatography on polyethylene glycol-type stationary phases (Löfstedt et al., 1986a. In the present paper pheromone biosynthesis in the codling moth is investigated by the same technique. Deuterium labeled fatty acids are applied topically to the pheromone gland and their incorporation into pheromone alcohols is studied.

METHODS AND MATERIALS

Insect Sources and Topical Application of Labeled Fatty Acids to Glands. Codling moths for the experiments with saturated fatty acids were obtained as pupae from Drs. H. Arn and E. Mani, Wädenswil, Switzerland. Moths for the experiment with labeled (*E*)-9-dodecanoic acid (*E*9–12 : acid) were obtained from a culture in our laboratory, initiated from eggs obtained from Dr. R. Bues, Avignon, France. The pupae and emerged insects were kept at a 16 : 8 hr light–dark cycle. Emerged insects were fed a 5% sucrose solution.

Labeled fatty acids in DMSO (4 μg in 0.2 μl) were applied topically to the pheromone glands of 2- to 4-day-old *Cydia pomonella* females as described earlier by Bjostad and Roelofs (1983) for other lepidoptera. After the application at the beginning of the dark period, the glands were held everted for 1 hr until they were dissected from the ovipositors and extracted for analysis.

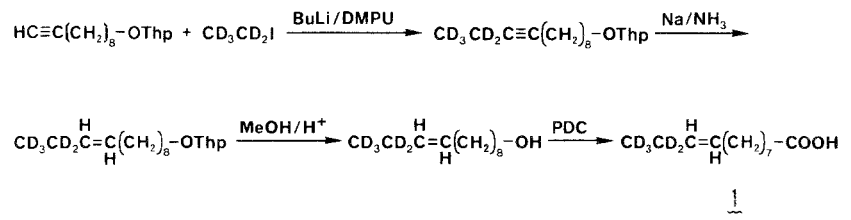
Pheromone Gland Extraction and Methylation. The pheromone glands were dissected from the ovipositors with a pair of fine forceps and then extracted with 10 μl of redistilled hexane for analysis of pheromone alcohols in the gland. After 10–30 min, the hexane extract was recovered and 10 μl of a 2 : 1 (v/v) mixture of chloroform and methanol was added for total lipid extraction (Folch et al., 1957). Under these conditions more than 90% of the acyl moieties were contained in the chloroform–methanol extract. Fatty acyl moieties in this extract were converted to methyl esters by base-catalyzed methanolysis as described in detail by Löfstedt et al. (1986b). The samples usually were analyzed immediately on the gas chromatograph or occasionally stored in the freezer at $-20°C$ until analysis.

Gas Chromatographic Analysis with Flame Ionization Detection and Selected Ion Monitoring. Capillary gas chromatography with flame ionization

detection (GC-FID) was performed on a Hewlett Packard model 5880 GC equipped with a 30-m × 0.25-mm-id DB-wax column (cross-linked polyethylene glycol) (J&W Scientific Inc., Rancho Cordova, California). Conditions of chromatography were: hydrogen carrier gas velocity 40 cm/sec at 80°C; split valve opened 1 min after injection; temperature maintained at 80°C for 2 min following injection and then programmed at 5°C/min to 230°C. Under these conditions omega-labeled ($^2H_3$) fatty acid methyl esters and acetates are resolved from the corresponding nonlabeled compounds, so that the labeled compounds elute slightly earlier (Löfstedt et al., 1986a). Synthetic samples of the deuterium-labeled alcohols [12,12,12-$^2H_3$]dodecanol, [14,14,14-$^2H_3$]tetradecanol, [16,16,16-$^2H_3$]hexadecanol, and (*E*)-[11,11,12,12,12-$^2H_5$]9-dodecenol were analyzed together with a series of homologous unlabeled straight-chain alcohols, and their equivalent chain lengths (ECLs) were calculated. ECL values of the saturated alcohols were 1197, 1396, and 1597, respectively. ECL of the labeled (*E*)-9-dodecenol was 1236 compared to 1242 for unlabeled. Mass spectrometry with electron impact ionization was performed on a Hewlett Packard model 5970B GC-MS system equipped with a 59970B computer system, and interfaced with a Hewlett Packard 5890 GC (courtesy of Dr. J. Eyem, Hewlett Packard, Sweden). The molecular ion of *E,E8, 10–12:OH* amounts to about 10% of the base peak in EI spectra of this compound and is suitable for sensitive and selective analysis by selected ion monitoring (SIM) in the EI mode (Löfstedt and Odham, 1984). An acquisition program was designed to monitor the incorporation of (*E*)- [11,11,12,12,12-$^2H_5$]9-dodecanoic acid into *E,E*8,10–12:OH. The ions *m/z* 181.20, 182.20, 185.20, 186.20, and 187.20 were monitored, being equal to $[M\text{-}1]^+$, and $[M]^+$ for the native *E,E*8,10–12:OH, and to $[M]^{+\cdot}$ for the corresponding alcohols with three, four, and five deuterium labels, respectively.

Chemicals. Deuterium-labeled saturated fatty acids were purchased from Larodan Fine Chemicals, Malmö, Sweden. The deuterium enrichment of these omega-labeled acids was 99%. The acids are abbreviated: [12,12,12-$^2H_3$]dodecanoic acid, [12-D_3]12:acid, etc.

(*E*)-[11,11,12,12,12-$^2H_5$]9-dodecenoic acid (1) [11,12-D_5]*E*9–12:acid) was prepared from 1-(2-tetrahydropyranyloxy)-decyne (1.4 g, 6 mmol), *n*-butyllithium (4.4 ml, 1.44 M in hexane) in dry THF and [$^2H_5$]ethyl iodide in 10 ml freshly distilled DMPU (1,3-dimethyloxohexahydropyrimidine) (Bengtsson and Liljefors, 1988). Reduction with sodium in liquid ammonia (Warthen and Jacobson, 1973) gave the pure *E* monoene, which was treated with *p*-toluene sulfonic acid in methanol to give the corresponding alcohol. Oxidation with pyridinium dichromate (PDC) in dry dimethylformamide (DMF) (Corey and Smidt, 1979) gave the final product (0.52 g, 40% overall yield) (Scheme 1).



SCHEME 1.

The product was purified by TLC mesh column chromatography (Taber, 1982) and argentation liquid chromatography (Houx et al., 1974). An EI mass spectrum of the acid was recorded on a Finnigan 4021 mass spectrometer and [^{1}H]NMR on a Varian XL-300 spectrometer in $CDCl_3$ solutions with Me_4Si as internal reference: *m/z* 203 (M^+, 2%), 185(2), 143(2), 123(3), 110(4), 97(15), 87(12), 83(24), 74(42), 69(45), 60(42), 55(78), 43(100), 33(6). [^{1}H]NMR ($CDCl_3$) (300 MHz); δ 1.30 (m, 8 H, CH_2CH_2), 1.56–1.67 (m, 2H, CH_2—C—COOH), 1.93–1.99 (m, 2H, CH_2—C=C), 2.34 (t, 2H, CH_2—COOH), 5.32–5.46 (m, 2H, CH=CH)

The deuterium enrichment of the acid was >95% according to FAB high-resolution mass spectroscopy on a ZAB-HF, VG Analytical, 11-250, mass spectrometer: $[M\text{-}H]^-_{calc}$ = 202.185, $[M\text{-}H]^-_{obs}$ = 202.178. [12,12,12-$^2H_3$]-Dodecanol, [14,14,14-$^2H_3$]tetradecanol, [16,16,16-$^2H_3$]hexadecanol, and (*E*)-[11,11,12,12,12-$^2H_5$]9-dodecenol were prepared from the corresponding acids by reduction with lithium aluminum hydride in dry diethyl ether.

RESULTS

In a first set of experiments, sex pheromone glands were incubated with [12-D_3]12:acid. The glands incorporated the labeled acid into the alcohols 12:OH, *E*9–12:OH, and *E*,*E*8,10–12:OH (Table 1, Figure 1A), as well as into the corresponding fatty acyl moieties 12:acyl, *E*9–12:acyl, and *E*,*E*8,10–12:acyl (Table 1, Figure 2A). The peaks, indicating 12-D_3-labeled pheromone component and pheromone precursor analogs, were all absent in chromatograms of unlabeled glands (Figures 1B, 2B). The relatively low amount of labeled methyl dodecanoate (12:Me) recovered indicates that only a fraction of the 4 μg of topically applied [12-D_3]12:acid is incorporated into the pheromone gland fatty acid metabolism. No labeled 14- and 16-carbon alcohols or acyl moieties were produced.

In a second set of experiments, pheromone glands were incubated with [14-D_3]14:acid and [16-D_3]16:acid (Table 1). The relative amounts of labeled

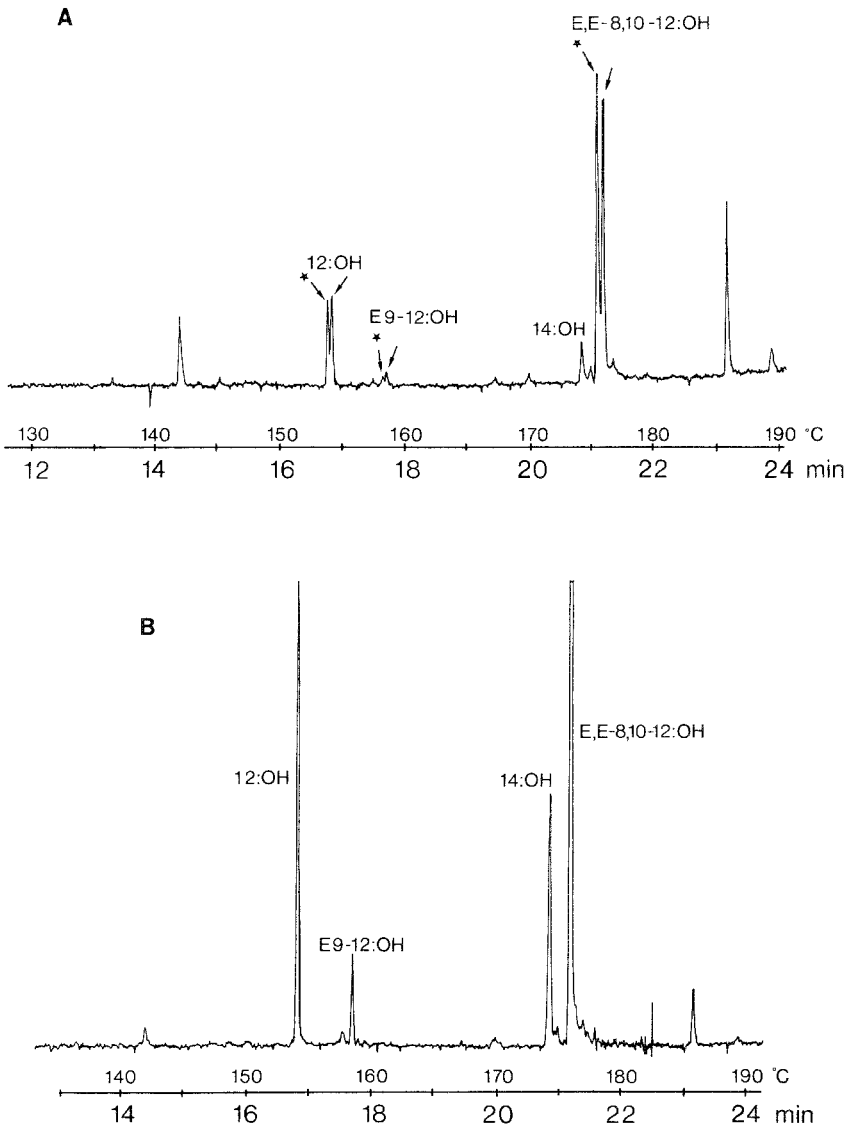

FIG. 1. Incorporation of deuterium label from topically applied [12,12,12-$^2H_3$]dodecanoic acid into pheromone components in glands of 8 female *Cydia pomonella*, monitored by capillary gas chromatography with flame ionization detection (A) and a control of two unlabeled glands (B). Peaks with (*) have the predicted retention times of omega-labeled ($^2H_3$) analogs of the pheromone components. See text for abbreviations.

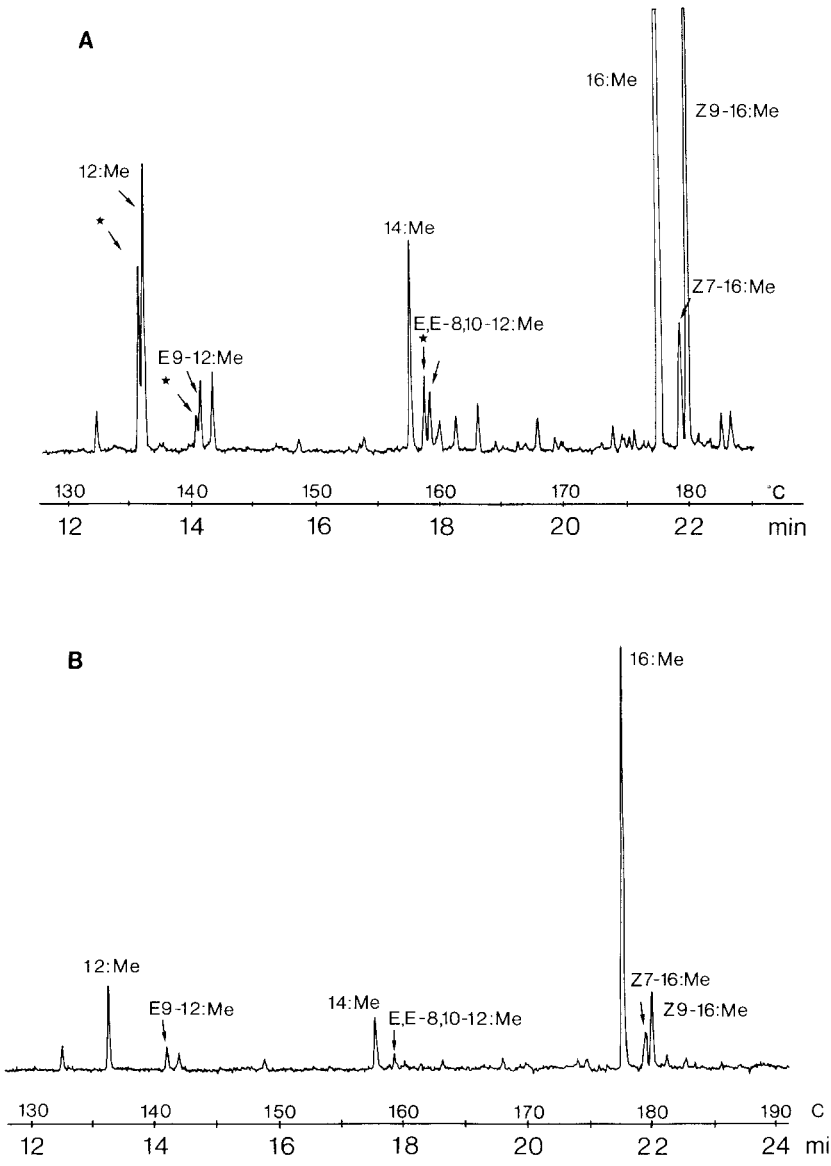

FIG. 2. Incorporation of deuterium label from topically applied [12,12,12-$^2H_3$]-dodecanoic acid into fatty acids in glands of eight female *Cydia pomonella*, monitored by capillary gas chromatography with flame ionization detection (A) and a control of two unlabeled glands (B). The first peak (*) in a pair has the predicted retention time of the omega-labeled ($^2H_3$) analog of the respective fatty acids. See text for abbreviations.

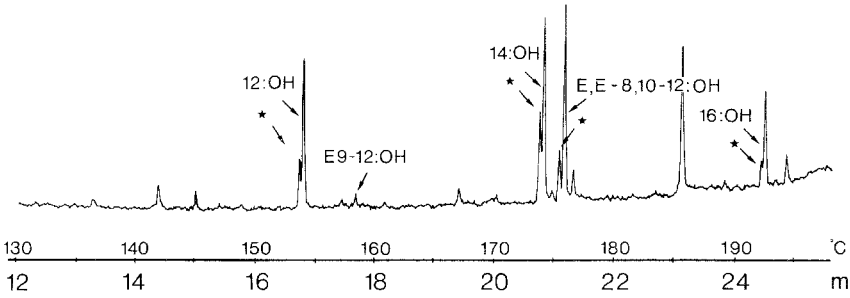

FIG. 3. Incorporation of deuterium label from topically applied [16,16,16-$^2H_3$]-hexadecanoic acid into alcohols in glands of four female *Cydia pomonella*, monitored by gas chromatography with flame ionization detection. The first peak (*) in a pair has the predicted retention time of the omega-labeled ($^2H_3$) analog of the respective alcohol. See text for abbreviations.

alcohols and acids produced with the [14-D_3]14:acid precursor were low, but still 4–8% of labeled *E,E*8,10–12:OH was obtained. This time, the label was found also in 14:OH and 14:Me. When glands were incubated with [16-D_3]16:COOH, the label was found in all the pheromone gland alcohols, including 16:OH (Figure 3).

Finally, pheromone glands were incubated with [11,12-D_5]*E*9–12:acid. These incubations produced large relative amounts of *E*9–12:OH and *E,E*8,10–12:OH, as well as their corresponding fatty acyl groups (Table 1). No label was incorporated into any of the saturated alcohols or acids studied. The incorporation of [11,12-D_5]*E*9–12:acid into *E,E*8,12:OH was further studied by mass spectrometric analysis of the products of an incubation. We found that incubation of glands with acid labeled with five deuterium atoms produced *E,E*8,10–12:OH labeled with four rather than five deuterons (Figure 4). The signal *m/z* 187 indicating [D_5]*E,E*8,10–12:OH was only 13% of *m/z* 186, indicating [D_4]*E,E*8,10–12:OH. The production of *E,E*8, 10–12:OH labeled with four deuterons should be due to metabolic (as opposed to mass spectrometric) loss of one deuterium atom as the mass spectrum of unlabeled *E,E*8,10–12:OH contained no detectable amounts of $[M-1]^+$.

DISCUSSION

We conclude that the major pheromone component of the codling moth *E,E*8,10–12:OH is biosynthesized from palmitic acid by two cycles of β-oxidation, followed by *E*9 desaturation of dodecanoic acid and a subsequent trans-

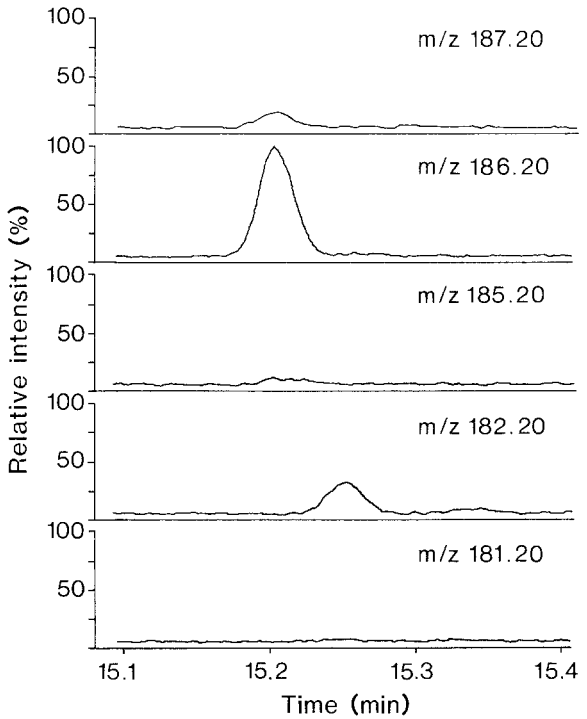

FIG. 4. Incorporation of deuterium label from topically applied (*E*)-[11,11,12,12,12-$^2H_5$]9-dodecenoic acid into (*E*,*E*)-8,10-dodecadienol in glands of seven female *Cydia pomonella*, analyzed by selected ion monitoring of ions *m/z* 181.20, 182.20, 185.20, 186.20, and 187.20. See text for details.

formation of the *E*9 double bond into the conjugated (*E*,*E*)-8,10-diene. The acid is finally reduced to produce the corresponding alcohol (Figure 5). The production of the conjugated diene before the reduction of acid to alcohol is supported by the presence of labeled *E*,*E*8,10–12 : acyl.

The fact that the unusual *E*9 desaturation of dodecanoic acid is a key step is supported by the absence of labeled chain-elongation products in the incubations with [12-D_3]12 : acid. An alternative route to the monoene could have been Δ 11 desaturation of tetradecanoic acid, a reaction widely distributed in tortricids (Roelofs and Brown, 1982), followed by chain shortening to give *E*9–12 : acyl. However, in this case [12-D_3]12 : acid should first have been elongated to labeled tetradecanoic acid (which we could not detect) and then desaturated and chain-shortened to produce the labeled *E*9–12 and *E*,*E*8,10–12 moieties.

We found that the incorporation of labeled precursors, as well as the amount of pheromone components in the glands, were quite variable from one experi-

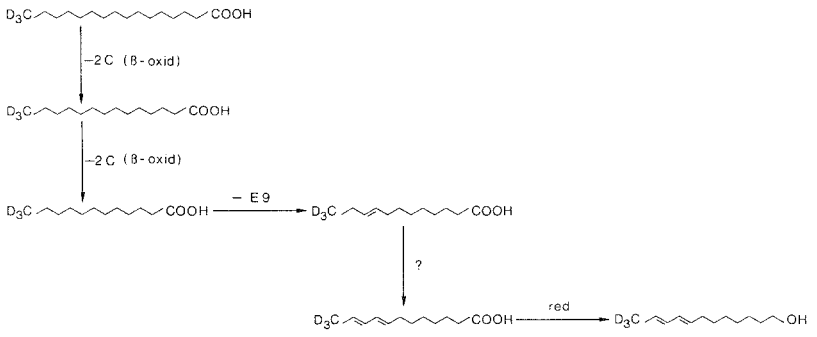

FIG. 5. Biosynthesis of sex pheromone gland constituents from hexadecanoic acid in the codling moth, *Cydia pomonella*. The proposed reactions involved are chain shortening (β-oxidation), *E*9 desaturation, conversion of the monoene into a conjugated diene, and reduction of the acids to alcohols.

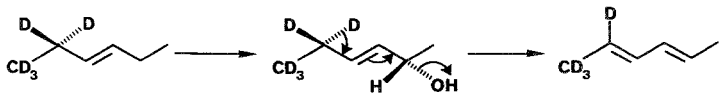
ment to another (Table 1), even though usually four or more females were included in one batch. This problem is not easily overcome by merely increasing the number of females in each batch, as Bjostad and Roelofs (1986) noticed the same phenomenon with as many as 20 glands used for each extraction. For this reason, we preferred to estimate the relative, rather than absolute, amounts of labeled compounds produced. Ideally, incorporation of each compound should have been measured relative to the incorporation of an internal standard, a compound with known metabolic activity, applied simultaneously.

The similarity of pheromone biosynthesis in the codling moth with that of *E*,*Z*10,12-16:OH in the silkworm moth is interesting, as the two species are representatives of two quite different lepidopteran families, Tortricidae and Lymantriidae, respectively. The loss of one deuteron, when the dienic pheromone precursor in *C. pomonella* is formed from [11,12-D_5]*E*9-12:acid, was not investigated in detail, but we suggest that the key steps involve oxidation of one of the α positions surrounding the double bond, followed by a 1,4 elimination of water (Scheme 2). Such a reaction mechanism accounts also for the



SCHEME 2.

biosynthesis of bombykol. Yamaoka et al. (1984) report 15% of $[M]^+$ for bombykol labeled with two deuterons relative to $[M]^+$ for the native bombykol when (*Z*)-[11,12-$^2H_2$]11-hexadecenoic acid is metabolized to bombykol. There is no indication of a product with one deuterium label only. This demonstrates that

both labeled atoms are retained when [11,12-$^2H_2$]Z11-16:acyl is converted to bombykol in *B. mori*.

*E*9 desaturation has not been described before in moth pheromone biosynthesis. Roelofs and Brown (1982) used information available on pheromone production in the Tortricidae to discuss taxonomy and the possible phylogeny of this group of Lepidoptera. Our finding of an *E*9-desaturase in *C. pomonella* does not resolve the classic controversy over the phylogenetic relationship among different tortricid subfamilies or tribes. However, the novel enzyme inferred tells us that there is no close biosynthetic relationship between the production of Δ 8 and Δ 10 monounsaturated compounds by a Δ 10-desaturase, and the production of Δ 8,10 doubly unsaturated compounds involving *E*9 desaturation. Whether the *E*9-desaturase is more closely related to the *E*11-, the Z10-, or the Z11-desaturase remains an open question, as does the phylogenetic position of the Olethreutinae relative to the Tortricinae.

IRIDOID GLYCOSIDES AS OVIPOSITION STIMULANTS FOR THE BUCKEYE BUTTERFLY, *Junonia coenia* (NYMPHALIDAE)

PATRICIA C. PEREYRA[1] and M. DEANE BOWERS

(Received December 30, 1986; accepted May 27, 1987)

Abstract—Females of *Junonia coenia* (Nymphalidae), a specialist on plants that contain iridoid glycosides, were found to use aucubin and catalpol, iridoid glycosides typical of a host plant, *Plantago lanceolata* (Plantaginaceae), as oviposition cues. Incorporating dried ground leaf material or pure iridoid glycosides into agar disks proved to be a very effective method of testing. In no-choice tests and choice tests, females laid more eggs on disks with *P. lanceolata* leaf material or iridoid glycosides, compared to agar controls. There was variation among individual females in preference for disks with *P. lanceolata* leaf material versus disks with iridoid glycosides. Females given a choice of three different concentrations of iridoid glycoside (0.2, 0.5, 1.0%) in the agar disks and a control laid more eggs on the disk with the highest concentration of iridoid glycoside.

Key Words—Iridoid glycoside, *Junonia coenia*, Lepidoptera, Nymphalidae, catalpol, aucubin, oviposition, *Plantago lanceolata*, insect–plant interaction.

INTRODUCTION

The oviposition behavior of a butterfly is a complex chain of stimuli and responses (Papaj and Rausher, 1983). It begins with the location of the host plant, where visual and olfactory cues are of primary importance. Once the butterfly has located a plant, however, contact chemoreception becomes

0098-0331/88/0300-0917$06.00/0

involved, and in specialist species, the leaf allelochemicals may be critical stimulants for oviposition (Schoonhoven, 1972; Stanton, 1979; Feeny et al., 1983; Ohsugi et al., 1985; Honda, 1986). Although other factors are certainly involved in the decision of whether or not to oviposit on an individual host plant or leaf (see Singer, 1982, 1983), leaf chemicals have been suggested, although seldom shown, to be critical as oviposition cues (Feeny et al., 1983; Chew and Robbins, 1984). In the Lepidoptera, the best studied systems are mustard oils and pierid butterflies (David and Gardner, 1962) and the swallowtail butterflies of the Papilionidae (Feeny et al., 1983 and references therein; Ohsugi et al., 1985; Honda, 1986).

The buckeye, *Junonia coenia* Hübner (Nymphalidae), is a specialist on plants containing iridoid glycosides (Bowers, 1984), as are butterflies of the genus *Euphydryas* (Bowers, 1981, 1983). Certain of these compounds characteristic of the host plants, such as aucubin and catalpol, serve as feeding stimulants and attractants for larvae of these insects (Bowers, 1983, 1984). Iridoid glycosides are characteristic of about 50 families of plants (El-Naggar and Beal, 1980), but they are particularly prevalent in the Scrophulariaceae and Plantaginaceae, the primary host-plant families of *J. coenia* and *Euphydryas* (Jensen et al., 1975; Bowers, 1983, 1984).

The importance of iridoid glycosides as critical cues for larval feeding preferences in *J. coenia* suggested that these compounds would also be important as oviposition stimulants, but this had not been demonstrated. The relationship between adult oviposition preference and larval requirements is not always clear, and errors in oviposition are not uncommon (Dethier, 1959; Singer, 1971, 1982; Wiklund, 1974; Chew, 1977; Chew and Robbins, 1984). In addition, the role of host-plant allelochemicals in determining oviposition behavior can be extremely complex and is not always as straightforward as suggested by the work of David and Gardner (1962) on pierids and mustard oils (see discussion in Feeny et al., 1983).

The objectives of the experiments described in this paper were to determine, first, if iridoid glycosides were oviposition stimulants for *J. coenia* and, second, whether females responded to differences in the concentration of iridoid glycosides in the oviposition substrate.

METHODS AND MATERIALS

Insects, Plants, and Iridoid Glycosides

Adult *J. coenia* were obtained by rearing larvae on leaves of *Plantago lanceolata* L. (Plantaginaceae), a commonly used host plant (Shapiro, 1974; Scott, 1975; Bowers, 1984). This plant species contains the iridoid glycosides catalpol and aucubin (Duff et al., 1965; Bobbitt and Segebarth, 1969). The

colony used for these experiments originated from a strain in North Carolina. *Plantago lanceolata* leaves were obtained from plants grown in the greenhouse or outside in a garden plot.

Newly emerged males and females were put into cylindrical net bags (30 × 30 × 45 cm) for mating, for a period of six days. Preliminary experiments had shown that this period was sufficient for most of the females to have mated. They were kept in growth chambers (photoperiod 16:8; light–dark, 30°C day, 25°C night). Butterflies were fed once a day with a solution of 2 g sucrose + 1 g glucose + 1 g fructose in 50 ml water. Females were isolated on the seventh day in individual plastic boxes without any oviposition stimulus.

The pure iridoid glycosides used in these experiments were obtained from W. Berkowitz at Queens College (aucubin) or extracted from *Catalpa bignonioides* (Bignoniaceae) (catalpol). Gas chromatography showed these compounds to be very pure (at least 99%, D. Gardner, personal communication; methods in Stermitz et al., 1986).

Oviposition Tests

Preliminary experiments showed that using paper "leaves" with test solutions (as used by Stanton, 1979; Feeny et al., 1983) did not work with *J. coenia.* Search of the literature and additional tests showed that a modification of the method used by Hovanitz and Chang (1964) worked extremely well. This method used agar disks molded in 5.5-cm-diameter Petri dishes as the oviposition substrate. The basic agar disk, 0.5 g agar mixed and cooked with 15 ml water, was used as the control. To this agar solution could be added various experimental components: 0.5 g dried, ground *P. lanceolata* leaf material, or various amounts and combinations of aucubin and catalpol. Since iridoid glycosides are polar compounds, they were easily combined with water and agar.

The test disks were all white except for those containing the *P. lanceolata* leaf material, which were dark green. Since females would oviposit well on the white disks, we did not try to control for color. Although visual orientation is clearly important in approaching host plants from a distance (Papaj and Rausher, 1983), in our experimental set-up, such cues were probably much less important than short-range chemical cues.

For the oviposition tests, individual females were isolated in clear plastic boxes (13.4 × 7.1 × 8.4 cm) or clear plastic cylinders between two large Petri dishes (12 cm high × 14 cm diameter). Three different experiments were carried out, including both no-choice and choice tests. Different sets of females were used for each experiment. All females used were 8, 9, or 10 days old at the beginning of an experiment.

Experiment 1, No-Choice Test. Twenty-four females were randomly assigned to each of three test groups, eight females to each group. Individual

females in each group were isolated with one of three oviposition substrates. Group 1 (control) females received pure agar disks, group 2 females received agar disks containing *P. lanceolata* leaf material (0.5 g leaf material/0.5 g agar), and group 3 females received agar disks with iridoid glycosides. For the group 3 females, on the first day, we used 0.01 g iridoid glycoside per disk (0.5 g agar), or 2.0% dry weight. The iridoid complement was 0.007 g catalpol + 0.003 g aucubin. This amount of pure iridoid was equivalent to 2% of the weight of *P. lanceolata* leaves used in those disks. Although the amount of iridoid glycosides in plants can vary dramatically (Stermitz et al., 1986; Harris et al., 1986; Fajer and Bowers, unpublished data), 1–2% of the dry weight of a leaf is common (Stermitz, personal communication) and is well within the range of what has been found in *P. lanceolata* (Duff, 1965). Because we were directly comparing leaf material and pure iridoid glycoside, we wanted the amounts of iridoid glycosides in disks with *P. lanceolata* leaves and pure iridoid glycoside to be roughly equivalent. On the second day, we used 1.0% dry weight (0.005 g) iridoid (1% of the weight of the leaf material).

We compared the number of eggs laid by individual females on each of the three groups over two consecutive 24-hr periods. Disks were collected after the first day and the eggs counted. Fresh disks of the same kind were given to each female and they were again allowed to oviposit for 24 hr.

The Kruskal-Wallis test (Conover, 1980) was used to compare the number of eggs laid on the three substrates.

Experiment 2, Paired Choice Test. Twelve females were presented with three different choice tests over three days: Agar versus *P. lanceolata* leaf material in agar (0.5 g leaf/0.5 g agar), agar versus catalpol in agar (0.005 g/0.5 g agar, 1% dry weight), and *P. lanceolata* leaf material versus catalpol (amounts as above). On the first day, four females were randomly assigned to each of the treatments. On the second day, each group of four females was given a different choice test, and on the third day, each group of four females was again given a different choice. Thus each of the 12 females was exposed to each of the three possible choices. Females were allowed to oviposit from 8:00 AM until 1:00 PM each day. After this, females were isolated without oviposition substrate until the next morning when they were given another choice. The females were 10 days old on the first day of the test. The number of eggs laid by each female on each test disk was counted after the 5-hr test.

Comparisons were made by one-way ANOVA on the arcsine-transformed percentages of the number of eggs laid on each substrate.

Experiment 3, Concentration Test. Four concentrations of catalpol were presented to individual females at the same time to determine, first, whether there was a threshold concentration necessary to elicit oviposition, and second, whether females discriminated among different concentrations. Each of 18

females was placed into a transparent cylinder and presented with four disks: 0% catalpol, 0.2% of the weight of the leaf material (0.001 g/0.5 g agar), 0.5% (0.0025 g/0.5 g agar), 1.0% (0.005 g/0.5 g agar). The females were allowed to oviposit for 48 hr and the number of eggs on each disk counted for each female.

The results were analyzed by one-way ANOVA on the arcsine-transformed percentages of the total number of eggs laid on each of the test substrates, followed by linear comparisons (Sokal and Rohlf, 1969).

RESULTS

No-Choice Test. Five females that did not lay any eggs at all during the two days were excluded from the analysis (two from the control group, two from the group receiving agar disks with *P. lanceolata* leaf material, and one from the group receiving agar disks with iridoid glycosides). We have no idea why they refused to lay eggs, when the others did so readily, and all the females used in these experiments subsequently laid fertile eggs and so were known to be inseminated. One female in the pure agar treatment died after the first day, having laid no eggs, and was also excluded.

Our results show that dried, ground *P. lanceolata* leaf material or pure iridoid glycoside stimulated oviposition, while the agar control did not (Figure 1). The total number of eggs laid by the females varied significantly with oviposition substrate (Figure 1) (Kruskal-Wallis test, $T = 8.19$, $df = 2$, $P < 0.025$). There was no significant difference in the number of eggs laid on disks with *P. lanceolata* leaf powder and pure iridoid glycosides (Kruskal-Wallis test, $P > 0.20$). The number of eggs laid on substrates with *P. lanceolata* leaf powder or pure iridoid glycosides was significantly different from the number laid on the control agar disks (Kruskal-Wallis test, *P. lanceolata* leaves—$P < 0.05$, pure iridoid—$P < 0.05$). Thus pure iridoid glycosides are sufficient to stimulate oviposition in *J. coenia* and at a level similar to that of *P. lanceolata* leaves.

Paired Choice Test. Females significantly preferred to oviposit on the substrates containing ground *P. lanceolata* leaf material or catalpol over the agar control (Figure 2). Although the mean for the percentage of eggs laid on the substrate with *P. lanceolata* leaf material was twice that on the substrate with catalpol, this was not significantly different, probably due to the variation among individual females (Figures 2 and 3). Although eight females laid more eggs on the disks with *P. lanceolata* leaf material, three preferred the substrate with catalpol, while one laid equal numbers of eggs on the two substrates (Figure 3).

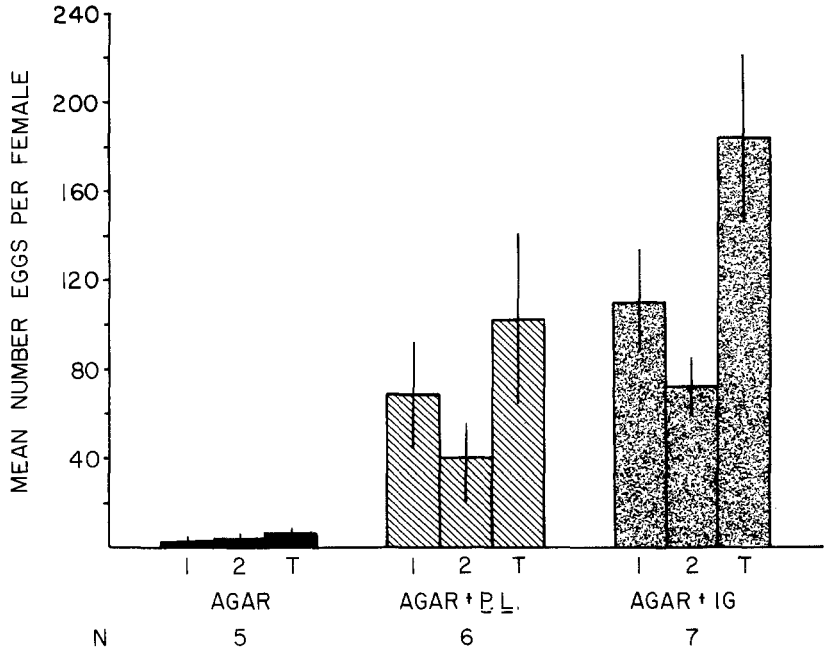

FIG. 1. Mean number of eggs laid by female *Junonia coenia* in a no-choice experiment. Results are shown for day 1, day 2, and the pooled data for days 1 and 2. Values are means ± standard error. N = number of females. AGAR = pure agar (control), AGAR + P.L. = agar + *P. lanceolata* leaf material (0.5 g/0.5 g agar), AGAR + IG = agar + catalpol and aucubin (0.007 g catalpol + 0.003 g aucubin/0.5 g agar).

Concentration Test. There was a highly significant difference in the number of eggs laid on the four test substrates (Figure 4) ($F = 7.853$, $df = 3,68$, $P < 0.001$). Linear comparisons (Sokal and Rohlf, 1969) showed that the number of eggs laid on the agar control was significantly less than that laid on any of the substrates with the iridoid glycoside, catalpol (Figure 4) ($F = 16.669$, $df = 1,68$, $P < 0.001$), as predicted by the results of the previous experiments. In addition, the females laid significantly more eggs on the substrate with 1% catalpol than on the other substrates with lower concentrations of the iridoid glycoside (Figure 4) ($F = 6.861$, $df = 1,68$, $P < 0.001$). Thus females were able to recognize the substrate containing the highest concentration of catalpol and laid most of their eggs there. There was no difference in the number of eggs laid on the substrates with 0.2% and 0.5% catalpol ($F = 0.027$, $df = 1,68$, NS).

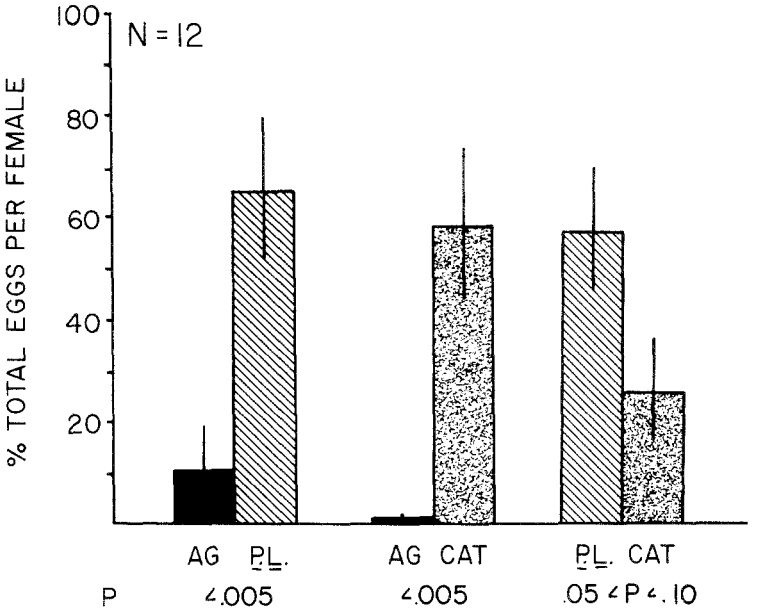

FIG. 2. Mean percent of eggs laid per female in a choice experiment. Values are means ± standard error. A total of 12 females were used. AG = pure agar (control), P.L. = agar + *P. lanceolata* leaf material (0.5 g/0.5 g agar), CAT = agar + catalpol (0.005 g/.5 g agar).

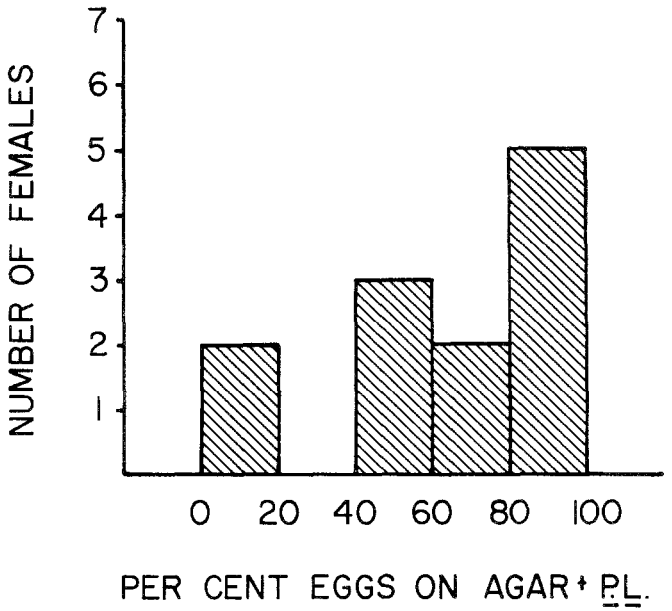

FIG. 3. Variation in the number of eggs laid by individual female *J. coenia* when given a choice of substrates containing *P. lanceolata* leaf material or pure catalpol. AGAR + P.L. = agar + *P. lanceolata* leaf material (0.5 g/0.5 g agar).

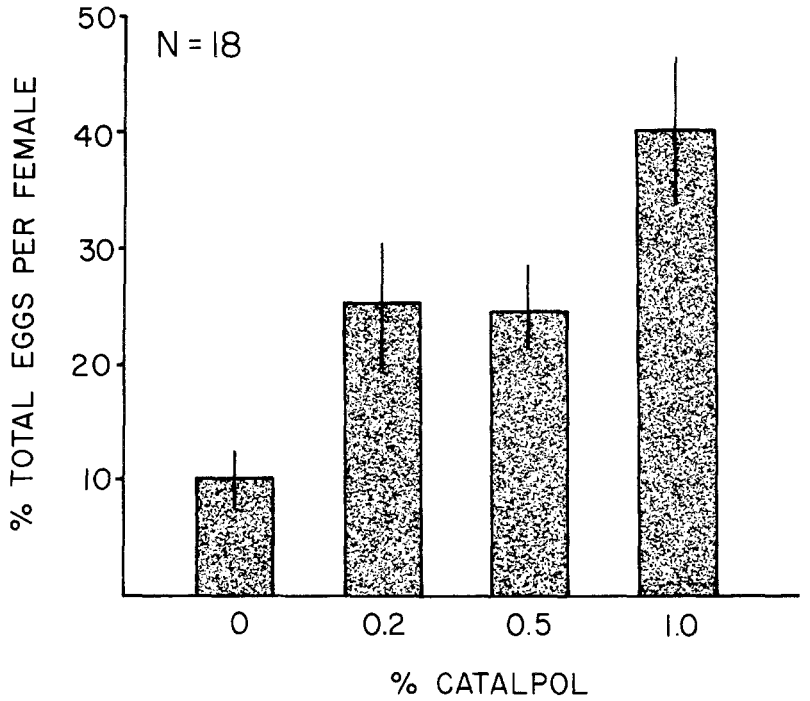

FIG. 4. Mean percent of eggs laid per female in a choice test of a control disk (pure agar) and disks with three different concentrations of catalpol. Values are means ± standard error.

DISCUSSION

Our results showed that *J. coenia* females used iridoid glycosides found in a typical host-plant species *P. lanceolata*, as oviposition cues. They responded positively to either a mixture of aucubin and catalpol, which are found in *P. lanceolata*, or to pure catalpol. Similar results were found in both choice and no-choice tests. In addition, females were able to discriminate among different concentrations and, when given a choice, laid significantly more eggs on the substrate with the highest concentration of catalpol.

The method of using agar disks to test compounds and plant material for oviposition activity (Hovanitz and Chang, 1964) proved to be very effective. Iridoid glycosides are generally polar compounds, and this method should work well with other polar compounds as well. Work with various species of *Papilio* has shown that the fractions of host-plant material eliciting oviposition behavior

are the polar ones (Nishida, 1977; Ichinose and Honda, 1978; Feeny et al., 1983). In addition, the presence of moisture appears to be essential for a positive contact response (Ichinose and Honda, 1978; Saxena and Goyal, 1978; Feeny et al., 1983), and this method provides that without the problems associated with evaporation from paper test substrates. Although we did not attempt to reuse disks, this should be possible. Disks begin to mold after 48 hr or so, but refrigeration or freezing would retard this process. Addition of mold inhibitors, such as those used in caterpillar artificial diets, might also aid in preventing mold growth. Drying out of the agar disks can also be a problem, but our use of plastic boxes or cylinders helped prevent this. This method of testing plant extracts, plant material, and pure polar chemical compounds has much potential.

Research on the chemical basis of oviposition behavior in butterflies has concentrated on two groups: the genus *Pieris* (Pieridae), which use cruciferous plants containing glucosinolates as hosts, and the Papilionidae. The classic example of a particular compound or group of compounds acting as oviposition (and larval feeding) stimulants is sinigrin and other glucosinolates for butterflies in the genus *Pieris* (David and Gardner, 1962). Attempts to find a similarly critical sign stimulus for oviposition in other butterfly species, such as the swallowtails which have been extensively investigated (Ichinose and Honda, 1978; Nishida, 1977; Feeny et al., 1983), have met with frustration (see discussion in Feeny et al., 1983). However, recent work by Honda (1986) has resulted in identification of flavanone glycosides as oviposition stimulants for a citrus-feeding swallowtail, *Papilio protenor* (Papilionidae). Work on *Pieris rapae* has shown that the chemical basis for oviposition in *Pieris* may be more complicated than previously thought (Renwick, 1985). In *J. coenia*, however, a single pure iridoid glycoside is sufficient to stimulate oviposition at levels similar to that of leaf material.

In conjunction with the demonstrated importance of other factors such as thermal requirements, environmental variation, host-plant demography, and previous experience of the ovipositing female, the importance of plant allelochemistry in the control of oviposition behavior is certainly complex and may vary from one system to another. Yet work on chemosensory systems of female butterflies has often shown that chemical cues are necessary for oviposition. The mechanisms of integration of chemical cues with other environmental and experiential cues to determine patterns of oviposition remain a mystery (Dethier, 1982). A first step, however, is to determine what chemical cues are involved. In *J. coenia* these cues are iridoid glycosides.

The behavioral response of the females to the agar disks containing ground leaves of *P. lanceolata* or pure iridoid glycosides was immediate: they began "drumming" (Ilse, 1937) immediately with the forelegs, curled the abdomen,

and oviposited. This response appeared to occur more quickly on these substrates than on intact leaves of *P. lanceolata.* Drumming behavior is believed to serve as a means of penetrating the plant cuticle to "taste" the leaf and obtain chemical information (Fox, 1966; Calvert and Hanson, 1983) via chemoreceptors on the foretarsi (Calvert, 1974). The agar disks appear to make such chemical information available more quickly than it would be in an intact leaf. If both foretarsi of *J. coenia* are cut, the number of eggs laid is reduced by 42% compared with females with foretarsi intact but with tarsi removed from one of the walking legs ($N = 18$ females) (Pereyra, unpublished). Similar results have been found in other butterfly species (Feeny et al., 1983).

Individual females given a choice of disks with *P. lanceolata* or catalpol varied in the percentage of eggs laid on these substrates (Figure 3)—some preferred *P. lanceolata* and others catalpol. Variation among individual females has been documented in other systems (Tabashnik et al., 1981; Singer, 1982; Papaj and Rausher, 1983) and is important in determining host-plant utilization patterns in nature (Stanton and Cook, 1984). Variation such as we observed among the females in the lab may be important in determining patterns of oviposition in the field.

The ability of *J. coenia* females to discriminate the disk with the highest concentration of catalpol (Figure 4) is intriguing. We used concentrations of iridoid glycoside that are well within the range of iridoid glycoside concentrations found in *P. lanceolata* (Duff et al., 1965) and other plants containing iridoid glycosides (Stermitz et al., 1986; Harris et al., 1986). Our results suggest that in nature, females might search for and prefer to oviposit on plants with a higher concentration of iridoid glycosides. Although *J. coenia* adults do not contain iridoid glycosides, the larvae do (Bowers and Puttick, 1986) [they are expelled in the meconium upon adult emergence (Bowers and Puttick, 1986)]. A higher concentration of iridoid glycosides in the larvae due to feeding on a host plant higher in iridoid glycosides may aid in protecting them from predation, as suggested generally for Lepidoptera feeding on toxic plants (Brower, 1984, p. 114). Thus female *J. coenia* able to discriminate and prefer higher concentrations of iridoid glycosides in the host plant might produce larval offspring protected by containing a higher concentration of iridoid glycosides.

Acknowledgments—We thank Lou Bjostad, Gillian Puttick, Frank Stermitz, and Bruce Tabashnik for comments on the manuscript; and Philip Chapman, Lou DiBernardo, Mike Freehling, and Steve Grunow for help with various aspects of this work. Dale Gardner provided the GC analyses of the iridoids. We are particularly grateful to Ramiro Sarandon and Gillian Puttick for help in many phases of this work and to Fred Nijhout for giving us the North Carolina strain of *J. coenia*. William Berkowitz generously provided the sample of aucubin. This research was supported by NSF grants BSR 83-07353 and RII 85-03816 to D. Bowers.

(Received January 12, 1987; accepted May 27, 1987)

Abstract—Ovipositor washings from virgin female *Earias vittella* (F.) (Lepidoptera: Noctuidae) moths were examined by gas chromatography (GC) linked to electroantennography (EAG). Six components were detected by the male moth. These were identified by comparison of their retention times with those of a range of synthetic standards on fused silica capillary GC columns as hexadecanal, (*Z*)-11-hexadecenal, (*E,E*)-10,12-hexadecadienal, octadecanal, (*Z*)-11-octadecenal, and (*E,E*)-10,12-hexadecadien-1-ol in 1:2:10:2:4:1 ratio. Field testing in Pakistan showed that a 2:10:2 mixture of (*Z*)-11-hexadecenal, (*E,E*)-10,12-hexadecadienal, and (*Z*)-11-octadecenal was as attractive to male *E. vittella* moths as the six-component mixture and equal in attractiveness to a virgin female moth. Omitting (*Z*)-11-hexadecenal or (*Z*)-11-octadecenal greatly reduced this attractiveness. It was found that synthetic lures must be protected from sunlight to prevent loss of attractiveness caused by isomerization of the conjugated diene aldehyde, and addition of (*E,Z*)-10,12-hexadecadienal, one of the products of isomerization, was shown to reduce attractiveness significantly. During this work, a 10:1 mixture of (*E,E*)-10,12-hexadecadienal and (*Z*)-11-hexadecenal was shown to be as attractive to *E. insulana* (Boisd.) male moths as a virgin female moth, and the attractiveness of this mixture was further increased by addition of (*E,Z*)-10,12-hexadecadienal.

Key Words—Spotted bollworm, *Earias vittella*, spiny bollworm, *Earias insulana*, Lepidoptera, Noctuidae, gas chromatography, electroantennography, pheromone traps, hexadecanal; (*Z*)-11-hexadecenal, (*E*,*E*)-10,12-hexadecadienal, (*Z*,*E*)-10,12-hexadecadienal, (*E*,*Z*)-10,12-hexadecadienal, octadecanal, (*Z*)-11-octadecenal, (*E*,*E*)-10,12-hexadecadien-1-ol.

INTRODUCTION

The spotted bollworm, *Earias vittella* (F.) (Lepidoptera: Noctuidae) is an important pest throughout the cotton-growing areas of the Indian subcontinent, southeast Asia, Indonesia, and northern Australia. The female moth lays eggs singly on the cotton bolls, and the larvae develop entirely within the cotton boll, reducing the quantity and quality of the cotton lint. Control with conventional insecticides is made difficult by the inaccessibility of the larvae. Control by novel methods, such as mating disruption with sex pheromones, necessitates the development of a sensitive, species-specific monitoring tool. This is particularly important in Pakistan where *E. vittella* coexists with the closely related spiny bollworm, *E. insulana* (Boisd.) (Lepidoptera: Noctuidae), and the pink bollworm, *Pectinophora gossypiella* (Saund.) (Lepidoptera: Gelechiidae). The sex pheromone of *P. gossypiella*, (*Z*,*E*)- and (*Z*,*Z*)-7,11-hexadecadienyl acetates, is well known (Bierl et al., 1974), and the major component of the sex pheromone of *E. insulana* was identified as (*E*,*E*)-10,12-hexadecadienal by Hall et al. (1980). This paper describes the identification and field evaluation of the female sex pheromone of *E. vittella*. Preliminary results were reported briefly by Cork et al. (1985a).

METHODS AND MATERIALS

Insect Material. For chemical analyses, pupae were sent from India by air to London. The pupae were left in their cocoons and placed in individual tubes held in an environmental cabinet on a reversed 12-hr/12-hr light–dark cycle with temperature alternating between 27°C and 22°C and relative humidity 85%. Adult moths were sexed on emergence and provided with 10% sucrose solution under the same conditions.

For field work in Pakistan, larvae were collected from cotton bolls, separated from *E. insulana* larvae, and reared on fresh cotton seeds. The resulting pupae were removed from their cocoons, sexed, and maintained singly in tubes on moist cotton wool until emergence.

Pheromone Collection. Ovipositor washings in carbon disulfide or heptane were prepared from virgin female moths up to 3 days old and between 4 and 12 hr into the dark period. Volatiles from virgin female moths were collected

on filters containing 5 mg of activated charcoal, as described previously (Grob and Zurcher, 1976; Nesbitt et al., 1979a; Tumlinson et al., 1982).

Gas Chromatography (GC). Analyses were carried out on a Carlo Erba Fractovap 4160 instrument equipped with Grob splitless injector at 200°C and flame ionization detector at 220°C. Fused silica capillary columns (25 m × 0.32 mm ID) were used with helium carrier gas (0.4 kg/cm^2) as follows: column (A), polar CP Wax 57CB (0.11 μm film thickness; chemically bonded Carbowax 20 M; Chrompack), oven temperature held at 70°C for 2 min, then programmed at 20°C/min to 90°C, then at 1°C/min to 190°C; Column (B), nonpolar CP Sil 5CB (0.15 μm film thickness; chemically bonded methylsilicone; Chrompack), oven temperature held at 70°C for 2 min, then programmed at 20°C/min to 100°C, then at 1°C/min to 190°C.

Retention times for the pheromone components are given in equivalent chain length (ECL) units relative to the retention times of straight-chain acetates. Retention times of series of synthetic isomers are given in minutes.

Electroantennography (EAG). Recording of male moth antennal responses to GC column effluent (GC-EAG) was carried out as described by Beevor et al. (1986), except that the electrodes were inserted into the interstitial membranes of the intact antenna. To record the EAG response profile to hexadecenal isomers, a solution of the test compound in hexane (2 μl) was syringed onto the inner wall of a disposable Pasteur pipet and solvent evaporated under a stream of nitrogen (500 ml/min for 6 sec). The pipet tip was then positioned 1 cm above the recording antenna and a pulse of nitrogen (500 ml/min for 3 sec) directed through the pipet. A 3-min interval was allowed between successive stimuli for the preparation to recover fully.

Synthetic Chemicals. Monounsaturated aldehydes were prepared by standard acetylenic routes and purified by kugelrohr distillation to give products containing less than 3% of the opposite geometric isomer.

(*Z*,*E*)-10,12-Hexadecadienol was prepared by Wittig reaction between (*E*)-2-hexenal (Aldrich) and the triphenylphosphonium salt from 9-bromo-1-decanol in tetrahydrofuran at −20°C with potassium *t*-butoxide as base. The product contained 91.8% *Z*,*E*, 0.7% *Z*,*Z*, and 7.5% *E*,*E* isomers and less than 0.1% of the *E*,*Z* isomer (cf. Klug et al., 1982).

(*E*,*Z*)-10,12-Hexadecadienol was prepared by Wittig reaction under the same conditions between (*E*)-11-(2-tetrahydropyranyloxy)-2-dodecenal and butyl(triphenyl)-phosphonium bromide (Hall et al., 1980). After deprotection, the product alcohol contained 85.8% *E*,*Z*, 3.2% *Z*,*Z*, 11.0% *E*,*E* isomers and less than 0.2% *Z*,*E* isomer.

(*E*,*E*)-10,12-Hexadecadienol was prepared by isomerization of the *Z*,*E* isomer, prepared as above, with thiophenol (Henrick et al., 1975; Hall et al., 1980), or, better, by exposing a solution in petroleum spirit containing a catalytic amount of iodine to sunlight (Klug, personal communication, 1983). The

isomeric mixture, containing 65–70% of the *E,E* isomer, was then recrystallized three times from petroleum spirit at −20°C to give the *E,E* isomer with less than 0.3% each of the *Z,E* and *E,Z* isomers and a negligible amount of the *Z,Z* isomer. The mother liquors could be isomerized again and recrystallized to give more product.

The diene alcohols were oxidized to the corresponding aldehydes with pyridinium chlorochromate in dichloromethane, and the products purified by fractional distillation (*E,E*) or kugelrohr distillation (*Z,E* and *E,Z*). No change in isomeric composition was detected on oxidation or distillation. Base-washed glassware was used for distillation and storage of the aldehydes to discourage trimerization (Dunkelblum et al., 1984).

Isomers of 9,11-, 11,13-, and 12,14-hexadecadienal and the corresponding alcohols were available from previous work (Hall et al., 1980).

Field Tests. Field testing was carried out in cotton fields near Multan, Pakistan, between 1982 and 1985. Pheromone dispensers were polyethylene vials (35 mm × 8 mm × 1.5 mm thick) loaded by adding the appropriate amount of a hexane solution of each pheromone component and 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant (10 mg/ml each), allowing the solvent to evaporate, and closing the lid. Sticky disk traps (60 cm diameter) were used in initial field tests carried out in 1982–1983. In subsequent tests, covered, yellow plastic funnel traps (10 cm diameter; Biological Control Systems Ltd., Treforest, U.K.) were used, and the pheromone dispensers were protected from sunlight by aluminium sleeves (55 mm × 12 mm), open at the lower end. Traps were positioned just above crop height (approx. 1.5 m) on wooden poles. Synthetic lures were hung just below the roof of the trap at the center, and they were not renewed during a trial unless they were stolen. For tests with virgin female moths as bait, single moths, 2, 3, or 4 days old, were housed in tubes (50 mm × 30 mm) covered with muslin at each end and suspended horizontally under the roof of the trap. Mortality was minimized by providing the moths with cotton wool soaked in sucrose solution, and by placing them in the traps as late in the afternoon as possible and recording catches early the following morning.

The experiments carried out in 1984 were set out in Latin square or completely randomized block designs with at least 30 m spacing between traps. There were up to four replicates of each treatment, and experiments were run for eight nights without renewing the pheromone dispensers or changing treatment positions. Catches of *E. vittella* and *E. insulana* male moths were recorded each day. The catches were transformed to $\log(x + 1)$ in order to stabilize the variance and then subjected to analysis of variance. Differences between mean catches for each treatment were assessed for significance by Duncan's multiple-range test (DMRT).

In 1985, six synthetic blends were tested with six replicates in 1-hectare plots at least 100 m apart. In each replicate, the treatments were set out randomly around the plot with at least 30 m between traps. Catches of the two species were recorded each day when the treatments were moved on one position within each replicate. Each replicate was run for 36 nights, i.e., six complete rotations, without renewing the pheromone dispensers unless one was stolen. Total catches over the 36 nights for each treatment in each replicate were transformed to $\log(x + 1)$ and subjected to analysis of variance. Differences between catches by the different treatments were tested for significance by DMRT.

In other experiments carried out during 1985, the attractiveness of the synthetic pheromone for *E. vittella* and for *E. insulana* was compared with that of 2-, 3-, and 4-day-old virgin female moths of the corresponding species. Three replicates of each treatment were run simultaneously for seven nights. Catches were recorded each day when female moths were renewed and each treatment moved on one position within a replicate. Data from traps found to contain dead female moths or no pheromone dispenser were discarded, and differences between mean catches in the female-baited traps and those baited with the synthetic lure were tested for significance by *t* tests.

RESULTS

The female sex pheromone of *E. vittella* was identified on the basis of GC retention times of components in female ovipositor washings that elicited EAG responses from the male moth in linked GC-EAG analyses, comparison of EAG responses of the male moth to synthetic compounds, and extensive field testing of synthetic mixtures.

Structure Determination. Ovipositor washings from virgin female moths were analyzed by linked GC-EAG on both polar (A) and nonpolar (B) fused silica capillary columns. Six components were detected that caused an EAG response from the male moth at least 10% greater than the background response in two or more analyses. These components were numbered I to VI in their order of elution on polar column A. Retention times on columns A and B are given in Table 1, along with the average relative proportions of the components from analyses of a total of 75 female equivalents.

The major component, III, had retention times consistent with those of conjugated hexadecadienals. These retention times were compared with those of isomers of 9,11-, 10,12-, 11,13-, and 12,14-hexadecadienal, using hexadecanal as internal standard (Table 2). Component III could not be distinguished from (*E*,*E*)-10,12-hexadecadienal and (*E*,*E*)-11,13-hexadecadienal on nonpo-

lar column B, but these two isomers were readily separated on polar column A, and the retention times of component III were consistent only with those of (*E*,*E*)-10,12-hexadecadienal (*E*,*E*10,12–16 : Ald) on both columns.

The ratio of the amplitudes of the GC peaks corresponding to components I and II was approximately 1 : 2, and the EAG responses to component I were much less than those to component II. Using these criteria, it was deduced that the order of elution of components I and II was reversed on nonpolar column B relative to their order of elution on polar column A. Component I cochromatographed with hexadecanal (16 : Ald) on both columns. The retention times of component II suggested it was a hexadecenal isomer, and comparison with the retention times of the available hexadecenal isomers showed that the retention times of component II matched only those of (*Z*)-11-hexadecenal (Z11–16 : Ald) on both columns (Table 3).

The retention times of components IV and V indicated that they were two-carbon homologs of components I and II (Table 1), and they showed the same reversal of elution order on the two columns. Component IV cochromatographed with octadecanal (18 : Ald) and component V had the same retention time as (*Z*)-11-octadecenal (Z11–18 : Ald) on both column A and column B. Only a limited number of octadecenal isomers was available for comparison (Table 4), but, by analogy with the hexadecenal isomers (Cork et al., 1985b),

*Z*13–18:Ald	67.30	64.22
*E*13–18:Ald	66.88	64.71

*Z*11–18:Ald should have had unique retention times under the conditions used. Other possible candidates for component V were thought to be the hexadecenyl acetates. However, the retention time of component V on polar column A was shown to be different from those of the *Z* and *E* isomers of 10-, 11-, 12-, 13-, and 14-hexadecenyl acetate.

In some analyses on polar column A, a significant EAG response was recorded to a component eluting between components IV and V at ECL 16.42 with a magnitude approximately 10% that of the major component III. A corresponding response was never recorded during analyses on nonpolar column B, and no further work was done to verify the existence of this component or identify it.

The GC retention times of component VI were consistent with those of a conjugated hexadecadien-1-ol. Only the isomers of 9,11-, 10,12-, and 11,13-hexadecadien-1-ol were available for comparison, but their retention times relative to each other were similar to those of the corresponding hexadecadienals (Table 2). The retention times of component VI matched only those of (*E*,*E*)-10,12-hexadecadien-1-ol (*E*,*E*10,12–16:OH) on both columns (Table 2).

Pheromone yields were much higher than those reported for *E. insulana* by Hall et al. (1980). Typically, approximately 25 ng of the major component III per female was obtained in ovipositor washings prepared 11–12 hr into the dark period. Relative abundances of the pheromone components were reasonably consistent in different batches of ovipositor washings, although the presence of impurity peaks gave high assays for *Z*11–16:Ald on column A and for 18:Ald on column B (Table 1). Entrainment of volatiles from virgin female

moths gave more EAG-active material during the first 6 hr of the dark period than during the second 6 hr. However, yields were poor, and only the major component was consistently detected in linked GC-EAG analyses.

EAG responses of a male moth to the available hexadecenal isomers were recorded at the 20ng level (Figure 1). The *E* isomers were consistently more active than the corresponding *Z* isomers, and, of the isomers tested, the (*E*)-12-, (*E*)-11-, and (*Z*)-11- isomers elicited the largest EAG responses. This pattern of responses to the monounsaturated hexadecenal isomers is consistent with the (*E*,*E*)-10,12 unsaturation assigned to the major, diunsaturated hexadecadienal pheromone component (Hall et al., 1980, and references therein). However, these responses were much lower than that to *E*,*E*10,12–16:Ald, 5 ng of which caused a response of 4.8 mV.

Field Tests. In 1982, the total mixture of six components in their naturally occurring ratios was tested in different trap types, including sticky disk traps, dry funnel traps, and delta sticky traps. In all cases, the lures remained attractive

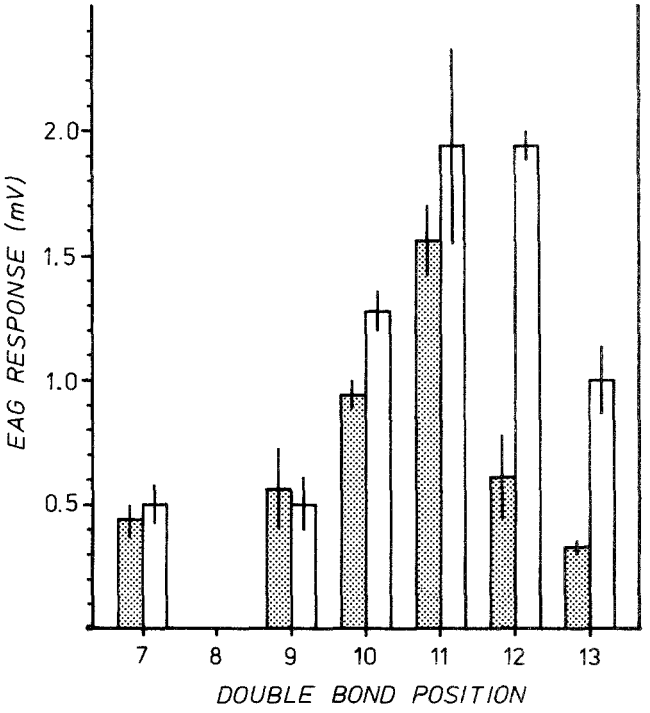

FIG. 1. EAG responses of a male *E. vittella* moth to hexadecenal isomers (20 ng); ▨ *Z* isomers; □ *E* isomers; bars indicate the spread of duplicate results; (*Z*)- and (*E*)-8-hexadecenal were not tested.

to male *E. vittella* moths for only a few days at best. It was thought that changes in the pheromone on exposure to sunlight might be responsible for this loss of attractiveness, and experiments were set up in 1983 to test this.

Using unprotected lures on white sticky disk traps, catches of *E. vittella* and *E. insulana* male moths in one representative experiment were 122 and 44, respectively, on the first night. On the second night, the catch of *E. vittella* was reduced to zero while that of *E. insulana* was 23. Subsequent GC analysis of these lures showed that the *E,E*10,12–16:Ald had been isomerized to the thermodynamic equilibrium mixture containing approximately 65% *E,E*, 15% *Z,E*, 15% *E,Z*, and 5% *Z,Z* isomers. In a parallel experiment, the lures remained attractive to *E. vittella* for at least 11 days when they were removed from the field during daylight hours. All subsequent experiments were carried out with the polythene vial dispensers shielded from sunlight with aluminium sleeves open at the lower end.

In 1984, tests were run to determine the effect on attractiveness of removing components from the six-component mixture. Removal of either or both of the saturated aldehydes, 16:Ald and 18:Ald, did not affect the catch significantly (Table 5, experiment 1), and these were omitted from most of the subsequent tests. If either of the monosaturated aldehydes, Z11–16:Ald or Z11–18:Ald, was subsequently removed, the catch was very significantly reduced. There was also an indication that omitting the diene alcohol, *E,E*10, 12–16:OH, increased the catch, but this was not statistically significant (Table 5, experiment 2).

In view of the importance of the monounsaturated aldehydes and possibly the *E,E*10,12–16:OH, experiments were carried out to examine the effects of changing the proportions of these components while keeping the others constant. Over the ranges of levels tested, there were no significant differences in catches between any of the treatments (Table 6). Variability in catches at different positions and from day to day was very high during these experiments, and this may have obscured small differences between the different treatments.

Previous results had suggested that isomerization of the conjugated diene aldehyde, *E,E*10,12–16:Ald, caused loss of attractiveness to *E. vittella* male moths. In order to study this further, the effect on catches of adding known amounts of isomerization products was studied. Addition of 10% *Z,E*10,12–16:Ald had no effect on catches, but a similar amount of *E,Z*10,12–16:Ald significantly reduced the catch (Table 7).

During 1984, populations of *E. insulana* were very low and very few moths of this species were caught in the pheromone traps.

In 1985, the results obtained above were consolidated in a highly replicated series of experiments run when populations of both *E. vittella* and *E. insulana* were high (Table 8). Omitting either of the monounsaturated aldehydes caused a very significant reduction in attractiveness to *E. vittella*, but the presence of

[a] Trap catches transformed to log $(x + 1)$; no significant differences between means in each experiment at the 5% level.

*E,E*10,12-16:OH at 10% of the major component had no effect. As was found in 1984, addition of *E,Z*10,12-16:Ald drastically reduced catches of *E. vittella*, but addition of *Z,E*10,12-16:Ald had no effect. Interestingly, *E,Z*10,12-16:Ald not only reduced the catches of *E. vittella* but also significantly increased the catches of *E. insulana* (Table 8).

Each replicate in this experiment was run for 36 nights without renewing the pheromone dispensers. Analyses of the pheromone remaining in vials containing the three main components were carried out after 30 days' exposure in traps in Pakistan. These analyses showed that approximately half the initial loading of pheromone remained and that little isomerization of the *E,E*10,12-16:Ald had occurred (*E,E*10,12-16:Ald, 0.50 mg; *Z*11-16:Ald, 0.09 mg; *Z*11-18:Ald, 0.09 mg; and 10,12-16:Ald, 94.1% *E,E* isomer).

In a final series of experiments, the attractiveness of synthetic lures for *E. vittella* and for *E. insulana* were compared with that of a caged virgin female moth of the corresponding species. The *E. vittella* lure used was the four component mixture of *E,E*10,12-16:Ald, *Z*11-16:Ald, *Z*11-18:Ald, and *E,E*10,12-16:OH. The *E. insulana* lure contained a binary mixture of

[b] In each experiment, there were no significant differences at the 5% level between the catch by the synthetic lure and the catches by any of the virgin female lures, using *t* tests.
[c] 1000 μg *E,E*10,12-16:Ald + 200 μg Z11-16:Ald + 200 μg Z11-18:Ald + 100 μg *E,E*10,12-16:OH.
[d] 1000 μg *E,E*10,12-16:Ald + 100 μg Z11-16:Ald.

*E,E*10,12-16:Ald and Z11-16:Ald in a 10:1 ratio. At the time, this was thought to be the most attractive lure for *E. insulana* since the results of the previous experiment were not available. For both species, there were no significant differences between the number of male moths caught in traps baited with the synthetic lures and those baited with a 2-, 3-, or 4-day-old virgin female moth (Table 9).

DISCUSSION

The results of analytical studies and field testing of synthetic mixtures indicate that the female sex pheromone of *E. vittella* is composed of six components: 16:Ald, Z11-16:Ald, *E,E*10,12-16:Ald, 18:Ald, Z11-18:Ald and *E,E*10,12-16:OH in the ratio of 1:2:10:4:2:1. A synthetic mixture based on the natural ratio of these components without the saturated aldehydes, 16:Ald and 18:Ald, was shown to be as attractive to the male moths as was a caged

virgin female moth, although the addition of *E,E*10,12–16:OH was probably not necessary. Removing either of the monounsaturated aldehydes, Z11–16:Ald or Z11–18:Ald, reduced the catch of male moths significantly. Thus, Z11–16:Ald and Z11–18:Ald together with the major component, *E,E*10,12–16:Ald, in the naturally occurring ratio of 2:2:10 constitute a highly effective synthetic attractant for this species.

Early indications that the synthetic lures lost their attractiveness through photochemically induced isomerization of the *E,E*10,12–16:Ald were supported by the finding that addition of *E,Z*10,12–16:Ald dramatically reduced catches of *E. vittella*. The other isomer that is formed in any quantity, *Z,E*10,12–16:Ald, had no effect on catches. Work is in progress to find dispensers that completely prevent isomerization of the conjugated diene aldehyde, but at present lures should be protected from sunlight with sleeves of aluminium tubing or foil.

*E,E*10,12–16:Ald was reported to be the major component of the female sex pheromone of *E. insulana* by Hall et al. (1980). Subsequent results (unpublished) suggested that addition of Z11–16:Ald increased the attractiveness of the diene aldehyde to *E. insulana*, and in this work a binary mixture of *E,E*10,12–16:Ald with 10% Z11–16:Ald was shown to be as attractive as a virgin female moth. This synthetic mixture is currently being used to monitor *E. insulana* in Pakistan and Egypt.

Whereas *E,Z*10,12–16:Ald decreased the attractiveness of synthetic lures to *E. vittella*, it increased the attractiveness of *E. insulana*. It remains to be seen whether Z11–16:Ald or *E,Z*10,12–16:Ald is produced by the virgin female *E. insulana* moth, but the presence of the latter component could help to ensure species specificity in mating by these sympatric species. Night observation work in Pakistan by Murlis and Bettany (personal communication) showed that male *E. insulana* are active during the first half of the night, while male *E. vittella* are only active much later, so that species specificity may not be entirely chemical in origin. This observation was in agreement with the laboratory finding that ovipositor washings from female *E. vittella* moths contained more pheromone when they were prepared during the latter part of the scotophase. Volatiles collected from female moths were apparently more EAG-active when collected during the first half of the dark period, but amounts of pheromone obtained by this method were very small, and quantification by GC analysis was not possible. If species specificity is achieved by a combination of chemical and temporal separation, then a certain degree of cross-attraction to pheromone traps might be expected because the synthetic lures emit pheromone throughout the night.

Z11–16:Ald has been reported to be a pheromone component of many moth species (Arn et al., 1986), and it was reported to attract *E. biplaga* (Wlk.) by Nesbitt et al. (1979b). To our knowledge, Z11–18:Ald has not been found in any other lepidopteran sex pheromone, although Z13–18:Ald is produced by

several species in the Pyralidae, Crambinae, and Phycitinae families (Arn et al., 1986).

Acknowledgments—The authors wish to thank the Pakistan Central Cotton Committee and in particular the Vice-Chairman, Dr. H. Huque, for their help and encouragement with the field work. The authors are also grateful to Dr. K.N. Rao, Tenali, India, for supplying most of the insect material used in the laboratory work; to Miss Shiela M. Green, TDRI, for advice and assistance with statistical analyses; and to Miss Jane L. Mullings, TDRI, for assistance with making up and analyzing pheromone dispensers.

(Received January 23, 1987; accepted May 27, 1987)

Abstract—Gas chromatography of hexane extracts of 3-day-old virgin *A. frontella* adults revealed a branched saturated hydrocarbon present only in females. This compound was isolated by argentation chromotography and preparative GC, identified by GC and GC-MS as 3,7-dimethylnonadecane, and subsequently synthesized. Three-day-old virgin females contained 54.1 ± 3.5 ng (±SEM; $N = 48$) of 3,7-dimethylnonadecane. Male cadavers do not elicit male courtship behavior, but when treated with ~ 18 ng of 3,7-dimethylnonadecane they were as attractive as cadavers of 3-day-old virgin females. Black cotton knots were less attractive than male cadavers when treated with 3,7-dimethylnonadecane, but all bioassays indicated that this compound is an important semiochemical modulating male mating behavior.

Key Words—Alfalfa blotch leafminer, *Agromyza frontella*, Diptera, Agromyzidae, 3,7-dimethylnonadecane, female sex pheromone, male response, synthesis.

INTRODUCTION

The alfalfa blotch leafminer (ABL), *Agromyza frontella* (Rondani), a species recently introduced to North America from Europe (Miller and Jensen, 1970), has spread throughout the eastern United States and Canada (Harcourt and Binns, 1980; Hendrickson and Plummer, 1983). Concern about the pest potential of *A. frontella* to alfalfa production stimulated considerable research of both an

0098-0331/88/0300-0947$06.00/0

applied and basic nature (e.g., Suzuki and Thomson, 1981; MacCollom et al., 1982; Tauber et al., 1982; McNeil and Quiring, 1983; Mellors and Helgesen, 1983; Quiring and McNeil, 1984a–e; Daley and McNeil, 1987; Harcourt et al., 1987).

In a recent study on the mating behavior of the alfalfa blotch leafminer (Carrière and McNeil, in press), it became clear that while the presence of the host plant was essential for mating, there was evidence of a female sex pheromone. Male cadavers, which are normally ignored, elicited the entire repertoire of male mating behavior when treated with a virgin female hexane extract. In this paper we report on the isolation, identification, and synthesis of this female sex pheromone.

METHODS AND MATERIALS

Insect Rearing. All *A. frontella* used in this study came from a laboratory colony, restocked annually and maintained on potted alfalfa (Saranac variety) in a greenhouse at 20 ± 2°C, 50 ± 10% relative humidity under a 16:8 light–dark photoperiodic regime. Newly formed pupae, <24 hr, were transferred from the colony and maintained, as well as the resultant flies, at 20 ± 1°C, 60 ± 5% relative humidity under a 14:10 light–dark regime. Upon emergence, adults were sexed, and virgin males and females were held in separate cages (ca. 40 per cage), in presence of alfalfa, until needed. Three-day-old virgin adults were killed, 3 hr after the onset of the photophase, by a 15-min exposure to a temperature of −16°C. Groups of ca. 40 males or females were soaked in hexane (5 μl per fly) for 3 hr, the extract collected with a Pasteur pipet and used for chromatographic analyses or bioassays within 8 hr. All bioassays were carried out using plants grown in isolation from the leafminer.

Bioassay Methods. The bioassay developed by Carrière and McNeil (in press) was used to test all extracts and synthetic material. Three freshly killed male cadavers were treated with 5 μl of the extract or product under consideration. They were then glued on the undersurface of each of the three leaflets of a single alfalfa leaf and placed in a 16-dram transparent plastic vial (10 cm high, 4.5 cm diameter) fitted with plastic screening at one end to permit air circulation. After 15 min, to allow for solvent evaporation, five virgin 1-day-old males were introduced and observed for 30 min. Bioassays were carried out at 25°C, 65% relative humidity, and males were transferred to these conditions 15 min before being bioassayed. The number of attempted copulations and the total number of contacts with the treated cadavers were recorded. The frequency and intensity of wing vibration, a male–male behavior exhibited when males are in the presence of the female hexane extract (Carrière and McNeil, in press), was also noted. Time spent by males on the plant was recorded using an event

recorder (Richardson and McNeil, 1987). In each bioassay, dead 3-day-old virgin female and male cadavers treated with hexane were used as controls. Ten replicates for each treatment in the bioassay were carried out.

Isolation and Identification. Hexane extracts of male and female flies were initially analyzed on DB-1 (25 m × 0.25 mm) and Carbowax 20 M (15 m × 0.25 mm) capillary columns (J & W Scientific), using a Hewlett Packard 5890 gas chromatograph equipped with a flame-ionization detector. The column temperature program used was 80°C for 1 min, increased to 175°C at 28°/min, maintained at 175°C for 1.5 min, and then increased to a final temperature of 275°C, at 20°/min. The detector was at 300°C, the splitless injector temperature was 275°C, and the carrier gas (H_2) flow was maintained at ca. 1 ml/min.

Argentation chromatography of the behaviorally active female extract was performed on silver nitrate-coated Florisil 60/200 mesh (Applied Science Laboratories). The active component was isolated from the hexane fraction by preparative GC, using the same instruments and temperature program mentioned above.

The purified biologically active compound was identified by EI (70 eV) and CI (isobutane) GC-MS, using a DB-1 capillary column (60 m × 0.32 mm ID) in a Finnigan 4000E GC-MS, with an Incos 2300 data system. The initial temperature was 50°C, increasing at 25°C/min to 100°C, then increasing to 280°C at 4°/min; He carrier gas was used.

Synthesis of 3,7-Dimethylnonadecane (1). Compound 1 was synthesized in 38% overall yield from dodecyltriphenylphosphonium bromide 2, as shown in Figure 1. The compound was obtained as a mixture of four stereoisomers, which were not resolved by capillary GC on DB-1, DB-5, or DB-1701 columns; bp ~ 150°C (0.1 torr) by Kugelrohr distillation. [^{1}H]NMR (CDC13): 1.35–1.2 (m, 32H, methylenes), 1.1–1.0 (m, 2H, methines), 0.89–0.81 (m, 12H, methyls). MS: see Figure 2. Anal. calcd. for $C_{21}H_{44}$:C, 85.04; H, 14.96. Found: C, 84.98; H, 14.86.

RESULTS AND DISCUSSION

The hexane extract of females contained a compound, having a retention time of 9.38 min, that was absent in male extracts. The compound was obtained by argentation chromatography followed by preparative GC. Male's responses to the isolated fraction were the same as those elicited by the crude extract. The compound was then identified by a combination of GC and GC-MS techniques.

The highest mass ion in the EI mass spectrum was at *m/z* 296, for a possible molecular formula of $C_{21}H_{44}$, corresponding to a saturated hydrocarbon. The isobutane CI mass spectrum gave a strong peak at *m/z* 295 (M − 1), confirming the molecular weight. In addition, there was no M + 1 peak at *m/z* 297

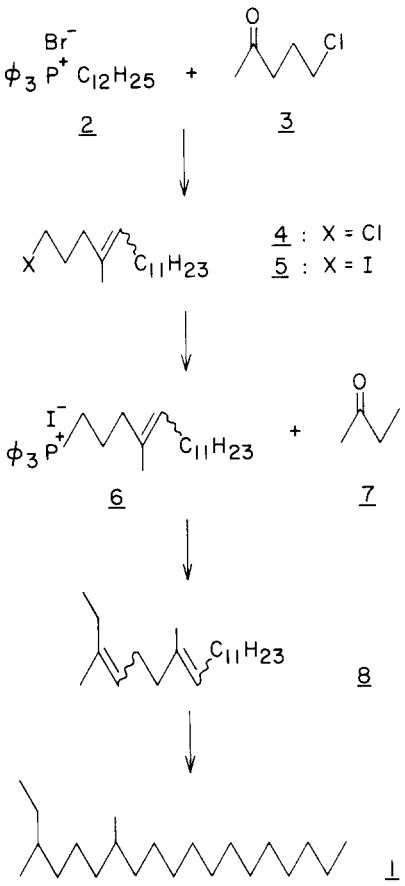

FIG. 1. Synthetic route to 3,7-dimethylnonadecane. Reaction conditions as follows: 2 → 4: i. *n*-BuLi, ether, −30°C; ii. 3, −78° →20°C. 4 → 5: NaI, acetone, reflux. 5 → 6: Ph_3P, 90°C. 6 → 8: i. *n*-BuLi, −30°C, THF; ii. 7, −78° → 20°C. 8 → 1: 5% Pd on carbon, H_2, hexane.

in the CI spectrum, confirming that the compound was a saturated hydrocarbon. The compound had a retention index relative to the *n*-alkanes of 2013 and 1994 on the DB-1 and Carbowax columns, respectively. This suggested a branched alkane.

Comparison of the EI spectrum of the unknown with that of the straight-chain C_{21} compound showed several fragments of enhanced intensity, indicative of cleavages at branch points. An ion of enhanced intensity at *m/z* 127 (Figure 2) indicated a cleavage into a C_9H_{19} and a $C_{12}H_{25}$ fragment, with the charge remaining on the C_9 fragment, thus locating the secondary carbonium ion from

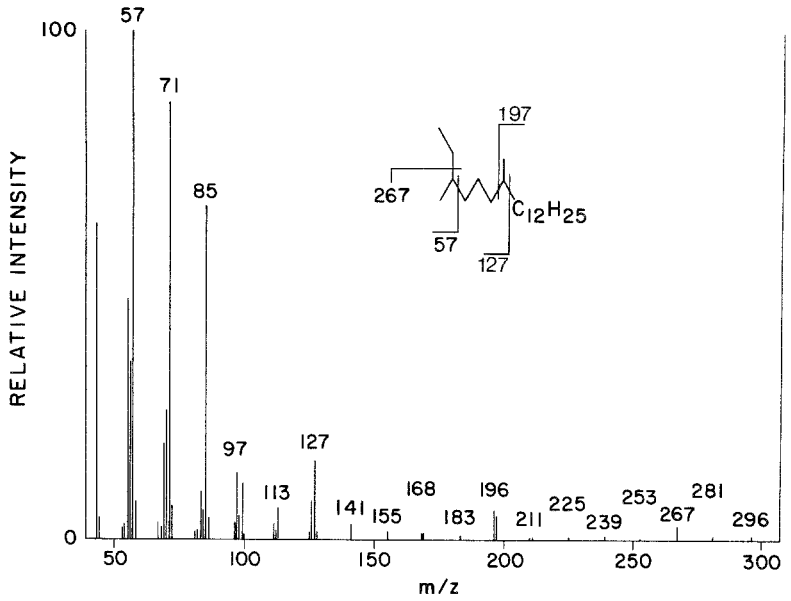

FIG. 2. EI mass spectrum of the behaviorally active compound found in *A. frontella* females.

the branch point cleavage on this fragment. Similarly, an enhanced ion at *m/z* 197 was indicative of a second cleavage into a C_7H_{15} and a $C_{14}H_{29}$ fragment, with the charge remaining on the C_{14} fragment. Taken together, the two sets of fragments indicate cleavage on either side of a methyl branch point, that is, a tertiary carbon substituted with a methyl group, a C_7 group, and a C_{12} group. The cleavage of the methyl group from this tertiary center is not favored, so only a very small ion at *m/z* 281 was seen.

There was also a slightly enhanced peak at *m/z* 267 (M-29), indicating a second branch point. This branch point was probably near one end of the alkyl chain, as would be found in a 3-methylalkane. If the ethyl branch were further along the chain, fragments of increased intensity from cleavages on the other two sides of the branch point would be expected: these were not seen. For a 3-methylalkane, an enhanced fragment at *m/z* 57 would be expected. However, as this ion is the base peak in the spectrum of the straight-chain hydrocarbon, it was impossible to tell whether this was the case.

From the above information, two possible structures were postulated, 3,12-dimethylnonadecane and 3,7-dimethylnonadecane, 1. The latter structure was favored due to consideration of possible biosynthetic pathways. That is, the 3,7-dimethyl fragment nicely fits the biosynthetic template of a head-to-tail fusion of two isoprene units.

On the strength of these observations, 3,7-dimethylnonadecane was synthesized as shown in Figure 1 and shown to have identical mass spectra (EI and CI) and retention times to the unknown compound. It should be noted that the synthetic material was a chromatographically inseparable mixture of four stereoisomers (two diastereomeric pairs of enantiomers), as there are two chiral centers in the molecule. The stereochemistry of the natural material is presently being investigated.

Male cadavers treated with 5 μl of the 3,7-dimethylnonadecane in hexane (17.6 ng/μl) elicited the same level of responses as either freshly killed 3-day-old virgin females or males treated with a female hexane extract, all of which were significantly higher than the responses to male cadavers treated with hexane only (Table 1). Males that had been treated with 88 ng of 3,7-dimethylnonadecane were soaked in 50 μl of hexane containing 127 ng of tetradecane as an internal standard. After 48 hr, extracts were analyzed by GC. Only 20 $\pm$ 5% of the 3,7-dimethylnonadecane was recovered, a loss undoubtedly due to runoff at the time of application. Three-day-old virgin females were weighed and their level of 3,7-dimethylnonadecane was determined using the same method as for males. The mean 3,7-dimethylnonadecane content per female was 54.1 $\pm$ 3.5 ng ($\pm$SEM; $N = 48$), with a positive correlation between female weight and the quantity of 3,7-dimethylnonadecane recovered ($R^2 = 0.25$, $F_{1,47} = 15.81$, $P = 0.001$). Thus, in bioassays, males had, $\sim$ 18 ng of 3,7-dimethylnonadecane, a quantity somewhat lower than levels found in 3-day-old virgin females.

To test that other cuticular chemicals, possibly present in both sexes of *A. frontella*, may be necessary together with 3,7-dimethylnonadecane to initiate male mating behavior, two concentrations (88 and 176 ng) of 3,7-dimethylnonadecane were applied to knots of black cotton. These knots were approximately the size of alfalfa blotch leafminer females and were tested using the standard bioassay technique. It is evident that while the time spent on the plants and the number of contacts with the treated knots (Table 2) were similar to values obtained when 88 ng of 3,7-dimethylnonadecane was applied to male cadavers (Table 1), the occurrence and intensity of males wing vibrating and especially the number of copulation attempts were lower. Furthermore, while there was a tendency for the behavioral responses to increase with a doubling of the concentration of 3,7-dimethylnonadecane, only the time spent on plant increased significantly (Table 2).

Based on the results obtained (Table 2), the possibility that other chemicals act synergistically at short range to influence the male mating behaviors cannot be ruled out. However, Carrière and McNeil (in press) presented evidence suggesting that while the female sex pheromone was important in bringing the male close to the female, there was also a short-range visual component involved in the mating behavior of *A. frontella*. It is therefore conceivable that the shape

of the knots did not sufficiently resemble an *A. frontella* adult to provide the correct visual stimulation, thus explaining the decrease in certain behaviors. It has been demonstrated for the crane fly *Tipula oleracea* that morphologic characteristics serve as one of the obligatory signals, in a stimulus–response behavioral reaction chain, for execution of male copulatory behavior (Stich, 1963; Matthews and Matthews, 1978). Furthermore, the necessity for the correct shape and size of the model to elicit male copulatory behavior has also been demonstrated for *Glossina morsitans morsitans* (Huyton et al., 1980). Another potential cause for the observed reductions in male copulatory response could be the absence of appropriate mechanical stimuli, given that the texture of the cotton knot is markedly different to the insect exoskeleton. However, regardless of the cause(s) of the reduction in certain parameters relating to male mating when artificial models were used, there is little doubt that 3,7-dimethylnonadecane is important in mediating mating behavior of *A. frontella* males.

SYNTHESIS OF CARRIER-FREE TRITIUM-LABELED QUEEN BEE PHEROMONE

FRANCIS X. WEBSTER[1] and GLENN D. PRESTWICH[2]

Department of Chemistry
State University of New York
Stony Brook, New York 11794-3400

(Received March 6, 1987; accepted May 27, 1987)

Abstract—A short synthesis of [4,5-$^3H_2$] (*E*)-9-oxo-2-decenoic acid (ODA), a high-specific-activity tritium-containing isotopomer of the queen bee pheromone, is described. Catalytic tritiation of the ketal of ethyl 9-oxo-4-decenoate introduces tritium into two positions, one of which is completely unactivated. Subsequent transformation by selenation, oxidation, and hydrolysis affords the labeled 9-ODA at >60 Ci/mmol. The material is suitable for biochemical studies of binding and catabolism in ovarian, antennal, and other target tissues.

Key Words—(*E*)-9-oxo-2-decenoic acid, tritium labeling, *Apis mellifera*, primer pheromone, radiosynthesis, Hymenoptera, Apidae.

INTRODUCTION

The chemical nature of the queen bee pheromone (Butler et al., 1961) and its dual role in the physiology of worker ovarian suppression (Butler, 1957; Butler and Gibbons, 1959) and in drone attraction (Gary, 1962) are well documented. Futhermore, the metabolic reduction of both the ketone and the alkene functionalities were reported two decades ago (Johnston et al., 1965). In stark contrast, there are no reported biochemical studies on the catabolic, transport, and receptor proteins which mediate the effects of this primer/sex pheromone on a

molecular level. The ^{14}C-labeled (*E*)-9-oxo-2-decenoic acid used by the Law group (Johnston et al., 1965) has too low a specific activity to detect proteins with submicromolar binding constants, and the tritiated material described by Butler et al. (1974) is unusable because the tritium is in exchangeable (enolizable) positions. We describe here a short radiosynthesis (Figure 1) of a high-specific-activity (>60 Ci/mmol) tritium-labeled queen bee pheromone isotopomer, in which at least one tritium atom is in an unactivated position.

METHODS AND MATERIALS

General. Anhydrous THF and ether were distilled from benzophenone ketyl. Flash chromatographic purifications were carried out on Woelm Silica 32–63 μm. TLC was performed using MN Polygram Sil G/UV 254 (4 x 8 cm) TLC plates. All products were homogeneous by TLC (R_fs are reported for 20% EtOAc–hexane). [^{1}H]NMR spectra were determined at 300 MHz on an NT-300 spectrometer or at 80 MHz on an CFT-20 instrument. Gas chromatography was carried out on a Varian 3700 equipped with a fused silica capillary column (DB-

5, 30 m x 0.263 mm). Radioactive samples were counted in an LKB 1218 RackBeta liquid scintillation counter using a PPO–POPOP–toluene or Scintiverse II scintillation cocktails. The efficiency for ^3H was 55–60%, as determined by an automatic external standardization ratio method.

Ethyl 2-carbethoxy-4, 9-decadienoate (I). Diethyl malonate (8.0 g, 50 mmol), triphenylphosphine (52.4 mg, 0.2 mmol), and palladium acetate (22.5 mg, 0.1 mmol) were heated while stirring until a homogeneous solution was obtained. This solution was transferred to a 50-ml stainless-steel bomb, butadiene (8.1 g, 150 mmol) was added, and the bomb was sealed and heated to 80° C for 16 hr. Distillation gave 10.32 g (77%) of the desired diene–diester I (Tsuji et al., 1977): bp 109–112°C/0.1 mm Hg.

Ethyl 2-carbethoxy-9-oxo-4-decenoate (II). A mixture of 2.97 g (30 mmol) of CuCl, 0.53 g (3 mmol) of $PdCl_2$, 1 ml of water, 8 ml of DMF, and 7.95 g (30 mmol) of the above malonate ester I were stirred under an atmosphere of oxygen for 30 hr. After this period, TLC indicated that the reaction was complete. The methyl ketone II (Tsuji et al., 1977) was isolated by distillation (bp 128–131°C/0.1 mm Hg) in 72% yield (5.86 g).

Ethyl 2-carbethoxy-9, 9-ethylenedioxy-4-decenoate (III). A 250-ml flask was charged with 5.52 g (20 mmol) of the methyl ketone II, 1.55 g (25 mmol) of ethylene glycol, and a catalytic amount of *p*-toluenesulfonic acid in 100 ml of benzene. The solution was heated under reflux with continuous removal of water for 4 hr. Usual work-up gave 5.12 g (80%) of the desired ketal which was used without purification.

Ethyl 9,9-ethylenedioxy-4-decenoate (IV). In 10 ml of 1 N KOH in MeOH was refluxed 3.18 g (10 mmol) of the ketal diester III for 1 hr. After cooling, the MeOH was evaporated, and the residue was dissolved in 10 ml of water. The aqueous solution was extracted with ether, acidified, and again extracted with ether. The ether solution containing the acid fraction was washed with brine, dried (Na_2SO_4), and evaporated. The oily residue was heated to 180°C in an oil bath under N_2 for 1 hr. The material was purified by flash chromatography on silica gel (Still et al., 1978) using 15% ethyl acetate–hexane. The unsaturated ketal ester IV was obtained in 52% yield (1.16 g): [^{1}H]NMR δ1.25 (t, J = 9 Hz, 3H), 1.31 (s, 3H), 1.46 (m, 2H), 1.61 (m, 2H), 2.00 (m, 2H), 2.36 (m, 4H), 3.92 (m, 4H), 4.24 (q, J = 9 Hz, 2H), 5.43 (m, 2H): [^{13}C]NMR δ15.2, 24.7, 24.8, 28.9, 33.5, 35.3, 39.5, 61.2, 65.5, 111.0, 129.3, 132.2, 174.1.

Ethyl [4,5-$^3H_2$]9,9-ethylenedioxydecanoate (V). The tritiation reaction was carried out at the National Tritium Labeling Facility at Lawrence Berkeley Laboratory. To 20 mg (0.078 mmol) of the unsaturated ketal ester IV in 3 ml of THF was suspended 7.1 mg of 10% Pd/C. The reaction was freeze–degassed and stirred for 1 hr under one atmosphere of carrier-free T_2 gas. The tritium gas and volatiles were removed *in vacuo* until the volume was reduced to 1 ml,

and then the solution was filtered and lyophilized. The residue was chromatographed on flash silica gel with 10% ethyl acetate–hexane to give homogeneous ketal ester V. This material was frozen in benzene and shipped to Stony Brook for futher transformations. All radiochemicals were kept cold ($< -10°C$) and stored below 500 mCi/ml in degassed, distilled 1:1 heptane–toluene to minimize radiolytic decomposition.

Ethyl [4,5-$^3H_2$]-9,9-ethylenedioxy-2-decenoate (VI). A solution of lithium isopropylcyclohexylamide (made from 16.9 mg, 0.12 mmol of isopropylcyclohexylamine, and 0.12 mmol of *n*-butyllithium in hexane) was prepared in 1 ml of dry THF and cooled to $-78°C$. To this stirred solution was added approximately 15 mg (0.06 mmol, 3.7 Ci) of the tritiated ketal ester in a minimum of THF. The solution was stirred for 30 min at $-78°C$ and quenched with 34.5 mg (0.18 mmol) of phenylselenenyl chloride. The reaction mixture was allowed to warm to room temperature and was treated with 50 μl of acetic acid and 250 μL of 30% H_2O_2. The mixture was stirred for an additional 45 min; the reaction was worked up and chromatographed on flash silica gel with 15% ethyl acetate–hexane to give 2.34 Ci (62%) of the unsaturated ester VI which was radiochemically pure by TLC.

(E)-[4,5-$^3H_2$]9-Oxo-2-decenoic acid (VII). The ketal ester was heated in 1 ml of 2 N methanolic KOH for 30 min. The MeOH was evaporated, and the residue was acidified with 2 ml of 6 N HCl. Five milliliters of ether were added and the two-phase solution was stirred overnight to cleave the ketal. The ether was separated, washed with brine, and dried to give 2.12 Ci of the "hot" queen bee substance. The material was only 90% pure by TLC of the derived methyl ester (from diazomethane). The material can be purified by converting to the methyl ester and purifying by flash chromatography on silica gel (15% ethyl acetate–hexane). The free acid is regenerated by heating with aqueous KOH for 30 min with continuous shaking. Acidification gives radiochemically pure acid.

RESULTS AND DISCUSSION

High-specific-activity, tritium-labeled pheromones are becoming an indispensable adjuvant in probing the biochemical machinery of pheromone transport, reception, and metabolism (Prestwich, 1987a,b; Prestwich et al., 1987a). Detailed insights have already been obtained in some Lepidopteran species, e.g., *Antheraea polyphemus* (Vogt *et al.*, 1985; Prestwich et al., 1986), *Heliothis virescens* (Ding and Prestwich, 1986), *Plutella xylostella* (Prestwich and Streinz, 1988), and *Lymantria dispar* (Prestwich et al., 1987b). To date, however, there have been no reports on studies involving proteins that mediate transport, reception, or metabolism of pheromones in the Hymenoptera. The

availability of tritium-labeled, high-specific-activity queen bee pheromone will allow us to begin these important biochemical studies in *Apis mellifera*.

The primary consideration in designing this synthesis was to allow for the incorporation of two tritons, at least one of which is nonexchangeable in aqueous solution and in positions that were unlikely to be initially metabolized. Thus, we felt that it was imperative to place the tritium atoms in the middle of the chain. For these reasons, we chose the unsaturated ketal IV as our target for tritiation.

The synthesis of IV was accomplished by modifying another queen bee pheromone synthesis (Tsuji et al., 1977). Palladium-catalyzed telomerization of butadiene with diethyl malonate has been reported previously (Hata et al., 1971). Oxidation of the terminal double bond to the corresponding methyl ketone was carried out in good yield using CuCl and catalytic $PdCl_2$ (Clement and Selwitz, 1964). The ketone moiety was protected as the ethylene ketal to avoid unwanted exchange during the tritiation reaction. Furthermore, protection of the ketone carbonyl was necessary during the ester–enolate formation to introduce the (*E*)-alkene. The synthesis of IV was completed by converting the substituted diethyl malonate to the half ester using one equivalent of KOH in methanol; acidification and decarboxylation gave the unsaturated ketal IV in moderate yield.

Reduction of the double bond in IV with carrier-free T_2 gas using 10% Pd/C as catalyst afforded material with a specific activity greater than the theoretical 58 Ci/mmol because of vinylic and allylic exchange reactions (cf. Evans et al., 1985) The conjugated *E*-double bond was introduced using a selenation–selenoxide elimination sequence (Sharpless et al, 1973). Saponification and acid catalyzed cleavage of the ketal gave material containing 10–15% of an impurity (estimated from TLC). The impurity apparently arises from saponification in alcoholic solvent. The pheromone can be purified by reesterification with diazomethane, flash chromatography, and saponification in aqueous KOH.

We are currently pursuing biochemical studies using this high-specific-activity pheromone isotopomer.

(Received February 19, 1987; accepted June 1, 1987)

Abstract—The alkanes (methylalkanes) were analyzed from both sexes of four members of the *palpalis* group of tsetse flies, *Glossina fuscipes fuscipes, G. palpalis gambiensis, G. palpalis palpalis, G. tachinoides* plus one *fusca* group member, *G. brevipalpis*, to determine structures, abundances, and the presence of unique or specific methylalkanes. These insects are unique in that trimethylalkanes were major components except in female *G. tachinoides* and both sexes of *G. brevipalpis* where 2-methylalkanes were the major components. The identification of novel long-chain tetramethylalkanes, including 11,15,19,23-tetramethylpentatriacontane, a minor component of female *G. f. fuscipes, G. p. gambiensis*, and *G. p. palpalis*, is reported here. Tetramethylalkanes were significant components of both sexes of *G. brevipalpis*. The major tetramethylalkane in *G. brevipalpis* is 3,7,11,15-tetramethylhentriacontane. The use of the methylalkanes as taxonomic indicators in tsetse is discussed.

Key Words—Cuticular hydrocarbons, alkanes, methylalkanes, trimethylalkanes, tetramethylalkanes, *Glossina* spp., Diptera, Glossinidae.

INTRODUCTION

The cuticular hydrocarbons of several species of tsetse flies have been investigated for their biological activity as sexual stimulants for males. In a previous study, only tsetse of the *morsitans* group were examined (Nelson and Carlson,

1986). Methylalkanes were identified by combined gas chromatography–mass spectrometry (GS-MS) in the surface lipids of three species of female tsetse flies, including several compounds that had new sequences of methyl branching with five or seven methylenes between the branch points of the trimethylalkanes. Sequences of 3,3-, 3,5-, 5,3- and 7,3-methylenes between adjacent methyl branch points were identified. There was some variation in isomeric composition of dimethyltritriacontane in female *G. pallidipes:* Those from England (laboratory reared), Kenya, Mozambique, and Zambia had 11,15-dimethyltritriacontane as the major 33B isomer, whereas females from Uganda and Zimbabwe had 13,21-dimethyltritriacontane as the major component of 33B.

Previously, tsetse fly females (*G. morsitans*) were shown to produce a trimethylalkane, 15,19,23-trimethylheptatriacontane, that stimulated the male to mate with a treated decoy, as did two less active dimethyl analogs, 15,19- and 17,21-dimethylheptatriacontane (Carlson et al., 1978). Synthetic 15,19-dimethyltritriacontane was stimulatory to male *G. austeni* (Huyton et al., 1980). Cuticular components were also implicated as sexual stimulants in *G. pallidipes* (Austen) (Langley et al., 1982) and *G. palpalis palpalis* Robineau-Desvoidy (Offor et al., 1981). Carlson et al. (1983, 1984) identified the active component of *G. pallidipes* as 13,23-dimethylpentatriacontane and confirmed the activity with the racemic synthetic compound, whereas McDowell et al. (1981) reported the aphrodisiac as a mixture of 13,17- and 15,19-dimethylpentatriacontane.

The species and subspecies of African *Glossina* are placed in three groups on the basis of morphological differences. The *palpalis* group consists of *G. caliginea* Austen, *G. tachinoides* Westwood, two subspecies of *palpalis* called *G. palpalis palpalis* and *G. palpalis gambiensis* Vanderplank; three subspecies of *fuscipes* called *G. fuscipes fuscipes* Newstead, *G. fuscipes martinii* Zumpt, and *G. fuscipes quanzensis* Pires; and two subspecies of *pallicera* called *G. pallicera pallicera* Bigot and *G. pallicera newsteadi* Austen. The *palpalis* group includes species that are the most important vectors of tsetse-borne diseases in West Africa, with the addition of *G. m. submorsitans*, the latter from the *morsitans* group that contains seven species and subspecies. The *fusca* group contains 14 more species and subspecies including *G. brevipalpis* Newstead (Dame, 1978).

Carlson (1982, 1983) reported that males of the *palpalis* group contained major alkanes that were unusual homologous methylalkanes with 27, 28, and/or 29 carbon backbones. These materials were not detected by GC in males of the *morsitans* group. Patterns of methylalkanes were shown to be species specific in other *palpalis* group females.

Some long-chain, methyl-branched hydrocarbons act as contact sexual stimulants in tsetse, and it appears that these materials are likely to be species specific. Therefore, we have examined the methylalkanes of four species of the

palpalis group of tsetse flies, *G. fuscipes fuscipes, G. palpalis gambiensis, G. palpalis palpalis*, and *G. tachinoides*, plus one *fusca* group member *G. brevipalpis*, to determine structures, abundances, and the presence of unique or specific methylalkanes. Several components could not be unequivocally identified from their mass spectra although suggested structures are indicated, but the spectra are included for the benefit of the reader and future investigators. The mass spectra of novel tetramethylalkanes have been included as well as mass spectra of trimethylalkanes from males.

METHODS AND MATERIALS

Samples for analysis were obtained as dried pinned specimens or as dried intact specimens shipped in capped vials. Neutral lipids from each sample were extracted in hexane and separated by liquid chromatography on silica gel, then argentation liquid and thin-layer chromatography to obtain the alkanes (Carlson et al., 1978). Further analysis and quantitation were conducted by temperature programmed capillary gas chromatography (CGC) on a 15-m × 0.23-mm ID column of DB-1 using a Nelson Analytical 3000 series data system (Carlson and Langley, 1986).

Most mass spectra (MS) were from pooled samples of several insects because of the larger quantities needed for packed column GC-MS. The EI-MS were obtained with a Varian/MAT SS-200 data system and a MAT 112S mass spectrometer coupled via a jet separator to a 3-m × 3.2-mm ID glass column of 3.5% OV-101 on 100–120 mesh Gas Chrom Q. The carrier gas was helium, and the temperature was programmed from 180° to 324°C at 2°/min. Scan time was 8 sec, and a new scan was started every 8.5 sec. Capillary GC-MS (CGC-MS) was conducted on a 12.5-m × 0.2-mm fused silica column coated with a 0.33-μm thick film of cross-linked methyl silicone using cool on-column injection without a splitter and ramping from 60° to 180°C at 28°/min. The temperature was then raised from 180° to 320°C at 3°/min. Scan time was 6 sec with 0.1 sec return. Separate GC runs were made to obtain the traces shown in Figure 1. The MS were interpreted as previously described (Carlson et al., 1984; Nelson and Sukkestad, 1970; Nelson et al., 1980, 1981; Nelson and Carlson, 1986).

RESULTS AND DISCUSSION

The CGC composition of alkanes from *G. f. fuscipes, G. p. palpalis, G. p. gambiensis, G. tachinoides*, and *G. brevipalpis* are presented in Figure 1 and tabulated in Table 1. An obvious feature is that the methylalkanes of the females consisted of longer chain-length components than did those of the males. The

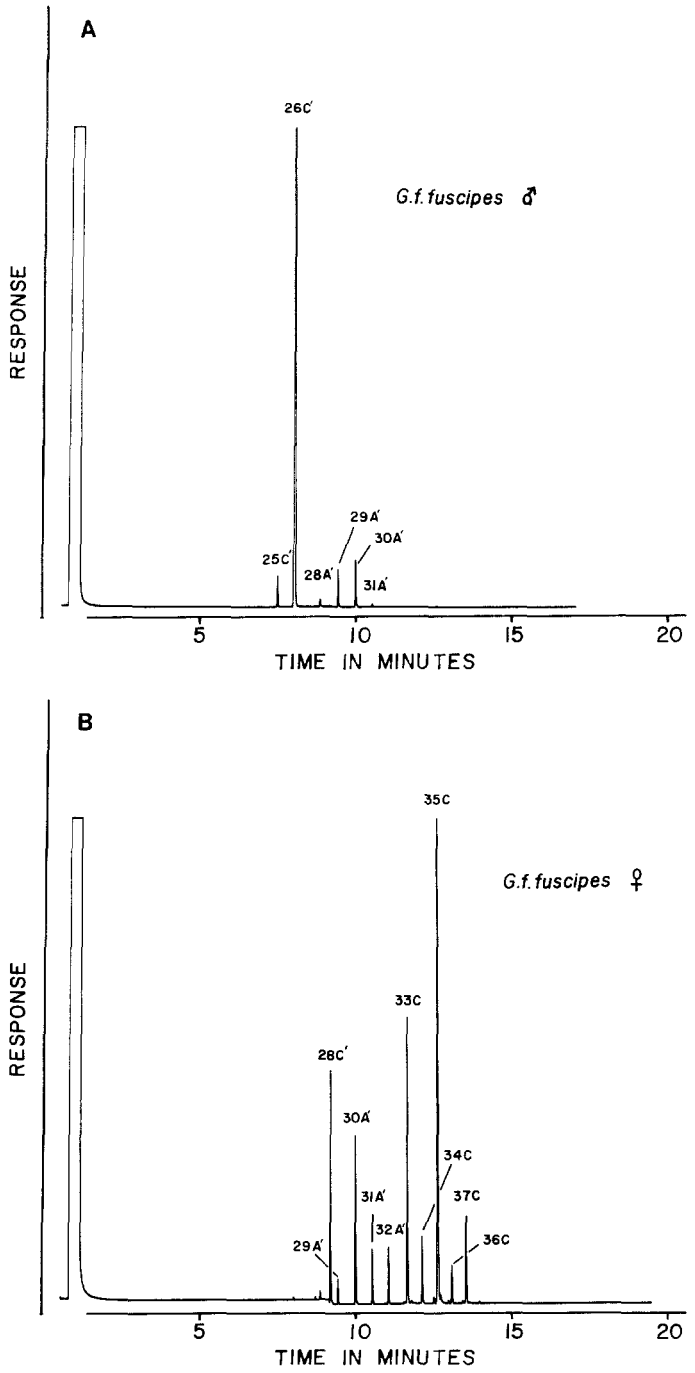

FIG. 1. (A–J) Capillary GC traces of methylalkanes from the surface lipids of male and female *G. f. fuscipes*, *G. p. gambiensis*, *G. p. palpalis*, *G. tachinoides*, and *G. brevipalpis*.

composition of each GC peak as determined by GC-MS or CGC-MS is tabulated in Table 2. The paraffins of these five species of tsetse flies are composed of methyl-branched alkanes, as *n*-alkanes are essentially absent. The GC peak number corresponds to the number of carbon atoms in the backbone of the methylalkane. The letters A, B, C, and D indicate one, two, three, and four methyl branches, respectively. The "prime" symbol indicates that one of the branches is near the end of the carbon chain, i.e., on carbon 2, 3, or 4. Generally, the closer a methyl branch is located to the end of the carbon chain, the slower the compound elutes, except that 2- and 4-methylalkanes elute together and before a 3-methylalkane (Mold et al., 1966; Nelson et al., 1981). This is also the situation when additional internal branches are present, as 4,8,12-trimethyloctacosane elutes earlier and is partially resolved from 3,7,11-trimethyloctacosane even on a packed column. In general, a mixture of different methylalkanes (plus *n*-alkane standards) elutes from a packed column in the following order: (31), 31A, 31A′ and 31B, 31C, 31D, 31B′ and (32), 31C′, 32A, 31D′. The components in 31A′ plus 31B may or may not separate, depending on the isomers present. GC peak 31B′ elutes at nearly the same time as 32-carbon *n*-alkane. Also, it is unlikely that 32A would be resolved from 31C′. Fortunately, all types of methylalkanes are not present in any one sample, and *n*-alkanes are virtually absent from the tsetse flies examined here, making interpretation of the mass spectra possible.

The methylalkanes mainly consisted of homologous series of 2-methylalkanes, and internally branched di-, tri-, and tetramethylalkanes. Few internally branched monomethylalkanes were present. Unique to these insects, except *G. tachinoides*, was the presence of significant amounts of tetramethylalkanes. Male tsetse of the *palpalis* group have a simpler methylalkane composition than the females [a similar sex difference was found in *morsitans* (Nelson and Carlson, 1986)]. Branched alkanes ranged in size from 28 carbons (25C′) to 35 carbons (33B) in males, and from 28 carbons (25C′) to 42 carbons (39C) in females.

The MS of the monomethylalkanes are readily interpreted and are not illustrated here. In those instances where 3-methylalkanes were found, they were only present as a trace component of the 2-methylalkane GC peak.

Dimethylalkanes from Female G. tachinoides *and* G. F. fuscipes. Dimethylalkanes were identified which had 3, 7, 9, or 11 methylenes between the branch points. The longest series of internally branched dimethylalkanes was found in female *G. tachinoides*. Because this series exhibited unusual variation in the separation of the methyl branch points, and because this insect was the only one in this study to have a significant amount of dimethylalkanes, the data are presented here in detail. The shorter-chain dimethylalkanes, 29B through 35B, had nine methylenes between the branch points except that GC peak 33B, a minor component, was a mixture of the isomers 11,15- and 11,21-dimethyl-

tritriacontanes with three and nine methylenes between the branch points, respectively (Figure 2A). This was the only three-methylene interrupted dimethylalkane found in *G. tachinoides*. The mass spectrum of 35B was due to a mixture of two nine-methylene interrupted isomers, 11,21- and 13,23-dimethylpentatriacontanes (Figure 2B).

GC peak 36B was composed of 12,22- and 13,23-dimethylhexatriacontanes (Figure 2C). Although the intensity of *m/z* 210 from the 13,23 isomer seems too small relative to the intensity of *m/z* 196, it must be kept in mind that the intensity of *m/z* 196 is increased by the 14-carbon primary ion from the 12,22 isomer. A small amount of a 10,20 isomer is supported by the ions at *m/z* 309 and 407, although there is no ion of significant intensity at *m/z* 252 as expected for this isomer. The ion at *m/z* 168 is derived from the 13,23 isomer rather than from an 11,21 isomer. Expected ions of significant intensity for an 11,21 isomer at *m/z* 393 and 323 are not present.

The MS of the major peak, GC peak 37B, from female *G. tachinoides* were interpreted as consisting of two major isomers with 11 methylenes between the branch points, 11,23- and the symmetrical 13,25-dimethylheptatriacontanes, in the ratio of 1.4:1 (Figure 2D). The correlation of the fragmentations with the diagnostic ions of major intensity is obvious. However, the ions of low intensity at *m/z* 252 and 323 indicated that a third isomer must be present, i.e., the 11,21 isomer is compatible with the mass spectrum.

[d]GC peak 32D′.
[e]GC peak 33D + 33D′.
[f]0.5% of trailing peak (KI 3790 = 37D).

The rationale for the interpretation of the MS of GC peak 38B (Figure 2E) was similar to that used above for GC peak 37B. The mass spectrum of GC peak 38 B corresponded to that of a mixture of 12,22- and 12,24-dimethyloctatriacontanes. The low intensity of the ions at *m/z* 252 and 337 relative to those at 182 and 407 indicated that two isomers must be present with the first methyl branch on carbon 12. The minor 12,24 isomer accounts for the intensity of ions at *m/z* 182 and 407 and for those at *m/z* 224 and 365. A comparison of the intensities of the ions at *m/z* 337 and 365 indicates that about twice as much of the 11-methylene interrupted isomer is present as the nine-methylene interrupted isomer. This is almost an exact reversal of isomer ratios as is observed in the MS of GC peak 36B (Figure 2C). The ion at *m/z* 196 is mainly from the 12,24 isomer rather than from a 13,?? isomer because no ion of significant intensity is present at *m/z* 393.

GC peak 39B from female *G. tachinoides* was concluded to be a mixture of dimethylisomers with nine and 13 methylenes between the branch points; 11,25- and 13,23-dimethylnonatriacontanes (Figure 2F). GC peak 39B was only a minor component of the methyalkanes, and good MS without column bleed could not be obtained. Initial inspection of the mass spectrum leads to the conclusion that the major (keeping in mind that the straight-chain tail of the isomer yielding the secondary ion at *m/z* 196 contributes to the intensity of the

[a] Plus and minus signs indicate the presence or absence of each isomer, as determined by GC-MS. Although listed separately, the A′ and B components usually elute as an unresolved GC peak. A string of minuses and/or a blank space means that no GC peak was observed. A "t" means that a trace amount was identified. A question mark means that that particular isomer was not positively identified. A "t?" means that a trace amount of a component was indicated on GC-MS but identification was not possible nor was confirmation that it belongs to the indicated series.

[b] A novel branching sequence is proposed.

ion at *m/z* 168) isomer is nine-methylene interrupted 13,23-dimethylnonatriacontane. However, the entire mass spectrum cannot be interpreted using this structure unless the second isomer is a 13-methylene interrupted dimethylalkane. In this study, the only species with nine- or 11-methylene interrupted dimethylalkanes were female *G. tachinoides*, and now it appears they also have

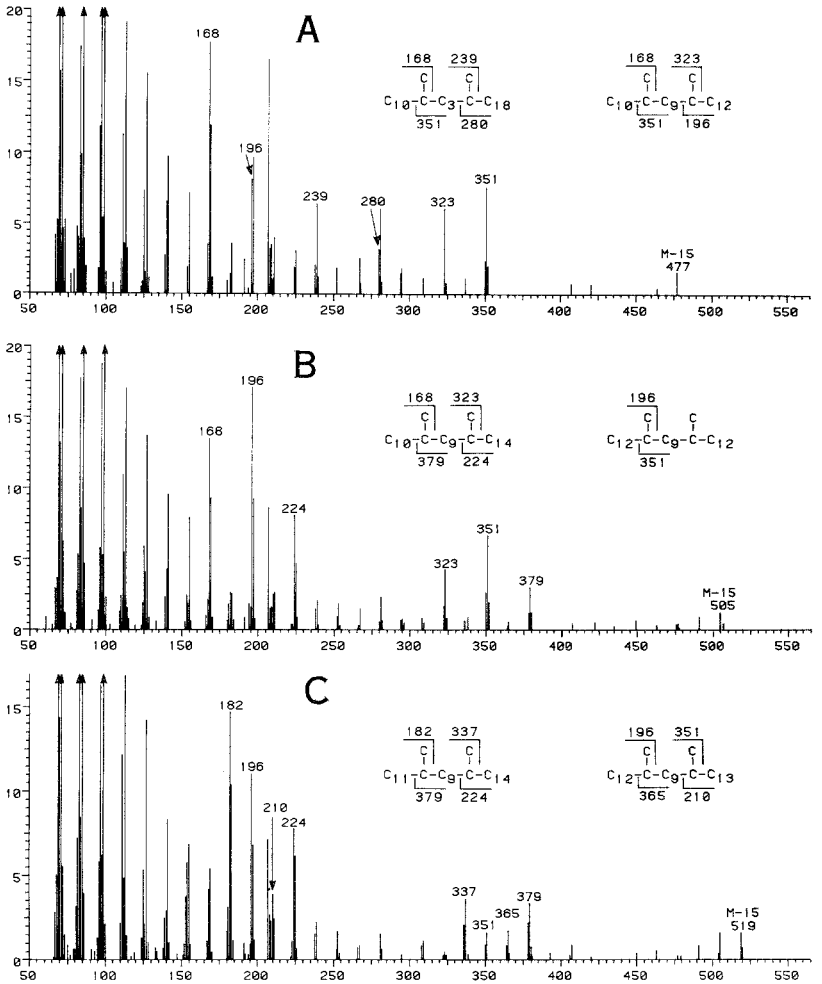

FIG. 2. CGC-MS spectra of dimethylalkanes from female *G. tachinoides*. (A) CGC peak 33B, 11,15- and 11,21-dimethyltritriacontanes; (B) CGC peak 35B, 11,21- and 13,23-dimethylpentatriacontanes; (C) CGC peak 36B, mainly 12,22- and 13,23-dimethylhexatriacontanes; (D) CGC peak 37B, 11,21-, 11,23-, and 13,25-dimethylheptatriacontanes; (E) CGC peak 38B, 12,22- and 12,24-dimethyloctatriacontanes; and (F) CGC peak 39B, 11,25- and 13,23-dimethylnonatriacontanes.

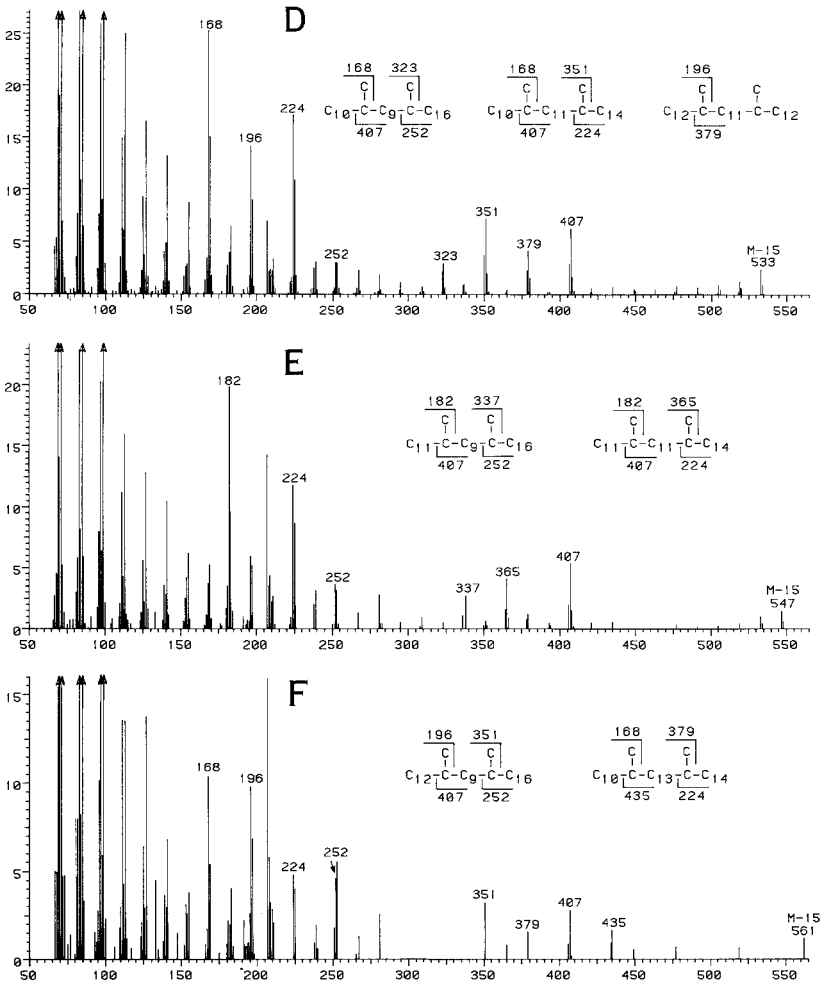

FIG. 2. Continued.

a 13-methylene interrupted dimethylalkane. How the biosynthetic mechanisms go from adding four two-carbon units before the second methyl branch is added in 35B, to adding six two-carbon units before the second methyl branch is added in 39B is an intriguing question.

GC peak 35B was of significant intensity only in female *G. tachinoides*. However, we were able to identify this peak in female *G. f. fuscipes* as being a mixture of 11,19- and 13,21-dimethylpentatriacontanes with seven methylenes between the branch points. The only other dimethylalkanes in female *G. f. fuscipes* were three-methylene interrupted (GC peak 36B) and seven-methylene interrupted (GC peak 37B).

Trimethylalkanes in Females. The methylalkane composition of the females was more complex and included longer chain length components than were present in the males. The major component in female *G. fuscipes, G. palpalis*, and *G. p. gambiensis* was GC peak 35C. The MS were similar for the three species and were interrupted as being a 1.4:1 mixture of 11,15,19- and 13,17,21-trimethylpentatriacontanes (Figure 3A). These isomers have a 3,3 sequence of methyl branching, and neither isomer is symmetrical. On the other hand, GC peak 35C was not identified in female *G. tachinoides*, although the CGC trace (Figure 1G) indicates that a trace amount may be present. The major components in female *G. tachinoides* were GC peaks 30A′ and 37B.

The occurrence of trimethylalkanes in which the number of methylenes between the first and second branch points was different from the number of methylenes between the second and third branch points was first described in *G. pallidipes* and *G. austeni* (Nelson and Carlson, 1986). In the present study, similar variations in branching sequences were not as obvious but may exist

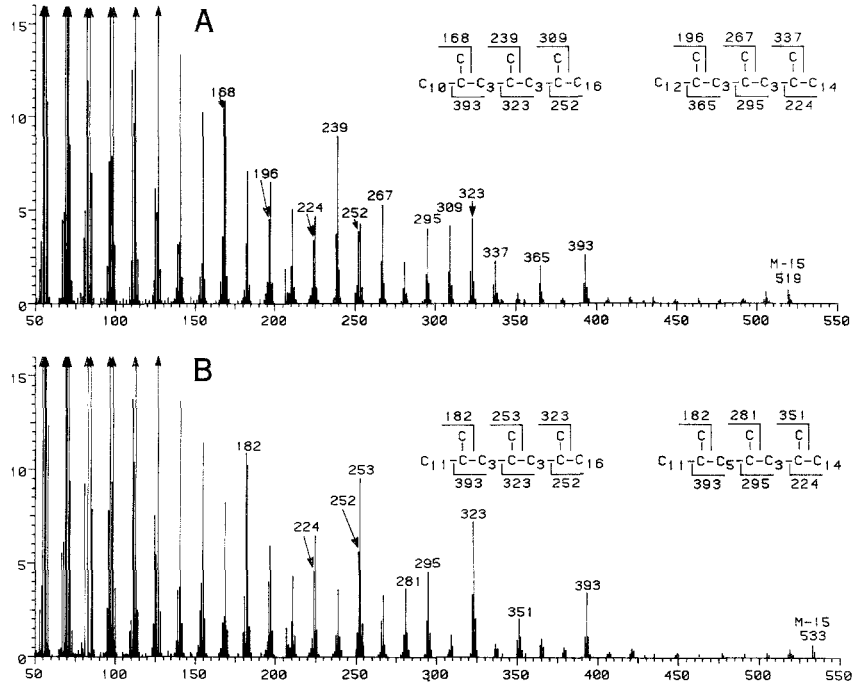

FIG. 3. GC-MS spectra of trimethylalkanes from female. (A) CGC peak 35C, from female *G. p. gambiensis*, 11,15,19- and 13,17,21-trimethylpentatriacontanes; (B) CGC peak 36C from female *G. p. palpalis*, predominantly 12,16,20-trimethylhexatriacontane; (C) GC peak 37C from *G. p. gambiensis*, predominatly 13,17,21-trimethylheptatriacontane; (D) CGC peak 37C from *G. p. palpalis*, a mixture with 11,15,21-, 11,17.21-, and 13,19,23-trimethylheptatriacontanes.

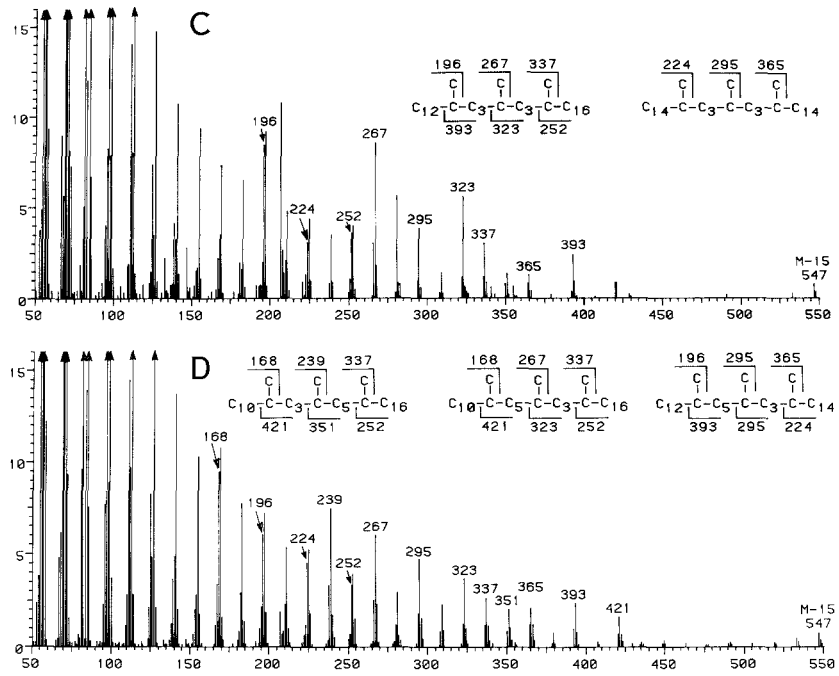

FIG. 3. Continued.

among the components of GC peaks 36C and 37C from female *G. f. fuscipes*, *G. p. palpalis*, and *G. gambiensis*. The MS of GC peaks 36C and 37C were similar for all three species.

The problem was to determine the positions of the methyl branches from the MS of a mixture of isomers. The major isomer in GC peak 36C was clearly 12,16,20-trimethylhexatriacontane (Figure 3B). However, the increased intensity of the ions at *m/z* 224, 281, 295, and 351 indicated that a second isomer was present. The lack of diagnostic ions at *m/z* 239, 309, 337, and 379 eliminated the 13,17,21 isomer from consideration, and the lack of diagnostic ions at *m/z* 210 and 365 ruled out the 14,18,22 isomer. We concluded that the second isomer could be 12,18,22-trimethylhexatriacontane with a 5,3 sequence of methyl branching.

The major isomer in GC peak 37C from female *G. gambiensis* was clearly 13,17,21-trimethylheptatriacontane (Figure 3C) with a 3,3 sequence of methyl branches. A second isomer is indicated by the ions at *m/z* 224, 295, and 365. These ions could be accounted for by the symmetrical 15,19,23 isomer. In addition, the less intense ions at *m/z* 168 and 421 show the presence of an 11,??,?? isomer. The low intensity of the ions at *m/z* 280 and 309 indicated

that the third methyl branch is not on carbon 19 as would be expected for a 3,3 branching sequence. However, the ions at *m/z* 239 and 351 indicate the second methyl branch may be on carbon 15.

GC peaks 37C from female *G. f. fuscipes* and *G. p. palpalis* had similar MS (Figure 3D) but were different to the MS of GC peak 37C from female *G. p. gambiensis* (Figure 3C). An isomer with a 3,3 branching sequence in these two species could not be clearly identified from the MS in Figure 3D. The ions at *m/z* 168/169 and 421 show the presence of an isomer with the first methyl branch on carbon 11, and the ions at *m/z* 239 and 351 establish a second methyl branch on carbon 15, and the ions at *m/z* 267 and 323 establish a second methyl branch on carbon 17. The low intensity of the ions at *m/z* 280 and 309 showed that a third methyl branch is not on carbon 19. Possible structures are 11,15,21-trimethylheptatriacontane with a 3,5 branching sequence and 11,17,21-trimethylheptatriacontane with a 5,3 branching sequence. The diagnostic ions at *m/z* 196, 224, 295, 365, and 393 could be accounted for by the presence of a third isomer, 13,19,23-trimethylheptatriacontane, with a 5,3 branching sequence. Considering the relative intensities of the ions, these three isomers could account for the diagnostic ions in the mass spectrum. However, the possibility of other isomers forming this spectrum or contributing to it cannot be ruled out.

Trimethylalkanes in Males. Males usually have simpler methylalkane composition and structures than females, but sometimes have higher alkanes of female origin from physical contact. Males of the *palpalis* group differ from other tsetse males because of the predominance of trimethylalkanes rather than 2-methylalkanes. The male methylalkanes ranged in size from 28 total carbons (25C′) to 35 carbons (33B) (compared to 28 carbons (25C′) to 42 carbons (39C) in females). The major methylalkanes in male *G. f. fuscipes* were 4,8,12-trimethylhexacosane (26%) and 4,8,12-trimethyloctacosane (31%). The major methylalkanes were 4,8,12-trimethylhexacosane (Figure 4A) and 2-methylnonacosane in male *G. p. palpalis*, 41% and 22%, respectively, and in male *G. p. gambiensis*, 37% and 22%, respectively. The major component (38%) in male *G. tachinoides* was 4,8,12-trimethyloctacosane.

Interestingly, the major trimethylalkane in males all had even-numbered backbones and the first methyl branch on carbon 4. Trimethylalkane with odd-numbered backbones had the first methyl branch on carbon 3, i.e., 3,7,11-trimethylheptacosane from male *G. tachinoides* (Figure 4B). However, in male *G. f. fuscipes*, the odd-numbered backbone trimethylalkanes, 25C′ and 27C′, had both isomers present, resolved by GC-MS, in which the first methyl branch occured on carbons 4 and 3 (Table 2).

Tetramethylalkanes. The tetramethylalkanes with branch sequences starting near the end of the molecule elute at about the same time as the internally branched dimethylalkanes with a backbone one carbon longer, i.e., 31D′ elutes

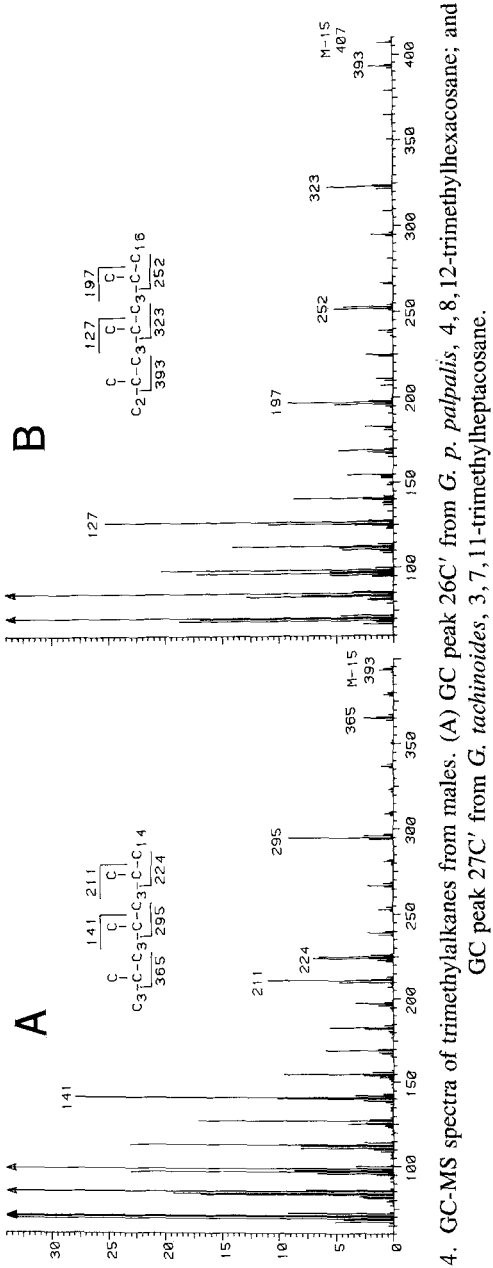

FIG. 4. GC-MS spectra of trimethylalkanes from males. (A) GC peak 26C′ from *G. p. palpalis*, 4, 8, 12-trimethylhexacosane; and (B) GC peak 27C′ from *G. tachinoides*, 3, 7, 11-trimethylheptacosane.

near 32A′ [Kovats index (KI) 3265, see Table 1], whereas 31D (KI 3190) elutes near the 32-carbon *n*-alkane. The presence of tetramethylalkanes in this group of insects made them unique. They were present only in females of *G. f. fuscipes*, *G. p. palpalis*, and *G. gambiensis* and were not identified in *G. tachinoides*, or in flies of the *morsitans* group in our previous study (Nelson and Carlson, 1986). Tetramethylalkanes were minor components except in *G. brevipalpis* where they were present in significant amounts in both sexes; the female having 31D′, 32D′, and 33D and the male, 31D′ and 32D′.

The smallest tetramethylalkane found in this study was 31D′, 3,7,11,15-tetramethylhentriacontane from both male and female *G. brevipalpis* (Figure 5A and Table 2). The ion at *m/z* 421 is from coeluting 2-methyldotriacontane present at about 20% of 31D′. Those tetramethylalkanes with an even number of carbons in the backbone had the first branch point on an even-numbered carbon, either 4 or 8 (Table 2). The mass spectrum (Figure 5B) of 4,8,12,16-tetramethyldotriacontane (32D′) depicts the fragmentation obtained. The *n*-propyl end of the molecule forms a diagnostic ion at *m/z* 463 (M-43). Cleavage internal to the first branch point to give the 5-carbon secondary ion did not increase the intensity of the ion at *m/z* 70, relative to those at *m/z* 69 and 71, to make it of diagnostic value.

In contrast to *G. brevipalpis*, the tetramethylalkanes from the other *palpalis* species were internally branched. For example, 35D, 11,15,19,23-tetramethylpentatriacontane (Figure 5C), and 35D, 7,11,15,19-tetramethylpentatriacontane (Figure 5D) were identified from sequential mass spectra recorded 8 sec apart and were found in female *G. p. palpalis* as a single peak. Although GC peak 35D was the major tetramethylalkane, it was only a minor component of the total methylalkanes. Interestingly, these compounds were homologs of trimethylalkanes and also characteristically contained three-methylene interrupted branch points.

Use of GC Composition for Species/Sex Identification. After identification of components from their mass spectra, it is intriguing to look for unique or characteristic components in each species and to correlate them with GC peak intensities (Table 1). The percent composition values are averages of two to five chromatograms of individual insects and so do not exactly match the gas chromatographic traces (Figure 1). Males of the two *G. palpalis* subspecies, *G. p. palpalis* and *G. p. gambiensis*, were distinguished by their 26C′ major peaks (KI 2720), which also appeared as the major component in *G. f. fuscipes* but were absent in *G. tachinoides*. There were traces of 27C′, 32A′, and 33A′ in *G. p. palpalis* that were undetectable in *G. p. gambiensis*; these are markers that separate the two *palpalis* subspecies. Both *G. f. fuscipes* and *G. tachinoides* males had major amounts of 28C′, which distinguished them from the two *palpalis* subspecies that contained only trace quantities. The absence of 26C′ in male *G. tachinoides* was sufficient to separate them from the other three *palpalis* group males and was noted earlier (Carlson, 1983).

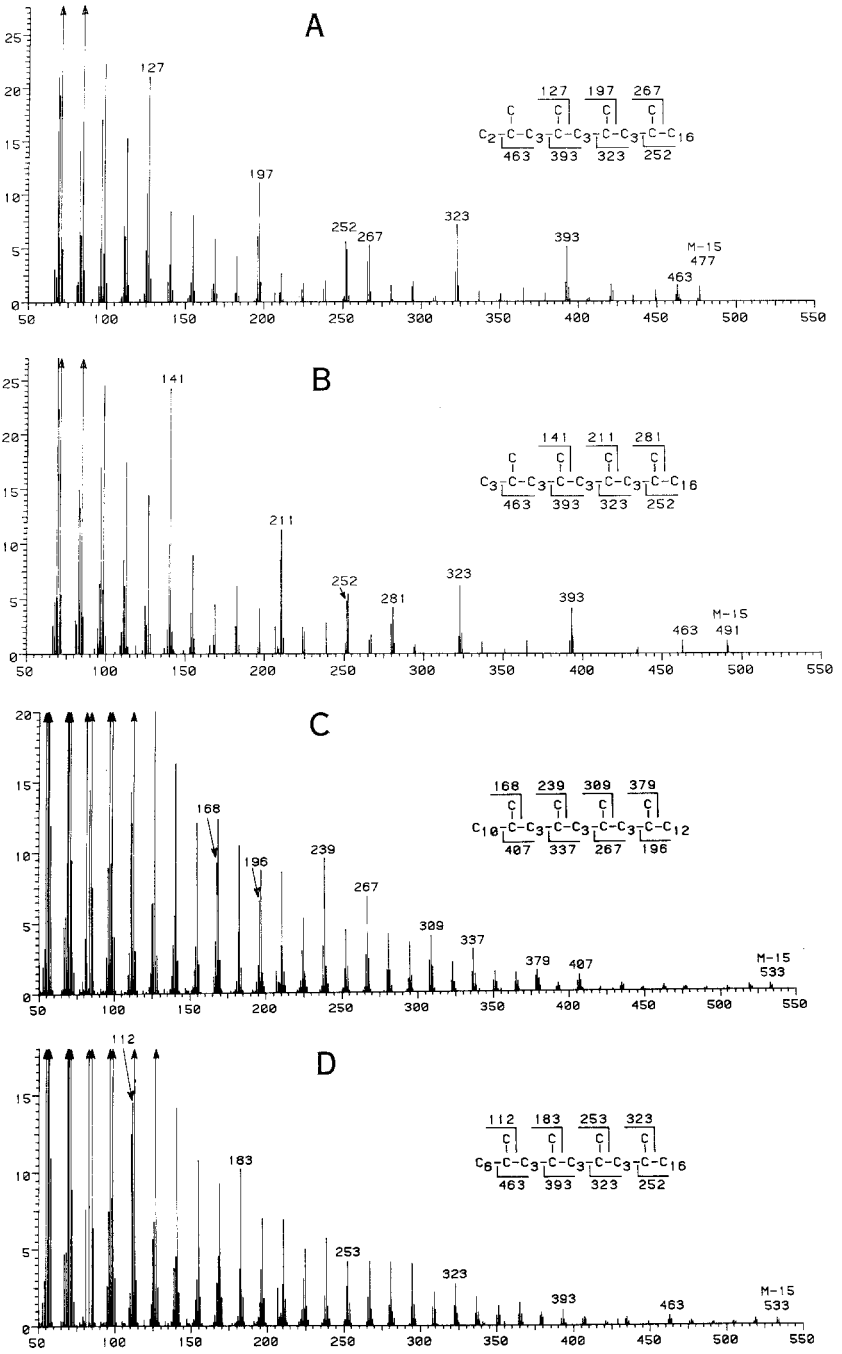

FIG. 5. CGC-MS spectra of tetramethylalkanes from females. (A) CGC peak 31D′ from *G. brevipalpis*, 3,7,11,15-tetramethylhentriacontane; (B) GC peak 32D′ from *G. brevipalpis*, 4,8,12,16-tetramethyldotriacontane; (C) GC peak 35D from *G. p. palpalis*, 11,15,19,23-tetramethylpentatriacontane; and a later scan from GC peak 35D, 7,11,15,19-tetramethylpentatriacontane.

The *G. f. fuscipes* females were readily distinguished from those of the *palpalis* subspecies by the smaller 33A′, 35D, 36C, and 37C peaks, whereas the *G. p. palpalis* and *G. p. gambiensis* females differed from each other by the presence of nearly equal quantities of 33A′ and 33C in the former and the lack of 33C and 34C in the latter. Also, *G. p. gambiensis* and *G. p. palpalis* were conspicuously different from *G. f. fuscipes* because of a very small 30A′ peak compared to a medium 30A′ peak in *G. f. fuscipes*, while all three had large 35C peaks. The *G. tachinoides* female profile was different from the other three species in this group because of its large 30A′, very small 31A′, conspicuous lack of major trimethylalkanes of 35C, 36C, and 37C, and large 37B.

Variation in the separation of the methyl branch points has been observed in dimethylalkanes of the Japanese beetle, *Popillia japonica* (Nelson, et al., 1977), and in the housefly, *Musca domestica* (Nelson, et al., 1981), with the transition occurring about 31B to 33B. However, the methylalkanes smaller than 31B always had the methyl branch points separated by three methylenes, and those larger than 33B had the methyl branch points separated by seven or nine methylenes. In *G. pallidipes* females, the smaller dimethylalkanes were variable (Nelson and Carlson, 1986) as GC peak 25B was a mixture of 11,15- and 5,13-dimethylpentacosanes (this was indicated incorrectly in Table 2 in that paper), 26B was 11,15-dimethylhexacosane, 27B was a mixture of 11,15- and 5,15-dimethylheptacosanes, 29B was 7,17-dimethylnonacosane, and 30B was 10,14-dimethyltriacontane.

Dimethylalkanes with 11 methylenes between the branch points have been reported in *Lasioderma serricorne* (Baker et al., 1979); *Zootermopsis augusticollis* (Blomquist et al., 1979), *Trichopsenius frosti* and *Reticulitermes flavipes* (Howard et al., 1980), *Onymacris marginipennis* (Breme) (Lockey, 1982), *Iridomyrmex nitidiceps* (Brophy et al., 1983), *Oncopeltus fasciatus* (Jackson, 1983), *Melanoplus packardii* and *M. sanguinipes* (Nelson et al., 1984), *Sitophilus zeamais* (Baker et al., 1984), *Cylindrocopturus adspersus* (LeConte) (Pomonis and Hakk, 1984), *Renatiella scrobipennis* (Lockey, 1984), *Periplaneta americana* (Lockey and Dularay, 1986); and 13-methylene interrupted dimethylalkanes have been identified in *O. fasciatus* (Jackson, 1983), *R. scrobipennis* (Lockey, 1984), and in the maize weevil, *S. oryzae* (Baker et al., 1984).

It will be an interesting study to elucidate the biosynthetic mechanisms involved in controlling the separation of the branch points as the chain length increases and how these mechanisms vary between species and orders. These insects synthesize major amounts of trimethylalkanes and the unique tetramethylalkanes from their only food source, animal blood. Langley and Carlson (1983) showed that succinate was incorporated into the methylalkanes of *G. morsitans* by the abdominal cuticle. The fact that di- and trimethylalkanes are known sex pheromones in several species of tsetse make further study of these insects worthwhile, especially since it appears that the 35C peak contains the

major sex pheromone components of *G. p. palpalis* and *G. p. gambiensis* (D.A. Carlson, submitted). Also, it is tempting to suggest that the unusual 37B components in *G. tachinoides* may comprise the sex stimulant pheromone in this species. Either 13,25- or 11,23-dimethylheptatriacontane might be biologically active. The former structure is symmetrical, a type of structure previously shown to be active in *G. morsitans* and *G. pallidipes*. Particularly interesting in this regard are the novel, potentially synergistic, potentially bioactive, tetramethylalkanes.

(Received March 17, 1987; accepted June 1, 1987)

Abstract—The maize-derived secondary chemical 6-methyoxybenzoxazolinone (MBOA) and a tritiated derivative were prepared synthetically for a detailed examination of their toxicity and toxicokinetics in the European corn borer (ECB), *Ostrinia nubilalis*. During feeding trials with MBOA incorporated into meridic diets (at 0, 0.5, 1.5, 2.5, and 4.0 mg/g diet), the mean time to pupation and adult emergence was significantly lengthened at concentrations of 1.5 mg MBOA/g diet and above. Increased mortality occurred at concentrations at 1.5 mg/g and above. A decrease in the sex ratio (female/total) and fecundity was observed at concentrations of 0.5 mg/g and above. The latter observations represent new biological effects related to MBOA. In tracer studies, both uptake and excretion of MBOA administered in diets to larvae increased linearly with concentration. Body burden values indicated that the ECB larvae were capable of excreting enough compound to maintain total tissue levels at approximately 50% of the dietary concentration. Total amount of label increased with larval stage, but decreased in adults due to a large amount of label eliminated in the pupal case. In topical application studies, elimination of the label in the frass was rapid, reaching 60% by 6 hr and 82% of applied dose by 24 hr. Accumulation of label in tissues other than hemolymph was small. The results show that MBOA is toxic to ECB, but the insect has efficient methods for minimizing these effects.

Key Words—MBOA, tritiated MBOA, 6-methoxybenzoxazolinone, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, European corn borer, toxicokinetics, life-cycle parameters, body burden values, topical application, corn, maize, feeding resistance.

INTRODUCTION

Leaf feeding resistance to the ECB (European corn borer, *Ostrinia nubilalis*) in some corn genotypes (*Zea mays*) has been strongly correlated with levels of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) present in the whorl of the corn plant (Klun and Brindley, 1966; Klun et al., 1967, 1970; Reed et al., 1972; Robinson et al., 1982). Development of inbred lines with high levels of DIMBOA has provided one of the principal means of control of the ECB (Lynch, 1980). Its glucoside form is present in uninjured corn tissue. Injury to the plant tissue, as would occur during larval feeding, results in the enzymatic conversion of the glucoside (1) to the aglycone, DIMBOA (2), by the hydrolytic enzyme β-glucosidase (Figure 1). DIMBOA decomposes in a reaction which is pH and temperature dependent (Woodward et al., 1978a; Perez and Niemeyer, 1986), through intermediates 3 and 4, to yield 6-MBOA (5) (6-methoxybenzoxazolinone) and formic acid (6). As the pH of the reacting medium is lowered, there is a decrease in the yield of MBOA from DIMBOA which has been attributed to the conversion of intermediate 3 to intermediates 7 and 8, resulting in the formation of 3,4-dihydroxy-7-methoxy-1,4-benzoxazin-2-one (9) (an isomer of DIMBOA) (Figure 1) (Bravo and Niemeyer, 1986).

DIMBOA and other hydroxamic acids (HA), present in several species of Poceae (Graminae), have been shown to play a role in the defense of the plants against several other insect species (Long et al., 1975; Argandoña et al., 1980, 1981), fungi (Long et al., 1975), and bacteria (Woodward et al., 1978b). DIMBOA, at concentrations corresponding to levels in resistant cultivars of maize

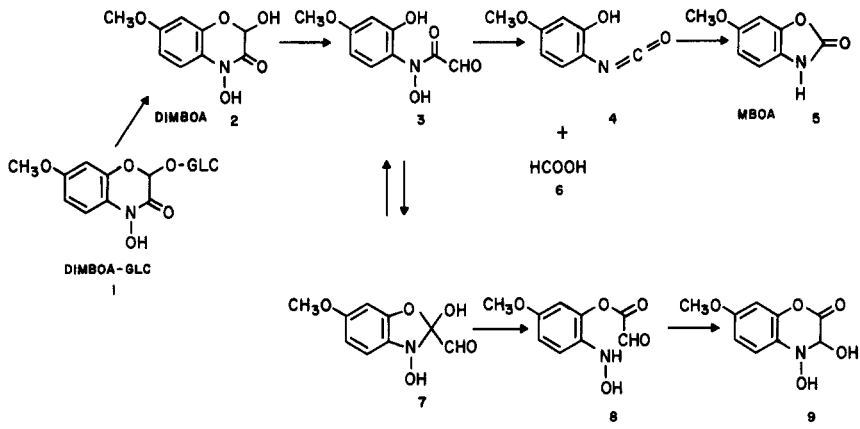

FIG. 1. Chemical degradation of DIMBOA-Glc. (Adapted from Bravo and Niemeyer, 1986.)

and wheat, reduce the rate of larval development of aphids (Corcuera et al., 1982) and greenbugs (Argandoña et al., 1983), as well as of ECB (Robinson et al., 1982). The reproductive capabilities of these adults is reduced, since the number of egg masses produced is lower. In addition, DIMBOA has also been shown to act as a feeding deterrent at high concentrations in the above species (Argandoña et al., 1983; Corcuera et al., 1985). Although DIMBOA is generally more active than its degradation product, MBOA is known to elicit biological effects on some plant pathogens. In the ECB, MBOA was shown to lengthen both larval and pupal periods (Klun and Brindley, 1966), while in aphids, MBOA had deleterious effects when incorporated in the diet, increasing the mortality of the insects (Argandoña et al., 1980).

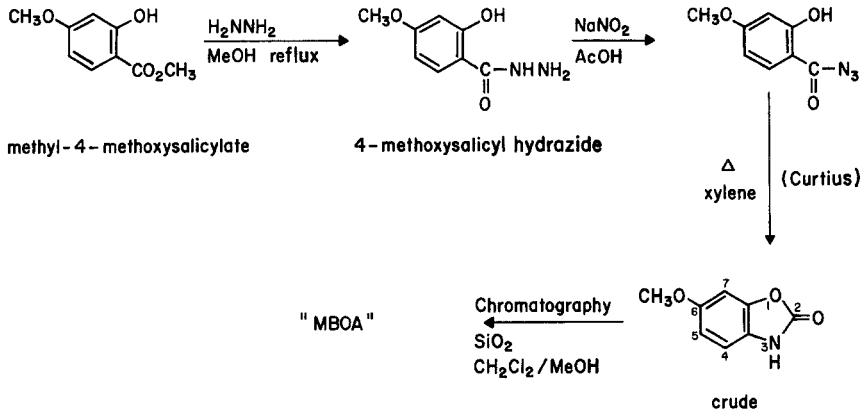
The yield of MBOA from the decomposition of DIMBOA increases with pH (Bravo and Niemeyer, 1986). It is important to note that the midgut (the principal site of digestion and assimilation) of most lepidopteran larvae has a pH of approximately 8.5 (Berenbaum, 1980), an environment which is suitable for the production of MBOA from the decomposition of DIMBOA, thus confounding the contribution of each compound to toxicity.

The differences in response to feeding dietary DIMBOA or MBOA suggest that there may be differential penetration, distribution, and metabolism, as well as a dissimilar mode of action of the compounds. The toxicokinetics of both substances are unknown at present; thus it is difficult to determine their relative role in insect deterrence. This report, the first of a two-part study on the pharmacokinetics of MBOA and DIMBOA, examines in detail the biological activity of MBOA on the ECB and the fate of labeled MBOA in feeding trials and topical applications to the insect. The object of this study was to determine the effect of MBOA on the ECB and the response of the insect to the plant compound. The doses of MBOA used represent a range of levels produced naturally in corn (Klun et al., 1970; Long et al., 1975; Tang et al., 1975), except the highest value (4 mg/g), which represents a value above what has normally been found, but is still potentially attainable in a breeding program.

METHODS AND MATERIALS

ECB Rearing. The bivoltine strain of ECB was originally obtained from the Agriculture Canada Research Station (London, Ontario). The culture was maintained in our laboratory according to the procedures and techniques of Guthrie et al. (1972). The MBOA-treated diets and control diets used in the experiments lacked corn cob grits so as to maintain textural uniformity.

6-Methoxybenzoxazolinone. MBOA was synthesized by the method of Kubo and Kamikawa (1983). These authors did not provide a detailed experimental procedure. Following is a description of our experimental method to



SCHEME 1. Synthesis of MBOA.

prepare MBOA (Scheme 1) based on the sequence of reactions used by Kubo and Kamikawa (1983). To 10.1 g of methyl-4-methoxysalicylate in 25 ml of methanol was added 16 ml of 95% hydrazine (Aldrich). The mixture was dissolved by warming and set to reflux for 8 hr. When cooled, the product 4-methoxysalicylhydrazide crystalized and was filtered and washed with cold methanol. Yield was 8.48 g (84%), mp 172.5–173.5°C. MS: *m/z* (%) 182 (28.8), 151 (100), 108 (21.4), 95 (23.7), 63 (10.5), 53 (10.6), 52 (14.2), 51 (12.1).

In a 500-ml round-bottom flask, 5.3 g of the hydrazide was disolved on 100 ml of glacial acetic acid. To this was added 100 ml of ether giving two phases. The stirred mixture was cooled in an ice bath to 10–12°C, and 5.3 g $NaNO_2$ in 20 ml of water was added dropwise over 10 min. After 30 min, the reaction was diluted with water and extracted with ether. Drying and evaporation of ethereals gave 5.3 g of azide (94%) as a peach-colored solid. MS: *m/z* (%) 193 (100), 165 (12.5), 151 (68.1), 150 (97.5), 122 (53.3), 109 (33.1), 108 (24.3), 107 (20.6), 106 (61.7), 95 (18.3), 94 (21.6).

The crude azide was immediately added to 500 ml of dry xylene and refluxed for 2 hr, whereupon TLC showed no azide remained. On cooling, a solid precipitated. This was collected and washed with hexane yielding 4.6 g crude MBOA.

Silica gel flash chromatography of this material provided varying amounts of pure MBOA with each reaction. Sufficient quantities of analytically pure MBOA (GC, MS, NMR) were obtained to perform the feeding trials.

The melting point of MBOA was 152.5–153.5°C (EtOH) [lit. 154°C (Nachman and Ronald, 1982), 168–170°C (Kubo and Kamikawa, 1983)]. [^{1}H]NMR (300 MHz), H_5 6.71 (dd), H_7 6.88 (d), H_4 7.01 (d), 3.78 (s). $J_{5,4}$

= 8.9 Hz, $J_{7,5}$ = 2.2 Hz, $J_{4,5}$ = 9 Hz, $J_{5,7}$ = 2.2 Hz. [^{13}C]NMR 156.6, 155.1, 145.3, 124.3, 110.3, 109.6, 97.5, 55.9. IR (C=O) 1750 cm^{-1}.

Tritiated MBOA was prepared by a modified high-temperature, dilute-acid method (Werstiuk and Timmins, 1981). The method was optimized with D_2O prior to the labeling experiments with tritiated water, thus establishing that the label was located at C-5. The specific activity was 2.0 mCi/mmol.

Partition Coefficient (Log P). The octan-1-ol–water partition coefficient for MBOA was determined using the shake flask method (Leo et al., 1971). [^{3}H]MBOA was utilized to facilitate the determination of the concentration of MBOA in each phase.

[^{3}H]MBOA as Tracer for MBOA. To determine if the uptake of the tritiated material by the insect was representative of the cold MBOA present in the diet and topical solution (i.e., that there was no isotope effect), third-instar larvae were fed diets containing 9.0, 27.1, 40.6, or 54.1 μg [^{3}H]MBOA/g diet to which was added sufficient unlabeled MBOA to bring the total to 60 μg/g. Thus the specific activity of the isotope varied, but the total dose remained constant. The larvae were maintained on these diets until fifth instar. Larvae and frass were recovered and burned in a sample oxidizer (Packard Tricarb model 306 using Permafluor and Monophase, Packard Instrument Company Inc.) to determine the total content of ^{3}H in each sample. ^{3}H content was measured using a Beckman scintillation counter and Scintilene scintilation fluid (Fisher Scientific Inc.)

Topical Application. Early fifth-instar larvae (five replicates with five larvae each) were topically applied with [^{3}H]MBOA (83.3 ng/mg insect) dissolved in 5 μl of dimethyl sulfoxide (DMSO). Larvae were allowed to feed on control diet until sampling time (1, 2, 6, 12, 24, and 48 hr). At these times and prior to dissection, larvae were rinsed in methanol to remove any of the compound from the surface of the cuticle that had not been absorbed. The dissection was performed on filter paper so as to trap the hemolymph at the time of cutting. The samples collected were: hemolymph, gut (with contents), fat bodies, cuticle, and frass. Tritium content of tissues were analyzed as before. Cross-contamination from hemolymph remaining on the tissues was evaluated by repeated rinsing of body tissues with saline and estimated to be 6.9 ± 1% of the total hemolymph content.

Dose-Related Uptake and Excretion of MBOA in Feeding Trials. MBOA and [^{3}H]MBOA were dissolved in ethanol and incorporated into freshly prepared meridic diets when the diet had cooled to approximately 40°C prior to solidifying. Final concentration of ethanol was 1% for all diets prepared including control diet. For each concentration of MBOA diet prepared (0.5, 1.5, 2.5, and 4.0 mg/g diet), 7 μg [^{3}H]MBOA/g diet (110,000 dpm/g diet) were added.

For each of the above concentrations, 100 eight-day-old larvae (second instar), fed from the neonate stage on the corresponding concentration, were

placed individually in vials plugged with cotton and provided with an appropriately treated diet cube. Twenty larvae for each concentration, plus 20 for control, were used for measuring growth parameters, while the remaining 80 larvae for each concentration were used for measuring the concentration of MBOA at various stages in development (fourth and fifth instar, pupal, and adult). For the 1.5 mg/g concentration, fourth and fifth instar, pupal, and adult stages were sampled to determine the body burden of MBOA through the development of the insect. For the remaining concentrations, 0.5, 2.5, and 4.0 mg/g, fifth instars, pupae, and adults were sampled to determine the body burden of MBOA under varying doses of MBOA in the diet. The fifth instar was dissected and the concentration of MBOA determined for various tissues (hemolymph, gut plus contents, fat body, and cuticle). Frass samples were also collected. The experiment measuring growth parameters was repeated twice.

RESULTS AND DISCUSSION

Growth Studies. When larvae were fed on varying concentrations of MBOA (0, 0.5, 1.5, 2.5, and 4.0 mg/g), the biological effects were clearly evident in the mortality data (Table 1). An increase in the mortality of the larvae, which occurred throughout larval development, was observed with an increase in concentration and ranged from 3.9% for controls to 22.5% for the highest concentration, 4.0 mg/g. Mortality occurring throughout the larval period has also been reported for ECB reared on a high DIMBOA line of corn (Reed et al., 1972). In the present study, an increase in concentration resulted in an increase in the duration of the larval period, which was significant at $P \leq 0.05$ (from 27.2 days for controls to 34.9 days for the 4.0 mg/g diet). Such a retardation in development was also reported by Klun and Brindley (1966) when they fed ECB on a diet of 0.5 mg MBOA/g diet as compared to control diet. Although there was a significant increase in the development time of the larvae, the final weight of the fifth-instar larvae was not affected.

A prolongation of development was not as clearly defined in the pupal instar as in the larval period, although the trend of increasing duration of this period is still present (Table 2). As with larval weights, pupal weights do not seem to be affected by the presence of MBOA in the diet. Pupal mortality, which ranged from 6.1 to 18.5%, appeared to be higher in the treated groups as compared to controls, but was not correlated to the concentration of MBOA.

The total duration of the development of the ECB was significantly increased with an increase in concentration of MBOA (Table 3), for both males and females, although the mean weight of the adults was not affected. A decrease in the sex ratio (females/total) was consistently observed when MBOA was present in the diet, although not well correlated to the concentration of MBOA. This suggests that ECB females are probably more susceptible to the effects of

MBOA during their development. Along with this decrease in the sex ratio, there was also a decrease in the number of egg masses per female (Table 4), although the number of eggs per egg mass was not affected. A small experiment on the effect of sex ratio indicated that this decrease in the number of eggs per female cannot be accounted for by the different sex ratios of adults in the dif-

[a] Obtained by placing all emerging males and females in mating chambers.

ferent MBOA-treated trials. This decrease in fertility has been observed with ECB fed on varieties of resistant corn, although the effects were attributed to DIMBOA (Reed et al., 1972). Since the effects of MBOA are observed at the F_1 generation as well as throughout development, even at doses of 0.5–2.5 mg/g, which are relavent to maize varieties, it may be concluded that MBOA does have biological effects on the ECB, contrary to previous reports (Klun et al., 1967).

Validation of [^{3}H]MBOA as Biological Tracer. The amount of ^{3}H isotope found in the insect and frass of the fifth-instar larvae, after feeding on diets with varying levels of [^{3}H]MBOA but the same total amount of MBOA, was directly related to the amount of ^{3}H isotope in the diet ($r = 0.993$, slope $= 0.26$, $P < 0.01$, and $r = 0.986$, slope $= 0.60$, $P < 0.01$ for the insect and frass samples, respectively) (Figure 2). This linear relationship suggests that there was no preferential uptake or excretion of the tritiated compound over the cold compound. Thus, the [^{3}H]MBOA used for these experiments was acting as a reliable tracer for the cold MBOA.

Uptake and excretion of labeled compound, in feeding trials using varying concentrations of the compound, was affected by concentration. The levels of [^{3}H]compound in all stages of development and in the frass increased approximately linearly with an increase in concentration, leading to a constant body burden (defined as the concentration in the tissues/concentration in the frass) (Figure 3, inset) ($r > 0.95$). This indicates that the ECB is unable to react to the presence of MBOA by increasing the excretion rate of the compound when

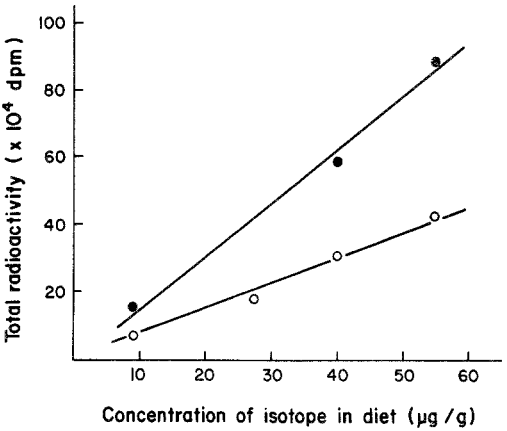

FIG. 2. Relationship between the concentration of labeled MBOA in the diet and that found in the fifth-instar larvae (○) of *Ostrinia nubilalis* and the frass (●) of the larvae. Total MBOA concentration was maintained at 60 mg/g diet by addition of cold compound. Total radioactivity in insect and frass are expressed on a per gram basis. The specific activity of MBOA was 2.0 mCi/mmole.

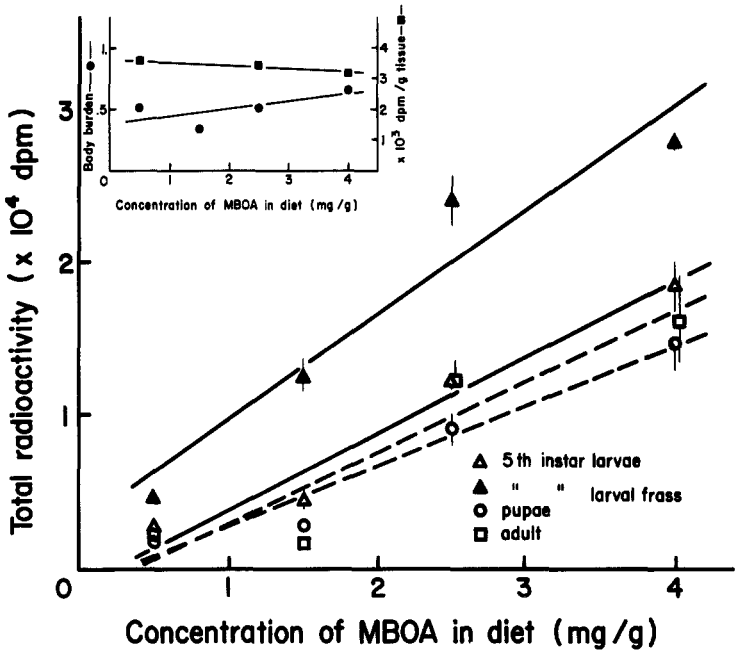

FIG. 3. Dose-related uptake and excretion of labeled compounds by the ECB, *Ostrinia nubilalis*, in feeding trials. Total radioactivity expressed on a per gram basis. The diets contained 1.0×10^4 dpm/mg MBOA. Inset shows the relationship between the concentration of MBOA in the diet and body burden (●) and the relationship between the concentration of MBOA in the diet and the total dpm present in the tissue (■).

a higher content is present in the diet. The body burden values, for the concentrations studied, showed that ECB is capable of excreting enough compound to maintain tissue levels at approximately 50% of the dietary concentration. The accumulation of [^{3}H]compound in the insect tissues increased during larval development (Figure 4) but declined when the insect pupated. The levels from the pupae to the adult further declined due to the transfer into the pupal case.

The [^{3}H]compounds were not sequestered in any specific tissue, as the data from Table 5 indicate. MBOA is a relatively hydrophilic molecule (log *P* value was calculated to be approximately 1.2), and thus it would not tend to accumulate in any specific tissue. The higher levels in the hemolymph indicate that any absorbed MBOA was readily transported to all tissues as well as rapidly excreted.

Since the same level (7 μg/g diet) of tritiated MBOA was used in all concentrations of diet, consumption can be inferred from these results. From Figure 3 (inset), the levels of [^{3}H]compound/g tissue did not change with an increase

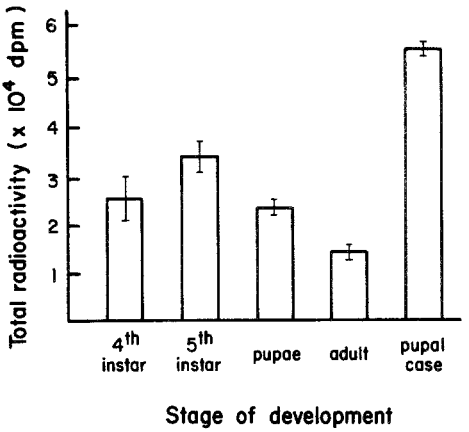

FIG. 4. The level of tritium label (dpm/g tissue) in ECB during its development when fed on a diet of 1.5 mg MBOA/g diet containing 1.19×10^5 dpm/g diet. Bars indicate SE.

in the concentration of MBOA in the diet (Tukey's Studentized test, $P \leq 0.05$), suggesting that all insect groups consumed the same amount of diet. We observed previously (Arnason et al., 1985) that the ECB has a greatly reduced antifeedant response to plant chemicals in artificial diets as compared to leaf disk. This result suggests that the effects observed with MBOA in artificial diets are due to toxic rather than antifeedant properties of this compound.

Some metabolites, as well as the parent compound, were found following TLC and HPLC analysis of insect and frass samples. These are currently being identified and will be reported in a subsequent article.

In fifth-instar larvae, topically applied [^{3}H]MBOA was rapidly absorbed

MBOA conc. (mg/g)	Hemolymph	Gut (with contents)	Fat body	Cuticle
0.5	32.2	22.7	23.8	21.5
	(2.13)	(1.67)	(1.04)	(0.75)
2.5	40.5	16.4	22.6	20.3
	(1.06)	(1.37)	(1.60)	(1.18)
4.0	35.8	21.1	19.5	23.7
	(2.4)	(0.60)	(0.50)	(2.71)

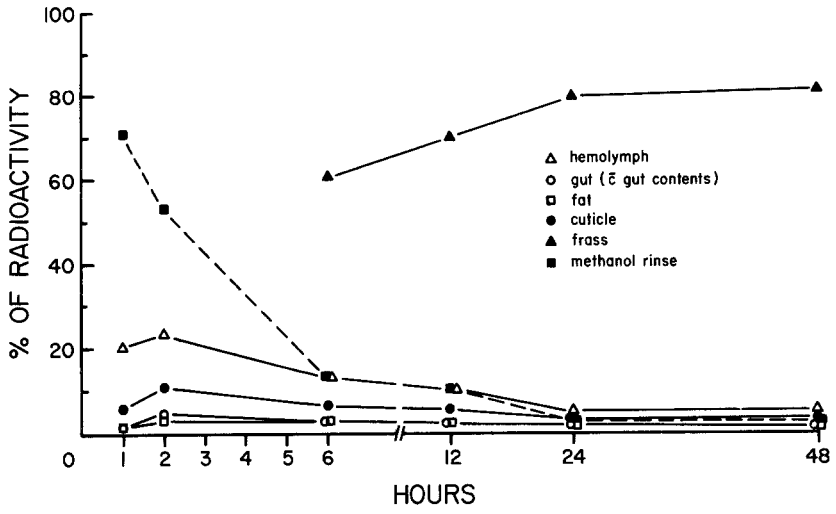

FIG. 5. Toxicokinetics of topically applied [^{3}H]MBOA on the fifth instar of the ECB, *Ostrinia nubilalis*.

through the cuticle as is demonstrated in Figure 5 by a sharp decrease in the percent of radioactivity in the methanol rinse (nonabsorbed compound from the surface of the cuticle). Six hours following application, only 13.8% of the ^{3}H isotope remained on the surface of the cuticle. Although MBOA was readily absorbed, elimination of the compound in the frass by the fifth instar was also rapid, reaching 60% by 6 hr and leveling off at 82% by 24 hr. The percent of ^{3}H isotope in other tissues (gut plus its contents, fat bodies, and cuticle) remained relatively low (the standard error for data points is less than 5%). The rapid rise in levels of ^{3}H isotope observed in the hemolymph during the first 2 hr, followed by its decline over 24 hr, indicates that transport and excretion of the compound occurred relatively quickly.

Previous studies by Olson and O'Brien (1963), and Chio (1976) have demonstrated that compounds having higher water solubility penetrate the insect cuticle faster than more lipophilic substances. The rapid decline in counts in the methanol rinse, which in this case indicated rapid penetration of MBOA, may be accounted for by the low log P value of this compound.

In conclusion, the growth and development data suggest that MBOA does act as a toxic substance, since a variety of effects were observed from mortality of larvae to reduction in fecundity at the F_1 level. The rapid uptake of the compound into the insect and its subsequent excretion may be as much a function of the hydrophilic nature of MBOA, as an adapative mechanism in handling the phytochemical. However, the insect does successfully minimize levels in

tissues other than hemolymph and eliminates a large amount of material in the pupal case. Further experiments with the parent compound, DIMBOA, should give a better indication as to the relative importance of MBOA in the resistance of corn against the ECB.

Acknowledgments—This work was supported by an NSERC strategic grant and the Ontario Ministry of Agriculture and Food. We thank Natalie Donskov for the maintenance of the ECB culture.

HALOACETATE ANALOGS OF PHEROMONES: Effects on Catabolism and Electrophysiology in *Plutella xylostella*

GLENN D. PRESTWICH and LUDVIK STREINZ[1]

Department of Chemistry
State University of New York
Stony Brook, New York 11794-3400

(Received March 18, 1987; accepted June 1, 1987)

Abstract—A series of mono-, di-, and trihalogenated acetate analogs of Z11-16:Ac were prepared and examined for electrophysiological activity in antennae of males of the diamondback moth, *Plutella xylostella*. In addition, two potential affinity labels, a diazoacetate (Dza) and a trifluoromethyl ketone (Tfp), were evaluated for EAG activity. The Z11-16:Ac showed the highest activity in EAG assays, followed by the fluorinated acetates, but other haloacetates were essentially inactive. The polar diazoacetate and the trifluoromethyl ketone were also very weak EAG stimulants. The effects of these analogs on the hydrolysis of [^{3}H]Z11-16:Ac to [^{3}H]Z11-16:OH by antennal esterases was also examined. The three fluorinated acetates showed the greatest activity as inhibitors in competition assays, with rank order F_2Ac > F_3Ac > FAc > Ac > Cl_2Ac > ClAc > Dza > Br_2Ac > BrAc > Tfp > I > Cl_3Ac > Br_3Ac > OH. The relative polarities of the haloacetates, as determined by TLC mobility, are in the order mono- > di- > trihalo, but F, Cl, Br, and I all confer similar polarities within a substitution group. Thus, the steric size appears to be the predominant parameter affecting the interactions of the haloacetate analogs with both receptor and catabolic proteins in *P. xylostella* males.

Key Words—Haloacetate, pheromone analog, catabolic protein, EAG, *Plutella xylostella*, Lepidoptera, Yponomeutidae, inhibition.

[1]On leave from Institute of Organic Chemistry, Czechoslovak Academy of Science, Flemingovo náměstí 2, 16610, Prague, Czechoslovakia.

INTRODUCTION

One approach to the study of the molecular mechanisms by which pheromones activate transductory processes in insect sensory neurons involves the use of radioligands to characterize pheromone binding and catabolic proteins in male olfactory sensillae (Prestwich, 1987a,b; Prestwich et al., 1987). A second approach involves the synthesis of pheromone analogs and then determination of their relative activities by electrophysiological methods (Roelofs, 1984; Bestmann, 1986; Priesner, 1979). To our knowledge, there are no reports for which both electrophysiological and biochemical studies were conducted with the same set of analogs using the same insect. Moreover, to our surprise, there has never been a systematic evaluation of the relative potency of the mono-, di, and trihalogenated acetate analogs of any acetate component of a pheromone blend.

Thus, we report the synthesis of haloacetate, diazoacetate, and trifluoromethyl ketone analogs of Z11-16:Ac (Figure 1) and their EAG activity for intact male antennae of the diamondback moth, *Plutella xylostella* (Lepidoptera: Yponomeutidae). Furthermore, we present data on the relative potency of the haloacetates as competitive inhibitors of the hydrolysis of [^{3}H]Z11-16:Ac to [^{3}H]Z11-16:OH by soluble antennal esterases.

METHODS AND MATERIALS

Insects

Plutella xylostella were obtained from continuous laboratory cultures from three locations. EAG experiments employed insects reared in Saskatoon (see

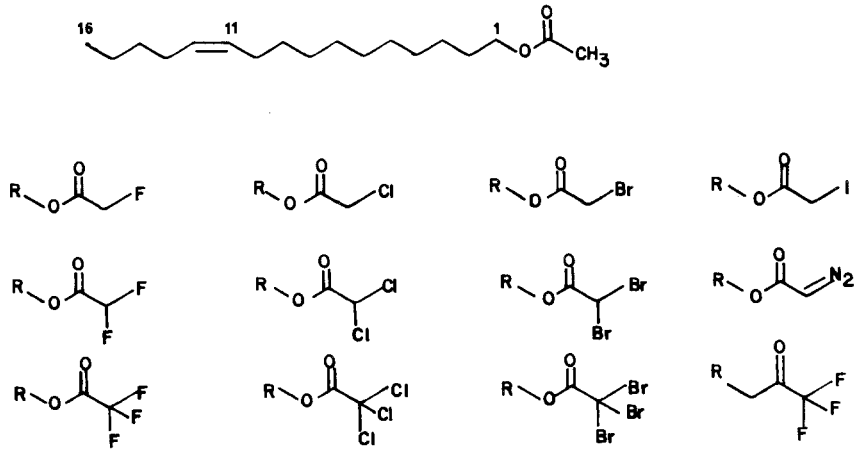

FIG. 1. Analogs of (Z)-11-hexadecenyl acetate prepared and evaluated *in vitro* and *in vivo*.

below); enzyme assays were performed with day 1 or 2 adults emerging from pupae obtained from Dr. B. Tabashnik and N. Cushing, University of Hawaii, and from pupae provided by Dr. K. D. Biever (USDA, Yakima, Washington).

Electroantennograms

EAG responses to synthetic compounds were measured using intact antennae of 2- to 4-day-old male diamondback moths by Drs. E. M. Giblin and E. W. Underhill, National Research Institute–Plant Biotechnology Institute, Saskatoon, Saskatchewan, Canada. Responses were elicited according to the procedure of Chisholm et al. (1975) in which a 1-ml "puff" of purified air, passed first over a filter paper disk containing 1 μg of compound, was admixed with an air stream (2.5 liters/min^{-1}) directed at the antennae. Alternating stimuli of Z11–16:Ac and each analog were administered at 15-sec intervals, and each response was corrected for background (mechanical) stimulation. Relative antennal responses were calculated by dividing the analog-elicited response by the mean of the Z11–16:Ac responses (3.59 $\pm$ 0.25 mV) recorded prior to and following that of the analog. The complete set of analogs, including the Z11–16:Ac stimuli, was administered to 11 male moths, the relative response data were analyzed by an analysis of variance test, and significant differences among means (5% level) were determined by Duncan's (1955) multiple-range test.

Tissue Preparations

Day 1 or day 2 emerged adults were sexed during normal photophase under CO_2 narcosis and were held below 8°C prior to processing. Antennae and legs from chilled, narcotized male and female insects were obtained using forceps and collected in a porcelain dish at 4°C. Tissues were homogenized at this temperature in either 10 mM Tris HCl, pH 7.0, or in 76 mM sodium phosphate buffer, pH 7.4, using a hand-operated ground-glass homogenizer. Typically, 100 pairs of antennae or 50 pairs of legs were homogenized in 400 μl of buffer, the homogenate was sonicated at 4°C in an ultrasonic cleaning bath for 10 min (Ferkovich, 1981), the homogenate was rinsed into a 1.5-ml polypropylene tube with two washes with 400 μl buffer, and the suspension was centrifuged (12,000 *g*) for 10 min to give a pellet and a supernatant. The supernatant was divided into portions for a single day's assays and frozen at −80°C.

Enzyme Assays

A typical enzyme assay is described. To each assay tube, first 90 μl of buffer was added, followed by 1.0 μl of an ethanol solution of inhibitor (100-fold the desired final concentration). The tubes were vortexed gently, placed in ice, and the homogenate (10 μl) was added. Using a repeating dispenser, 1.0 μl of 50 μM solution of [^{3}H]Z11–16:Ac (synthesis described below) in ethanol

was added. The substrate solution was prepared for a week's use from a 4 mM stock solution of tritiated pheromone (see below) in 1 : 1 heptane–toluene stored at −80°C to retard autoradiolysis (Prestwich, 1987a). The reaction mixtures were incubated at 26°C for 30 min, the reaction tubes were cooled in an ice bath, 100 μl of ethyl acetate was added, and the tubes were vigorously mixed on a vortex mixer for 10 sec. For each compound, a series of nine concentrations from 0.1 μM to 100 μM was performed, and IC_{50} values were obtained graphically.

A 3-μl aliquot of the organic layer was taken for direct liquid scintillation counting (LSC) to confirm the total extractable radioactivity, and duplicate 3-μl aliquots were spotted onto TLC plates which had been marked into zones and prespotted with unlabeled Z11-16:Ac and Z11-16:OH. The plates were developed in 10% EtOAc–hexane, visualized with iodine, and the alcohol (product) and acetate (substrate) zones were cut into LSC vials containing 4 ml of Scintiverse II (Fisher). Liquid scintillation counting was performed on an LKB RackBeta Model 1217 instrument with automatic external ratio standardization. For many assays, the plates were also analyzed using a Bioscan Imaging Analyzer to reveal the overall distribution of radioactivity in a given zone on the plate. The percentage conversion was calculated as alcohol/(alcohol + acetate), which corrects for errors in sampling and chromatography. The results are most conveniently compared as relative percent hydrolysis, by normalizing a single day's assay results to the uninhibited control with correction for the nonenzymatic hydrolysis in a blank.

Synthesis of Radioligand

[11, 12-$^3H_2$](Z)-11-Hexadecenyl acetate was prepared by reductive tritiation of the corresponding 11-alkyne (see Ding and Prestwich, 1986), prepared in turn by alkylation of the acetylide of 1-tetrahydropyranyloxy-11-dodecyne with 1-bromobutane in the THF/HMPA (Henrick, 1977). Acid hydrolysis of the THP ether (HOAc–THF–H_2O, 4:2:1), acetylation (Ac_2O, pyridine), and flash chromatography provided the necessary starting material.

The tritiation was carried out (May 15, 1985) at the National Tritium Labeling Facility at Lawrence Berkeley Laboratory under the supervision of Dr. Hiromi Morimoto (see Prestwich, 1987a). A flask containing 30.8 mg (0.11 mmol) of alkyne, 2 mg of quinoline, and 5.7 mg of 5% Pd/$BaSO_4$ in 5 ml of methanol was vacuum degassed three times with nitrogen flushing and then stirred at room temperature under 0.9 atmospheres of carrier-free tritium gas for 30 min. The specific activity obtained from this procedure is about 25–30 Ci/mmol, due to vinylic exchange from the protic solvent; this has been minimized in later partial tritiations by using dry THF as solvent to give >45 Ci/mmol specific activities (Prestwich, 1987a). Approximately 40% radiodecom-

position had occurred when the heptane–toluene stored samples were repurified in November 1986. The labeled acetate used for enzyme assays was >98% radiochemically pure as assessed both by LSC and scanning analysis.

Synthesis of Analogs (Figure 2)

Haloacetates. The haloacetates were synthesized from (Z)-11-hexadecen-1-ol prepared in our laboratories according to Vinczer et al. (1984) and shown to possess less than 6% of the *E* isomer. [^{1}H]NMR spectra were obtained in $CDCl_3$ solutions with Varian HFT-80 spectrometer. Chemical shifts are expressed in δ (ppm) relative to δ (TMS) = 0 ppm. IR spectra were obtained on Perkin Elmer 727 spectrometer. Products were purified on a simple column chromatography 30-fold excess silica gel (Merck) by elution with 9:1 hexane–ethyl acetate. Products were dried at 70°C and 0.1 torr for 1 hr. Each haloacetate was repurified by flash chromatography on Woelm 30-63 μm silica prior to use for EAG or esterase inhibition assays. Capillary GC (30 m × 0.25 mm DB-5 fused silica column) analysis indicated that none of the Z11-16:OH was present; however, thermal decomposition of the pure haloesters was observed for the bromo-, iodo-, and diazoacetates. There were two methods used for preparation of haloacetates:

In method A, to a cooled, stirred solution of the haloacetyl chloride (0.166 mmol) in dry ether (1 ml) under N_2 was added a solution of (Z)-11-hexadecen-1-ol (0.1 mmol) and pyridine (0.166 mmol) in ether (2 ml). The reaction mixture was allowed to warm up to room temperature and then worked up by evaporation of solvent to dryness, dissolution of the solid in 5 ml of water, extraction with three portions of ether (5 ml), and drying the combined organic phases with $MgSO_4$.

In method B (Neises and Steglich, 1978), to the solution of (Z)-11-hexadecen-1-ol (0.068 mmol) and α-halogenated acetic acid (0.102 mmol) in dry ether was added 4-(*N*, *N*-dimethylamino) pyridine (0.01 mmol) followed by dicyclohexylcarbodiimide (0.102 mmol). The reaction mixture was stirred at room temperature for 15 hr and then worked up by evaporation to dryness, addition of 2 ml of water, and extraction with three 2-ml portions of hexane. Table 1 summarizes the yields, diagnostic proton NMR resonances, and carbonyl stretching frequencies (IR) for each compound.

(Z)-11-Hexadecenyl-diazoacetate. The procedure used for *A. polyphemus* diazoacetate (Prestwich et al., 1984), *E*6, Z11-16:Dza, was modified to minimize the formation of a sulfinate ester by-product (Corey and Myers, 1984). To a stirred 0°C solution of (Z)-11-hexadecen-1-ol (14.6 mg, 0.061 mmol) in 1 ml of dry methylene chloride under Ar was added glyoxylic acid chloride *p*-toluenesulfonyl hydrazone (29.6 mg, 0.113 mmol) in 1 ml of methylene chloride. Then, 14 μl of *N*, *N*-dimethylaniline was injected, and the mixture was

A solution of (Z)-12-heptadecenyl magnesium bromide, prepared from (Z)-12-heptadecenyl bromide (0.212 g, 0.667 mmol) and magnesium turnings (0.024g, 1.0 g-at.) in 5 ml of dry ether was cooled (0°), and a solution of *N*-methoxy, *N*-methyl trifluoroacetamide (0.158 g, 1.0 mmol) (Shaw and Tuominen, 1985) in 3 ml of ether was added slowly. The reaction mixture was then stirred for 60 min at room temperature and then decomposed with ice and 3 ml of 5% hydrochloric acid, extracted with three 10-ml portions of hexane–methylene chloride (1:1), and dried ($MgSO_4$). Distillation afforded 63.5 mg of desired product (bath tem-

perature 120–170°C, vacuum 0.1 torr). IR (CCl_4): 3110, 2850–2950, 1770 cm^{-1}. [^{1}H]NMR: δ 0.89 (br t, J = 6 Hz, 3H), 2.05 (m, 4H, $C\underline{H}_2CH=$), 2.70 (m, 2H, $-C\underline{H}_2CO$), 5.34 (m, 2H, $-C\underline{H}=$).

RESULTS AND DISCUSSION

The diamondback moth, *Plutella xylostella* (L.), is a major, worldwide pest of cruciferous oil-seed and vegetable crops. A potent and highly species-specific field attractant has been reported (Chisolm et al., 1983) comprised of Z11-16:Al (70 μg) + Z11-16:Ac (30 μg) + Z11-16:OH (1 μg) + Z9-14:OH (10 μg). Three of the four compounds have been identified as components of the sex pheromone of this pest and include Z11-16:Al, Z11-16:Ac (Chow et al., 1977; Tamaki et al., 1977), and Z11-16:OH (Underhill, unpublished); Z9-14:OH, which has not been reported as a pheromone component, increased male captures and improved lure specificity (Chisholm et al., 1983).

Studies at Stony Brook have been focused on the chemical interactions between catalytic proteins and binding proteins found in insect antennae, with a practical goal being the design of novel mating disruptants (Prestwich, 1986, 1987a, b; Prestwich et al., 1987). In order to achieve this goal, we have prepared chemically reactive analogs for a number of pheromones, and we have sought to evaluate their biological activity in behavioral and electrophysiological assays in parallel with biochemical assays. The biochemical assays employ radiolabeled pheromones at very high specific activity and allow monitoring of binding and catabolism at physiological (nanomolar to micromolar) concentrations (Prestwich, 1987a, b). In this study we wished to explore the interactions of halogenated acetates with acetate-recognizing proteins in male antennae, with the hope that we could correlate analogs active in signal transduction with the recognition of these analogs by catabolic proteins.

Synthesis

The pheromone analogs were prepared from known precursors as shown in Figure 2. In the synthesis of the haloacetates, either the haloacetyl chloride or the haloacetic acid was condensed with (Z)-11-hexadecen-1-ol under standard conditions. The mono-, di-, and trihaloacetates were thus prepared for X = F, Br, and Cl. Only the monoiodoacetate was readily prepared. Comparison of the polarities of these 10 haloacetates revealed a striking correlation between number of halogens and TLC mobility on silica gel, while there was little difference in polarity among the different halogens. Monohaloacetates are more polar than dihaloacetates, and trihaloacetates are the least polar. Surprisingly, the monohaloacetates showed essentially the same mobility as the parent acetate, Z11-16:Ac.

The diazoacetate was prepared using the Corey-Myers modification (Corey

and Myers, 1984) to minimize formation of the unwanted and difficult to remove *p*-toluenesulfinate by using *N*, *N*-dimethylaniline as the first base in the condensation of glyoxylic acid chloride tosylhydrazone with Z11–16:OH and triethylamine as the second base to produce the diazoester. The diazoacetate can, in principle, function as either a photoaffinity label or as an enzyme inhibitor. Precedent for the first role is available from our studies with the sensillar pheromone-binding protein and dendritic membrane proteins of *Antheraea polyphemus*, successfully employing [^{3}H]*E*6, Z11–16:Ac as a photoaffinity label (Prestwich et al., 1987; Prestwich, 1987a, b; Vogt et al., 1988). In contrast, the pheromonal diazoacetate and several geometrical isomers were found to be generally weak competitive inhibitors of the sensillar esterase from the same tissues (Vogt et al., 1985; Prestwich et al., 1986b).

The final analog, trifluoromethyl ketone Z11–16:Tfp (where Tfp is shorthand for 1,1,1-trifluoropropanone), was prepared as a steric and electronic mimic of the enzyme-bound intermediate in ester hydrolysis (Hammock et al., 1982) (see below). These long-chain aliphatic analogs are not readily prepared in high yields by conventional methods. All methods using trifluoroacetic acid, trifluoroacetic anhydride, lithium trifluoroacetate, and magnesium trifluoroacetate as the acceptor for the Grignard component gave complex mixtures with large proportions of the alkene (protonolysis) and the tertiary alcohol (second addition of Grignard to regenerated carbonyl) products. The cleanest and highest-yield method employed the *N*-methoxy, *N*-methyl trifluoromethylacetamide as the acceptor (Shaw and Tuominen, 1985) and is strongly recommended for future work on aliphatic trifluoromethyl ketones where the aliphatic moiety is precious and functionalized.

Electrophysiology

The responses of antennae of male *P. xylostella* to the haloacetates, the diazoacetate, and the trifluoromethyl ketone were determined relative to the response to the natural Z11–16:Ac component. Alternating stimuli of Z11–16:Ac and each analog of the complete set of 12 were administered at 15-sec intervals to 11 replicated single antennal preparations. The average relative responses, obtained from the ratios of blank-corrected millivolt response for the analog to millivolt response for the standard (Z11–16:Ac), are shown in Figure 3. The fluorinated acetates possess potent EAG activity, with the monofluoroacetate response significantly lower than Z11–16:Ac but significantly higher than the di- and trifluoroacetate responses. While the trichloroacetate showed some activity, the remaining chlorinated, brominated, and iodinated acetates produced much lower responses (or no response in most insects tested). Similarly, the diazoacetate showed negligible activity, and the fluoroketone showed low activity similar to the monochloroacetate.

While this is the first examination of a complete series of haloacetates for

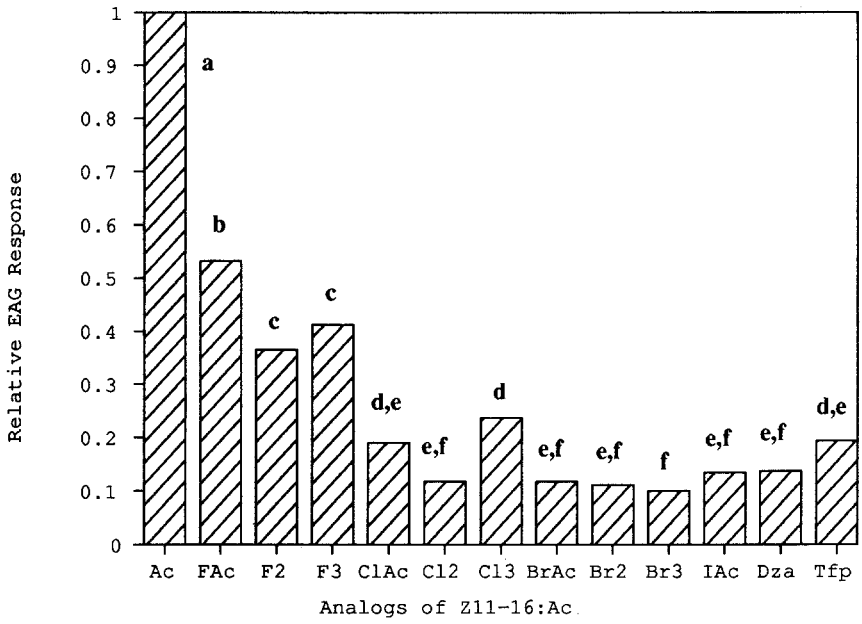

FIG. 3. Average electroantennogram responses to haloacetates and two other analogs of Z11–16 : Ac by antennae of male *Plutella xylostella*. Bars represent the mean responses of 11 separate trials, and bars with different letters are significantly different at $P < 0.05$. Numerical relative response values (±SE): FAc, 0.53 (0.05); F_2Ac, 0.36 (0.04); F_3Ac 0.41 (0.04); ClAc, 0.19 (0.04); Cl_2Ac, 0.12 (0.03); Cl_3Ac, 0.24 (0.03); BrAc, 0.12 (0.03); Br_2Ac 0.11 (0.04); Br_3Ac, 0.10 (0.03); IAc, 0.13 (0.03); Dza, 0.14 (0.03); Tfp, 0.19 (0.02).

electrophysiological activity, there are several reports of selected acetate analogs in other species. Baker et al. (1981) and Albans et al. (1984) have patented several reactive "antipheromones" related to Z9–14 : Ac and Z9–16 : Al for use against *Heliothis virescens* (Figure 4A). The *N*-methylcarbamate analog (Z9–14 : Nmc) reduced oviposition by this insect on cotton in field trials. In lab tests using preexposure to 100 mg (!) of test compound, the carbamate compound, Z9–14 : F_3Ac, Z9–14 : Cl_3Ac, and (Z)-12-heptadecan-2-one (replacement of oxygen by methylene in Z9–14 : Ac) all acted as competitive antipheromones for *H. virescens*, producing reversible inhibition of behavioral (flight activation) responses. Unfortunately, EAG assays were not reported by these workers, so it is unclear whether the Z9 analogs described mimic Z9–14 : Ac, Z9–14 : Al, Z11–16 : Ac, or Z11–16 : Al. In contrast, they found that a variety of saturated analogs, alkenyl regioisomers, shorter or longer unsaturated ketones, mono-

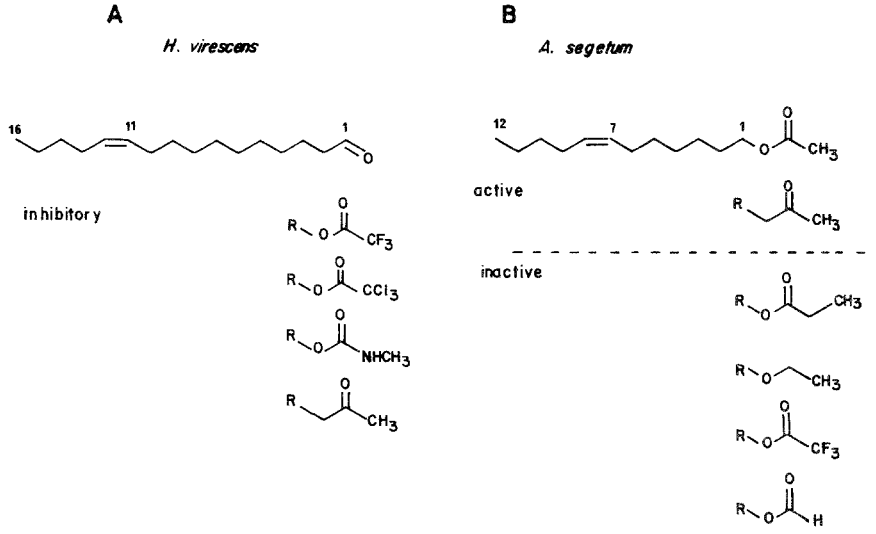

FIG. 4. (A) Structures of antipheromones for *H. virescens* based on Z9–14:Al (Prestwich et al., 1986a) and Z9–14:Ac (Albans et al., 1984). (B) Structural analogs of Z7–12:Ac, the pheromone of *A. segetum* (Liljefors et al., 1984).

chloroacetates, alcohols, alkenes, acrylate esters, dimethylcarbamates, and methyl carbonates were essentially inactive as antipheromones. In a related study, the acyl fluoride Z9–14:Acf produced unusual aphrodisiac-like responses in male *H. virescens* (Prestwich et al., 1986a).

The *N*-methylcarbamate could, in principle, be an irreversible inhibitor of the esterase by carbamoylation of the active site. I. Ujvary and M. Toth (personal communication, cited in Prestwich, 1987a) prepared the Z11–16:Nmc and saturated C_8, C_{12}, and C_{16} *N*-methylcarbamates. In preliminary EAG assays with male *Mamestra brassicae* antennae, the Z11–16:Nmc elicited a response slightly less than that of Z11–16:Ac, while the saturated carbamates produced no response. Furthermore, subsequent responses to Z11–16:Ac were unaffected by a preexposure to the carbamate analog. We found this compound is only a weak inhibitor of the antennal esterase of *P. xylostella* (L. Streinz, I. Ujvary, and G. D. Prestwich, unpublished results), in the same range as the Z11–16:Tfp analog.

The responses of sensory cells from male antennae of the turnip moth *Agrotis segetum* (Noctuidae) were measured during stimulation with analogs of Z7–12:Ac (Figure 4B), the major pheromone component of this species (Liljefors et al., 1984). Replacement of the alcohol oxygen with a methylene to

obtain the methyl ketone afforded a weakly active stimulus, as in the higher homolog reported by Albans et al. (1984) for *H. virescens*. In contrast, the propionate, the ethyl ether (methylene replaces carbonyl), the trifluoroacetate, and the formate analogs of Z7–12 : Ac were all essentially inactive. All portions of the acetate group, electronic and steric, are apparently important to pheromonal activity for this moth.

Finally, the diazoacetate *E*6, Z11–16 : Dza was an excellent stimulant for single-cell responses of the *E*6, Z11–16 : Ac sensillae of the wild silkmoth, *Antheraea polyphemus* and its sister species, *A. perneyi* (Saturnidae) (Ganjian et al., 1978; Kaissling, 1986). About 10% of the normal acetate response was produced from equal quantities in filter paper, and in view of the lower volatility of the polar diazoacetate, the activity is likely to be underestimated. In addition, R. G. Vogt and G. D. Prestwich have determined that the diazoacetate binds effectively to both soluble and membrane associated proteins in *A. polyphemus* male sensillar homogenates (Vogt et al., 1988; Prestwich 1987a, b; Prestwich et al., 1987).

The importance of the electronic effects found for *A. segetum* deserves further comment. The straight-chain olefinic acetates are attractants of numerous lepidopterous species (cf. Steck et al., 1982; Tamaki, 1985). The models used to explain pheromone–receptor interactions focus on the acetate functionality, the olefin, and the terminal methyl group. Binding may occur by a static three-point mechanism (Kafka and Neuwirth, 1975) or by a dynamic, stepwise association invoked by Bestmann (Bestmann, 1986; Bestmann and Vostrowsky, 1982), or by other mechanisms.

Liljefors et al. (1984) calculated van der Waals surfaces of methyl acetate, formate, propionate, trifluoroacetate, as well as the ethyl ether and the ketone analog 2-butanone in a homogeneous medium. The trifluoroacetate, methyl ketone, and ethyl ether are quite similar in size and shape to the acetate. On the other hand, while the dipole moments of the methyl ketone and acetate are of similar direction and magnitude, the trifluoroacetate dipole vector is orthogonal in this simple example. The Swedish group inferred that the dipole moment of the acetate functionality may be important in the receptor interactions. However, these interactions may be formed by additional orientational effects due to the lipid bilayer membrane in which the putative receptor protein(s) reside.

For *P. xylostella*, this solution model fails to explain the high EAG activity of all three fluorinated acetate analogs and the low activity of other halogenated acetates of similar polarities. These analogs have similar molecular geometries but very different dipole moments. Thus, it appears that for *P. xylostella*, the steric size of the halogenated acetate group dominates over compound polarity in determining the summed electroantennogram responses. Based on our data, we cannot exclude the possibility that the haloacetate analogs are stimulating sensory cells other than the Z11–16 : Ac-specific cell(s).

Esterase Activity

The removal of an olfactory stimulus is crucial to the normal functioning of the insect pheromone-sensing system (Ferkovich, 1981). Various models have been suggested to account for the translocation of the stimulus from the air to the dendritic membrane of the responsive neuron (Vogt and Riddiford, 1986b; Kaissling, 1986; reviewed by Vogt, 1987), and approaches to understanding the electrical transduction have been made (de Kramer and Hemberger, 1987; Kaissling, 1986). It has become clear that the biochemical properties, i.e., maximal velocity, substrate specificity, and *in vivo* concentrations, of the antenna-specific pheromone processing enzymes fully account for their role as the primary modulators of stimulus concentration in the lumen of the receptor hair (Vogt, 1987; Vogt et al., 1985). This is now well documented for acetate esterases and aldehyde dehydrogenases in *Choristoneura fumiferana* (Morse and Meighen, 1984, 1986, 1987; Lonergan, 1986), for aldehyde dehydrogenases in *Heliothis virescens* (Ding and Prestwich, 1986; Prestwich, 1987a,b), for acetate esterases in *Antheraea polyphemus* (Prestwich et al., 1986b; Vogt et al., 1985; Vogt, 1987; Klein, 1987), for acetate esterases in *Trichoplusia ni* (Ferkovich, 1981; Ferkovich et al., 1982a, b), and for epoxide hydrolases in *Lymantria dispar* (Prestwich et al., 1987; Prestwich, 1987a, b). Other tissues of both sexes possess enzymatic activity for pheromone degradation in these insects as well (Ferkovich et al., 1982a, b; Vogt and Riddiford, 1986a), and this presumably reflects the need to prevent becoming one's own slow-release dispenser.

Thus, we wished to examine the effects of these haloacetate analogs on the hydrolysis of [^{3}H]Z11–16:Ac by *P. xylostella* male antennae (Figure 5). Indeed, we have demonstrated electrophoretically unique esterase bands in *P. xylostella* antennal tissues, and we have shown tissue specificity for hydrolysis of [^{3}H]Z11–16:Ac by tissues (antennae, legs, and abdominal tips) of both sexes (G. D. Prestwich, R. G. Vogt, and L. Streinz, unpublished results). Biochemical characterization of the leg and antennal enzymes will be reported in full elsewhere. For this study, we used the esterase assay to measure the ability of the haloacetates and the other two analogs to reduce the rate of hydrolysis of the labeled pheromone *in vitro*.

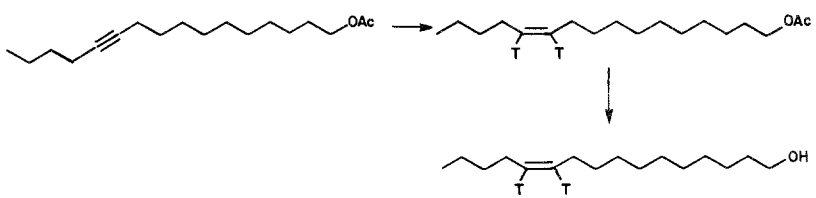

FIG. 5. Radiosynthesis and enzymatic hydrolysis of [11, 12-$^3H_2$]Z11–16:Ac.

Antennae were removed from anesthetized male moths one or two days posteclosion, homogenized in an ice bath, sonicated for 10 min in an ultrasonic bath to more thoroughly fracture the short sensory hairs (Ferkovich, 1981), and then centrifuged to remove cuticular and cellular debris. The antennae obtained in this fashion contain significant quantities of hemolymph proteins, but this is the only practical approach to the initial study of antennal proteins. In insects with plumose antennae adorned with abundant long sensory hairs, purified sensory hair preparations can be obtained in which blood proteins are essentially absent (Klein and Keil, 1984; Vogt et al., 1985). The antennae of *P. xylostella* males are also rich in cuticle and annular scales, and the esterase activity remaining in the low-speed pellet is due to scale esterases associated with these tissues (Vogt and Riddiford, 1986a; Ferkovich, 1982; Klein, 1987). A dilution series is performed on the supernatant, and an aliquot of this solution is used such that 30–50% hydrolysis occurs at 26°C with 0.5 μm [^{3}H]Z11-16:Ac. For male antennae, this level of activity was obtained with about 1.6 antennae/100 μl assay; each antenna contained 1.2 μg of soluble total protein. The assay mixture contains up to 4% ethanol (used to deliver competitors and inhibitors), but we have not observed any significant diminution of activity compared to controls with less than 0.5% ethanol. The enzymic hydrolysis is not affected by preincubation with 0.5 mM diisopropylfluorophosphonate, but boiling the enzyme solution for 5 min prior to addition of substrate completely destroys hydrolytic activity. Recently, we have kinetically resolved two distinct enzymes activities (slow, tight-binding and fast, loose-binding) in antennal tissues (G.D. Prestwich and L. Streinz, unpublished results).

In contrast to the potent inhibition of the sensillar esterase of *A. polyphemus* by 1,1,1-trifluoro-2-tetradecanone (Vogt et al., 1985), the trifluoromethyl ketone (Z11-16:Tfp), which should sterically mimic Z11-16:Ac, shows only very modest inhibition. For convenience in shorthand notation and to emphasize the isosteric substitutions involved, we introduce Tfp, or 1,1,1-trifluoropropyl, for the $CH_2C(O)CF_3$ analog to $OC(O)CH_3$. These compounds are so-called "transition state analogs" for ester hydrolysis (cf. Hammock et al., 1982); in reality, those which are highly active esterase inhibitors form stable tetrahedral hemiketals with serine hydroxyl groups, and these stable adducts are steric and electronic mimics of the tetrahedral intermediate in normal ester hydrolysis. Figure 6 illustrates this analogy for the present example. We observed that the trifluoroketones react rapidly with Tris buffer (a primary amine) and slowly with hydroxylic solvents to produce adducts inactive as esterase inhibitors.

Figure 7 illustrates the effects of the haloacetates, diazoacetate, and fluoroketone on the hydrolysis of 0.5 μM [^{3}H]Z11-16:Ac. In this assay, we have essentially measured competition for both binding and hydrolysis. Binding involves both the hydrophobic chain and the ester functionality. Hydrolysis involves only the ester group and can be susceptible to electronic effects (e.g.,

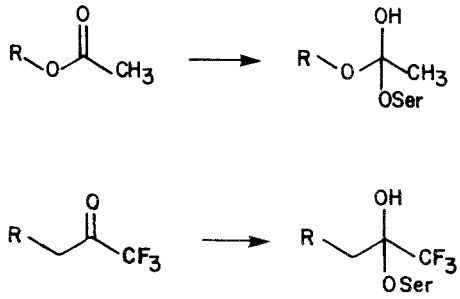

FIG. 6. Mimicry proposed for the tetrahedral intermediate involved in hydrolysis of Z11-16:Ac and the stable tetrahedral hemihydrate of a trifluoromethyl ketone which corresponds sterically to the pheromone.

the basicity of the leaving haloacetate anion) as well as steric (size) effects. As we have demonstrated in *A. polyphemus*, competition for binding can slow hydrolysis even when the steric parameters of the ester preclude its hydrolytic removal in the active site (Vogt et al., 1985; Prestwich et al., 1986b).

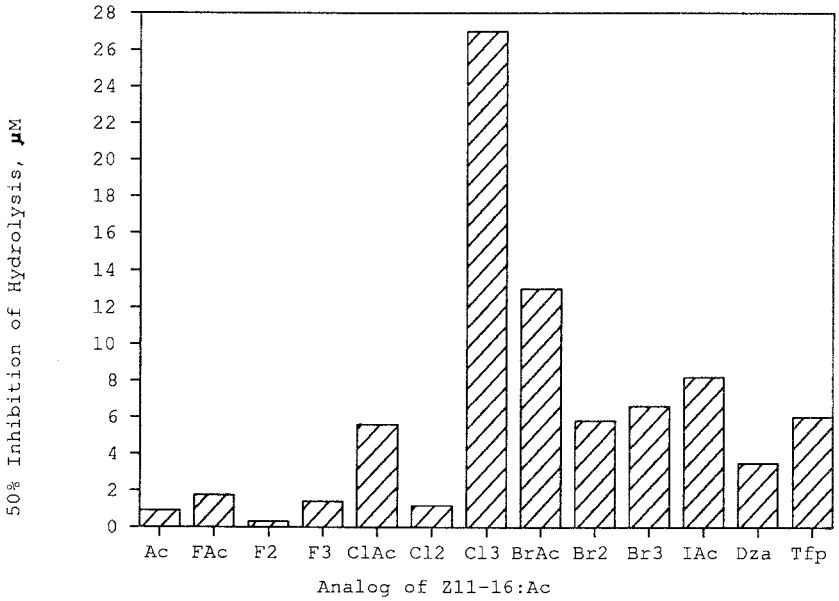

FIG. 7. Inhibition of male antennal esterase activity by analogs of Z11-16:Ac. Bars show the concentrations required for 50% reduction in hydrolysis of a 0.5 μM solution of labeled Z11-16:Ac by the supernatant of a homogenate containing 1.6 antennal equivalents/100 μl assay.

Addition of unlabeled Z11-16:Ac reduces hydrolysis effectively with an apparent I_{50} of 1 μM. [This turns out to be quite close to the K_m of the high affinity enzyme (Prestwich and Streinz, unpublished results).] The product, Z11-16:OH is 20–50 times less potent, and the saturated 16:Ac is less potent by a factor of 3 to 5. Of the halogenated acetates, the fluorinated acetates all showed strong competitive inhibition, with the difluoroacetate showing the greatest reduction in substrate hydrolysis. The diazoacetate, iodoacetate, bromoacetates, and trichloroacetates were poor inhibitors in this assay. The mono- and dichloroacetates were modest inhibitors. The enzyme kinetics will be described in detail elsewhere. We interpret these results to suggest that there is a limiting steric size which can be accommodated by the hydrolytic site. When an analog has too bulky an ester group, then only the weaker competitive hydrophobic effects are possible. Apparently, the maximum van der Waals radius tolerated by this hydrolytic site corresponds to two chlorines on the acetate methyl.

CONCLUSION

It is clear that the steric size of a haloacetate analog is of primary importance in both recognition by the postulated dendritic receptor protein involved in transduction and by the pheromone-degrading esterase responsible for maintaining a low stimulus noise level in the sensilla. In both assays, the differences in relative polarity of the fluorinated acetates and relative basicity of the fluorinated acetate anion were overshadowed by the difference in size relative to the chlorinated, brominated, and halogenated acetates regardless of polarity. It is gratifying to observe this agreement between *in vitro* and *in vivo* assays with *P. xylostella*.

Note Added in Proof—Electrophoretic studies of antennal esterases of *Plutella xylostella* have also been reported by Maa and Lin (1985) [MAA, W.C.-J. and LIN, Y.-M. 1985. Esterase of diamondback moth (*Plutella xylostella* L.). II. The antennal carboxylesterase of adult male with reference on male response to synthetic female sex pheromone. *Bull. Inst. Zool. Acad. Sinica* 24:165-176]. Also, an elegant molecular mechanics approach to pheromone-receptor interactions has been reported by the Liljefors group [LILJEFORS, T., BENGTSSON, M. and HANSSON, B.S. (1987) Effects of double bond configuration on interaction between a moth sex pheromone component and its receptor: A receptor-interaction model based on molecular mechanics. *J. Chem. Ecol.* 13:2023–2040.

Acknowledgments—We thank the National Science Foundation (DMB 8316931 to G.D.P.) for financial support. G.D.P. is the recipient of research awards from the Alfred P. Sloan Foundation, the Camille and Henry Dreyfus Foundation, Rohm & Haas Co., and Stuart Pharmaceuticals, which are gratefully appreciated. Electrophysiological assays and statistical analyses were generously performed by Drs. E.M. Giblin and E.W. Underhill of the National Research Institute-Plant Biotechnology Institute, Saskatoon, Saskatchewan. We are grateful for their seminal role in conducting the assays and suggesting manuscript revisions. Indispensable assistance at National Tritium Labeling was provided by Dr. H. Morimoto. We are grateful to Dr. B. Tabashnik and Ms. N. Cushing (University of Hawaii) and to Dr. K.D. Biever (USDA) for *P. xylostella* pupae and eggs. Dr. R.G. Vogt assisted with the initial conduct of the esterase assays.

(Received February 2, 1987; accepted June 2, 1987)

Abstract—Volatile substances in the atmosphere surrounding gregarious locusts *Schistocerca gregaria* and *Locusta migratoria* were captured and investigated by combined gas chromatography–mass spectrometry. Three aromatic derivates have been identified: phenol, guaiacol, and veratrole. Their relative percentages differ for different ages and species. Behavioral tests show that essentially phenol, guaiacol, and the mixture of the three products tend to increase the aggregation behavior in both species and thus act as "cohesion pheromones."

Key Words—Locusts, Orthoptera, Locustidae, *Schistocerca gregaria*, *Locusta migratoria*, pheromones, phenol, guaiacol, veratrole, aggregation, gregarious locusts.

INTRODUCTION

The great predatory locusts are well known for their ability to change their kind of life from isolated or "solitary" to crowded or "gregarious" phases (Uvarov, 1921), which differ in all their morphological, behavioral, and physiological characteristics. Visual or tactile stimuli play a part in these changes (Chauvin, 1941; Ellis, 1959). Chemical stimuli can also come into play (Loher, 1960; Norris, 1970; Gillett, 1975), but they have not been clearly identified until now.

0098-0331/88/0300-1023$06.00/0

A gregarization pheromone, which seems to turn solitary locusts into gregarious ones, was postulated by Nolte (1968) as a result of the study of some pigmentary and morphometric tests, and in particular, an important new analysis was made of the frequency of chiasmata in adult males (Nolte et al., 1970), which seems to increase with gregarization. Nolte et al. (1973) also isolated ethyl guaiacol, called "locustol," from extracts of 1 kg of feces from a gregarious population. These investigators concluded that other substances may exist, and in a complementary paper locustol was compared with chemical analoges (Nolte, 1976). Later Dearn (1974) showed that the chiasmata test is not reliable, and thus doubts were cast upon the efficacy of ethyl guaiacol in the natural situation of gregarious populations. It is difficult to know if a substance from the feces is effective in the surrounding atmosphere of living locusts. Gillett (1975) agrees with the existence of a chemical volatile factor that causes *Schistocerca gregaria* individuals to turn into gregarious insects in some of their characteristics. However, the breeding conditions were not natural (no nycthemeral changes of light and temperature) and thus may have given artificial results. Moreover, Gillett (1983) described later the occurrence in young adult populations of an unknown atmospheric factor from adult feces that caused the insect to change to the solitary type.

In this study, we have analyzed the chemical composition of the environmental atmosphere in gregarious populations with gas chromatography and mass spectrometry, looking for the behavioral effect of the substances isolated from this atmosphere on gregarious insects.

METHODS AND MATERIALS

Strains and Insects. Two species were used in this work: the desert locust, *Schistocerca gregaria*, and the migratory locust, *Locusta migratoria*. For the latter, we principally used the subspecies *migratorioides* from Africa, but a comparison was also made with the subspecies *cinerascens* from Sardinia. All were bred during their gregarious phase in cages 60 × 60 × 60 cm that contained 500–200 individuals of both sexes. They were reared in a special room with a nycthemeral temperature and light cycle of 12 : 12 hr light–dark and 33–23 °C; they received fresh corn shoots and bran daily.

Trapping the Atmosphere. To collect the volatile products of the atmosphere contained in a cage as described above, a current of air was sucked out by a vacuum pump through a burrow in one lateral part of the cage at a rate of 10 liters/hr. A glass container, maintained in a Dewar flask of crushed ice, was connected in one direction through the burrow into the cage, and in the other to the vacuum pump, so that the volatile products were condensed in the con-

tainer with the atmospheric water vapor. (If the atmosphere was too dry, we inserted a damp piece of cotton into the cage). The products were collected during the photophase over a period of 50 hr. Between two photoperiods, the condensate was put in a freezer at −15°C. At the end of the collection period, the condensate (10–20 ml) was immediately extracted three times with 15 ml of Freon 11 which was previously distilled. After drying with $MgSO_4$, the Freon was distilled by slight heating at 25°C. Evaporation was completed in a small fine tube into which we introduced 5–15 μl of pure hexane. The solution obtained was kept in a freezer, ready to be analyzed.

Analyses. The analyses were carried out by gas chromatography (GC) and combined gas chromatography–mass spectrometry (GC-MS). Mass spectra were obtained on a Nermag R10-10 spectrometer associated with a PDP8 calculator (Digital Equipment Instrument) and coupled to a Girdel 31 chromatograph with a splitless injector. Fractions to be analyzed were temperature programmed from 40°C to 300°C, at 4°C/min, on a capillary column (25 m × 0.32 mm) coated with CpSil 5 CB Chrompack. The integrations of chromatographic peaks were made with a Hewlett-Packard 3390A integrator associated with a Varian 3700 chromatograph which was equipped with a column already described, programmed from 40°C to 300°C at 4°C/min with a delivery of 18 cm/sec, and an on column injector.

Behavioral Tests. The tests were carried out on both sexes of fifth-instar nymphs, young immature adults two days after ecdysis, copulating mature adults, and mature adults at the time of laying the eggpods, for each strain in the gregarious state. For this first study, we avoided the use of the solitary phase. The work was based on an olfactometric method similar to that described by Siddiqi and Khan (1982).

Four 1-liter compartments (numbered 1, 2, 3 and 4) were arranged in the form of a cross joined by a middle compartment, "M," with four tunnels. An equal current of air was passed through lateral compartments 2, 3, and 4 and drawn into number 1 by a vacuum pump with delivery of 85 liters/hr, so that the middle space, "M," received air coming from the three lateral ones. The air arrived from outside (the campus is in the middle of large gardens in the country) and was preheated to the same temperature (33°C) as the apparatus. The apparatus was made of glass to allow observation of the insects and proper cleaning between each experiment. Correct functioning was tested by many preliminary assays using the attractive smell of fresh corn shoots with fasting animals. We found that the best results were obtained with compartment 1 as the starting point for the animals, and the smell in one lateral compartment, number 4, so that the locusts could also go to number 3 (straight on) or 2 (90° angle) with pure air. The light was uniform. In assays without any smell, we confirmed that there were no subtle factors which gave asymmetric behavior.

Only compartment 4 showed a few animals in controls because of the presence of white filter paper which we had to introduce to carry out the experiments. Since this phenomenon was consistent, we consider it had no influence on our calculations and conclusions. Numeric observations were made every 3 min over a period of 15 min after the release of 10 fifth-instar larvae or five adults. We did not work with single insects because the response is too long and we wanted to study interferences between identified substances and gregarism in conditions close to the natural ones.

Each substance detected by analyses was tested: hexane solutions of 10^{-3} M were prepared, either pure or as a mixture with percentages given by the previous analyses corresponding to the ages of the animals tested. Whenever possible, we took the results of atmosphere analyses as the basis for calculation of mixture solutions (see Results). A 5-μl solution was deposited on a filter paper on which a drop of 10 μl of paraffin oil had been previously deposited to moderate the evaporation of the very volatile components involved. Controls were made with filter paper where hexane and oil had been deposited without the phenols. All of this was done in a separate room. The paper was quickly put into compartment 4, which was taken into the olfactory room and placed in the apparatus. Compartment 1 with the locusts to be tested was immediately put in place (time = 0).

To interpret the results, preliminary experiments were done with a special compartment 4 where crowded locusts (10–15) were kept contained by a special partial glass stopper which permitted the air with locust odor to pass normally. It was observed that insects tested in these experimental conditions always tend to assemble in the middle M, so we decided to study statistically the general distribution by the χ^2 test and look particularly at the number of individuals in M.

For these tests, we used only the strains *Schistocerca gregaria* and *Locusta migratoria migratorioides* (because the subspecies *cinerascens* was found to be too poor in the chemical analyses) in a first series with fifth-instar larvae and in a second series, only a group of *Locusta migratoria migratorioides* that had been followed from fifth instar to mature adults in order to see if any change could be detected for different ages of the same animals.

RESULTS

Analyses. All chromatograms show four major substances (Figure 1), which are the same for both species but which differ in each case in their relative quantities. Three of the four products are identified by mass spectrometry; they

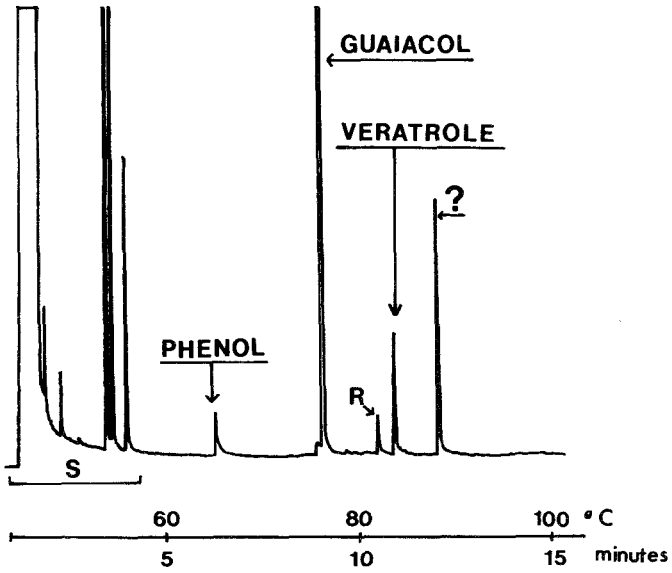

FIG. 1. An example of the chromatogram obtained with the mixture of substances in a capturing liquid: *Schistocerca gregaria* young adult. Three substances are identified: phenol, guaiacol, and veratrole, the fourth (?) is unknown. R = product used as reference (*o*-methyl acetophenone). S = solvent and impurities.

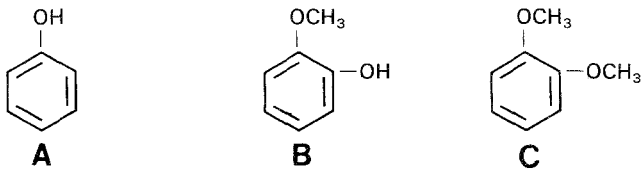
are all aromatic derivatives (Scheme 1): phenol (A), guaiacol (B), and veratrole (C). We are not yet able to identify the product corresponding to the fourth peak.

The mass spectra of these products agree with data in previous studies, *m/z* (intensity): phenol 94 (100), 66 (56), 65 (45), 39 (32), 55 (14), 50 (11); guaiacol 109 (100), 124 (74), 81 (55), 39 (21), 53 (22), 52 and 51 (17); veratrole 138 (100), 95 (50), 77 (44.2), 123 (36), 52 (32.7) (Barnes and Occlowitz, 1963; Cornut and Massot, 1966). Identity and retention times are in agreement



SCHEME 1.

with those of the three commercial products assayed and used in behavioral tests.

Chromatograms and mass spectra are obtained for the atmosphere trapped for each of the three strains described, and for each strain, the four described states of the same animals which have been followed. Results are presented in Table 1. For all insects, the percentages of each products are calculated by integration of peak surfaces obtained in gas chromatography except in the case of fifth-instar larvae of *Locusta migratoria cinerascens*, where the quantities of products are smaller, so that we obtain the percentages by integration of the ionic current areas in mass spectrometry. In two cases, the young adults of *Locusta migratoria migratorioides* and *cinerascens*, we cannot do any calculation because of the small amounts of material trapped. The quantities of trapped products in all other cases are only a few micrograms, but sufficient for experiments.

We see that the percentages differ from one sample to another, but in the three strains guaiacol is always the major product. Both minor products, phenol and veratrole, vary greatly from one strain to the other and also among the different ages of the same animals. *Schistocerca gregaria* give the best results

TABLE 1. PRODUCTS DETECTED IN CAPTURING MIXTURES FOR FOUR DIFFERENT AGES OF *Schistocerca gregaria*, AND *Locusta migratoria* (subspecies *migratorioides* and *cinerascens*).[a]

Insects	Phenol (%)	Guaiacol (%)	Veratrole (%)	Unknown product (%)
Schistocerca gregaria				
Fifth-instar larvae	3.70	94.40	1.95	Trace
Young adults	4.45	71.00	8.50	16.00
Copulating adults	5.05	56.50	22.80	15.55
Laying adults	8.40	62.00	24.70	4.90
Locusta migratoria migratorioides				
Fifth-instar larvae	9.85	63.60	3.50	23.00
Young adults		Traces of products		
Copulating adults	5.50	86.00	4.10	4.40
Laying adults	5.30	84.80	9.70	Tr.
Locusta migratoria cinerascens				
Fifth-instar larvae	13.10	65.00	2.00	19.80
Young adults		Traces of products		
Copulating adults	5.60	86.20	4.60	3.50
Laying adults	5.00	80.60	7.60	6.80

where all ages provide enough substance for easy calculation. It seems that the young immature adults always correspond to a lower concentration of volatile products. In the same species, *Locusta migratoria*, both subspecies present approximately the same atmosphere composition, although that of *cinerascens* seems to be less concentrated. The percentages of phenol and veratrole increase between larvae and laying adults for *Schistocerca*. In contrast, in *Locusta*, phenol decreases and veratrole increases. It is difficult to discuss the importance of the unidentified product.

Behavioral Tests. As described before, it was necessary to know the molecular concentrations of the solutions. Response coefficients of phenol, guaiacol, and veratrole in GC, based on normal solutions of them, were calculated. The reference was veratrole. The relative areas calculated from an equimolecular mixture of the three identified products are 1 for veratrole and 0.7 for guaiacol and phenol; thus it is possible to deduce the molar concentrations from the respective areas of the products in the chromatograms (Table 2) for both strains and each age. Since we know the percentages of molar concentrations of the mixtures (Table 2), it becomes easy to prepare suitably diluted solutions (Table 3).

The distribution of larvae in each compartment is presented in Table 4. The most marked response was an aggregation in the middle, M, where the products or a mixture of them statistically affect the distribution of the insects in the different experiments. However, the responses differ basically between *Schistocerca* and *Locusta*: guaiacol is very active on *Schistocerca* and not on *Locusta*. Veratrole alone has no effect under our conditions. Phenol is active in

TABLE 2. MOLAR CONCENTRATIONS OF THREE IDENTIFIED PRODUCTS DETECTED IN CAPTURING MIXTURES FOR DIFFERENT AGES OF *Schistocerca gregaria* AND *Locusta migratoria migratorioides*[a]

Insects	Molar concentration (%)

both species, but more strongly on *Locusta*. It is also interesting to note that a mixture of the three products always has a marked effect on both species.

Table 5 shows the change in the same *Locusta migratoria* in response to the mixture of products at the four different ages. In all cases, males and females were tested together, except when they were mature. It is clear that the mixture always tends to aggregate the animals. In no cases are the substances attractive: animals never assemble in compartment 4 as they do in preliminary assays with the volatiles of fresh corn shoots. We also emphasize that controls, too, have a few animals in compartment 4.

DISCUSSION

Guaiacol was found in 1973 by Nolte et al. (1973) with 5-ethylguaiacol in the products obtained through extraction and purification of mixtures of substances extracted by hot water steam from 1 kg of feces of *Locusta migratoria* larvae. In the present investigations, based on extraction from the atmosphere in which the locusts are living, we never found the 5-ethylguaiacol described by Nolte et al. (1973) as the gregarization pheromone and called "locustol."

It is possible that this substance exists in the feces in derived form, which may be hydrolyzed through extraction by steam. In contrast, we always found phenol and veratrole, which had not been detected by Nolte. Thus, it does not seem possible to call 5-ethylguaiacol, an active biological volatile pheromone, Locustol, even if it is present in the feces. It is evident that, in the field, only volatile substances in the air may potentially act as a pheromone.

It is to be emphasized that both species of locusts have the same volatile products in their breeding atmosphere during the gregarious phase, but the relative percentages are variable from one species to the other and from one age to the other. Both subspecies, *migratorioides* and *cinerascens*, are similar to each other, but the atmosphere for *cinerascens* seems to be less rich in products, and this may be related to the fact that *cinerascens* is less apt to crowd in its higher geographic latitude. Further assays will allow to statistical comparison of the different ages of each strains.

It is also possible that variations obtained in the relative quantities of products through different analyses lead one to conclude that some of these products play another pheromonal role for which further special research is necessary.

Behavioral tests clearly show, under our conditions, that the mixture of the three products and also pure guaiacol or phenol have the effect of keeping more animals together and seem to have the properties of a "cohesion pheromone," which may act in the field and contribute to the maintenance of the large migratory groups. But these substances that act as a cohesion pheromone are not acting as an attractant pheromone at our concentrations (compartment 4 shows only a few animals responding to phenols cases). It is possible that these pheromones act only when other stimuli, visual and tactile, already play a part in the formation of crowds (Gillett et al., 1976).

It is also interesting, even without special studies here, to note that the volatiles may come from the animals themselves (see preliminary assays) without feces. Since Nolte et al. (1973) has worked only with feces, this is perhaps the reason for the difference between our results; trapping the surrounding atmosphere is of greater interest in relation to the problem of substances that may act as true natural pheromones.

Since we have completed only short-term behavioral tests, we do not know yet if these volatile products have direct long-term effects during ontogenesis and when they might have a true gregarisation effect. Further research is required for this second problem.

(Revised April 6, 1987; accepted June 3, 1987)

Abstract—Colonies of *Zootermopsis* were collected from the central Sierra Nevada and the Monterey Penninsula in California, and from southern Arizona. Cuticular hydrocarbons were identified by gas chromatography–mass spectrometry (GC-MS) and quantified by gas–liquid chromatography (GLC) for each caste of all colonies. Four consistent and distinct cuticular hydrocarbon patterns, or chemical phenotypes, were identified. Unique and abundant monomethyl- and dimethylalkanes, and an *n*-alkene provided easy separation of the various phenotypes. Significant differences in the proportions of the various components were found among castes within a colony and colonies within phenotypes from California. Differences in the hydrocarbon proportions for castes were not consistent between colonies. The current taxonomy of the genus *Zootermopsis* recognizes three species. Our identification of four consistent, unique cuticular hydrocarbon phenotypes from the three described species should alert systematists and others to a major concern. If there are truly only three extant species, then the hypothesis that cuticular hydrocarbon profiles in this genus are species specific is not acceptable. Conversely, if cuticular hydrocarbon profiles are truly species specific, then there is at least one new, undescribed species of *Zootermopsis*.

Key Words—Chemotaxonomy, Isoptera, Termopsidae, termites, methyl-branched hydrocarbons, lipids, agonisitic behavior, cuticular hydro-carbons.

INTRODUCTION

The surface of all terrestrial insects is covered with a complex mixture of aliphatic material. This surface lipid plays a key role in survival of the insect by providing protection from desiccation, as well as serving as a barrier to abrasion, microorganisms, and chemicals. Hydrocarbons are ubiquitous components in insect cuticular lipids (Blomquist and Dillwith, 1985; Jackson and Blomquist, 1976; Hadley, 1980, 1985). They have been shown to be important in chemical communication as sex attractants and aphrodisiacs; as territory-marking, recruitment, and alarm pheromones; as defense secretions; and as kairomones, and they have been postulated as species and caste recognition cues (Howard and Blomquist, 1982).

Moore (1969) was the first to report the composition of cuticular hydrocarbons from a termite, *Nasutitermes exitiosus* (Hill). He found the majority of the hydrocarbons to be paraffins from C_{24} to C_{47} with the odd-carbon-numbered compounds predominating. Blomquist et al. (1979) and Howard et al. (1978, 1980, 1982) have completely characterized the cuticular hydrocarbons of a *Zootermposis* species and two *Reticulitermes* species. Because the mixtures of hydrocarbons of these three species were markedly different from one another and *N. exitiosus*, they postulated that these compounds might serve as semiochemical cues for caste and species recognition. Furthermore, Howard and Blomquist (1982) noted that there are extremely few reports of two insect species having identical hydrocarbon mixtures. Because of this, we were curious about their usefulness as taxonomic characters for separating morphologically similar species.

In preliminary work, we collected what we tentatively identified as colonies of *Z. angusticollis* (Hagen) from the vicinity of Burney, California, on the Lassen National Forest, and extracted their cuticular hydrocarbons. Our chemical analyses identified the same hydrocarbon components as published by Blomquist et al. (1979) but in markedly different proportions. This was our first clue that considerable intraspecific variation might exist in the mixtures of cuticular hydrocarbons of *Zootermopsis* and prompted us to examine this genus more thoroughly.

Zootermopsis is a genus of primitive termites in the family Termopsidae, which is restricted to western North America. Three species are recognized: *Z. angusticollis*, *Z. nevadensis* (Hagen), and *Z. laticeps* (Banks). The former two species occur in the forested areas along the Pacific Coast, in the Cascade Mountains and Sierra Nevada, and in some of the inland ranges west of the Continental Divide. The latter species occurs east and southeast of the Sonoran Desert in trees along water courses and around ponds (Weesner, 1970). Present keys to the species, written decades ago, are based on a limited number of specimens and use morphological features and measurements of the head, pronotum, and/or wings of either soldiers or imagoes (Emerson, 1933; Sumner,

1933). A thorough morphological analysis of *Zootermopsis* has never been done. The material studied by these early taxonomists was collected from a narrow geographic range, and we now recognize that this genus may be in need of revision.

With only three extant species, we felt that this genus would be ideal to test the hypothesis that cuticular hydrocarbon profiles are species specific. To date, no one has satisfactorily examined the qualitative or quantitative variation in cuticular hydrocarbons of castes within a termite colony or species, among different colonies in a species, or, most important of all, among all species within a genus. In this paper we report: (1) identification of all cuticular hydrocarbons from each recognized species of *Zootermopsis*, and (2) intercaste, intracolony, and intercolony variation in hydrocarbon mixtures within two species.

METHODS AND MATERIALS

Zootermopsis colonies or portions of colonies were collected in spring and summer of 1985 from the following two locations: near Placerville, California, on the Eldorado National Forest (eight colonies), and from Cypress Point near Pacific Grove, California, on the Monterey Peninsula (seven colonies). In the spring of 1986 additional collections were made at Cypress Point (nine colonies) and on the Eldorado National Forest (10 colonies). Also in the spring of 1986 samples from five colonies of *Z. laticeps* were obtained from an area along the Santa Cruz River near Rio Rico, Santa Cruz County, Arizona.

Two sets of chromatographic analyses were completed. Termites were removed from their galleries and placed in plastic dishes containing moist host wood. In the first analysis, one to five individuals of each caste from each of the colonies collected in 1985 were placed in separate numbered vials (one termite/vial) and kept at −20°C until extracted for hydrocarbon analysis. Individual termites were coded by number; thus the species or location was unknown before gas chromatographic analysis. In the second analysis, groups of five individuals from each caste from each of the colonies collected in 1985 and 1986 were placed in numbered vials as were the individual termites. Termites used in both the first and second analysis were removed from their host wood and frozen within days of collection.

Individual termites or groups of individuals were removed from the freezer and allowed to come to ambient temperature. Cuticular lipids were extracted by immersion of termites in 10 ml of hexane for 10 min. After extraction, hydrocarbons were separated from other nonpolar components by pipetting the 10-ml extract through a minicolumn packed with 100–200 mesh BioSil A activated overnight at 70°C in a drying oven. This hydrocarbom extract was then evaporated to dryness under a stream of nitrogen and redissolved in 30 μl of hexane for GLC analysis. After extraction, the insects

were stored in 70% ethanol for later identification by morphological features and to serve as voucher specimens. All voucher specimens will be deposited in the U.S. National Museum, Smithsonian Institution, Washington, D.C.

The first analysis of cuticular hydrocarbons was performed on a Hewlett Packard 5790A gas chromatograph using a wide-bore capillary column (30 m × 0.75 mm ID SPB-1) with a flame ionization detector (FID). Peak resolution was adequate with this system to observe obvious qualitative differences in cuticular hydrocarbon mixtures and allowed us to separate the California *Zootermopsis* into three obvious chemical phenotypes (see Results and Discussion). Individual termites were used for these analyses, which permitted us to quantify each hydrocarbon with the exception of a few which coeluted in the same peak. Peaks were characterized by retention time, and areas under curves (= quantity of a particular component) were automatically quantified by a Hewlett Packard 3390A electronic integrator. The total hydrocarbon was calculated by summing the area for each component and proportion of each component then calculated. For each of the three California chemical phenotypes, proportions of each hydrocarbon were transformed to the arcsine of the square root of the proportion and subjected to analysis of variance to evaluate differences among castes and within and among colonies, and to provide summary statistics.

Better hydrocarbon separation was obtained with the acquisition of a Hewlett Packard 5890 gas chromatograph equipped with a fused silica capillary column (30 m × 0.32 mm ID, SPB-1), FID, and operated in the split mode (with a split ratio of 33:1). The temperature program in each case had a starting temperature of 200°C. Temperature was increased at 3°C/min to 300°C, with a final holding time of 12 min. Helium carrier gas flow was 25 cc/min on the HP 5790A and 3 cc/min on the HP 5890. Hydrocarbons were quantified as in the first analysis.

Routine identification of all hydrocarbons was based on external standards or retention times from hydrocarbons identified by GC-MS. Equivalent chain length (ECL) for each hydrocarbon was calculated by comparing the retention time of a given peak to known *n*-alkanes in external standards. GC-MS analyses were performed on a Finnigan 4023 mass spectrometer interfaced with an INCOS data system. Electron impact (EI) mass spectrometry was performed at 70 eV. Mass spectra of methylakanes were interpreted according to the criteria of Nelson et al. (1972), Nelson (1978), and Pomonis et al. (1978). *n*-Alkenes were isolated by silver nitrate chromatography (column and/or TLC), and the positions of double bonds were determined by GC-MS analysis of the monomethoxy and dimethoxy derivatives of the parent compounds after methoxymercuration–demercuration (Blomquist et al., 1980).

To assure correct species identification and to correlate cuticular hydrocarbon mixtures with species, preserved, extracted specimens (imagoes and soldiers, if both were present) were shipped in numbered vials, one individual per vial, to termite specialists for identification. The termites were identified by

these specialists solely on the basis of external morphology without knowledge of location or host. The only information provided was the association of individuals from the same colony. The keys used were from Banks and Snyder (1920), Snyder (1954), Sumner (1933), and Weesner (1965).

RESULTS AND DISCUSSION

All of the abundant hydrocarbon components (mean percent $\geq 0.5\%$ of the total hydrocarbon component) and most of the less abundant components were identified for each location and/or species (Tables 1 and 2, Figure 1). All col-

[a] A triple + indicates ≥5.0% of the total, ++ from 1.0 to 5.0% of the total, and + from 0.5 to 1.0% of the total hydrocarbon component. Some trace (tr.) components appear infrequently or consistently in very small quantities (<0.5% of the total). A zero indicates the hydrocarbon was never identified for the phenotype.

[b] Hydrocarbon identifications by GC-MS (see Table 1 and Figure 1).

[c] Phenotypes and collection locations: I = Eldorado NF, California, *Z. nevadensis*; II and III = Pacific Grove, California, *Z. angusticollis* and *Z. nevadensis*, respectively; IV = Rio Rico, Santa Cruz County, Arizonia, *Z. laticeps*.

onies from the Eldorado National Forest possessed qualitatively identical mixtures of hydrocarbons, which we will call phenotype I. Ninety-one percent of the taxonomic determinations for this phenotype were *Z. nevadensis*; the remaining 9% were determined to be *Z. angusticollis*. Two different hydrocarbon phenotypes (II and III) were recognized from the Pacific Grove area; both were qualitatively different from phenotype I. All colonies in either phenotypes II or III had the same hydrocarbon components. All of the taxonomic determinations for phenotype II were *Z. angusticollis*; 84% of the determinations for phenotype III were *Z. nevadensis*. Colonies collected from Rio Rico in southern Arizona were identified as *Z. laticeps*. These termites all had qualitatively identical hydrocarbon profiles that were qualitatively different from phenotypes I, II, and III. *Zootermopsis laticeps* constitutes phenotype IV.

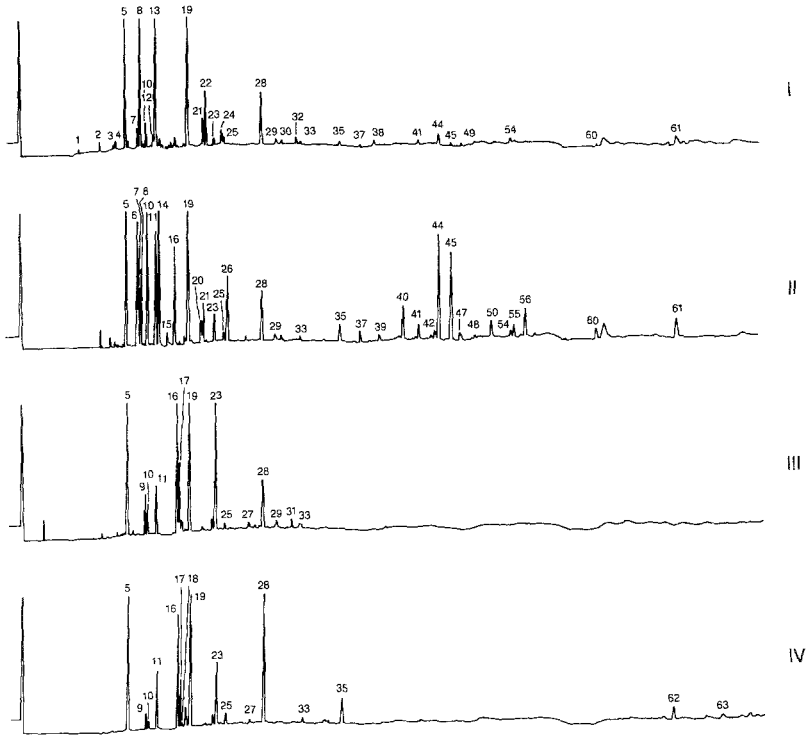

FIG. 1. Gas chromatograms of the surface hydrocarbons of four phenotypes of *Zootermopsis*. Numbers identify peaks whose compositions are listed in Table 1.

GC-MS was used to characterize each of the major hydrocarbon components of each phenotype, and the mass spectra of some of the components unique to certain phenotypes are presented in Figures 2–6. The mass spectrum of peak 13 (Figure 1), which elutes about one equivalent chain length (ECL = 22.04) in front of the corresponding *n*-alkane and is identified as the symetrical 5, 17-dimethylheneicosane, is presented in Figure 2. The strong *m/z* 84/85 ion (Figure 2) is interpreted as arising from cleavage internal to the methyl group on carbons 5 and 17 giving rise to a six-carbon fragment ion. Cleavage external to the methyl groups gives rise to ions at *m/z* 266/267, in which the much greater intensity of the odd-numbered ion is consistent with the fragment containing a second methyl group.

Peak 16 from phenotype IV is interpreted as 2-methyldocosane based on its retention time and mass spectrum (Figure 3). The ECL = 22.63 and strong M − 15 ion at *m/z* 309 and M − 43 ion at *m/z* 281 are consistent with a 2-methylalkane. In some spectra of components identified as 2- or 4-methylal-

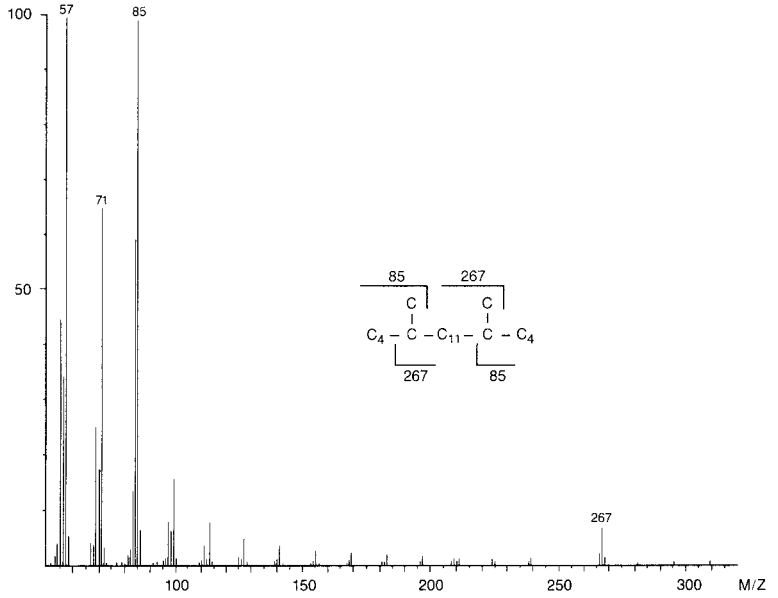

FIG. 2. EI mass spectrum of peak 13, Figure 1, identified as 5,17-dimethylheneicosane.

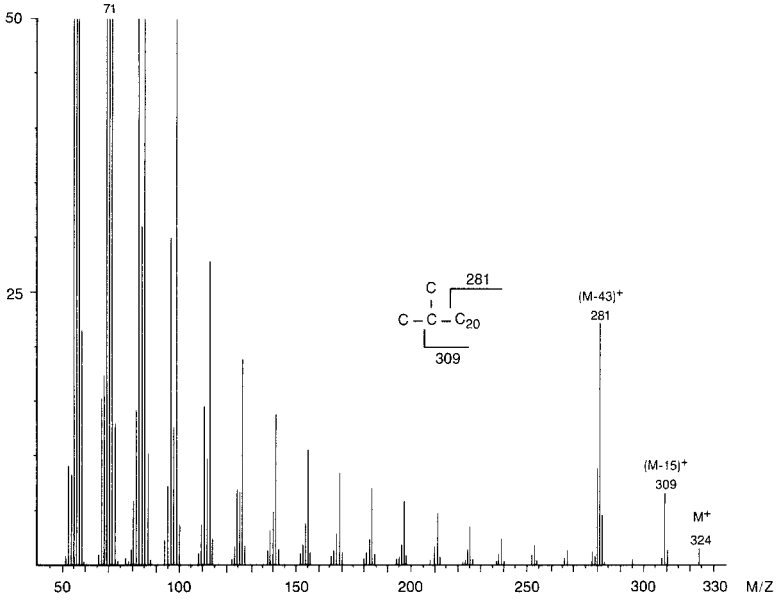

FIG. 3. EI mass spectrum of peak 16, Figure 1, identified as 2-methyldocosane.

kanes, there is a relatively strong ion pair at M-71:M-72, indicating that 4-methylalkanes may also be present. The M-71:M-72 ion from the alkanes identified as 2- or 4-methylalkanes varied in intensity among different spectra and therefore are designated as either 2- or 4-methylalkanes. Even when the M-71:M-72 ions are relatively strong, we cannot rule out the possibility that the peak also contains a 2-methylalkane.

Phenotype II also contains peaks identified as a mixture of 3,11- and 3,13-dimethylalkanes. In Figure 4 we show the mass spectrum of peak 26, which is identified as a mixture of 3,11- and 3,13-dimethyltetracosanes. The major isomer appears to be the 3,11- component, which gives rise to ions at *m/z* 182/183, 196/197, and 322/323. The 3,13- isomer gives rise to ions at *m/z* 168/169, 210/211, and 322/323. This phenotype appears to be the only one that contains 3,11- and 3,13-dimethylalkanes (peaks 14 and 26, Figure 1, Table 2).

Phenotypes III and IV contain an alkene (peak 17), which we identify as 9-tricosene from the mass spectra of its mono- and dimethyoxy derivatives. The spectra (Figures 5A and 5B) show the expected fragment ions (*m/z* 157, 171, 227, and 241 for the monomethoxy derivative and 157 and 227 for the dimethoxy derivative). Phenotype IV also contains two unique dimethylalkanes, 7,11-dimethylpentatriacontane and 7,13-dimethylheptatriacontane (peaks 62 and

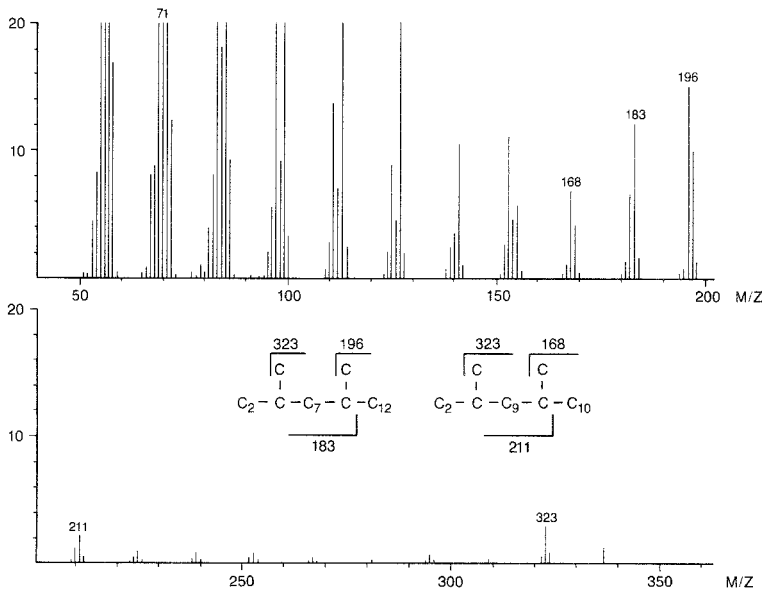

FIG. 4. EI mass spectrum of peak 26, Figure 1, identified as 3,11- and 3,13-dimethyltricosane.

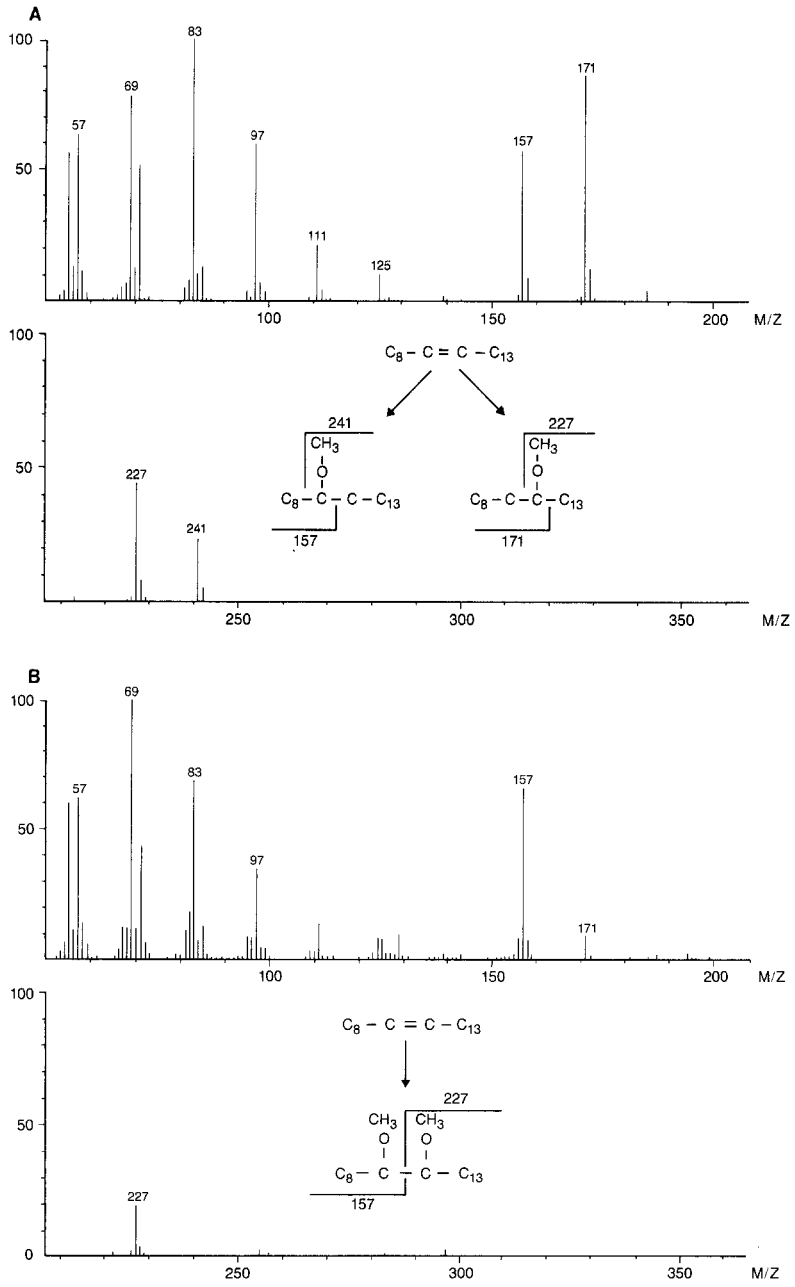

FIG. 5. EI mass spectra of (A) monomethoxy and (B) dimethoxy derivatives of 9-tricosene.

63). One of these (peak 63) elutes much later than any of the other components in any of the *Zootermopsis* phenotypes. The mass spectrum of 7,11-dimethylpentatriacontane is presented in Figure 6. Cleavage internal to one or the other of the branching methyl groups gives rise to fragments at *m/z* 112/113 and 364/365. Cleavage external to the branching methyl groups gives rise to fragments that contain a second methyl branch and are at *m/z* 183 and 435.

Mass spectra of each of the other major components for all four phenotypes were interpreted in a similar manner to that described above, and each component and its diagnostic ions are presented in Table 1.

Phenotype I contains major amounts (ca. 10% of the total hydrocarbon) of the symmetrical dimethylalkane 5,17-dimethylheneicosane (peak 13, Figure 1 and Table 3). This dimethylalkane is not shared with any other phenotype (Table 2). Phenotype I is rich in minor 5,17-dimethyl components including a homologous series of 5,17-dimethyl C_{25}, C_{27}, C_{29}, C_{31}, C_{35}, and C_{37}. With the exception of 5,17-dimethyl C_{31}, C_{35}, and C_{37}, these components of this homologous series are unique to phenotype I (Table 2).

Phenotype II is the most complex of the *Zootermopsis* chemical phenotypes, sharing many of the components eluting before *n*-nonacosane with at least one of the other phenotypes. This phenotype possesses many unique compounds in major quantities (>1.0%, Table 4): an isomeric mixture of 9- and

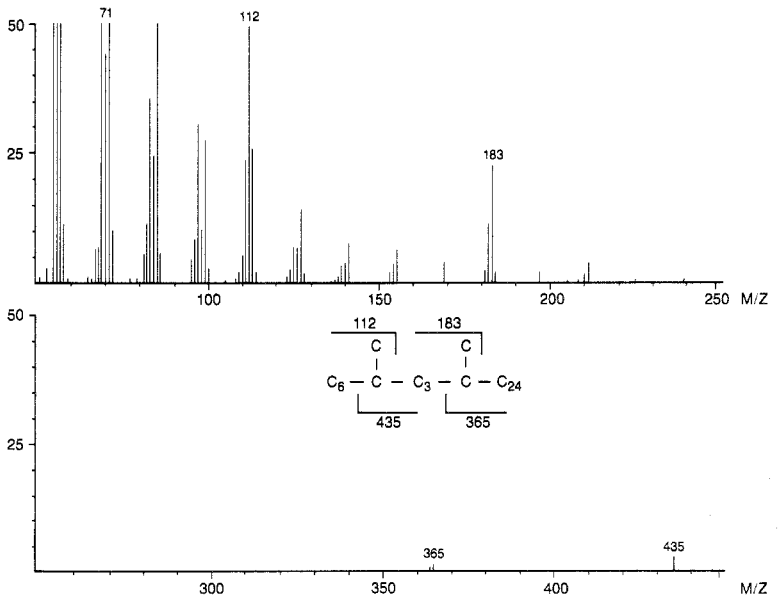

FIG. 6. EI mass spectrum of peak 62, Figure 1, identified as 7,11-dimethylpentatriacontane.

TABLE 3. STATISTICS FOR PERCENT HYDROCARBON FROM FOUR CASTES FROM EIGHTEEN COLONIES

[a] Hydrocarbons and peak numbers are the same as those reported in Table 1 and Figure 1. Carbon number is the total number of carbons, including methyl groups.

[b] Values not necessarily zero but may have had a very low quantity (<0.1% of total hydrocarbon) or were simply not detectable for a given GLC analysis.

[c] Proportion of the 53 chromatograms where a given hydrocarbon was not detectable.

[d] Castes are SO = soldier, PS = pseudergate, NY = nymph, and AL = alate (imago).

[a] Hydrocarbons and peak numbers are the same as those reported in Table 1 and Figure 1. Carbon number is the total number of carbons, including methyl groups.

[b] Values not necessarily zero but may have had a very low quantity (<0.1% of total hydrocarbon) or were simply not detectable for a given GLC analysis.

[c] Proportion of the 20 chromatograms where a given hydrocarbon was not detectable.

[d] Castes are SO = soldier, PS = pseudergate, NY = nymph, and AL = alate (imago).

[e] Proportions of each hydrocarbon were transformed to the arcsine of the square root of the proportion and subjected to analysis of variance. Asterisk indicates significant difference (α = 0.05) between colony, caste, or interaction term for a given hydrocarbon. Analysis of variance was done only for hydrocarbon components detectable from individual termites from collections made in 1985. The gas chromatograph with a 0.75-mm-ID capillary column was used.

TABLE 5. STATISTICS FOR PERCENT HYDROCARBON FROM FOUR CASTES FROM EIGHT COLONIES

		Overall (N = 27)

[a] Hydrocarbons and peak numbers are the same as those reported in Table 1 and Figure 1. Carbon number is the total number of carbons, including methyl groups.
[b] Values not necessarily zero but may have had a very low quantity (<0.1% of total hydrocarbon) or were simply not detectable for a given GLC analysis.
[c] Proportion of the 27 chromatograms where a given hydrocarbon was not detectable.
[d] Castes are SO = soldier, PS = pseudergate, NY = nymph, and AL = alate (imago).

11-methylheneicosane (peak 6), 3,11- and 3,13-dimethylheneicosane (peak 14, which elutes at nearly the same time as the unique peak 13 found in phenotype I), 3,11- and 3,13-dimethyltricosane (peak 26), 2- or 4-methyloctacosane (peak 40), and 2- or 4-methyhentriacontane (peak 56).

Phenotype III clearly contains the simplest hydrocarbon profile of the phenotypes from California. Only 10 hydrocarbon components comprise greater than 1.0% of the total hydrocarbon fraction (Table 5). This is the only phenotype we collected from California with an olefin (peak 17). All of the other

[e] Proportions of each hydrocarbon were transformed to the arcsine of the square root of the proportion and subjected to analysis of variance. Asterisk indicates significant difference (α = 0.05) between colony, caste, or interaction term for a given hydrocarbon. Analysis of variance was done only for hydrocarbon components detectable from individual termites from collections made in 1985. The gas chromatograph with a 0.75-mm-ID capillary column was used.

major (>5.0%) or significant (>1.0%) components of phenotype III are shared with at least one of the other phenotypes. Phenotype IV is also fairly simple, with only 13 significant components (Table 6), and is quite similar to phenotype III. The major differences are the four unique compounds: 2- or 4-methylheneicosane (peak 9), unknown 1 (peak 18) eluting between *n*-tricosene and *n*-tricosane, 7,11-dimethylpentatriacontane (peak 62), and 7,13-dimethylheptatriacontane (peak 63).

Variation in the proportions of hydrocarbons among individuals of each

[a] Hydrocarbons and peak numbers are the same as those reported in Table 1 and Figure 1. Carbon number is the total number of carbons, including methyl groups.
[b] Includes one analysis of a group composed of four pseudergates and one soldier.
[c] Values not necessarily zero but may have had a very low quantity (<0.1% of total hydrocarbon) or were simply not detectable for a given GLC analysis.
[d] Proportion of the eight chromatograms where a given hydrocarbon was not detectable.
[e] Castes are SO = soldier, PS = pseudergate, and NY = nymph.

caste, among castes within a colony, and among colonies within phenotypes I, II, and III was examined during the first hydrocarbon analyses with individual termites. By using individual termites and the wide-bore (0.75 mm ID) capillary column, we were not able to separate and quantify all hydrocarbon components. Furthermore, in many of the individual chromatograms, one or more of the components were not detected, probably because of insufficient sample. In any case, we conducted analyses of variance of the transformed proportions of each hydrocarbon component (or coeluting components) for phenotypes I, II, and III and found numerous statistically significant differences (Table 3–5). For many of the hydrocarbon components, we observed statistically significant interactions among colonies and castes. This implies that caste-specific blends of hydrocarbons within a phenotype are not consistent from colony to colony. Furthermore, the minimum and maximum values for any given hydrocarbon component for colonies or castes were quite distant.

Much better hydrocarbon resolution and more consistent quantification were achieved with the 0.32-mm-ID capillary column and extraction of five individual termites (of the same caste and from the same colony). Quantification of the percentage of each hydrocarbon component for the four phenotypes of *Zootermopsis* are presented in Tables 3–6. The data for the California phenotypes are more precise because of the increased sample size: 18 colonies for phenotype I, seven colonies for II, and eight colonies for III. Although we did not statistically analyze these data, from the range of the colony and caste means it appears that colony-to-colony differences account for most of the variation. With the exception of the underrepresented alates, variation among the castes was small. Many more minor components ($<0.5\%$ of the total) were detected with the 0.32-mm-ID capillary column. The minimum value for nearly all of the minor components is zero because the component was very low in quantity or was simply not detected for a given GLC analysis (Tables 3–6).

These data suggest caution in assuming that cuticular hydrocarbons serve as semiochemical cues for caste recognition (Howard and Blomquist, 1982). None of the previous studies involved bioassays to test the caste-recognition hypothesis (Howard et al., 1978, 1982; Blomquist et al., 1979), and such bioassays will be very difficult to execute. The information content in these cuticular hydrocarbon mixtures is great. However, if members of a colony are, in fact, cognizant of the caste of each of the other members that they encounter, a chemical cue could involve many classes of compounds other than or in addition to hydrocarbons. This question remains to be resolved, and more data are needed to prove or disprove the hypothesis that hydrocarbons act as caste-recognition cues.

The results of this study clearly identify four distinct, consistent cuticular hydrocarbon phenotypes. Thus far, we (M.I.H., M.P., and L.J.N.) have collected 143 additional *Zootermopsis* spp. colonies throughout much of northern

California to study the geographic distribution of these phenotypes. We have also received live samples from Washington, Oregon, the San Francisco Bay area, and southern California, and have yet to see an additional hydrocarbon phenotype.

Agonistic bioassays pairing a soldier of one phenotype and three pseudergates or nymphs of the same phenotype or a different phenotype indicate that these cuticular hydrocarbon phenotypes are capable of recognizing one another (B.L. Thorne, personal communication). Preliminary results indicate that an encounter between a soldier from one colony and nymphs from a second colony of the same chemical phenotype very rarely produces a highly aggressive response (mandible snapping or biting). Similar encounters between chemical phenotypes II and III virtually always evoke an immediate soldier biting response, as do encounters between soldiers of phenotypes I, II, or III and nymphs of phenotype IV. Finally, encounters between soldiers of phenotype I and nymphs of either phenotype II or III or between soldiers of phenotype II or III and nymphs of phenotype I produce occasional highly aggressive responses that seem to depend on the individual soldier involved and perhaps on the nymphs' parental colony. Agonistic experiments never evoke intraphenotype aggression. All other pairwise interchemical phenotype interactions elicit highly aggressive responses all or part of the time. These results are potentially consistent with the hypothesis that individual termite recognition is based, at least in part, on cuticular hydrocarbon composition. Further evaluation of this behavior is obviously necessary and is the subject of continuing studies (Haverty and Thorne, unpublished).

To summarize the results of this study, identification of four consistent, unique cuticular hydrocarbon phenotypes from three extant species, and inconsistent identification of species using existing morphological keys, should alert insect biochemists, systematists interested in chemotaxonomy with cuticular hydrocarbons, and termite biologists to a major concern. If there are truly only three extant species, then we cannot accept the hypothesis that cuticular hydrocarbon profiles in this genus are species specific. Conversely, if cuticular hydrocarbon profiles are truly species specific, then there is at least one new, undescribed species of *Zootermopsis*. It would appear that *Z. angusticollis* and *Z. laticeps* are valid species, but *Z. nevadensis* is a complex of at least two species or one species with polymorphic hydrocarbon chemistry. We feel that it is extremely important to clarify the taxonomic status of this genus, as it has been frequently used as a model for behavioral and caste-determination studies. Determination of specific status of each phenotype may take many different approaches, including bioassays of aggressive behavior (in progress), breeding experiments (in progress), correlation of hydrocarbon chemistry and external morphology from an extensive geographic collection (in progress), enzyme analysis, DNA hybridization, etc. These studies will probably result in a revision of the genus.

Acknowledgments—The authors thank those who helped them during the course of this study. The Pebble Beach Corporation was most cooperative in allowing us to collect termites from their property adjacent to the Cypress Point Golf Course, as was R. Smart, District Ranger of the Placerville District of the Eldorado NF. Many helped collect *Zootermopsis* specimens or provided live material from other geographic locations. They include: P. M. Haverty, B. L. Thorne, M. K. Rust, R. H. Scheffrahn, T. D. Schowalter, R. B. Rosengaus, T. G. Myles, W. L. Nutting, P. Hahn, and D. Azuma. W. L. Nutting, T. G. Myles, M. S. Collins, and D. Nickle provided identifications of extracted termites. R. Scholl, Natural Products Laboratory, University of Nevada, Reno, performed the GC-MS analyses. B. L. Thorne provided preliminary results of agonistic bioassays to be included in the manuscript to support the validity of the chemical phenotypes. D. R. Nelson and W. L. Nutting and especially B. L. Thorne and R. W. Howard provided helpful reviews of the manuscript. These reviews clarified our interpretations and greatly improved the manuscript.

(Received January 6, 1987; accepted April 19, 1987)

Abstract—Cuticular hydrocarbons of young *Drosophila* flies are singular with very long chains and complex diene mixtures. A precise characterization of these substances was carried out by epoxidation and analysis of the products by GC-MS with negative chemical ionization. In *D. melanogaster*, double bonds of dienes are more probable at carbon positions 11 or 13 and 21 or 23. In *D. simulans*, double bonds are shifted more towards the interior of the chain. Such a difference is also found among monoenes of both species. The analyses of monoenes and dienes confirm the similarity of cuticular compounds of young flies of both sexes in both species. A main cuticular compound of *D. erecta* females, 9, 23-tritriacontadiene, is also presented.

Key Words—*Drosophila melanogaster, Drosophila simulans*, Drosophilidae, Diptera, aphrodisiac pheromone, cuticular hydrocarbon, double bonds, epoxidation, chemical ionization, mass spectrometry, (Z,Z)-7,11-heptacosadiene, alkenes, olefins.

INTRODUCTION

The behavioral effects of long-chain unsaturated hydrocarbons in *Drosophila melanogaster* have been clearly demonstrated. Cuticular extracts of these substances from mature female flies can induce wing vibration in males. This is one of the most characteristic precopulatory behaviors in these insects (Jallon and Hotta, 1979). Using such a bioassay, we were able to identify the molecules responsible for this response as being between 25 and 29 carbons long in a complex mixture, the principal component of which is (Z,Z)-7,11-heptacosa-

0098-0331/88/0400-1071$06.00/0

diene, a substance that is characteristic of mature females (Antony et al., 1985). (Z)-7-tricosene has been shown to be an aphrodisiac for males of the sympatric sibling species, *Drosophila simulans* (Jallon, 1984).

Other behavioral analyses have shown that in *D. melanogaster*, young flies of both sexes are courted by mature males, suggesting that young flies produce signals that mimic those of mature females (Cook and Cook, 1975; Jallon and Hotta, 1979; Tompkins et al., 1980). The exact nature of the chemical stimuli produced by these young flies is therefore of interest. Preliminary chromatographic analyses of young *D. melanogaster* revealed a very particular hydrocarbon pattern with similar profiles for the two sexes: the major components were long chains of 29 to 35 carbons. Branched alkanes were abundant, and unsaturated hydrocarbons seemed to consist of a complex mixture of position isomers (Antony and Jallon, 1981; Antony, 1984).

The localization of double bonds in olefins is a classic problem of analytical chemistry. Direct methods involving GC-MS with chemical ionization using gases like isobutane, methylamine, or methyl vinyl ether, have been established. However, extrapolation of such methods to high-molecular-weight dienes and polyenes was not simple (Budzikiewics and Busker, 1980; Einhorn et al., 1985; Doolittle et al., 1985). Many methods involve first a derivatization (Baker et al., 1963; Aplin and Coles, 1967; Suzuki et al., 1981) but the analysis of the products is always more or less laborious. Mass spectrometry with electron impact has been helpful in the analysis of several of these substances, although a significant amount of the product was necessary in the determination (Capella and Zorzut, 1968; Blomquist et al., 1980; Suzuki et al., 1981; Dunkelblum et al., 1985).

For the study of the structure of mixtures, chemical ionization is better than electron impact as it minimizes background and therefore the diagnostic fragment peaks are more obvious (Budzikiewics and Busker, 1980). Tumlinson et al. (1974) have analyzed a series of epoxydecanes in this way, with methane and isobutane as reagent gases, but the mass spectra were not so simple.

In the past we have used methoxymercuration–demercuration coupled with CI mass spectrography analysis to describe the monoenes of mature *D. melanogaster* males, and mature flies of both sexes in *D. simulans* (Pechiné et al., 1985). This method revealed that in mature *D. melanogaster* females the double bonds were mainly in positions 7 and 11 (Antony et al., 1985). However, there was an inherent difficulty in this method because the derived methoxy products which correspond to a given isomer produce two pairs of two fragmentation peaks separated by 14 mass units. Such a method was therefore not sufficiently precise for the study of complex mixtures.

Bouchoux et al. (1987) have recently developed a new method to localize the epoxide ring position in short aliphatic chains by negative ion chemical ionization–mass spectrometry. Abundant pseudomolecular anions $(M-H)^-$ are

produced. Moreover each isomer yields only two major characteristic peaks: one with a higher mass and one with a lower mass.

After checking the applicability of such a method to heavy unsaturated hydrocarbons already characterized by other methods, we have used it to compare monoenes and dienes present as a complex mixture in the cuticles of young males and females of both *D. melanogaster* and *D. simulans.*

METHODS AND MATERIALS

GC-MS Analysis. Raw products were injected into a Girdel 31 chromatograph. The machine contained an all-glass solid injector, and separation took place in a CP Sil 5 (Chrompack) capillary column, 25 m × 0.34 mm, programmed between 200 and 300°C at 5°C/min. which well separated monoenes and dienes of a given chain length. The chromatograph may be coupled to a Nermag R10-10 mass spectrometer. Either electron impact ionization (70 eV) or chemical ionization was used. In the latter case, negative chemical ionization took place by placing into the source 0.1 torr of a mixture containing 90% methane and 10% nitrous oxide (N_2O). The ionizing agent was therefore the OH^- ion. The temperature of the source was maintained at 200°C. This technique allowed us to characterize quantities of dienes of as little as 10^{-10} mol.

Cuticular Extracts of Insects. Pools of young flies ($N = 250$), of each sex and each species (*D. melanogaster* Canton S and *D. simulans* Seychelles) were collected 3–6 hr after eclosion and washed with hexane as previously described (Antony and Jallon, 1982).

Their compositions were deduced from direct GC-MS analysis with electron impact (70 eV) (Table 1). In all cases they consisted of long chains, mainly with 27–37 carbons. Branched alkanes, with methyl mainly on position 2 (as in mature flies) were specially abundant for 29 carbons as were 31-carbon monoenes. Dienes with 31–37 carbons were more abundant in young *D. simulans* flies

Epoxidation of Double Bonds. Cuticular extracts containing on average 10^{-8} mol/μl of unsaturated hydrocarbons were dissolved in hexane. Ten microliters of this extract were mixed with a 10-μl solution of methylene chloride, containing 3×10^{-6} mol of metachloroperbenzoic acid together with 1 μl of a solution of sodium bicarbonate in water (5×10^{-4} mol). The mixture was agitated for 3 hr at ambient temperature. The products were analyzed immediately and without prior separation using GC-MS. In such conditions all double bonds are epoxidized and dienes are completely transformed into diepoxydes. It is possible to keep the products for 24 hr in a freezer before analysis without significant degradation.

Chemical Compounds. 9-Tricosene was obtained commercially (Sigma).

[a] GC-MS analysis with EI ionization.
[b] meC: *D. melanogaster* Canton S; si S: *D. simulans* Seychelles; F: female; M: male.

Diepoxides were prepared according to the method described above, using the following dienes: 7,11-heptacosadiene present in mature *D. melanogaster* females (Antony et al., 1985) and a tritriacontadiene present in mature *D. erecta* females (Jallon and David, 1987).

RESULTS

Application of the Method to Analysis of Known Simple Compounds. Commercial 9-tricosene produces a mono epoxy compound, 9,10-epoxytricosane, the spectrum of which is presented in Figure 1A. The molecular mass can be

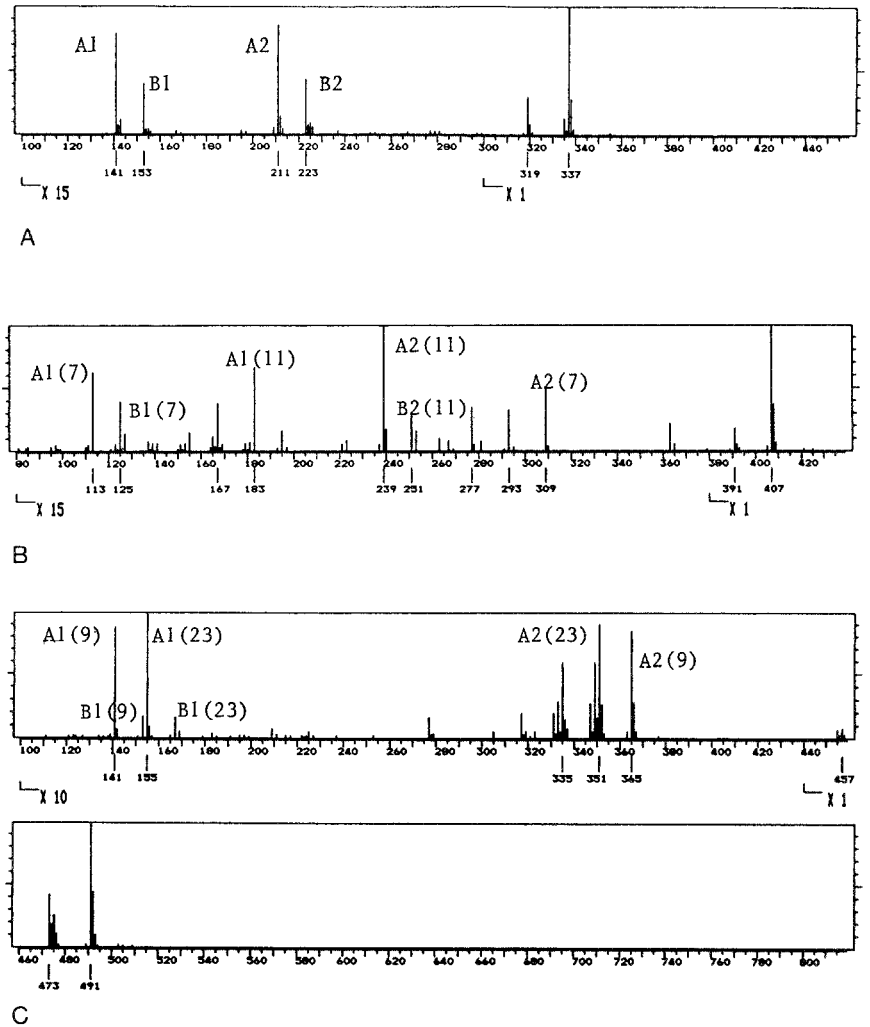

FIG. 1. Mass spectra of epoxyderivatives of various model compounds, negative chemical ionization (OH^-). (A) 9-epoxy-tricosane; (B) 7,11-diepoxy-heptacosane; (C) 9,23-diepoxy-tritriacontane.

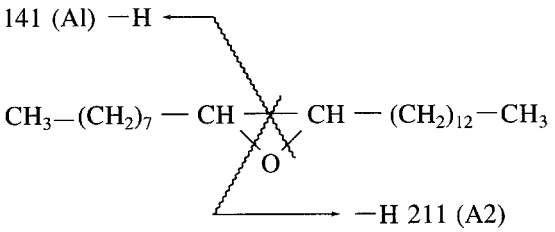
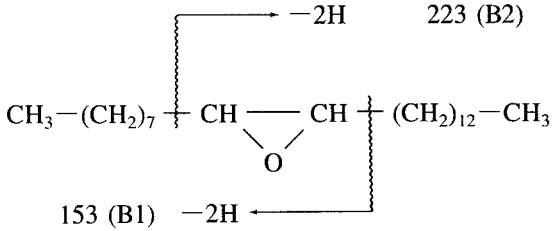
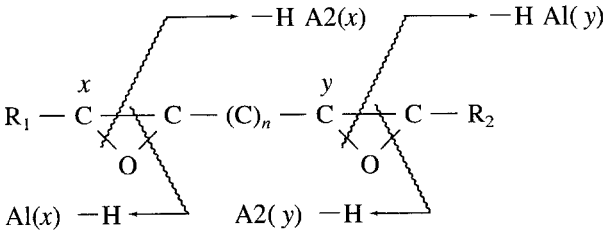
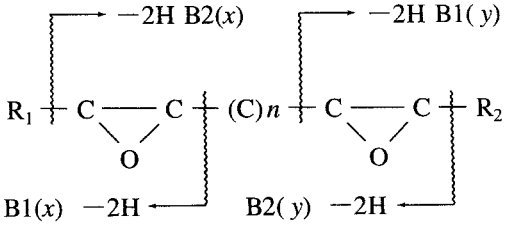
deduced as being *m/z* 338 from *m/z* 337 (for the M−H ions) and from *m/z* 319 (for $M-H-H_2O$). Two other fragmentation types (A, B) are associated with the epoxide group. Type B produces low intensity peaks; type A produces peaks that are higher than B, but still relatively low.





Figures 1B shows the mass spectrum of the diepoxide derived from 7,11 heptacosadiene, the main cuticular component produced by mature *D. melanogaster* females Canton S and already described (Antony et al., 1985). Two main fragments, A and B, were produced for each of the two epoxy groups situated at carbon positions *x* and *y*.





For this 7,11-diepoxy heptacosane, where the positions of the two epoxide groups are relatively close, the fragmentation produced the main following peaks: A1(7) = 113, A2(7) = 309, B1(7) = 125, A1(11) = 183, A2(11) = 239, and B2(11) = 251. Secondary ions from type A dioxygenated ions were produced by elimination of oxygen, water, and formaldehyde (ions *m/z* 137, 167, 263, 277, and 293).

Figure 1C shows the mass spectrum of the diepoxide of a major dienic component of the cuticle of *D. erecta* females. This member of the *Drosophila melanogaster* species subgroup is characterized by a marked sexual dimorphism, with mature females having hydrocarbons of a much greater length than in the other seven species of the subgroup (Jallon and David, 1987). In this diepoxide, a simpler mass spectrum is obtained where type A fragments are predominant. The A ions containing two oxygen atoms, at *m/z* 351 and 365, after loss of oxygen produce ions at *m/z* 335 and 349, and after loss of water produce ions at *m/z* 333 and 347; subsequent losses of oxygen and water produce ions at *m/z* 317 and 331. In this *D. erecta* female-specific $C_{33}H_{64}$, it is possible to localize the epoxide groups which are relatively far from each other, at positions 9 and 23.

Spectra 1B and also 1C show that negative chemical ionization with OH^- enables the two epoxide groups to be easily localized even in a long carbon chain. Two main fragment ions are visible, corresponding to each epoxide function, and the resultant masses are characteristic of their respective positions. Although these two substances have the same degradation scheme, certain fragmentations are favored in either isomer, and they produce characteristic and markedly different mass spectra.

Analysis of Cuticular Monoenes of Young D. melanogaster Males and Females. The same method was used to study the mixtures of unsaturated compounds present in the cuticles of young *D. melanogaster* flies. In both sexes, the cuticle of the young flies includes long chains, mainly of 27–35 carbons consisting of branched alkanes, mainly 2 methyl, and linear monoenes and dienes.

The monoenes with 29–31 and 33 carbons show a few quantitative differences between males and females (Table 1). Moreover, among monoenes, mixtures of position isomers were found in both sexes. The double bond may exist at any carbon between positions 5 and 16. Figure 2 (A,B) shows two examples of double bond distributions in monoene chains with 31 and 33 carbons of young *D. melanogaster* C5 males. Uneven carbon positions are preferred for the double bonds as against even carbon positions. Position 9 is more favored in C_{31} (and also in C_{29}) than in C_{33} where position 11 is more probable. Whatever the chain length, the probability for one double bond being in position 13 is always

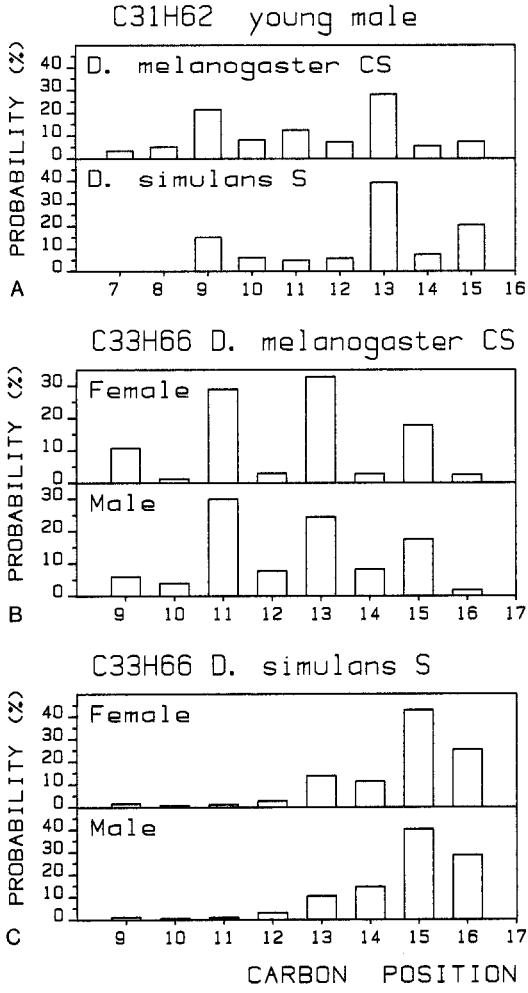


FIG. 2. Examples of double bond distributions in young flies' cuticular monoenes. The probability for a double bond being present on a given carbon as deduced from the analysis of negative chemical ionization of monoepoxyderivatives of monoenes and the distribution histograms are shown. (A) Hentriacontenes of either *D. melanogaster* (Canton S) or *D. simulans* (Seychelles) young males. (B) Tritriacontenes of young *D. melanogaster* Canton S of either sex. (C) Tritriacontenes of young *D. simulans* Seychelles of either sex.

more than 25%. The same situation was observed in young *D. melanogaster* females with small quantitative differences (Figure 2B).

Analysis of Cuticular Dienes Extracted from Young D. melanogaster CS Males and Females. Cuticular dienes of young *D. melanogaster* CS females were analyzed first. Figure 3A shows the spectrum corresponding to the diepoxides produced for the most abundant dienes: tritriacontadienes. The fragmentation pattern is complex and seems to be produced by several isomers. A similar result was found for dienes of 31, 35, and 37 carbons. The ions produced by the A fragmentations (113, 127, 141, 155, etc.) are present in a greater proportion than those produced by the B ruptures (125, 139, 153, 167, etc). This mass spectrum is substantially different from that of 7,11-diepoxide heptacosane reported above (Figure 1*B*) but seems closer to that of 9,23-diepoxy tritriacontane (Figure 1*C*). It seems, therefore, that in these compounds the major epoxide groups are far apart. The major ions (127–211 and 295–379) therefore correspond, respectively to type A monoxygen ions [A1(x) and A2(y)] and dioxygen ions [A2(x) and A1(y)].

By measuring the intensities of the characterized ions, it is possible to construct a histogram showing the probabilities of the double bond being found at each carbon position. Figure 3B shows such a histogram for the tritriacontadienes of young female flies, which show a clear bimodal distribution.

Figure 4 shows the position probabilities for the other dienic compounds in young males and young females. These figures show that the probability distribution is symmetrical in either half of the chain, with a marked preference for the center of each half (for example, positions 11 and 22, or 10 and 23, are equivalent for tritriacontadienes). The results for the young males and young females are rather similar: There seems to be little dimorphism in the composition of dienic cuticular compounds in young *D. melanogaster* CS flies.

The first double bond in the hentriacontadienes ($C_{31}H_{60}$) is mainly situated between carbons 9 and 12, and the second between carbons 21 and 24; for the tritriacontadienes ($C_{33}H_{64}$), the distribution is similarly between 9–12 and 21–24. For the pentatriacontadienes ($C_{35}H_{68}$), the double bonds are mainly found between carbons 11–14 and 21–24. The double bonds in the heptatriacontadienes ($C_{37}H_{72}$) are generally situated between carbons 11–16 and 21–26.

Analysis of Monoenes and Dienes in Cuticular Washes of Young D. simulans. We performed similar studies on cuticular compounds of young male and female flies of the species *D. simulans* (Seychelles strain). (Table 1).

Monoenes showed a mixture of position isomers less rich than in *D. melanogaster*, with little difference between the sexes. Figure 2 (A,C) shows that the double bond distributions are less different between both species for chains of 31 carbons than for chains of 33 carbons. In the former case, position 13 is

FIG. 3. Cuticular tritriacontadienes of young females of *D. melanogaster* Canton S. (A) Negative chemical ionization mass spectra of diepoxide derivatives of these tritriacontadienes. (B) Histogram of double bond distribution in these tritriacontadienes.

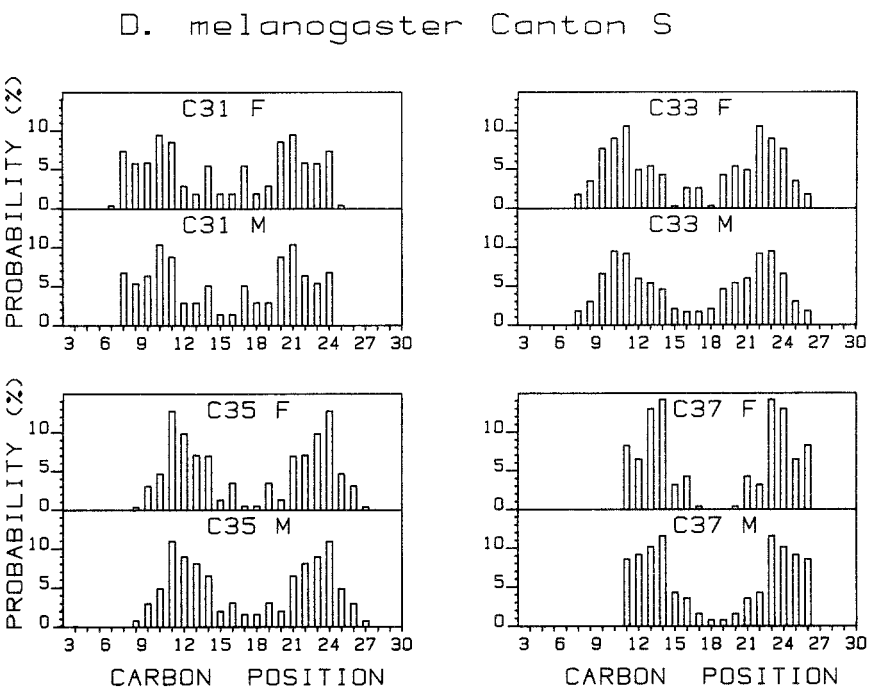

FIG. 4. Distributions are compared of double bonds in cuticular dienes of both young females and young males of *D. melanogaster* (strain Canton S) deduced from the mass spectral analyses of diepoxyderivatives. Respective chain lengths are 31, 33, 35, and 37 carbons.

preferred in both species but position 15 is more represented in *D. simulans*. In the latter case, position 15 is favored in *D. simulans* and positions 11–13 in *D. melanogaster*.

Distributions of double bonds in dienes of young *D. simulans* deduced in a similar way from epoxidation of the dienes and analysis of diepoxy products by negative chemical ionization GC-MS are presented in Figure 5. These distributions are clearly different from the bimodal distributions of *D. melanogaster* CS. The simulans distributions appear trimodal for chains with 33 and 35 carbons, with an obvious maximum in the middle. There is a relatively high probability of finding a double bond between carbons 15 and 19. It should be recalled here that in monoenes position 15 was also favored among tritriacontenes. The distributions obtained for the two sexes were again not very different.

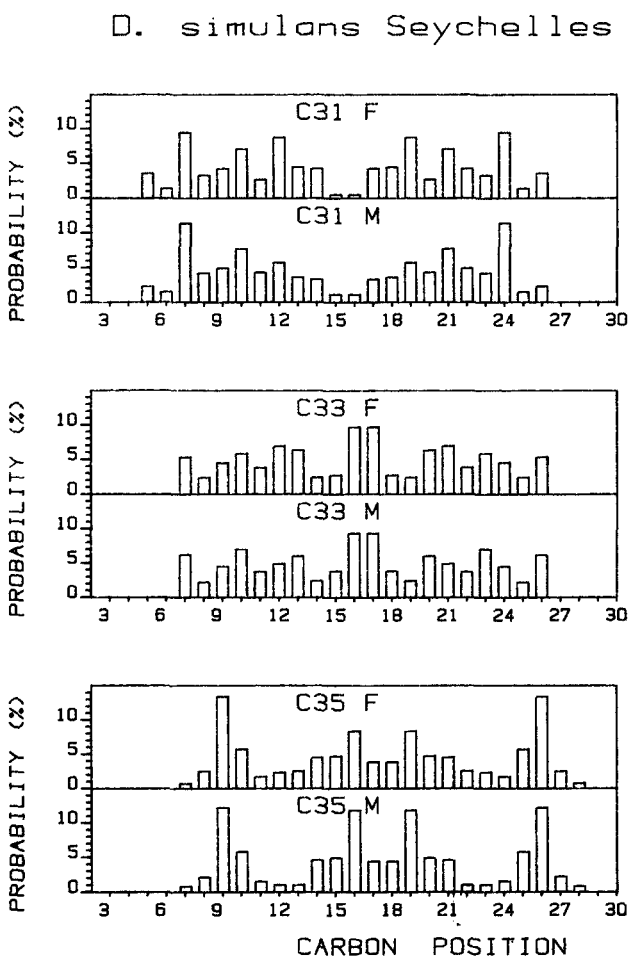

FIG. 5. Distribution is compared of double bonds in cuticular dienes of both young females and young males of the species *D. simulans* (strain Seychelles) deduced from the mass spectra analyses of diepoxyderivatives. Respective chain lengths are 31, 33, and 35 carbons.

DISCUSSION

We have used a recently developed method combining a chemical derivatization with negative chemical ionization analysis of its products which has good sensitivity and does not require any intermediate purification (Bouchoux et al., 1987). Using this method we have characterized the complex mixtures

of long chain unsaturated hydrocarbons present in pools of young *Drosophila*. We were able to establish the probability of a double bond being on a given carbon, but we were not able to determine with certainty which two double bonds were present in a given diene molecule.

In *D. melanogaster* small quantitative differences and no qualitative differences were detected among cuticular hydrocarbons of young males and females 3–6 hr after eclosion. They were all longer than those of mature flies, 27–37 carbons instead of 23–29 carbons. Like mature females, young flies possess dienes. However, their double bonds are not in discrete positions (7, 11) but are scattered over several carbons. These double bonds are farther apart than in mature females, one tending to be on carbon 11 or 13, the other on carbon 23 or 21. Among major monoenes, double bonds are also scattered among various positions, especially carbons 13, 11, and 9, and not the position 7 favored in mature flies. There is one more structural similarity between monoenes and dienes of young flies: there is a tendency for the more probable position of double bonds to shift towards the inside of the chain when this chain becomes longer. It is strongly suggested that double bonds are widely separated in the dienes of these young flies, a marked difference from the 2 CH_2 distance in 7,11-heptacosadiene, characteristic of the mature female.

The existence of singular long chain dienes in young flies has been recently reported in two other species of *Drosophila*: *Drosophila virilis* (Jackson and Bartelt, 1986) and *Drosophila pseudoobscura* (Blomquist et al., 1985). Moreover, in *Drosophila virilis*, the position of double bonds among monoenes and dienes was observed to change with age (Jackson and Bartelt, 1986).

Although dienes are completely absent in mature females of the species *D. simulans*, young flies of this species do produce such compounds, as in the case of young *D. melanogaster* flies. The dienes of young flies of both species appear to share some structural features: double bond distributions in the spectrum of isomers are similar between sexes, but not similar according to chain length. However, the detected isomers in *D. simulans* are different from those of homologous hydrocarbons of young *D. melanogaster* as a trimodal distribution was observed in *D. simulans* and a bimodal one in *D. melanogaster*. There were also obvious differences among monoenes of both species.

We have clearly shown that the heavy hydrocarbons specific to young flies also show a species specificity. It remains unclear whether this wide heterogeneity of isomers reflects variations between young individuals, between the different parts of each fly from which the components are unequally extracted, or actually reflects the complexity of the mixture borne by a single individual. Indeed, although sensitive, the method requires pools of flies.

Live young flies producing such complex mixtures of unsaturated hydrocarbons have been shown to stimulate wing vibrations from mature tester males

as much as mature females do (Jallon and Hotta, 1979). However, bioassays of hexane washes of young flies showed a poor reproducibility and were much less stimulatory than those for mature female washes. We cannot be certain if we extracted only the efficient cuticular hydrocarbons, or if we mixed in the extract inhibitors derived from internal tissues. Another possibility is that the poor results obtained with bioassays involving these heavy hydrocarbons might be linked to any defect in reconstituting the hydrocarbon layer of the epicuticle.

These singular compounds of young flies, whose biological role remains unclear, tend to disappear during the first two days, so after eclosion, together with young males attractivity, while sex-specific compounds of mature flies appear and become more and more abundant (Antony and Jallon, 1981). We have also shown that such long chain dienes with distant double bonds (9–23) are present in the cuticle of mature females (and not in mature males) of the related species *D. erecta*.

(Received February 24, 1987; accepted June 9, 1987)

Abstract—Topical application of the juvenile hormone analog, fenoxycarb, in acetone induced newly emerged male California five-spined ips, *Ips paraconfusus* Lanier, to become attractive to females, as measured by positive responses to male abdominal extracts in a laboratory bioassay. Two pheromones, ipsdienol and ipsenol, were detected by gas chromatography in the abdominal extracts of fenoxycarb-treated males. Pheromone production was minimal at a dose of 0.1 μg/insect of fenoxycarb, maximal at 10 μg, and was reduced to unmeasurable amounts at a dose of 100 μg. In comparison, peak production of pheromones was induced at a dose of 0.1 μg/insect of natural juvenile hormone (JH III). Treatment with 10 μg of fenoxycarb resulted in the occurrence of pheromones 12 hr after exposure, maximal pheromone content between 16 and 20 hr, and undetectable amounts after 36 hr. The demonstration that fenoxycarb is an active juvenile hormone analog for a bark beetle suggests that it may have practical utility in managing these insects.

Key Words—Juvenile hormone analog, juvenile hormone, JH III, *Ips paraconfusus*, Coleoptera, Scolytidae, bark beetles, aggregation pheromones, pheromones, ipsenol, ipsdienol.

INTRODUCTION

Encouraging prospects for the practical use of juvenile hormone analogs (JHAs) has arisen from recent tests with fenoxycarb, ethyl[2-(*p*-phenoxyphenoxy)ethyl]carbamate, a nonneurotoxic insecticide that exhibits strong juvenile hormone activity against numerous insect pests in various orders (Anonymous,

0098-0331/88/0400-1087$06.00/0

1983; Dorn et al., 1981; Masner et al., 1981). This compound achieved satisfactory control of a broad spectrum of lepidopterous and coleopterous pests in stored products (Kramer et al., 1981). It was also efficacious against leafrollers in orchards (Reede et al., 1984, 1985). Fenoxycarb is highly persistent in various environmental conditions, with residual activity up to one year in stored wheat (Edwards and Short, 1984) and at least four weeks on apple leaves (Dorn et al., 1981; Reede et al., 1984). On the other hand, fenoxycarb demonstrates a very low mammalian toxicity (acute oral LD_{50}, rat, $>10{,}000$ mg/kg; Anonymous, 1983). Trials under laboratory and various field conditions have shown that fenoxycarb appears to be innocuous against beneficial arthropods (Dorn et al., 1981; Parrella et al., 1983; Reede et al., 1984). Furthermore, it is effective against insects which have developed resistance to conventional insecticides (Edwards and Short, 1984). Finally, the compound is easy to synthesize and is therefore relatively inexpensive (Karrer and Farooq, 1981). It would be highly desirable if fenoxycarb could be used for control of bark beetles, which are major forest insect pests throughout much of the Northern Hemisphere.

Aggregation pheromones play a vital role in the reproductive biology of scolytid beetles (Borden, 1982, 1985). Research has demonstrated that pheromone production by bark beetles is under the influence of juvenile hormone (Borden et al., 1969; Hughes and Renwick, 1977a,b; Harring, 1978; Bridges, 1982). It is significant, therefore, to investigate the effect of a JHA on pheromone biosynthesis of a bark beetle as an indicator of its bioactivity and potential use. This paper reports the effect of fenoxycarb on pheromone production by the California five-spined ips, *Ips paraconfusus* Lanier. We chose *I. paraconfusus* because it is established that pheromone biosynthesis in this beetle is under neuroendocrine control (Hughes and Renwick, 1977a) and that it is inducible by exogenous JH treatments (Borden et al., 1969; Hughes and Renwick, 1977a). Moreover, it is easily cultured in the laboratory and readily responds to its pheromones in laboratory olfactometers (Wood and Bushing, 1963; Borden, 1967).

METHODS AND MATERIALS

Insect Rearing. I. paraconfusus were obtained from a continuously reared, laboratory culture maintained on logs of ponderosa pine, *Pinus ponderosa* Laws., in laboratory cages at $25 \pm 1°C$ and variable relative humidity. Emergent brood beetles were collected daily and sexed by the presence of the pars stridens on the posterior dorsal area of the head of females, but not males (Wood, 1961). Beetles were stored on moistened paper towels in glass jars at 4°C until used for experiments.

Treatment of Beetles. Fenoxycarb (96.6% purity, Elanco Division, Eli Lilly Canada Inc., Winnipeg, Manitoba) and JH III (96.9%, Sigma Chemical Co., St. Louis, Missouri), respectively, were dissolved in acetone to give 0.1, 1, 10, and 100 μg/μl of solution. Newly emerged male beetles were immobilized by cooling at 4°C and stuck on scotch tape with their abdominal venter upward. Each beetle received two topical applications, made to the abdominal venter, of 0.5 μl of a given solution approximately 1 min apart administrated with a 25-μl Hamilton syringe attached to a 50-stop Hamilton repeating dispenser. Treated beetles were incubated individually for a specific length of time at room temperature in glass cylinders (1.78 cm ID) placed in Petri dishes (Conn, 1981). All Petri dishes contained a water-saturated cotton wick and were sealed with parafilm to minimize loss of moisture.

Preparation of Abdominal Extracts. Groups of 12 or 24 male beetles were either: (1) treated topically with acetone extracts of fenoxycarb or JH III at 0.1, 1, 10, or 100 μg/insect and incubated at room temperature for 20 hr; (2) treated with 1 μl acetone applied in the same manner and held as above; (3) left untreated and held as above; or (4) introduced into preformed holes in ponderosa pine logs (Miller and Borden, 1985) and allowed to bore in the inner bark for 20 hr. For analysis by gas chromatography (GC), additional groups of 12 males were topically treated with 10 μg of fenoxycarb and incubated for 12, 16, 28, or 36 hr. All insects were taken from Petri dishes or excised from the bark, and their abdomens (containing hindgut and Malpighian tubules) were removed and immediately immersed in double-distilled pentane in 2 ml glass vials in Dry Ice.

For bioassays, 24 beetle abdomens from each treatment group were pooled and crushed with a glass rod in 200 μl of pentane. After crushing, samples were allowed to warm up slightly at room temperature and the clear extracts were transferred to clean 2-ml glass vials with one pentane rinse to give a 240-μl extract at a concentration of 1 abdomen/10 μl of solution. Vials containing extracts were covered with Teflon-lined lids and stored at −44°C until used in bioassays.

For analysis by GC the same extraction procedure was followed except that: (1) single abdomens were extracted with 100 μl of pentane without a rinse; and (2) solutions of two internal standards, 3- and 2-octanol, each at a concentration of 2.5 μl (2 mg) in 10 ml of pentane, were added before and after crushing, respectively, at the rate of 2.5 μl/sample (Conn, 1981).

Bioassay Procedure. The attractiveness of male abdominal extracts was bioassayed with recently emerged female *I. paraconfusus* in an open arena olfactometer (Conn, 1981). The arena was a 24-cm-diam. disposable filter paper. A glass tube (7 cm long × 1 cm ID) containing a rolled-up filter paper (4.25 cm diam.) impregnated with a stimulus was placed to allow an air stream

to flow at a rate of 1500 ml/min through it toward the insect release point at the center of the arena. Bioassays were conducted at room temperature under red light.

Three types of stimuli were tested: (1) beetle abdominal extracts; (2) a pentane control; and (3) a pheromone standard consisting of racemic ipsenol, racemic ipsdienol, and *cis*-verbenol (Borregaard, A.S., Sarpsborg, Norway) at concentrations of 2, 1.5, and 1 ng/μl in pentane, respectively. Each stimulus was assayed at the rate of 20 μl, or two male equivalents for abdominal extracts, for each group of test females. A fresh stimulus tube was used for each test, and the arena was changed for each new stimulus.

Beetles that walked normally and had no missing appendages were held in groups of 20 in 35-mm-diam. Petri dishes lined with moistened filter paper at 2–4°C. They were brought to room temperature about 2 min prior to use. Each group of insects was released in the center of the arena and given 2 min to respond. An insect was counted as a positive responder if it walked upwind and stopped within 1 cm of the stimulus source or circled around the edge of the airstream more than once. It was classified as a nonresponder if it walked off the arena or remained in the arena after 2 min without responding. Once its status was classified, an insect was returned to the Petri dish, which was placed at the end of a rotation of 13 other Petri dishes. No group of insects was reused for at least 60 min. There was no evidence that this procedure resulted in a change in response through time in this or in studies with other scolytids (Conn, 1981; Stock and Borden, 1983).

The bioassay experiment was completed in two sessions of 4 hr each in the same day. Assays were conducted before each session with pentane and the pheromone standard to ensure that the insects were responding consistently.

Gas Chromatography. GC analysis was conducted on a Hewlett-Packard 5880A gas chromatograph fitted with a flame-ionization detector and a glass capillary column (30 m × 0.50 mm ID) coated with SP-1000 (Supelco Inc., Bellefonte, Pennsylvania). The oven temperature was programmed from 120 to 180°C at 4°C/min, with injector and detector temperatures of 260 and 275°C, respectively.

Samples which were kept in Dry Ice were warmed to room temperature, and 2 μl of each sample was injected manually into the injection port. A standard sample consisting of the synthetic pheromones, ipsenol, ipsdienol, and *cis*-verbenol was recurrently analyzed under identical conditions as the beetle extracts. Determination of pheromone content in the samples was based on comparison of retention times with those of the standard sample. Quantification of ipsenol and ipsdienol was achieved by using the area under the 3-octanol peak as a reference. The 2-octanol peak was used to check for possible loss of volatiles during processing of the samples.

Statistical Analysis. Proportional data, including percentages of respond-

ing females in bioassays and males containing pheromones in GC analyses were converted using an arcsin transformation and compared using a Newman-Kuels test modified for testing proportions (Zar, 1984).

A maximum likelihood method[3] was used to adjust the mean amounts of pheromone produced by males treated with fenoxycarb or JH III, and to estimate trace amounts of pheromone when they were below the measurable threshold (8.0 ng) of the GC equipment. By replacing zero values with estimated values, this method greatly reduced sample variances. Differences among estimated means were then assessed by the Newman-Kuels test, and differences from zero by *t* tests.

RESULTS AND DISCUSSION

Within 20 hr after topical treatments of male beetles with fenoxycarb or JH III their abdominal extracts became attractive to females, when compared with the responses of females to pentane or extracts of either untreated or acetone-treated males (Table 1). Response was maximal to extracts of males treated with 10 μg of fenoxycarb, but significantly less than maximal to extracts of males subjected to the 100-μg treatment. Abdominal extracts from males treated with 0.1 μg of JH III were as attractive to females as those from males treated with 10 μg of fenoxycarb (Table 1). However, there was a progressively weaker response as the dose of JH III increased. The pheromone standard and extracts from males fed in logs (and thus exposed to the pheromone precursor, myrcene) elicited the strongest responses by females (Table 1).

The bioassay results were supported by gas chromatographic analysis (Table 2). Treatment of male beetles with fenoxycarb or JH III resulted in the occurrence of ipsenol and ipsdienol in their abdominal extracts (as determined by identical retention times as those of synthetic ipsenol and ipsdienol). In agreement with the bioassay results (Table 1), the optimal dosages for fenoxycarb and JH III were 10 and 0.1 μg, respectively. However, there was no measurable pheromone (threshold = 8.0 ng) in males treated with 100 μg of either fenoxycarb or JH III. On the other hand, treatment with fenoxycarb at a dose of 0.1 μg resulted in substantial increases in percentages of treated males containing pheromone and in amount of pheromone content (Table 2).

The results of both bioassays (Table 1) and GC analysis (Table 2) corroborate the conclusions of Borden et al. (1969) and Hughes and Renwick (1977a) that JH stimulates pheromone biosynthesis in *I. paraconfusus*, even though the

potency of JH III was found to be at least 100× higher than in the experiment conducted by Borden et al. (1969). The results also clearly indicate that fenoxycarb mimics the function of juvenile hormone in stimulating pheromone biogenesis in *I. paraconfusus* and suggest that it possesses high biological activity for scolytid beetles.

The diminished pheromone activity (Table 1) or detectable content (Table 2) with treatment dosages higher than optimal has not been observed before in *I. paraconfusus*. However, inhibitory effects on pheromone production with exogenous JHs or JHAs has been observed in a number of insects, and several hypotheses have been proposed to account for this phenomenon. Hedin et al. (1982) found that JH III incorporated at 1.0 ppm in the diet of male boll weevils, *Anthonomus grandis* Boheman, caused a threefold increase in the biosynthesis of four pheromone compounds. However, at dosages of 10 and 100 ppm, there was a decrease in pheromone synthesis. The results obtained by Hedin et

[a] Percentages followed by the same letter are not significantly different, Newman-Kuels test (α = 0.05) modified for testing proportional data (Zar, 1984).

[b] Zero values indicate no detectable amount (< 8.0 ng) of pheromone. Where mean amounts > 0.0, original data (excluding data from males in logs 20 hr) have been replaced by maximum likelihood estimates of means from an exponential model derived from the original data. Exponentiality is assumed because by the Anderson-Darling statistic, there is no evidence that the data do not follow an exponential distribution. Adjusted means within a column followed by the same letter are not significantly different, Newman-Kuels test (α = 0.05). All adjusted means are significantly different from zero, t test, $p < 0.05$.

al. (1982) are consistent with Staal's (1975) hypothesis that the failure of increasing amounts of JH to elicit increasingly greater effects may be due to a cellular sensitivity which limits the capacity of a cell to respond to a given stimulus.

Decreases in pheromone content following application of JHA in southern pine beetles, *D. frontalis* Zimmerman, were observed by Bridges (1982), who suggested that JH might stimulate release of pheromones. Treatment with JHAs resulting in a significant reduction in pheromone activity was also observed in female yellow mealworms, *Tenebrio molitor* L. (Menon and Nair, 1972), and in female cockroaches, *Byrsotria fumigata* (Guerin) (Bell and Barth, 1970). For

both insects, the reduced activity was attributed to stimulation of yolk deposition by an excess of JHA, which might in some way have inhibited pheromone production.

Fockler and Borden (1973) reported that a high dosage (50 μg) of a JHA inhibited mating activity of the striped ambrosia beetle, *Trypodendron lineatum* (Olivier), whereas a lower dosage (0.05 μg) accelerated the activity. They attributed this phenomenon to a toxic effect of high dose of JHA since there was some mortality in treated insects. However, such a toxic effect was not evident in our experiments; there was no mortality or apparent loss of vigor of *I. paraconfusus* treated with any dose of fenoxycarb or JH III. Therefore, the failure to detect pheromone following treatment with high dosages of either material suggests an inhibitory effect. Such an effect could result from negative feedback on the release of brain hormone, which, as demonstrated by Hughes and Renwick (1977a), is essential for normal pheromone biogenesis in *I. paraconfusus*. Inhibition of brain hormone release by high JH titer has been reported for certain diapausing larval lepidopterans, such as the Asiatic rice borer, *Chilo suppressalis* (Walker) (Yagi and Fukaya, 1974), and the tobacco hornworm, *Manduca sexta* (L.) (Nijhout and Williams, 1974; Rountree and Bollenbacher, 1984). Thus, the optimal (noninhibitory) effect of 100 μg of JH III found by Borden et al. (1969) may have been due to the nonvolatile solvent, peanut oil, which might have served as a slow release medium. The same dosage of the same compound carried by the highly active solvent acetone may have caused a rapid saturation of JH receptors on the corpora cardiaca (Hughes and Renwick, 1977a) or may have activated some other negative feedback mechanism that inhibited pheromone biosynthesis.

When male beetles were treated with 10 μg of fenoxycarb and then extracted and analyzed at various posttreatment times, pheromone was first detected 12 hr after treatment (Figure 1). The highest proportions of individuals contained pheromone at 16 and 20 hr; pheromone-containing males were fewer after 28 hr, and none contained detectable pheromone after 36 hr. The proportions of beetles containing pheromone were reflected by the amount of ipsenol, and to a lesser extent ipsdienol, content per male (Figure 1B).

These results agree in part with those of Borden et al. (1969), who concluded that it required at least 12 hr for JH-induced pheromone synthesis to produce sufficient pheromone to elicit a positive response by females, whereas it required only 3 hr for beetles boring and feeding on fresh ponderosa pine bark to possess highly attractive guts. The lag between pheromone synthesis induced by stimuli associated with boring and feeding activity and by exogenous JH treatment may provide indirect evidence for Hughes and Renwick's (1977a) hypothesis regarding neural and hormonal control mechanisms of pheromone biosynthesis in *I. paraconfusus*. The production of JH and subsequent release of brain hormone in response to the removal of neural inhibition, e.g., as a

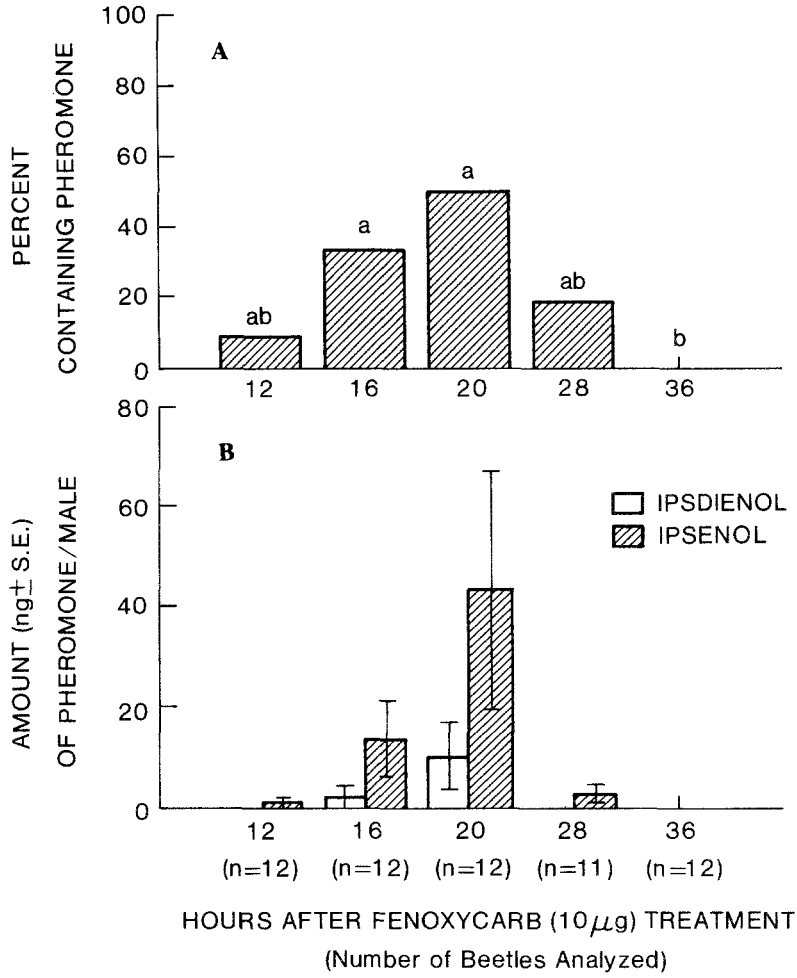

FIG. 1. Relationship between time after treatment of male *Ips paraconfusus* with fenoxycarb and percent of treated males containing ipsenol, ipsdienol, or both (A), and ng ($\bar{X} \pm$ SE) of pheromone content per male (B). Bars in A with same letter above are not significantly different, Newman-Kuels test ($\alpha = 0.05$) modified for proportional data.

result of gut distention by feeding (Hughes and Renwick, 1977a; Harring, 1978), might occur quite rapidly. On the other hand, subtle changes in hemolymph JH titers resulting from slow rates of penetration of topically applied material through the cuticle and transport to the target tissues could limit the rate of pheromone production. Possibly, however, beetles in fresh host material simply may have abundant supplies of ingested myrcene as a pheromone precursor

(Byers, 1981), and thus produce detectable levels of ipsdienol and ipsenol in a shorter time than JH- or JHA-treated beetles, which must dederivatize limited amounts of sequestered precursor (Hughes, 1975) prior to converting it to ipsdienol and ipsenol. Borden et al. (1969) and Hughes and Renwick (1977a) monitored the pheromone content in treated male *I. paraconfusus* for only 24 and 22 hr, respectively. As JH III- or fenoxycarb-treated beetles were denied food, their pheromone production must be constrained by the amount of endogenous sequestered precursor (Borden, 1985). It is likely, therefore, that this supply was exhausted within about 20 hr after treatment and that the volatile pheromones were lost eventually by emission from the hindgut (Pitman et al., 1965; Renwick et al., 1966) to the external environment and/or by diffusion into the hemocele, resulting in undetectable levels by 36 hr (Figure 1). The observation that pheromone production induced by exogenous JH or JHA varies not only with dosage but also with time may be of concern in future studies.

(Received March 2, 1987; accepted June 10, 1987)

Abstract—A new butenolide, isosiphonodin [3-hydroxymethyl-2(5H)-furanone], along with a trace of siphonodin [4-hydroxymethyl-2(5H)-furanone], was isolated from fifth-instar larvae of the small ermine moth *Yponomeuta cagnagellus*. Leaves of its host plant spindle-tree, *Euonymus europaeus*, were found to contain the same two butenolides with siphonodin being present as the major compound. TLC showed that isosiphonodin was also present in larvae or pupae of six other small ermine moths which did not feed on spindle-tree. In *Y. cagnagellus* butenolides might be plant derived, while isosiphonodin in the other investigated small ermine moths is probably synthesized by the insect. The possible role of butenolides in the chemical defense of small ermine moths is discussed.

Key Words—*Yponomeuta* spp., Lepidoptera, Yponomeutidae, host plants, *Euonymus europaeus*, Celastraceae, butenolides, siphonodin, isosiphonodin, plant–insect relationship, chemical defense, small ermine moth, spindle-tree.

INTRODUCTION

Nine species of small ermine moth, *Yponomeuta* spp., are native to Europe. Except for members of *Y. padellus*, European small ermine moths are mono-

0098-0331/88/0400-1099$06.00/0

phagous and their larvae restrict their feeding to one plant genus or species only (Figure 1). In preliminary trials, we noticed that birds were reluctant to eat small ermine moths when offered as prey. Certain lepidopterous species are known to store secondary metabolites from their food plants (Rothschild, 1973; Brower, 1984). They benefit from this sequestration as these compounds are toxic to predators.

Larvae of three Euopean species of small ermine moths feed on leaves of

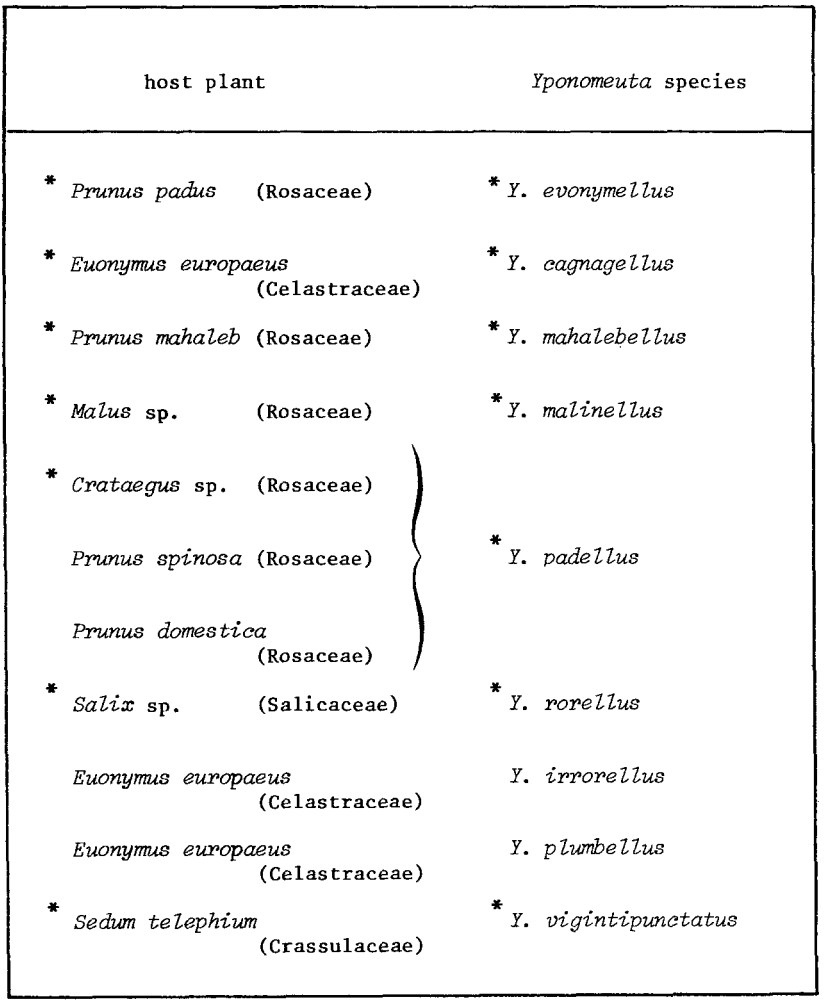

FIG. 1. The respective host plants of the European representatives of the genus *Yponomeuta*. *Species analyzed in this study.

spindle-tree, *Euonymus* sp. A screening has revealed that toxic secondary substances are present in leaves of 16 *Euonymus* taxa; all tested material contained cardenolides and, in some instances, also alkaloids (Fung, 1986). Sequestration of cardiac glycosides from food plants is known to occurt in Lepidoptera (Rothschild and Reichstein, 1976; Brower, 1984). The assumed unpalatability of small ermine moths prompted us to investigate whether these insects and their host plants contained any cardenolides.

Extracts of seven small ermine moth species and the leaves on which the larvae were found feeding were screened by TLC and a pharmacological test. Since all tested insect's extracts were colored by reagents specific for the butenolide ring in cardiac glycosides, we decided to isolate these unknown principles from *E. europaeus* and *Y. cagnagellus* in order to determine their structure.

METHODS AND MATERIALS

Insect and Plant Material. For the screening of cardenolides, larvae of all *Yponomeuta* spp., except for *Y. vigintipunctatus*, and leaves on which they were feeding were collected in the field in May and June 1985. Pupae and female and male adults of *Y. cagnagellus* were obtained by rearing fifth-instar larvae on leaves of *E. europaeus* in the laboratory (20°C). Third-instar larvae of *Y. vigintipunctatus* and flowers of *Sedum telephium* were collected in September 1985. In the laboratory, these larvae were reared until the fifth instar on leaves and flowers of *S. telephium* from our experimental garden. Prior to freezing, larvae were kept without food for one day so that gut contents would not be reflected in the assays. Insect and plant material were freeze-dried, ground, and stored in a desiccator until use. For the extraction of the active principles, bulk amounts of plant and insect were gathered. Late fifth-instar larvae of *Y. cagnagellus* were collected in June 1985 from the dunes of the Amsterdamse Waterleiding Duinen at Vogelenzang and subsequently killed by freezing at −25°C. Twigs with leaves of *E. europaeus* were collected from the dunes of the Pan van Persijn at Katwijk in August 1985. Plant and insect material was dried for 24 hr at 60°C. TLC showed no substantial loss of butenolides as a consequence of this heating process as compared to freeze-drying. After drying, the material was kept at −25°C until extraction.

Extraction and Purification for Screening. A purification with lead acetate, developed after the procedure of Rowson (1952), was employed. First insect material was defatted by extraction with petroleum ether 40–60°C (1 g/10 ml, 30 min, 40–50°C). Insect and plant material was then treated as follows: 1 g was extracted with 25 ml 70% ethanol (1 hr, 75–85°C); after filtration the residue was washed with 2 × 10 ml 70% ethanol. The filtrate was concentrated under reduced pressure at 45°C, and 2.5 ml 10% lead acetate solution was

added to the aqueous suspension. After 10–15 min, 2.5 ml 4% disodium hydrogen phosphate was added to precipitate excess lead, the suspension was centrifuged, and the precipitate rinsed with 2 × 2.5 ml 30% ethanol. The combined aqueous solution was extracted with 3 × 12.5 ml chloroform and 3 × 12.5 ml chloroform–ethanol (3:2). The combined organic layers were washed with 5 ml saturated sodium sulfate solution and dried over anhydrous sodium sulfate. Then the solution was filtered, washed with 5 ml chloroform, and the filtrate was dried under reduced pressure.

Thin-Layer Chromatography. After purification, the dried extract of 1 g material was dissolved in 400 μl methanol. This solution (20 μl) was applied on the chromatographic plates (silica gel 60 F_{254} plates, Merck); chromatograms were developed in saturated chambers. Digitoxin was applied as a reference compound for cardiac glycosides. Two solvent systems were used: (1) ethylacetate–methanol–water (81:11:8) (Wagner et al., 1983) and (2) chloroform–methanol–formamide (90:6:1); chromatograms were developed four times in system 2 (Roeske et al., 1976). Spray reagents employed were: (1) 2% 3,5-dinitrobenzoic acid solution in methanol; after air drying chromatograms were sprayed with 17% benzyltrimethylammonium hydroxide solution in 33% methanol (Doelker et al., 1969) (the use of the organic base stabilized the colors developed); (2) 0.4% 2,2′,4,4′-tetranitrodiphenyl in toluene, followed by spraying with the same base as under 1; and (3) 25% antimony(III) chloride solution in chloroform, after spraying, chromatograms were heated at 100°C for 6 min and inspected in daylight and UV light (365 nm). Reagents 1 and 2 are spray reagents for the butenolide ring in cardenolides, while reagent 3, a general reagent for several classes of natural products, gives colored products with the steroid part of cardiac glycosides.

Pharmacological Test. The purified and dried extract of 1 g material was dissolved in 1–2 ml 0.9% sodium chloride solution (5% ethanol), the appropriate volume of ethanol being first added to the dried extracts to facilitate dissolution. Precipitates formed were removed by centrifugation. Inotropic action of the extract was determined in a rat Langendorff preparation. Male or female white rats were decapitated, and the heart was excised and transferred to the Langendorff perfusion apparatus. Tyrode solution, maintained at 37°C and gased with a mixture of 95% oxygen and 5% carbon dioxide, perfused the heart. Cardiac contractile force was monitored on a Hewlett-Packard Sandborn 780-6A visoscope; 0.1 ml of each sample was injected. Ouabain (2.5 mg/ml) was used as standard.

Extraction and Purification of Butenolides from E. europaeus *and* Y. cagnagellus. Ground twigs and leaves of *E. europaeus* and fifth-instar larvae of *Y. cagnagellus* were extracted, and the extracts were purified by partition in different solvents as outlined in Figure 2. The purification steps were followed by

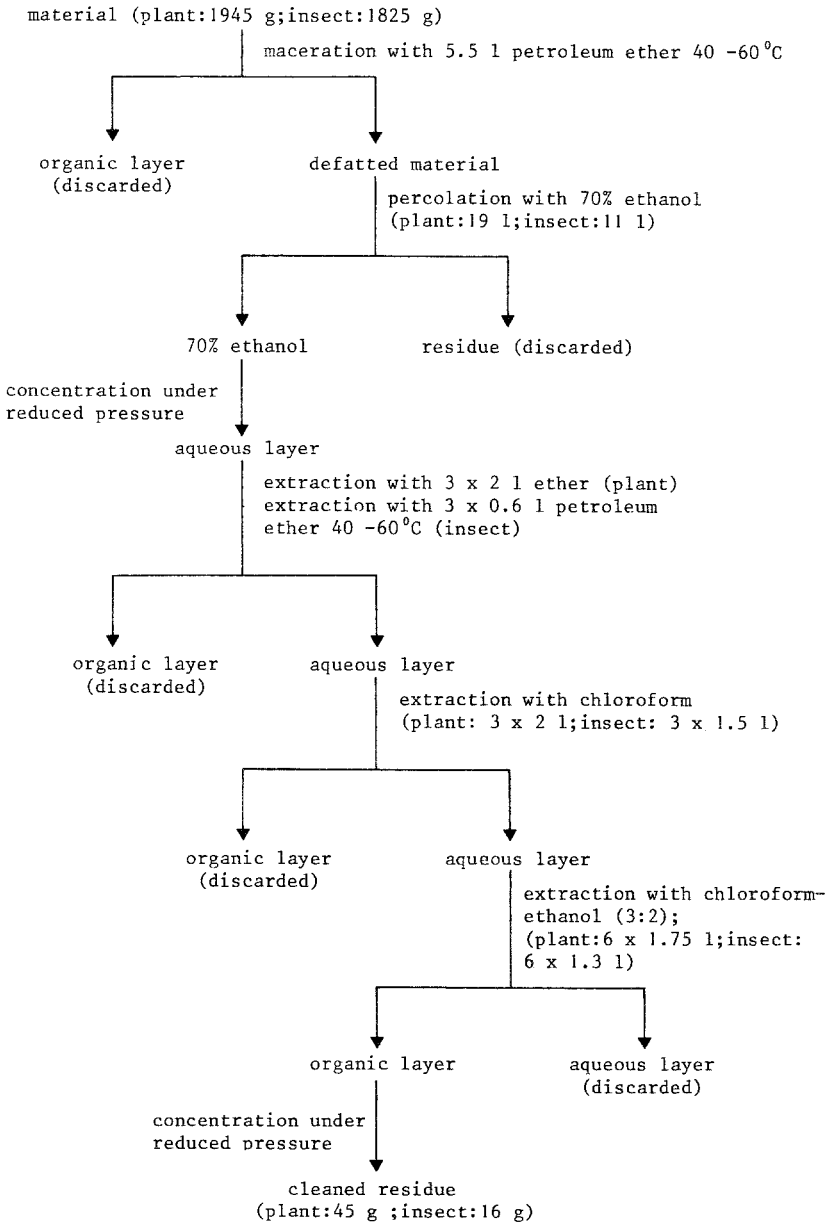

FIG. 2. Scheme of extraction and purification by solvent partition of extracts of *E. europaeus* and *Y. cagnagellus*.

TLC; fractions which gave no or slight coloring with Kedde's reagent (2% 3,5-dinitrobenzoic acid in methanol and 1 N methanolic potassium hydroxide) were not treated further and were discarded. Residues after solvent partitioning were further cleaned by vacuum liquid chromatography (Pelletier et al., 1985) on silica gel (plant: 422 g; insect: 168 g). The residues were first suspended in methanol and mixed with diatomaceous earth. After drying, aliquots of the mixture were applied on the silica gel columns. Ethylacetate–methanol–water (81:11:8) was used as eluent. Fractions with positive reactions on TLC with Kedde's reagent were concentrated under reduced pressure. The residues were then fractionated by repetitive silica gel column chromatography (Lobar Lichroprep Si 60 columns, Merck). Elution was performed with ethylacetate–methanol (9:1 and subsequently 8:2). Fractions with butenolides were pooled and concentrated. Separation of butenolides was achieved by preparative TLC (PSC-Fertigplatten silica gel 60 F_{254}, Merck). Plates were developed four times in chloroform–methanol–formamide (90:6:1). Bands with butenolides, detected by spraying a small strip of the partially uncovered plate with Kedde's reagent, were scraped off, ground and extracted with 95% ethanol. Both the plant and insect extracts yielded two butenolides (plant: E3 and E4; insect: Y1 and Y2). Final purification of the four fractions was achieved by reverse-phase column chromatography (Lobar Lichroprep RP-18 column, Merck) with 30% or 40% methanol as eluent. Yield: E3, 4 mg; E4, 18 mg; Y1, 46 mg; and Y2, 3 mg.

Spectral Data. The UV spectra were recorded on a Beckman DU-50 spectrophotometer, IR spectra on a Pye Unicam SP3-200 infrared spectrophotometer, [^{1}H]NMR spectra on a Bruker WM 300 at 300 MHz, and [^{13}C]NMR APT spectra on a Jeol JNM-FX 200 at 50.1 MHz. EI-MS was performed by direct introduction at 75 or 100°C in a Kratos MS 9/50 or a LKB-2091 mass spectrometer (70 eV). FAB-MS was carried out using a VG Micromass ZAB-2F mass spectrometer, coupled to a VG 11-250 data system. Samples were loaded in thioglycerol onto a stainless-steel probe and bombarded with xenon atoms having 8 keV energy. During the high resolution FAB-MS measurements a resolving power of 25,000 (10% valley definition) was used.

RESULTS

Screening of Extracts. TLC screening indicated that leaves of *E. europaeus* and all investigated stages of *Y. cagnagellus* contained compounds which were colored by spray reagents 1 and 2 (see Methods and Materials) (Figure 3). The colors developed, purple with reagent 1 and blue with reagent 2, are specific for a butenolide, a five-membered α,β-unsaturated γ-lactone. In natural products, this lactone ring is often part of a cardenolide. TLC in solvent system

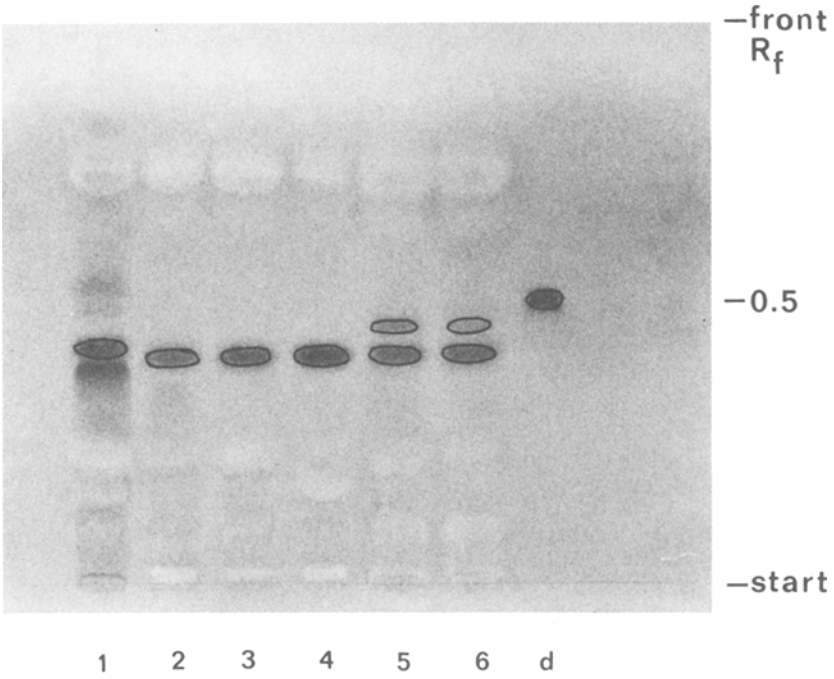

FIG. 3. TLC butenolides in *E. europaeus* and *Y. cagnagellus*. The plate was developed in solvent system 1, encircled spots are butenolides visualized with spray reagent 1. d: digitoxin (cardenolide), 1: leaf *E. europaeus*, 2: third– and fourth-instar larvae *Y. cagnagellus*, 3: fifth-instar larvae *Y. cagnagellus*, 4: pupae *Y. cagnagellus*, 5: male moths *Y. cagnagellus*, 6: female moths *Y. cagnagellus*.

2 showed that the main compound in the insect was not identical to the major butenolide in the plant.

Pupae or larvae from six other *Yponomeuta* species also contained butenolides (Figure 4). The major substance in these six small ermine moths was identical to the main butenolide in *Y. cagnagellus*. Butenolides could not be detected in extracts of the host plants *Prunus mahaleb*, *P. padus*, *Malus* sp., *Crataegus* sp., and *Salix alba*. In flower heads of *Sedum telephium* on which *Y. vigintipunctatus* larvae were collected, unidentified substances were detected which reacted with spray reagents 1 and 2. Leaves and flower heads of *S. telephium* from our experimental garden contained less of these compounds. Future studies have to reveal whether these substances are butenolides.

In testing the effect of the extracts on the rat Langendorff preparation, a small pharmacological activity was ascertained for the extracts of the seven ermine moths and of spindle-tree. This activity was different from the reaction of the standard ouabain, and it seemed that the pharmacological effect of the tested plant and insect extracts was not identical to the inotropic action of a cardenolide.

Structures of Butenolides from E. europaeus *and* Y. cagnagellus. During the isolation of butenolides from *E. europaeus* and *Y. cagnagellus*, it became clear that coloring of the extracts by antimony(III) chloride on TLC was caused by interfering substances and not the butenolides themselves. The pure compounds E3, E4, Y1, and Y2 did not react with this agent even after prolonged heating of the chromatograms. [^{13}C]NMR spectra of both E4 and Y1 showed the presence of only five carbon atoms; thus the pharmacological action and coloring with antimony(III) chloride were different from cardenolides as the steroid part is lacking in these unknown molecules.

Compound E4. $C_5H_6O_3$. Yellow oil. On the basis of similar UV, IR, and [^{1}H]NMR spectra, this main butenolide from *E. europaeus* was identified as siphonodin [4-hydroxymethyl-2(5H)-furanone] (Figure 5). This is the second record of the occurrence of this structurally simple butenolide in Celastraceae; previously siphonodin was isolated from *Siphonodon australe* (Wagner and Flitsch, 1981).

UV (nm): 207(methanol); IR (neat, cm^{-1}): 3450–3200, 2910, 1775(sh), 1735, 1635, 1440, 1270, 1175, 1135, 1060, 1035, 1010, 930, 895, and 845; EI-MS (*m/e*, % relative intensity): 115[$(M+H)^+$, 100], 85(72), 55(48), 84(45), 39(31), 70(29) and 97(16); FAB-MS (*m/e*, % relative intensity): 115]$(M+H)^+$, 100], 137[$(M+Na)^+$, 71], 251[$(2M+Na)^+$, 19], 153[$(M+K)^+$, 13], and 229[$(2M+H)^+$, 12]. NMR spectra were recorded in $CDCl_3$–CD_3OD (3:1) with TMS as internal standard. [^{1}H]NMR (ppm):δ 6.03(H_3, 1H, quintet, $J_{H3\text{-}H5}$ = $J_{H3\text{-}H6}$ = 1.8 Hz), 4.90 (H_5, 2H, doublet, $J_{H3\text{-}H5}$ = 1.8 Hz), and 4.52 (H_6, 2H, doublet, $J_{H3\text{-}H6}$ = 1.8 Hz); [^{13}C]NMR(ppm: δ 175.8(C_2), 172.9(C_4), 114.5(C_3), 72.4(C_5), and 58.7(C_6). The [^{13}C]NMR spectrum was assigned by comparison

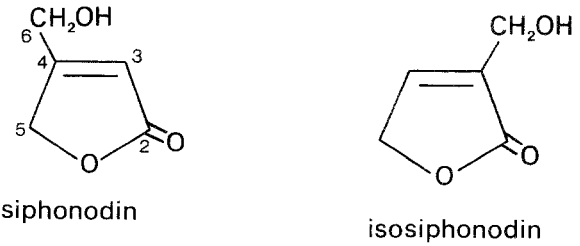

FIG. 5. Butenolides in *E. europaeus* and *Y. cagnagellus*.

with values reported for cardenolides since the same α,β-unsaturated γ-lactone ring is present in siphonodin and cardenolides (Tori et al., 1973).

Compound Y1. $C_5H_6O_3$. Yellow oil. The chromatographic behavior of this major substance from *Y. cagnagellus* and of siphonodin is much alike. Several TLC solvent systems were tested in order to achieve a separation of Y1 and the minor compound Y2 (which is identical to siphonodin, see Compound Y2 later in this section), but only the application of solvent system 2 was successful. Y1 has the same maximum in its UV spectrum as siphonodin, indicating a conjugation of the double bond and the carbonyl in the lactone ring. The NMR spectra show that Y1 is an isomer of siphonodin with signals corresponding to five carbon atoms and five protons (due to proton exchange with CD_3OD no chemical shift was recorded for the hydroxyl group). There is a close resemblance in the [^{13}C]NMR spectra of Y1 and siphonodin. Two differences were noted: in siphonodin the chemical shift of the tertiary C_3 is observed at 114.5 ppm and of the quaternary C_4 at 172.9 ppm, while Y1 showed signals at 133.9 ppm, corresponding to a quaternary carbon atom, and at 146.8 ppm, corresponding to a tertiary carbon atom. This suggests that the hydroxymethyl is attached to C_3 instead to C_4 as in siphonodin. This suggestion is confirmed by the [^{1}H]NMR spectrum. In Y1 the chemical shift of the olifinic proton is 7.47 ppm, while in siphonodin the signal of H_3 is observed at 6.03 ppm. In 5-hydroxymethyl-2(5H)-furanone, the chemical shifts of the olifinic protons H_3 and H_4 are reported at, respectively, 6.20 and 7.60 ppm (Camps et al., 1982). On the basis of this evidence, we suggest that Y1 is the butenolide 3-hydroxymethyl-2(5H)-furanone, a new product for which we propose the name isosiphonodin (Figure 5). The IR spectrum is in accordance with the proposed structure: next to the carbonyl stretching band at 1740 cm^{-1}, a second band is observed at 1690 cm^{-1}; the lower band can be attributed to the presence of intramolecular hydrogen bonding between the hydroxymethyl and the adjacent carbonyl. Fermi resonance of the carbonyl stretching mode, present in siphonodin at 1775 cm^{-1}, is absent in isosiphonodin.

UV (nm): 207(methanol); IR (neat, cm^{-1}): 3440–3190, 2915, 2880, 1740, 1690, 1610, 1445, 1390, 1350, 1310, 1205, 1090, 1050, 1020, 940, and 835; EI−MS (*m/e*, % relative intensity): 85(100), 39(70), 31(62), 96(60), 55(58), 57(53), 68(51), 45(24), and 113[$(M-H)^+$, 22)]; FAB−MS (*m/e*, % relative intensity); 57(100), 115[$(M+H)^+$, 75], 131(69), 237(45), 73(45), 89(40), and 61(26). NMR spectra were recorded in $CDCL_3$–CD_3OD (3 : 1) with TMS as internal standard. [^{1}H]NMR (ppm): δ 7.47(H_4, 1H, quintet, $J_{H4-H5} = J_{H4-H6} = 1.8$ Hz), 4.88(H_5, 2H, double doublet, $J_{H4-H5} = 1.8$ Hz, $J_{H5-H6} = 2.3$ Hz), and 4.35(H_6, 2H, double doublet, $J_{H4-H6} = 1.8$ Hz, $J_{H5-H6} = 2.3$ Hz); [^{13}C]NMR (ppm): δ 173.9(C_2), 146.8(C_4), 133.9(C_3), 71.2(C_5), and 56.3(C_6).

Compound E3. $C_5H_6O_3$. Its chromatographic behavior and EI−MS are

similar to Y1; therefore this minor butenolide from *E. europaeus* is identified as isosiphonodin.

Compound Y2. $C_5H_6O_3$. Its chromatographic behavior and EI−MS show that Y2 from *Y. cagnagellus* is identical to siphonodin. The butenolides Y1 and Y2 were isolated from fifth instar larvae which probably still contained some leaf material in their guts. Since siphonodin is the main butenolide in *E. europaeus*, siphonodin from the insect probably stems from plant material in the gut. TLC shows that siphonodin is absent in the pupal and adult stages of *Y. cagnagellus*.

DISCUSSION

In a previous work, screening for alkaloids and cardenolides in leaves of 16 *Euonymus* taxa was undertaken. It was concluded that cardenolides were present in all leaves tested (Fung, 1986). In the leaf extract of *E. europaeus*, six butenolides can be detected on TLC. Two of them we now identify as structurally simple butenolides. The major butenolide in dried leaves of *E. europaeus* is siphonodin. TLC shows that this same compound also occurs in several other *Euonymus* taxa (Fung, 1986). It is likely that *Euonymus* spp. contain both cardenolides and simple butenolides, as, in some investigated leaves, six to eight compounds are present, which are colored not only by Kedde's reagent but also by antimony(III) chloride, indicating the presence of both an α, β-unsaturated γ-lactone and a steroid part in these unidentified substances.

Next to the major substance siphonodin, a trace amount of the new compound isosiphonodin is isolated from *E. europaeus*. Siphonodin and isosiphonodin are isomers, formed probably by the same biosynthetic pathway. As these two products are not interconvertible by a single reaction, an early branching must have taken place in the biosynthesis of these butenolides.

From leaves of *Siphonodon australe*, siphonodin and its glucoside siphonoside were isolated (Wagner and Flitsch, 1981). In this plant, siphonodin was present as the major compound, the yields of siphonodin and siphonoside being 1.12 g and 45 mg, respectively. Since we restricted our isolation to major compounds in the extracts and did not consider minor components, we only isolated the aglucons siphonodin and isosiphonodin from *E. europaeus*. We need further analysis to ascertain whether glucosides of these butenolides are also present in *E. europaeus*.

Isosiphonodin is found to be the major butenolide in small ermine moths. Since the investigated *Yponomeuta* spp., with the exception of *Y. cagnagellus* and possibly *Y. vigintipunctatus*, do not feed on plants containing butenolides, isosiphonodin is probably synthesized by these insects. In the case of *Y. cag-*

nagellus however, selective uptake of isosphonodin from its host plant is possible. Secondary substances in insects are sometimes sequestered from their food plants, but *de novo* synthesis has also been demonstrated in several cases. Defensive secretions of leaf beetles from the genera *Chrysolina*, *Chrysochloa*, and *Dlochrysa* contain cardiac glycosides; evidence indicates that these cardenolides are probably synthesized by the insect from plants sterols (Pasteels and Daloze, 1977). Recently, it was shown that both sequestration and synthesis of cyanogenic glycosides are possible in the moth *Zygaena trifolii* (Nahrstedt and Davis, 1986).

We started this study with the aim of characterizing unknown compounds in small ermine moths, which could account for their repellent taste. Early in our work, we assumed that cardiac glycosides were involved in the chemical defense of *Y. cagnagellus* (Rothschild et al., 1986). As our results have shown, we did not find cardenolides but did isolate the butenolides siphonodin and isosiphonodin from this moth. Isosiphonodin was also detected in six other small ermine moth species. Since the palatability of small ermine moths has not been extensively studied, and the deterrency and/or toxicity of simple butenolides to predators of insects are not known, we cannot state at this stage whether the presence of isosiphonodin in small ermine moths will be of any use in their chemical defense. It would not be surprising if future studies reveal that this is indeed the case, as several simple butenolides are physiologically active compounds. Siphonodin and its derivatives, especially siphonoside, are reported to possess cytotoxic activity (Wagner et al., 1981). Tulipalin from tulip bulbs is shown to be a fungitoxic substance and the cause of the allergic skin reaction "tulip fingers" (Bergman et al., 1967; Brongersma-Oosterhoff, 1967). (±)-4-Hydroxy-3-methoxy-2-buten-4-olide from *Narthecium ossifragum* produces antibiotic activity against *Bacillus subtilis* (Tschesche and Hoppe, 1971). Protoanemonine, identified in extracts of several species of the Ranunculaceae, causes skin irritation and is an antibiotic agent (Ruijgrok, 1967).

Acknowledgments—We wish to thank J.J.M. van Brussel for recording the IR spectra, A.W.M. Lefeber and C. Erkelens for recording the NMR spectra, J.J. van Houte and R. Fokkens for recording the MS spectra, and S. Boers for technical assistance in the pharmacological test. We are much obliged to Prof. Dr. R. Hegnauer for stimulating discussions.

DAMAGE-INDUCED ALKALOIDS IN TOBACCO: Pot-Bound Plants Are Not Inducible

IAN T. BALDWIN

Section of Neurobiology and Behavior
Cornell University
Ithaca, New York 14853

(Received April 2, 1987; accepted June 10, 1987)

Abstract—Field-grown wild tobacco plants (*Nicotiana sylvestris*) were subjected to a defoliation regime designed to mimic the rate and amount of leaf mass removed by one tobacco hornworm per plant. Undamaged leaves on these plants undergo a dramatic (457% for leaf position 5, 410% for leaf position 8) increase in total leaf alkaloids compared to same-age and positioned control leaves on undamaged control plants. However, potted greenhouse-grown plants fail to exhibit the same damage-induced increase in alkaloid content. The greenhouse environment differs from the field environment in factors known to influence leaf alkaloid content, particularly soil N, P, K, near-UV radiation, and relative humidity. However, altering these environmental factors does not make potted plants able to increase their leaf alkaloid levels in response to defoliation. Transplanting plants into larger pots with more soil does allow the plants to respond to defoliation. Thirty days after transplanting, the plants are again unresponsive to damage, probably as a result of becoming "pot-bound." This result suggests a mechanism for the induction response, specifically that leaf damage triggers synthesis of these alkaloids in the roots, and offers a potentially valuable experimental tool for the study of induced-plant defenses in tobacco and other plants that synthesize alkaloids in their root tissues.

Key Words—*Nicotiana sylvestris*, leaf alkaloids, defoliation, induced defense, pot-binding, nicotine.

INTRODUCTION

The herbivore-induced increases in plant secondary metabolites have received much attention in the ecological literature (Rhoades, 1979; Schultz and Baldwin, 1982; Haukioja, 1982) and have lent support to the hypothesis that plant

0098-0331/88/0400-1113$06.00/0

secondary metabolites are not just "waste products" of plant metabolism, but, rather, a component of plants' evolved defense responses against herbivory and pathogen attack. These responses have received little attention from plant physiologists. The mechanisms of only two herbivore-induced defense responses are understood in any detail: the induction of proteinase inhibitors in tomato leaves (Ryan, 1983) and quinolizidine alkaloid in lupine leaves (Wink, 1983). Understanding the mechanistic details of the induction response would greatly augment research into the ecological significance and evolutionary origins of such plant defensive responses. The first step in a mechanistic quest is to reproduce the response in the laboratory under controlled conditions.

Members of the genus *Nicotiana* produce pyridine-containing alkaloids that are toxic to most herbivores (Gordon, 1961; Hassall, 1969; Schmetz, 1971) and even, if present in adequate concentrations, deleterious to insects that feed primarily on these alkaloid-containing plants. In artificial diet experiments, Parr and Thurston (1972) showed that tobacco hornworms—despite their ability to efficiently excrete ingested tobacco alkaloids (Self et al., 1964)—reared on diets containing 2% or higher concentrations of nicotine had significantly reduced survivorship and larval performance.

Decapitation—topping—at the onset of flowering is standard practice in the production of cultivated tobacco (*N. tabacum*); it increases the size, weight, and alkaloid content of leaves (Woetz, 1955). Although it has long been known that damage to the flowering top of a tobacco plant increases the total alkaloid content of the plant (Reuter, 1957), the possible ecological significance of this response, namely, that a plant may increase its leaf alkaloid content after damage as a defensive response to herbivore attack, has gone unnoticed.

Here I demonstrate substantial increases in the alkaloid content of undamaged leaves of field-grown wild tobacco plants suffering damage not to their flowering tops, or apical or lateral buds, but only to their fully expanded leaves. However, plants grown under normal greenhouse conditions are not responsive to damage. Unrestrained root growth appears to be necessary for the response to occur.

METHODS AND MATERIALS

Alkaloid Quantification. The four principal alkaloids of *Nicotiana* species (Saitoh et al., 1985)—nicotine, anabasine, nornicotine, and anatabine—were separated by isocratic high-pressure liquid chromatography; detected by absorbance at 254 nm; quantified with a reporting integrator using the techniques of Saunders and Blume (1981); and modified by the use of (−)-scopolamine hydrochloride as an internal standard. The retention times (minutes) of standard alkaloids were: nornicotine (11.05), anabasine (12.30), anatabine (13.99), sco-

polamine (20.68), and nicotine (23.35). All samples were injected twice and the values expressed as a percentage of dry weight leaf (mean ± SD).

Alkaloid Extraction. Fresh leaf samples, rather than air-dried samples, were used to determine alkaloid contents. Replicate extractions ($N = 10$ per group; mean = ± SD % alkaloid content) of a pooled homogeneous leaf sample extracted after 24 hr (1.243 ± 0.188), 48 hr (1.115 ± 0.531), and 72 hr (0.969 ± 0.515) of air drying at 50°C produced lower ($P < 0.0001$) and more variable ($P < 0.0005$) results than an analysis of fresh leaf material (1.924 ± 0.011). Fresh leaf samples were weighed to 0.2 mg, frozen in liquid N_2, ground to a fine powder with a glass rod, and extracted in a single extraction step in 40% methanol 0.1% N HCl (Saunders and Blume, 1981) containing the internal standard at a concentration of 50 μg/ml. Four sequential extractions of 10 replicate leaf samples revealed that 97.86% ± 0.42 of the total alkaloids was removed in the first extraction when the concentration of leaf material in the extraction solvent was 10 mg fresh wt/ml extraction solution. The alkaloid extraction and quantification technique proved to be both precise—30 samples of tobacco leaves containing a wide range of alkaloid concentrations (0.03% minimum, 2.46% maximum) extracted in duplicate had a mean percentage diffference between replicates of 0.04—and accurate—when 10 leaf samples were spiked with known amounts of nicotine, better than 95% of the alkaloid was detected.

Plant Cultivation and Leaf Sampling for Alkaloids. Seeds of *Nicotiana sylvestris* Spegazzini and Comes were originally obtained from the USDA Beltsville Agricultural Research Center, Beltsville, Maryland. Seeds from one greenhouse plant (thus plants were full sibs) were germinated in Cornell Mix A (Boodley and Sheldrake, 1977) under greenhouse conditions and either planted in a field plot at Cornell University or under greenhouse conditions in 18-cm fiber pots with 3.5 g Osmocote 14-14-14 fertilizer. The field plot was a roto-tilled old field consisting of four rows of 10 plants with 61 cm between plants and rows. The plot was neither fertilized nor watered and was manually weeded only during the first two weeks after planting. In order to minimize possible edge effects, only the two middle rows were used in this study. All plants were grown to the buttoning stage before experimentation began. The eighth fully expanded leaf from the top was designated the sample leaf and labeled with a twist-tie. The fifth leaf of each field-grown plant was also designated a sample leaf. Leaf samples were removed in a 1-cm band (Rosa, 1973) one half the leaf length from the top, across the leaf but excluding the midrib; leaf samples were then immediately weighed and extracted. A comparable band adjacent to the sample band was removed, weighed, dried at 50°C for 48 hr, and reweighed to obtain a percent dry weight calculation.

Experimental Treatments. Plants were grouped by height (±5 cm to the developing flower button) and randomly assigned to a treatment with 10 plants per treatment. Plants were damaged in order to simulate the feeding of one

Manduca sexta larva, a common lepidopteran pest of cultivated tobacco. During its larval life, a caterpillar will eat approximately 2100 cm^2 of leaf area, of which 90% will be consumed in the last larval instar (Madden, 1945). Greenhouse-grown plants are smaller at the buttoning stage than are field-grown plants. For field-grown plants, 2000 cm^2 of leaf area represents approximately 50% of the shoot weight. Thus, instead of removing the same amount of leaf area as in the field-defoliation treatment, the same proportion of leaf area was removed. Fully expanded leaves from positions 3 through 12, excluding positions 5 and 8 (the sample positions), were cut daily with scissors over an eight-day period. Cuttings was placed in labeled bags, air-dried at 50°C, and weighed. Plants assigned to a fertilizer treatment were watered daily with 100 ml/pot of a fertilizer solution consisting of 1 kg of Peter's 20-20-20 per 400 liters of water for eight days prior to the initiation of the damage regime. Plants assigned to a transplant treatment were removed from their pots and placed in 30-cm fiber pots containing 4.2 times the volume of Cornell Mix A contained in the 18-cm pots. Control plants in the transplant experiment were removed from their 18-cm pots and returned to these pots.

Statistical Treatment. Alkaloid values were N-scored (Ryan et al., 1982) and found to be normally distributed. Alkaloid values were compared with the Student's *t* test modified for unequal variances; values from field-grown plants were compared with a paired *t* test for between-treatment comparisons (Sokal and Rohlf, 1981). Percentages were arcsin-transformed.

RESULTS AND DISCUSSION

The alkaloid composition of leaves in positions 5 and 8 of *N. sylvestris* was dominated by a single compound: nicotine. The percent composition of the alkaloid profile of the 130 leaves sampled in this study was 90.3 $\pm$ 8.6% nicotine, 9.2 $\pm$ 4.2% nornicotine, 0.6 $\pm$ 0.5% anabasine, and 0.1 $\pm$ 0.1 anatabine, which is consistent with the previous work on this species (Saitoh et al., 1985). Nicotine was the only alkaloid significantly ($P < 0.05$) influenced by any of the treatments.

Field-grown plants subjected to the eight-day defoliation regime lost 50.13 $\pm$ 13.34% of their shoot mass and had more than four times the total alkaloid content in their undamaged sample leaves (Table 1). The alkaloid content of sample leaves higher on the stalk (position 5) was not significantly different ($P = 0.60$) from that of leaves on the lower stalk position (8) on undamaged plants, but tended to be higher on damaged plants ($P = 0.057$).

Greenhouse-grown plants subjected to the defoliation treatment lost 45.2 $\pm$ 7.2% of their shoot mass over the eight-day cutting period. However, unlike the experiment with field plants, no difference ($P = 0.28$, $DF = 19$) was found

TABLE 1. TOTAL ALKALOIDS OF SAMPLE LEAVES IN TWO LEAF POSITIONS FROM DAMAGED AND UNDAMAGED FIELD-GROWN WILD TOBACCO PLANTS

	% of dry wt sample leaf total alkaloid			
	N	Mean	SD	*P*
Leaf position 5				
Damaged plant	10	2.527	1.210	0.00001
Undamaged plant	10	0.553	0.308	
Leaf position 8				
Damaged plant	10	1.985	0.791	0.00001
Undamaged plant	10	0.484	0.163	

between the alkaloid contents of undamaged sample leaves from damaged (0.189 $\pm$ 0.053) and undamaged (0.196 $\pm$ 0.049) plants.

Soil nutrients, particularly B, Ca, and N, are known to substantially affect leaf nicotine contents (Tso, 1972). Deficiency in soil B and Ca increases leaf nicotine contents but also destroys the plants' apical buds (Tso, 1972). Because the apical buds of greenhouse-grown plants appeared healthy, an experiment was conducted with an N-P-K fertilization treatment. Fertilizer increased the alkaloid contents of both damaged (0.578 $\pm$ 0.135) and undamaged (0.595 $\pm$ 0.151) plants, but the damage had no effect on leaf alkaloid contents ($P = 0.80$, $DF = 19$).

The greenhouse environment differs from the field environment in that the glass of the greenhouse substantially decreases the amount of near-UV radiation and the intensity of visible light. Both alterations of the light environment are known to decrease leaf alkaloid concentration (Anderson and Kasperbauer, 1973). Plotted plants placed outdoors for 10 days prior to the defoliation treatment had elevated alkaloid levels, but sample leaves did not differ ($P = 0.33$, $DF = 19$) between damaged (0.584 $\pm$ 0.216) and undamaged (0.492 $\pm$ 0.194) plants.

Potted plants transplanted into larger pots with more soil prior to a one-day defoliation treatment (removing 35.0 $\pm$ 6.0% of the total leaf dry weight with a single cutting) had substantially more nicotine in undamaged sample leaves of undamaged plants (Table 2). The transfer of a plotted plant into a larger pot with more soil apparently enables the plant to increase its leaf alkaloid level after leaf damage. The ability to respond to damage wanes 30 days after the transfer to the larger pot.

The increase in leaf alkaloid content in cultivated tobacco (*N. tabacum*) after topping is largely due to increased nicotine synthesis in the roots (Mizusaki et al., 1973). However, decreased leaf nicotine degradation rates in the leaves

(Yoshida, 1962) and leaf nicotine synthesis (Bose et al., 1956) may play a role in the topping-induced increase in leaf alkaloid levels. Most nicotine synthesis is thought to occur in young dividing root tips (Dewey et al., 1955). Although the hypothesis needs to be experimentally demonstrated, the increased leaf alkaloid content after leaf damage is likely due to a similar physiological process. Pot-bound plants, those growing in a pot for 30 days or more, may be unable to initiate new root growth after leaf damage, and be hence unable to synthesize more alkaloids. This hypothesis is consistent with the observation that soil depth is positively correlated with constitutive leaf nicotine concentrations (Wolf and Bates, 1964).

The observation that pot-bound plants are not responsive to leaf damage may prove to be an important experimental tool for demonstrating the ecological consequences of altered leaf chemistry on herbivorous insects. Herbivore damage has dramatic effects on leaf secondary chemistry, as well as on primary metabolites such as protein (Wagner and Evans, 1985) and sugars (Valentine et al., 1983). In some studies leaf damage apparently increased the nutritional quality of the leaves to herbivores (Williams and Myers, 1984). Hence a plant cultivation technique that allows for manipulation of a damage-induced alteration in a secondary metabolite, against a background of damage-induced alterations in primary metabolities, would be an exciting experimental tool in the study of induced plant defenses. This phenomenon may also be applicable to other plant alkaloids that are synthesized in the roots, such as hyoscyamine in *Datura*, *Atropa*, and *Hyoscyamus*; and betaines in *Beta* (Mothes, 1960).

(Received February 2, 1987; accepted June 12, 1987)

Abstract—Observations in the laboratory and in the field indicated that male *Anticarsia gemmatalis* (Hübner), the velvetbean caterpillar (VBC), are attracted to conspecific courting males. Male VBC subsequently were found to be attracted to extracts of male abdominal tips including the extrudable hairpencils. The active chemical in these extracts was identified as (*Z,Z,Z*)-3,6,9-heneicosatriene, which is also one of the major components of the female VBC sex pheromone. Male VBC in a wind tunnel and in the field exhibited a bimodal response distribution to a range of ratios of the (*Z,Z,Z*)-3,6,9-heneicosatriene and (*Z,Z,Z*)-3,6,9-eicosatriene, with one maximum at the pure heneicosatriene alone and the other at the 60:40 female blend. This demonstrates that the male response to the male hairpencil component is distinct from that to the female sex pheromone.

Key Words—*Anticarsia gemmatalis*, velvetbean caterpillar, Lepidoptera, Noctuidae, attractant, pheromone, hairpencils, (*Z,Z,Z*)-3,6,9-heneicosatriene, male-produced pheromone.

INTRODUCTION

During field studies of the sex pheromone behavior of the male velvetbean caterpillar (VBC), *Anticarsia gemmatalis* (Hübner) (Heath et al., 1983), males

[1]This article reports the results of research only. Mention of a proprietary product does not constitute an endorsement or the recommendation for its use by USDA.

0098-0331/88/0400-1121$06.00/0

were observed orienting to other males that were responding at close range to synthetic female sex pheromone [40:60 ratio of (*Z*,*Z*,*Z*)-3,6,9-eicosatriene (C-20 triene) and (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene) (C-21 triene)]. Similar behavior had been observed during studies of VBC sex pheromone behavior in a flight tunnel, involving calling females and multiple males (unpublished data). Whether these were visual responses of males to the shape of a moth or possibly a response to male-produced chemicals was not apparent.

Male-produced sex pheromones have been reported or suggested for a number of moth species, based on chemical analyses, behavioral studies of attraction and courtship, or hairpencil or brush morphology. Overt responses by females to male-produced pheromones have been demonstrated in few cases. Baker et al. (1981) demonstrated short-range attraction of female *Grapholitha molesta* (Busck) to a male sex pheromone released during courtship from abdominal hairpencils. *Ephestia elutella* (Hübner) females flex the abdomen ventrally in response to male sex pheromone (Krasnoff and Vick, 1984). Other studies suggest an aphrodisiac role for many male sex pheromones (Birch, 1974), and intrasexual responses to male pheromone have been reported in a few cases. Baker (1983) demonstrated that displaying *G. molesta* males attract other males at close range. Male attraction to males, resulting in aggregations in the field, is known for *Estigmene acrea* (Drury) (Willis and Birch, 1982). Also, male pheromone may reduce the attractiveness of calling females in *Heliothis virescens* (Boddie) (Hendricks and Shaver, 1975) and *Pseudaletia unipuncta* (Haworth) (Hirai et al., 1978).

Like many other species of Lepidoptera, male VBC have sexually dimorphic brushes and hairpencils. Greene (1974) described long scales on the prothoracic femorae and mesathoracic tibiae of VBC males. Male VBC also possess terminal abdominal hairpencils and scent brushes on the venter of the eighth abdominal segment. While it is presumed that these brushes and hairpencils are involved in courtship interactions possibly for the dispersal of pheromones affecting female behavior, their functions and the products of any associated exocrine glands are unknown.

We report here the results of experiments demonstrating attraction of male VBC to extracts of the male abdominal tips, including the hairpencils, and the identification of a chemical from those extracts that was attractive to other male VBC in a flight-tunnel bioassay and in field trapping tests.

METHODS AND MATERIALS

Insect Rearing and Maintenance. All insects were obtained as pupae from a colony maintained as described by Leppla (1985) at the USDA Insect Attrac-

tants, Behavior, and Basic Biology Research Laboratory, Gainesville, Florida. Pupae were sorted by sex, placed in 24 × 24 × 24-cm plastic screen and Plexiglas cages, and supplied with a sucrose solution on cotton. Males and females were held in separate environmental chambers on a 14:10 light–dark cycle at 24°C and 65% relative humidity. Pupae were transferred daily to new cages to provide adult moths of known age. Males were tested when 4–7 days old. Bioassays were conducted during third to fifth hours of the scotophase. Pheromone extracts from males were obtained during the first hour of the scotophase.

Bioassays of Male VBC Extracts. Preliminary bioassays of extracts of abdominal tips, whole insects, and leg scales indicated the attractant activity was confined to the abdominal tip. Male VBC abdominal tips were extruded by squeezing the abdomens between the thumb and index finger, extruding the terminal hairpencils, and exposing the ventral brushes. The tip was cut between the more anterior ventral brushes and hairpencils. Tips were placed in vials that contained 1 ml hexane in 50 or 25 tip batches. After several hours, the solvent extract was transferred to a new vial.

Tip extracts were tested for attractiveness to male VBC in a flight-tunnel bioassay in comparison to hexane blanks and female abdominal tip extracts [two female equivalents (FE)]. Extract dosages (as male equivalents) were placed on filter papers and, after 2 min of air drying under a fume hood, were hung on a stand near the center of the upwind end of the flight tunnel. Males were released singly at the middle of the length of the tunnel, ca. 2 m from the upwind end. Moths were scored during a 2-min period for upwind-oriented flight to the filter paper.

Abdominal tip extracts of male VBC were tested at dosages of 0.2, 1.0, and 5.0 male equivalents (ME). Either 5 or 10 males were tested (assayed) individually per treatment on each of seven different days to provide data sets composed of male responses to the female pheromone, hexane blanks, and the three dosages of male extracts.

Isolation and Identification. An initial purification of the male abdominal tip extracts was obtained on a gravity flow glass column (5 × 0.62 cm ID) prepared by slurry packing 60–100 mesh silica (J.T. Baker Chemical Co.) in hexane. Solvents used to elute the column were hexane, 10% ether–hexane, 50% ether–hexane, and 100% ether. The active fraction from the gravity flow was further purified using a Varian 1400 gas chromatograph (GC) equipped with a flame ionization detector. A glass column (2 m × 2.3 mm ID) packed with 4.4% OV-101 on 80–100 mesh Chromosorb G-HP was used, and 2% of the effluent was routed to the detector. The remaining 98% of the effluent was collected in a cooled 30-cm glass capillary tube according to the method described by Brownlee and Silverstein (1968). Helium was used as the carrier

gas (28 ml/min), and the column was temperature programmed from 80 to 240°C at 10°/min. Analyses of the active fraction eluted from the packed GC column and of the synthesized chemicals used in this study were obtained using a Varian 3700 GC equipped with splitless capillary injector and flame ionization detector. The output of the detector was interfaced with a Nelson 4000 data system. Helium was used as the carrier gas for all analyses at a linear flow velocity of 18 cm/sec. Columns used for analyses (from Quadrex Corp., New Haven, Connecticut) were a 50 m × 0.25mm ID fused silica column coated with a 0.25-μm film of methyl silicone and a 30 × 0.25 mm ID fused silica column coated with a 0.25-μm film of Carbowax 20 M. Columns were held at an initial temperature of 60°C for 2 min and then temperature programmed to 200°C at 32°/min. Additionally, a 30 m × 0.25 mm ID cholesterol para-chlorocinnamate liquid crystal capillary column was used isothermally at 160°C (Heath et al., 1979). Confirmation of the identity of a compound was made by cochromatography with a synthetic standard. Additionally, mass spectral data (methane chemical ionization and electron impact using a Nermag model R1010) were obtained on the active material from abdominal tip extracts. Mass spectrometry samples were introduced with an HP 5790 gas chromotograph equipped with a splitless injector and the 50-m methyl silicone column described previously.

Bioassays of Synthetic Pheromone. In a flight-tunnel bioassay, male VBC were tested for response to a range of ratios of the two components identified as the female sex pheromone and the active material obtained from male abdominal tip extracts and over a range of dosages. The pheromone was formulated in rubber septa at combined loads of 1, 2, 20, or 200 μg/septum dissolved in 100 μl of hexane and air dried for 2 days prior to use. Load ratios tested were 0:100, 2:98, 6:94, 10:90, 18:82, 45:55, 64:36, 85:15, and 100:0 of the C-20 triene–C-21 triene, respectively, with predicted release ratios (Heath et al., 1986) of 0:100, 6:94, 15:85, 22:78, 33:67, 66:34, 81:19, 90:10, and 100:0 of C-20 triene–C-21 triene. Release ratios were confirmed by analysis of volatiles collected from septa using the system described previously (Mitchell and Heath, 1986).

At each dosage, 40 male VBC were tested as four sets of 10 moths flown one at a time to each ratio. Males were scored for attraction to within 5 cm of the source and for reorientation to the source. All bioassay conditions were as described above.

Field Test of Synthetic Pheromone. The attractiveness of a range of ratios of the female sex pheromone and male pheromone component was evaluated in the field in a trapping test at 200-μg and 1-mg dosages on rubber septa. Screen cone traps (Hartstack et al., 1979) were mounted on steel poles (with the septa

positioned at the base of the cone) just above the vegetation. The test was conducted in a soybean field near Alachua, Alachua County, Florida, during September 1984. Two sets of nine traps were placed in rows perpendicular to the prevailing wind (north to south), with 10 m between traps and 90 m between rows of traps. The traps were checked daily and captured moths were identified to species, sexed, and counted. The positions of the traps were randomized daily. Daily trap catch data were converted to ranks by treatment for analysis of variance. Treatment rank means were separated using Duncan's new multiple-range test at the $P = 0.05$ level (Duncan, 1955).

RESULTS

Extracts of male abdominal tips were attractive to other males in the flight-tunnel bioassay at all dosages tested. At 0.2 ME, 36.7% of males tested responded (oriented flight upwind to the filter paper), 44.6% to the 1.0 ME samples, and 63.8% to the 5.0 ME samples. No males responded to the hexane blanks, and 94% of those tested responded to the 2 FE female abdominal tip extract standard. All of the activity from the tip extracts was recovered in the hexane fraction of the gravity-flow silica column. Male response was not increased by the addition of fractions obtained by further elution of the column using 10% and 50% ether–hexane and the 100% ether as the solvent. The active hexane fraction from the gravity-flow column was further purified by GC using the packed OV-101 column. All the activity was obtained in one peak that had a Kovats index of 2071. Further analysis of this peak on the 30-m polar Carbowax and 50-m apolar methyl silicone capillary columns resulted in a single peak.

Mass spectra obtained using electron impact and methane chemical ionization of the active peak from the packed column were identical to that obtained for the (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene reported previously as one of the pheromone components obtained from female VBC (Heath et al., 1983). Further analysis on a cholesterol para-chlorocinnamate column capable of resolving all eight possible isomers confirmed that the geometry was *Z*,*Z*,*Z*.

Using GC analysis on both polar and apolar capillary columns, it was determined that 4- to 7-day-old males contained an average of 5.9 ng/male (SD = 5.09, $N = 24$) of the (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene.

Bioassays of Synthetic Pheromone. At all dosages tested, C-21 triene was attractive to male VBC when tested alone, and at most ratios with C-20 triene (Figure 1). The greatest percentages were observed to load ratios which were

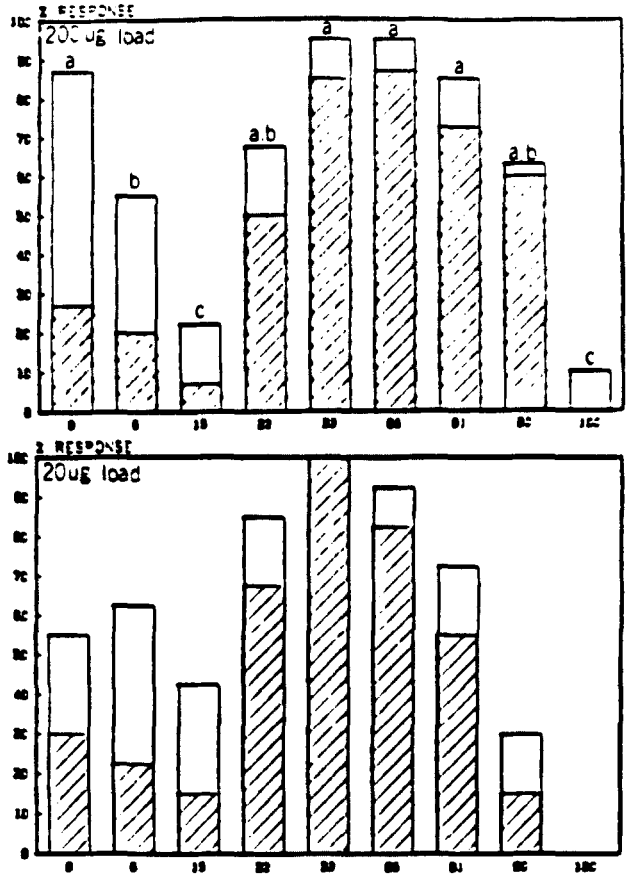

FIG. 1 Mean percentages of male *A. gemmatalis* attracted (open bar) and then reoriented (slash bar) to various release ratios of (Z,Z,Z)-3,6,9-eicosatriene and (Z,Z,Z)-3,6,9-heneicosatriene in a flight tunnel bioassay at 1-, 2-, 20-, and 200-μg loads on rubber septa. At the 200-μg load, columns having the same letter are not significantly different (Duncan, 1955).

similar to the 40:60 ratio (equivalent to a 60:40 release ratio) found in female VBC abdominal tips (Heath et al., 1983). At higher release rates, an unexpected bimodal distribution of male response was observed with minima at the 15:85% ratio of C-20–C-21 triene hydrocarbons and 100% C-20 triene hydrocarbon. At the 200-μg load, the mean percentages of males attracted to the source for the

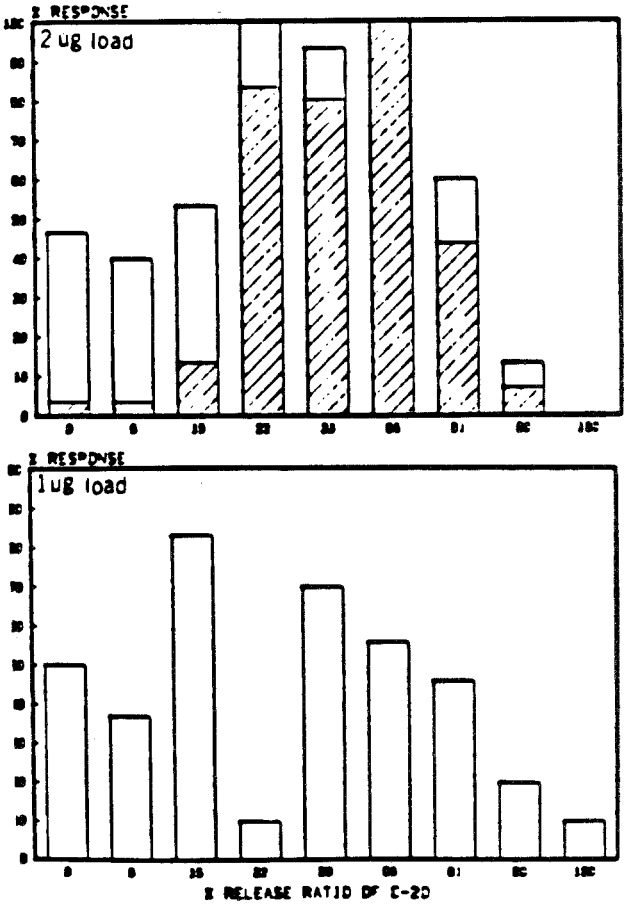

FIG. 1. Continued.

100% C-21 triene septa and the septa that released the 22, 33, 66, 81, and 90% ratios of the C-20–C-21 trienes were not significantly different.

Field Tests. At the 200-μg dose, a unimodal distribution of male response with a maximum at the female pheromone ratio (66% C-20 and 34% C-21 triene) occurred (Figure 2). However, at the 1-mg dose, a pattern similar to that observed in the wind tunnel using the 200-μg loaded septa was obtained in the field (Figure 2). That is, males were captured in a bimodal distribution, where the C-21 triene alone attracted significantly more males than septa releasing the 6:94 ratio of C-20–C21 triene.

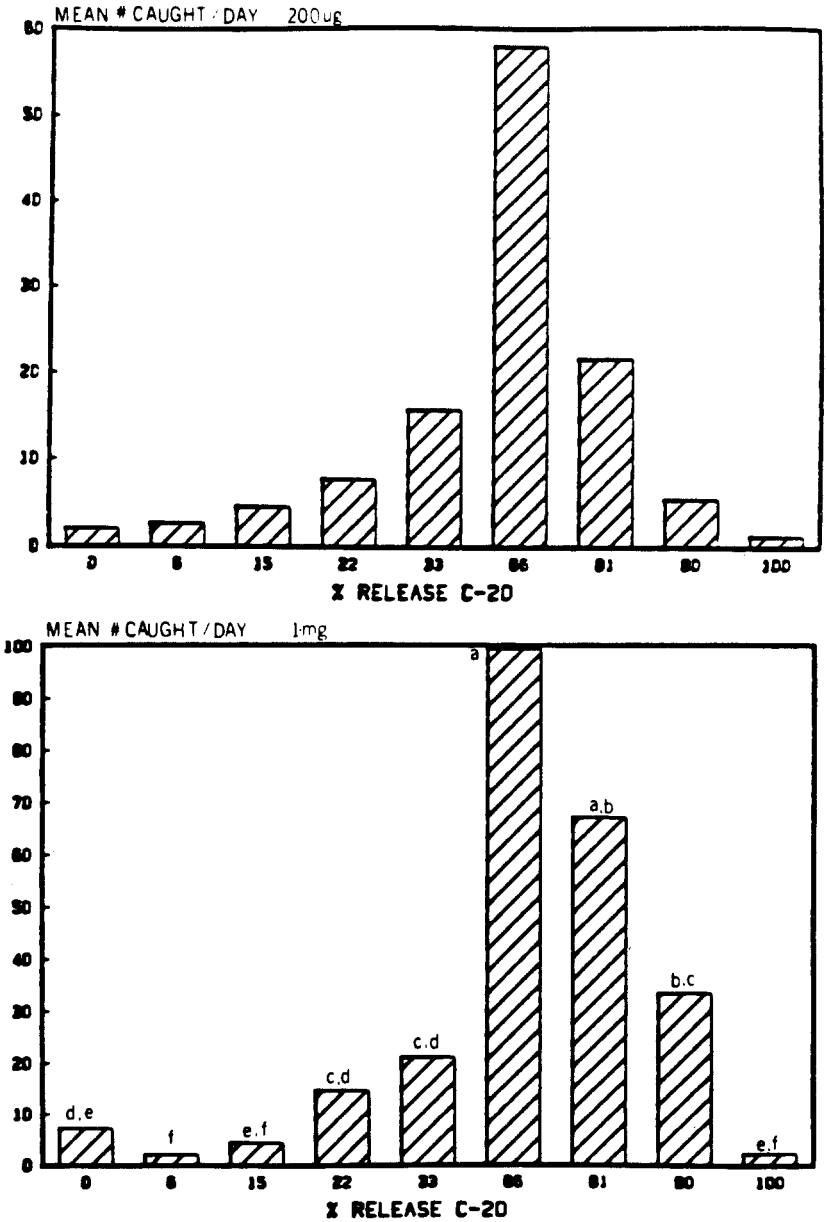

FIG. 2. Mean percentage of total trap catches of male *A. gemmatalis* in cone traps baited with ratios of (Z,Z,Z)-3,6,9-eicosatriene and (Z,Z,Z)-3,6,9-heneicosatriene at 200-μg and 1-mg loads on rubber septa. At the 1-mg load, columns having the same letter are not significantly different (Duncan, 1955).

DISCUSSION

The results of these studies demonstrate the presence of (Z,Z,Z)-3,6,9-heneicosatriene in abdominal tips of male VBC. This compound also is found as one of the sex pheromone components produced by female VBC. Male response to the male component alone and in combination with the C-20 triene produced by females resulted in a bimodal distribution.

It is doubtful that males release pheromone specifically as an attractant signal to conspecific males. According to Leppla et al. (1987), male VBC display the abdominal hairpencils and abdominal scent brushes when very near the female, as they approach, and during courtship interactions preceding mating. This suggests a courtship function for the male pheromone, directed at a calling female, possibly as an aphrodisiac. Male attraction to this signal possibly then is a secondary phenomenon resulting from male–male competition for females. Baker (1983) found that the mating success of courting *G. molesta* was reduced greatly by late-arriving competitors, which succeeded in mating 21% of the time. Behavior exhibited by late-arrivals was attraction to the first-arrivals' display, which caused the first male to misdirect a copulatory thrust, thereby disrupting normal courtship (Baker, 1983). Male VBC may be similarly able to interrupt courtship and successfully mate if they arrive before coupling. In other words, as in *G. molesta*, VBC males close by may be attracted to other courtship signals because they can sometimes interfere with an ongoing male–female courtship and gain opportunities for mating with that female.

The results from the field experiments supported in part the observations of the laboratory experiments. At the 200-μg load, no significant response (trap catch) was obtained with the male VBC pheromone. However, when septa were loaded with 1-mg amounts of pheromone, the trap catch pattern for the ratios of C-20 and C-21 triene tested resulted in a bimodal distribution similar to that observed in the wind-tunnel experiments: The male pheromone, a blend distinct from the female pheromone, was significantly more attractive than were other ratios differing from the female blend. One possible explanation of the trap catch data at the higher dose is that males release their component only during courtship and over a very short time period, perhaps at a relatively high release rate. Thus, only males in close proximity to males releasing the C-21 triene may be responsive to this male chemical cue.

We have presented in this study the identification of a compound produced by male VBC, which is also found as one of the components of the sex pheromone of female VBC. Additionally, we have demonstrated this male compound is attractive to other males in wind-tunnel and in field tests. We suspect that the primary function of this compound is as a courtship pheromone to evoke female acceptance, although this remains to be demonstrated.

(Received September 26, 1986; accepted June 12, 1987)

Abstract—The sex pheromones of *Neodiprion pinetum* (Norton) and *Diprion similis* (Hartig) consist of two isomers, 2*S*,3*S*,7*S* and 2*S*,3*R*,7*R*, in either the acetate or propionate forms of 3,7-dimethylpentadecan-2-ol, respectively. The 2*S*,3*S*,7*S* acetate isomer is utilized by *N. pinetum* as the major pheromone component and the 2*S*,3*R*,7*R* acetate as a synergist. Conversely *D. similis* utilizes 2*S*,3*R*,7*R* as propionate the major pheromone component and 2*S*,3*S*,7*S* propionate as a synergist. This was confirmed in the field in both Michigan and Wisconsin. Capillary gas–liquid chromatographic analyses revealed that these two isomers are present in the natural pheromones of both species at the ratios close to those predicted by artificial blending of the two optical isomers.

Key Words—Sawflies, *Neodiprion pinetum*, *Diprion similis*, Hymenoptera, Diprionidae, 3,7-dimethylpentadecan-2-ol, *Pinus strobus*, sex pheromone.

INTRODUCTION

The sex pheromones of diprionid pine sawflies were described as the acetate or propionate of 3,7-dimethylpentadecan-2-ol (diprionol) (Jewett et al., 1976). However, when tested in the field against three diprionid sawfly species, the

[2]Present Address: Department of Plant Science, University of Ife, Ile-Ife, Nigeria.

0098-0331/88/0400-1131$06.00/0

racemic synthetic compounds were not as active as the natural pheromone. When *Neodiprion lecontei* (Fitch) showed a significant response to (2*S*,3*S*,7*R/S*)-3,7-dimethylpentadecan-2-ylacetate (2*S*,3*S*,7*R/S*-A) in the field (Matsumura et al., 1979), it became clear that only certain optical isomers of diprionol esters were active. This was also confirmed in *N. pinetum* (Kraemer et al., 1979), which showed a response to 2*S*,3*S*,7*S*-A, but not to 2*R*,7*R*,7*R*-A, and 2*R*,3*R*,7*S*-A. The *N. pinetum* study was the first to show that a *Neodiprion* species responded to the 2*S*,3*S*,7*S*-isomer, although it had been predicted when 2*S*,3*S*,7*R/S*-A-baited traps attracted male *N. lecontei* in the field (Matsumura et al., 1979). Further investigations revealed that *N. lecontei, N. nanulus nanulus* Schedl, *N. sertifer* (Geoffroy), and *N. taedae linearis* Ross responded mainly to the 2*S*,3*S*,7*S* isomer (Kraemer et al., 1983), whereas two Old World species, *Diprion similis* (Hartig) and *Gilpinia frutetorum* (Fabricius), preferred the 2*S*,3*R*,7*R* isomer (Kikukawa et al., 1982a). A field study in 1980, at Higgins Lake, Michigan, by Kikukawa and Matsumura (unpublished) established that *N. pinetum responded mainly to* 2*S*,3*S*,7*S*-A and that males responded better to the acetate than to the propionate isomers. However, no definite conclusion was made from either their data or those of Kraemer et al. (1979) as to the effect of isomer blends.

The conclusion that *D. similis* responded to 2*S*,3*R*,7*R*-P isomer was based on the field response of males to the partially racemic compounds 2*S*,3*R*,7*R/S*-P; 2*S*,3*R*,7*R/S*–2*R*,3*S*,7*R/S*-P; and 2*R/S*,3*R*,7*R*-P isomers. Of these racemates, 2*R/S*,3*R*,7*R*-P was the most active, but not significantly above the others. In the same study, the natural pheromone was far superior, approximately 2500-fold. The discrepancy between the natural and synthetic was originally attributed to the racemic nature of the synthetics. There is evidence for enantiomeric specificity in the pheomones of many scolytid Coleoptera (Hedden et al., 1976; Wood et al., 1976; Borden et al., 1976, 1980). It has also been hypothesized that some racemates elicit response-inhibitory effects on the receptor system of insects that naturally respond to one enantiomeric form only (Vité et al., 1976). Experience with other *Neodiprion* sawflies showed that species respond mainly to one enantiomeric form (2*S*,3*S*,7*S*-A), but such response may be synergized by another enantiomeric form, either 2*S*,3*R*,7*R*-A or 2*S*,3*S*,7*S*-A depending on species (Kikukawa et al., 1983; Olaifa et al., 1984). This study reports on the interaction of optical isomers in field response and capillary gas-liquid chromatographic (GLC) analyses of the natural pheromones of *N. pinetum* and *D. similis*, two important defoliators of *Pinus strobus* Linneaus in North America.

METHODS AND MATERIALS

Field Tests. Field trapping of *N. pinetum* was carried out in Michigan and Wisconsin. In Michigan, two tests areas, Sec. 25 and 30, Higgins Lake State

Forest, Roscommon County, and Sec. 33, McGee on Highway M66, Kalkaska County, were used. Both consisted of pure white pine stands, each about 1.6 km square. The ground cover consisted of grasses and fern, *Pteridium aquilium* (L.) Kuhn. In Wisconsin, pure white pine stands 2 miles west of Siren were used. The larval colonies of *N. pinetum* were collected by M. Kraemer of University of Wisconsin and reared in the laboratory. They were morphologically identical to the field-trapped *N. pinetum* from Michigan.

Most of the field trapping for *D. similis* was in Kalkaska County, Michigan. All the white pine at this location were shrubby and fully exposed to the sun. Undergrowth was mainly grasses and sweet fern, *Comptonia peregrina* (L.) Coult. Also, but infrequently, used were the Higgins Lake site and the Rose Lake Wildlife Experimental Station at Bath Township in Ingham County, Michigan. At all locations, eggs, larvae, cocoons, and adults of *D. similis* were collected. Methods of bioassay have been described (Kikukawa et al., 1982a).

Pherocon II traps were used throughout, and trap preparations have been described (Kraemer et al., 1979). A randomized complete block design was used with the block choice based on rows of clearings at the two locations. At least one rerandomization of treatments within and between blocks was done, and the record of trap catch taken weekly. The data so collected were evaluated with analysis of variance and the differences among means graded at $P = 0.05$ according to Duncan's new multiple-range test. Trapped males were removed, washed with *n*-hexane to remove the sticky material, and stored in 70% alcohol. Each trapped male was examined and compared to laboratory-reared specimens. All field data were analyzed by Duncan's multiple-range test. Significant differences among samples were recognized at $P \leq 0.05$.

Natural Pheromone. Pheromone extracts (Kikukawa et al., 1982a) were obtained from adult females of *D. similis* and *N. pinetum*, reared from field-collected larvae. However, extracts used for the GLC were not treated with KOH. For capillary GLC analyses, the natural pheromone preparations from *D. similis* were hydrolyzed and reesterified to form acetate by the method of Kikukawa et al. (1982a).

Synthetic Pheromones. The propionate esters of 2*S*,3*S*,7*S*-; 2*R*,3*R*,7*R*-; 2*R*,3*R*,7*S*-; and 2*S*,3*S*,7*R*-diprionol were synthesized by Mori et al. (1978). The same group also synthesized 2*S*,3*S*,7*S*-A. Synthesis of the racemic compounds 2*S*,3*R*,7*R*/*S*-P and 2*S*,3*R*,7*R*/*S*-A; and 2*S*,3*R*,7*R*/*S*-P and 2*R*,3*S*,7*R*/*S*-P was by Tai et al. (1978). By the method described by Kikukawa et al. (1982a), the 2*R*/*S*,3*R*,7*R*-P and 2*R*/*S*,3*S*,7*S*-P were modified from one enantiomeric form from Mori et al. (1978). Kikukawa et al. (1982b) recently synthesized 2*S*,3*S*,7*S*-P; 2*S*,3*R*,7*S*-A; 2*S*,3*R*,7*R*-P; and 2*S*,3*R*,7*R*-A. As judged by NMR analyses, none of erythro preparations were contaminated by threo enantiomers and vice versa (detection limit, approx. 1%). GLC analyses (see below) on DB5 and Carbowax 20 M columns revealed no detectable enantiomer contamination (detection limit 1 ng, or about 1%). These compounds are pre-

pared in desired concentrations in 1 ml *n*-hexane sealed in glass ampules until used in the field.

Purification of Synthetic Isomers by Charcoal–Celite Column. Thirty-six grams of charcoal (Norit A., J. T. Baker Chemical Co., New Jersey) preheated for 2 hr at 180°C, were mixed thoroughly with 9 g Celite (Fisher Scientific Co.) and washed with 20 ml acetone in a funnel with Whatman No. 2 filter paper. The mixture was stirred into a 200-ml beaker with 140 ml 10% ether in hexane using a glass rod. The slurry was packed in a 50-cm × 2-cm-ID glass column. A 20-ml solvent was first used to wash the slurry down the walls of the column, followed by 80 ml in two equal volumes to stabilize the column. A maximum of 7 mg sample was introduced to the column and was eluted with 10% of ether in *n*-hexane at 0.2 ml/min of flow rate. Recovery was about 60%, but with samples less than 500 μg it was less. Sixty-three 10-ml fractions were collected using a microfractionator.

A small aliquot from each fraction was injected into a gas–liquid chromatograph (GLC) equipped with a flame ionization detector (FID). Fractions 33–63 contained the sample, but fractions 33–42 and 61–63 contained the sample and impurities while fractions 43–60 contained the pure sample. Columns less than 35 cm failed to purify the samples.

Preparative GLC Fraction Collection. A Varian 1700 preparative gas chromatograph fitted with stainless-steel column 6 m × 3 mm packed with 10% Carbowax 20 M on 80–100 mesh Chrom Q was used for fraction collection of seven synthetic isomers and the pheromone peaks of *N. pinetum* and *D. similis*. The fractions of the synthetics consisted of the front and back portions each of the GLC peaks of 2*S*,3*R*,7*R*-P; 2*S*,3*R*,7*S*-P; 2*S*,3*S*,7*S*-P; 2*S*,3*S*,7*R*-P; 2*R*,3*R*,7*R*-P; 2*R*,3*R*,7*S*-P; and 2*R*/*S*,3*S*,7*S*-P (Figure 1). The natural pheromone peaks of *N. pinetum* and *D. similis* were collected at two column temperatures: first at 200°C, then at 220°C. A 9:1 postcolumn splitter, which directed 90% of the injected material for collection and 10% to the detector, was used with a 15-cm Pyrex collection tubing bent into a U at the middle. Hexane-moistened glass wool was used to plug the distal end of the tubing, and the bent portion of the tubing contained a small amount of hexane. Trapping efficiency was about 80%. The front and back fractions were bioassayed separately in the field. The natural pheromones were concentrated for further capillary GLC analysis.

Capillary GLC Analysis. A Varian 3700 capillary GLC equipped with two FID was used. Synthetic standards containing a 1 mg/ml mixture of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A at ratios of 1:1, 1:2, and 2:1 were used. Also used were 1 mg/ml mixtures of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*S*-A prepared in the same ratios as above. The 2*S*,3*S*,7*S*-A was used in both species to spike the natural pheromones. Natural extracts derived from the purification were used. Concentration of natural pheromone was in the order of 5000 female equivalents/ml. Two

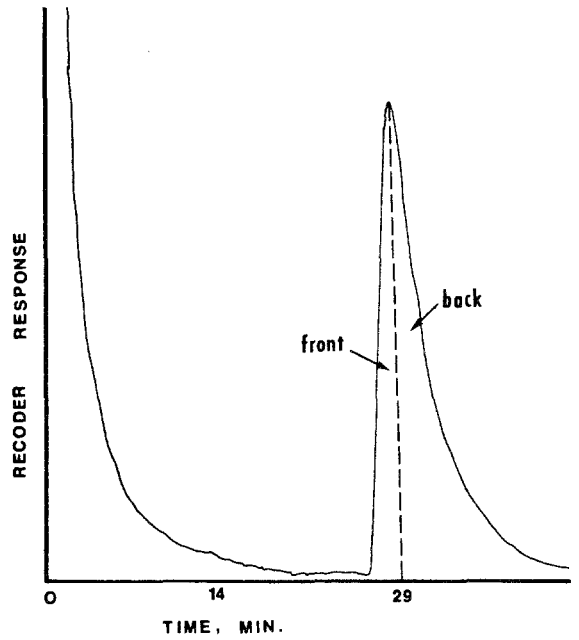

FIG. 1. GLC pattern of the 2*S*,3*R*,7*R*-P on 5% carbowax 20M column. The fractionation pattern into the front and back is shown by arrows.

fused silica capillary columns, Carbowax 20 M, 30 m × 0.25 mm ID, and DB5, 40 m × 0.25 mm ID, were used. These systems were capable of resolving threo diastereomers from erythro counterparts. In addition, in spiked samples it was possible to separate 3*S*,3*R*,7*S*-A and 2*S*,3*R*,7*R*-A. Runs were made isothermally at 180°C and temperature programmed from 130 to 190°C at 4°/min, with initial hold at zero minute, and a final hold of 18 min. The total analysis time for one injection was 32 min.

RESULTS

N. pinetum Studies. Previous studies (Kraemer et al., 1979; Kikukawa et al., 1982a) indicated that the acetate of 2*S*,3*S*,7*S*-diprionol was more attractive potent than the corresponding propionate. Therefore, various combinations of enantiomers were tested along with 2*S*,3*S*,7*S*-A.

Among those traps baited with mixtures of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A showed a significant trap catch (Table 1). This experiment compared two pure isomers, 2*S*,3*R*,7*S*-A and 2*S*,3*R*,7*R*-A, with the racemic 2*S*,3*R*,7*R/S*-A, which

was synergistic in the earlier results. The synergistic effect of 2*S*,3*R*,7*R*-A was manifested when mixed either with 2*S*,3*S*,7*S*-A from both Mori et al. (1978) or Kikukawa et al. (unpublished). The 2*S*,3*S*,7*S*-A sample from Kikukawa et al. was utilized in all subsequent experiments. Essentially identical results were obtained at Siren, Wisconsin (May 15 to June 30, 1981) and at Higgins Lake, Michigan (May 15 to June 20, 1981). In Kalkaska, the males of *N. pinetum* were also attracted to a mixture of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A at 1:1 and 1:2 ratios, but the latter ratio was superior (Table 2). The 2*S*,3*R*,7*S*-A and 2*R*/*S*,3*R*,7*S*-A were not active as synergists. By holding the concentration of 2*S*,3*S*,7*S*-A constant at 5 μg and varying the concentration of the synergist isomer 2*S*,3*R*,7*R*-A from 0.001 to 20 μg, it was established that maximum effectiveness of the mixture was achieved at a concentration of 10 μg of the synergist (Table 3). This implies that a 1:2 ratio gave the most active blend. When the ratio was increased to 1:4, a significant reduction in catch was recorded. Using the 2*S*,3*R*,7*R*/*S*-A as the synergist of the 2*S*,3*S*,7*S*-A isomer in Siren, Wisconsin, we again demonstrated significant effectiveness of the mixture at a blend ratio of 1:3 of 2*S*,3*S*,7*S*-A to 2*S*,3*R*,7*R*/*S*-A (data not shown).

The 1984 field tests compared the effectiveness of 2*S*,3*R*,7*R*-A and 2*S*,3*R*,7*S*-A in synergizing 2*S*,3*S*,7*S*-A in view of the results of the GLC analysis below. It was clear (Table 4) that: (1) 2*S*,3*R*,7*R*-A was indeed synergistic to 2*S*,3*S*,7*S*-A in attracting male *N. pinetum*; (2) 2*S*,3*R*,7*S*-A was not a good synergist; (3) male catches were dose related; and (4) male catch with the nat-

ural pheromones was less than catches with 10 μg synthetic pheromones. Lower concentrations of synthetic pheromones were not tested.

D. similis Studies. Using crude synthetic pheromones, a series of investigations was undertaken at various locations in Michigan. The results confirmed earlier reports by Kikukawa et al. (1982a) that 2*R*/*S*,3*R*,7*R*-P; 2*S*,3*R*,7*R*/*S*-P; and 2*S*,3*R*,7*R*-P were active against *D. similis*. The 2*R*/*S*,3*R*,7*R*-P was the most active in most instances (the data not shown). In one test, crude 2*S*,3*R*,7*R*/*S*-P was more effective than pure 2*S*,3*R*,7*R*/*S*-P (purified through charcoal-celite fractions 43–60 and purity confirmed by FID GLC) which a total catch

of 31 males for the former and five for the latter in an experiment replicated seven times. The 2*S*,3*R*,7*R*-P was purified and tested with similar results. There could be two possibilities for the poor performance of the pure 2*S*,3*R*,7*R*-P preparation. First, the inhibitory substance is one of the stereoisomers of 2*S*,3*R*,7*R*-P. Second, it is possible that a synthetic inhibitor that is not a stereoisomer, but has the same retention time as 2*S*,3*R*,7*R*-P on the chromatographic systems (GLC, TLC, and column chromatograph), is present. Testing the first possibility was not easy because there is no convenient method to measure the optical purity of each active carbon in the final synthetic product. Even the NMR spectroscopic analysis, which gives information on the diastereomeric arrangement on the 2-carbon and 3-carbon (Jewett et al. 1976), is reliable only to about 99%. However, it is known that the erythro and threo isomers could be separated by a Carbowax 20 M column (Mori et al., 1978). An attempt was made to collect the front and back portion of the peak of 2*S*,3*R*,7*R*-P (Figure 1). The same approach could also test the second possibility that the 2*S*,3*R*,7*R*-P peak contained other inhibitors. When that was done and field tested, it was found that the front part was much more active than the back part total trap catch, being 40 for the former and 12 for the latter (for nine traps).

We expected all erythro isomers to come at the front part, and therefore this excludes the possibility that any erythro enantiomers are the inhibitors. The observation, consequently, favors the second possibility that contaminants which align with the back part of the peak inhibit the effectiveness of 2*S*,3*R*,7*R*-P. Indeed for the first time, we could show that a 2*S*,3*R*,7*R*-P preparation (GLC front) was more effective than 2*R*/*S*,3*R*,7*R*-P. In view of the discovery of synergistic enantiomers for the major pheromone in many *Neodiprion* sawfly spe-

[a] Test conducted at Kalkaska, Michigan, June 1–16, 1984.
[b] Means of three replicates. Means followed by same letter not significantly different at 5% level.

cies, combinations of the 2*S*,3*R*,7*R*-P GLC front with six candidate synergists were made. The results showed that 2*S*,3*S*,7*R*-P; 2*S*,3*R*,7*S*-P; 2*S*,3*S*,7*S*-P; and 2*R/S*,3*S*,7*S*-P showed some promise as synergists. The 2*S*,3*R*,7*R*-P GLC back preparation, as well as the back fraction of all the candidate synergist isomers, when mixed with the 2*S*,3*R*,7*R*-P GLC front, was not active. It is thus clear that there is a synthetic inhibitor whose retention time aligns with the back fraction.

In 1984, we pursued further the aspect of synergistic interaction of some of the isomers with 2*S*,3*R*,7*R*-P and found that the 2*R/S*,3*S*,7*R*-P; 2*S*,3*S*,7*R*-P; and 2*S*,3*R*,7*S*-P isomers were indeed synergistic to 2*S*,3*R*,7*R*-P in attracting male *D. similis* in the field (Table 5). The 2*S*,3*S*,7*S*-P isomer was the best synergist of the three at blend ratios of around 80:0.06 and 80:0.006 of 2*S*,3*R*,7*R*-P to 2*S*,3*S*,7*R*-P. The poorer performance of 2*R/S*,3*S*,7*R*-P as a synergist indicated that interaction on the 2-carbon is not important. That both 2*S*,3*S*,7*R*-P and 2*S*,3*R*,7*S*-P isomers were synergistic suggested that the synergist interaction occurred mainly on the 3-carbon and to some extent on the 7-carbon. The synergistic effect of 2*S*,3*S*,7*R*-P was again proved and the optimum blend ratio of 80:0.006 of 2*S*,3*R*,7*R*-P to 2*S*,3*S*,7*R*-P confirmed (Table 6). Concentration as low as 0.001 μg of this mixture attracted males. At the same location and time, the 2*S*,3*S*,7*S*-P isomer, at a much higher concentration than the 2*S*,3*S*,7*R*-P isomer, gave superior synergism to 2*S*,3*R*,7*R*-P isomer (Table 7), confirming synergistic interactions on the 3- and 7-carbons. The optimum blend ratio is 80:16 for 2*S*,3*R*,7*R*-P to 2*S*,3*S*,7*S*-P.

Capillary GLC Analysis. At 180°C (isothermal), the retention time of 2*S*,3*S*,7*S*-A was 12.17 min and 20.00 min on Carbowax 20 M (30 m × 0.25 mm ID) and DB5 (40 m × 0.25 mm ID), respectively. The retention time for

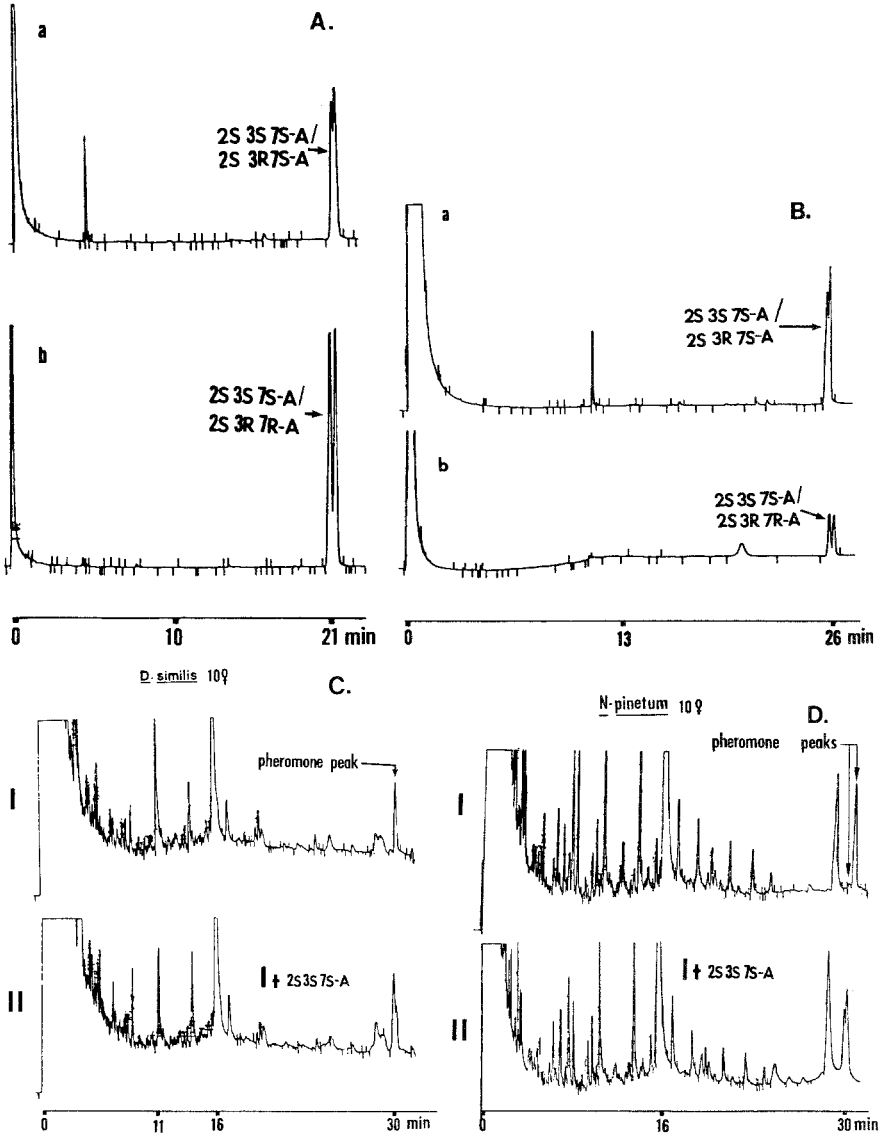

FIG. 2. (A) Capillary GLC separation on DB5 column at isothermal 180°C: (a) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*S*-A mixture, 100 ng; (b) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*R*-A mixture, 100 ng. (B) Capillary GLC separation on DB5 column temperature programmed 130–190° at 4°/min: (a) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*S*-A mixture, 100 ng; (b) 2*S*,3*S*,7*S*-A/2*S*,3*R*,7*R*-A mixture, 50 ng. (C) (I) Capillary GLC recordings of acetylated natural pheromone of *D. similis*, 10 FE, (II) Capillary GLC recordings of acetylated natural pheromone of *D. similis*, 10 FE (female equivalent) spiked with 100 ng of 2*S*,3*S*,7*S*-A. (D) (I) Capillary GLC recordings of acetylated natural pheromone of *N. pinetum*, 10 FE, (II) Capillary GLC recordings of acetylated natural pheromone of *N. pinetum*, 10 FE spiked with 100 ng of 2*S*,3*S*,7*S*-A.

thetic 2*S*,3*S*,7*S*-A has a retention time on the average of 30.20 min, whereas 2*S*,3*R*,7*R*-A was retained for 30.53 min. They were thus separated by 0.33 min. Under the same conditions, 2*S*,3*R*,7*S*-A had a retention time of 30.40 min, being separated from 2*S*,3*S*,7*S*-A by 0.20 min and from 2*S*,3*R*,7*R*-A by 0.13 min. This shows for the first time that 2*S*,3*S*,7*S*-A; 2*S*,3*R*,7*S*-A; and 2*S*,3*R*,7*R*-A can be separated and recognized by using retention time. Also, separations of 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*R*-A as well as 2*S*,3*S*,7*S*-A and 2*S*,3*R*,7*S*-A were possible on the DB5 column either when run at isothermal 180°C (Figure 2A) or temperature-programmed 130–190°C at 4°/min (Figure 2B). However, the mixture of the 2*S*,3*R*,7*R*-A/2*S*,3*R*,7*S*-A could not be separated in our system. Separation occurs only when either of the two is in mixture with 2*S*,3*S*,7*S*-A. When the acetate of the natural pheromone extract of *D. similis* was injected, two pheromone peaks were observed. The major peak corresponds to 2*S*,3*R*,7*R*-A, whereas the minor peak corresponds to 2*S*,3*S*,7*S*-A (Figure 2C). Also, the natural pheromone of *N. pinetum* indicated two peaks (Figure 2D). On spiking the sample with 2*S*,3*S*,7*S*-A, one large peak was observed which was separated by the computer into peaks corresponding to retention times of 20.06 and 20.28 min, respectively. The larger peak corresponds to 2*S*,3*S*,7*S*-A and the second peak could be aligned with either 2*S*,3*R*,7*R*-A or 2*S*,3*R*,7*S*-A. In both *D. similis* and *N. pinetum*, one virgin female contained 10 ng pheromone. This agrees with earlier reports on virgin *N. sertifer* with 10 ng/female (Kikukawa et al., 1983).

DISCUSSION

D. similis and *N. pinetum* are sympatric, sharing the same host, time span, and foliage zones. Their host specificity is strictly limited to *Pinus strobus*. One common observation about *D. similis* in the field is that the males are more discriminating than the *Neodiprion* species in response to sex pheromone regarding optical and nonoptical impurities, correctness of the chirality of the diastereomers, and choice of ester moiety. For example, while species like *Neodiprion sertifer* (Geoffroy) (Kikukawa et al., 1983) and *N. nanulus nanulus* Schedl (Kraemer et al., 1983), two normally acetate species, would respond actively to nonpurified pheromone and propionate ester of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol (2*S*,3*S*,7*S*-P), males of *D. similis* strictly prefer propionate and any impurity in the pheromone will result in little or no response.

The most important aspect of our current findings is that 2*S*,3*S*,7*R*-P interacts synergistically with 2*S*,3*R*,7*R*-P in attracting male *D. similis* in the field. This constitutes novel information as it is the first time among diprionid sawflies that an isomer which is *R* on the 3-carbon and 7-carbon will be synergized by one which is *S* on 3-carbon and 7-carbon. It is directly opposite to the situation

among pheromone systems of *N. pinetum* and other *Neodiprion* species in general where the 2*S*,3*S*,7*S* isomer is the major component and 2*S*,3*R*,7*R* or 2*S*,3*R*,7*S* is the synergist (Kikukawa et al., 1983; Olaifa et al., 1984). However, one similarity is evident: in all instances synergism occurs at a specific optimum combination, response is dose related up to that optimum, and above the optimum response inhibition sets in. In *D. similis*, the optimum blend appeared at a concentration where 2*S*,3*S*,7*R*-P constituted about 0.06–0.2% of the mixture and when 2*S*,3*S*,7*S*-P constituted about 4.8–16% of the mixture.

The evolutionary significance of this type of pheromone system in *D. similis* may be reproductive isolation from the *Neodiprion* species and *N. pinetum* in particular. These two spring-flying species share white pine as the preferred host plant. Apart from being widely divergent with respect to choice of ester moiety, acetate for *N. pinetum* and propionate for *D. similis*, the males of the former do not respond to the 2*S*,3*R*,7*R* isomer alone, even though this isomer constitutes about 66% of its optimum pheromone mixture (Table 5). It may be concluded from our experience with the pheromone systems in these two species that the sex pheromones constitute effective reproductive isolation as no male *N. pinetum* were ever caught in traps baited with pheromone of *D. similis*, be it synthetic or natural.

Acknowledgments—Supported by Michigan Agricultural Experiment Station, College of Agriculture and Natural Resources, Michigan State University and College of Agriculture and Life Science, University of Wisconsin-Madison. We thank Dr. Kenji Mori, University of Tokyo, and Dr. Akira Tai, Osaka University, for kindly providing us with some of the optically defined isomers of diprionol.

HIMACHALOL AND β-HIMACHALENE: Insecticidal Principles of Himalayan Cedarwood Oil[1]

D. SINGH and S.K. AGARWAL

Central Institute of Medicinal and Aromatic Plants (CIMAP-CSIR)
Post Bag No. 1, P.O. RSM Nagar
Lucknow-226016, India

(Received November 20, 1986; accepted June 15, 1987)

Abstract—Chromatographic fractions of Himalayan cedarwood oil (*Cedrus deodara*) were bioassayed against the pulse beetle (*Callosobruchus analis* F.) and the housefly (*Musca domestica* L.). Almost all fractions showed insecticidal activity against both test species. Fractions I and V led to the highest mortality and also produced a quick knockdown effect. Fractions I and V, after rechromatography and purification, yielded himachalol (3%) and β-himachalene (31%), based on essential oil weight, respectively. Further evaluation of these two naturally occurring sesquiterpenes indicated 97.5% mortality at 0.56 μmol/insect against the pulse beetle. These biologically active natural products of plant origin may serve as a suitable prototypes for development of commercial insecticides.

Key Words—Himalayan cedarwood oil, *Cedrus deodara*, himachalol, β-himachalene, pulse beetle, housefly, Coleoptera, Diptera, Muscidae, insecticide, *Musca domestica*, *Callosobruchus analis*.

INTRODUCTION

Over 2000 species of plants are known to possess insecticidal properties. However, only a few of these plants containing pyrethrins, rotenoids, and alkaloids have been used commercially to meet the growing worldwide demand for natural pesticides (Balandrin et al., 1985). Among these, pyrethrum is the most commonly used. Total world production of pyrethrum is, however, not enough to satisfy the world demand for mosquito control alone. In addition, many products containing pyrethrum have an unpleasant odor (Singh et al., 1984), and

[1] CIMAP Publication No. 598.

0098-0331/88/0400-1145$06.00/0

some insects have already been reported to have developed resistance against this material (Lloyd and Parkin, 1963).

Some secondary plant metabolites, the essential oils, are known to possess numerous biological activities for pest control in addition to their perfumery and cosmetic values. The insecticidal action of essential oils was first noted in 1939, when the ovicidal effect of volatile oils was recorded against *Cochliomyia americana* (Bushland, 1939). Essential oils of some plant species have been screened in search of plant-based natural pesticides (Saxena and Koul, 1978). To date, none has been commercialized owing to inadequate efficacy, chemical complexity, and/or high cost of production.

The Himalayan cedarwood, *Cedrus deodara* Roxb. Loud. (Pinaceae) is naturally distributed in an average estimated area of 0.2 million hectares, yielding 0.75 million m^3 annual production of wood (Anonymous, 1950). Sizable quantities of wood are used for distillation of essential oils which are used worldwide in the soap industry as an inexpensive source of perfume. The toxicity and resistant properties of wood against termites (Sen-Sharma, 1963) and protection to cloth and carpeting against moths and beetles by the oil (Atwal, 1976) have been reported.

From our screening program of natural products for insecticidal properties, we have already found a knockdown property in Himalayan cedarwood oil against adult Indian mosquitoes, *Anopheles stephensi*, at low concentrations (KD_{50} 0.4452% in acetone) (Singh et al., 1984; Anonymous, 1985). The abundant availability of raw material, pleasant odor, low cost, and high potency against mosquitoes prompted us to investigate further the insecticidal principle of Himalayan cedarwood oil.

METHODS AND MATERIALS

Collection of Essential Oil. The fresh wood chips of Himalayan cedarwood (*Cedrus deodara*) were steam distilled to yield 5.0% essential oil.

Chromatography and Isolation of Active Principles. The Himalayan cedarwood oil was chromatographed on neutral alumina using cyclohexane, hexane, hexane–chloroform, chloroform, and chloroform–methanol mixtures as eluents. The various eluates were combined according to visual comparison following thin-layer chromatography on silica gel, resulting in nine chromatographic fractions. Fractions VI and VIII contained little material and thus only fractions I–V, VII, and IX were bioassayed. Because of the quick knockdown (KD) activity and high mortality in fractions I and V, these were rechromatographed on neutral alumina yielding a partially purified fraction and himachalol (I) (yield 3%), respectively. The partially purified fraction showed two spots (one major, the other minor) on $AgNO_3$ (10%) –silica gel TLC plates. Column chromatography

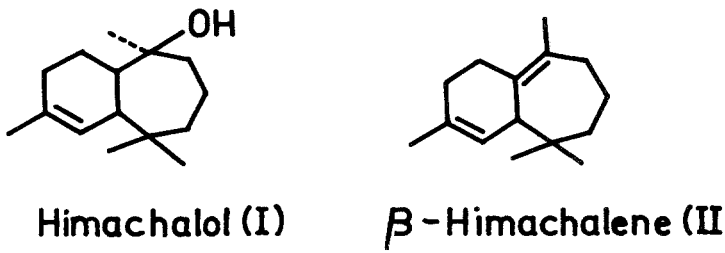

FIG. 1.

over silica gel–10% $AgNO_3$ yielded β-himachalene (II) (yield 31%). Both himachalol and β-himachalene (Figure 1) were identified by MS, NMR, GLC, and compared with authentic samples (Joseph and Dev, 1968). These purified isolates were bioassayed at different dosages by topical application.

Insects and Bioassay. Adults of the pulse beetle (*Callosobruchus analis* F.) and the housefly (*Musca domestica* L.) were used for bioassays. Pulse beetles were reared on gram (chick-pea) seeds under laboratory conditions. Adult houseflies were collected from the field. Both the test animals were starved (12 hr for *C. analis* and 2 hr for *M. domestica*) and anesthetized with diethyl ether before treatment with different fractions of Himalayan cedarwood oil or isolates of himachalol and β-himachalene.

Various chromatographic fractions of Himalayan cedarwood oil were dissolved in acetone (1 : 1 ratio v/v) and insects were treated individually at 1 μl/insect applied to the thoracic notum using an Arnold Hand Microapplicator (M/s Burkard Manufacturing Co. Ltd., London, U.K.). Controls were treated with 1 μl of acetone. For each treatment, four replicates of 10 insects were tested.

Efficacy of various chromatographic fractions was recorded in terms of mortality, i.e., adults could no longer stand (Briggs et al., 1974). Activity of different fractions was recorded 2 and 24 hr after application in the case of *C. analis*, whereas in the case of *M. domestica* the counts were taken after 2 hr only. The insecticidal action of himachalol and β-himachalene on the pulse beetle was recorded 2 hr after application.

Data are reported as percent mortality of treated insects, corrected using Abbott's formula (Abbott, 1925).

RESULTS

Data on corrected percent mortality (Table 1) indicate that, except for fraction IX against the housefly, all other fractions of Himalayan cedarwood oil exhibit some insecticidal activity against both test species. Two hours after

TABLE 1. EFFICACY OF VARIOUS CHAROMATOGRAPHIC FRACTIONS OF HIMALAYAN CEDARWOOD OIL AGAINST PULSE BEETLE AND HOUSEFLY ADULT BY TOPICAL APPLICATION

Chromatographic fraction[a]	Mean[b] % mortality (corrected)[c]		
	Pulse beetle adult (*C. analis*)		House fly adult (*M. domestica*)
	2 hr	24 hr	2 hr
I	100.0[d]	100.00	97.5[d]
II	77.5	91.7	86.7
III	32.5	83.3	12.5
IV	90.0	100.0	NT
V	95.0[d]	100.0	25.0
VII	92.5	97.2	10.0
IX	65.0	94.4	00.0
Acetone (control)	00.0	—	00.0

[a] Fractions VI and VIII not tested due to less recovery during chromatography.
[b] Mean of four replications, 10 insects per set.

[d] Quick knockdown effect. NT, not tested due to small amount of fraction IV.

application, mortality ranged from 32.5 to 100% for the pulse beetle and from 0 to 97.5% for the housefly. In the case of the pulse beetle, mortality was also recorded 24 hr after application. We found that fractions III and IX, which were less potent at 2 hr (32.5 and 65% mortality, respectively), resulted in 83.3 and 94.4% mortality, respectively, after 24 hr.

Of the chromatographic fractions, fraction I had the highest activity and rapid KD effect against both test species, while similar activity of fraction V was observed only against the pulse beetle. Other fractions that showed some insecticidal activity were fractions II, IV, and VII against the pulse beetle and fraction II against the housefly. However, all these fractions were devoid of KD effect. Fraction IX was inactive against the housefly.

Fractions I and V, which showed the highest biological activities (quick KD and mortality), were rechromatographed to purify the active principles. Rechromatography of fractions I and V on neutral alumina resulted into the isolation of a partially purified fraction containing chiefly β-himachalene and himachalol, respectively.

Biological activities of these two compounds were assessed at three different dosages (0.56, 1.12, and 2.24 μmol/insect) against the pulse beetle (*C. analis*). At the 0.56 μmol/insect dose, mortality from both compounds was 97.5%, with complete lethality at 1.12 μmol/insect (Table 2). Although both

Control (acetone)	00.0	00.0	00.0

[a] Test procedure as in Table 1, replicated four times.
[b] Quick knockdown effect just after treatment.

the isolates were found to possess similar insecticidal potency, only himachalol exhibited the rapid KD effect.

DISCUSSION

An earlier study (Singh et al., 1984) reported the insecticidal potential of Himalayan cedarwood (*Cedrus deodara*) oil against Indian mosquitoes, *Anopheles stephensi* under laboratory conditions. In the present communication, insecticidal activity of different fractions of Himalayan cedarwood oil against insect pests of agriculture (*Callosobruchus analis*) and human health (*Musca domestica*) is reported.

Of the different fractions of Himalayan cedarwood oil, fraction I produced the highest mortality with quick KD effect against both test species, while similar activity of fraction V was observed against the pulse beetle only. Alternatively, adult houseflies may be able to metabolize the active principle of fraction V. Species-specific activity of naturally occurring products of plant origin has also been observed by Isman et al. (1986), who noted precocene-II to be more toxic against grasshopper nymphs than encecalin, the latter compound having better activity against cutworms.

The KD activity is thought to result from rapid penetration of the chemical into the insect's body (Briggs et al., 1974; Chen et al., 1985). Similar biological activity in insects has also been noted previously for other naturally occurring botanical insecticides, such as pyrethrins. The primary target of the pyrethrins is thought to be the nervous system, judging from their quick actions (Matsumura, 1980). The quick KD activity in fractions I and V could result from a similar action. Lack of KD activity in fraction V against the housefly adults

may be due to limited penetration into the body or enhanced metabolic detoxification. However, the major component of this fraction is inactive, thus the KD activity in the crude fraction V must result from some minor components.

Wood chips of *Cedrus deodara* have been reported to possess juvenile hormone-like activity against the red cotton bug, *Dysdercus koenigii* (Bhan et al., 1984), and wood extracts have been shown to reduce the total protein content of the hemolymph, silk glands, and eggs, as well as viability of larvae of silk worm, *Bombyx mori* (Gigolashvili et al., 1983). It is also repellent to termites (Sen-Sharma, 1963) and toxic to white ants (Akhtar, 1981). Essential oils obtained from Himalayan cedarwood have been reported to be toxic to Indian mosquitoes, *Anopheles stephensi* (Singh et al., 1984; Anonymous, 1985), and to reduce fecundity of the red cotton bug, *D. koenigii* (Singh and Rao, 1986).

Two insecticidal sesquiterpenes, himachalol and β-himachalene, have been isolated as active principles of Himalayan cedarwood oil. These compounds could possibly be modified to enhance their biological activity, which could give rise to new pest control products for commercial use.

Acknowledgments—We wish to thank Dr. A. Husain, director of our institute for his keen interest, encouragement, and facilities; Dr. A. Singh for constructive suggestions in preparing the manuscript; Mr. Ateeque Ahmad for his assistance; and Dr. Sukh Dev, Malti-Chem Research Centre, Baroda, for a supply of the β-himachalene sample.

(Received March 23, 1987; accepted June 17, 1987)

Abstract—Some male carpenter bees (*Xylocopa* spp.) possess massive propodeal exocrine glands that produce copious quantities of multicomponent blends of lipoidal material. Some of these compounds are volatile, producing a "flowery" aroma that can be easily detected several meters downwind from a territorial male. Chemical characterization of these secretions showed them to be blends of terpenoid compounds or fatty acid derivatives. In *X. varipuncta*, the mixture is composed of all *trans*-geranylgeraniol, all *trans*-farnesal, and an isomer of 3,7,11-trimethyl-2,7,10-dodecatrienal in an approximate 9:6:1 ratio. The secretion of *X. micheneri* contains isopropyl oleate, (Z)-11-eicosen-1-ol, oleyl alcohol, and methyl palmitate at approximately 63:24:11:1. We hypothesize that these compounds act as phero-

mones that aid in attracting and holding conspecific females to symbolic nonresource encounter sites where mating occurs. They also appear to have utility as chemotaxonomic markers at the subgeneric level.

Key Words—Thoracic glands, secretion, *Xylocopa varipuncta*, *Xylocopa micheneri*, Hymenoptera, Anthophoridae, terpenoid, fatty acid ester, fatty alcohol.

INTRODUCTION

Carpenter bees in the genus *Xylocopa* Latreille comprise a group of more than 400 species with worldwide distribution. They are part of the tribe Xylocopini within the large family Anthophoridae. These are characterized by their habit of nesting in dead wood, with the exception of the Old World genus *Proxylocopa*, which nests in the soil.

Arizona is rich in bee species, including eight species of *Xylocopa* in five subgenera. *X. varipuncta* Patton (subgenus *Neoxylocopa*) is common in southern Arizona where it nests in old inflorescence stalks of century plants (*Agave* spp.) or in dead branches of native and ornamental plants. In Tucson, the species is easily found nesting in dead wood of chinaberry trees (*Melia azedarach* L.) and may even invade soft structural timbers such as redwood. The other species, *X. micheneri* (Hurd) (subgenus *Stenoxylocopa*), is much rarer and is not known to nest within city limits. *Xylocopa micheneri* is at the northern limits of its range and apparently inhibits only isolated localities in "island-like" desert mountains of southern Arizona (e.g., Baboquivari, Santa Catalina, and Santa Rita mountains) as reported by Hurd (1978). In Arizona, *X. varipuncta* typically has one generation per year, while *X. micheneri* may produce a second generation. Both sexes in each species are long-lived as adults, and the active flight season begins in April and usually extends until early September. Larvae metamorphose and adults of both sexes remain in their nests, or males (as in the case of *X. micheneri*) may disperse to communal "bachelor" aggregation/sleeping sites for the fall and winter to later become sexually active during the following spring.

The present investigation was stimulated by observations by Marshall and Alcock (1981) and Minckley (unpubl.) that hovering male *X. varipuncta* in lek territories emit a sweet perfume while hovering within tree crowns. An observer 2–4 m downwind from a resident male can easily detect a sweet floral fragrance emanating from the male. This odor originates in a gland in the thoracic region and is the subject of this chemical report.

During the time these behavioral observations were conducted, a paper appeared (Vinson et al., 1986) describing presumably unique thoracic glands (named dorsal mesosomal glands by them) in two Costa Rican carpenter bees.

They (Vinson et al., 1986) also described flowery aromas produced by hovering male *X. fimbriata* and *X. gualanensis* (in the subgenera *Megaxylocopa* and *Neoxylocopa*, respectively), which were further described as "terpenoid." This report was followed recently by a study of Williams et al. (1987), who determined the chemical composition of glandular contents from these two Costa Rican species. In our study, the contents of the dorsal mesosomal glands of *X. varipuncta* and *X. micheneri* are investigated and the results are compared with those from other *Xylocopa* species.

METHODS AND MATERIALS

Isolation of Glandular Components. Males of *X. varipuncta* were collected from nests in chinaberry trees within the city limits of Tucson, Pima County, Arizona, during February to April 1986. Male *X. micheneri* were collected from male overwintering clusters inside burrows in century plant (*A. palmeri*) stalks. All bees were transported back to the laboratory on ice where they were immediately dissected.

Glands from nine male *X. varipuncta* and 14 male *X. micheneri* were excised and placed in 3-ml glass-distilled hexane. After several days, the hexane solution was filtered through glass wool and reduced to a volume of 1.0 ml under a gentle stream of nitrogen.

Capillary GC was carried out on a Varian 3700 instrument equipped with a FID and a 25 m × 0.32 mm DB-1701 fused silica column (J & W). The carrier gas was helium, and the oven temperature was programmed from 100°C to 250°C at 10°/min. Injector and detector temperatures were 270°C, and 350°C, respectively. All injections were made in the split mode, with a split ratio of 70:1. Peak area measurements used to determine relative quantities were made by electronic integration, and retention indices were calculated with the homologous *n*-alkane series (Van den Dool and Kratz, 1963).

Preparative GC was carried out on the same instrument as above, equipped with a 1.7 m × 4 mm ID glass column packed with 3% OV-17 on Gas-Chrom-Q (80/100). Helium was used as the carrier gas, and the temperature was programmed from 100°C to 250°C at 4°/min for *X. varipuncta* extracts and from 150°C to 250°C at 4°/min for *X. micheneri* extracts. Injector and detector temperatures were held at 270°C and 350°C, respectively. Fractions were collected using a glass-lined effluent splitter (Scientific Glass Co., 9.5:0.5 split ratio), and a thermal gradient fraction collector cooled with a Dry Ice–methanol bath (Brownlee and Silverstein, 1968). Isolated compounds were collected in 300 mm × 0.5 mm ID capillary tubes that were flame-sealed after collection.

Spectroscopic Analysis. Electron impact–gas chromatography–mass spectrometry (EI-GC-MS) (70 eV) was performed on a Finnigan triple-stage quad-

rupole instrument interfaced with a gas chromatograph equipped with a 30 m × 0.32 mm DB-1 fused silica column. The chromatographic conditions were similar to those described above. A Varian MAT instrument was also employed coupled with a gas chromtograph, with a 30 m × 0.25 mm fused silica bonded phase of OV-1 capillary column. Chemical ionization (CI) GC-MS was performed on the Finnigan instrument using isobutane (0.3 torr) as the reagent gas and the same chromatographic conditions as above.

Proton and carbon NMR spectroscopy were performed with a Bruker WM 300 WB spectrometer using 5-mm tubes and $CDCl_3$ as the solvent. When sufficient material was available, the DEPT experiment was used to determine carbon types (CH_3, CH_2, CH, C).

Methoxymercuration–Demercuration. A solution of *X. micheneri* glandular extract (ca. 200 μg) in hexane was evaporated to near-dryness and dissolved in 500 μl methanol. To this solution, 0.5 mg mercuric acetate was added, and the mixture was left in the dark at room temperature for 16 hr. Sodium borohydride (0.5 mg) was then added, and after 1 hr the mixture was diluted with distilled water. The aqueous mixture was extracted with three volumes (1 ml) of anhydrous diethyl ether. After drying over anhydrous sodium sulfate, the ether extracts were concentrated under a stream of nitrogen and analyzed by EI-GC-MS.

Severe tailing was observed with hydroxylated methoxy derivatives, so these samples were evaporated to dryness and trimethyl silylated with Trisil (Pierce Chemical). The mixture was incubated at 60°C for 1 hr and analyzed by EI-GC-MS.

RESULTS

Xylocopa varipuncta Studies. Initial capillary analysis indicated that three components were present in large quantities (Figure 1A and Table 1), with 3 and 2 being the most abundant.

Spectral data indicated that compound 3 was an acyclic tetraunsaturated diterpene alcohol with the molecular formula $C_{20}H_{34}O$. CI-MS: *m/e* 291 (M + H), 273; EI-MS: *m/e* 290 (M), 272, 203, 161, 69; [^{1}H]NMR: δ 5.41, t (J = 6.9 Hz), 1H; 5.09, m, 3H; 4.15, d (J = 6.9 Hz), 2H; 2.04, m, 12H; 1.67, s, 6H; 1.59, s, 9H. These data are consistent with the assignment of 3 as an isomer of geranylgeraniol. Determination of the geometry of asymmetrical unsaturations was accomplished by comparison of the chemical shift values for methylene resonances in the ^{13}C spectrum with published assignments made for acyclic monoterpenoids (Bohlmann et al., 1975). A cluster of three methylene resonances at δ 39.7, 39.7, and 39.6 were assigned to the methylene groups adjacent to the methyl branched carbons and indicated an *E* configuration for

(D) Structures of glandular components from *X. micheneri*.

TABLE 1. COMPOSITION OF GLANDULAR SECRETION OF *X. varipuncta* AND *X. micheneri*

X. varipuncta			*X. micheneri*		
Compound	RI[a]	Rel. %	Compound	RI[a]	Rel. %
1a, b	1869	6.2	4	1995	1.0
2	1898	34.6	5	2186	11.1
3	2348	56.2	6	2280	62.6
			7	2401	24.8

[a] Retention indices (RI) were calculated using the DB-1701 column

all three unsaturations. Therefore, 3 was assigned as all *trans*-geranylgeraniol (Figure 1B).

Compound 2 was determined to be a geometrical isomer of farnesal ($C_{15}H_{24}O$), based on the following spectral data. CI-MS; *m/e* 221 (M + H), 203; EI-MS; *m/e* 220 (M), 205, 136, 84, 69; [^{1}H]NMR: δ 9.98, d (J = 8.0 Hz), 1H; 5.88, d (J = 8.0 Hz), 1H; 5.07, m, 2H; 2.22, m, 4H; 2.16, s, 3H; 1.67, s, 3H; 1.59, s, 6H. The location of the methylene signals (δ 40.0, 39.6, 26.6, 25.7) in the ^{13}C spectrum indicated an *E,E* configuration. Compound 2 was thus identified as all *trans*-farnesal (Figure 1B).

The mass spectra of 1 were very similar to those of 2, indicating that this compound was also an isomer of farnesal. The [^{1}H]NMR data were as follows: δ 9.91 d (J = 8.2 Hz), 1H; 5.81, d (J = 8.2 Hz), 1H; 5.11, m, 2H; 2.59, t (J = 7.5 Hz), 2H; 2.24, m, 2H; 2.02, m, 2H; 1.98, s, 3H; 1.67, s, 3H; 1.59, s, 6H; 1.53, (H_2O contaminent + CH_2). The presence of a doubly allylic methylene group (δ 2.59) showed that compound 1 was a geometrical isomer of 3,7,11-methyl-2,7,10-dodecatrienal. Because of a lack of sufficient quantities of isolated material, only a weak ^{13}C spectrum was obtained. However, the positions of four apparent methylene resonances (δ 26.6, 27.0, 32.6, 39.6) suggested that unsaturations were present in both the *E* and *Z* configurations. Since not all resonances were detected, assignment of configuration of specific bonds could not be made with certainty, and two possibilities are illustrated in Figure 1B.

Several minor components comprising less than 1% each of the glandular contents were detected by capillary GC. No attempts have been made to identify these at this time.

Xylocopa micheneri Studies. The *X. micheneri* mixture contained three major components and a single minor component comprising about 1% of the mixture (Figure 1C and Table 1). Chromatographic data indicated that the *X. micheneri* mixture had no components in common with that of *X. varipuncta*.

The spectral data for compound 7 indicated a monounsaturated linear alcohol with the molecular formula $C_{20}H_{40}O$. CI-MS: *m/e* 297(M + H), 278; EI-MS: *m/e* 123, 109, 67, 96, 82, 55. [^{1}H]NMR: δ 5.35, m, 2H; 3.63, m, 2H; 2.00, m, 4H; 1.52, m, 2H; 127, m, 26H; 0.87, t (J = 6.7 Hz), 3H. Mass spectrometry of the silylated methoxy derivative (*m/e* 157, 171) revealed a ω-9 unsaturation, and a resonance due to allylic methylene carbons at δ 27.3 in the ^{13}C spectrum showed *Z* configuration (Johnson and Jankowski, 1978). Therefore, compound 7 was determined to be (*Z*)-11-eicosen-1-ol (Figure 1D).

Compound 6 was found to be an isopropyl ester of a monounsaturated fatty acid with the molecular formula $C_{21}H_{40}O_2$. CI-MS: *m/e* 325 (M + H), 283; EI-MS: *m/e* 324 (M), 282, 265, 264; [^{1}H]NMR: δ 5.33, m, 2H; 4.99, m, 1H; 2.24, t (J = 7.4 Hz), 2H; 2.00, m, 4H; 1.60, m, 2H, 1.27, m, 20H; 1.22, d (J = 6.3 Hz), 6H; 0.87, t (J = 6.7 Hz), 3H. The mass spectrum of the methoxy derivative showed a ω-9 unsaturation, and the ^{13}C spectrum indicated the *Z* configuration. On the basis of these data, compound 6 was identified as isopropyl (*Z*)-9-octadecenoate (isopropyl oleate, Figure 1D).

The mass spectral and [^{1}H]NMR data for compound 5 indicated that it was an 18-carbon homolog of compound 7. Analysis of the methoxy derivative again indicated a ω-9 unsaturation, and comparison of capillary retention characteristics with an authentic standard verified that this compound was (*Z*)-9-octadecen-1-ol (oleyl alcohol, Figure 1D).

A fourth component (4) was detected that made up 1% of the glandular mixture. This compound had a retention index of 1995 on DB-1701, and was identified as methyl palmitate (Figure 1D) on the basis of CI and EI mass spectral data.

DISCUSSION

The exocrine gland chemistry of male and female *Xylocopa* has received relatively little attention, although these bees are natural-products chemists *par excellence*! Various secretions are used in nest construction, territorial defense, and mate attraction. Previous studies have dealt with the chemical constituents of mandibular gland secretions in *X. hirsutissima* (Wheeler et al., 1976) and *X. sulcatipes* (Hefetz, 1983), and Dufour's gland secretions in *X. micans* (Williams et al., 1983), *X. sulcatipes* (Kronenberg and Hefetz, 1984), *X. virginica texana* (Frankie and Vinson, 1977; Vinson et al., 1978), and *Proxylocopa olivieri* (Kronenberg and Hefetz, 1984). The morphological and histochemical relationships of other exocrine glands (''yellow glands'') have also been studied (Gerling et al., 1979). Only recently has information pertaining to the thoracic glands of male *Xylocopa* been presented (Vinson et al., 1986; Williams et al., 1987).

Histological studies by Buchmann (unpublished) and Vinson et al. (1986) have demonstrated the *Xylocopa* thoracic exocrine glands as massive, paired

structures occupying areas under scutellar, metanotal, and propodeal cuticles. They are composed of darkened tubules that fill the area between the cuticle and flight musculature. The glandular complex of the two Arizona species is composed of secretory and storage tubules, each leading to the exterior (not as a separate basal gland as described for *X. fimbriata* by Vinson et al., 1986). The gland is a massive structure that can produce and store large quantities (usually 10–25 μl) of secretion. This large reservior would appear to ensure the availability of volatile secretions for long periods of territorial display.

Although both *X. varipuncta* and *X. micheneri* share apparently homologous glands, each species produces a characteristic blend of glandular components, with no shared compounds. The larger *X. varipuncta* males produce a three-compound blend of terpenoids. This secretion is dominated by all *trans*-geranylgeraniol, and also contained substantial amounts of all *trans*-farnesal and its isomer, 3,7,11-methyl-2,7,10-dodecatrienal.

In marked contrast to *X. varipuncta*, males of *X. micheneri* have terpene-free secretions that contain only fatty alcohols and fatty acid esters. The dominant component in this species is isopropyl oleate, followed by (*Z*)-11-eicosen-l-ol, and oleyl alcohol. Also present was a trace quantity of methyl palmitate. Isopropyl esters have not been reported in the exocrine secretions of any hymenopterous insects but are known to occur in staphylinid beetles where they serve as surfactants for quinone defensive secretions (Dettner, 1984).

The secretions of these two species of desert carpenter bee arise by different biosynthetic pathways and could potentially serve as important phylogenetic markers. Components of the *X. varipuncta* secretion are most likely derived from mevalonic acid via the isoprenoid pathway, while the *X. micheneri* components are derived from acetate via fatty acid synthetase. These identifications and the recent identification of male thoracic gland constituents from two Costa Rican species (William et al., 1987) provide encouraging evidence for their role as phylogenetic markers. *X. varipuncta* and the Costa Rican species *X. gualanensis* Cockerell have been placed in the subgenus *Neoxylocopa* based on morphological characters. Williams et al. (1987) report that the secretion of *X. gualanensis* is very similar to that of *X. varipuncta*, being dominated by geranylgeraniol and two isomers of farnesal. Although the farnesal structures were not specifically determined, the less abundant isomer of the *X. gualanensis* mixture is possibly 3,7,11-trimethyl-2,7,10-dodecatrienal, and the more abundant may be all *trans*-farnesal.

X. micheneri is classified in a different subgenus (*Stenoxylocopa*) than *X. varipuncta* and *X. gualanensis*, and this is reflected in the vastly different composition of the thoracic gland mixture. Williams et al. (1987) report that *X. fimbriata* Fabr., a representative of a third subgenus (*Megaxylocopa*), contains a mixture dominated by 2-heptadecanone, farnesol, and farnesyl acetate. This secretion is of mixed biosynthetic origin, and could represent a third biosyn-

thetic catagory of thoracic gland mixture. These data suggest that analyses of glands from additional *Xylocopa* species will provide useful information on phylogenetic relationships at the subgeneric level.

The reproduction biology, especially male mating strategies, have been studied for very few North American carpenter bees. More is known about the biology of Old World *Xylocopa* (see Gerling et al., 1983). One study (Marshall and Alcock, 1981) focused on male behavior and mating in *X. varipuncta* in Arizona. They found that males occupied territories during the late afternoon in the crowns of nonflowering trees along desert washes. They stated that females and other males occasionally visited a hovering male, "probably drawn by sex pheromone" (Marshall and Alcock, 1981). As with most territorial male bees, the *X. varipuncta* males are bellicose toward all intruders (both animate and inanimate) into their airspace, where they attempt to repel males and inseminate females. These hovering territories contain neither nests, potential nest sites, nor floral nectar or pollen resources for females or themselves. Thus, the defense of such landmark territories has been referred to as a dispersed lek mating system.

The precise role of the male thoracic gland secretion of *Xylocopa* spp. is presently unknown. We hypothesize, however, that the lipid secretions may function as pheromones in the dispersed lek mating system (Marshall and Alcock, 1981; Minkley, unpublished data, University of Arizona, Tucson, Arizona). The large quantity of volatile material liberated by the male mesosomal gland may attract females and may also provide the female with an indicator of male fitness. Information pertaining to fitness could be contained in the quantity of volatilized pheromone in the vicinity of the landing/marking site (see Marshall and Alcock, 1981, for a description of *X. varipuncta* mating behavior). Studies are now in progress to elucidate the role of the thoracic gland secretion in the mating behavior of these two Arizona *Xylocopa* species.

Acknowledgments—We are particularly indebted to Drs. Robert O. Ryan, Justin O. Schmidt, and John H. Law for their comments on the proposed biosynthetic pathways. The manuscript has been helpfully reviewed by Drs. John Alcock, Gordon Frankie, Dan Gerling, Abraham Hefetz, Charles D. Michener, Justin O. Schmidt, and S. Bradleigh Vinson. We especially appreciate their critically useful comments and suggestions, which we regard to as significant contributions to this paper.

PHEROMONE GLAND COMPONENTS OF SOME AUSTRALIAN TORTRICIDS IN RELATION TO THEIR TAXONOMY

M. HORAK, C.P. WHITTLE, T.E. BELLAS, and E.R. RUMBO

Division of Entomology, CSIRO, GPO Box 1700
Canberra, A.C.T. 2601, Australia

(Received March 17, 1987; accepted June 18, 1987)

Abstract—A survey has been carried out to identify the major sex pheromone gland components in 30 species of Australian tortricid moths. While more than half the species examined have (*Z*)-11-, (*E*)-11-, and/or (*Z*)-9-tetradecenyl acetates as the principal components, these compounds were not detected in some plesiomorphic taxa where combinations of (*Z*)-5 and (*Z*)-7 or (*Z*)-8 and (*Z*)-10 isomers are present. The results are discussed in relation to tortricid classification and current theories on pheromone evolution.

Key Words—Lepidoptera, Tortricidae, sex pheromone, pheromone biosynthesis, pheromone evolution.

INTRODUCTION

Tortricids use a restricted range of chemicals as sex attractants, comprising mainly C_{12} and C_{14} alkenyl acetates, with a few C_{10} and C_{16} compounds (Roelofs and Brown, 1982; Priesner, 1984; Arn et al., 1986). A review of tortricid sex attractants and pheromones by Roelofs and Brown (1982) indicated a correlation between the chemical nature of pheromone components and the taxonomic position of tortricid moths. This correlation is not a strict direct correspondence between specific chemical compounds and taxonomic units, but rather one of trends for a predominance of certain compounds in certain higher taxa. Thus, while a particular compound may appear as a characteristic major component in congeneric species, the same compound may also be represented in taxonomically widely separate groups. Nevertheless, certain generalizations are possible. Each of the three tortricid subfamilies is characterized by the predominance of compounds with a particular chain length in their pheromones.

0098-0331/88/0400-1163$06.00/0

Tortricine species use mostly C_{14} compounds, while C_{12} compounds predominate among the Olethreutinae. C_{16} compounds have been reported as attractants for two species of *Isotrias* Meyrick and one of *Olindia* Guenée (Priesner, 1984), the only members so far examined from the third tortricid subfamily, the Chlidanotinae. No correlations have been demonstrated below the subfamily level, except for the tribe Cnephasiini s. str. (i.e., the genera closely associated with *Cnephasia* Curtis), which is characterized by C_{12} compounds, and is thus distinctive within the Tortricinae. However, any overall analysis of tortricid pheromones is greatly hampered by the current inadequate understanding of tortricid phylogeny and, in particular, by the great number of taxa assigned on the basis of purely superficial similarity to quite unrelated groups.

Extensive studies on tortricid pheromone biosynthesis, especially of *Argyrotaenia velutinana* (Walker), have provided a fairly complete picture of the biosynthetic pathway employed by the majority of tortricines, involving Δ^{11}-desaturation and chain shortening of C_{16} and C_{18} acyl intermediates (Roelofs and Brown, 1982; Roelofs and Bjostad, 1984; Bjostad and Roelofs, 1986). This mechanism can account for the pheromone components of most but not all tortricids. Two other related mechanisms have been proposed (Roelofs and Bjostad, 1984) to explain the formation of the (*Z*)-5- and (*Z*)-7-tetradecenyl acetates (*Z*5- and *Z*7-14:OAc) and (*Z*)-8- and (*Z*)-10-tetradecenyl acetates (*Z*8- and *Z*10-14:OAc) present in some generalized (i.e., less evolved, plesiomorphic) tortricids (Young et al., 1985; Galbreath et al., 1985; Foster et al., 1986), with the suggestion that the biosynthetic pathways may reflect the evolutionary status of the groups involved.

The presence in Australia of other morphologically generalized Tortricidae prompted an investigation of the large and diverse archaic element in the Australian tortricid fauna. We have attempted no more than a preliminary survey of the pheromone gland components of representatives of typical Australian groups, with special attention to taxa which are presumed to be plesiomorphic (underived) but whose affinities are not yet understood. The aim of the work has been to provide chemotaxonomic information on endemic Australian groups, to test techniques for pheromone analysis, particularly under circumstances where little insect material is available, and to identify groups of interest for further detailed study.

METHODS AND MATERIALS

Insect Material. Virgin females used in this study were reared from field-collected eggs, larvae, or pupae, or from eggs deposited by field-collected mated females (Table 1). Most larvae were reared on the host material from which they were obtained in an air-conditioned laboratory under a natural light regime. Pupae were segregated according to sex. Moths were provisionally identified prior to analysis and retained for more detailed taxonomic examination after the

chemical results had been obtained. The numbers of insects available were often limited because of the incidental collecting inherent in a survey and high levels of parasitism. The species studied, collection sites, food plants, and sampling methods are summarized in Table 1. Voucher specimens of all species have been deposited with the Australian National Insect Collection (ANIC).

So far, no consensus has been reached on the higher classification of the Tortricidae (Roelofs and Brown, 1982; Horak, 1984), and any conclusions on pheromone evolution will partly depend on the presumed phylogeny for the family. It is necessary to ensure a reference system of strictly monophyletic groups, whatever their present taxonomic rank, in order to make meaningful comparisons. The results of this study are presented according to a tentative classification (Table 2) (Horak, 1984; Horak and Brown, 1988), reflecting our present phylogenetic understanding of the Tortricidae, except for *Isochorista* Meyrick which is here included among the Epitymbiini. Names in quotes, such as "*Capua*" *euphona* Meyrick, refer to taxa whose presently valid name does not correctly denote their taxonomic position.

Pheromone Gland Extraction. Moths were sacrificed not less than two days after eclosion and within three hours of dusk, on the assumption that most tortricid females call near to dusk. Moths were immobilized by brief refrigeration, the ovipositor extruded by gentle pressure on the abdomen, and the ovipositor excised anterior to the pheromone gland. Volatiles from single abdominal tips were either extracted by allowing the tip to stand in hexane (Waters Associates, HPLC grade, 10 μl) for 15 min, or evaporated from the tip at 135°C under helium (5 ml/min) and trapped in a glass capillary.

GLC analyses were carried out on a Varian 3700 gas chromatograph fitted with an SP1000 SCOT column (43 m × 0.5 mm), an SGE Pty Ltd Unijector in the splitless mode, and a Hewlett-Packard HP3390A integrator. Hexane

washes of single abdominal tips or gland volatiles collected by evaporation from the abdominal tips were analyzed by a method to be described in detail elsewhere (Whittle and Bellas, unpublished results), which is an extension of the method described by Klun et al. (1980). Where sufficient material was available, portions (from trapped volatiles) were reduced with lithium aluminium hydride and/or submitted to ozonolysis by techniques that are similar to those described elsewhere (Beroza and Bierl, 1976; Fieser and Fieser, 1967). Coinjection of *n*-alkanes as standards allowed the calculation of Kovats indices (KI) (Bellas, 1975) with an accuracy of ± 0.5 KI units. The limit of detectability was of the order of 200 pg. Pheromone gland components and derivatives were identified by comparison of KI values with those of known compounds. With a combination of these methods, it was possible to distinguish all the possible geometric and positional isomers of the tetradecenyl acetates.

Electroantennograms (EAGs). Live male insects were immobilized by waxing them down by the wings and head. The tip of the antenna (about 10 segments) was cut off and a Ag–AgCl–0.5% NaCl glass microelectrode inserted into the exposed segment. A cut in the abdomen was covered with 0.5% NaCl–1% agar gel and a ground connection made with a chloridized silver wire. To elicit the EAG response, 1-ml puffs of air from a syringe were blown through a Pasteur pipet, containing 10 μg of compound on paper, and over the antennae. A continuous flow of 500 ml/min of humidified air was maintained around the pipet. The EAG signal was amplified by a GRASS P16B microelectrode amplifier and digitized with a microcomputer system at 12-bits resolution and 200 readings a second. A maximum of 12 sources (selected from *Z* and *E* unsaturated acetates) including a blank, were used for each set of measurements. Sources were chosen at random from the set and the whole set repeated four times, whenever the lifetime of the insect preparation permitted. Readings were normalized by dividing by the mean amplitude for all sources, excluding the blank, within each set.

Field Trapping. Some pheromone blends were tested in sticky traps in the field. Mixtures with 100 μg of the major component were placed on rubber baits in delta traps in the appropriate biotopes.

RESULTS

In order to survey as many species as possible, analyses were carried out to determine only the major components in the pheromone glands. Components obtained from single abdominal tips were identified from KI values and, where possible, by the GLC of products from lithium aluminium hydride reduction and ozonolysis reactions. In some cases, supporting evidence was obtained from EAG measurements and from use of the synthetic compounds as lures in traps in the field. Except for one species, *Phricanthes asperana*, which contained Z9–12:OAc, the predominant components were found to be tetradecenyl acetates (Table 3).

[a] a, GLC of gland extract; b, ozonolysis/GLC; c, $LiAlH_4$ redn./GLC; d, electroantennogram; e, sticky trap; f, GC-MS.

Individual moths generally contained at least 5 ng of the major component, although there were some exceptions. Nine extracts from *Proselena tenella* failed to show significant peaks on GLC. For one extract, GC-MS, with selected ion monitoring, was able to detect 70 pg of Z11-14:OAc. For the three *Meritastis* species other than *M. laganodes*, a GLC peak consistent with less than 1.0 ng of Z9-14:OAc was observed. Strong EAG responses were recorded for this compound for the two species for which males were available.

For many of the species examined, GLC data showed the unsaturated acetates to be accompanied by the corresponding saturated acetate. In one case, *Acropolitis hedista*, tetradecyl acetate was consistently the major peak in the GLC trace in a ratio of 65:35 with *E*11-14:OAc. The average amount of saturated acetate was less than 5% of the major unsaturated acetate for the species 1, 4, 7, 9, 11, 12, 16–18, and between 8% and 85% for species 8, 13–15, 24, 26, 28, and 29, but the proportion of the saturated acetate in the blend often varied greatly between individuals of the same species.

Other peaks that often appeared at levels of less than 10% of the major component were consistent with the corresponding unsaturated alcohol (species 1, 8, 10, 13–16, 18, 24–26, 29, 30). The C_{19}, C_{21}, and C_{23} normal hydrocarbons were also usually detected in small amounts.

Two species for which GLC data could not be obtained have also been included in Table 3. "*Tortrix*" *incompta* showed a marked response to Z11-14:OAc in EAG measurements, and *Isochorista helota* was captured in large numbers in a trap baited with a 1:4 mixture of Z5-14:OAc and Z7-14:OAc.

DISCUSSION

The present work shows that current analytical techniques permit the characterization of candidate pheromone components from very few insects, often just one moth. Results obtained from such analyses can be of assistance in distinguishing species that cannot be readily separated on morphological grounds. For example, the *Cryptoptila* sp. collected on the same food plant in two different localities (species 8a, 8b, Table 3) warrants a closer morphological study. However, the most salient result of our survey is the frequent occurrence in the pheromone glands of Australian Tortricinae of tetradecenyl acetates with other than Δ^9 or Δ^{11} unsaturation.

The large majority of known tortricine pheromones contain combinations of (*Z*)-11- and (*E*)-11-tetradecenyl acetates and less commonly (*Z*)-11- and (*Z*)-9-tetradecenyl acetates (Roelofs and Brown, 1982). In fact (*Z*)-11-tetradecenyl acetate has been described as a "key component" of the Tortricinae (Tamaki, 1985). Tortricine pheromones based on a C_{14} compound with a double bond in other than the 11 or 9 position have only recently been found in morphologically

generalized New Zealand archipines (Roelofs and Brown, 1982; Galbreath et al., 1985; Young et al., 1985; Foster et al., 1986). Presence of the same (*Z*)-5-, (*Z*)-7-, (*Z*)-8-, and (*Z*)-10-tetradecenyl acetates is reported here for several groups of the Australian Epitymbiini s. lat. Whereas both the *Z* and *E* isomers of tetradecenyl acetates with a double bond in the 9 or 11 position have been identified as components of tortricine pheromones, as well as the corresponding aldehydes and alcohols, so far only the *Z* isomer of the tetradecenyl acetates with a double bond in the 5, 7, 8, or 10 position has been found in both Australian and New Zealand tortricines.

The different positional isomers observed in our survey strongly reflect the taxonomic groupings at the generic level. *Epitymbia* and its undescribed sister genus (represented by "*Capua*" *euphona* and "*Grapholita*" *decolorana*) are characterized by *Z*5–14 : OAc and/or *Z*7–14 : OAc. Only *Z*9–14 : OAc has been found for all the *Meritastis* species examined so far. *Capnoptycha ipnitis* and *Asthenoptycha* sp., which are closely related if not congeneric, both contain *Z*8–14 : OAc and *Z*10–14 : OAc in their pheromone blends. This is in obvious contrast to the wide spectrum of positional isomers found for probable sibling species within the genera *Planotortrix* Dugdale and *Ctenopseustis* Meyrick in New Zealand (Foster et al., 1986). It remains to be seen whether a larger sample of the Australian fauna will confirm this correlation of pheromone compounds with generic groupings.

Attempts to correlate the distribution pattern of pheromone components with tortricid classification at a tribal level are promising for certain groups. The three tortricid subfamilies are each broadly characterized by the predominance of compounds with a particular chain length in their pheromone blends. Some of the exceptions to this generalization form morphologically very distinct groups.

Whereas exclusively C_{12} compounds are found among the Cnephasiini s. str., the presence of C_{14} and C_{16} compounds among some taxa of the Cnephasiini s. lat. (Priesner, 1984) is strong evidence for the latter being a polyphyletic assemblage of taxa with only superficial similarity. If *Isotrias* and *Olindia*, referred to the tribe Polyorthini of the Chlidanotinae by Razowski (1979), and *Eulia ministrana* L., which shares only plesiomorphies with the Cnephsiini s. str., are removed, then there remains a morphologically well-defined group which is characterized by pheromones based on C_{12} compounds. On this basis, the tetradecenyl acetates identified in *Arotrophora arcuatalis* and *Syllomatia pertinax* are evidence for the Australian "Cnephasiini" not being genuine members of this tribe, as already suggested on morphological grounds by Powell and Common (1985). As for the tribe Phricanthini, further taxa will have to be analyzed to establish whether C_{12} compounds, as found in *Phricanthes asperana*, are characteristic at a tribal level.

The few data available from the small olethreutine tribes Gatesclarkeanini,

Bactrini, and Microcorsini indicate that all three preferentially use C_{14} derivates in their pheromones rather than the C_{12} compounds typical for the majority of the subfamily. *Z*10–14:OAc is an attractant for several species of *Endothenia* Stephens (Arn et al., 1986) in the tribe Gatesclarkeanini and is the main component in the pheromone of *Bactra verutana* Zeller (Bactrini) (Roelofs and Bjostad, 1984), whereas *E*10–14:OAc is an attractant for *Bactra lancealana* (Hübner) (Arn et al., 1986). The major gland components of an Australian species of *Cryptaspasma* Walsingham (Microcorsini) are *Z*9–14:OAc and *Z*9–14:OH. This compares with *Z*9–14:OAc and *Z*7–12:OAc reported as an attractant mixture for another species of the same tribe (Roelofs and Brown, 1982).

Exclusive correlations cannot be made between the presence of pheromones based on tetradecenyl acetates with double bonds in the 5, 7, 8, or 10 position and the tribal affinity of the respective species. All four compounds, as the *Z* isomers, have been identified from New Zealand archipines as well as from Australian Epitymbiini s. lat. Moreover, Δ^{10} unsaturated tetradecenyl acetates have been reported as pheromones or attractants for the olethreutine Gatesclarkeanini and Bactrini. These groups are not closely related, but they are all rich in morphological plesiomorphies. The New Zealand *Ctenopseustis* Meyrick and relatives are demonstrably the most generalized Archipini s. str. (Horak, 1984), and there are numerous indications that the Epitymbiini s. str. and *Isochorista* also are overall rather generalized Tortricinae (Horak, 1984; Horak and Common, 1985). Gatesclarkeanini, Bactrini, and Microcorsini are the three least evolved olethreutine tribes (Horak and Brown, 1988). Our results thus support the hypothesis that pheromones based on a C_{14} compound, with double bonds in the 5, 7, 8, or 10 positions, represent a plesiomorphy for tortricids (Roelofs and Bjostad, 1984) found in plesiomorphic members of Tortricinae as well as Olethreutinae.

Roelofs and Bjostad (1984) proposed three biosynthetic schemes for the formation of certain lepidopteran pheromones, suggesting a possible evolution from Δ^9 through Δ^{10} to Δ^{11} desaturation of C_{16} and C_{18} acyl intermediates. The ultimate proof of the validity of this scheme may well rest upon isolation and characterization of the particular enzymes involved. Nevertheless, circumstantial evidence can be obtained from the detection of appropriate precursors in the pheromone gland and also from the particular combinations of products formed. It can be seen from Figure 1 that various combinations of components are suggestive of one or another of the proposed pathways. The combinations found in this survey and their distribution in relation to tortricine classification is compatible with such a scheme.

Within the frame-work of the above hypotheses (Figure 1), the presence of *Z*5–14:OAc in some Epitymbiini can be explained by simple chain shortening of a Δ^9 C_{18} acyl intermediate, following the action of a general Δ^9 desa-

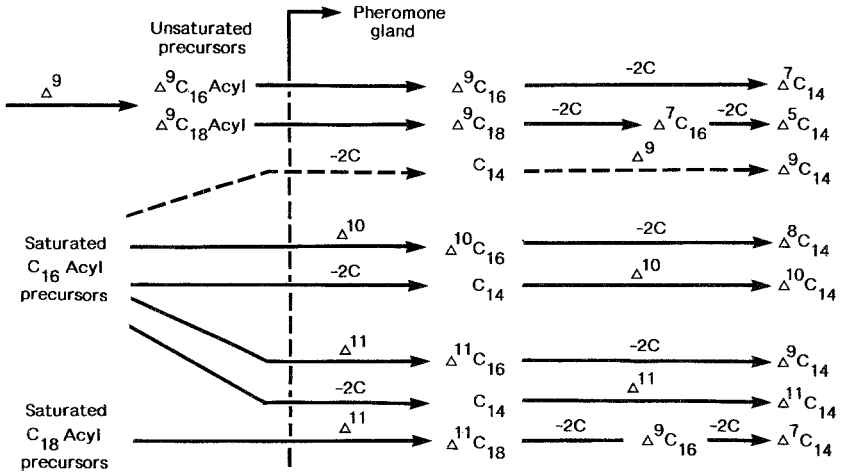

FIG. 1. Possible pathways to acyl intermediates in the biosynthesis of tetradecenyl acetates as pheromone components in Tortricinae: "-2C" indicates chain shortening by two carbon atoms; "Δ^n" indicates the action of a Δ^n desaturase, i.e., the introduction of a double bond between carbon atoms n and $n + 1$ (adapted from Roelofs and Bjostad, 1984).

turase. The occurrence of Z10–14:OAc in other Epitymbiini and the two generalized olethreutine tribes Gatesclarkeanini and Bactrini suggests the presence of a Δ^{10} desaturase. Z7–14:OAc and Z9–14:OAc could be derived with or without the action of a Δ^{11} desaturase, and only a detailed analysis can identify the underlying biosynthetic pathway. Absence of a Δ^{11} desaturase in *Meritastis* and in the olethreutine Microcorsini, both with Z9–14:OAc or derivatives thereof as the only identified pheromone gland components, would further underline the plesiomorphic nature of the two groups.

Although our results lend support to the hypothesis of three successively evolved pathways for tortricid pheromone biosynthesis, it must be pointed out that more evolved pheromones have been found for a number of morphologically very archaic Tortricidae. The Δ^{11} tetradecenyl acetates identified for *Cryptoptila* and *Taeniarchis catenata* and indicated for "*Tortrix*" *incompta* and *Eulia ministrana* L. (Priesner, 1984), as well as the Δ^{11} hexadecenyl acetates reported as attractants for the chlidanotine *Olindia* and *Isotrias* (Priesner, 1984), indicate that a Δ^{11} desaturase must have been present very early in tortricid evolution. Furthermore, the presence of the various positional isomers in several clearly monophyletic groups such as the Olethreutinae, the Epitymbiini s. str., the Cnephasiini s. str., and *Ctenopseustis* and relatives suggests repeated, parallel appearance of both the Δ^{10} and the Δ^{11} desaturase in several tortricid lineages.

If this trend towards pheromones associated with a Δ^{11} desaturase in the more evolved members of tortricid lineages is further confirmed, explanations will have to consider possible selective mechanisms. Pheromones based on C_{14} compounds with a double bond in the 11 position are clearly dominant among tortricines, with blends of *Z*11–14:OAc and *E*11–14:OAc apparently the most common combination. Mechanisms for pheromone biosynthesis, dissemination, and perception will all have to be taken into account for consideration of possible adaptive advantages of a particular compound or blend.

Acknowledgments—Dr. I.F.B. Common, Toowoomba, and Mr. P.B. McQuillan, Hobart, kindly provided some particularly interesting larvae. We thank Dr. M.J. Lacey for GC-MS analysis, Ms. J.A. Cristofani for technical assistance, and the staff of the Australian National Botanic Gardens, in particular Mrs. E. Mullins, for assisting with food plants. Comments on parts of the manuscript by Drs. J.S. Dugdale and S.P. Foster, Auckland, are gratefully acknowledged.

RESPONSES OF NORTHERN AND WESTERN CORN ROOTWORMS[1] TO SEMIOCHEMICAL ATTRACTANTS IN CORN FIELDS[2]

D.R. LANCE

USDA, ARS, NPA, Northern Grain Insects Research Laboratory
Rural Route #3, Brookings, South Dakota 57006

(Received March 16, 1987; accepted June 22, 1987)

Abstract—Small plots (18 × 18 m) were treated with grids of cotton wicks that contained semiochemicals for adult *Diabrotica barberi* Smith and Lawrence, the northern corn rootworm (NCR). In plots treated with eugenol (350 g/hectare), NCR were attracted to point sources of the compound, but there were no significant changes in numbers of either NCR or *D. virgifera virgifera* LeConte, the western corn rootworm (WCR), found on plants in the plots. In plots treated with 12.5 mg/hectare of 8*R*-methyl-2*R*-decyl propanoate (2*R*,8*R*-MDP, the apparent female-produced sex pheromone of NCR and WCR), males of both species were attracted to point sources, but beetles did not congregate within treated plots. With racemic 2,8-MDP at 1.0 g/hectare, male WCR were attracted into plots, but NCR of both sexes were strongly repelled. In a separate study, capture of beetles at pheromone-baited traps declined when the surrounding area contained wicks that emitted racemic 2,8-MDP. In treated plots, male WCR were relatively inefficient at finding pheromone sources. With NCR, emigration from plots could account totally for the observed 3- to 10-fold reduction in catch at 0.01–1.0 g/hectare.

Key Words—Coleoptera, Chrysomelidae, *Diabrotica virgifera virgifera*, *Diabrotica barberi*, sex pheromone, 8-methyl-2-decyl propanoate, eugenol, attractant, repellant, disruption, diastereomers.

INTRODUCTION

Numerous semiochemicals have recently been identified for the northern corn rootworm (NCR), *Diabrotica barberi* Smith and Lawrence, and the western

[1] Coleoptera: Chrysomelidae.

corn rootworm (WCR), *D. virgifera virgifera* LeConte. The work of Guss et al. (1984, 1985) indicates that females of NCR and WCR produce the same single-component sex pheromone, 8*R*-methyl-2*R*-decyl propanoate (2*R*,8*R*-MDP). Eugenol, a plant-derived volatile, attracts NCR to traps (Ladd et al., 1985); indole and several phenyl propanoids are attractants for WCR (Andersen and Metcalf, 1986; Lampman et al., 1987). Cucurbitacins, bitter principles found in many Cucurbitaceae, are potent arrestants and feeding stimulants for *Diabrotica* beetles in general (Metcalf et al., 1980).

Several researchers have suggested using these semiochemicals to aid in the control of adult beetles (Rhodes et al., 1980; Johnson et al., 1985). In theory, beetles could be attracted from untreated portions of corn fields into treated areas, lured to toxic baits within treated areas, and induced to feed selectively upon toxins. Very small amounts of actual insecticide could yield effective, specific control. In this study, NCR and WCR were monitored in small plots to determine whether various semiochemicals may be useful for attracting beetles from untreated portions of fields into treated areas, luring beetles to point sources of insecticide, or disrupting mating communication.

METHODS AND MATERIALS

Influence of Attractants on Distribution of Beetles. Tests were run in a commercial cornfield near Brookings, South Dakota. The following treatments were applied to a series of 18 × 18-m plots: (1) 8*R*-methyl-2*R*-decyl propanoate (2*R*,8*R*-MDP) at 0.0125 g/hectare, (2) racemic 2,8-MDP at 0.05 g/hectare (= 0.0125 g/hectare 2*R*,8*R*-MDP), (3) racemic 2,8-MDP at 1.0 g/hectare, (4) eugenol at 330 g/hectare, (5) 1.0 g/hectare 2,8-MDP plus 330 g/hectare eugenol, and (6) untreated control. The 2*R*,8*R*-MDP was from the same lot used by Guss et al. (1984) and thus contained ca. 0.3% 2*S*,8*R* and 1.9% 2*R*,8*S*. In each treated plot, the chemicals were deployed on cotton wicks that were arranged in a 6 × 6 grid with a 3-m spacing. Each wick (1-cm-diameter × 3-cm dental roll) was loaded with neat eugenol or with 2,8-MDP in 50 μl 4:1 hexane–trioctanoin; wicks were then attached (paper clips) to corn leaves at ear height. Treatments were assigned to plots in a complete, randomized-block design with four replicates. There were 100 m between blocks and 35 m between plots within blocks. Wicks were placed August 14, 1986, and were renewed four days later. During this period, corn in the field was in the early dent stage.

White sticky traps (Guss et al., 1985) were wrapped around corn plants at ear height to monitor populations of beetles. These traps were not baited with semiochemicals and thus provided a "passive" indication of beetle populations and activity within the plots. Two traps were placed 6 m apart near the center of each plot. All NCR and WCR were removed from traps every second day

from August 16 to 22; beetles were returned to the laboratory where they were counted and sexed. When traps were checked, beetles were also counted on eight plants in each plot.

Attraction to Point Sources of Semiochemicals. Capture at point sources of attractant was evaluated using a trap similar to that of Shaw et al. (1984). Ten 0.5-cm holes were drilled at arbitrary locations around the upper 3/4 of the perimeter of a 16-dram, amber plastic medicine vial. A piece of synthetic sponge (ca. 0.125 cm^3) was glued inside the vial and was loaded with a toxic bait. The bait consisted of a feeding stimulant that contained cucurbitacin (chloroform extract of 0.2 ml of dried, powdered root of *Cucurbita foetidissima* H.B.K.) in 0.1 ml 19:1 olive oil–Sevin XLR. Using garden ties, traps were attached to corn plants at ear height. Four traps were placed at 1-m intervals along a row near the center of each treated plot; two of the traps contained toxic bait plus wicks identical to those in the surrounding plot, and two contained only toxic bait. These traps were checked concurrently with sticky traps.

Disruption of Orientation to 2R,8R-MDP. Plots for this study were similar to those above, but were only 15 × 15 m with 5 × 5 grids of cotton wicks. Wicks were loaded with racemic 2,8-MDP as described above to give effective treatment rates of 0, 0.01, 0.1, and 1.0 g/hectare. Unlike the previous study, the two sticky traps in each plot were baited with rubber septa (A.H. Thomas No. 8753-D22) that were loaded with 1.0 μg of 2*R*,8*R*-MDP in 50 μl hexane; no vial traps were used. Plots were arranged in a randomized complete block design with three replicates, and there were 125 m between adjacent plots. Wicks were placed September 11, 1986, and, on each of the following two days, NCR and WCR were counted on traps and on 20 plants in each plot. The corn on this field was planted late and was in the 12- to 14-leaf stage (i.e., just prior to tasseling) when the study was conducted.

RESULTS

Distributions of Beetles. The two species of beetles responded very differently to 2,8-MDP in the plots. In plots treated with 1.0 g/hectare 2,8-MDP, capture of male WCR on unbaited sticky traps was ca. 10 times higher than in control plots, but counts of WCR on plants were only two to three times higher (Table 1). In plots treated with low levels of 2,8-MDP, capture of male WCR on sticky traps was 1.7–2.2 times higher than in untreated plots. Numbers of female WCR on traps were not significantly affected by 2,8-MDP. In contrast, racemic 2,8-MDP repelled NCR from plots (Table 2). As with WCR, the effect of 2,8-MDP on trap catch (81–91% reduction relative to controls) was greater than its effect on plant counts (25–60% reduction); unlike WCR, both sexes of NCR responded to the 2,8-MDP. Also, capture of male NCR was reduced sig-

[d] For each mean, two traps in each of three plots were sampled twice; data were transformed to ln $(x + 1)$ prior to ANOVA (actual means shown).

with eugenol plus 2,8-MDP captured significantly fewer beetles than unbaited traps. With NCR, 2*R*,8*R*-MDP and eugenol both attracted beetles to vial traps, whereas racemic 2,8-MDP inhibited trap catch (Table 3). When eugenol and racemic 2,8-MDP were combined in vial traps, their effects on capture of NCR appeared somewhat counterbalanced.

Disruption of Orientation to 2R,8R-*MDP.* Capture of WCR on pheromone-baited sticky traps was significantly higher in untreated plots than in plots treated with racemic 2,8-MDP (Table 4). Capture was relatively constant over treatment rates of 0.01, 0.1, or 1.0 g/hectare, but larger amounts attracted greater numbers of WCR into plots. With NCR, capture on traps declined significantly as the amount of 2,8-MDP was increased in the surrounding plot (Table 4). Racemic 2,8-MDP apparently repelled NCR from plots in a dose-dependent fashion; in plots with higher treatment rates, fewer NCR were found on plants.

DISCUSSION

For both WCR and NCR, 2,8-MDP had less relative effect on plant counts than on capture at unbaited sticky traps. With WCR, 2,8-MDP not only attracted males into plots but apparently increased their level of activity, making the beetles prone to capture on sticky traps. Similarly, 2,8-MDP may have inhibited activity of both male and female NCR. Also, beetles of both species were often

found feeding on tips of ears under husks and thus may have been shielded from the semiochemicals. If beetles often remained in individual ears for several days, those that were feeding on ear tips could have kept plant counts relatively stable in plots where numbers of active beetles changed greatly. Accordingly, 1.0 g/hectare of 2,8-MDP caused counts of NCR to decline only ca. 60% in plots where ears were available vs. >90% in plots (disruption study) with corn that had not yet tasseled.

With both WCR and NCR, numbers of beetles captured on pheromone-baited traps were reduced if the traps were surrounded by sources, of 2,8-MDP. Reasons for this reduction in capture, however, differed for the two species. With WCR, the mechanism appeared to be analogous to "false trail following" of Bartell (1982): rather than being attracted to the traps, numerous beetles congregated on and around plants with wicks (DRL, personal observation). With NCR, 2,8-MDP did not appear to affect the efficiency with which males located sources of pheromone. Instead, NCR simply emigrated from treated plots. The potential effect of this response on mating success is unknown, especially since both males and females were repelled.

The repellency of racemic 2,8-MDP to NCR is probably caused by the 2*S*,8*R* diastereomer. Guss et al. (1985) caught two to eight times more NCR males on unbaited traps than on traps baited with rubber septa that contained 1.0 μg 2*R*,8*R* plus 0.5–2.5 μg 2*S*,8*R*; on traps baited with 2*R*,8*R* plus only 0.1 μg 2*S*,8*R*, capture was similar to that on unbaited traps. Responses of NCR to 2*S*,8*R* also may explain the low capture NCR on sticky traps in plots treated with 2*R*,8*R*. Due to impurities (see Guss et al., 1984), each wick in these plots contained 0.03–0.04 μg of 2*S*,8*R*. This was not enough to negate attraction of NCR to point sources of 2*R*,8*R* but may have caused some NCR to emigrate or reduce their activity. Although it is not certain that female NCR were responding solely or primarily to 2*S*,8*R* when they avoided the racemate, contamination by 2*S*,8*R* could have influenced the data of Ladd et al. (1985). They caught more female NCR on traps baited with eugenol alone than on traps that were baited with eugenol plus a rubber septum containing 10 μg 2*R*,8*R*. Their 2*R*,8*R* came from the source of Guss et al. (1984), so each septum contained ca. 0.03 μg 2*S*,8*R*.

To date, repellency of 2*S*,8*R*-MDP to NCR appears to be a unique phenomenon. Certainly, it is relatively common for efficiency of pheromone-baited traps to decline when enantiomers of pheromone components are added to lures (response category 5 of Silverstein, 1979). Also, in pheromone systems of some bark beetles, two enantiomers can have synergistic and inhibitory effects on the activity of a second compound (Vité et al., 1985). I know of no instance, however, in which an enantiomer of a sex pheromone actually elicits different (in this case, functionally opposite) behavior from that produced in response to

pheromone alone. Indeed, Silverstein (1979) did not even include this scenario among his categories of possible responses of insects to enantiomers of their pheromone components.

NCR may be used 2*S*,8*R*-MDP as a kairomone to ensure reproductive isolation. The 2*S*,8*R* isomer is the apparent pheromone for several members of the *Diabrotica virgifera* group, including the NCR's sibling species, *D. longicornis* (Say) (Krysan et al., 1986, and references therein). Krysan et al. (1986) also found that 2*R*,8*R* inhibits orientation of *D. longicornis* to 2*S*,8*R*, although no repellent effect was evident. It is hoped future studies will clarify the roles of these isomers in mating and reproductive isolation in the *virgifera* group.

In contrast to the current practice of prophylactically applying soil insecticides, semiochemical-based technology for control of corn rootworms will have to be tailored to individual *Diabrotica* species. For example, racemic 2,8-MDP could be used to attract male WCR to sources of toxic bait, and this tactic might have the added benefit of delaying mating. Where NCR predominate, however, racemic 2,8-MDP would repel beetles from the toxin (although the repellency, in itself, may be of some practical value). The 2*R*,8*R* isomer attracts males of both species, but individual isomers of 2,8-MDP are currently too expensive for use in commercial preparations.

For semichemical–toxicant mixtures, plant-derived volatiles appear to be the attractants of choice. Eugenol could be used to bring NCR of both sexes to point sources of toxin; other plant volatiles are similarly effective against WCR (D.R.L., unpublished data). Although interactions of various volatiles with the different *Diabrotica* must be worked out, use of plant-derived attractants may allow for highly effective control while using very small amounts of actual toxin.

Abstract—Female-emitted pheromones and sex attractants of Noctuidae were investigated using a specific computer procedure to analyze data collected from the literature. Correspondence analysis was used to survey the structure–activity relationships of sex pheromones in seven subfamilies. Structural, stereochemical, and functional features of active molecules were related to taxonomy. This multidimensional analysis revealed that the prevalent chemical frame of noctuid moth pheromones was a monounsaturated acetate with *Z* stereochemistry and a double bond on the fifth carbon closest to the nonfunctional branch of the molecule. Possible phylogenetic relationships within Noctuidae and between Noctuidae and other families are discussed in light of the sex pheromone biochemistry. Female sex pheromones appeared to be an additional character to be considered in the classification of noctuid moths.

Key Words—Lepidoptera, Noctuidae, sex attractants, sex pheromones, correspondence analysis, chemotaxonomy, multidimensional analysis.

INTRODUCTION

The mating behavior of moths is mediated by female-emitted sex pheromones that attract males from a distance, then induce courtship behavior. Although courtship behavior is quite variable, even in related species, attraction of males to females is present in almost all families.

The specificity of attraction, disregarding the differences in rhythm of activity or ecological factors, is supported by the well-defined chemical structure of these pheromones. Accordingly, this feature is expected to provide a basis for a chemotaxonomic classification to be compared to the existing classifications.

Roelofs and Brown (1982) first demonstrated that the chemical structure of the sex pheromones emitted by female Tortricidae moths is clearly correlated with the taxonomic position of the species. Furthermore, a multidimensional analysis of data from the literature revealed that eight tribes of Tortricidae and structural features of their sex pheromones are closely related. (Doré et al., 1986b). In this paper we used the same method as Doré et al (1986b) to investigate the relationships between taxonomic status and chemical structure of the sex pheromones of Noctuidae. Noctuidae are one of the largest families in Lepidoptera, including more than 25,000 known species, among which are numerous pests. The size of the family and its worldwide distribution have brought about great difficulties in constructing the higher classification of Noctuidae and their division in subfamilies (Kitching, 1984).

Our aim was to assess the value of the chemical structure of sex pheromones as a new character for the classification of Noctuidae. Through a multidimensional approach of the chemical structures of their pheromones, we investigated the following questions: (1) Does a relationship exist between the chemistry of sex pheromones and the taxonomic position of the noctuid moths (chemotaxonomic standpoint)? (2) Can the structural features of the pheromones be used to develop phylogenetic relationships between superior taxa (evolutionary standpoint)? (3) Could a taxon be characterized by a chemical structure and could the grouping of given genera be reconsidered on the basis of the chemistry of their sex pheromone (analytic and taxonomic standpoint)?

METHODS AND MATERIALS

Data Collection. The data were compiled from the literature using sources up to 1984, including review articles (Inscoe, 1982; Tamaki, 1984; Steck et al., 1982). Some references deal with the identification of the constituents of the natural sex pheromone of a given species. Other sources deal with the attrac-

tive effect of synthetic compounds, used either alone or mixed with other compounds, during field trapping experiments.

Thus, data included both natural components of pheromone blends, isolated and identified from female secretions, and synthetic sex attractants, discovered through field screening of laboratory produced compounds. The latter sources included a few dubious reports of attractivity based on trap captures of only a few individuals. However, in a statistical approach they bring useful information. One must admit that if the majority of the species of a taxonomic group tends to respond positively to the same molecules their pheromones are, at least, closely related compounds. Moreover, factorial correspondence analysis (FCA) minimizes the effect of faulty data on the final result by categorizing atypical data into minor factors.

In addition to field trapping experiments, chemical analyses of pheromone gland constituents have established that most lepidopteran pheromones consist of blends of two or more compounds. In this paper, we considered each constituent of the pheromone blend separately. Data concerning 44 molecules of pheromones and 200 species of Noctuidae were collected.

The 467 insect–molecule connections were used to construct a frequency table indicating how many times (variable k) a given molecule, i, was a component of the natural pheromone blend or synthetic attractant for a species of subfamily, j. The citation frequency for molecule, i, in subfamily, j, was used as the numerical variable, k, in the mathematical analysis (Table 1).

Formulae of pheromone or sex attractant molecules mentioned in this article have been assigned according to a mode commonly utilized in the pheromone literature. This designates each molecule according to distinctive structural features, i.e., stereochemistry of the double bond (Z or E), location of the unsaturations (mainly 5, 7, 9, 11, or 12), length of the hydrocarbon chain (10, 12, 14 or 16 carbon atoms), terminal functional groups (primary alcohol, OH; aldehyde, Ald; or acetate, Ac). Thus, Z7–12 : Ac, Z11–16 : Ald, and Z9–14 : OH designate Z7-dodecenyl acetate, Z11-hexadecenal and Z9-tetradecenol, respectively.

The selection of subfamilies as the basic analytical unit was obviously very restrictive. Although a lower taxonomic level such as tribe or genus would have been more desirable, this proved to be impossible because: (1) A major decrease in the number of citations within inferior systematic groups would produce a multidimensional analysis of poor reliability. (2) It would have been difficult to classify species belonging to the world fauna into tribes, because tribes are often described for local fauna and differ among the authors.

The division of Noctuidae into subfamilies as defined by Franclemont and Todd (1983) was adopted. Of the 19 subfamilies they described, only seven contained enough species with pheromones or sex attractants described well

[a] This frequency matrix indicates how many species, k, of subfamily, j, are attracted by a pheromone or a synthetic attractant blend comprising a given molecule, i,.

enough to be included in our study: Acontiinae, Amphipyrinae, Cuculliinae, Hadeninae, Heliothinae, Noctuinae, and Plusiinae.

The chemical structure of attractants of subfamily Catocalinae seem to be unique in Noctuidae. Therefore, this subfamily was not included in our analysis.

Data on a few other subfamilies (Acronictinae, Chloephorinae, Herminiinae, and Hypeninae) are too scarce to permit statistical analysis and were not included.

The sex pheromones of the remaining subfamilies (Agaristinae, Eutelinae, Hypenodinae, Nolinae, Pantheinae, Rivulinae, Sarrothripinae, and Stictopterinae) have never been reported. Male moths of these subfamilies have never been trapped by Noctuidae attractants, and male antennae of some species are not sensitive to the pheromones of noctuid moths (Renou et al., 1986). It has been suggested that these subfamilies produce pheromones whose chemical structures differ from those of other Noctuidae.

Mathematical Analysis. The frequency matrix (44 × 7) (Table 1) was subjected to factorial correspondence analysis (FCA). This multidimensional data reduction procedure was developed by Benzécri et al. (1973) and fits specifically the contingency table. Unlike principal component analysis (PCA), FCA employs chi^2 metrics, and hence does not require handling of an exclusive covariance matrix. The following gives a brief outline of this approach as used herein.

The (n) molecules ($n = 44$ sex attractants) were distributed in a multidimensional subfamily space R^p ($p = 7$ dimensions). The position of each pheromone within this space is defined by ratio $f_{ij}/f_{i\cdot}$ where: f_{ij} is the relative frequency of occurrence of molecule (i) and subfamily (j): $f_{ij} = k_{ij}/\Sigma_{ij}k_{ij}$; and $f_{i\cdot}$ is the marginal relative frequency of pheromone (i) in the various subfamilies: $f_{i\cdot} = \Sigma_j f_{ij}$.

Each point corresponding to a pheromone defines its distribution among the seven subfamilies of noctuid moths (subfamily profile). Two pheromones are close neighbors in this space, if they occur as many times in the same subfamilies.

In the pheromone space R^n, the distribution of the p subfamily points is symmetrically defined by formula $f_{ij}/f_{\cdot j}$; the equivalence between the row and the column spaces is then the main characteristic of factorial correspondence analysis. To represent these two sets of points with minimum loss of information, principal projection axes (factorial axes) are established, as in principal component analysis, by determining eigenvalues (λ) and eigenvectors (V_x). A symmetrical matrix is constituted by distances $S_{jj'}$ between subfamily pairs (chi^2 distance):

$$R = \{S_{jj'}\} = \left[\sum_{i=1}^{n} \frac{1}{f_{i\cdot}} \frac{f_{ij} f_{ij'}}{\sqrt{f_{\cdot j} f_{\cdot j'}}} \right]$$

Calculation is performed by solving the equations: $[R] - \lambda[I] = 0$ and $[R]\cdot[V_x] = \lambda_x[V_x]$ (diagonalization of the symmetrical matrix) where I is the identity matrix. In FCA this is simplified by the fact that one of the sets of points is given by matrix $[R] = [M]\cdot[M']$. Permuting the indices is thus equivalent to transposing the matrix to the other set of points $[M']\cdot[M]$ with the same eigenvalues as R.

The coordinates of the various subfamily points on factorial axes are easily derived from these parameters by the equation:

$$\varphi_{\alpha j} = \lambda_\alpha^{1/2} V_{\alpha j} / f_{\cdot j}^{1/2}$$

where φ is the coordinate of subfamily for the factorial axis; λ_α, the corresponding non trivial eigenvalue; $V_{\alpha j}$ the corresponding eigenvector; $f_{\cdot j}$ the marginal relative frequency of subfamily j for the various pheromones.

Transition formulae, whose symmetry indicates that the representations for the two spaces are equivalent, give the coordinates of the pheromones for the different factors.

$$\varphi_{\alpha i} = \left(\frac{1}{\lambda_\alpha^{1/2}}\right) \sum_{j=1}^{p} (f_{ij}/f_{i\cdot})\varphi_{\alpha j}$$

$$\varphi_{\alpha j} = \left(\frac{1}{\lambda_\alpha^{1/2}}\right) \sum_{i=1}^{n} (f_{ij}/f_{\cdot j})\varphi_{\alpha i}$$

The result is a projection of the different points onto the factorial planes that have been constituted by taking the axes two by two. Several authors have developed the principles and the applications of FCA. Among the books published in English that more fully discuss FCA are those of Mardia et al. (1979) and Greenacre (1983).

In the last few years, we have used the FCA method for analysis of the multiple relationships between chemical structures and biological activities in various fields: pharmacology (Doré and Miquel, 1981; Doré et al., 1986a), toxicology (Doré et al., 1983), and biochemistry (Doré et al., 1982; Labia et al., 1983a, b). This method was also used to investigate the mechanisms of some psychophysiological responses (chemical classification of olfactive nuances, Doré et al., 1984). Similar attempts led us to define some correlations affecting pheromones and electroantennographic responses (Doré and Renou, 1985).

The calculations were made on a Hewlett-Packard 9836 microcomputer (16/32 bits of 655 kbytes RAM) using a program of correspondence analysis rewritten by us into BASIC from Fortran ANACOR program (Lebart et al., 1979). The factorial maps were drawn on a HP 7225A plotter under the direct control of the microcomputer with a precision of 0.25 mm.

RESULTS

Developed from an initial six-dimension system, the FCA method extracted 96% of the total inertia from the five first axes (Figure 1). The chi^2 metrics allowed us to consider row space (pheromone molecules) and column space (Noctuidae subfamilies) symmetrically. Therefore, the space of molecules and the space of insects could be evenly considered according to the Euclidian planes designated by factors φ_1 to φ_5. This technique provided a reciprocal structuring and also a close comparison of the elements of the two spaces charted on the factorial maps.

Each factor was characterized by its own rate of inertia. In FCA, inertia is equivalent to variance as defined in PCA and represents the percentage participation of each factor to the system structure.

The absolute contribution (AC) of each item i (molecule) or j (subfamily) to each factor represents the share of this item in the structure of this factor.

The relative contribution [RC = $\cos^2(\varphi_n)$] of each item of both spaces assessed the level of explanation of its location by factor φ_n.

Lastly, the coordinates of each item allowed us to consider each factor as an axis and to draw up positive or negative correlations between items. The two-by-two combination of these factorial axes provided the fractional view of the system structure in the form of Euclidian planes or factorial maps.

The use of these maps is closely related to that of topographic ones: the closer items are associated, the nearer their location on the factorial map. In the same way, with a few precautions, items of each space could be compared to define their correlation ratio. Finally, the further from the axis origin the various points representing the studied elements are, the more reliable are the correlations between the elements belonging to the two spaces.

Relative and absolute contributions and coordinates are displayed in Tables 2 to 4 and will be considered sequentially.

Factor φ_1. The first factor, φ_1, accounted for about one third (38%) of the total system inertia (Figure 1). This factor related to four subfamilies in the

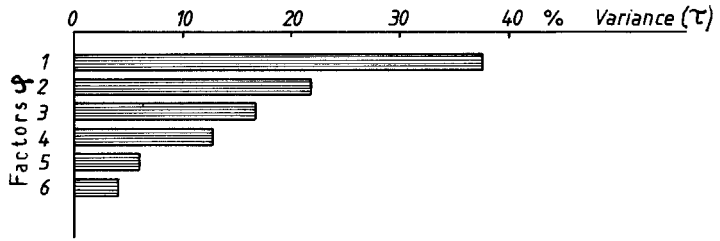

FIG. 1. FCA of the correlation between seven Noctuidae subfamilies and their sex pheromones: percent inertia (τ or variance) explained by FCA factors (φ_1 to φ_6).

lies were described very well by this factor [$\cos^2(\varphi_1)$ between 0.36 and 0.49], whereas the relative contributions to φ_1 of the last three subfamilies (Amphipyrinae, Cuculliinae, and Acontiinae) were less than 0.17.

The most involved molecules in the attractant space had 12-carbon and 16-carbon chains (Table 3B). The most striking feature was the negative correlation, or opposition, between Z7-12:Ac (AC = 24.4%, negative coordinates) and Z11-16:Ald (AC = 12.4%, positive coordinates).

On the whole, the decene or dodecene molecules were projected negatively along the φ_1 axis and were essentially correlated with Plusiinae and Noctuinae.

Hexadecenes were generally projected positively onto the φ_1 axis. The most involved molecules (Z11-16:Ald, AC = 12.4%; Z9-16:Ald, AC = 9%; 16:Ald, AC = 4.3%, on the one hand, and Z11-16:Ac, AC = 5.3%; Z11-16:OH, AC = 5.7%, on the other hand) made the hexadecene distribution bipolar.

The hexadecenals, with positive coordinates with high absolute value on φ_1, were associated with Heliothinae. Z11-16:Ald is the main component of the natural pheromone secretions of the five species studied so far: *Heliothis armigera* (Hübner) (Nesbitt et al., 1979), *H. punctigera* Wallengreen (Rothschild et al., 1982), *H. subflexa* (Guenée) (Teal et al., 1981), *H. virescens* (F.) (Klun et al., 1980a), and *H. zea* (Boddie) (Klun et al., 1980b). Furthermore, this aldehyde is a basic constituent of every attractive synthetic mixture for male *Heliothis*. Z9-16:Ald gained prominence since this compound, although uncommon in noctuid moth pheromones, has been identified in the secretions of all the species studied, except in *H. virescens*. It is an important secondary component for the attraction of male *Heliothis* as are a few other aldehydes.

Z11-16:Ald and other aldehydes were not specific to Heliothinae. They

elicit strong electroantennogram responses in various neotropical Amphipyrinae and Hadeninae species (Renou et al., 1986). However, Heliothinae show relatively exclusive responses to aldehydes in general and to Z11-16:Ald in particular; they are not attracted by acetates or alcohols. However, available data on *Heliothis* concern almost exclusively the genus *Heliothis*, although other genera would perhaps exhibit different sensitivity.

Conversely, although Z11-16:Ac and Z11-16:OH had positive coordinates, they were projected closer to the origin of the factorial axis φ_1. These features associated them with the Hadeninae.

Tetradecenes poorly contribute to the factor φ_1. 14:Ald and Z9-14:Ald have to be kept apart (AC = 2.6% for both) since their coordinates associate them with hexadecenals.

Examination of the relative contributions (Table 4B) confirmed these observations. The first factor explained between 40% and 70% of the characters of the previously mentioned dodecenes and hexadecenes. The C_{16} aldehydes and some C_{14} aldehydes were explained to the same degree by φ_1 [$\cos^2(\varphi_1)$ between 0.33 and 0.70].

Factor φ_2. The second factor, φ_2, accounted for 22% of inertia (Figure 1). In the insect space, this factor was influenced by Heliothinae (AC = 57.2%) and Plusiinae (AC = 22.3%). Both had positive coordinates on φ_2 (Table 4A). On the other hand, Hadeninae (AC = 12.4%) and, to a smaller extent, Amphipyrinae (AC = 9.8%) projected negatively onto the φ_2 axis.

In the molecule space, the 2nd factor was mainly under the influence of Z7-12:Ac (AC = 16.3%), Z9-16:Ald (AC = 16.8%), and Z11-16:Ac (AC = 7.4%).

Within the group of hexadecenes, the dualism between aldehydes 16:Ald, Z9-16:Ald and Z11-16:Ald with positive coordinates on φ_2 axis and Z11-16:Ac and Z11-16:OH with negative coordinates was confirmed. Therefore hexadecenals were associated with Heliothinae, while Z11-16:Ac and Z11-16:OH were correlated to Hadeninae.

Several tetradecenes displayed a significant absolute contribution to φ_2 (Table 3B), especially Z9-14:Ac (AC = 5.7%), Z11-14:Ac (AC = 4.4%), and Z9,E12-14:Ac (AC = 3.8%). Most of these tetradecenes projected negatively onto the φ_2 axis and were associated with the group of Hadeninae-Amphipyrinae.

At this stage of our explanation, scrutiny of the factorial map constituted by the φ_1 and φ_2 axes (Figure 2) allowed us to propound a preliminary organization of the insects–molecules system.

Chain length appeared to be important. C_{10} and C_{12} molecules gathered in a homogeneous cloud with which Noctuinae, Plusiinae, and to a lesser extent, Acontiinae were correlated. These three subfamilies preferentially displayed short chains.

The distribution of tetradecenes was more complicated; they formed an

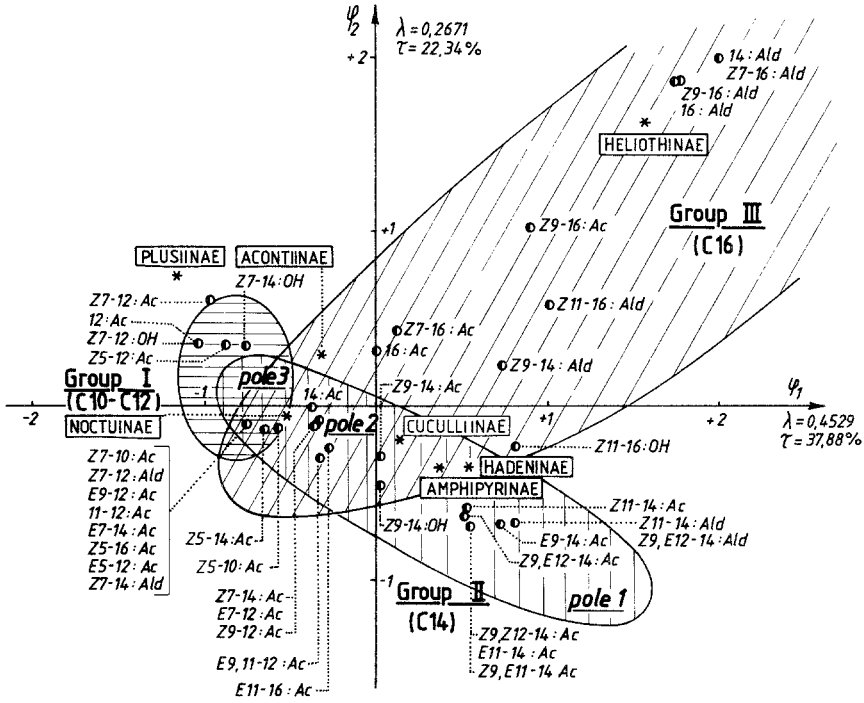

FIG. 2. FCA of the correlation between seven Noctuidae subfamilies and their sex pheromones: main factorial map ($\varphi_1\varphi_2$). λ = eigenvalue of φ_n, τ = percent inertia for φ_n.

elongated cloud and were organized in three poles: first pole, Δ9, Δ12: dienes and Δ11 monoenes; second pole, Δ9 monoenes; and third pole located around the Δ5 and Δ7 monoenes. The inferior rank axes, particularly Δ3 and Δ4 allowed us to ascertain this distribution.

Hexadecenes were scattered over the factorial map φ_1 φ_2 (Figure 2). Their location is explained by the 90% ratio reached with these two factors. Their distribution was composed of an opposition between hexadecenals correlated with Heliothinae, and Z11-16:Ac—Z11-16:OH correlated with Hadeninae.

The distribution of pheromonal molecules over the factorial map φ_1 φ_2 seemed to take into account various, equally important structural features (i.e., hydrocarbon chain length, occurrence of the aldehyde functional group, and location of double bond). These features were predominant in the typological analysis of Noctuidae pheromones.

Factor φ_3. The third factor, φ_3, accounted for 17% of the system inertia; it led to the analysis of the secondary organization of the components within the poles designated by higher rank factors (Figure 3C).

In the insect space, the third factor was mainly composed of Noctuinae

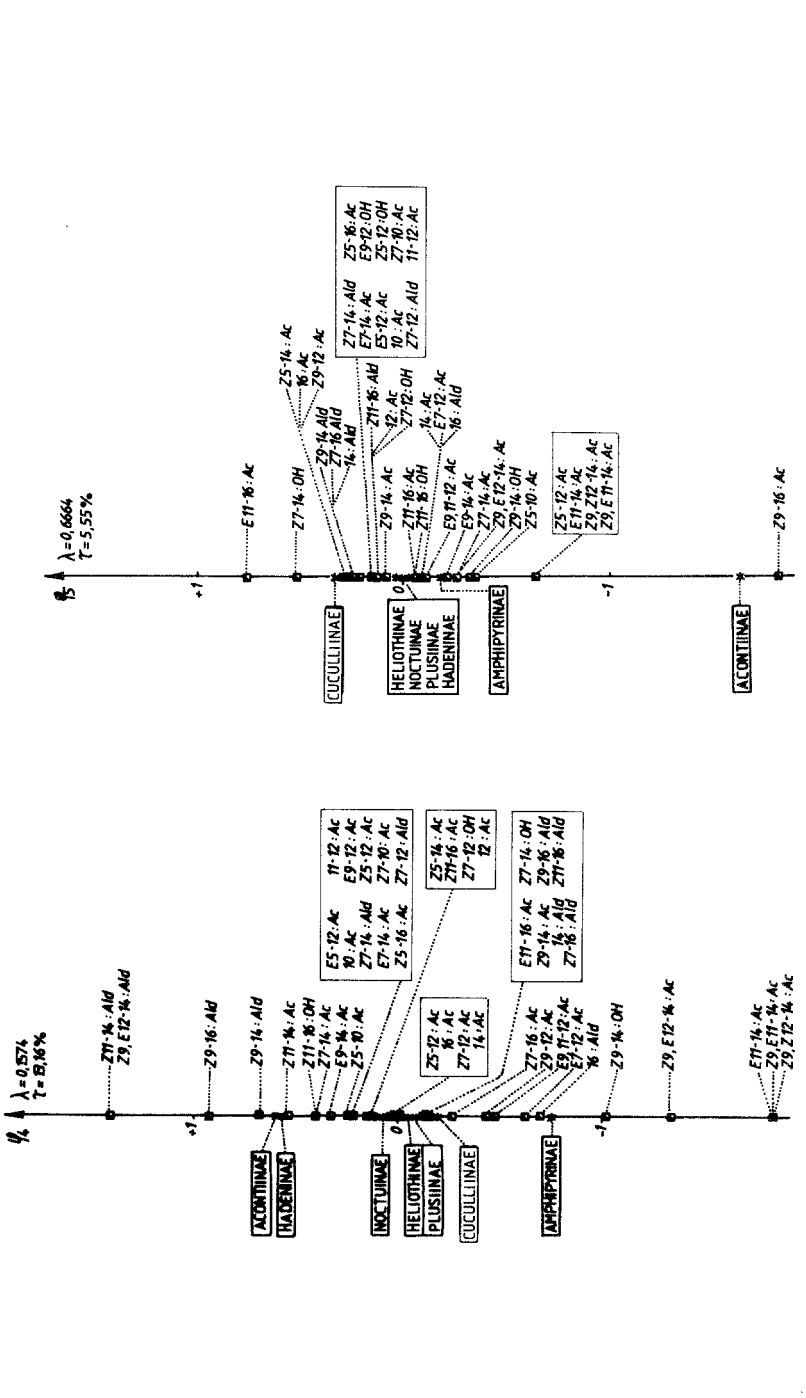

FIG. 3. Distribution of pheromone molecules and noctuid subfamilies on factorial axes φ_1 (3A), φ_2 (3B), φ_3 (3C), φ_4 (3D), and φ_5 (3E).

(AC = 42.8%), which projected positively onto the φ_3 axis, opposite Plusiinae (AC = 37.4%), which projected negatively.

In the molecule space, φ_3 accounted for the opposition between Z7–12 : Ac (AC = 29.5%, positive coordinates) and Z5–10 : Ac (AC = 14.5%, negative coordinates).

Z7–12 : Ac, with positive coordinates, was correlated with Plusiinae. As a matter of fact, the great majority of sex attractive blends for male Plusiinae contain Z7–12 : Ac.

Z5–10 : Ac, with negative coordinates, like the two other decenes studied (10 : Ac, AC = 4.1%; and Z7–10 : Ac, AC = 1.4%), was correlated with Noctuinae. This association is rather specific. Several species of genera *Agrotis* and *Euxoa* emit pheromone blends containing Z5–10 : Ac (Underhill et al., 1981; Löfstedt et al., 1982). This compound is rarely detected in the other Noctuidae, which explained that factor φ_3 displayed a strong correlation between Z5–10 : Ac and Noctuinae, despite that Z7–12 : Ac is also a powerful attractant for Noctuinae.

The φ_3 axis also had a high absolute contribution from Z5–14 : Ac (AC = 9.1%). This molecule possessed negative coordinates on φ_3 and was associated with Noctuinae. Although this attractant occurred only nine times, eight cases (Table 1) were related to Noctuinae. This attractant was atypically located with respect to the other tetradecenes. Z5–14 : Ac is identified as the main component in *Agrotis exclamationis* (L.) pheromone blend (Bestmann et al., 1980) and is present in small proportions (less than 4% of the total blend) in the pheromone blend of *Euxoa drewseni* (Staudinger) (Struble, 1983). Z5–14 : Ac is also reported to be a constituent of attractive mixtures for several other *Agrotis* or *Euxoa* species (Steck et al., 1982). Thus, Z5–14 : Ac is probably an important, specific secondary component of sex attractants for male Noctuinae.

E9, 11–12 : Ac and 11–12 : Ac poorly contributed to φ_3 (AC = 1.4% for both of them); they are located like the other dodecenes. This phenomenon is explained by their rare occurrence. They are uncommon compounds and are only identified in *Diparopsis castanea* Hampson (Nesbitt et al., 1975). This Noctuinae species is remarkable because of its unusual sex pheromone.

Factor φ_4. The fourth factor, φ_4 (Figure 3D), accounted for 13.2% of the system inertia and determined a subsidiary dualism between Amphipyrinae (AC = 54.5%) and Hadeninae (AC = 38.9%). The most meaningful molecules for φ_4 were Z9,E12–14 : Ac (AC = 25.8%) and Z9,E11–14 : Ac (AC = 8.1%). These two tetradecadienes are projected negatively onto the φ_4 axis and were correlated with Amphipyrinae. As a matter of fact, they are specific to *Spodoptera*.

Z11–14 : Ald contributed significantly to φ_4 (AC = 7.4%); it projected positively onto the axis and was associated with Hadeninae. This molecule is rarely present in Noctuidae sex attractants, and it occurred only in three species

of Hadeninae: *Melanchra picta* (Harris) (Underhill et al., 1977), *Lacanobia atlantica* (Grote), and *Orthosia hibisci* (Guenee) (Steck et al., 1982). Some other aldehydes (mainly Z11–16:Ald, and Z9–14:Ald) are components of Hadeninae sex attractants. They also attract insects of some other subfamilies (Heliothinae, etc.) and thus are less specifically emphasized by the factorial analysis.

Factor φ_5. The fifth factor, φ_5 (Figure 3E), with a 5.6% value for inertia, was under the unique influence of subfamily Acontiinae [$\cos^2(\varphi_5) = 0.74$]. Conversely, this subfamily was poorly explained by the first four factors [$\Sigma \cos^2(\varphi_1 - \varphi_4) = 0.14$].

In the molecule space, Z9–16:Ac (AC = 49.6%) almost exclusively determined the structure of φ_5. Its location implied that this hexadecene is not attractive to Heliothinae and Hadeninae, which are usually responsive to C_{16}. In contrast, Z9–16:Ac was correlated with Acontiinae. It is a constituent of the sex pheromone blend of the Acontiinae *Naranga aenescens* (Moore) (Ando et al., 1977). This fact explains its importance for a subfamily which is barely mentioned because of a lack of data.

The subfamily Cuculliinae was poorly explained by factors φ_1 to φ_5 (Σ RC < 10%). This subfamily was only moderately represented (34 citations). The chain length (C_{12}, C_{14}, or C_{16}: Z9–12:Ac, Z9–14:Ac, or Z11–16:Ac), the position of the double bond, and the functional group of their attractants seemed various and nonspecific. These observations explain why Cuculliinae contribute little to the opposition between molecules and were located close to the origin of the different factorial axes.

Factor φ_6. The sixth factorial axis, φ_6, accounted for only 4.1% of the system inertia. Cuculliinae, which were poorly explained by factors φ_1 to φ_5, were well explained by φ_6 [$\cos^2(\varphi_6) = 0.59$]. In the same way, E11–16:Ac was mainly explained by φ_6 [$\cos^2(\varphi_6) = 0.61$] and was correlated with Cuculliinae. But this correlation was based on a single occurrence and did not allow us to conclude the specificity of E11–16:Ac toward Cuculliinae.

The overall multidimensional analysis presented deals with each attractive compound individually. Because the compounds are chemically analogous, it is worth examining each of their functional and structural features, i.e., chain length, functional group, and location of the double bond. For this purpose, we calculated the barycenter of the groups of molecules containing a common feature. This barycenter corresponds to the center of gravity of the x molecules of the group in a two-dimensional space and was used as an additional variable in the factorial data analysis (Table 5). This procedure is correct since it takes into consideration the distributional equivalence concept inherent in the correspondence analysis (Fénelon, 1981). We examined the citation frequency of each group of isomers in the attractive compound list and the projection of each barycenter on the main factorial map φ_1 φ_2.

TABLE 5. COS^2 OF PROJECTIONS OF 11 BARYCENTERS (ACCORDING TO THREE STRUCTURAL CLASSES: CHAIN LENGTH, FUNCTIONAL GROUP, POSITION OF DOUBLE BOND) OF PHEROMONE AND ATTRACTANT MOLECULES FOR NOCTUIDAE ON SIX FACTORIAL AXES

Effect of Chain Length. Chain lengths C_{12}, C_{14} and C_{16} occurred equally, with C_{10} molecules less frequently observed (21 citations). Noctuidae produce molecules of various chain lengths and, even in the same species, pheromone blends may have components of different chain lengths. The biosynthesis of sex pheromones involves chain shortening through β-oxidation steps of the fatty acid precursor, generally hexadecanoic acid (palmitic acid) (Roelofs and Bjostad, 1984). Successive chain shortenings yield C_{14}, C_{12}, then C_{10} molecules. Changing chain length probably did not cause any important modification of the enzymatic mechanism present in the pheromone glands. This fact could explain the chain length diversity among the pheromones of Noctuidae subfamilies.

The factorial map (Figure 4) shows the opposition between short chains (C_{10} and C_{12}, with negative coordinates on φ_1 axis) and long chains (C_{14} and C_{16}, with positive coordinates). C_{10} and C_{12} are associated with Acontiinae and Plusiinae (two Quadrifine subfamilies of Noctuidae) and with Noctuinae (Trifines), while C_{14} and C_{16} are associated with all the other Trifine noctuid subfamilies.

Functional Groups. The acetates are the most frequent functional group with 376 citations out of 467 (Table 1). Alcohols and aldehydes are less common with 36 and 56 citations, respectively. Several biochemical studies have

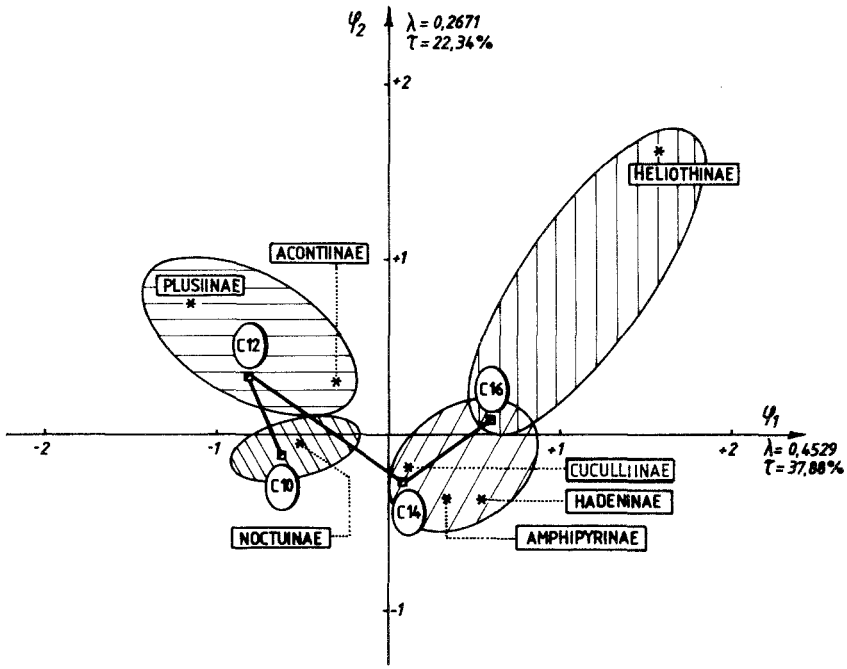

FIG. 4. Projection of noctuid subfamilies and chain length barycenters of their pheromones on the main factorial map ($\varphi_1\varphi_2$).

demonstrated that in the investigated moth species acetates are the metabolic precursors of alcohols and aldehydes (Silk et al., 1980; Morse and Meighen, 1982; Teal and Tumlinson, 1986). Thus, owing to their frequent occurrence and their biosynthetic importance, acetates may have been the ancestral pheromone components of Noctuidae. Alcohols and aldehydes would then arise in some species to provide improved pheromone specificity. The barycenters of acetates and alcohols are located close to the origin of axes φ_1 and φ_2 (Figure 5). The acetates, located near this origin, could not be specifically associated with any subfamily. Alcohols are more frequent in Hadeninae (11% of the citations) than in Cuculliinae (4.2%) and Acontiinae, but they were poorly explained by φ_1 and φ_2, and their location was not significant. The barycenter of aldehydes was strongly correlated with Heliothinae, many species of which are attracted by aldehydes.

Stereochemistry and Location of Double Bond. Most of the attractants are monoenes. There are also some saturated compounds (25 citations) and a few dienes (18 citations). The saturated compounds are never attractive in themselves but are parts of sex pheromone blends. Dienes are rare (five of 45 mol-

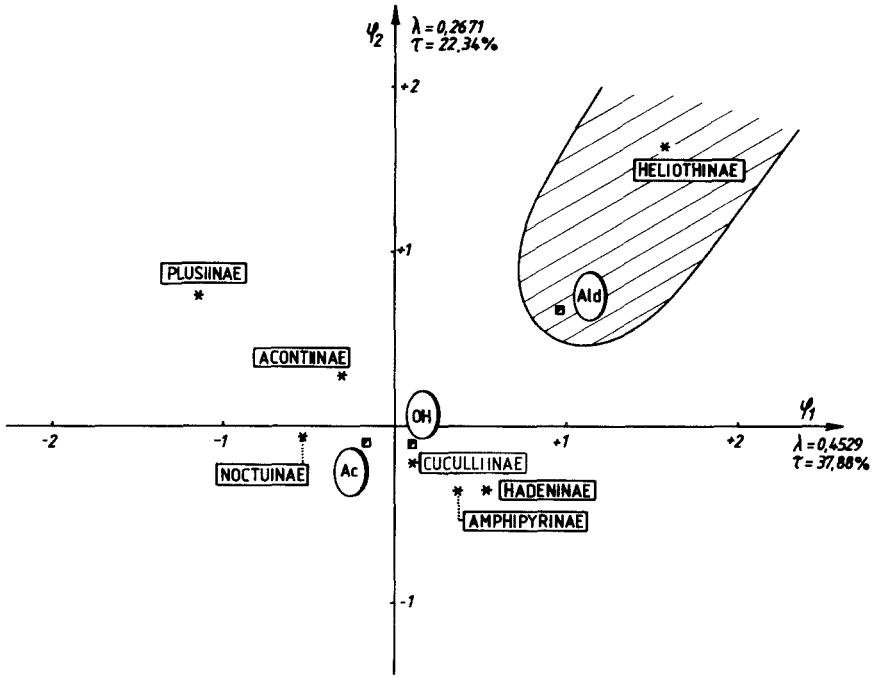

FIG. 5. Projection of noctuid subfamilies and functional group barycenters of their pheromones on the main factorial map ($\varphi_1\varphi_2$).

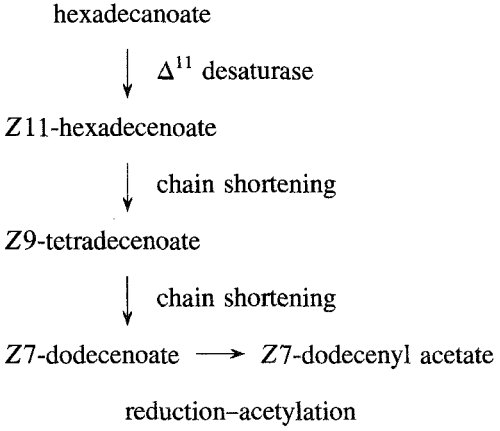
ecules). As an example, *Z*9,*E*12–14 : Ac and *Z*9,*E*11–14 : Ac are highly specific to genus *Spodoptera* (Amphipyrinae), as is *E*9,11–12 : Ac for the genus *Diparopsis* (Noctuinae; Nesbitt et al., 1975).

Almost all the monoenes (394 of 422 citations) possess the *Z* stereochemistry, while only a small number (28 citations) possess the *E* one.

The double bond of monoenes is always located on an odd-numbered carbon atom. According to the conventional numbering system, the double bond is designated by the number of its carbon atom closest to the functional group in the chain. However, β-oxidation chain-shortening steps, which play a prominent role in pheromone biosynthesis (Roelofs and Bjostad, 1984), occur on the functional group moities. This produces an apparent displacement of the considered double bond through a shift of two carbon atoms.

For example, the pheromone gland of *Trichoplusia ni* (Hübner) (Noctuinae), in which *Z*7–12 : Ac is the main pheromone component, contains the immediate fatty ester precursor, *Z*7-dodecenoate, and a large quantity of *Z*11-hexadecenoate (Bjostad and Roelofs, 1983). Labeling experiments show that

Z11-hexadecenoate is chain-shortened to Z9-tetradecenoate, which is in turn chain-shortened to Z7-dodecenoate according to the following scheme (Bjostad et al., 1985).



Thus, it appeared more adequate for the interpretation of the position of the double bond to number it starting from the carbon atom closest to the hydrocarbon end of the chain and to organize these attractive molecules into four groups corresponding to the four new locations so defined. Such a class included molecules derived from a common precursor involved in successive β-oxidation and chain-shortening steps. These new groups were classified as follows: ω3 corresponding to the Δ7–10:, Δ9–12:, and Δ11–14:; ω5 corresponding to the Δ5–10:, Δ7–12:, Δ9–14:, and Δ11–16:; ω7 corresponding to the Δ5–12:, Δ7–14:, and Δ9–16:; and ω9 corresponding to the Δ5–14: and Δ7–16: chain branches where Δ and ω mean an *E* or *Z* double bond in the corresponding position.

This additional rule of numbering emphasized a structural lineage interrelating the four most frequent attractants: Z5–10:Ac, Z7–12:Ac, Z9–14:Ac, and Z11–16:Ac. If the alcohol and aldehyde derivatives are also included, one observe that together they collected 320 of 467 citations (68%). Their molecular skeleton was:

$$\underset{1}{CH_3}-(CH_2)-\underset{5}{CH}=\underset{6}{CH}-(CH_2)n-X$$

with $n = 3$, 5, 7, or 9 and X = CHO, CH—OH, or CHOAc.

The other locations of the double bond were less frequent, 30 citations for ω3, 45 citations for ω7, 15 citations for ω9. These molecules could be produced

either through the action of the Δ11 desaturase on fatty acids of different chain lengths, or through the action of another desaturase on a single precursor. For example, insect cells contain a Δ9 desaturase (Roelofs and Bjostad, 1984). Conversely the pheromone gland of *Trichoplusia ni* contains Z11-hexadecenoate and Z11-octadecenoate, which result from the activity of a Δ11 desaturase on the corresponding saturated fatty acids (Roelofs and Bjostad, 1984).

On the factorial map (Figure 6), we observe that the ω5 attractant molecules are positioned near the axis origin without any special association with any of the subfamilies.

The barycenter of ω3 attractants was associated with Amphipyrinae and Hadeninae (Figure 6). Z11–14 : Ac was moderately correlated with Hadeninae (10 citations for this single subfamily).

The barycenter corresponding to ω7 monoenes was associated with Noctuinae. Table 1 shows that there are 10 citations for the Z7–14 : Ac and six citations for Z5–12 : Ac.

The barycenter corresponding to ω9 was also associated with the Noctuinae (eight citations for the Z5–14 : Ac).

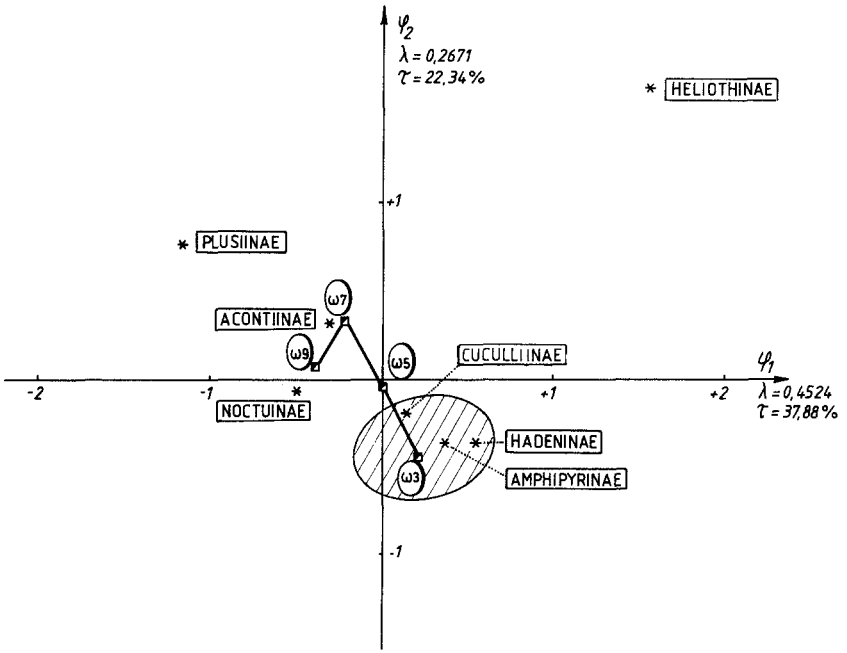


FIG. 6. Projection of noctuid subfamilies and double-bond position barycenters of their pheromones on the main factorial map ($\varphi_1\varphi_2$).

DISCUSSION

The pheromones and the sex attractants of the seven subfamilies of Noctuidae considered are linear chains containing an even number of carbons (10–16). The molecules have one or two double bonds and an acetate, alcohol, or aldehyde functional group. These chemical characteristics led to consideration of nearly 300 different homolog molecules. Of these, only 44 attract male noctuid moths. Furthermore, among these 44 molecules, four account for half of the citations while the other 40 molecules are only sparsely cited.

The prevalent chemical frame is a monounsaturated acetate with the *Z* stereochemistry and the double bond located on the fifth carbon atom closest to the nonfunctional branch of the molecule. Considering the biosynthetic pathway in the pheromone glands, the majority of pheromone constituents appear to be produced through the conversion of a restricted number of precursors, the most common being hexadecanoate. A few specific biochemical reactions then lead to the various isomers present in the sex pheromone blend.

Unlike Tortricidae, Noctuidae do not produce blends of various proportions of *Z* and *E* isomers in order to ensure the specificity of their sex pheromones. Moreover, they appear to possess a unique desaturase, whereas in Tortricidae another class of desaturase allows biosynthesis of Δ8 and Δ10 compounds (Roelofs and Brown, 1982). The basic carbon chain possesses 12, 14, or 16 carbon atoms; the chain length is a less stable structural feature, although the long carbon chains (14 and 16) are more frequent.

If we reject the hypothesis of an experimental bias related to a larger use of these latter pheromonal compounds during field screening of synthetic pheromones, we might consider Z9–14 : Ac and Z11–16 : Ac as sex pheromones of a common ancestral type of Noctuidae.

However, one must point out the lack of data for half of the noctuid moth subfamilies. Furthermore, within the subfamilies investigated, the data are focused on some tribes but ignore other tribes of possibly different phyletic origin.

The Trifines sex pheromones are the best known, and almost all the subfamilies have been investigated. Two other subfamilies, Acronictinae and Pantheinae, very likely use the same kind of compounds as the other Trifines. Dodecenyl acetates or aldehydes are attractive for *Acronicta grisea* Walker (Steck et al., 1982) and *A. sperata* Grote (Underhill et al., 1977), tetradecenal for *Simyra henrici* (Grote) (Steck et al., 1982), and Z7–12 : OH for *Raphia frater* Grote (Weatherston et al., 1974).

The female sex pheromones of most Quadrifines subfamilies are unknown. Apart from Plusiinae and Acontiinae, the structure of the sex pheromone of only one Chloephorinae, *Earias insulana* (Boisduval), has been elucidated. It

is a dienic aldehyde, *E*10,*E*12–16:Ald (Hall et al., 1980); the males of the related species *E. biplaga* Walker are attracted by *Z*11–16:Ald (Nesbitt et al., 1979).

Several recent works deal with Catocalinae sex pheromones. The active molecules are either polyenic hydrocarbons or their monoepoxyde derivatives. The monoepoxydes are sex attractants for several Herminiinae, one Hypeninae, and one Rivulinae (Wong et al., 1985). Thus, the chemical structure and the biosynthetic pathways of the sex pheromones of the deltoid group are different from those of the other Noctuidae. Their biosynthesis probably involves as precursors two essential fatty acids from food, linoleic and linolenic (Roelofs and Bjostad, 1984), instead of the de novo synthesis of saturated fatty acids, as proposed for the common pheromones. Then, one can hypothesize an early differentiation of Catocalinae, Hypeninae, and Herminiinae. These subfamilies were previously grouped in deltoids by others.

The sex pheromones of Arctiidae, Geometridae, and Catocalinae are alkenes or epoxides with double bonds on carbons 3, 6, and 9. Arctiidae are related to Noctuidae; both families belong to the Noctuidoidea superfamily and a lineage between Arctiidae and those of Noctuidae producing the same sex pheromones can be hypothesized. This is evidence for the application of pheromone science to the analysis of relationships between Noctuidae and the other Noctuidoidea. Conversely, Geometridae belong to a different superfamily and more information on their pheromones and those of related families are needed before drawing conclusions on phylogeny.

Within the seven subfamilies considered in this study, the pheromonal compounds were differentiated according to the following features: modification of the functional group, displacement of the double bond, or existence of an additional double bond (dienes). Considering the homogeneity of the basic chemical structure of the sex attractants, one can hardly characterize the subfamilies with exclusive sex pheromones criteria. At least the multidimensional analysis yields a heterogeneous statistical ordering of the chemical structures. For example, Noctuinae are strongly correlated with C_{10} molecules and Heliothinae with aldehydes.

Because of this structural homogeneity, it is difficult to explain the chemistry of the pheromone, in phylogenetic terms, since the same structural features could have arisen simultaneously in different lines. At most, discrete evolutionary trends are revealed by factorial analysis.

On the other hand, some groups (*Spodoptera* and *Diparopsis*) are individualized because of the peculiar chemical features of their pheromones. In this case, the pheromones bring an additional character to the species diagnosis.

In conclusion, the classification of the high taxa of noctuid moths is subject to reexamination and controversy (Kitching, 1984), and the contribution of a potentially new character should not be disregarded. The image of the family

Noctuidae depicted in that paper is a snapshot based on the current knowledge. This classification will certainly be reconsidered as new components are identified and new subfamilies studied, especially those of tropical fauna. Advances in pheromone biochemistry will throw new light on the science of pheromones. Male-emitted pheromones (Birch, 1972a, b) or other biochemical characters might also prove to be helpful.

Acknowledgments—We are deeply indebted to Mrs. M. F. Comeau (C.N.R.A., Versailles, France) for revision of the English translation, and to three anonymous reviewers for their critical reading of our manuscript. Thanks are extended to Dr. Sid Mayer (U.S.D.A., Gainesville) for helpful comments on the manuscript.

(Received April 3, 1987; accepted June 30, 1987)

Abstract—Antennal olfactory (electroantennogram) and laboratory and field behavioral tests were carried out on the response of *Dendroctonus frontalis* to its aggregation pheromone frontalin and analogs. The analogs were compounds modified by altering the position and methyl groups and/or by their deletion. Any modification to the frontalin structure significantly reduced both the antennal olfactory and behavioral response by *D. frontalis*. Beetle response, although significantly reduced, was elicited at the receptor level and in a laboratory bioassay by all analogs. However, only one analog (*endo*-5,7-dimethyl-Frontalin) elicited significant response from field populations of the beetle.

Key Words—*Dendroctonus frontalis*, Coleoptera, Scolytidae, bark beetle, pheromone, frontalin, electroantennogram, bioassay, pheromone trap, pheromone analogs.

INTRODUCTION

Frontalin (1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane) is the major aggregation pheromone of the southern pine beetle, *Dendroctonus frontalis* Zimmerman (Coleoptera: Scolytidae) (Kinzer et al., 1969; Payne et al., 1978). In combination with host odor, attractiveness of frontalin to the beetle is significantly enhanced (Kinzer et al., 1969). Other pheromones and host odors, in the absence of frontalin, are significantly less attractive or totally unattractive to *D. frontalis*, indicating a high level of specificity for frontalin (Payne et al., 1978).

In an effort to gain insight into the structural activity relationships of frontalin, we conducted electrophysiological, laboratory behavioral, and field studies on the response of *D. frontalis* to analogs of the pheromone.

METHODS AND MATERIALS

Insects used in laboratory experiments were newly emerged from naturally infested loblolly pine trees.

Structure and purity of the compounds used are presented in Table I. The

TABLE 1. STRUCTURE AND PURITY OF COMPOUNDS TESTED

Compound number	Structure	Name	Purity (%)[a]	Field elution (mg/day)

8		6,8-dioxabicyclo[3.2.1]octane	100	3

[a] Determined by analytical gas chromatography.

compounds were synthesized with known and modified procedures in order to provide a systematic series of modifications to the structure of frontalin. Details on synthesis of the compounds will be published elsewhere.

The electroantennogram (EAG) technique used to measure antennal olfactory response was previously described in detail (Dickens and Payne, 1977) and was a modification of earlier techniques (Schneider, 1957; Payne, 1975). Only male beetles were used in the EAG experiment since, in a previous study, both sexes showed similar antennal olfactory responses to frontalin (Payne, 1975).

Stimuli were diluted in nanograde pentane and were delivered as 10 μl samples of 1 μg/μl placed on filter paper inserted into glass cartridges oriented toward the preparation from ca. 1 cm. Stimulus duration was 2 sec and air flow was ca. 1 liter/min. Three to 5 min were allowed between each stimulation. This time interval was found to be adequate for complete recovery of the EAG. Four replicates were obtained to each stimulus. Each preparation was exposed to nanograde pentane in air as a control, and response to the control was subtracted from subsequent responses to the compounds for a given preparation.

Frontalin at 1 μg/μl was used as the standard to which all responses were normalized in order that responses obtained from different preparations could be compared. Stimulation with the standard followed the control and every two stimulations. Responses to intervening test stimuli were represented as a percent of the mean of the two responses to the standard closest in time to a given test stimulus.

The amplitude of the EAG depolarization was considered a measure of the relative number of responding receptor sites (acceptors) (Payne, 1975; Dickens and Payne, 1977) and a relative measure of the sensitivity of *D. frontalis* to a given stimulus. Responses were compared for significant differences using the Student's *t* test.

A pedestrian bioassay (Payne et al., 1976) was used to test attraction to the compounds, which were delivered at 1 μg/μl/min in nanograde pentane in a 1 liter/min air flow. For each assay, five beetles of a single sex were used. At least 30 min were allowed to pass before a group was tested against a different stimulus. All beetles were assayed within 24 hr of emergence.

Ten replicates (50 beetles) per sex were assayed against each compound. Results were recorded as percent positive response per replicate of response to frontalin as a standard. The Student's *t* test was used to compare responses between compounds and between sexes per compound.

Field tests were carried out during May through July 1986 in the east Texas pine forest. Funnel-barrier traps (Rose et al., 1981), positioned at 20–30 m apart, were used to monitor response of *D. frontalis* to the compounds. The compounds were eluted from 2-dram ampules which had been severed at the neck (Table 1). Turpentine, as a host odor, was released separately at ca. 1440 mg/day through an 18-cm-long alcohol burner wick (7 cm exposed) from a 125-

ml amber bottle (Fisher Scientific). Host odor has been shown to be significant to the attractiveness of frontalin to field populations of *D. frontalis* (Renwick and Vité, 1969; Payne et al., 1978; Billings, 1985). Traps and compounds were repositioned within the trap line after each replicate. Data collected consisted of the total number of male and female *D. frontalis* that responded to each compound and the control traps per three- to four-day replicate. The Student's *t* test was used to compare the responses to compounds and between sexes per compound.

RESULTS AND DISCUSSION

Electrophysiology. Response to the standard was $\bar{X} = 1.04$ mV $\pm$ SE = 0.07 ($N = 36$). Response by *D. frontalis* to frontalin (compound 1, Table 1) was significantly greater ($P < 0.05$) than response to other compounds. The level of response decreased significantly as the structure of the compound was altered from that of frontalin (Figure 1). Consequently, response to compound 8 (no methyl groups) was significantly less ($P < 0.01$) than response to all other compounds.

Response to 1-methyl-frontalin (compound 3) was significantly greater (*P*

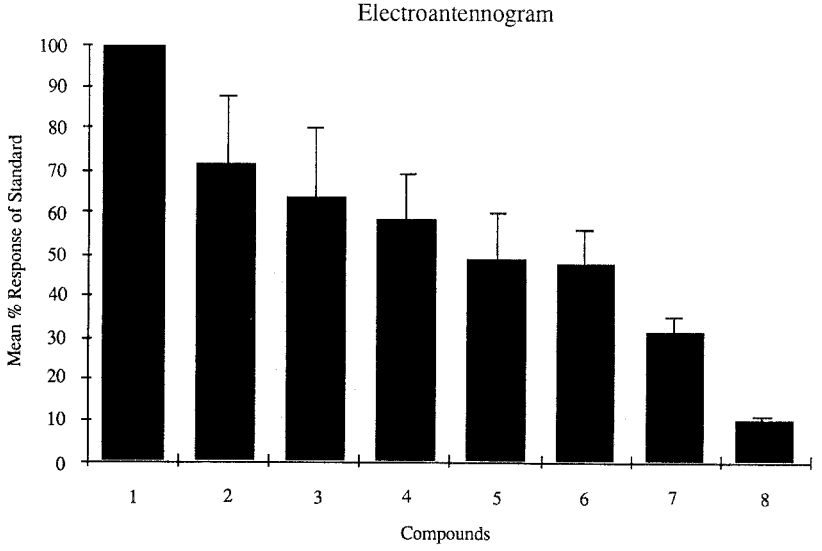

FIG. 1. Mean percent ($\pm$SE) EAGs to frontalin and analogs by male *D. frontalis*. N = 4/compound. All compounds presented as 10 μg on filter paper. Standard = frontalin. See Table 1 for compound name.

< 0.05) than response to 5-methyl-frontalin (compound 7), indicating a greater level of receptor specificity for a methyl in the 1 position than in the 5 position. By comparison, the level of response to the 7-methyl-frontalin compounds (compounds 5 and 6) was intermediate between response to compounds 3 and 7, but not significantly different.

Laboratory Bioassays. Both male and female beetles responded to all of the compounds, and there were no significant differences between the sexes for a given compound (Figure 2). As expected, response to frontalin was significantly greater ($P < 0.05$) than to any of the other compounds, and response to compound 8 was significantly less than to the other compounds. Response to compound 3 was not significantly different from response to the other methyl-

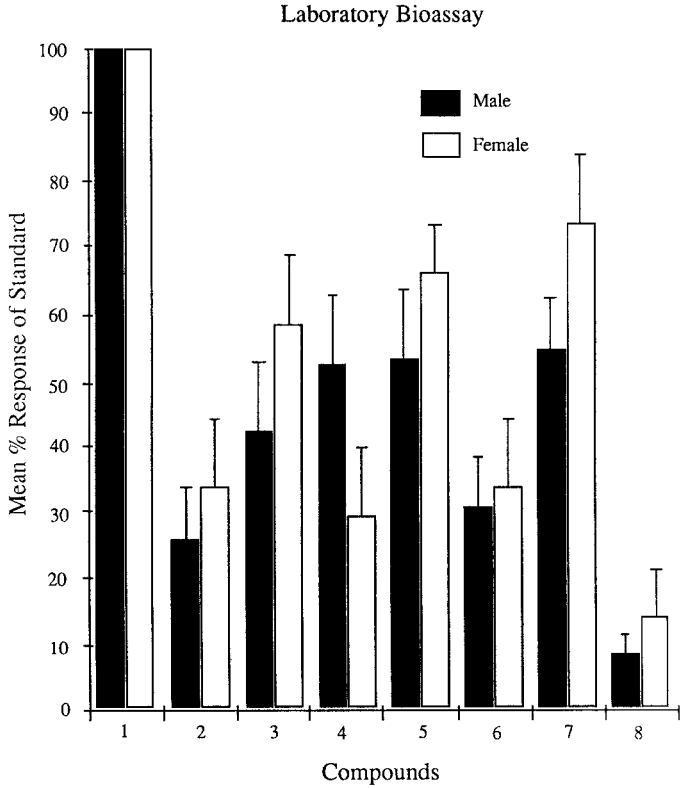

FIG. 2. Mean percent response (±SE) to frontalin and analogs by male and female *D. frontalis* in a laboratory bioassay. $N = 50$ beetles/compound/sex. All compounds presented at 1 μg/min. Standard = frontalin. See Table 1 for compound name.

ated compounds (except frontalin), indicating that a methyl in position 1 was not as significant to behavioral response in the bioassay as it appeared to be in receptor response. In fact, the absence of significant differences in response to compounds 3, 4, 5, and 7 indicate that the position and number of methyl groups (other than in the frontalin structure) are not critical to the walking response in the laboratory bioassay.

Field Tests. Significantly more *D. frontalis* were caught in response to frontalin than to any of the analogs (Figure 3). Of the analogs, only compound 2 caught numbers of beetles significantly different ($P < 0.01$) from the blank ($\bar{X} = <1$, $\bar{X} = 2$) and turpentine only ($\bar{X} = 1$, $\bar{X} = 2$), male and female, respectively. Obviously, any structural modification to frontalin greatly reduced or eliminated its attractiveness to flying populations of *D. frontalis*.

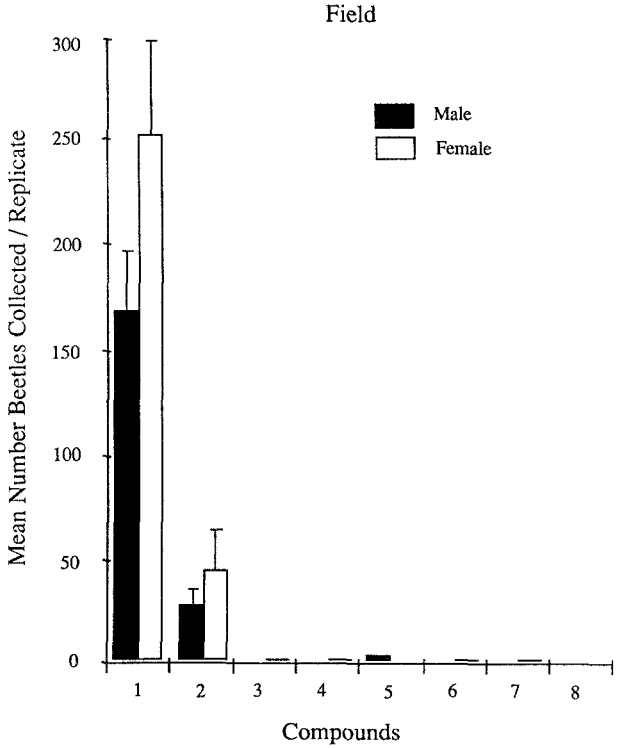

FIG. 3. Mean number (±SE) of male and female *D. frontalis* caught in traps baited with frontalin and analogs. Data from eight 3- to 4-day replicates. All compounds released with turpentine as a host odor. See Table 1 for compound name.

CONCLUSION

Any modification to the structure of frontalin significantly reduced antennal olfactory and behavioral response in *D. frontalis*. Similar findings were reported for the structural activity relationships of pheromones in several lepidopterous species (Payne, 1969; Roelofs and Comeau, 1971; Gaston et al., 1972; Roelofs, 1977).

The results show that *D. frontalis* possesses receptors capable of responding to analogs of frontalin. However, whether or not all of the analogs interact with the same receptors as frontalin is not known. Single-cell studies will be required to provide that information. It is likely that compound 2 does interact with the receptors for frontalin since the compound was attractive to natural populations of the beetle. The fact that the other analogs elicited behavioral responses in the laboratory bioassay, but not in the field, leads to the speculation that the compounds might interact with receptors that function in close range olfactory behaviors such as might occur on the host tree surface.

Acknowledgments—The authors thank Dr. M.T. Smith, Texas A&M, for review of the manuscript, and Bruce Buie, Texas A&M, for assistance in the field test.

ASTRINGENCY OF DOUGLAS-FIR FOLIAGE IN RELATION TO PHENOLOGY AND XYLEM PRESSURE POTENTIAL

JOHN D. HORNER

Department of Biology
University of New Mexico
Albuquerque, New Mexico 87131

(Received April 27, 1987; accepted June 30, 1987)

Abstract—Astringency (tannin content) of Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] foliage was examined in relation to phenology and water status. Foliage was sampled from control trees, trees on south-facing slopes, and trenched trees prior to budbreak and at periods of two, six, and 12 weeks after budbreak. Astringency of prebudbreak foliage from untrenched trees was comparable to that of mature foliage. Foliage expansion was accompanied by dilution of the tannin content. Percent relative astringency of control trees was significantly and positively related to the absolute value of predawn xylem pressure potential, while this relationship was negative for trees in the south-facing group. Coefficients of determination for the relationship between astringency and predawn xylem pressure potential were high (0.67 and 0.79 for the control and south-facing groups, respectively). Astringency of foliage from trees in the south-facing group also was affected significantly by daytime xylem pressure potential. Astringency of foliage from trees in the control and south-facing groups was not significantly related to tissue age, while that from trenched trees was significantly related only to age. Results demonstrate that water status is a better predictor of foliage astringency than is tissue age in unperturbed trees of this species and that, depending on the magnitude and/or timing of water deficits, opposite relationships between astringency and xylem pressure potential can be observed.

Key Words—Astringency, Douglas-fir, moisture stress, phenology, polyphenols, *Pseudotsuga menziesii*, tannins, xylem pressure potential.

INTRODUCTION

Herbivores and pathogens may be affected by tannin content of foliage (Feeny, 1976; Rhoades and Cates, 1976), which in turn may be affected by both phe-

0098-0331/88/0400-1227$06.00/0

nology and environmental stress. Tannin concentration is often higher in mature than in immature leaves (Dement and Mooney, 1974; Feeny, 1970; Feeny and Bostock, 1968; Mooney et al., 1983; Tempel, 1981). The lower concentration in immature tissue has been suggested to result from compartmentalization problems, potential for autotoxicity, physiological constraints imposed by source and sink strengths, and/or lower predictability of the tissue to herbivores (Feeny, 1976; Rhoades and Cates, 1976). In many perennial plants, leaf buds are produced months before foliage expansion and potentially are exposed to herbivores for long periods. Unexpanded foliage in leaf buds represents a large potential source of carbon gain and should be well defended. In plants with a favorable carbon balance, such as those with large reserves and/or the capacity to photosynthesize throughout the year, unexpanded foliage in buds could contain relatively high tannin contents if compartmentalization and autotoxicity problems do not prevent it. Therefore, both unexpanded and mature foliage may have higher concentrations of tannins than rapidly expanding foliage. The tannin content of foliage in buds rarely has been studied (but see Crankshaw and Langenheim, 1981).

In addition to phenological change, tannin content of plant tissues also can vary in response to such environmental stresses as water deficits. Most reports on the relationship between tannin content and water status have been implicit, with no measure of plant water status. For instance, the tannin content of cotton (*Gossypium hirsutum*) leaves has been correlated with the frequency of irrigation (Guinn and Eidenbock, 1982). Few studies have attempted to correlate foliar tannin content with indices of water status such as xylem pressure potential (see Gershenzon, 1984). Since such factors as stomatal conductance, photosynthesis, use of storage reserves, and growth are affected differentially as moisture stress progresses, the magnitude of stress may affect the response of plants to moisture stress (Salisbury and Ross, 1978; Waring and Schlesinger, 1985). In addition, prior exposure may have an effect: plants that regularly experience water deficits may exhibit physiological adaptations and respond differently to a given level of stress than plants that have not been previously stressed. Therefore, the duration as well as the magnitude of stress may affect the response of a plant. Lastly, since water relations in many habitats change seasonally, it is often difficult to separate the relative effects of tissue age and water status on tannin content of tissues (Tempel, 1981).

The objectives of this study were: (1) to examine the phenological patterns that occur in astringency of prebudbreak and expanding foliage of Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco]; (2) to ascertain whether tissue age or plant water status is a better predictor of foliage astringency; and (3) to identify differences in the effects of magnitude and duration of water deficits on foliage astringency. Results indicate that xylem pressure potential is a better predictor than tissue age of foliage astringency in unperturbed trees and that opposite

relationships between astringency and xylem pressure potential can be observed depending on the magnitude and/or timing of water deficits.

METHODS AND MATERIALS

Study Site. The study site was located in a canyon in the Jemez Mountains, Santa Fe National Forest, New Mexico (35° 54′ N, 106° 42′ 30″ E). The median elevation of the canyon bottom was 2440 m (range 2375–2500 m). The dominant vegetation in the area was Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] and white fir (*Abies concolor* Lindl. and Gord.). Some Colorado blue spruce (*Picea pungens* Engelm.), ponderosa pine (*Pinus ponderosa* Laws.), quaking aspen (*Populus tremuloides* Michx.), and several oak (*Quercus*) species also occurred in the study area.

Field Methods. Twelve trees, eight in the canyon bottom and four on south-facing aspects, were selected along a 4-km section of the canyon. Study trees were similar in age, height, diameter at breast height, and increment in bole diameter over the previous five years (Table 1). Four of the bottomland trees served as controls. The other four bottomland trees were trenched at the dripline to a depth of 1 m in early June, 1980. The trenches were lined with polyethylene sheets and back-filled. The understory vegetation beneath the crown of each tree was removed, and the ground from bole to dripline was covered with polyethylene sheets. The plastic was used to prevent precipitation and throughfall from replenishing soil moisture. By so doing, it was hoped that these trees would gradually deplete the soil moisture and develop a water deficit, thus representing trees under a short-term moisture stress. It was assumed that the four trees on south-facing slopes had experienced a long-term moisture deficit.

Prior to budbreak, 55 buds were selected and tagged in the midcrown of the south-facing quarter of each tree. Selected buds were similar in length,

Treatment	Age (yr)[a]	Height (m)	DBH (cm)[b]	IBD (cm)
Control	36.8 ± 0.5	11.4 ± 0.4	22.4 ± 0.4	1.70 ± 0.1
South-facing	37.8 ± 1.7	12.1 ± 1.5	25.7 ± 3.1	1.28 ± 0.3
Trenched	35.0 ± 1.6	11.6 ± 1.7	21.4 ± 2.5	2.08 ± 0.3

[a] Values are mean ± SE. $N = 4$ in each case. Numbers in columns are not significantly different ($P > 0.05$).

[b] Abbreviations: DBH = diameter at breast height; IBD = increment in bole diameter over the previous five years.

amount of swelling (i.e., width) and distension of the bud scales. Current foliage was collected on June 13, June 26, July 25, and September 7, 1981. These dates corresponded to about three days prior to budbreak and periods of two, six, and 12 weeks after budbreak. Mature tissue produced during the previous year also was collected on June 13. On each sampling date, nine tagged buds (or the shoots developing from these buds) were clipped from each tree. The tissue was placed on ice in airtight plastic bags for transport to the laboratory. Tissue samples were frozen upon arrival at the laboratory.

Predawn xylem pressure potentials represent the minimum to which the water deficit can be reduced under conditions of minimum transpiration and are less variable than those measured during daylight hours. On the other hand, xylem pressure potential measurements obtained during the daylight hours can reveal the maximum water deficit experienced in the course of a day. It seems reasonable that either or both of these parameters might affect the physiology of trees. Xylem pressure potentials were measured on the distal 10 cm of a branch originating at about 3 m height using a Scholander pressure bomb. Daytime xylem pressure potentials were measured between 1300 and 1600 hr; only shaded sprigs were used. Predawn xylem pressure potentials were measured between 0100 and 0500 hr. Xylem pressure potentials were measured on all postbudbreak collection dates. Because of logistical problems, the data set from the first postbudbreak collection was very unbalanced. Therefore, only measurements from the last two collection dates were included in the analysis.

Laboratory Methods. Bud scales and twigs were removed and discarded prior to analysis. Foliage from three buds (shoots) per tree from each sampling date were dried at 60°C to determine the water content and dry weight.

The suggested ecological importance of tannins has been attributed to their capacity to form recalcitrant complexes with proteins and other substrates. Since correlations between astringency and estimates of tannin content obtained by other methods are insignificant or weak both within and between species (Horner, unpublished data; Martin and Martin, 1982), relative astringency determinations seem the best analytical methods to obtain the desired information in ecological studies (Martin and Martin, 1982). Foliage astringency was analyzed by the hemanalysis method of Schultz et al. (1981), except that the stock hemoglobin solution was prepared from fresh human blood and leaf tissue was ground under liquid nitrogen. Douglas-fir (and gymnosperms in general) apparently do not produce hydrolyzable tannins (see Haslam, 1981, for a general review); the condensed tannins of Douglas-fir have been partially characterized by Stafford and Cheng (1980) and Stafford and Lester (1980, 1981). Although a condensed tannin may have been the best choice for a standard, I was unable to obtain a condensed tannin standard of adequate purity. Therefore, percent relative astringency was calculated from a standard curve generated from the action of tannic acid (a hydrolyzable tannin) solutions of known concentration and

expressed as tannic acid equivalents (TAE). Use of tannic acid rather than a condensed tannin results in differences in values obtained but not in the trends observed (Horner, unpublished data). Total relative astringency of current shoot foliage was calculated from percent TAE and total dry mass of current shoot foliage. Because of the small mass of prebudbreak foliage, foliage was composited from two unopened buds per tree for analysis of prebudbreak tissue.

Data Analysis. Physical parameters of the trees of each experimental group were compared by one-way analysis of variance (ANOVA) (Zar, 1974). Predawn and daytime xylem pressure potentials were analyzed by two-way ANOVA. The factors for the two-way ANOVAs were date (two levels) and treatment (three levels). Differences between levels of a factor were identified by Duncan's multiple-range test.

Tannin data were analyzed in terms of both percent and total relative astringency of current shoot foliage. Percentage astringency data were normalized by arcsine transformation, and foliage weight data were normalized by log transformation before statistical analysis. Astringency data were analyzed by analysis of covariance, with treatment as a fixed class variable and both age and xylem pressure potential as concomitant variables (Sokal and Rohlf, 1981). Since an objective was to determine whether foliage astringency was better explained by age or xylem pressure potential, a forward stepwise regression technique for maximal r^2 improvement was employed. Selection criteria for entering into the model were an improvement in r^2 of 0.05 and a significant ($P < 0.05$) overall model.

RESULTS AND DISCUSSION

Phenological Patterns in Astringency. In all experimental groups, foliage percent astringency showed an initial postbudbreak decrease followed by a gradual increase (Figure 1a). Decreased concentration during foliage expansion could be due to a number of factors, including reduced or halted production of tannins or a dilution effect (i.e., the allocation to primary metabolites and growth exceeding that to tannins). Total relative astringency of current shoot foliage generally increased during the first six weeks after budbreak (Figure 1b). This indicates that production continued during foliage expansion and that the decrease in percent TAE observed during foliage expansion is due at least in part to a dilution effect rather than complete cessation of tannin production.

Relative to their mass, leaf buds represent disproportionately large potential sources of carbon gain. As a result, they should be relatively valuable to the plant. Since tannins appear to be important in reducing herbivory in Douglas-fir (Walters and Stafford, 1984), it is interesting that relative astringency levels were high in prebudbreak foliage of untrenched trees. Percent relative

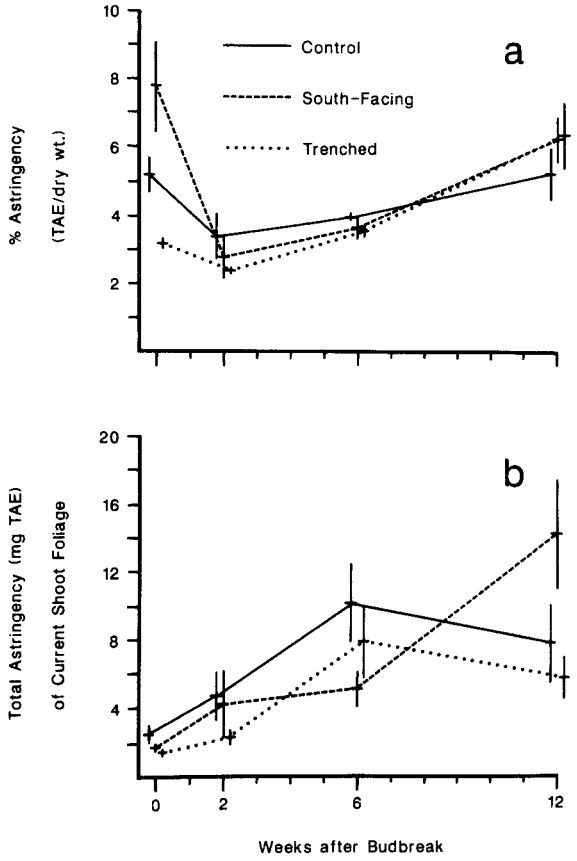

FIG. 1. Seasonal changes in (a) % relative astringency (tannic acid equivalents; TAE) and (b) total relative astringency of current shoot foliage from trees in control, south-facing, and trenched experimental groups. Horizontal bars are means and vertical bars are 2 SE. Collections at each time interval were made on the same day; data for each treatment were separated horizontally to minimize overlap.

astringency of prebudbreak foliage from trees in the control and south-facing groups (5.18 $\pm$ 0.48 and 7.83 $\pm$ 1.31, respectively; mean $\pm$ SE; Figure 1a) was comparable to that in mature foliage (5.73 $\pm$ 0.54 and 6.11 $\pm$ 0.57, respectively; $P > 0.05$ between prebudbreak and mature foliage within the control and south-facing groups). High tannin content in immature foliage may be possible in plants with a favorable carbon balance, such as those that are slow growing, capable of photosynthesizing throughout the year, or that have adequate storage reserves (Crankshaw and Langenheim, 1981; Dement and

Mooney, 1974; Mooney et al., 1983). Autotoxicity has been suggested as a reason for low tannin concentrations in immature foliage (Feeny, 1976), but this is obviously not the case in prebudbreak foliage of untrenched Douglas-fir. In contrast to unperturbed trees, tannin content of prebudbreak foliage from trenched trees was significantly lower than that of mature foliage (3.21 $\pm$ 0.15 and 7.12 $\pm$ 0.68, respectively; $P > 0.05$).

Treatment-Related Differences in Xylem Pressure Potential. ANOVA revealed significant treatment effects on both predawn ($P < 0.0001$) and daytime ($P > 0.03$) xylem pressure potentials (Table 2). However, differences between the experimental groups were not consistent throughout the season, as indicated by significant date $\times$ treatment interactions ($P > 0.0002$ and $P < 0.02$ for predawn and daytime measurements, respectively). During July, both predawn and daytime xylem pressure potentials of control trees were significantly less negative than those of trees on south-facing aspects. In September, on the other hand, the average daytime xylem pressure potential of trees on south-facing slopes was significantly less negative than that of control trees, while predawn xylem pressure potentials were not significantly different. Although the xylem pressure potentials of trenched trees were never significantly different from those of control trees, the former were consistently lower (more negative) than the latter (Table 2). It therefore appears that trenching had not yet elicited significantly decreased water potentials by the end of the first growing season following trenching. Predawn and daytime xylem pressure potentials were not significantly correlated ($P > 0.10$). This could have resulted from different seasonal patterns of soil moisture recharge in the experimental groups.

Astringency in Relation to Tissue Age and Xylem Pressure Potential. Analysis of covariance revealed significant ($P > 0.05$) treatment effects on foliage

TABLE 2. SEASONAL AND TREATMENT-RELATED VARIATION IN XYLEM PRESSURE POTENTIAL

	Xylem pressure potential (—bars)[a]		
Sampling	Control	South-facing	Trenched
Predawn			
July 25	3.8b $\pm$ 0.2 (4)	8.5a $\pm$ 1.0 (3)	5.4b $\pm$ 0.4 (4)

astringency. Since xylem pressure potential was significantly affected by treatment, and since it was hypothesized that the treatments might elicit different effects on production of astringency, treatments were separated for stepwise regression analysis. Inasmuch as predawn and daytime xylem pressure potentials were not significantly correlated, the regression analysis included both predawn and daytime xylem pressure potential measurements as well as age. The percent relative astringency of foliage from trees in both the control and south-facing groups was strongly affected by predawn xylem pressure potential (Table 3). The coefficients of determination were surprisingly high. Interestingly, while the relationship between astringency and the absolute value of predawn xylem pressure potential was positive for control trees, this relationship was negative for trees in the south-facing group. The percent relative astringency of foliage from trees in the south-facing group also was affected significantly by daytime xylem pressure potential, but in this case the relationship was positive. Total astringency of current shoot foliage was not significantly related to either tissue age or xylem pressure potential in any treatment.

The differences between the control and south-facing groups in the relationship between xylem pressure potential and foliage astringency may have been due to differential effects on carbon gain versus carbon allocation patterns brought about by differences in water status during a critical growth period. Mild water deficits may reduce foliage expansion and growth, while more extreme water deficits can reduce stomatal conductance and carbon acquisition (Salisbury and Ross, 1978). Therefore, a positive relationship between the absolute value of xylem pressure potential and astringency, as observed in the control group, may indicate an effect on carbon partitioning between primary and secondary metabolites caused by a reduction in growth. An inverse relationship may indicate a reduction in stomatal conductance and carbon fixation. Both predawn and daytime xylem pressure potentials of trees in the south-facing

TABLE 3. SUMMARY OF SIGNIFICANT STEPWISE REGRESSION STATISTICS FOR ASTRINGENCY ON AGE AND XYLEM PRESSURE POTENTIAL[a]

Treatment	Step	Variable entered[b]	Total P	Total r^2	Slope[c]	Intercept
Control	1	Predawn XPP	0.01	0.67	1.06	−0.09
South-facing	1	Predawn XPP	0.003	0.79	−0.82	10.71
	2	Daytime XPP	0.0008	0.94	0.46	−2.75
Trenched	1	Age	0.02	0.61	0.30	2.41

[c] For ease of interpretation, slopes and intercepts are given for untransformed regression equations using single independent variables.

group were significantly more negative than those in the control group during the middle of the growing season (July 25; Table 2). The inverse relationship between tannin content and absolute value of predawn xylem pressure potential observed in trees in the south-facing group may have been due to a reduction in carbon gain. Unfortunately, no measurements of stomatal conductance were made in this study. Wagner (1986) also reported a decrease in tannin content of *Pinus ponderosa* Dougl. ex Laws seedlings stressed with polyethylene glycol. The positive effect of daytime xylem pressure potential on tannin content observed in the south-facing group is more difficult to explain. It suggests a contribution of reduced foliage expansion related to more negative daytime xylem pressure potentials in this group. An alternative to the carbon acquisition/allocation hypothesis might be that there were unmeasured correlates to xylem pressure potential that differed between control trees and those on south-facing aspects.

Outbreaks of herbivorous insects often occur during periods of plant environmental stress, and this has been suggested to be the result of reduced defenses during these periods (Rhoades, 1979). Results from this study suggest that the timing and magnitude of water deficits may be important factors affecting the production of plant chemical defenses.

In contrast to the other two experimental groups, only age had a significant effect on relative astringency of trenched trees (Table 3). Several lines of evidence suggest that trenching produced effects other than the desired effect on water relations. First and most obviously, neither predawn nor daytime xylem pressure potentials of trenched trees were significantly different from those of controls. Second, unlike unperturbed trees, the foliar tannin content of trenched trees showed no significant relationship to xylem pressure potential. Lastly, the tannin content of prebudbreak foliage from trenched trees was significantly lower than that of mature foliage, unlike the relationships observed in the control and south-facing groups. Together, these data suggest that trenching may have had other effects. Reduced moisture and elevated temperatures beneath the plastic might have altered nutrient mineralization (Floate, 1970; Swift et al., 1979) and availability to trenched trees. Additionally, despite an effort not to cut large roots during trenching, some root cutting may have occurred and could be expected to have effects other than diminishing water uptake. Because of probable undesired side effects brought about by trenching, this study did not adequately test the effects of duration of water deficits. Wagner (1986) also found somewhat anomalous results in foliar tannin content of trenched trees, and I reiterate his caveat toward the use of trenching as a means for inducing water stress in field studies.

Final Considerations. It should be mentioned that differences in astringency may not be directly related to differences in carbon allocation to tannins. Beart et al. (1985) have shown that chain length and astringency of hydrolyzable

tannins are not necessarily directly correlated. Although a similar phenomenon has been suggested to occur with condensed tannins (Goldstein and Swain, 1963; White, 1957), this has not been directly demonstrated. Furthermore, qualitative as well as quantitative differences in tannin composition may affect astringency (Asquith and Butler, 1986; Zucker, 1983).

Conclusions. Astringency of prebudbreak foliage in unperturbed trees was comparable to that of mature tissue. The postbudbreak decrease in percent relative astringency appeared to be due at least in part to a dilution effect rather than a cessation of tannin production. Percent astringency of current shoot foliage of unperturbed trees was better explained by the absolute value of predawn xylem pressure potential than by tissue age. The relationship was positive for control trees but negative for trees on south-facing aspects, suggesting differences in carbon acquisition and allocation related to magnitude and/or timing of water deficits.

(Received January 5, 1987; accepted July 7, 1987)

Abstract—Two plant-derived allelochemicals, berberine and α-terthienyl (α-T), were tested for their effects on the European corn borer, *Ostrinia nubilalis*, and its endoparasitoid *Diadegma terebrans*. The compounds were administered to the host insect in meridic diets, and the responses of the host larvae and parasitoids reared from treated hosts were measured in terms of growth parameters and survival. In *O. nubilalis*, survival to pupation and adult emergence were reduced significantly by the inclusion of berberine and α-T in larval diets at a concentration of 100 μg/g. However, in the parasitoid, adverse effects were much more apparent with the α-T treatment than with the berberine treatment. α-T and one of its metabolites were found in host larvae and in emerged adult parasitoids and their cocoons. Berberine residues were not detected. The implications of these responses to compounds of widely differing physiological properties are discussed with reference to host-plant resistance and biological control.

Key Words—Third trophic level interaction, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, *Diadegma terebrans*, Hymenoptera, Ichneumonidae, α-terthienyl, berberine, allelochemicals.

INTRODUCTION

The effects of secondary plant substances on the parasitoids of phytophagous insects have been the subject of few publications. Thurston and Fox (1972) demonstrated that nicotine in the diet of the tobacco hornworm, *Manduca sexta* (L.), reduced the emergence of *Cotesia congregata* (Say) (=*Apanteles congregatus*). Campbell and Duffey (1979, 1981) demonstrated that α-tomatine in the host

0098-0331/88/0400-1239$06.00/0

diet had negative effects on *Hyposoter exiguae* (Viereck), a parasitoid of the tomato fruitworm, *Heliothis zea* (Boddie). Apparently, α-tomatine was not directly toxic, but rather produced these effects by imparing sterol utilization.

The effects of nicotine on two parasitoids—*C. congregata* (a parasitoid of *M. sexta*) and *Hyposoter annulipes* (the parasitoid of the fall armyworm, *Spodoptera frugiperda* [Smith],—were studied in detail by Barbosa et al. (1986). As found by Thurston and Fox (1972), they observed reduced emergence for both parasitoid species. They also reported that cocoon formation was inhibited. In *H. annulipes*, the toxic effects of nicotine were more severe; sublethal effects were also apparent, including prolonged larval development and reduced adult size.

Toxic effects on the third trophic level were also recently reported for the tomato phenolic rutin (Duffey et al., 1986). In this case, the lethal and sublethal effects of *H. exiguae* depended on the nutritional quality of the host's diet, particularly with respect to levels of protein. For each of the two noctuid hosts *H. zea* and *Spodoptera exigua* (Hbn.), specific levels of protein in host diets were found to enhance the expression of toxicity in the parasitoids.

Nicotine (Barbosa et al., 1982, 1986) and α-tomatine (Campbell and Duffey, 1979) were shown to persist in the host and were detected in emerged parasitoids reared from alkaloid-fed hosts. Carotenoids (Rothschild et al., 1977) and pyrrolizidine alkaloids (Benn et al., 1979) from food plants have also been found to persist in and travel through herbivorous insects into their parasitoids.

Investigations of three trophic level interactions have focused on the effects of one particular toxin within these host–parasitoid food chain models. We have examined the physiological effects of two secondary plant substances with different physiological properties and biological sites of action on the European corn borer, *Ostrinia nubilalis* (Hübner) (Pyralidae), and its endoparasitoid *Diadegma terebrans* (Gravenhorst) (Ichneumonidae). *O. nubilalis* is a polyphagous species (Caffrey and Worthley, 1927; Hodgson, 1928), and as such has been exposed to a wide range of allelochemicals during its evolutionary past.

The two compounds used in this study were berberine (Figure 1), an iso-

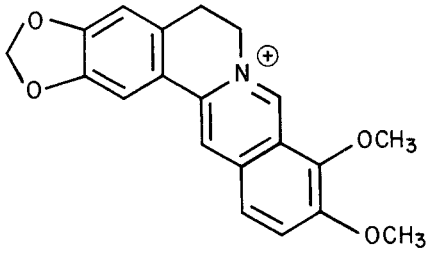

FIG. 1. Molecular structure of berberine.

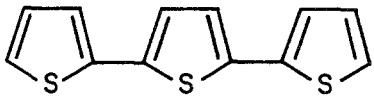

FIG. 2. Molecular structure of α-terthienyl.

quinoline alkaloid found in at least 26 genera of 10 plant families (Suffness and Cordell, 1985), and α-terthienyl (α-T) (Figure 2), a thiophene characteristic of numerous genera of the Asteraceae (Bohlmann et al., 1973), including most genera of the subtribe Pectinidae (Downum et al., 1985). The two compounds are different with respect to polarity: berberine is a quaternary ammonium compound (cationic), while α-T is highly lipophilic (McLachlan, 1984). Berberine-containing plants are not normally attacked by *O. nubilalis*, while plants containing thiophenes are among those preferentially attacked by the insect (Caffrey and Worthley, 1927; Hodgson, 1928). The very different physical properties of berberine and α-T provide a basis for studying a range of responses possible in one host–parasitoid system.

METHODS AND MATERIALS

Growth and Survival Studies with Ostrinia nubilalis. A laboratory colony of *O. nubilalis* was maintained by using the methods of Guthrie et al. (1971) except that corncob grits were added to the diet used for routine culture maintenance. The diets used in the experiments were prepared by mixing berberine (dissolved in water) or α-T (95% ethanol solution added to α-cellulose powder and solvent evaporated) to warm, unsolidified meridic diet at concentrations of 10, 31, and 100 μg/g (wet weight). These concentrations are realistic with respect to natural concentrations in plants and were selected after preliminary feeding tests in which chronic effects on *O. nubilalis* could be demonstrated. Control diets were prepared with an appropriate aliquot of water (for the berberine experiments) or α-cellulose (for the α-T experiments). Corncob grits were not included in these diets in order to ensure uniform distribution of the compounds throughout the media.

Experimental larvae were reared in a growth chamber under the following conditions: photoperiod 18:6 hr (light–dark) with a day–night temperature regime of 26.5°C/19°C and a constant relative humidity of 85%. Because both of the experimental compounds are potentially phototoxic, conditions of subdued photosensitizing ultraviolet (UV) illumination were used. Lighting within the environmental chamber was provided by four 20-W solar-simulating flu-

orescent lamps (Vitalight 48T12 U.H.O.) separated from the chamber by a 3-mm sheet of Plexiglas. The resultant light intensity was measured to be 7.6 W/m, with a UV cutoff at 390 nm.

Neonate *O. nubilalis* were placed on the appropriate treated or control diets in glass scintillation vials plugged with cotton wool. After eight days, 10 surviving larvae were randomly chosen from each treatment and placed in individual vials with fresh diet. Subsequently, every four days, vials and diets were changed. The larvae were observed daily and growth parameters were recorded. This procedure was replicated three times, such that data was generated from 30 individuals per treatment.

Growth and Survival with Diadegma terebrans. *O. nubilalis* were reared from hatching on the variously treated and control diets until they were of the instar and weight range of control larvae at age 9 days. At this time, 100 second-instar larvae ranging in weight from 2 to 7 mg were selected from each treatment and placed on 25–30 1 cm pieces of chopped corn stalk (Silver Queen, Stokes Seeds Ltd.) in a round plastic rearing box (18.3 cm diameter, 7.8 cm high). These larvae were allowed to feed and burrow into the corn overnight. The presence of host-plant tissue provided necessary visual and chemical cues for parasitization by *D. terebrans*.

The following morning, the dish with the corn and larvae was placed in the *D. terebrans* rearing cage for 1 hr, which enabled the female wasps to "saturate" the larvae and parasitize all acceptable hosts. The parasitization occurred within a controlled environment chamber (25°C and 70% relative humidity), with a high light intensity (8 W/m^2) provided by six 20-W solar-simulating fluorescent lamps (Vitalight 48T12 U.H.O.). The *O. nubilalis* larvae were then removed from the corn and returned to their appropriate diets in vials. A 5-cm square of paper towelling was placed in each vial above the diet cube. This provided a dry place within which the emerging *D. terebrans* could pupate. Pupae were held in gelatin capsules until adult emergence. Growth parameters were recorded.

As the different treatment larvae were parasitized within one week of each other, separate control groups (100 larvae each) were run for each treatment. Control groups were parasitized one day prior to the treated groups. A full day was left between treatment and control parasitizations in order to allow the female wasps to feed and replenish their ovarioles with mature eggs. In this way, at least 30 larvae were parasitized in each of the treatment and control groups.

Analysis for Body Burden of Compounds in Host Larvae and Parasitoids. The analysis for body burden of berberine and α-T was performed on second- and third-instar *O. nubilalis* larvae which had been reared since eclosion on treated diets and then allowed to feed on fresh corn stalks for 24 hr in order to clear their guts of the compounds. *D. terebrans* adults and cocoons (including the fluid meconia) were collected on the day of adult emergence. Samples of

corn borer larvae, wasps, and cocoons were weighed and preserved in sample groups of three individuals in 2 ml HPLC grad methanol and held at −4 to −6°C until extraction. Three groups of each type of sample were analyzed.

The extraction protocol was as follows. Each sample was thoroughly ground using a 15-ml Wheaton homogenizer. An additional 3 ml methanol was added, and the slurry was futher homogenized. The suspension was refrigerated for two days at 4°C to allow the compounds to dissolve from the insect material. Samples were then vortexed and centrifuged for 10 min at 500*g* to remove macromolecular debris. The supernatant was evaporated to dryness under vacuum using a rotary evaporator. HPLC grade acetonitrile (0.5 ml) was added to the dried sample, and this was then sonicated for approximately 1 min to ensure that the compounds absorbed to the interior of the vials would be dissolved. Samples were then filtered using a millipore filter (Schleicher and Schuell, 0.45 μm), and 20-μl aliquots were analyzed by HPLC.

HPLC was performed using a Beckman system (Series 332), equipped with a model 165 variable wavelength UV–visible light detector. Reversed phase (C_{18}) columns, 25 cm × 4 mm internal diameter, packed with Ultrasphere octadecylsilicate (ODS), pore size 5 μm, were used for both compounds. The ion-pairing system for berberine consisted of 50% 0.1 M trichloroacetic acid (aqueous), buffered to pH 2.15 with saturated NaOH, and 50% acetonitrile, run isocratically at 1 ml/min. Berberine was monitored at 343 nm, one of the maximum absorbance wavelengths for the compound, and the minimum level of detection for this compound was 1.8 ng in a 20-μl injection. The retention time was 11.2 min.

Alpha-T was run isocratically with 85% acetonitrile and 15% water, and monitored at 350 nm. The minimum level of detection for this compound was 0.16 ng in a 20-μl injection, and the retention time under these conditions was 7.0 min. Insect extracts run in both solvent systems yielded very clean chromatograms (no more than two peaks), and the compound (if present) was readily distinguishable. Control larvae, wasps, and pupal cases were also extracted and analyzed in both solvent systems, to ensure that peaks in treated samples were not present in the controls. Untreated insects were also homogenized after injecting them with known amounts of berberine and α-T; the extraction efficiency was 80% for both compounds.

RESULTS AND DISCUSSION

The investigations with the two compounds under study demonstrate that the biological activity of secondary plant substances may be expressed differently in the host than in the parasitoids. The growth and survival studies with *O. nubilalis* alone on diets containing berberine did not demonstrate significant changes in the duration of the developmental stages (Table 1). A significant

[a]For growth parameters, males (M) and females (F) were analyzed separately. Time measurements were subjected to the Kruskal-Wallis test ($P = 0.05$). Weight measurements were subjected to Duncan's multiple-range test: Means in columns followed by the same letter are not significantly different ($P = 0.05$). The chi square test was applied to data expressed as percentages: significant differences from the controls ($\alpha = 0.05$) are denoted by an asterisk.

reduction in female pupal weight was observed in the 100 μg/g berberine treatment compared to the controls. However, the weights of surviving adults were not significantly different between any of the concentrations tested. Although sublethal effects on growth parameters were not highly pronounced with berberine in the diet, survival to pupation and adult emergence was significantly decreased in the 100 μg/g treatment.

With α-T in the diet, sublethal effects on *O. nubilalis* alone were more obvious (Table 2). Mean time to adult emergence was significantly prolonged for females fed 31 μg/g α-T. With the 100 μg/g treatment, the duration of the developmental stages was increased significantly for both males and females. In addition, pupal and adult weights were significantly reduced with this treatment. These results confirm and extend observations first made by Champagne et al. (1986): the growth rate of *O. nubilalis* larvae was significantly reduced with 100 μg/g α-T in the diet. in the present study, survival to pupation and adult emergence of *O. nubilalis* was also significantly reduced with 100 μg/g α-T in the diet.

Parasitoids reared from hosts fed diets containing berberine did not exhibit sublethal effects in their growth (Table 3), except for an increase in mean pupal weight in the 31 μg/g treatment group. Although no significant differences from the controls were apparent in survival to pupation on any of the berberine treatments, survival to adult emergence was significantly decreased with 100 μg/g berberine in the host's diet. The parasitoids reared from hosts fed 100 μ/g berberine did not incur as much mortality (significantly different by the chi square test at $\alpha = 0.05$) as did the unparasitized host larvae (Table 1), which suggests that the parasitoids were less susceptible than their hosts to the effects of berberine.

Parasitoids reared from hosts fed α-T at concentrations of 10 and 31 μg/g in the diet were similar to the controls in the growth parameters of surviving insects (Table 4). However, the male parasitoids reared from hosts fed 100 μg/g α-T were significantly smaller than the controls. No females were produced in this treatment group. Mean time to pupation and adult emergence was not significantly affected by any concentration of α-T. Survival to adult emergence was somewhat reduced with the 31 μg/g treatment ($P > 0.90$ by the chi square test). However, significant mortality occurred with 100 μg/g α-T in the host diet. The mortality caused by 100 μ/g α-T was significantly higher (by the chi square test at $\alpha = 0.05$) in *D. terebrans* than in the unparasitized hosts. The parasitoid was apparently more susceptible to the thiophene than its host.

The chromatographic analyses for berberine did not show any evidence of the compound either in host larvae (removed to corn for 24 hr) or emerged wasps and cocoons. In contrast, α-T and/or a metabolite were detected in groups of each of the sample types analyzed (Tables 5 and 6). Despite the differences between the detection efficiencies of berberine and α-T (1.8 and 0.16 ng in a

	(0.34)	(0.29)	
Cocoons + meconia	4.17	0.23	3.19
	(2.97)	(0.023)	(1.68)

[a] Units are in μg/g insect material. Values are means of three samples. Standard deviations are in parentheses. ND = not detected at lowest level of detection.

20-μl injection, respectively), an estimated minimum body burden of 1.9 μg berberine per gram insect material would be detectable by HPLC. This was not present even in the pupal cases, where waste products are often execreted as meconia by the metamorphosing parasitoids. The absence of berberine in insect samples is not surprising, considering that berberine is a quaternary ammonium compound and likely to be rapidly excreted (Bodor et al., 1981). The concentration of berberine in the host hemolymph would probably be much less than was originally ingested by the host.

The absence of berberine in insect samples is consistent with the data pertaining to the biological effects of berberine (Tables 1 and 3). Although survival was decreased for both host and parasitoid, the mortality in *D. terebrans* was not as severe as that observed in unparasitized *O. nubilalis*. In fact, mortality during the parasitoid's internal (feeding) stages was not significantly different

TABLE 6. RELATIVE QUANTITIES OF α-TERTHIENYL METABOLITE IN INSECT SAMPLES[a]

	(1.07)	(0.32)	(2.80)
Cocoons + meconia	9.75	12.75	8.25
	(6.72)	(8.17)	(6.10)

[a] Values are in absorbance units $\times 10^{-5}$/mg insect material, representing the mean of three samples. Standard deviations are in parentheses.

between the berberine treatments and the controls. This suggests that berberine may have indirectly affected *D. terebrans* by reducing the quality of the host as a food source (Duffey et al., 1986), but this was only manifested during metamorphosis in the group reared from hosts fed diets containing 100 μg/g berberine. The results with α-T demonstrate that this compound is clearly capable of accumulating in insect tissues, which is to be expected of a highly lipophilic xenobiotic. Although *O. nubilalis* larvae reared on diets containing 10μg/g α-T did not appear to sequester the thiophene, α-T was present in the larvae with 31 and 100 μg/g α-T. The level of α-T in the larvae fed 100 μg/g α-T was relatively low compared to the 31 μg/g samples. Apparently, less α-T was accumulating in the 100 μg/g-fed larvae, and this may have been the result of reduced feeding with this treatment. The 100 μg/g α-T has been previously shown to effectively deter feeding in *O. nubilalis* larvae (Champagne et al., 1986).

Alpha-T was recovered from parasitoid adults reared from hosts fed 10 and 31 μg/g α-T but not from hosts feed 100 μg/g α-T. Cocoons from all three groups contained α-T. The levels of α-T were relatively high in the cocoons of the parasitoids in the 10 and 100 μg/g treatments compared to the levels of the compound in the emerged wasps. This is similar to the findings of Barbosa et al. (1986) with nicotine: the parasitoids apprently dispose of such toxins via the cocoon silk and meconium.

The presence of α-T in the emerged parasitoids and cocoons suggests that the thiophene could have had a direct toxic effect on *D. terebrans*, in contrast to the indications of the data on berberine. Although the highest parasitoid mortality occurred with 100 μg/g α-T in the host diet, the surviving wasps did not contain detectable levels of α-T. This was a small and relatively resilient segment of the experimental population, which may have been inherently superior in their ability to metabolize α-T.

In addition to detecting the parent compound in the insects treated with α-T, a polar metabolite of α-T was found (Table 6). The compound has a typical thiophene spectrum, with a retention time of 1.7 min under the conditions of this HPLC system. As the structure and extinction coefficient of the metabolite have not yet been elucidated, absolute quantification was not possible. However, relative quantities (based on absorption at 350 nm) have been determined (Table 6). Relatively higher quantities of the metabolite were found in the cocoon samples than in the adult parasitoids. This is further evidence for the suggestion of Barbosa et al. (1986) that wastes from host-ingested allelochemicals are shunted by the parasitoid into the cocoon silk and meconia.

In the present study, the adverse effects on immature *D. terebrans* were much more severe with the highly lipophilic thiophene, α-T, than with the polar alkaloid, berberine, even though the parasitoid was capable of detoxifying and possibly metabolizing α-T. This suggests that pest management startegies which

take advantage of secondary plant substances for breeding resistance could run into problems with compounds which tend to be lipophilic (reminiscent of the pesticide bioaccumulation problem). On the other hand, an amphiphilic compound such as berberine may be relatively innocuous for the parasitoid, even though it can dramatically reduce host survival.

It is clear from this and other studies that allelochemical effects on herbivores do not necessarily reflect the consequences of these substances on the third trophic level. Novel allelochemicals with potential for agricultural applications should be examined for effects on natural enemies in order to assess their real usefulness for pest management strategies involving biological control.

Acknowledgments—*O. nubilalis* egg masses were periodically supplied by M. Hudon (Agriculture Canada, St. Jean, Quebec) and D. McLeod (Agriculture Canada, London, Ontario). The *D. terebrans* colony originated from the laboratory of R.L. Jones (Department of Entomology, University of Minnesota, St. Paul, Minnesota). The authors are grateful to Paul Swedenborg (of same laboratory) for his assistance. Synthetic α-t was provided by P. Morand (Department of Chemistry, University of Ottawa). S.S. Duffey and M.B. Isman reviewed the manuscript. This work was supported by NSERC.

Abstract—Susceptible and resistant tomato cultivars were assayed for root tomatine concentrations at different developmental times. No correlation between high tomatine levels and resistance toward *Meloidogyne incognita* was apparent. In plants infected with nematodes, tomatine in the roots was the same as in uninfected controls. Tomatine concentration, as measured by bulk analysis, does not appear to play an important role in resistance toward the nematode studied.

Key Words—Tomatine, nematode resistance, *Lycopersicon esculentum*, *Meloidogyne incognita*, host-plant resistance.

INTRODUCTION

The steroidal glycoalkaloid α-tomatine (Figure 1) has been recognized as an allelochemical agent that imparts resistance in certain tomato varieties toward insect pests (Juvik and Stevens, 1982; Elliger et al., 1981) and fungal attack (Roddick, 1974). A report on the nematicidal effect of tomatine upon *Panagrellus redivivus* (Allen and Feldmesser, 1970) suggested that this alkaloid may be important in conferring nematode resistance as well. They also observed (Allen and Feldmesser, 1971) that a related glycoalkaloid, α-chaconine, which occurs in potato (*Solanum tuberosum*), was toxic to this nematode and that the pH dependence of toxic action showed the free base to be the form of the compound responsible for activity. This was also the case for tomatine; however, no attempt was made to correlate alkaloid levels with nematode resistance in vivo. A brief report (Okopnyi and Sadykin, 1976) stated that resistance to the nematode *Meloidogyne incognita* could be related to tomatine content in the

0098-0331/88/0400-1253$06.00/0

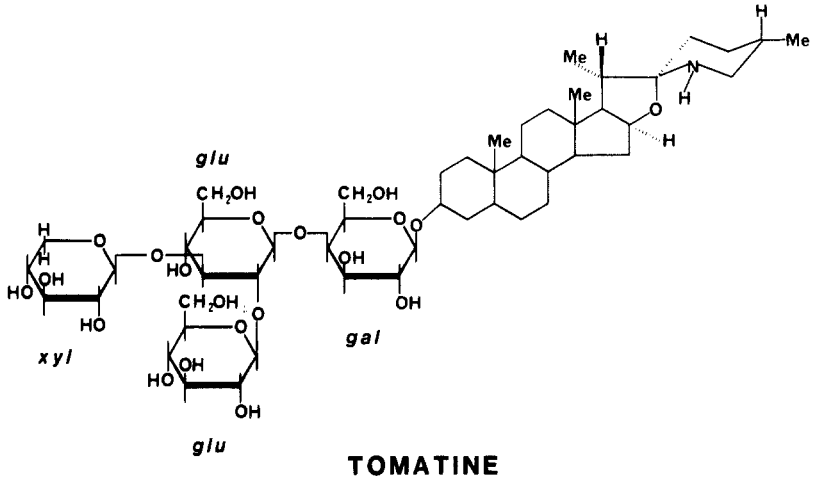

FIG. 1.

roots of resistant tomato plants. These authors found that resistant varieties had a tomatine content of ca. 11–12 mg/g in dry root material, whereas susceptible varieties contained about one third to one half that amount. No information on plant age or concentration with respect to time was provided, however. Since *M. incognita* is a significant pest of tomatoes and since a wide range of susceptibility or resistance can be obtained between numerous cultivars (Hadisoeganda and Sasser, 1982), we investigated the relationship of root tomatine with respect to resistance toward this nematode.

METHODS AND MATERIALS

Nematodes. A culture of *Meloidogyne incognita* (Kofoid and White) Chitwood was obtained from E.C. Jorgenson, U.S. Cotton Research Station, Shafter, California, and confirmed as race 3 by differential host test (Sasser, 1954; Taylor and Sasser, 1978). Nematode colonies were maintained on tomato roots (cv. Rutgers) and differentially selected on cotton (cv. Deltapine-16). The degree of nematode infestation on plant root material was determined by fixation and staining for 4 hr in 50:50 HOAc–EtOH containing 17.5 mg/liter acid fuchsin followed by 12–24 hr clearing in saturated aqueous chloral hydrate and preservation in lactophenol solution (Dropkin et al., 1969). Nematode counts were determined manually by microscopic examination. Nematode motility was assayed by counting the relative number of individuals that migrated through cellulose tissues (Kaplan et al., 1980).

Tomato Plant Material. Readily available tomato cultivars that had already

been assayed for resistance toward *M. incognita*, race 3 (Hadisoeganda and Sasser, 1982), were obtained as seed from commercial sources and were germinated and grown on beds of sand (ca. 1- to 3-mm particles) saturated with half strength Hoagland's solution (Johnson, 1980) using 150-ml beakers about one third full contained within plastic boxes (to establish 100% humidity). These plant boxes were held in a growth chamber maintained at 22°C with a 16-hr light period per 24 hr. Illumination was by six F40CW fluorescent tubes supplemented by four 100-W incandescent bulbs. At approximately weekly intervals the liquid remaining within the sand was aspirated off using a pipet inserted to the beaker bottom, and fresh nutrient was added. Root samples were taken at the cotyledon stage and at later physiological ages corresponding to the full development of two, four, and six true leaves. Roots were cut from the stem at about the level of the sand, washed free of sand grains, and freeze-dried. Dry root material was screened through a mesh smaller than the sand to ensure complete removal of extraneous material. Exudates from developing plants could be isolated from liquid surrounding the roots.

Tomatine Analyses. Qualitative analysis for tomatine in root exudates was conducted by initial passage of liquid through a Waters Associates C-18 Sep-Pak followed by water wash to remove nonabsorbed material with desorption of any tomatine being effected by methanol. TLC on material retained from the aqueous solutions was carried out on Merck Si60 plates using as solvent $CHCl_3$–MeOH–2% NH_4OH, 70:30:5 (Jellema et al., 1981) with detection by anisaldehyde spray reagent (Waldi, 1962).

Quantitative determination of tomatine in tomato roots was accomplished by initial hydrolytic removal of sugar residues to give the aglycone, tomatidine, followed by GLC determination of the latter material. Thus, 5–10 mg of dry root powder was weighed into 2-ml serum cap vials, 0.5 ml of 1 N HCl in 50:50 methanol–water was added, and the caps were crimped in place. The vials of hydrolysis mixture were warmed at 100°C (block heater) for 90 min. After cooling, they were vented with a hypodermic needle to relieve the pressure which occasionally built up, and 0.6 ml of 1 N sodium hydroxide was injected. Into each of the now slightly basic mixtures was injected 0.500 ml of ethyl acetate containing 25 μg/ml of cholesterol valerate as internal standard. The vials were thoroughly agitated by a vortex homogenizer to ensure complete mixing of contents, after which the now partly emulsified layers were separated by centrifugation. About 0.25 ml of the upper phase was taken from each vial by syringe and transferred to conical cavity vials for evaporative removal of ethyl acetate and associated water under nitrogen at 30°C. Methylene chloride, 0.1 ml, was added to all samples, and complete solution was ensured through brief immersion of the vials in an ultrasonic bath. GLC analysis of the methylene chloride solutions was conducted on a 2-ft × $\frac{1}{4}$-in. glass column containing 3% OV-101 on 80–100 mesh Chromasorb W(HP) (Pierce Chemical Co.) using a HP-5880 gas chromatograph equipped for on-column injection. At oven

temperature 255°C and carrier gas flow (N_2) of 40 ml/min, tomatidine and cholesteryl valerate had respective retention times of 4 and 6 min, and all other component peaks emerged earlier. Every set of root material analyzed included at least one tomatine standard that had been subjected to the above hydrolysis and extraction.

RESULTS AND DISCUSSION

Preliminary examination of nematode-susceptible (cv. Rutgers) tomato plants grown in close contact with resistant plants (cv. Small Fry) showed that, after artificial infestation, the degree of susceptibility was lessened for the former plants. This suggested that a diffusable material might be migrating from the roots of resistant plants and lessening the viability of nematodes in the vicinity of otherwise susceptible roots. Examination by TLC of diffusate from Small Fry roots after absorption and concentration on RP-18 Sep-Pak showed qualitatively that tomatine was present. Assay of tomatine in vitro with *M. incognita* gave results similar to those involving *P. redivivus* (Allen and Feldmesser, 1970, 1971), indicating that the free base form was the active nematistatic agent and that tomatine might reasonably be expected to play a role in resistance toward *M. incognita*.

We examined 12 cultivars of tomato for root tomatine content over the initial developmental stages of the plants (Figure 2). Although it had been pre-

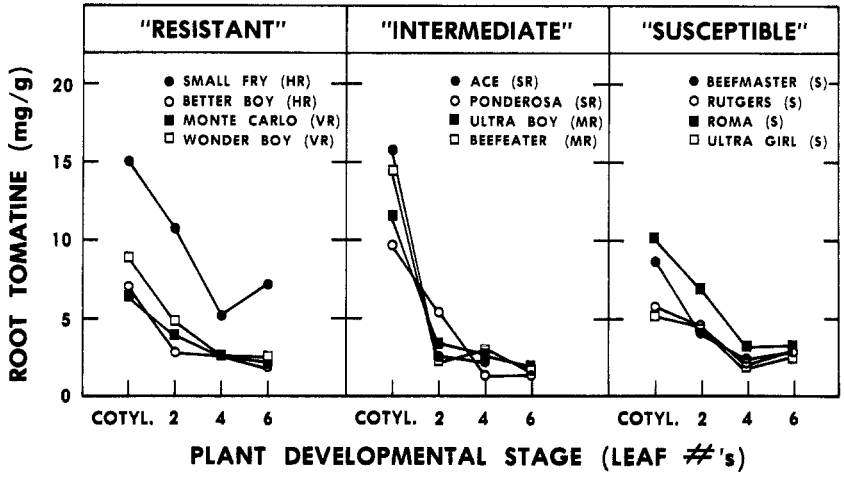

FIG. 2. Tomatine content of resistant and susceptible tomato cultivars vs. developmental age. Degree of resistance is according to Hadisoeganda and Sasser (1982). HR, VR, MR, SR are designations of highly, very, moderately, and slightly resistant, respectively. S refers to susceptible plants. Analyses were on combined root material from three to five plants.

viously reported that tomatine in root sap increased with time (Ali and Schlösser, 1977), we found that for all varieties, tomatine levels showed a general decrease with increasing plant age after germination (no tomatine is present in seeds). Initial content varied from ca. 15 mg/g to as low as one third that amount. After the plants had reached an age corresponding to the development of four to six true leaves, tomatine was present to the extent of 2–6 mg/g in the roots. Although certain tomato varieties showed high initial tomatine content, it was clear that this alone did not account for nematode resistance inasmuch as plants showing the highest content at the cotyledon stage were not necessarily the most resistant, and, additionally, at later developmental times all plants had about the same amount.

It might be suggested that tomatine could increase in amount after nematode attack has taken place. Such postpredation elevation of allelochemical content has been described as an energetically conservative means whereby a plant may preserve its chemical resources (Rhoades, 1979). Indeed, increased tomatine concentration in tomato leaves has been observed after fungal attack (Smith and MacHardy, 1982). If nematode penetration of root tissue were to stimulate tomatine production in resistant tomato cultivars, then growth and reproduction of *Meloidogyne* could still be adversely influenced. We examined the effect of nematode infestation upon root tomatine content in a resistant and a susceptible tomato cultivar to assay this possibility. The varieties, Better Boy and Rutgers characterized, respectively, as highly resistant and susceptible to *M. incognita*, race 3 (Hadisoeganda and Sasser, 1982), were allowed to grow to the point where four true leaves had developed. At this time a suspension containing about 800 nematodes was added to each container in which there were generally three plants. Roots were assayed for tomatine at three, seven, and 14 days after inoculation and compared with control samples from plants free of nematodes. In both varieties, infection of nematode-inoculated plants was confirmed by root staining and nematode counts. Both cultivars failed to show much difference in root tomatine levels between infected and control samples (Table 1), further confirming the inefficacy of tomatine as the determining agent of resistance. Rutgers (susceptible) plants exhibited an infection 2.4 times greater than that of Better Boy (highly resistant); additionally, the former cultivar supported a more robust population of nematodes. It was observed on stained roots that for Rutgers all nematodes were at least second-stage juveniles, whereas of those infecting Better Boy, only 10% had attained this growth stage. We did not attempt to explore host suitability for reproduction or extended survival of the nematodes, it being sufficient that infestation could be maintained over the time interval chosen for tomatine assay.

In conclusion, it can be stated that despite tomatine having nematistatic properties in vitro, we could find no evidence from comparisons of bulk root concentrations that it played a role in nematode resistance over the time course studied. In only one resistant variety (Small Fry) was tomatine content consist-

ently high, but even in this example the difference at later times was not extremely great in comparison to more susceptible cultivars. Other comparably resistant lines did not show as high a tomatine level and were, in fact, lower in root tomatine content than completely susceptible plants. This points to the presence of some other diffusable factor, at least in the case of Small Fry, and we are investigating root diffusates of this cultivar at the present time. A possible means by which tomatine could nevertheless adversely affect nematodes and thereby impart resistance may be in conjunction with the incompatible reaction shown by resistant varieties whereby localized necrosis (Giebel, 1982) takes place at the site of nematode penetration. If tomatine buildup should occur in response only at these sites, then the demonstrated toxic effect of the alkaloid may still be important. However, such localization would be difficult to assay by methods of bulk analysis because the overall tomatine concentration may still be quite low. This may explain why no difference in postinfection tomatine content was discernable.

(Received April 19, 1987; accepted July 7, 1987)

Abstract—Cage experiments revealed that accessions of the wild tomato species *Lycopersicon hirsutum* were preferred sites for oviposition by *Heliothis zea*. Hexane extracts from the leaves of *L. hirsutum* were also preferred sites of oviposition in choice experiments among extracts from several *Lycopersicon* species. Extracts of *L. hirsutum* were still biologically active several days after application, indicating that the phytochemical(s) involved are relatively stable and of low volatility. Gas chromatographic analysis of leaf hexane extracts from 12 different accessions of the *L. hirsutum* complex and three tomato cultivars revealed substantial qualitative and quantitative variation in the chemical composition of these extracts. Comparison of these results with extract oviposition studies implicate a group of structurally related compounds as the active agents. Mass spectroscopy has tentatively identified these compounds as sesquiterpenes with the chemical formula $C_{15}H_{22}O_2$. These compounds are apparently synthesized and secreted from glandular trichomes on the leaf surface. These phytochemicals did not stimulate ovipositional behavior in females of the cabbage looper, *Trichoplusia ni*. The existence of genetic variation for the presence and amount of kairomones that serve as cues for insect orientation and oviposition could be utilized in a breeding program to develop tomato cultivars with genetically modified allelochemic profiles that would disrupt the sequential behavioral processes of insect host-plant selection.

Key Words—*Heliothis zea*, corn earworm, Lepidoptera, Noctuidae, *Trichoplusia ni*, cabbage looper, *Lycopersicon hirsutum*, tomato, allelochemics, kairomone, oviposition, preference, sesquiterpenes, trichomes, host-plant selection, host-plant resistance.

INTRODUCTION

In the past, research on the role of allelochemics in insect host-plant selection has predominantly focused on plant compounds that act as feeding stimuli (Hedin et al., 1974). Plant chemical factors that influence host choice by holometabolous female adults for oviposition have received surprisingly little attention considering that successful completion of an insect's life cycle depends on the female parent's location and oviposition on or near a plant that can supply the necessary ingredients for larval growth and development. Volatile plant chemicals that can impinge on the olfactory chemoreceptors of the insect have been implicated as agents mediating the process of host-plant selection (Kennedy, 1977). Individual plants in a cabbage field that contained higher than average amounts of volatile allyl nitriles were found to be favored sites for oviposition by females of *Pieris brassicae* (Mitchell, 1977). The complex of "green leaf" volatiles from potato plants were found to elicit a positive anemotactic response in Colorado potato beetles (Visser and Avé, 1978). The onion volatiles *n*-dipropyl disulfide and *n*-propyl mercaptan were found to act as attractants and oviposition stimulants for the onion fly, *Hylemia antiqua* (Matsumoto, 1970). As exemplified by the cucurbitacins that have been shown to operate as kairomones for a wide variety of Diabroticina and Aulacophorina beetles (Metcalf et al., 1982), insects have apparently evolved the sensory apparatus to detect and discriminate within their environment the discrete phytochemical profiles of their host plants.

Although *Heliothis zea* (Boddie) (Lepidoptera: Noctuidae) is a major insect pest of corn, tomatoes, and cotton, there is remarkably little pertinent literature concerning its oviposition behavior and oviposition stimulants. Johnson et al. (1975) have made a detailed study on the ovipositional response of *H. zea* to various phenological states of corn, cotton, tobacco, and soybean and have constructed a preference matrix. The ovipositional response decreased in the order: corn > tobacco > soybeans > cotton. In tomatoes, *H. zea* was found to oviposit preferentially on leaf surfaces rather than on blooms, fruit, or stems (Alvarado-Rodriguez et al., 1982). According to Snodderly and Lambdin (1982), the preferred ovipositional site for caged *H. zea* was on the underside of leaves in the interior of the plant canopy, while stems and petioles were less preferred. In corn (Widstrom et al., 1979) and cotton (Lukefahr et al., 1971), genotypes with heavier leaf pubescence were preferred hosts for oviposition.

Numerous volatile compounds have been isolated from corn silk (Flath et al., 1978), corn kernels and husks (Buttery et al., 1978), and corn tassels (Buttery et al., 1980) that may act as attractants to *H. zea*. These compounds include C_2–C_{12} alkanols, hexadienal, decadienal; esters such as ethyl acetate and ethyl cinnamate; ketones including pentanone, nonanone, and octadienone; and various methylated benzenes and naphthalenes. Centello and Jacobsen (1979)

reported that phenyl acetaldehyde, a volatile constituent of corn silk, acts as an attractant to *H. zea*. The corn volatile triacetin was found to be the most effective of 33 structurally related compounds in stimulating oviposition behavior in *H. zea* (Jones et al., 1973). Individually none of these compounds was competitive with corn extracts for stimulating oviposition. *H. zea* apparently responds to a complex mixture of corn volatile compounds that act as attractants or oviposition stimulants.

There have been several reports of chemical factors in tomatoes that influence host-plant selection and oviposition by other lepidipterous pests. A nitrogen-containing phenolic glycoside ($C_{17}H_{29}O_{10}N$), isolated from cultivated tomato leaves, was found to stimulate oviposition by the tobacco hornworm, *Manduca sexta* (Yamamoto and Fraenkel, 1959). Tichenor and Seigler (1980) have shown that aqueous extracts and steam distillates of cultivated tomatoes induced electroantennogram activity and stimulated oviposition by *M. sexta*. Bordner et al. (1983) have reported on the presence of an orientation factor for *M. sexta* in the steam distillate of cultivated tomato leaves. Ethanolic extracts of tomato leaves were found to elicit oviposition by the potato tuber moth, *Phthorimaea operculella* (Meisner et al., 1974). A chemical factor on the foliar surfaces of a tomato cultivar was shown by Burton and Schuster (1981) to act as an oviposition kairomone to the tomato pinworm, *Keiferia lycopersicella*.

A review of the literature has uncovered no reports on tomato phytochemicals that affect *H. zea* orientation or host plant selection for oviposition. This study was conducted to survey the genus *Lycopersicon* for the existence of allelochemicals that may influence the oviposition behavior of *H. zea*.

METHODS AND MATERIALS

Plant Material. Seeds of wild and cultivated species of the genus *Lycopersicon* were procured from Dr. C.M. Rick, Department of Vegetable Crops, University of California, Davis, and from the USDA Plant Introduction Station, Ames, Iowa. Seeds of Chico III and Jet Star were purchased from the Harris-Moran Seed Company. Seeds of the different accessions were planted into flats containing potting soil consisting of peat, vermiculite, and soil (1 : 1 : 1). Seedlings with two to four true leaves were transplanted into either 7.57-liter pots in the greenhouse or into field plots on the University of Illinois Vegetable Crops Research Farm in south Urbana, Illinois.

Insects. The gravid female moths of *Trichoplusia ni* (Hubner) and *Heliothis zea* (Boddie) (Lepidoptera: Noctuidae) used in these experiments were obtained from colonies maintained in incubators in the authors' laboratory. The *T. ni* colony was initiated from eggs provided by Ms. Paula Peters of the USDA Insect Biological Control Laboratory of the Department of Entomology, Uni-

versity of Missouri, Columbia. Dr. Gilbert Waldbauer in the Department of Entomology, University of Illinois, Champaign–Urbana, supplied eggs that were the original source of our *H. zea* colony. The larvae, pupae, and adult moths are reared in Percival incubators at 25°C and 75% relative humidity with a daily regimen of 14 hr light and 10 hr darkness. The *T. ni H. zea* populations are maintained on artificial diets following the methods described by Waldbauer et al. (1984). The same dietary mix is used to feed the larvae of both insect species. Unlike *H. zea*, the larvae of *T. ni* are not cannibalistic, allowing for the rearing of 20–30 larvae in individual 237-ml paper containers with clear plastic lids purchased from Lily-Tulip, Inc. (Augusta, Georgia). To reduce inbreeding in the insect populations, wild collections of the Illinois insect species are added to the cultures every summer. To minimize microbial diseases in the colonies, eggs and pupae of each generation are surface sterilized.

Oviposition Studies of Caged Plants. For experiment 1, three plants of the wild tomato accession LA 716 (*L. pennellii*), LA 1306 (*L. chmielewskii*), LA 1335 (*L. pimpinellifolium*), LA 1777 (*L. hirsutum*), LA 407 (*L. hirsutum* f. *glabratum*), and the processing tomato cultivar, UC82B (*L. esculentum*), were placed in a screened cage (1.8 m on a side, 1.2 m high) in a greenhouse with a 28°C/18°C ± 3°C day–night temperature regimen. The plants were four weeks old and displaying vegetative growth. The pots were randomly positioned within the cage to allow for maximum distance between each plant. Twenty-five gravid *H. zea* moths were released within the cage between 3 and 5 PM and allowed to oviposit on preferred host plants for 24 hr. After sundown, the cage was covered on all sides with black plastic to reduce any positional effect that may have occurred due to light sources in the greenhouse. Twenty-four hours after the moths were released, the plants were removed from the cage, eggs marked with a red felt-tip pen, and total egg numbers for each plant recorded. When returned to the cage, plants were randomly assigned new locations to further reduce positional bias. At 48 hr, a second egg count was conducted followed by a third and final count at 72 hr. Moths that had died during the first and second nights were replaced with new females to maintain total moth numbers. Within 48 hr of the final egg count, all plants were prepared for leaf extraction. The aboveground portion of each plant was harvested and weighed. Leaves and stems of each plant were then separated and weighed.

For experiment 2, three plants of the accessions LA 1306 (*L. chmielewskii*), LA 407 (*L. hirsutum* f. *glabratum*), LA 1777 (*L. hirsutum*), and the processing tomato cultivar Chico III were tested for *H. zea* oviposition preference using the procedures described above. To separate the variance resulting to positional effects, plants were separated into three blocks within the cages where each block contained one plant of each species. Species were randomized within the blocks. Replication was achieved by repeating the experiment four times with new plants and insects. Within 48 hr of the final egg count, all plants from

each replicate were prepared for leaf extraction. Measurements from each plant included: total leaf weight, total leaflet weight, stem weight, total plant weight, and leaf area (leaf area in cm^2 of approximately five leaflets measured on a Li-Cor leaf area meter).

Arena Leaf Extract Oviposition Studies. Preliminary studies of leaf extracts of the *L. hirsutum* accessions LA 1777 and PI 379013 indicated that in equal-weight leaf samples extracted in hexane, chloroform, ethanol, and water, the hexane extracts stimulated *H. zea* oviposition the most. For this reason, hexane was used as the solvent for our extract oviposition bioassays. A 5.00-g sample of leaflets from each plant in experiments 1 and 2 was extracted three times in hexane aliquots of 20 ml, 15 ml, and 15 ml. Hexane and leaflets were placed in 50-ml capped nalgene centrifuge tubes and shaken at 300 rpm for 15 min on a G24 Environmental Incubator Shaker (New Brunswick Scientific Co.). Each extraction aliquot was poured through Whatman No. 1 filter paper into a 150-ml Erlenmeyer flask containing approximately 8 g of sodium sulfate crystals to remove water from the extract. After the third hexane rinse, the extract was brought to total volume of 50 ml in a volumetric flask. Extracts were transferred into 20-ml glass scintillation vials and stored at −70°C for later use. Prior to the moth oviposition studies, plant extracts of the same genotype from experiment 1 were bulked and concentrated in a Buchler vortex–evaporator at 40°C at 150 rpm with a vacuum at −80 kPa. Sample volumes were manipulated so as to achieve concentrations of 0.5 g of original wet weight leaflet tissue per milliliter of concentrated extracts. While this same concentration was used in the plants from experiment 2, four separate concentrated extracts of plants of the same genotype were saved from each replicate.

The extract oviposition studies were conducted in 30-cm-diameter round cake carriers inverted to allow the bottom to serve as a lid. A 23-cm-diameter hole was cut out of the lid and fine insect netting glued over the hole to allow for air flow. Whatman 3-mm sheet chromatographic paper (0.33 mm thick) was cut to an exact fit to cover completely the inside wall of the containers. Eighteen small squares of two-sided tape were affixed at even intervals (approximately every 6.2 cm), 3.5 cm beneath the upper edge of the chromatographic paper. Whatman No. 1 filter paper disks with a diameter of 4.25 cm were permeated with 1.0 ml of the different extracts, dried under a hood, and attached to the squares of two-sided tape. In experiment 1, six filter disks were permeated with 1.0 ml of extract from each of the six *Lycopersicon* species. Two filter disks of each of the species extracts and six control filter disks previously permeated with 1.0 ml of hexane were randomly attached to the chromatographic paper fitted to the inside wall of each of the three cake carriers (hereafter called arenas). Fifteen gravid female *H. zea* were then placed within each arena. To improve moth survival and oviposition, a Petri dish containing sterile cotton fiber infused with a 10% solution of honey was positioned in the center of each

arena. The arenas were then placed within a Percival growth chamber at 25°C, 75% relative humidity, and a 14 : 10 hr light–dark cycle. A 1/4-watt night light was placed approximately 15 cm above the center of the lid of each arena to stimulate moth oviposition. At 24 and 48 hr, the arenas were removed from the incubators, the moths anesthetized with carbon dioxide, and the sheet removed for counting. After the eggs were counted and recorded for each disk, the sheets were returned to the containers, dead females replaced with living ones, and a fresh honey solution added to the Petri dish. A third and final count was conducted at 72 hr after the experiment was initiated.

In experiment 2, three filter disks were permeated with 1.0 ml of extract of each genotype for each of the four replicates. Disks from the different replicates were placed into four separate arenas. Extract disks were randomly arranged with six hexane blanks for each arena. The experiment was conducted as described above. In both experiments, extract oviposition preference values were calculated by dividing the average number of eggs per filter disk of a specific species by the mean number of eggs laid on the hexane controls. Values significantly less than one indicated nonpreference for *H. zea* oviposition, while those greater than one were preferred sites for oviposition.

Trichoplusia ni *Leaf Extract Oviposition Study.* The concentrated extracts from each replicate of the four species in experiment 2 were bulked to test for *T. ni* oviposition preference. Three filter disks permeated with 1.0 ml of the concentrated extract from leaves of each of the four species and a hexane control were randomly arranged in each of three separate arenas. Fifteen gravid *T. ni* females were released in each of the areas. The experiment was conducted similarly to the *H. zea* studies.

Variation in H. zea *Oviposition Preference—Volatile or Contact Chemical Action.* To ascertain if the chemical basis for *H. zea* oviposition preference is due to the interaction of volatile compounds with moth orientation or if physical contact of the insect with the extract disks is required for oviposition stimulation, the following experiment was conducted. Twenty-five grams of fresh leaflets from field-grown plants of *L. esculentum* cultivar, Chico III, and the wild *L. hirsutum* accessions, PI 379013 and LA 1777 were extracted in hexane and concentrated to 0.5 g of original leaf fresh weight per milliliter; 1 ml of each of the extracts was pipetted onto four filter disks and allowed to dry. These disks and six hexane blanks were randomly attached to a single sheet of chromatographic paper precut to fit inside a cake carrier as described above. The side of the sheet with the attached filter disks was then completely covered with eight layers of prewashed and sterilized cotton gauze. A fine line was drawn on the gauze indicating the position of the filter disk located directly beneath. This porous gauze layer, which was approximately 3 mm thick, prevented any direct contact between the extract disks and the 15 female moths used for the ovipo-

sition study. For replication, three arenas were prepared in this manner for *H. zea* oviposition studies.

H. zea *Oviposition Preference among Extracts of* L. hirsutum. Samples of leaf tissue from 12 different wild tomato accessions of *Lycopersicon hirsutum* and *L. hirsutum* f. *glabratum* were harvested from plots on the Department of Horticulture's Vegetable Research Farm in Urbana, Illinois. Each sample was a composite of leaves collected from 10 plants of each wild accession. Only undamaged leaves from the fifth or sixth node below shoot meristems were harvested. Leaves were carefully handled to minimize damage and disturbance to the leaf trichome vestiture. From each accession, 25.0 g of leaflets were weighed out and placed in 500-ml nalgene screw-top bottles. The samples were then extracted three times with 100-ml aliquots of hexane using the procedure previously described. Sample volumes were manipulated to achieve concentrations of 1.0 g of original leaflet tissue per milliliter of extract for each of the *L. hirsutum* accessions. One milliliter from each of the 12 accession extracts was applied to each of the four filter disks. One complete set of disks of each accession's extract and three hexane controls were randomly arranged in each of four arenas to test the *H. zea* oviposition preference among extracts.

To ascertain the volatile constituents of the leaf hexane extracts from these accessions, aliquots were diluted 10-fold and injected into a Hewlett Packard model 5790a gas chromatograph with an HP 7671a autosampler, a 12.5-m cross-linked methyl silicone capillary column (0.2 mm internal diameter and 0.33 μm film thickness), flame ionization detector, and an HP 3390a integrator. One microliter of each sample was injected by the autosampler into the injection port where the volatile constituents were loaded onto the column at a split ratio of 10:1 with helium as a carrier gas at 1.0 ml/min. Figure 1 presents a typical chromatogram of the hexane extract from leaves of the *L. hirsutum* accession LA 1777, with information on the temperature program used for these analyses. The retention time and area of each peak (greater than 1% of total peak area) of each genotype's extract was recorded. These data were then compared with the *H. zea* oviposition response to the same extracts.

To compare the chemical nature of the leaf hexane extracts with that of trichome exudates, absorbent cotton was very lightly rubbed over the surface of attached leaves of greenhouse-grown LA 1777 plants. The cotton was then extracted in hexane and the extract gas chromatographed as described above. This chromatogram was then compared to a chromatogram of a hexane extract from cut leaflets of the same plants. These two extracts of LA 1777 were compared for relative *H. zea* oviposition preference in a single arena study.

GC-Mass Spectroscopy of Hexane Extracts. For the purposes of preliminary compound identification, hexane extracts of the *L. hirsutum* accessions LA 1777 and PI 379013 were run through a Hewlett Packard 5995 gas chromatog-

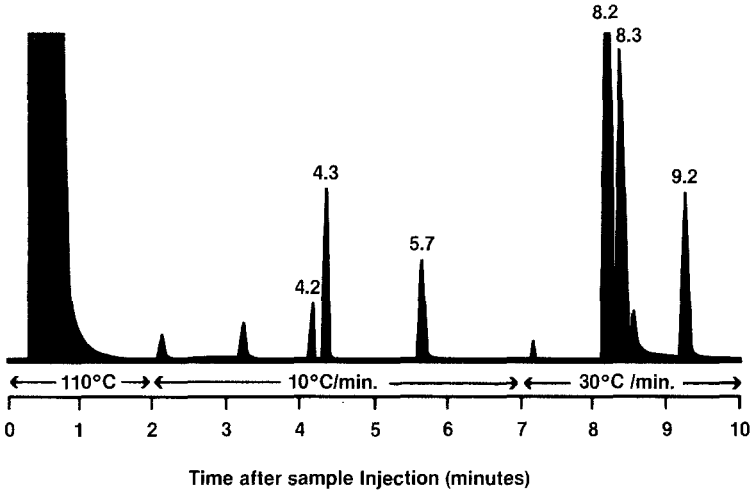

FIG. 1. Gas chromatogram of leaf hexane extract of the *Lycopersicon hirsutum* accession LA 1777.

raphy–mass spectrometer. One microliter of extract was injected in the splitless mode and loaded on to a 10-m cross-linked methyl silicone capillary column (0.2 mm internal diameter) with helium as a carrier gas at 1.0 ml/min. After 1 min at 80°C, the oven temperature was programmed to increase at 20°C/min to a final temperature of 260°C. As the individual volatile chemical constituents entered the quadrapole mass spectrometer, fragmentation was achieved by electron impact at 70 eV. Fragmentation patterns were recorded and analyzed with an HP 236 Quicksilver data processor. Individual peak fragmentation patterns were compared and matched against an MS software library of 39,000 known compounds.

RESULTS AND DISCUSSION

Table 1 presents the results of experiment 1 where six different accessions from five separate species of *Lycopersicon* were tested for both *H. zea* oviposition on plants and on extracts from leaflets of the same plants. Plants of the *L. hirsutum* accession LA 1777 were significantly preferred hosts for oviposition both on the basis of total egg numbers per plant and on eggs per 100 g of foliage. The hexane extracts from this accession were also preferred sites of oviposition in the arena study. These findings strongly suggest that a chemical factor(s) in the hexane extract of leaves of this accession possesses kairomonal properties that modify moth orientation and oviposition response. The correla-

[a]Numbers followed by different letters are significantly different at $P = 0.05$ (protected LSD test). Linear regression of *Heliothis zea* oviposition on plants per 100 g of foliage with oviposition on leaf extracts provides a highly significant correlation coefficient ($r = 0.95$, $P < 0.01$).

tion between moth oviposition per 100 g of leaf tissue and preference values from the arena studies for the six accessions was $r = 0.95$ ($P < 0.01$), implying that kairomonal phytochemicals on the leaves of *Lycopersicon* may serve as important token stimuli in the behavioral processes of *Heliothis* host-plant selection for oviposition. While extracts of the cultivated tomato stimulated oviposition, those of the *L. pennellii* and *L. pimpinellifolium* accessions were not significantly different from the control. The action of repellent or oviposition-inhibiting chemical stimuli was not observed in this study.

The results from experiment 2, presented in Table 2, tend to agree with the preceding experiment. *H. zea* oviposition on plants of LA 1777 (as determined by total egg numbers, eggs per 100 g foliage, or eggs per leaf area) and the hexane leaf extracts of these plants was significantly greater than that observed for the other accessions. The final column of this table presents the results of the response of gravid *T. ni* females to the same extracts. The moths exhibited no significant ovipositional preference for any of the extracts. While the values were less than 1.0, indicating extract nonpreference, oviposition on any of the extract disks was not significantly different from egg numbers found on control disks. This study suggests that the chemical factor(s) stimulatory to *H. zea* oviposition does not appear to induce a similar behavioral response in

T. ni. This finding corroborates previous evidence (Schoonhoven, 1972) indicating that different insect species have evolved chemical sensory organs that show discretion to phytochemical stimuli generally associated with their hosts.

The results from the arena studies of experiments 1 and 2 indicated that the chemical factor(s) stimulatory to *H. zea* oviposition maintained their biological activity for at least three days. While the relative oviposition preference for the disks permeated with extracts of LA 1777 decreased slightly (12%) over the course of the 72-hr arena study, this change was statistically nonsignificant. In contrast, the preference displayed for extracts from tomato cultivars decreased from the first to the third day's measurement by nearly 50%. This suggests that the kairomone in LA 1777 is both relatively stable and has no or low volatility under the conditions maintained for the arena studies. It also suggests that different compounds may be operating as kairomones in the extracts from the different tomato species.

In the arena test where cotton gauze prohibited physical contact between *H. zea* and the extract discs, oviposition on the gauze overlying disks permeated with extracts from LA 1777 and PI 379013 was significantly greater than that associated with the hexane controls. The mean egg numbers per 24 hr over disks of LA 1777, PI 379016, Chico III, and the hexane controls was 62.0(a), 50.6(b), 47.4(bc), and 40.9(c), respectively (means with the same letter are not significantly different according to the protected LSD test). Moth oviposition behavior was modified without the need for direct physical contact between

chemoreceptors (on the moths tarsi, maxillae, and antennae) and the hexane soluble phytochemicals in the filter disks. Volatile constituents in the extracts are apparently serving as olfactory stimuli responsible for chemotactic orientation (possibly positive anemotaxis) by *H. zea* female moths (Kennedy, 1977). The mixing of extract volatile compounds within these comparatively small containers invalidates any conclusions from these studies on the moth chemotactic orientation for distances greater than several centimeters separating the chemical source and the insect. The close agreement between extract oviposition preferences of *H. zea* for LA 1777 plants in the large cages and extracts in the arenas does suggest, however, that the volatile chemical(s) may be operating as an attractant over longer distances. The much greater preference values associated with uncovered LA 1777 extract disks may be a result of a much greater kairomone concentration gradient very close to the disk or to the interaction of this olfactory cue with chemical and tactile stimuli detected upon physical contact of the insect with the filter disk.

Results of the gas chromatographic analysis of the hexane leaf extracts from 12 different accessions of *L. hirsutum* and *L. hirsutum* f. *glabratum* and results from *H. zea* oviposition preference for the same extracts are presented in Table 3. The chromatograms contained seven major and recurrent peaks with retention times of less than 10.0 min (250°C). Many other minor peaks (less than 1% of total peak area) were observed but not included in Table 2. There were also a number of peaks with retention times beyond 10 min that came off the column at oven temperatures between 250 and 325°C. Areas of these peaks were generally quite small (0–2% of total area) and their presence consistent among all the extracts. Table 3 indicates that there is significant qualitative and quantitative variation within the *L. hirsutum* complex for hexane-soluble leaf phytochemicals. Most of the genotypes can be discriminately "fingerprinted" by their individual chromatograms. The *L. hirsutum* accessions appear to fall into three or four "chemotypic" groups.

There were also significant differences exhibited by female *H. zea* moths for oviposition among the extracts in the arena study. When the areas of the primary peaks were compared to the relative oviposition preference of the leaf extracts, areas of the peaks with GC retention times of 8.2 and 8.3 min were highly correlated with *H. zea* oviposition preference. Regression analysis of these data revealed that the equation: Relative *H. zea* oviposition preference = 0.0289 (area of 8.2-min peak) − [0.0000461 (area of 8.3-min peak)]^2 + 2.75, describes 88% of the total variation in extract oviposition preference. This highly significant correlation coefficient ($P < 0.001$) suggests that these two peaks are the traces of compounds that stimulate *Heliothis* oviposition. In the chromatograms of LA 1777 and PI 365936 these two peaks accounted for 70–80% of the total area, suggesting that they represent the major chemical components in the hexane extracts. The y-intercept value of 2.75 indicates that after removal

[a] Areas of peaks with retention times of 8.2 and 8.3 were highly correlated with *H. zea* oviposition preference.

of the effects of the chemicals with retention times of 8.2 and 8.3 min there are other compounds in the extracts that stimulate oviposition. This "background" chemical stimulation is present in most of the extracts from the *L. hirsutum* complex and is not clearly associated with the presence or absence of individual peaks on the chromatograms.

The preceding studies suggest the *L. esculentum* tomato cultivars also possess similar stimulatory chemical cues. Chromatograms from extracts of *L. esculentum* cultivars displayed only trace amounts of the compounds with retention times of 8.2 and 8.3 min. These peaks are apparently not involved in the oviposition preference displayed by *Heliothis* for hexane extracts from Chico III, Jet Star, or UC 82B. Other kairomones with greater volatility are implicated.

The same peaks in roughly the same proportion were observed in chromatograms of the LA 1777 hexane leaf extract and from the cotton-wiped leaf tissue. The minor peaks with retention times greater than 10 min (250–300°C) found in the extracts were missing from the leaf surface wipe. The high boiling point, ubiquity among extracts, and the regular spacing in the chromatograms of these compounds suggest they may be cuticular waxes. The peaks with retention times of 8.2 and 8.3 min were found to account for 71% of the total peak area in the leaf hexane extracts compared to 79% in the leaf wipe chromatogram. When the concentration of the LA 1777 leaf wipe hexane solution was adjusted so that the area under the 8.2- and 8.3-min peaks were approximately equivalent to that of the leaf hexane extract, *H. zea* oviposition preference was nearly identical when extracts were tested in the arenas.

Comparison of the mass spectrum of specific GC peaks of the LA 1777 and PI 379013 hexane extracts with known spectra provided superior match quality (>0.95) for only the peaks with retention times of 5.0 and 9.2 min. The 5.0 min peak is definitely the ketone, 2-tridecanone, since the mass spectrum and GC retention time of this peak was identical to a commercially available source (Pfaltz & Bauer, Inc., Stamford, Connecticut). The peak at 9.2 min closely matched (0.98) the spectra of 9,12,15-octadecatrien-1-ol. The molecular weight of the extract peak was 278, 14 units greater than that of the matched compound, suggesting that the unknown may contain an additional methylene group (CH_2). The mass spectrum of the 4.3-min peak shared some homology with zingiberene, a sesquiterpene that is one of the principal volatile components of ginger (Moshonas and Lund, 1970). Lundgren et al. (1985) have reported on the presence of this compound in volatile collections from leaves of *L. hirsutum.*

When GC oven conditions were manipulated to provide for maximum separation of the 8.2- and 8.3-min peaks in LA 1777, three additional peaks in this range of retention times were uncovered. When the area under all these peaks was combined, what was originally the 8.2-min peak accounted for 51% of this

total and the 8.3-min peak for 35%. A third peak which preceded the 8.2-min peak by 8 sec accounted for 12%, while two very small peaks were responsible for the remainder. On the basis of similar fragment size, abundance, and the apparent molecular weight as determined from the mass spectra, the three largest of these peaks represent compounds that are structurally similar. The mass spectra of the major (8.2 min) peak is presented in Figure 2 and yielded the following major peaks: *m/e* (% relative intensity), 93(100), 41(51), 91(49), 79(43), 77(36), 119(35), 107(34), 39(26), 43(26), 94(26), 55(25), 121(24), 105(22), 100(21), and 53(21). A low-voltage scan indicated a compound molecular weight of 234. A diagnostic peak was observed at *m/e* 219 (molecular ion $-$ CH_3). This fragmentation pattern is quite similar to the mass spectrum of an essential oil fraction of a distillate from leaves of the *L. hirsutum* accession PI 251303. Patterson et al. (1975) suggested, on the basis of the mass spectrum and other analytical tests, that the major component of this distillate fraction was a sesquiterpene. The mass spectrum of the 8.2-min peak tentatively suggests the compounds of interest are sesquiterpenes with chemical formulas of $C_{15}H_{22}O_2$. Lundgren et al. (1985) also reported that one of the major volatile components from leaves of one accession of *L. hirsutum* was the sesquiterpene, α-santalene. This sesquiterpene, or a derivative of it, could well be the olfactory kairomone stimulating *H. zea* oviposition. Isolation and precise identification of the structure of these sesquiterpenoids from LA 1777 and validation of their biological activity are reported elsewhere (Coates et al., 1988).

Chromatograms of the leaf wipes suggest that these compounds are present on the leaf surface. Their presumed source is the glandular trichomes known to be found on leaf surfaces of most *Lycopersicon* species. Of the five types of glandular trichomes described by Luckwell (1943) to exist in *Lycopersicon, L. hirsutum* accessions generally display abundant densities of types I, IV, and VI. Type I trichomes have a long multicellular stalk with a very small bulbous

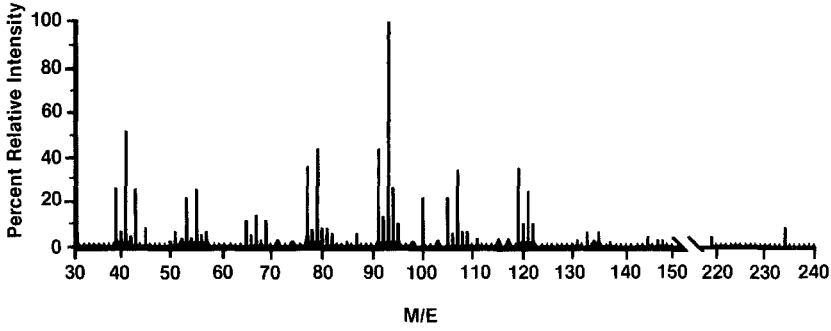

FIG. 2. Mass spectrum of the 8.2-min peak from the hexane leaf extract of LA 1777.

swelling at the tip. The smallest of these glandular hairs, type IV trichomes, have a short multicellular stalk with a droplet of exudate at the tip. Type VI trichomes hve a short stalk with a large tetralobulate glandular head at its apex. Type VI trichomes on leaves of *L. esculentum* were found to synthesize and store phenolic compounds, primarily rutin and chlorogenic acid (Duffey and Isman, 1981), while type VI trichomes in the *L. hirsutum* f. *glabratum* accession, PI 134417 were found to synthesize 2-tridecanone (Dimock and Kennedy, 1983), a compound highly toxic to the tobacco hornworm, the tomato fruitworm, and the potato aphid (Williams et al., 1980). The density of type IV trichomes in the *L. hirsutum* accession, PI 251303 has been associated with resistance to the spider mite (Snyder and Carter, 1984). This resistance was not associated with leaf sesquiterpene (zingiberene or curcumene) content, but appears to operate through mite nonpreference. Microscopic viewing of leaflets of LA 1777 and PI 365936 (*H. zea* preferred) revealed a dense vestiture of what appear to be type IV trichomes, each with a tiny droplet of exudate on their tips. The abundance of these trichomes and the apparent amount of total exudate suggest they are major contributors of the chemical components in the hexane and leaf wipe extracts.

It is difficult to understand why a volatile compound from the leaf surface of several accessions of *L. hirsutum* is acting as a putative olfactory stimulus for *H. zea* orientation and host-plant selection. Wild accessions of *L. hirsutum* inhabit a rather limited zone on the western slopes of the Andes at elevations from 500 to 3300 m from central Peru to northern Ecuador (Rick, 1973). As an ephemeral perennial, this species is usually found at very low population densities in its environment and as such represents a relatively poor resource for phytophagous insects. In addition, previous work has shown that LA 1777 foliage provides the poorest diets for survival and growth of larvae of *Spodoptera littoralis, Plusia chalcites, Phthorimaea operculella*, and *Heliothis armigera* (Juvik et al., 1982). When neonate larvae of *H. zea* were reared on the foliage of 45 different accessions of *Lycopersicon*, survival after four days was lowest on leaflets of LA 1777 (unpublished data). This tends to indicate that *H. zea*'s behavioral response to the kairomonal chemical factor on LA 1777 and other accessions does not represent an evolutionary adaptation by the insect for the location and host selection of *L. hirsutum* plants. This is supported by evidence showing that females of *Heliothis armigera*, a species related to *H. zea* but endemic to the Old World, also display ovipositional preference for LA 1777 plants (Juvik et al., 1982). A more likely explanation for the kairomonal properties of this compound or of a structural analog is that it is synthesized by one or more other sympatric host plant species that are or have been in the past a significant food resource for developing *Heliothis* larvae.

The existence of species variation in the qualitative presence and quanti-

tative amount of *Lycopersicon* allelochemics that serve as cues for *H. zea* orientation and oviposition could be utilized in a breeding program to develop tomato cultivars with genetically modified allelochemic profiles. Such as modification might disrupt the sequential behavioral processes of *H. zea* host-plant selection and colonization. Altering a tomato plant's allelochemic constitution could prevent female *H. zea* in search of oviposition sites from recognizing that plant as an acceptable host for the growth and development of its young. Such disruption in an agricultural ecosystem could result in reduced crop damage from larval feeding. The *H. zea* ovipositional kairomone in *L. hirsutum*, once isolated and identified, may be of use to trap moths for field monitoring of female population levels for effective pest management strategies. Alternatively, the compound might be usable when combined with pesticide baits for actual control.

Acknowledgments—The authors thank Richard Lampman and Dr. Robert Metcalf for conducting the mass spectroscopy of the tomato extracts, Dr. David Seigler for his help in analyzing the mass spectra, and Dr. Joseph Sullivan for advice on statistical analysis. A portion of this research was funded by a grant provided by Campbell's Institute for Research and Technology, Davis, California, and by project number 65-0348 of the Agricultural Experiment Station, College of Agriculture, University of Illinois at Urbana-Champaign.

DETOXIFICATION OF ISOTHIOCYANATE ALLELOCHEMICALS BY GLUTATHIONE TRANSFERASE IN THREE LEPIDOPTEROUS SPECIES

RICHARD W. WADLEIGH and SIMON J. YU

Department of Entomology and Nematology
University of Florida
Gainesville, Florida 32611

(Received April 13, 1987; accepted July 8, 1987)

Abstract—Glutathione transferase activity towards various plant isothiocyanates was studied in larvae of the two generalists, fall armyworm [*Spodoptera frugiperda* (J.E. Smith)], and cabbage looper [*Trichoplusia ni* (Hübner)], and the specialist, velvetbean caterpillar (*Anticarsia gemmatalis* Hübner) using the midgut soluble fraction as enzyme source. The generalists, but not the specialist, are adapted to feeding on isothiocyanate-containing crucifers. Allyl and benzyl isothiocyanate were found to be metabolized by glutathione transferase from the two generalist species, but no activity was detected with the specialist. The transferase activity towards these allelochemicals in the cabbage looper was two- to sixfold higher than that in the fall armyworm. In all instances, activity was induced by various allelochemicals including indole 3-acetonitrile, indole 3-carbinol, flavone, xanthotoxin, and its own substrates. The induction ranged from 1.3- to 10.1-fold depending on the allelochemical, with the fall armyworm being more inducible. The transferase system of fall armyworm also metabolized another analog, 2-phenylethyl isothiocyanate, but activity can only be observed after induction. Bioassay results showed that these isothiocyanates were all toxic to the lepidopterans, causing acute toxicity in neonates and final-instar larvae. The results suggest that glutathione transferase plays an important role in the detoxification of isothiocyanates and hence food-plant adaptation in phytophagous insects.

Key Words—Glutathione transferase, isothiocyanate metabolism, fall armyworm, *Spodoptera frugiperda*, cabbage looper, *Trichoplusia ni*, velvetbean caterpillar, *Anticarsia gemmatalis*, Lepidoptera, Noctuidae.

INTRODUCTION

The glutathione transferases are a group of enzymes that catalyze the conjugation of reduced glutathione to electrophilic compounds. The reaction is considered an important pathway for xenobiotic detoxification since the resulting conjugates are further transformed to more excretable metabolites such as mercapturic acids (Boyland and Chasseaud, 1969).

In insects, glutathione transferases catalyze the metabolism of organophosphorus and organochlorine insecticides and are involved in the development of resistance to these compounds (Motayama and Dauterman, 1980; Tanaka et al., 1981; Clark and Shamaan, 1984). It is also believed that glutathione transferase plays an important role in insect herbivory through the detoxification of toxic plant allelochemicals. However, unlike insecticides, knowledge about the detoxification of plant allelochemicals by this enzyme is limited. Recently, we demonstrated that toxic α,β-unsaturated carbonyl allelochemicals such as *trans*-cinnamaldehyde, *trans,trans*-2, 4-decadienal, *trans*-2-hexenal, and benzaldehyde were detoxified by glutathione transferase prepared from the midguts of fall armyworm larvae (Wadleigh and Yu, 1987). Transferase activity towards these compounds was induced by various dietary allelochemicals including, in some cases, the substrate itself.

In cruciferous plants, isothiocyanates (RNCS) are an important component of the chemical defenses against nonadapted insect herbivores, but they provide no protection against adapted herbivores that include crucifers in their normal host range (Feeny, 1977). The mechanism of isothiocyanate detoxification in the adapted herbivores is not completely understood. Previous research has shown that 2-phenylethyl isothiocyanate was a substrate for microsomal oxidases in the fall armyworm (Yu, 1987a). Detoxification by glutathione transferase is also likely since allyl and benzyl isothiocyanate were metabolized in vivo via glutathione-dependent conjugation in mammals (Brüsewitz et al., 1977; Mennicke et al., 1983). The reaction occurs as follows: RNCS + GSH $\rightarrow$ RNHC(S)SG.

The purpose of this research was to examine the detoxification of isothiocyanates by glutathione transferase in the fall armyworm, cabbage looper, and velvetbean caterpillar. The role of enzyme induction in detoxification was also investigated. The fall armyworm and cabbage looper are generalists adapted to feeding on isothiocyanate-containing crucifers. The velvetbean caterpillar is a specialist insect feeding primarily on certain species of plants in the Leguminosae.

METHODS AND MATERIALS

Insects. Larvae of the fall armyworm, *Spodoptera frugiperda* (J.E. Smith) (FAW), cabbage looper, *Trichoplusia ni* (Hübner) (CL), and velvetbean cat-

erpillar, *Anticarsia gemmatalis* Hübner (VBC), were reared on an artificial diet (Burton, 1969) and maintained in environmental chambers at 24°C with a 16:8 hr light–dark photoperiod.

Chemicals. Ellagic acid, flavone, indole 3-acetonitrile, indole 3-carbinol, quercetin, juglone, and reduced glutathione were purchased from the Sigma Chemical Company, St. Louis, Missouri. Triphenyltin chloride, allyl isothiocyanate (AITC), and benzyl isothiocyanate (BITC) were from the Aldrich Chemical Company, Milwaukee, Wisconsin. 2-Phenylethyl isothiocyanate (PITC) was obtained from Fluka AG, Hauppauge, New York.

Treatments of Insects. In the induction experiments, groups of final-instar larvae of FAW and CL (newly molted) and VBC (1 day old) were individually fed on artificial diet containing allelochemicals and held at 24°C in 1-oz. plastic cups for two days before the enzyme assays were conducted. Control larvae of all species were fed the artificial diet alone.

To study the toxicity of the allelochemicals, groups of 15 one-day-old first-instar FAW larvae were fed the allelochemicals mixed in their artificial diet and reared to adulthood, as described earlier. Mortality counts were made 24 hr later. The surviving larvae were weighted at day 12 and shortly after the fifth molt. Survivorship and the time required to reach pupation and adult emergence were recorded.

The acute toxicity of AITC was also determined using larvae of the CL (two days after the final larval molt) and VBC (three days after the final larval molt) as test stages. In these experiments, groups of 15 or 20 larvae were fed an artificial diet containing the allelochemicals for 24 hr before mortality counts were taken.

Enzyme Preparation. The midguts of 24 larvae were dissected and the gut contents removed. The guts were washed in ice-cold 1.15% KCl and homogenized in 0.1 M sodium phosphate buffer (pH 6.5) followed by differential centrifugation to obtain the soluble fraction as described previously (Yu, 1982). The protein concentration was determined by the method of Bradford (1976) using bovine serum albumin as the standard.

Glutathione Transferase Assays. Glutathione transferase activity towards the isothiocyanate was studied using the allelochemical-dependent glutathione depletion assay (Boyland and Chasseaud, 1967). The 4-ml reaction mixture contained equimolar concentrations of allelochemicals (AITC, 3 mM; BITC and PITC, 1.5 mM) and reduced glutathione, 0.1 M sodium phosphate buffer (pH 6.5), and the soluble fraction (equivalent to 1 mg of protein per incubate). Duplicate reaction mixtures were incubated for 2 min at 25°C in a water bath with shaking. The concentration of glutathione remaining in the reaction mixture at the end of the incubation period was measured using the method of Ellman (1959). All reactions were corrected for nonenzymatic activity using boiled soluble fraction as a blank.

Statistical Analysis. Enzyme assay data were subjected to analysis of var-

iance (SAS Institute, 1985) followed by Dunnett's test (Steel and Torrie, 1960) when the ANOVA was significant at $P < 0.05$. Probit analysis was performed on acute toxicity data (SAS Institute, 1985).

RESULTS

Glutathione Transferase Activity Towards Isothiocyanates. Glutathione transferase activity towards isothiocyanates was characterized in the FAW using AITC as a model substrate. The assays were conducted at pH 6.5 to avoid the severe nonenzymatic conjugation of AITC with GSH that occurs at higher pHs. Enzyme activity was maximized by inducing newly molted sixth-instar larvae with indole 3-acetonitrile (0.2%) for two days before preparation of the soluble fraction. At pH 6.5, enzyme activity against AITC reached its maximum after 2 min of incubation and was linear up to 1.5 mg protein/sample (data not shown). The transferase activity was inhibited by the known glutathione transferase inhibitors guercetin, triphenyltin chloride (Wadleigh and Yu, 1987), ellagic acid (Das et al., 1984), and juglone (Kulkarni et al., 1978) at 10^{-4} M (Table 1). Juglone and triphenyltin chloride were the most potent inhibitors, reducing activity by 99% at this concentration.

The results summarized in Table 2 showed that glutathione transferase prepared from the midgut homogenates of noninduced FAW and CL larvae catalyzed the conjugation of GSH with AITC and BITC but not PITC. The transferase activity in the CL was two- to sixfold greater than that in the FAW. In all instances, no activity towards these allelochemicals was detected in VBC larvae.

TABLE 1. In Vitro EFFECT OF INHIBITORS ON GLUTATHIONE TRANSFERASE ACTIVITY TOWARDS ALLYL ISOTHIOCYANATE IN FALL ARMYWORM LARVAE

Inhibitor (10^{-4} M)	Glutathione transferase (μmol AITC conjugated/ 2 min/mg protein)[a]	Inhibition (%)
Control	1.47 ± 0.01	0
Triphenyltin chloride	0.02 ± 0.02[b]	99
Juglone	0.02 ± 0.02[b]	99
Ellagic acid	0.31 ± 0.08[b]	79
Quercetin	0.80 ± 0.10[b]	46

[a] Newly molted sixth-instar larvae were fed 0.2% indole 3-acetonitrile for two days before the enzyme assays were conducted. Mean ± SEM of three experiments.
[b] Value significantly different from the control ($P < 0.05$).

TABLE 2. GLUTATHIONE TRANSFERASE ACTIVITY TOWARDS ISOTHIOCYANATES IN THREE SPECIES OF LEPIDOPTEROUS LARVAE

Substrate	Glutathione transferase (μmol substrate conjugated/2 min/mg protein)[a] Velvetbean caterpillar	(N)	Fall armyworm	(N)	Cabbage looper	(N)
Allyl isothiocyanate	0	(2)	0.19 ± 0.09	(5)	1.14 ± 0.04	(4)
Benzyl isothiocyanate	0	(3)	0.16 ± 0.06	(3)	0.34 ± 0.13	(3)
2-Phenylethyl isothiocyanate	0	(3)	0	(4)	0	(3)

[a] Mean ± SEM of N experiments.

From Table 3 it is seen that various allelochemicals induced glutathione transferase activity towards AITC, BITC, and PITC in FAW larvae. Transferase activity towards AITC was induced by indole 3-acetonitrile, indole 3-carbinol, flavone, xanthotoxin, and its own substrate, AITC. The induction ranged from 5.4- to 10.9-fold, with indole 3-acetonitrile being most active. Transferase activity with BITC was induced up to 10-fold by its own substrate and nearly sixfold by indole 3-acetonitrile. In the case of PITC, conjugase activity can only be detected in induced larvae.

TABLE 3. INDUCTION OF GLUTATHIONE TRANSFERASE ACTIVITY TOWARDS ISOTHIOCYANATES IN FALL ARMYWORM LARVAE

Treatment[a]	Glutathione transferase with substrate (μmol allelochemical conjugated/2 min/mg protein)[b] Allyl isothiocyanate	Benzyl isothiocyanate	Phenylethyl isothiocyanate
Control	0.12 ± 0.07	0.16 ± 0.03	0

[c] Value significantly different from the control ($P < 0.05$).

TABLE 4. INDUCTION OF GLUTATHIONE TRANSFERASE ACTIVITY TOWARDS ALLYL ISOTHIOCYANATE IN TWO SPECIES OF LEPIDOPTEROUS LARVAE

Treatment[a]	Glutathione transferase (μmol AITC conjugated/2 min/mg protein)[b]	
	Velvetbean caterpillar	Cabbage looper
Control	0	1.17 ± 0.04
Indole 3-acetonitrile (0.2%)	0	1.63 ± 0.15[c]
Allyl isothiocyanate (0.025%)	0	1.50 ± 0.09[c]

[a] Final-instar larvae were fed an artificial diet containing allelochemicals, at the concentrations indicated in parenthesis, for two days before the assays were conducted. VBC larvae were fed 0.1% indole 3-acetonitrile.
[b] Mean ± SEM of three experiments.
[c] Value significantly different from the control ($P < 0.05$).

The results obtained from studies of induction of glutathione transferase activity towards AITC in VBC and CL larvae are shown in Table 4. Surprisingly, the induction in CL larvae was only marginal; increases of 39% and 28% by indole 3-acetonitrile and AITC, respectively. No such transferase activity was observed in VBC larvae even though larvae were exposed to these known inducers.

Data in Table 5 show that the induction by indole 3-acetonitrile in FAW larvae was dose-dependent, causing gradual increases in activity from 0.01% to 0.2% in the diet.

Toxicity of Isothiocyanates. Table 6 shows that all of the allelochemicals were acutely toxic when fed to first-instar FAW larvae at 0.005% or greater. However, these compounds had no effect on larval weight, development time,

TABLE 6. TOXICITY OF ISOTHIOCYANATES TO FIRST-INSTAR FALL ARMYWORM LARVAE

Allelochemical	Mortality (%) at indicated concentration[a]		
	0.005%	0.01%	0.05%
Allyl isothiocyanate	0	23	100
Benzyl isothiocyanate	29	93	100
2-Phenylethyl isothiocyanate	29	100	100

[a] One-day-old larvae were fed an artificial diet containing the allelochemicals for 24 hr before mortality counts were made.

TABLE 7. TOXICITY OF ALLYL ISOTHIOCYANATE TO THREE SPECIES OF LEPIDOPTEROUS LARVAE

Species[a]	LC_{50} (% in diet)	95% fiducial limits of LC_{50} (%)
Fall armyworm	0.09	0.08 – 0.1
Velvetbean caterpillar	0.17	0.14 – 0.22
Cabbage looper	0.22	0.16 – 0.25

[a] Groups of 15 (VBC) or 20 (FAW and CL) final-instar larvae were fed an artificial diet containing AITC for 24 hr before mortality counts were made.

and percent pupal emergence of larvae that survived the initial 24-hr exposure (data not shown). AITC was also acutely toxic to final-instar larvae of FAW, CL, and VBC, the LC_{50} values ranging from 0.09% to 0.22% (Table 7). The FAW was most susceptible to AITC, whereas the VBC and CL were equally tolerant.

DISCUSSION

Isothiocyanates, which are the hydrolysis products of glucosinolates (mustard oil glucosides), are widely distributed in cruciferous plants. The hydrolysis is catalyzed by an enzyme known as thioglucosidase, which is stored separately in plant tissue and comes in contact with its glucosinolate substrates when the tissue is fed upon by insects or otherwise damaged (Fenwick, et al., 1982). There is much evidence to suggest that isothiocyanates are insecticidal (Lichtenstein et al., 1964; Seo et al., 1982; and this study, Tables 6 and 7) and as such are important in chemical defense against nonadapted insect herbivores. However, isothiocyanates present no barrier to insect herbivores that are adapted

to feeding on isothiocyanate-producing plants and may act even as attractants and ovipositioning and feeding stimulants (Thorsteinson, 1953; Nair and McEwen, 1976; Vincent and Stewart, 1984).

The results of the present study demonstrate that the isothiocyanates (AITC, BITC, PITC) are metabolized by glutathione transferase in the FAW and CL. In the case of PITC, activity can only be observed after FAW larvae were fed inducers. This suggests that the FAW possesses different glutathione transferase isozymes, some of which can only be detected after induction. Our results also showed that levels of glutathione transferase activity (towards isothiocyanates) in phytophagous insects were correlated with the degree of adaptation to cruciferous plants. The CL, which feeds more widely on crucifers, possessed higher transferase activity than the less crucifer-adapted fall armyworm (Tietz, 1972). On the other hand, the specialist VBC, which feeds mainly on soybeans, did not show any detectable transferase activity towards these compounds. Apparently, the glutathione transferase activity was quite different from that towards DCNB (1,2-dichloro-4-nitrobenzene), CDNB (1-chloro-2,4-dinitrobenzene), or PNPA (*p*-nitrophenyl acetate) in these insects. In a previous report (Yu, 1987b), we showed that glutathione transferase activity was active against all of these model substrates in VBC larvae, their activity with DCNB and PNPA being comparable to FAW larvae.

The data also showed that, as in the case of glutathione transferase towards the model substrates and certain α,β-unsaturated carbonyl allelochemicals (Yu, 1982, 1984; Wadleigh and Yu, 1987), glutathione transferase activity against isothiocyanates was inducible by various allelochemicals including its own substrates. We find it of interest that the CL, which contained 10-fold higher transferase activity than the FAW, was only slightly inducible by allelochemicals. Assuming the rate of feeding was similar in these two species, the differential inducibility of the transferase activity may reflect the nearly fully expressed gene activity in the CL compared to the less expressed gene in the FAW. Alternatively, the CL may have detoxified the inducers at a higher rate than the FAW after administration, resulting in less inducer available for induction. More work is needed to answer this question.

The role of enzyme induction in plant–insect interactions was further clarified by our data showing a dose-dependent response of glutathione transferase to an inducer (Table 5). These results suggest that when an insect feeds on an isothiocyanate-containing plant, the degree of induction is likely influenced by the concentration of the allelochemicals in the plant. In this connection, it was reported that factors such as variety, plant part, and seasonal variation affected levels of isothiocyanates and their parent compounds, the glucosinolates, in plants (Itoh et al., 1984; Rodman and Louda, 1984, 1985).

The bioassay results (Table 7) showed that the VBC was as tolerant of allyl isothiocyanate as the CL. The fact that the VBC contained no detectable

glutathione transferase activity (with isothiocyanates), as compared with the highly active CL, suggests that factors other than glutathione conjugation are also involved in determining the toxicity of the isothiocyanate. It is likely that the microsomal oxidase system which was found to metabolize 2-phenylethyl isothiocyanate (Yu, 1987a) plays an important role in the detoxification of isothiocyanates in the VBC. This insect has been shown to possess high microsomal oxidase activity including epoxidation and hydroxylation (Christian and Yu, 1986; Yu, 1987b).

It is now obvious that glutathione transferase can detoxify numerous plant toxins including α,β-unsaturated carbonyl compounds (e.g., *trans*-cinnamaldehyde, *trans,trans*-2,4-decadienal) and isothiocyanates (this study) in phytophagous insects. Since the transferase activity can also be induced by various allelochemicals (including its own substrates) commonly found in their food plants, glutathione transferase must play a significant role in the detoxification of plant toxins in certain insects. In addition to the compounds mentioned above, there are numerous other allelochemicals such as thiocyanates, coumarins, quinones, terpenoids, cardenolids, and alkaloids that possess the structural requirements to serve as substrates for glutathione transferases. Work is now in progress to explore this area of knowledge which is essential for future pest management.

(Received March 17, 1987; accepted July 10, 1987)

Abstract—Electroantennograms (EAGs) from male and female *Ips avulsus*, *I. calligraphus*, and *I. grandicollis* to their pheromones and selected host odorants or kairomones verified the presence of antennal olfactory receptors in both sexes of each species capable of detecting ipsdienol, ipsenol, *cis*- and *trans*-verbenol, *endo*-brevicomin α-pinene, frontalin, and verbenone. Each species possesses receptors with lower thresholds and in greater abundance for the compounds they produce and to which they are behaviorally most responsive. Detection of both *Ips* and *Dendroctonus* pheromones by the three cohabiting species provides a sensory basis for olfactory interactions among the species. Differences in both threshold and saturation levels for EAGs for the various behavioral chemicals could denote differences in specific behavioral roles for each compound.

INTRODUCTION

The orchestration of host selection, aggregation, and colonization by scolytids cohabiting southern pine involves a chemical communication system composed of both intra- and interspecific chemical messengers. Three engraver beetle species are among the five scolytid species comprising the southern pine bark beetle guild. The *Ips* species, *I. avulsus* (Eichhoff), (four-spined engraver), *I. calligraphus* (Germar), (six-spined engraver) and *I. grandicollis* (Eichhoff), (five-spined engraver), together with *Dendroctonus frontalis* Zimmerman (southern pine beetle) and *D. terebrans* (Olivier) (black turpentine beetle), often coexist and compete for resources in the same host trees.

Chemical communication by this bark beetle guild is complicated and involves both beetle- and host-tree-produced compounds that can function as pheromones, kairomones, allomones, and possibly synomones (Kinzer et al., 1969; Vité et al., 1978; Birch et al., 1980; Svihra et al., 1980). The sequence of arrival and competitive interactions among the three *Ips* species, and sympatric *D. frontalis*, as they colonize pine trees has been investigated (Dixon and Payne, 1979; Birch and Svihra, 1979; Svihra et al., 1980). Furthermore, olfactory communication among these scolytid species may play a significant role in defining their temporal and spatial patterns of colonization and ultimate attack density (Svihra et al., 1980).

In the past, considerable attention has been given to describing the behavioral responses of the species to selected behavioral chemicals or chemical combinations in the field (Vité et al., 1964, 1976a,b, 1978; Renwick and Vité, 1972; Vité and Renwick, 1971a; Werner, 1972; Hedden et al., 1976; Richerson and Payne, 1979; Birch and Svihra, 1979; Dixon and Payne, 1980; Billings, 1985). More recently, studies have concentrated on response patterns of the beetles to trees or logs containing various species of the guild (Hedden et al., 1976; Birch and Svihra, 1979; Svihra et al., 1980; Svihra, 1982). Electrophysiological analyses of antennal olfactory response have been reported for *D. frontalis* and *D. terebrans* (Payne 1970, 1971, 1975; Payne and Dickens, 1976; Dickens and Payne, 1977, 1978; Payne et al. 1982, 1987) and in a preliminary study of *I. calligraphus* (Dickens, 1979). Therefore, the study reported here was undertaken to determine in detail antennal olfactory response of the three sympatric *Ips* species to beetle- and host-tree-produced compounds implicated in the aggregation behavior of the beetles and to provide insight into intra- and interspecific whole organism behavior of the beetles. Results from the study should afford a broader understanding of the olfactory communication systems of the beetles by providing information at the olfactory receptor level for inte-

gration with data on pheromone production, behavioral relationships, niche breadth, and resource partitioning.

METHODS AND MATERIALS

Insects. Bolts of loblolly pine (*Pinus taeda* L.), naturally infested with *I. avulsus, I. calligraphus*, and/or *I. grandicollis*, were collected in eastern Texas and placed in an emergence chamber (Browne, 1972). Upon emergence, adult beetles were sorted, sexed, and stored at 5°C on moist filter paper in Petri dishes until use.

Behavioral Chemicals. The compounds used in the study, and their source and purity, are listed in Table 1. Tenfold serial dilutions of each compound (0.00001 μg/μl to 100 μg/μl) were prepared in nanograde pentane.

Electrophysiological Technique. Olfactory responses were measured using the electroantennogram (EAG) technique, previously described in detail (Dick-

ens and Payne, 1977) and modified from earlier techniques (Schneider, 1957a,b; Payne, 1975). Glass capillary Ag–AgCl microelectrodes filled with 3 M KCl were used. The recording electrode was inserted into the distal end of the antennal club following prepuncture with an electrolytically sharpened tungsten needle. The indifferent electrode was implanted either in the head capsule or mouth of the beetle. EAGs were recorded on Polaroid film with a Tektronix C-27 oscilloscope camera.

Stimulation. Test stimuli were delivered as 5-μl aliquots onto a piece of Whatman No. 1 filter paper (20 × 7 mm) inserted into a glass cartridge (75 mm long × 5 mm ID). The cartridge was oriented toward the antennal preparation from ca. 1 cm for delivery of the stimulus. Odor molecules evaporating from the filter paper were carried over the preparation by a filtered air flow of ca. 1 liter/min. Stimulus duration was 1 sec. An odor delivery system previously described in detail (Payne and Dickens, 1976) was modified for a single compound.

Serial dilutions were presented in order from the lowest to the highest concentration for a given compound. Three minutes were allowed between each stimulus, except at higher concentrations when 5 min were allowed. These intervals were found to be adequate for complete recovery of the EAG. Each dilution was replicated three to eight times for each sex of each species. Five microliters of nanograde pentane served as the control. Response to the control was subtracted from responses to test stimuli.

The use of a common standard, 10 μg of ipsdienol, for all preparations allowed for normalization of data and comparisons among compounds and sexes. Stimulation with the standard either preceded or followed each test stimulus. Responses to test stimuli were represented as a percentage of the mean of the two closest responses to the standard (Dickens, 1978).

Data Analysis. Dosage–response curves plotted from mean responses to each compound were used to determine the relative sensitivity of the olfactory receptors to each compound. The threshold of response, the minimum stimulus concentration at which an EAG was detectable above background, was considered an indication of olfactory receptor sensitivity to a given compound. The maximum level of response (saturation level) was considered a measure of the relative number of responding acceptors (Payne, 1975). Responses were compared using the nonparametric Kruskal-Wallis test (Snedecor and Cochran, 1967).

RESULTS AND DISCUSSION

Response (mV) to the standard, ipsdienol at 10 μg, was similar for each sex of each species tested: (*I. avulsus* males = 2.56 ± 0.66, females = 2.36 ± 0.74; *I. calligraphus* males = 1.58 ± 0.55, females = 2.20 ± 0.68; *I. grandicollis* males = 1.80 ± 0.92, females = 1.37 ± 0.48). Response to the standard was not significantly different between the sexes of a given species.

All compounds tested elicited detectable EAGs from males and females of each species (Figures 1–3). Detection of the compounds suggests a possible past, present, or even potential future behavioral role for the compounds in the olfactory communication systems of the species.

Intraspecific Responses. EAGs for each species generally increased with increasing stimulus concentration above threshold for all test compounds. Similarity of the slopes and shapes of the dosage–response curves for a given compound suggest similar receptor mechanisms for both sexes of each species as was reported in single-cell studies of *Ips pini* (Mustaparta et al., 1979). There were no significant differences in responsiveness between sexes for each compound within each species ($P < 0.05$), except female *I. calligraphus* were significantly more sensitive to *endo*-brevicomin than were males ($P < 0.05$) (Figure 2f).

The threshold and saturation level for each compound varied according to sex and/or species, which suggests probable differences in sensitivity and/or acceptor population size for the compounds tested. Difference in threshold and saturation level might be indicative of the role of each compound in the aggregation process. *I. avulsus* possess larger populations of acceptors with greater sensitivity for ipsdienol, α-pinene, *endo*-brevicomin, and racemic and enantiomeric frontalin than for the other compounds tested (Figure 1). *I. calligraphus* had lower thresholds of response and larger EAGs (to the upper range of concentrations tested) for ipsdienol, α-pinene and *endo*-brevicomin than for the other compounds tested (Figure 2). For *I. grandicollis* the threshold level was lower and saturation level greater for ipsenol, ipsdienol, α-pinene, *endo*-brevicomin, and *trans*-verbenol (Figure 3). The lower thresholds for the respective compounds in each species might indicate the ability of the species to perceive the compounds in low concentrations at greater distances form its source. The higher thresholds for the other compounds (i.e., ipsenol, *cis*- and *trans*-verbenol, and racemic and enantiomeric verbenone for *I. avulsus*; ipsenol, *cis*- and *trans*-verbenol, and racemic and enantiomeric verbenone and frontalin for *I. calligraphus*; *cis*-verbenol and racemic and enantiomeric frontalin and verbenone for *I. grandicollis*) indicate that these compounds might function in short-range orientation and/or arrestment. Intermediate thresholds might be indicative of a compound that functions in intermediate or short-range host orientation or synergism (Dickens, 1981). Similarly, in EAG studies of *I. typographus*, Dickens (1981) reported that 2-methyl-3-buten-2-ol is probably a short-range orientation and/or arrestment substance. This hypothesis was based on the very high response threshold and narrow response width to saturation in EAG measurements. Birgersson et al. (1984) suggest that the adaptive value of a short-range orientation substance is its ability to orient and concentrate the beetles to a tree in the critical initial aggregation phase when the pioneering males must overcome the tree's natural defenses, primarily its heavy resin flow.

Insight into the specificity of a volatile messenger may enter all levels of the communication system, for example: pheromone production, olfactory per-

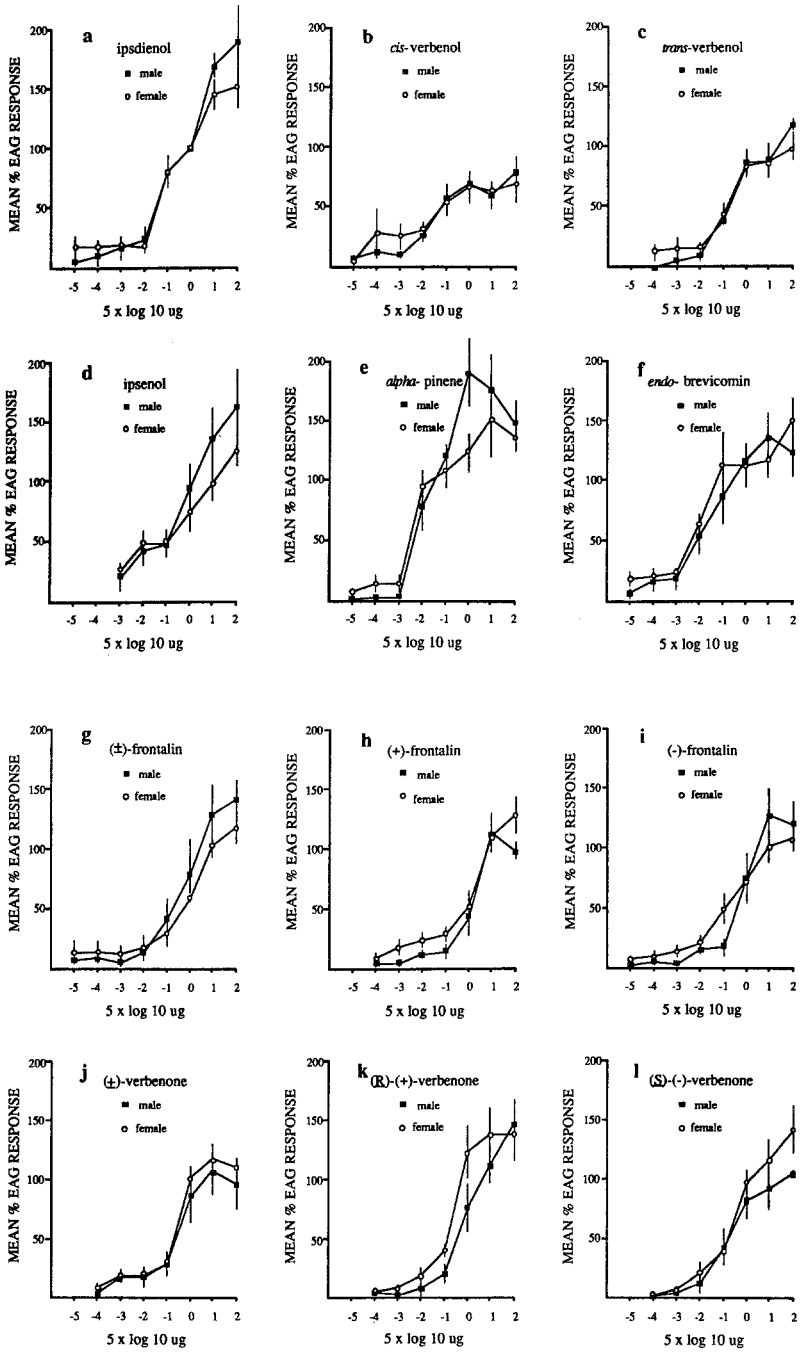

FIG. 3. Mean percent response (±SE) of *I. grandicollis* to behavioral chemicals. Means are percent of EAG to the standard ipsdienol.

ception, and behavioral response. Specificity in bark beetle species has been considered via behavioral response rather than pheromone production or perception (Pitman et al., 1969; Vité and Francke, 1976). However, pheromone production as well as behavioral response information provide supportive evidence for the olfactory perception data presented here.

The high sensitivity of *I. avulsus* and *I. calligraphus* to ipsdienol, and of *I. grandicollis* to ipsenol, is not surprising since these compounds are produced by males, and they are believed to be the primary aggregation pheromones of the respective species (Vité and Renwick, 1971b; Renwick and Vité, 1972; Vité et al., 1972; Hughes 1974). Each species had a somewhat lower sensitivity to *cis*- and *trans*-verbenol which are produced by males of each species, as well as females of *I. calligraphus* (Renwick and Vité, 1972; Vité et al., 1972).

There have been only a few studies of the olfactory behavior of *I. avulsus*, *I. calligraphus*, and *I. grandicollis*; therefore, data are limited for correlation with antennal olfactory response. Compounds tested under field conditions and shown to be attractants, synergists, and/or interruptants of *I. avulsus*, *I. calligraphus*, and *I. grandicollis* are summarized in Tables 2, 3, and 4, respectively. Additionally, based upon behavioral response of the three species to pine bolts infested with the various species of the southern pine bark beetle guild, compounds released by each species, as well as the host, are implicated as functioning in various behavioral capacities (Table 5). Collectively, these data show behavioral significance and possible correlation for the antennal olfactory responsiveness of the three *Ips* species to all compounds tested.

Interspecific Responses. Except for *cis*-verbenol, the olfactory receptors of *I. grandicollis* had lower threshold and higher saturation levels for all compounds tested than those observed for *I. avulsus* and *I. calligraphus* (Figure 4).

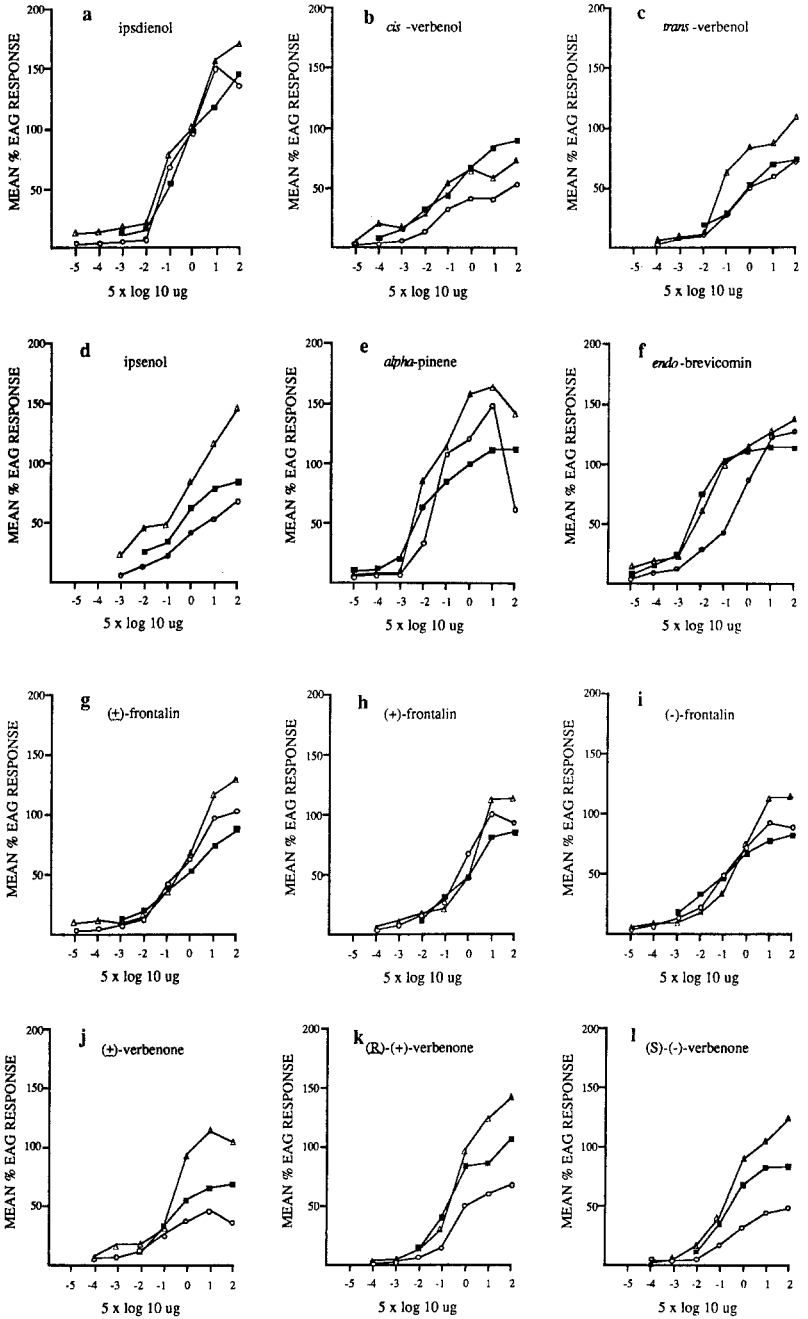

FIG. 4. Mean percent response of *I. avulsus*, *I. calligraphus* and *I. grandicollis* to behavioral chemicals. Means are percent EAG to the standard ipsdienol. ○ = *I. avulsus*; ■ = *I. calligraphus*; △ = *I. grandicollis*.

This was particularly apparent for ipsenol, α-pinene, *endo*-brevicomin, and (*S*)-(−)-verbenone. For field tests, *I. grandicollis* was more general in its response to intra- and interspecific olfactory stimuli than were the other species of the bark beetle guild (Vité et al., 1964). Birch et al. (1980) stated that, in terms of overlapping areas of colonization on a given host, *I. grandicollis* was the least interactive species among the southern pine beetle guild and was largely confined to the larger branches of the crown. Furthermore, Paine et al. (1981) found *I. grandicollis* occupied significantly less area when in the presence of any other bark beetle species or pair of species. The apparent sensitivity of *I. grandicollis* for the compounds may orchestrate this host selection and/or partitioning phenomenon. In comparison, *I. avulsus* and *I. calligraphus* were somewhat less sensitive to the compounds and are more often found with overlapping patterns of colonization.

Interestingly enough, *trans*-verbenol acceptors in *I. grandicollis* are more abundant than similar acceptors possessed by *I. avulsus* and *I. calligraphus* (Figure 4c). *trans*-Verbenol is known to be a synergist of (*S*)-(−)-ipsenol in the pheromone system of *I. grandicollis* (Vité and Renwick, 1971b). Also noteworthy, *cis*-verbenol acceptors are more abundant in *I. calligraphus* than in *I. avulsus* and *I. grandicollis* (Figure 4b). *cis*-Verbenol is not a synergist, but together with (*R*)-(−)-ipsdienol, it is the primary attractant in the apparently dual component pheromone system of *I. calligraphus* (Vité et al., 1978).

EAG results presented here correlate well with the fact that the antennal olfactory receptors of the species are relatively sensitive to compounds that have been implicated as playing a role in interspecific olfactory behavior (Tables 2–5).

CONCLUSIONS

Each *Ips* species possesses receptors with lower thresholds and in greater abundance for the compounds they produce and to which they are behaviorally most responsive. Detection of both *Ips* and *Dendroctonus* pheromonal compounds by the three cohabiting *Ips* species shows a sensory basis for interaction among the species. The fact that differences in both threshold responses and relative numbers of acceptors for the various behavioral chemicals do occur could denote differences in specific behavioral roles for each compound. Although past studies have indicated various attractancy and/or inhibitory interactions among these species (Vité and Renwick, 1971b; Vité et al., 1964; Hedden et al., 1976; Hertel et al., 1969; Birch and Svihra, 1979; Svihra et al., 1980; Svihra, 1982; Birch et al., 1980; Paine et al., 1981), future research may reveal more covert relationships of the intra- and interspecific chemical messengers among the species.

These data provide the basis for a detailed investigation of the underlying sensory mechanisms that enables interspecific olfactory communication. Single-cell analysis aimed at providing this information is currently underway in our laboratory.

(Received September 15, 1986; accepted July 13, 1987)

Abstract—Volatiles were found to be distributed throughout adult Douglas-fir beetles, *Dendroctonus pseudotsugae* Hopkins, suggesting that the hindgut may not be the sole site of production. The volatile content of individual beetles increased dramatically with feeding; qualitative changes reflected the different bark habitats of newly emerged and established beetles. All detected volatiles were also found in beetle frass. Myrcene was the predominant monoterpene of emergent beetles and α-pinene of fed beetles. Linalool and bornyl acetate occurred in significant amounts after feeding, and diacetone alcohol and sulcatol were also detected for the first time. The presence of sulcatol explains the reported cross-attraction with *Gnathotrichus* spp.. *cis*-Verbenol was also found to occur in addition to *trans*-verbenol. The volatile content of male beetles was similar to that of females but amounts of individual compounds were less. Acetic acid was found in both emerged and fed beetles and in lesser amounts in frass, suggesting that microbial metabolism could be a potential source of volatile production.

Key Words—Douglas-fir beetle, *Dendroctonus pseudotsugae*, Coleoptera, Scolytidae, monoterpenes, volatiles, frass, cross-attraction.

INTRODUCTION

The Douglas-fir beetle, *Dendroctonus pseudotsugae* Hopkins (DFB), is an important pest of Douglas-fir, *Pseudotsuga menziesii* Mirb. (Franco), throughout its natural range (Furniss and Carolin, 1977). One approach to its control has been the use of semiochemicals either to induce attack and contain infestations around trees baited with attractive semiochemicals (Pitman, 1973; Ringold et al., 1975), or to repel beetles from trees treated with pheromone components (Furniss et al., 1972, 1974, 1977).

A number of beetle-produced compounds have been reported to act singly or in combination to aggregate DFB and include frontalin (Kinzer et al., 1969), *trans*-verbenol (Rudinsky et al., 1972), 3,2-seudenol (3,2-MCHol) (Rudinsky et al., 1973), and 1,2-seudenol (1,2-MCHol) (Libbey et al., 1983) (see Table 1 for trivial names of some of these compounds used in this paper). In addition, certain host monoterpenes, notably α-pinene, camphene (Pitman and Vité, 1970), ethanol and *trans*-3-penten-1-ol (Pitman and Vité, 1970) may act as attractive kairomones either alone or by synergizing the attractive pheromones (Pitman, 1973).

In contrast, 3,2- (Kinzer et al., 1971) and 3,3-MCH-one (Rudinsky and Ryker, 1980) and verbenone (Rudinsky et al., 1973) were found to act as antiaggregation pheromones, although both verbenone and 3,2-MCH-one were claimed to be concentration-dependent, multifunctional pheromones (Rudinsky and Ryker, 1980).

The female hindgut has been suggested as the site of production of frontalin, *trans*-verbenol, 3,2- and 1,2-MCHol, verbenone, and *trans*-3-pentenol.

TABLE 1. ABBREVIATED OR TRIVIAL AND CHEMICAL NAMES OF CERTAIN VOLATILES MENTIONED IN THIS PAPER

Trivial name[a]	Chemical name	Reference
1,2-MCHol	1-methyl-2-cyclohexen-1-ol	Libbey et al. (1983)
3,2-MCHol	3-methyl-2-cyclohexen-1-ol	Vité et al. (1972)
3,2-MCH-one	3-methyl-2-cyclohexen-1-one	Kinzer et al. (1971)
3,3-MCH-one	3-methyl-3-cyclohexen-1-one	Libbey et al. (1976)
Sulcatol	6-methyl-5-hepten-2-ol	Borden et al. (1976)
Sulcatone	6-methyl-5-hepten-2-one	Ryker et al. (1979)

[a] 3,2-MCHol was originally given the trivial name "seudenol" (Vité et al., 1972) and 3,2-MCH-one has been commonly referred to as MCH (Borden, 1982). However, the occurrence and activity of 1,2-MCHol demands either a new trivial name be given or that the trivial names seudenol and MCH be replaced by more descriptive abbreviations. We have chosen the latter option. On the other hand, we have used the trivial name sulcatone for 6-methyl-5-hepten-2-one which corresponds well with the established trivial name sulcatol.

Other volatiles include 3,2- and 3,3-MCH-one released by female DFB and 6-methyl-5-hepten-2-one released by both males and females (Ryker et al., 1979). Fresh DFB frass was found to be highly attractive to male DFB in laboratory bioassays (Borden et al., 1968), but frass volatiles have not been analyzed exhaustively.

The objectives of this investigation were to assess and compare the volatiles of unfed and fed DFB of both sexes and DFB frass.

METHODS AND MATERIALS

Beetle-infested, Douglas-fir bark was collected from different sources throughout the Fraser Valley and Canyon in southern British Columbia. The bark was stored at 4–5°C or incubated at 28°C to induce emergence. Individual beetles were excised from bark from infested stumps and felled trees at the University of British Columbia Research Forest, Maple Ridge, British Columbia and at the British Columbia Forest Service Cowichan Lake Experiment Station, Mesachie Lake, British Columbia.

Beetles were established within 24 hr of emergence in vertical, 2-month-old, Douglas-fir logs at two-day intervals by inserting a female, and 6 hr later a male, into a 0.5-cm-diameter hole cut with a cork borer. A gelatin capsule pressed into each hole prevented escape of beetles. Capsules were replaced every two days, and the collected frass was weighed and stored in screw-cap vials at −20°C.

All beetles, whether excised from bark prior to emergence, after establishment, or allowed to emerge naturally, were handled identically thereafter. Individual beetles were placed in numbered vials on Dry Ice. The frozen beetle was sexed, weighed, and sectioned transversely between the prothoracic–elytral junction and the separate sections placed into 100 μl of pentane in chilled 2-ml vials. Sectioning divided the alimentary system in the vicinity of the proventriculus so that the anterior section contained the foregut and the posterior section contained the mid- and hindguts.

Standard solutions of 2- and 3-octanol were prepared by adding 2.5 μl of the appropriate alcohol to 10 ml of redistilled pentane. The frozen sections were allowed to thaw and 2 μl of 2-octanol solution were added to each vial. The sections were refrozen, crushed with the flat head of a stainless-steel probe, and 2 μl of 3-octanol solution added. Minimal difference in the subsequent peak heights of 2- and 3-octanol indicated little loss of volatiles during maceration. Vials were permitted to thaw at room temperature and shaken to ensure solvent penetration; the tissue was refrozen and the pentane extract transferred to clean vials which were sealed with Teflon-lined caps prior to storage at −20°C.

Weighed samples of frass were covered with a known volume of pentane

containing 2-octanol marker, capped, and allowed to stand for 16 hr at 10°C. The water and frass components were frozen on Dry Ice, and the pentane extract transferred to clean vials and stored.

Thirty-gram samples of bark, containing either overwintering or attacking beetles, were steam distilled in a glass still for 1 hr, cooled, and the distilled oil collected in pentane containing octanol markers.

Individual extracts and oil samples were analyzed by splitless injection of 2 μl of extract into a Hewlett-Packard 5830A gas chromatograph programmed to run isothermally at 65°C for 8.5 min after elution of the solvent peak and thereafter to 160°C at 5°C/min. A glass capillary column (30 m $\times$ 0.66 mm ID) coated with SP-1000 (Supelco Inc., Bellefonte, Pennsylvania) was employed. The retention times of different compounds were compared to those of a standard quantitative mix of monoterpenes and compounds reported in DFB volatiles and octanol markers. The identities of all known pheromones and kairomones and additional, commonly occurring compounds were verified by mass spectrometry.

The percentage content of identified compounds was divided by that obtained for the 2-octanol marker to make separate runs comparable. Comparisons with the octanol peaks allowed conversion of amounts of each compound into micrograms per beetle segment or micrograms per milligram of frass.

The data obtained for different life-stage classes of beetles and their frass were analyzed following $\log_{10}(x + 1)$ transformation, except where otherwise stated, and comparisons of mean volatile contents of individual compounds between different classes of beetles were by the Newman-Keul's test. The untransformed means and standard errors of amounts of extracted volatiles are shown in the tables to indicate the increasing variability in the volatile status between individual beetles with time. Proportional amounts of compounds in beetles and bark extracts were compared, following arcsin transformation.

RESULTS

Twenty-one compounds were commonly found in extracts of DFBs and their frass; amounts of individual compounds varied with stage of adult development and behavior.

No difference was found between the monoterpenoid volatiles in anterior and posterior sections of individual female beetles, with the exception of *trans*-verbenol (Table 2). Emergent beetles contained less and fewer volatiles than beetles which had experienced 48 hr feeding and maturation within new host material. At emergence, the myrcene content was relatively high, but after feeding, levels of monoterpenes, with the exception of myrcene and terpinolene, increased significantly (Table 3). The α-pinene content increased 225-fold (P

TABLE 2. COMPARISON OF MONOTERPENOID VOLATILES EXTRACTED FROM ANTERIOR AND POSTERIOR SECTIONS OF 9 NEWLY EMERGED DFB FEMALES

Compound	Volatiles/section (μg, $\bar{X} \pm$ SE)	
	Anterior section	Posterior section
α-Pinene	0.117 ± 0.020	0.155 ± 0.013
Camphene	0.015 ± 0.002	0.014 ± 0.004
β-Pinene	0.101 ± 0.020	0.100 ± 0.016
Δ-3-Carene	0.140 ± 0.019	0.139 ± 0.016

Terpinolene	0.009 ± 0.003	0.011 ± 0.001
cis-Verbenol	0.005 ± 0.001	0.005 ± 0.004
trans-Verbenol	0.005 ± 0.001	0.048 ± 0.023
Verbenone	0.011 ± 0.002	0.013 ± 0.004
α-Pinene/myrcene ratio	0.020 ± 0.004	0.027 ± 0.007

< 0.05), but myrcene declined 11-fold in comparison to the levels at emergence ($P < 0.05$). Levels of the monoterpene derivatives, *cis*- and *trans*-verbenol and verbenone, also increased but linalool and bornyl acetate only occurred after beetles had fed in new bark (Table 3). Acetic acid was consis-

TABLE 3. COMPARISON OF MONOTERPENOID VOLATILES EXTRACTED FROM POSTERIOR SECTIONS OF EARLY FEEDING DFB FEMALES WITH LITTLE FOOD IN MIDGUT ($N = 5$) AND FULLY FED FEMALES WITH MIDGUT FULLY DISTENDED WITH FOOD ($N = 12$)

Compound	Volatiles/section (μg, $X \pm$ SE)	
	Early feeding females	Fed, preoviposition females
α-pinene	0.335 ± 0.043	25.500 ± 8.959
Camphene	0.001	0.326 ± 0.106
β-Pinene	0.047 ± .019	2.404 ± 1.124
Δ-3-Carene	0.030 ± .026	0.070 ± 0.040
Myrcene	0.132 ± .004	0.489 ± 0.178
Limonene	0.024 ± .004	0.292 ± 0.119
Linalool	0.083 ± 0.048	0.371 ± 0.162
Bornyl acetate	0.053 ± 0.048	0.194 ± 0.058
cis-Verbenol	0.025 ± 0.010	1.214 ± 1.037
trans-Verbenol	0.036 ± 0.021	0.256 ± 0.143
Verbenone	0.016 ± 0.006	1.307 ± 0.937
α-Pinene/myrcene ratio	13.73 ± 5.01	52.77 ± 16.56

tently detected, but in differing amounts in postdiapause (active), emergent, and newly established beetles; maximum amounts were recorded at emergence (Tables 4 and 5).

The differences in the distribution of volatiles of emerged and fed beetles reflected in a general way the monoterpene composition of the respective bark habitats which differed in age, degree of infestation, and food and moisture status. In a comparison of the relative proportions of host tree volatiles within beetles and bark oils, 14 individual compounds in both beetles and bark oils were highly correlated between fed and mature beetles in fresh bark ($r = 0.972$; $N = 14$; $P < 0.005$) but less so between emergent beetles and the bark from which they emerged ($r = 0.531$; $N = 14$; $P < 0.10$).

Compounds not detected in bark oil volatiles but present in beetles on emergence were frontalin, diacetone alcohol, 1,2-MCHol, 3,2-MCHol, and 3,2-MCH-one. Levels of these compounds changed significantly after feeding in new hosts (Table 4). The same materials were recovered from the frass of beetles that had been feeding for approximately 48 hr. With the exception of myrcene and terpinolene, all monoterpenes and their derivatives increased in frass. Similarly, levels of frontalin and 1,2-MCHol increased, but 3,2-MCHol and 3,2-MCH-one declined. Sulcatol and sulcatone were also detected in mature females (Tables 4 and 5), and relatively high amounts of sulcatol were detected in 48-hr frass (Table 5). An unidentified sesquiterpene (molecular ion 204, fragments 161, 189, and retention time 14.19 min) was detected in small amounts in emergent and fully fed beetles.

Beetles established in a relatively fresh (five weeks old) log had consis-

tently high levels of sulcatone but little sulcatol. In contrast, beetles attacking the same log four weeks later showed a 10-fold increase in sulcatol but little change in sulcatone (Table 6).

The volatile content of male DFBs that had been resident with females in fresh bark for 48 hr was significantly greater, both qualitatively and quantitatively ($P < 0.05$), than that of diapausing or emerged males (Table 7). At this time, levels of all compounds were significantly less ($P < 0.05$) than that of their female partners, but small amounts of frontalin were detected despite its absence on emergence.

The data were examined to assess any significant correlations between the various compounds. The two forms of verbenol were detected either singly or

regression was significant for females ($r = 0.77$; $N = 6$; $P < 0.025$) but not for males ($r = 0.81$; $N = 8$; $P < 0.25$).

Of 66 females, either established in logs or collected from the field, 40% contained sulcatone but no sulcatol; 44% contained sulcatol only; and eight beetles had both compounds among their volatiles. Significant relationships between the occurrence of sulcatol and sulcatone ($r = 0.87$; $N = 8$; $P < 0.05$), 1,2-MCHol and 3,2-MCHol ($r = 0.52$; $N = 15$; $P < 0.05$), and 3,2-MCH-one and 3,2-MCHol ($r = 0.57$; $N = 14$; $P < 0.05$) were found but only in active, preoviposition beetles. Sulcatol did not occur, and there was no significant relationship between either 1,2-MCHol and 3,2-MCHol or 3,2-MCHol and 3,2-MCH-one in newly emerged beetles.

DISCUSSION

Our investigation has demonstrated for the first time the occurrence of the following volatiles in the DFB: sulcatol, *cis*-verbenol, linalool, bornyl acetate, and diacetone alcohol. Frontalin (Pitman and Vité, 1970), *trans*-verbenol (Rudinsky et al., 1972), verbenone (Rudinsky et al., 1973), 1,2-MCHol (Libbey et al., 1983), and 3,2-MCHol (Vité et al., 1972) were previously identified from dissected and extracted hindguts of female DFBs. Reference to an unpublished account of the production of 1,2-MCHol in the hindgut of DFB females had been made earlier (Renwick and Hughes, 1975). However, 3,2-MCH-one was found in the headspace above male and female beetles (Kinzer et al., 1971), while 1,2-MCH (Libbey et al., 1976) and sulcatone (Ryker et al., 1979) were identified from male volatiles only.

Our results demonstrate that many volatiles are distributed throughout the beetle, suggesting that sequestering of volatiles, in addition to their production and release, may occur in the anterior region of the beetles as well as the posterior. These findings contrast with those of Zenther-Moller and Rudinsky (1967) and Hughes (1973). The former authors considered that pheromone production was localized within the hindgut and/or the Malpighian tubules; the latter author hypothesized that attractants produced outside the alimentary tract, in response to exposure to monoterpene vapors, were secreted into the hindgut via the Malpighian tubules. Furthermore, with the exception of frontalin, the volatile spectrum of males and females was qualitatively identical.

The occurrence of frontalin in males cohabiting galleries with females is similar to that in males of other *Dendroctonus* spp., such as *D. ponderosae* Hopkins (Libbey et al., 1985), despite its absence at emergence. Two hypotheses could explain the occurrence of frontalin in these males, as well as the concurrent dramatic increases in other volatiles between emergence and after feeding: (1) the males synthesize or sequester these volatiles directly from the host, or (2) males ingest the borings of female beetles.

Monoterpene levels in fed beetles and new host bark were more closely correlated than those between emergent beetles and the bark from which they had emerged. The relatively high content of Δ-3-carene, myrcene, and limonene in emerged beetles suggests that such materials are preferentially retained, while more volatile components, e.g., α-pinene, are either voided or sequestered in a nonvolatile, nonextractable form, as has been suggested for the mountain pine beetle. Evidence of verbenol production proportional to α-pinene content was found. For the first time, *cis*-verbenol was found to occur either singly or associated with *trans*-verbenol. The occurrence of either form of the verbenols in 25% of the beetles analyzed reflected a difference in temporal production. A preferential biosynthetic production was suggested by the closer correlation of verbenone levels to those of *cis*- rather than *trans*-verbenol.

Borden et al. (1968) found that frass produced by females in the first 4–8 hr in a fresh log was most attractive to male DFBs, suggesting defecation was a major mechanism of volatile release. Furthermore, differences in aeration and microbial activity between frass and the hindgut (Brand et al., 1975, 1976) could potentiate the production of volatiles, e.g., *cis*- and *trans*-verbenol and verbenone. Neither *trans*-verbenol nor verbenone is attractive to DFB, while *cis*-verbenol has yet to be evaluated.

In addition to materials previously reported, 1,2-MCHol was also detected, and levels of this compound were correlated to those of 3,2-MCHol. However, 1,2-MCH-one (Libbey et al., 1983) was not detected and levels of 3,2-MCH-one were related significantly only to 3,2-MCHol. The low amount of variation explained by the regressions is perhaps indicative of the labile nature of these compounds, and no such relationships were found in beetles which had not fed. Similarly, linalool and bornyl acetate, which occurred in high amounts in fed beetles, were absent from both active postdiapause, emerging, and newly established, unfed beetles.

The positive correlation between sulcatone and sulcatol supports the proposition that sulcatone is either a precursor or product of sulcatol (Brand et al., 1977). The production of sulcatol by the DFB adult and its occurrence in frass undoubtedly explains the cross-attraction of *Gnathotrichus* spp. to DFB-attacked logs (Rudinsky and Daterman, 1964), as this compound is a major pheromone utilized by members of this genus (Borden, 1982).

Although acetic acid content was highest at emergence, the increase recorded after feeding and its absence in frass at this time further emphasizes the importance of both aeration and microbial activity in generating biologically active volatiles (Brand et al., 1975, 1976, 1977).

During the course of the experimentation, it was found that the practice of establishment of many beetles by manual insertion into logs of variable and unknown quality produced aberrant results. Despite extensive gallery formation, many of these beetles were found by dissection not to contain any material within the alimentary tract, and myrcene remained the dominant monoterpene. In contrast, beetles that had freely selected and attacked host material contained appreciable amounts of phloem tissue, and α-pinene was the dominant volatile. Therefore, this commonly employed practice must be approached with caution, for it may bypass changes that occur during flight, does not always permit normal host acceptance, and may result in a sequence of volatile changes that rarely occur under natural conditions.

Acknowledgments—We thank L.J. Chong and D.R. Miller for assistance in the laboratory and field. N. Davies confirmed the identity of many of the volatiles detected and gave constructive comment. The research was supported by the National Research Council, Canada, Operating Grant A3881 and Strategic Grant G1039.

AGGREGATION PHEROMONES IN *Drosophila borealis* AND *Drosophila littoralis*

ROBERT J. BARTELT,[1] ANGELA M. SCHANER, and LARRY L. JACKSON

Department of Chemistry
Montana State University
Bozeman, Montana 59717

(Received January 23, 1987; accepted July 14, 1987)

Abstract—Mature males of *Drosophila borealis* and *D. littoralis* (Diptera: Drosophilidae) produce pheromones that attract both males and females in a wind-tunnel bioassay. Ethyl tiglate is a major pheromone component in both species. Isopropyl tiglate is a minor component, as active as ethyl tiglate on an equal-weight basis, but less abundant in the flies. Both species respond to (Z)-9-heneicosene, a compound they do not possess, but which is a pheromone component in closely related species. *D. borealis* and *D. littoralis* are also able to discriminate among various heneicosene isomers. These responses to hydrocarbons may represent artifacts of evolution in this group. For both species, the pheromone was strongly synergized by an extract of fermenting aspen bark, a "host" material of *D. borealis*. Benzyl alcohol was identified as one active component, although it did not account for all the activity of the extract. In nature, the flies probably respond to mixtures of fly-derived and host-derived volatiles.

Key Words—Diptera, Drosophilidae, *Drosophila borealis*, *Drosophila littoralis*, pheromone, aggregation, ethyl tiglate, heneicosene, benzyl alcohol, *virilis* group.

INTRODUCTION

The existence of aggregation pheromones has been demonstrated in a number of *Drosophila* species (Bartelt and Jackson, 1984; Bartelt et al., 1985a,b, 1986a;

[1] Present address: USDA-ARS, Northern Regional Research Center, 1815 N. University St., Peoria, Illinois 61604.

0098-0331/88/0400-1319$06.00/0

Moats et al., 1987; Schaner et al., 1987). Mature males produce compounds that attract both males and females in a laboratory wind-tunnel bioassay. Many of the taxa that have been studied belong to the *virilis* species group. Comparative research on this group was of particular interest because the phylogeny of this group is well known (Throckmorton, 1982).

The *virilis* group consists of the *virilis* and *montana* phylads (Throckmorton, 1982). In the *virilis* phylad, four of the five taxa use heneicosenes as pheromone components. *D. virilis* uses (*Z*)-10-heneicosene (Z10–21), while *D. a. americana*, *D. a. texana*, and *D. novamexicana* use (*Z*)-9-heneicosene (*Z*9–21). The fifth taxon, *D. lummei*, lacks an active hydrocarbon. In contrast to the differences with respect to hydrocarbons, all the *virilis* phylad taxa possess the same five male-specific esters: ethyl tiglate, methyl tiglate, isopropyl tiglate, methyl hexanoate, and ethyl hexanoate. Ethyl tiglate was always the most abundant of these and was active in the pheromone bioassay for all these taxa except *D. a. americana*. The esters present in smaller amounts were also active in some cases. Thus the aggregation pheromones in this phylad generally consist of hydrocarbon and ester components, but *D. lummei* uses only the esters, primarily ethyl tiglate. Curiously, *D. lummei* responds readily to *Z*9–21 and *Z*10–21 in the bioassay, although it possesses neither compound, perhaps an evolutionary artifact (Bartelt et al., 1986a).

This research continues the study of the *virilis* group by considering two species of the *montana* phylad, *D. borealis* and *D. littoralis*. *D. borealis* is a North American species, while *D. littoralis* is European. Of particular interest was whether these species shared any of the ester pheromone components present in the *virilis* phylad. Secondly, these species were tested for responsiveness to heneicosenes, even though they possessed none nor was there any male–female dimorphism in hydrocarbon profiles (Bartelt et al., 1986b). We wished to know whether these species would respond to heneicosenes as *D. lummei* does. Such information could add to the understanding of how pheromone systems evolve.

METHODS AND MATERIALS

The *D. borealis* (strain 2077) and *D. littoralis* (strain 2096.1) cultures were obtained from Dr. L.H. Throckmorton. Rearing of cultures was as described previously (Bartelt and Jackson, 1984). Bioassays were conducted in a wind-tunnel olfactometer containing ca. 1000 one- to four-day-old flies which had been starved overnight before tests began. An extract, fraction, synthetic compound, or control solvent was applied to a filter paper strip inserted around the lip of a glass vial. Each bioassay test consisted of placing two such treated vials, to be compared, into the olfactometer for 3 min. Counts of flies entering the

vials were recorded. Details of bioassays, experimental design, and statistical analysis were as presented earlier (Bartelt and Jackson, 1984; Bartelt et al., 1986a).

Chromatographic methods and identification of tiglic and hexanoic esters were described previously (Bartelt et al., 1985a, 1986a). Briefly, crude extracts were separated into nonpolar and polar bioassay fractions by column chromatography on silicic acid, the solvents for the two fractions being 10% ether in hexane and 10% methanol in methylene chloride, respectively. Alternatively, the column was eluted with hexane before 10% ether in hexane, affording the "hydrocarbon" and "ester" subfractions of the nonpolar fraction. Esters were identified by capillary gas chromatography relative to synthetic standards and were quantitated using an internal standard. Purified synthetic esters and hydrocarbons were on hand from previous work.

The aspen (*Populus tremuloides* Michx.) extract was prepared by peeling ca. 5 g of bark from field-collected, dead, water-soaked aspen branches, <1.0 cm in diameter, and immediately treating the bark with 100 ml of methylene chloride in a Soxhlet apparatus for 3 hr. This extract was used for bioassays at the rate of 10 μl per test. Portions of the extract were fractionated by column chromatography on silicic acid, and these were also bioassayed. Identification of one active compound was based upon the electron impact mass spectrum and GC retention relative to an authentic standard.

RESULTS AND DISCUSSION

Ester Pheromone Components. Bioassay experiments that demonstrated the existence of aggregation pheromones in these species and that led to the chemical identification are summarized in Table 1. Unlike the members of the *virilis* phylad (Bartelt and Jackson, 1984; Bartelt et al., 1986a), *D. borealis* and *D. littoralis* never responded clearly to the extracts of mature males (Table 1A). Although significantly over control levels in most tests, these extracts seldom attracted more than two or three flies per 3-min test period. However, the pheromone preparations were strongly synergistic with an extract of fermented aspen bark. By adding the aspen extract to all subsequent bioassay vials (treatments and controls), larger bioassay catches and clearer tests for pheromonal activity were consistently obtained. Synergism between pheromones and "host" volatiles was previously demonstrated for all species of the *virilis* phylad (Bartelt et al., 1986a). The aspen extract was chosen for the present studies because *D. borealis* is known to use aspen as a host (Throckmorton, 1982).

As in the previously studied species, the extracts of mature males were far more active than those of females (Table 1B), but both sexes responded significantly. In Table 1B, for example, the captured *D. borealis* were 68% males and the *D. littoralis*, 71% males. A male–female sex ratio of ca. 2:1 was fre-

Treatment[a]	Mean catch[b]	
	D. borealis	*D. littoralis*
A. Demonstration of activity of extract from mature males and synergism with aspen extract ($N = 18$)		
Male extract	2.2b	1.8b
Aspen extract	1.5b	1.3b
Male + aspen extracts	9.5a	11.3a
Control (solvent)	0.2c	0.1c
B. Activity of extracts from mature males and females ($N = 20$)		
Female extract + aspen	2.4b	2.2b
Male extract + aspen	11.3a	11.5a
Control (aspen extract)	1.9b	1.3c
C. Activity of polar and nonpolar fraction of mature male extract ($N = 18$)		
Nonpolar fraction + aspen	8.2a	9.4a
Polar fraction + aspen	2.3b	2.1b
Crude extract + aspen	10.8a	11.2a
Control (aspen extract)	2.6b	1.9b
D. Activity of hydrocarbon and ester subfractions from mature male nonpolar fraction ($N = 18$)		
Hydrocarbon subfraction + aspen	4.9b	2.2b
Ester subfraction + aspen	10.9a	10.1a
Nonpolar fraction + aspen	14.6a	11.0a
Control (aspen extract)	2.5c	1.7b
E. Activity of synthetic ester mixture vs. nonpolar fraction from mature males ($N = 24$)		
Synthetic ester mix + aspen	9.8a	12.4a
Fly-derived nonpolar fraction + aspen	8.1a	10.5a
Control (aspen extract)	1.9b	2.4b
F. Comparison of male-specific esters on equal weight basis ($N = 12$)		
Methyl tiglate + aspen	3.6bc	4.1b
Ethyl tiglate + aspen	10.5a	10.9a
Isopropyl tiglate + aspen	10.8a	8.8a
Methyl hexanoate + aspen	4.1bc	4.6b
Ethyl hexanoate + aspen	5.2b	4.3b
Synthetic ester mixture + aspen	10.9a	10.3a
Control (aspen extract)	2.9c	3.1b
G. Cross attraction of *D. borealis* and *D. littoralis* (mature male extracts, $N = 8$)		
D. borealis nonpolar fraction + aspen	7.4a	7.9a
D. littoralis nonpolar fraction + aspen	9.1a	8.9a
Control (aspen extract)	1.8b	1.9b

[a] *D. borealis* fractions and extracts used at 2 fly equivalents per test. Those for *D. littoralis* used at 1 fly equivalent per test. Extract of fermented aspen bark added to all treatments in experiments B–G. Synthetic esters used at 10 ng/test in experiment F and in amounts comparable to fly-derived extracts in experiment E.

[b] In each experiment, means followed by the same letter are not significantly different at the 0.05 level, LSD. All statistical analysis conducted in the log $(x + 1)$ scale to stabilize variance.

quently seen in these experiments but generally reflected the sex ratio of the flies placed into the olfactometer rather than a greater propensity for males to respond. Again as with the *virilis* phylad, the active compound(s) in the extracts were relatively nonpolar (Table 1C), and the subfraction with the polarity of esters contained the majority of this activity (Table 1D). Although the hydrocarbon fraction of *D. borealis* appeared to possess slight activity also, this response was not consistent enough from day to day to allow isolation of active compounds.

The mature males of *D. borealis* and *D. littoralis* possessed the same tiglic and hexanoic esters (Table 2) that were found previously in the members of the *virilis* phylad (Bartelt et al., 1986a), except that no ethyl hexanoate was detected in *D. borealis*. Ethyl tiglate was the most abundant in both species. These esters were never detected in females or newly emerged males. Correspondingly, the nonpolar fractions derived from immature males were inactive in bioassay. For example, the mean bioassay catches for newly emerged *D. borealis* males, mature males, and controls (all with aspen extract) were 3.2b, 10.9a, and 3.2b, respectively. For *D. littoralis* these catches were 2.1b, 8.7a, and 2.5b, respectively (eight replications per treatment, different letters indicate significance at the 0.05 level).

The male-derived nonpolar fractions and corresponding synthetic ester mixtures (prepared according to Table 2) were comparable in bioassay activity (Table 1E). Thus the synthetic esters could account for all the activity in the male-derived fractions. On an individual basis, only ethyl tiglate and isopropyl tiglate were clearly active, compared to controls (Table 1F). Thus the flies can discriminate among certain individual esters. Since ethyl tiglate was the most abundant, as well as among the most active, this ester is believed to be the major pheromone component. The mixture of all esters, in the proportions found in male flies, was not significantly different from an equal weight of ethyl tiglate or isopropyl tiglate. The bioassay equivalence of ethyl tiglate and the ester mix-

TABLE 2. ESTERS ISOLATED FROM MATURE MALES BUT NOT DETECTED IN FEMALES OR NEWLY EMERGED MALES

Compound	Amount (ng/mature male ± SD)	
	D. borealis	*D. littoralis*
Methyl tiglate	1.0 (±0.1)	1.8 (±0.3)
Ethyl tiglate	6.5 (±0.5)	14.2 (±1.3)
Isopropyl tiglate	1.3 (±0.1)	0.8 (±0.1)
Methyl hexanoate	0.5 (±0.1)	0.9 (±0.1)
Ethyl hexanoate	—	0.2 (±0.1)

ture (Table 1F) suggests the minor components are not crucial to the pheromone response, and the function of these minor esters remains uncertain.

Finally, both *D. borealis* and *D. littoralis* responded clearly to the male-derived nonpolar fractions of the other species (Table 1G). Cross attraction would be expected since both possess ethyl tiglate. There is no evidence for a species-isolating mechanism involving pheromones, but since the species are allopatric, none would be anticipated.

Attractive Hydrocarbons. Both *D. borealis* and *D. littoralis* responded to Z9–21 significantly above control levels (Table 3A). In fact 10 μg of this hydrocarbon was comparable in activity to the male-derived pheromone extract. (This level of heneicosene was chosen during earlier work with the *virilis* phylad, where it produced clear responses and represented ca. 2–10 male equivalents). Not only was the hydrocarbon active by itself, but it was also synergistic with ethyl tiglate (Table 3B).

Neither *D. borealis* nor *D. littoralis* possesses any heneicosene (Bartelt et al., 1986b), but both were clearly attracted to Z9–21, a "pheromone-like" response. We suggest that the use of heneicosenes as pheromone components is a primitive trait in the *virilis* species group. Although some species no longer possess these hydrocarbons (e.g., *D. borealis*, *D. littoralis*, and *D. lummei*), they still retain the ability to respond to them. Since most of the species in this group are allopatric, and since even those with overlapping ranges use different hosts/microhabitats, present kairomonal use of these hydrocarbons is not suspected.

TABLE 3. BIOASSAY ACTIVITY OF Z9–21, A HYDROCARBON POSSESSED BY SEVERAL *virilis* GROUP SPECIES, BUT NOT BY *D. borealis* OR *D. littoralis*

Treatment[a]	Mean bioassay catch ($N = 8$)[b]	
	D. borealis	*D. littoralis*
A. Comparison of Z9–21 to nonpolar fraction from mature males		
Z9–21 + aspen	14.3a	7.1a
Male nonpolar fraction + aspen	10.3a	9.8a
Control (aspen extract)	2.4b	2.9b
B. Syngerism of ethyl tiglate and Z9–21		
Z9–21 + aspen	5.6c	6.4b
Ethyl tiglate + aspen	9.9b	9.0b
Z9–21 + ethyl tiglate + aspen	21.6a	22.5a
Control (aspen extract)	1.8d	3.2c

[a] *D. borealis* fraction used at 2 fly equivalents per test. Fraction from *D. littoralis* used at 1 fly equivalent per test. Z9–21 used at 10 μg per test, ethyl tiglate at 10 ng per test.

[b] In each experiment, means followed by the same letter not significantly different at the 0.05 level (LSD).

If the ancestral stock did use heneicosenes as pheromones, then a certain amount of structural specificity might still be evident. As shown in Table 4, both species are able to discriminate to some extent among various isomeric heneicosenes. *D. borealis*, especially, was able to distinguish between Z9–21 and Z10–21 and showed preference much like *D. americana* and *D. novamexicana* of the *virilis* phylad (Bartelt et al., 1986a). *D. littoralis* responded most strongly to Z8–21, but showed significant responses to Z7–21, Z9–21, and Z10–21 as well. Neither species responded significantly to *E* isomers, which was also true for the members of the *virilis* phylad.

Aspen Extract. The activity of the aspen extract appears to be due to a mixture of rather polar compounds. In Table 5, part A, the bioassay results indicate the activity is similar in polarity to alcohols and carboxylic acids; any hydrocarbons in the aspen extract are clearly inactive. The ether fraction consists primarily of one compound (by GC, accounting for >60% of the total peak area). This compound agrees in GC retention (DB-5 capillary column) and mass spectrum with benzyl alcohol. The seven largest mass spectral peaks had mass to charge ratios of 50 (13%), 51 (22%), 77 (63%), 79 (100%), 91 (19%), 107 (70%), and 108 (91%). (Intensities are relative to base peak.)

In Table 5, part B, it is evident that benzyl alcohol accounts for a portion of the extract's activity but not all of it. It is probable that one or more organic acids also contribute to the activity, since treatment of the extract with aqueous 5% NaOH rendered the organic layer significantly less active, but reacidifica-

TABLE 4. RESPONSIVENESS OF *D. borealis* AND *D. littoralis* TOWARD SEVEN HENEICOSENE ISOMERS

Heneicosene[a]	Relative activity[b]	
	D. borealis	*D. littoralis*
Z6-21	12	4
Z7-21	22	62*
Z8-21	69*	100*
Z9-21	100*	44*
Z10-21	3	32*
E9-21	6	12
E10-21	11	8

[a] Heneicosenes used at 10 μg per test. Each was combined with the aspen extract for bioassay. The aspen extract was used as the control.

[b] Each hydrocarbon was tested against Z9–21 and controls in a balanced incomplete block experiment. Relative activity based on mean catches. Relative activity = 100 × [(test isomer − control)/(Z9–21 − control)]. For *D. littoralis*, relative activities rescaled so that the most active isomer (Z8–21) was represented by 100. Overall means for Z9–21 and controls were 10.7 and 2.7, respectively, for *D. borealis*, and 9.9 and 3.0 for *D. littoralis*. (*) Indicates that the heneicosene differed from the control at the 0.05 level.

TABLE 5. PROGRESS TOWARD IDENTIFICATION OF ACTIVE COMPOUNDS IN ASPEN EXTRACT: BIOASSAY RESULTS FOR *D. borealis*

A. Activities of silicic acid fractions of aspen extract

Fraction	Mean bioassay catch ($N \geq 4$)[a]	
	Fraction[b]	Control[b]
Hexane	1.6	2.8
5% Ether–hexane	2.1	1.5
10% Ether–hexane	5.5*	1.5
25% Ether–hexane	13.2***	1.7
Ether	20.5***	1.5
10% Methanol–CH_2Cl_2	6.5	2.8
Crude aspen extract	21.6***	2.8

B. Additional bioassay experiments

Treatments	Mean bioassay catch ($N \geq 8$)[c]
Benzyl alcohol[d] + ethyl tiglate	20.4b
Aspen extract[d] + ethyl tiglate	41.5a
Control (ethyl tiglate)	9.5c
Aspen extract, treated with NaOH[e] + ethyl tiglate	32.5b
Aspen extract + ethyl tiglate	62.1a
Control (ethyl tiglate)	17.3c
Aspen extract treated with NaOH, then HCl[e] + ethyl tiglate	52.5a
Aspen extract + ethyl tiglate	55.6a
Control (ethyl tiglate)	12.3b

[a] Significant differences from controls at 0.05 and 0.001 levels denoted by (*) and (***), respectively.
[b] In part A of this table all treatments and controls contained 10 ng ethyl tiglate + 10 μg Z9–21.
[c] In each experiment, means followed by the same letter not significantly different (LSD, 0.05).
[d] Benzyl alcohol, identified as the major component of the ether fraction, tested at 900 ng; the aspen extract had an equivalent amount.
[e] See text for details.

tion with HCl restored most of the activity. In this series of experiments, the flies were unusually responsive. Using only ethyl tiglate as a coattractant produced some mean catches as high as 60 flies per 3-min test. Although absolute responsiveness varied throughout these experiments, synergistic effects were still obvious in a relative sense.

Conclusion. Like the other members of the *virilis* group studied previously, mature males of *D. borealis* and *D. littoralis* produce compounds that

attract both males and females in a wind-tunnel olfactometer. These species were difficult to study in that fly-derived compounds by themselves never elicited clear bioassay responses. However, using an extract from a likely host, fermenting aspen bark, as a bioassay coattractant allowed strong pheromone responses to be seen. In nature, flies would probably respond to such combinations of fly-derived and host-derived volatiles, since the flies aggregate at appropriate host sites to mate and lay eggs as well as to feed (Spieth, 1974).

Ethyl tiglate is the key attractant in both of these species. The same ester was previously found to be a pheromone component in other members of the *virilis* group and even in the more distantly related *D. hydei* (Moats et al., 1987). Both *D. borealis* and *D. littoralis* respond to Z9–21 and, in varying degrees, to other heneicosene isomers. Neither species produces heneicosenes, but these hydrocarbons were previously shown to be pheromone components in closely related species. These responses may be related to the evolution of pheromone systems in this species group.

Acknowledgments—We are indebted to Dr. L.H. Throckmorton of the University of Chicago for supplying the fly cultures used in this work. This research was supported by NSF grant DCB-8509976 and is published as paper number J-1938 in the Montana Agricultural Experiment Station Journal Series.

Announcement

The fifth annual meeting of the International Society of Chemical Ecology will take place June 24–27, 1988, in Athens, Georgia (USA). Abstracts for contributed papers and posters should be submitted to the conference host, Dr. Murray S. Blum, Laboratory of Chemical Ecology, Department of Entomology, University of Georgia, Athens, GA 30605. Dr. Blum is planning a number of symposia and these will be announced in the Newsletter of ISCE to members.

Requests for information on housing, meals, and other logistics should be sent to Mr. I. A. Little, Conference Facilitator, Georgia Center for Continuing Education, University of Georgia, Athens, GA 30602.

(Received March 24, 1987; accepted July 17, 1987)

Abstract—The synthesis and biological activity of some analogs of (*Z*)-13-hexadecen-11-ynyl acetate **1**, the major component of the sex pheromone of the processionary moth *Thaumetopoea pityocampa* is described. The analogs have been formally derived by structural modification of the enyne and acetate functions of the parent compound **1**. In field tests, trifluoroacetate ester **16** and the analog, **11**, with fluorine substitution at the olefin site, decreased the pheromone action, whereas epoxy derivative, **10**, from epoxidation of the olefin moiety in **1**, and propionate ester **15** gave synergistic activity. The formate **14** had a variable effect according to the composition of the lure. Formal reduction of the enyne to give the acetylene **2** was found to retain activity. Alcohols **12** and **13**, resulting from hydrolysis of the enyne **1** and acetylene **2**, respectively, inhibited the action of their parent compounds.

Key Words—Sex pheromone, inhibition, synergism, processionary moth, *Thaumetopoea pityocampa*, Lepidoptera, Thaumetopoeidae.

INTRODUCTION

It is generally accepted that in the perception process of insect sex pheromones, there are very strict structural requirements for successful interaction between

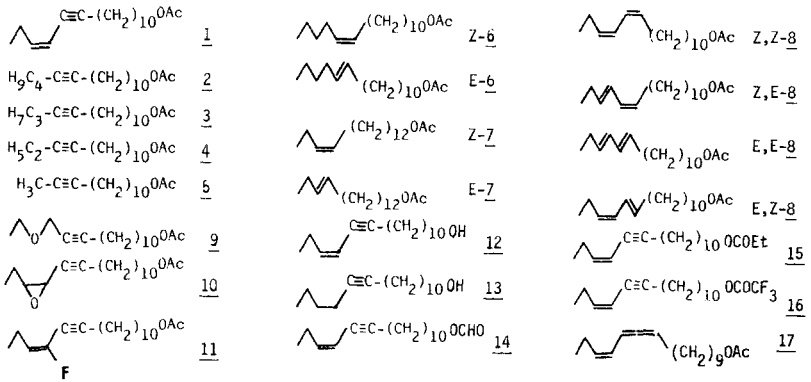
[1] Lepidoptera, Thaumetopoeidae.

0098-0331/88/0500-1331$06.00/0

substrate and the receptor cells in the dendritic membrane of the antenna. This interaction may involve electrostatic, hydrophilic, hydrophobic, van der Waals forces or a hydrogen bonding mechanism and can be modulated by flexible receptor proteins, which can adopt the required conformational changes to achieve a successful recognition of the substrate molecule.

In this context, the knowledge of the sex pheromone critical molecular parts may be essential for a better understanding of the overall attractant perception process, and for the establishment of structure–activity relationships (Priesner, 1979; Liljefors et al., 1984) to help in the design of new synergists and inhibitors, capable of either increasing or decreasing the biological activity of the natural pheromone (Roelofs and Comeau, 1971).

In this paper, we report on the synthesis and biological activity of a variety of compounds structurally related to (*Z*)-13-hexadecen-11-ynyl acetate **1** (pityolure), the major component of the sex pheromone of the processionary moth *Thaumetopoea pityocampa* (Denis and Schiff.) (Guerrero et al., 1981; Camps et al., 1981a,b, 1983, 1987a; Cuevas et al., 1983; Michelot et al., 1982; Shani et al., 1983). These compounds, **2–17** (Scheme 1) proceed from modifications on the three putative key molecular parts of the parent molecule **1**, the double and the triple bonds and the acetate group, which may be directly involved in the interaction process with the receptor.



SCHEME 1.

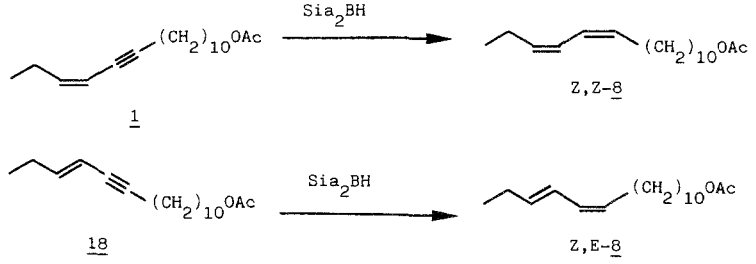
Thus, acetylenic derivatives **2–5** would result from saturation of the double bond and shortening of the chain length of the nonfunctionalized part of the sex pheromone component **1**. Likewise, partial reduction of the enyne moiety would lead to dienic compounds **8**, from which olefins **6** and **7** could be derived. On the other hand, whereas in oxa-analog **9** one of the olefinic carbons has been replaced by an oxygen atom, in the epoxy derivative **10** the double bond has been transformed into an oxirane ring. In fluorinated analog **11**, a fluorine atom

has been substituted for a vinyl hydrogen, whereas alcohols **12** and **13** would, obviously, derive from the corresponding esters **1** and **2**. Finally, in esters **14**, **15**, and **16**, the acetate moiety has been replaced by the formate, propionate, and trifluoroacetate groups, respectively.

METHODS AND MATERIALS

Boiling points are uncorrected. IR spectra were recorded in CCl_4 solution on Perkin Elmer 257 and 399B grating spectrometers [^{1}H]NMR spectra were determined in $CDCl_3$ solution on a Bruker WP80SY or on a Varian XL200 spectrometer, operating at 80 and 200 MHz, respectively, and absorptions are expressed in δ scale relative to TMS. [^{13}C]NMR spectra were recorded on a Bruker WP80SY instrument at 20.15 MHz in $CDCl_3$ solution, and the values are expressed in δ scale relative to TMS. GLC analyses were performed on Carlo Erba models 2350 and 4130 equipped with a FID detector, using 3% OV-101 glass column 2 m × 3 mm ID on Chromosorb W (nitrogen as carrier gas), or a fused silica capillary column SE-54 50 m × 0.32 mm ID (hydrogen as carrier gas).

Reactions requiring anhydrous and oxygen-free conditions were performed under dried inert atmosphere (N_2 or Ar). Anhydrous solvents were prepared as follows: tetrahydrofuran (THF) by distillation from Na/benzophenone, diethyl ether from lithium aluminium hydride (LAH), CCl_4 from P_2O_5, pyridine from KOH, and hexamethylphosphoric triamide (HMPT) from CaH_2.



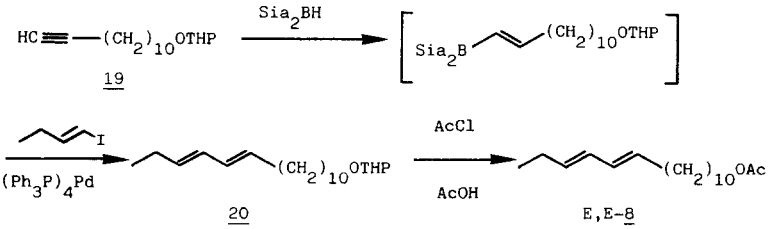
SCHEME 2.

Chemicals. Acetylenic acetates **2–5** were prepared by alkylation of the corresponding tetrahydropyranyloxy acetylides in HMPT (Brattesani and Heathcock, 1973) followed by hydrolysis and acetylation. Monounsaturated derivatives *Z*-**6**, *Z*-**7**, *E*-**6**, and *E*-**7** have been prepared by stereoselective reduction of the parent acetylenic compounds to the *Z* (H_2/Pd-C) or to the *E* isomer (Na/NH_3). The acetylenic precursor for preparation of compounds **7** was obtained by triple bond migration of tetradec-11-yn-1-ol with potassium

3-aminopropylamide (KAPA) in 1,3-propylenediamine (Brown and Yamashita, 1975), followed by hydroxyl protection as the tetrahydropyranyl derivative, alkylation of the resulting terminal acetylene with ethyl bromide, hydrolysis, and acetylation. The epoxyacetate **10**, which was prepared by epoxidation of the natural compound **1**, was subsequently transformed into fluorinated analog **11**, with a 2:1 *E*:*Z* isomer ratio, by a route previously described by us (Camps et al., 1986). Formate **14**, propionate **15**, and trifluoroacetate **16** have been prepared by esterification of the parent alcohol **12**. On the other hand, eneallene **17** was kindly supplied by Dr. Jahyo Kang (Sogang University, Seoul, South Korea).

(Z,Z)-*11,13-Hexadecadienyl Acetate* (Z,Z)-*8* (Scheme 2). In a two-neck 25-ml round-bottomed flask was placed 0.065 ml (0.5 mmol) of a 8 M BH_3 · THF complex. To this solution, previously cooled to 0°C, was added, under N_2, 0.070 g (1 mmol) of 2-methyl-2-butene. The resulting mixture was stirred for 2 hr at room temperature and cooled again to 0°C. Then, 0.115 g (0.42 mmol) of (*Z*)-13-hexadecen-11-ynyl acetate **1** in 2 ml of anh. ether was added. Stirring was kept at room temperature for 4 hr, then 0.3 ml of glacial acetic acid was added and the resulting solution further stirred for 12 hr at 30–35°C. Oxidation was carried out by stirring for 30 min in the presence of 1 ml of 6 N NaOH and 0.25 ml of 30% hydrogen peroxide, keeping the temperature below 40°C. The reaction mixture was poured into ice and extracted with hexane (4 × 8 ml). The combined organic layers were washed with brine and dried ($MgSO_4$) to yield, after evaporation of the solvent, 0.116 g of an oil, which was purified by column chromatography on silica gel, eluting with hexane–ethyl acetate 95:5, to afford pure (*Z*,*Z*)-**8** in 76% yield (isomeric purity higher than 99% by GLC analysis on capillary column).

Anal.: Calcd. for $C_{18}H_{32}O_2$: C, 77.14; H, 11.42. Found: C, 77.15; H, 11.72. IR: ν 2960, 2930, 1860, 1745, 1240 cm^{-1}. [^{1}H]NMR: δ 1.00 (t, J = 7.5 Hz, 3H, $C\underline{H}_3CH_2$), 1.28 (b, 14H, $CH_2C\underline{H}_2CH_2$), 1.62 (c, 2H, $C\underline{H}_2CH_2O$), 2.05 (s, 3H, $C\underline{H}_3CO$), 2.16 (c, 4H, $C\underline{H}_2C{=}C$), 4.05 (t, J = 6.7 Hz, 2H, $C\underline{H}_2O$), 5.44 (c, 2H, $CH_2C\underline{H}{=}$), 6.24 (c, 2H, ${=}C\underline{H}\text{-}C\underline{H}{=}$). [^{13}C]NMR: δ 64.7 (C-1), 28.7–29.7 (C-2 and C-4 to C-9), 26.0 (C-3), 27.5 (C-10), 133.6 (C-11), 123.2, 123.6 (C-12 and C-13), 132.1 (C-14), 20.9 (C-15 and C-1′), 14.2 (C-16), 171.0 (CO).



SCHEME 3.

(Z,E)-*11,13-Hexadecadienyl Acetate* (Z,E)-***8*** (Scheme 2). The same procedure described above for compound ***Z,Z*-8** was applied, using compound **18,** the *E* isomer of **1**, previously prepared by coupling of (*E*)-1-iodo-1-butene with 11-dodecynyl acetate in the presence of tetrakis(triphenylphosphine)palladium (Michelot et al., 1982). Thus, starting from 88 mg (0.31 mmol) of **18**, 72 mg (82%) of dienic acetate (*Z,E*)-**8** was obtained, after purification by column chromatography on silica gel, eluting with hexane–ethyl acetate 95:5. Compound (*Z,E*)-**8** had a 98:2 *Z,E*:*E,E* isomeric purity by GLC analysis on capillary column.

Anal.: Calcd. for $C_{18}H_{32}O_2$: C, 77.14; H, 11.42. Found: C, 77.17; H, 11.63. IR: ν 2960, 2930, 1745, 1240, 980 cm^{-1}. [^{1}H]NMR: δ 1.01 (t, J = 7.4 Hz, 3H, $C\underline{H}_3CH_2$), 1.29 (b, 14H, $CH_2C\underline{H}_2C\underline{H}_2$), 1.61 (c, 2H, $C\underline{H}_2CH_2O$), 2.05 (s, 3H, $C\underline{H}_3CO$), 2.16 (c, 4H, $C\underline{H}_2C{=}$), 4.05 (t, J = 6.7 Hz, 2H, $C\underline{H}_2O$), 5.31 (dt, J = 10.8 and 7.3 Hz, 1H, H-14), 5.70 (dt, J = 15 and 6.7 Hz, 1H, H-11), 5.95 (t, J = 10.8 Hz, 1H, H-13), 6.31 (dd, J = 15.1 and 10.9 Hz, 1H, H-12). (E,E)-*11,12-Hexadecadienyl Acetate* (E,E)-***8*** (Scheme 3). In a three-neck round-bottomed flask was placed, at 0°C under N_2, a mixture of 0.178 ml (1.52 mmol) of a 8 M $BH_3 \cdot S(CH_3)_2$ solution and 0.210 g (3 mmol) of 2-methyl-2-butene. The resulting solution was stirred at room temperature for 2 hr and then a solution of 0.353 g (1.27 mmol) of 2-(11-dodecynyloxy)tetrahydropyran **19** in 2 ml of anh. THF was added. The mixture was stirred for 2 hr to complete the formation of the intermediate vinylborane. After this time, a solution of 8 mg (1% molar) of tetrakis(triphenylphosphine)palladium in 1 ml of anh. THF, previously stirred at room temperature for 30 min on the dark and under N_2, was added along with 0.231 g (1.27 mmol) of (*E*)-1-iodo-1-butene (Michelot et al., 1982). The mixture was stirred for 2 hr more at room temperature and treated with a solution of 0.1 g of NaOH in 1.2 ml of deoxygenated water for 14 hr at 70°C. Oxidation was carried out by addition at 0°C of 1.2 ml of 6.5 N NaOH and 0.4 ml of 30% H_2O_2, followed by stirring for one additional hour at room temperature. The reaction mixture was poured into ice and extracted with hexane (5× 10 ml). The combined organic layers were washed with brine and dried ($MgSO_4$) to afford, after evaporation of the solvent, 0.36 g of the expected THP-protected dienic alcohol **20**, which was directly acetylated by treatment with 0.25 ml of acetyl chloride and 1 ml of acetic acid in 2 ml of CCl_4 under reflux for 7 hr. Then, the reaction mixture was cooled, and after addition of solid $NaHCO_3$, poured into ice and extracted with hexane (5× 10 ml). The organic layers were washed with brine and dried ($MgSO_4$). Removal of the solvent and purification by column chromatography on silica gel, eluting with hexane–ethyl acetate 95:5, afforded 0.155 g (43%) of compound (*E,E*)-**8**, isomerically pure (99%) by GLC analysis.

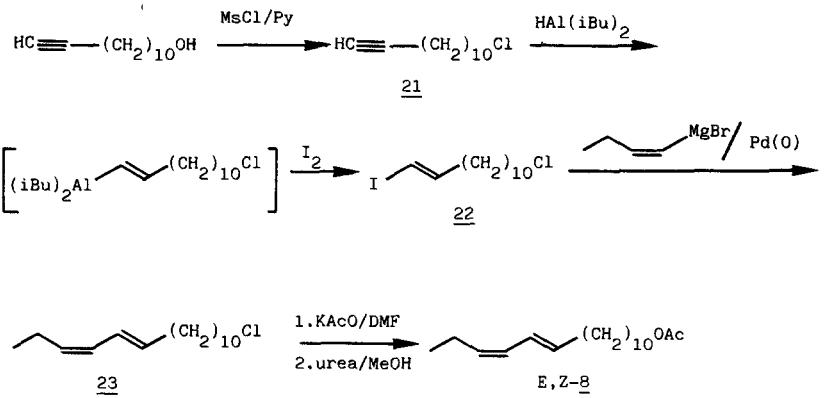
Anal.: Calcd. for $C_{18}H_{32}O_2$: C, 77.14; H, 11.42. Found: C, 77.04; H, 11.30. IR: ν 2960, 2930, 2860, 1745, 1240, 990 cm^{-1}. [^{1}H]NMR: δ 0.99 (t, J = 7.4 Hz, 3H, $C\underline{H}_3CH_2$), 1.29 (b, 14H, $CH_2C\underline{H}_2CH_2$), 1.62 (c, 2H, $C\underline{H}_2CH_2O$), 2.04 (s, 3H, $C\underline{H}_3CO$), 2.06 (c, 4H, $C\underline{H}_2C{=}$), 4.05 (t, J = 6.7 Hz, 2H, $C\underline{H}_2O$), 5.58 (c, 2H, $CH_2C\underline{H}{=}$), 6.00 (c, 2H, $=C\underline{H}\text{-}C\underline{H}{=}$). [^{13}C]NMR: δ 64.5 (C-1), 28.5–29.3 (C-2 and C-4 to C-9), 25.8 (C-3), 32.5 (C-10), 132.2 (C-11), 130.5 (C-12), 130.3 (C-13), 132.0 (C-14), 25.4 (C-15), 13.5 (C-16), 21.0 (C-1′), 170.9 (CO).



SCHEME 4.

12-Chloro-1-dodecyne ***21***. In a three-neck round-bottomed flask provided with a magnetic stirrer, N_2 inlet, septum, reflux condenser, and calcium chloride tube were placed 1.13 g (6.2 mmol) of 11-dodecyn-1-ol and 0.54 g (6.8 mmol) of anh. pyridine in 3 ml of anh. dimethylformamide (DMF). To this solution was added 0.52 ml (6.76 mmol) of methanesulfonyl chloride, and the reaction mixture was heated at 75°C for 16 hr. The resulting solution was poured into ice-water and extracted with hexane (5× 20 ml). The combined organic layers were washed with brine and dried ($MgSO_4$). Removal of the solvent left a residue which was distilled (bp 60–65°C/0.3 torr) to yield 1.0 g (88%) of pure chloroalkyne **21**.

Anal.: Calcd. for $C_{12}H_{21}Cl$: C, 72.07; H, 10.58. Found: C, 72.15; H, 11.00. [^{1}H]NMR: δ 1.32 (b, 14H, $CH_2C\underline{H}_2CH_2$), 1.79 (c, 2H, $C\underline{H}_2CH_2Cl$), 1.94 (t, J = 2.5 Hz, 1H, $\underline{H}C{\equiv}$), 2.16 (c, 2H, $C\underline{H}_2C{\equiv}$), 3.55 (t, J = 6.6 Hz, 2H, $C\underline{H}_2Cl$). [^{13}C]NMR: δ 68.0 (C-1), 84.4 (C-2), 18.2 (C-3), 28.4–29.2 (C-4 to C-9), 26.8 (C-10), 32.5 (C-11), 44.8 (C-12).

(E)-*12-Chloro-1-iodo-1-dodecene* ***22***. To a solution of 1.4 g (7 mmol) of alkyne **21** in 7 ml of anh. hexane was added dropwise, under N_2, 7 ml (7 mmol)

of a 1 M diisobutylaluminiumhydride (DIBAH) soln. in hexane. The reaction mixture was stirred at 50°C for 4 hr, cooled to −40°C, and subsequently treated with 1.77 g (7 mmol) of iodine in 7 ml of anh. THF. Stirring was continued for 1 hr at room temperature. The mixture was cooled to −10°C and 5 ml of 20% H_2SO_4 was slowly added. After pouring into ice and extraction with hexane (5× 20 ml), the combined organic layers were washed with 5% $NaHSO_3$ and brine and dried ($MgSO_4$). Evaporation of the solvent yielded a crude, which was chromatographically purified (silica gel) to afford 1.42 g (62%) of compound **22**, isomerically pure (>99%) by GLC analysis on a capillary column.

Anal.: Calcd. for $C_{12}H_{22}ClI$: C, 43.94; H, 6.76, Cl, 10,81; I, 38.69. Found: C, 43.77; H, 7.09; Cl, 10.79; I, 38.66. IR: ν 2930, 2860, 1605, 950 cm^{-1}. [^{1}H]NMR: δ 1.31 (b, 14H, $CH_2\underline{CH_2}\underline{CH_2}$), 1.82 (c, 2H, $\underline{CH_2}CH_2Cl$), 2.05 (c, 2H, $\underline{CH_2}C=$), 3.55 (t, J = 6.6 Hz, 2H, $\underline{CH_2}Cl$), 5.97 (dt, J = 14.4 and 1.6 Hz, 1H, $=\underline{CH}I$), 6.52 (dt, J = 14.5 and 7.4 Hz, 1H, $=\underline{CH}CH_2$). [^{13}C]NMR: δ 74.2 (C-1), 146.7 (C-2), 36.0 (C-3), 28.3–29.4 (C-4 to C-9), 26.9 (C-10), 32.6 (C-11), 45.0 (C-12).

(E,Z)-*11,13-Hexadecadienyl Acetate* (E,Z)-**8** (Scheme 4). A THF solution of the Grignard reagent of (*Z*)-bromo-1-butene, obtained as previously described (Norris, 1959), was prepared from 0.4 g (3 mmol) of the alkene and 86 mg (3.6 mmol) of magnesium. The organomagnesium reagent was slowly added, via syringe, to a solution of 0.329 g (1 mmol) of compound **22** and 0.173 g (0.15 mmol) of tetrakis(triphenylphosphine)palladium in 7 ml of anh. THF. The resulting mixture was stirred at room temperature for 2 hr, poured into ice-water and extracted with hexane (5× 10 ml). After conventional work-up, 0.170 g of crude (*E,Z*)-11,13-1-chlorohexadecadiene **23** was obtained, which was directly treated with 0.490 g (15 mmol) of KOAc in 10 ml of DMF at 120°C for 90 min. The reaction mixture was quenched and worked up as usual to provide 0.162 g of a crude, which was purified by column chromatography on silica gel, eluting with hexane–ethyl acetate 94:6, to furnish 0.146 g (52% from **22**) of diene acetate (*E,Z*)-**8**, of isomeric purity *E,Z*:*E,E* 82:18 on GLC analysis. Removal of the contaminating *E,E* isomer was achieved by treatment with a saturated solution of urea in methanol to afford compound (*E,Z*)-**8** in 97% stereomeric purity.

Anal.: Calcd. for $C_{18}H_{32}O_2$: C, 77.14; H, 11.42. Found: C, 77.42; H, 11.36. IR: ν 2980, 2930, 1745, 1240 cm^{-1}. EAG Bioassays. The electroantennogram activity of the test compounds was determined on an EAG set-up with a new non-operator-dependent sample injection system (Guerrero et al., 1986).

Field Tests. The required amount of test compound in each bait was mixed with 2.5 mg of paraffin wax to slow down the release rate in the field (Cuevas et al., 1983), and dissolved in 1 ml of nanograde hexane. The solutions were transferred into closed polyethylene vials (3 × 1.1 cm ID) which were used as dispensers. Field trials were carried out in Mora de Rubielos (Teruel) and Cieza (Murcia) from 1984 to 1986. Traps used throughout the test seasons were "dry" (no glue added) and specially designed for processionary moth catches (Montoya, 1984). Traps were hung on trees at a height of 1.7–2.0 m above ground and those located in the same parcel were spaced 50 m apart. Minimum distance between parcels was 150 m apart. They were set out in statistically randomized blocks and revised and rotated every day. Ten traps were generally used for each formulation. In each parcel, the number of catches of the different formulations was compared with that of pityolure. Trap catches were subjected to a square-root transformation followed by analysis of variance, and the data were analyzed statistically for significance according to Duncan's multiple-range test. When appropriate, Student's t test was used to assess the significance of differences between mean numbers of catches within the same parcel.

RESULTS AND DISCUSSION

As shown in Table 1, the biological activity of fluorinated analog **11** was studied in 1984 and 1985 field trials. While traps baited with compound **11** alone were only slightly active (parcel I, test 1), lures with mixtures of **11** and the natural pheromone **1** caught variable number of males, depending on their composition. Remarkably, when a 3:1 ratio of **11**:**1** was used, an approximately 50% inhibitory effect on the activity of the pheromone was observed (parcel III, tests 1 and 2), whereas the results were not statistically significant when the 1:1 ratio was utilized.

The effects exhibited by propargylic ether **9**, epoxide **10**, formate **14**, propionate **15**, and allene **17** were studied in other experiments carried out in 1984 and 1985 (Table 2). Significant synergistic effects appeared to be displayed by

ether **9** and epoxide **10** when mixed with pityolure **1** in 1:10, 1:1 and 2.3:1 ratios (parcel I, test 1, and parcels I and II, test 2 for compound **9**; and parcel III, test 1, and parcels VII and VIII, test 2, for compound **10**). On the other hand, formate **14** behaved in a strikingly different way, depending upon the composition of the bait. Thus, when this compound was mixed with pityolure in a 1:10 ratio, it showed a significant synergistic effect (parcel IV, test 2), whereas at higher ratios (2.3:1 parcel II, test 1, and 10:1 parcel VI, test 2) a marked decrease in catches was observed. Almost no effect was shown in baits charged with 1 mg of both compounds (parcel V, test 2).

Previous authors have also reported on the synergistic effect exhibited by ethers obtained by replacing an olefinic carbon by oxygen in the pheromone structure of a different species, such as the red-banded leaf roller moth *Argyrotaenia velutinana* (Roelofs and Comeau, 1971). In this case, both oxygen analogs exhibited similar activities. Unfortunately, in the present study, we

[c] Only two traps per formulation.

could not prepare the alternative positional isomer of ether **9**, 13-oxahexadec-11-ynyl acetate, due to its inherent chemical instability.

With regard to the variable effect of the formate **14**, it should be noted that, in other cases, blends of natural pheromones with other synthetic compounds can considerably increase or decrease trap catch, depending on the relative ratios used in the bait (Kamm and McDonough, 1980).

When propionate **15** was mixed with pityolure **1** in a 1:10 ratio (parcel

IX, test 2), an increase in the number of catches was observed, whereas no significant effect was found when both compounds were mixed in a 1 : 1 ratio (parcel X, test 2). This nonsignificant effect differs from the inhibitory action elicited by a mixture of the sex pheromone of the red-banded leaf roller moth and the corresponding propionate analog with the same relative ratio. Therefore, it might be assumed that effects shown by the same type of analogs are species-specific and that no general validity may be extrapolated from the results obtained in one particular case. On the other hand, when the allene **17** was tested in baits with pityolure **1** (1 : 1 ratio, parcel III, test 2), no appreciable variation in trap catches was observed.

A wide range of EAG activities was exhibited by compounds depicted in Scheme 1. While compounds **4**, **5**, *E*-**6**, *Z*-**7**, and *E*-**7** with very low EAG responses in comparison with that of pityolure **1** (<20%) were not further investigated, the intrinsic activity of the remaining analogs was studied in a new set of field experiments (Table 3). In comparison with the sex pheromone component, some of these analogs, such as epoxide **10**, ether **9**, (*E*,*Z*)-**8**, and acetylene **3**, had slight attractant activity. However, we found that acetylene **2** had a fairly good activity amounting up to 65% of the efficiency of natural compound **1** (Camps et al., 1987b). Likewise, propionate **15** was also a good pheromone mimic, with a 40% relative trapping efficiency.

Figure 1 shows the trap catch vs. time for the sex pheromone component **1**, propionate **15**, and acetylene **2**. Although the activity pattern of the propionate vs. pheromone is similar, the activity of acetylene **2** seems to be better than

TABLE 3. RELATIVE INTRINSIC ATTRACTANT ACTIVITY OF ANALOGS **2**, **3**, *Z*-**6**, **8**, **9**, **10**, **14**, AND **15** COMPARED WITH PITYOLURE **1** (Mora de Rubielos, 1985)

propionate **15** except for the last part of the experiment. This was initially rationalized in terms of the possibly higher inhibitory effect of alcohol **13**, resulting from partial hydrolysis of the parent acetylene **2**, when compared with that of alcohol **12**, similarly originated from the natural pheromone **1** and propionate **15** under environmental conditions. However, analysis of the corresponding carriers after field trials showed a very small amount of alcohols **12** and **13**.

Furthermore, as shown in Table 4, in field tests designed to investigate the above hypothesis, it was found that the inhibitory effect shown by alcohol **12** on pityolure **1** was apparently higher than that promoted by alcohol **13** on its

parent compound **2**. These results were further confirmed in EAG bioassays (see below). Other alternative possibilities to explain these differences in the activity pattern of these compounds are being considered in planning further studies. On the other hand, when alcohol **13** was mixed with pityolure **1**, no significant decrease in catches was observed. This fact combined with the clear inhibitory effects shown by alcohols **12** and **13** on pityolure **1** and the acetylene **2**, respectively, may suggest the presence of two different specific receptor cells, with high affinity for compounds **1** and **2**. However, this assumption has not been appropriately substantiated by cross-effect experiments or single-cell recording studies.

Remarkably, the trifluoroacetate **16**, although intrinsically inactive, inhibited significantly the activity of the sex pheromone component when mixed with **1** in 0.1 : 1, 1 : 1, and 10 : 1 ratios (Table 4). Both effects were also confirmed in EAG bioassays by presaturation of the antennal receptors for 4 hr with dif-

ferent amounts (0.1, 1, 10, 100, and 1000 μg) of trifluoroacetate **16** and further exposure to pheromone (10 μg) "puffs," whereby a very small response was recorded. In addition, we have found that, under field conditions, trifluoroacetate **16** is not substantially hydrolyzed to alcohol **12**, which might be held responsible for this inhibitory effect. In this context, Albans et al. (1984) observed an antipheromone action in field trials with the trifluoroacetate analog of the sex pheromone of a different species (*Heliothis virescens*).

Conclusions. Selected structural modifications of the three putative critical molecular parts of pityolure **1** have led to the synthesis of analogs **2–17**, which have exhibited diverse effects, mimicking, enhancing, or decreasing the activity of the sex pheromone component in field and laboratory bioassays. In general, preservation of the acetylene group at C-11 of the original structure is shown to be essential for high activity. On the other hand, fluorine substitution for vinyl hydrogen at C-13 or replacement of the acetate moiety by a trifluoroacetate group induced antipheromone activity. Likewise, alcohols **12** and **13** exhibited inhibitory effects on the corresponding acetates. In addition, synergistic effects have arisen from the transformation of the double bond into the corresponding epoxide or into an oxymethylene group, as well as when the acetate group was replaced by propionate or formate functions. However, surprisingly, in this latter analog, the synergistic action could be reversed into inhibition, according to the relative ratios used in the bait, when mixed with the sex pheromone component.

It is noteworthy to point out that the conjugated enyne moiety of the major component of the female sex pheromone of *Thaumetopoea pityocampa* has not been found in any other insect pheromone structure. From our results, it appears that, in this unique moiety, the triple bond is essential to elicit pheromonal activity.

Abstract—Release rate and degree of isomerization of pheromones with conjugated double bonds were studied in dispensers prepared from several rubber substrates. The substrates compared were made of rubber, cured with elemental sulfur or accelerators based on organic sulfur compounds or organic peroxides. Isomerization of the double bonds occurs immediately after impregnation of the substrate, and the degree of isomerization increases during field use and/or storage. The propensity of the isomers to isomerize corresponds to their proportion in the equilibrium mixture. An *E,Z* isomer is isomerized faster than the *E,E* isomer, and finally a near-equilibrium mixture of the four isomers is present. Minimal isomerization was found in non-sulfur-cured substrates which are the material of choice.

Key Words—Insect pheromones, conjugated dienes, pheromone formulations, rubber pheromone dispensers, isomerization, dispensers.

INTRODUCTION

The use of sex pheromones in traps for insect monitoring ideally requires a uniform and prolonged release of the effective dose of the active compound during the whole period of the pest flight. Many controlled-release pheromone systems have been described (see review by Zeoli et al., 1982). However, these systems hardly meet all the requirements for a good pheromone dispenser. Currently, rubber septa are the most common substrates for pheromone dispensers

0098-0331/88/0500-1347$06.00/0

in monitoring traps (Daterman, 1982, and references therein). Important information on their preparation, particularly from multicomponent mixtures, is given by Kydonieus (1977), Butler and McDonough (1979, 1981), and McDonough and Butler (1983). In recent years, a growing number of papers point out that not all rubber substrates are suitable for use as pheromone releasers, since some of them contain components with adverse effects on pheromones (Steck et al., 1979; Daterman, 1982; Minks, 1984).

Besides controlling the evaporation rate, an effective pheromone dispenser must protect the biologically active compounds against atmospheric oxidation, light, and other adverse environmental factors. Pheromones with conjugated double bonds are less stable, undergoing photooxidation (Shani and Klug, 1980; Ideses et al., 1982) as well as rubber-induced isomerization (Guerin et al., 1983; Davis et al., 1984; Brown and McDonough, 1986; Hrdý et al., 1986). In spite of the fact that the function of dispensers depends critically on the release rate and purity of the active compounds, the dispensers are usually characterized only by the amount and ratio of the active compounds applied. In order to develop standardized commercial lures so that all field data could be comparable, it is necessary to know the effect of various substrates on the purity and release rate of the active compounds.

Many sex pheromones of economic pests contain conjugated diene systems (Reed and Chisholm, 1985; Arn et al., 1986). Not all the species, however, are equally tolerant to the presence of other geometric isomers; thus, according to electroantennograph measurements, (8*E*,10*E*)-8,10-dodecadien-1-ol acetate is the most active stimulant for the pea moth, *Cydia nigricana* (F.), and has also been found in the extracts of abdominal tips of females (Greenway, 1984). On the other hand, when formulated into the dispensers, this compound shows only a limited activity in field tests (see, e.g., Greenway and Wall, 1981). However, the same dispensers are effective for the lucerne moth, *Cydia medicaginis* (Kuzn.) (see Bournoville, 1979; Horák et al., 1980; Hrdý et al., 1983).

Thus, high-purity compounds can be degraded to give low or even no activity when formulated in substrates containing additives that may react with the pheromones. Brown and McDonough (1986) investigated the effect of sunlight on the isomerization of (7*E*,9*Z*)-7,9-dodecadien-1-ol acetate, (9*Z*,11*E*)-9,11-tetradecadien-1-ol acetate, and (8*E*,10*E*)-8,10-dodecadien-1-ol and its acetate in sulfur-cured natural rubber septa and phenolic resin-cured halobutyl elastomer septa. The two most important factors for minimizing the isomerization noted in these studies are the absence in the rubber of isomerization catalysts such as sulfur, and minimum exposure to sunlight.

In this paper, we report the results of studies on the effect of various rubber substrates on the isomerization rates of pheromones with conjugated double bonds evaporated from the dispensers.

METHODS AND MATERIALS

Pheromone Chemicals. (8*E*,10*E*)-8,10-Dodecadien-1-ol (*E*8,*E*10–12:OH), purity 99.5%, with less than 0.1% of the other isomers; (8*E*,10*E*)-8,10-dodecadien-1-ol acetate (*E*8,*E*10–12:Ac), purity 99.0%, with less than 0.1% of the other isomers; and (7*E*,9*Z*)-7,9-dodecadien-1-ol acetate (*E*7,*Z*9–12:Ac), purity 93.1%, with 6.3% of the *E*,*E* isomer were prepared in this laboratory. (7*E*,9*Z*)-7,9-Dodecadien-1-ol acetate, purity 86.7%, containing 10.7% of the *E*,*E* isomer, was purchased from the Wolfson Unit of Chemical Entomology, Department of Chemistry, University of Southampton, Southampton, Great Britain.

Formulation Substrates. These were supplied by the following manufacturers: (A) Gumárne SNP n.p. (Dolné Vestenice, Czechoslovakia): (1) Aa—205 IR (ČSN 62 2625.14), synthetic isoprene rubber, sulfur-cured, 15 × 15 × 2-mm sheets, dispenser weight 0.6 g; Ab—159 (ČSN 62 2616.07), natural styrene–butadiene rubber, thiuram-cured, 15 × 15 × 2-mm sheets, dispenser weight 0.55 g; Ac—321 (ČSN 62 2035.03), sulfur-cured blend of isoprene, chloroprene, and styrene–butadiene rubber, 15 × 15 × 2-mm sheets, dispenser weight 0.6 g; Ad—3263 (ČSN 62 2245.14), sulfur-cured natural rubber, tubes, external diameter 7 mm, length 20 mm, wall thickness 1 mm, weight 0.55 g; Ae—162 (ČSN 62 2446.07), styrene–butadiene rubber, sulfur-cured, 15 × 15 × 2-mm sheets, dispenser weight 0.7 g; Af—rubber septa CM-4408 (ČSN 62 0011), sulfur-cured, thiuram-accelerated blend of synthetic isoprene and styrene–butadiene rubber, diameter 18 mm, dispenser weight 1.5 g.

All these substrates are commercially available and contain various amounts of other components such as fillers, antioxidants, plasticizers, and pigments.

(B) Rubena n.p., (Náchod, Czechoslovakia): Ba—3303, natural + isoprene rubber, cured with a mixture of zinc diethyldithiocarbamate, tetramethylthiuram disulfide and orthotolylbiguanide; septa, diameter 12 mm, thickness 2 mm, dispenser weight 0.45 g.

(C) JZD Květen-Nehvizdy (Czechoslovakia): custom-made substrates from rubber mix of simple composition, slightly conical cups of 10 mm diameter, height 10 mm, wall thickness 1.7 mm. They had the following compositions: Ca—natural rubber SMR 20, cured with dicumyl peroxide (2% wt), dispenser weight 0.55 g; Cb—natural rubber SMR 20, (82% wt), carbon black HAF (16% wt), cured with dicumyl peroxide (2% wt), dispenser weight 0.6 g; Cc—natural rubber SMR 20 (80% wt), carbon black HAF (16% wt), cured with dicumyl peroxide (4% wt), dispenser weight 0.6 g; Cd—natural rubber SMR 20 (90% wt), zinc oxide (5% wt), stearic acid (2% wt), phenyl-β-naphthylamine (1% wt), cured with tetramethylthiuram disulfide (2% wt), dispenser weight 0.6 g.

Impregnation of Substrates with Pheromone: General Procedure. A solu-

tion of the active compound (0.5, 1.0, or 2.0 mg per dispenser) in toluene (usually 0.5 ml per dispenser) was agitated in a rotary evaporator under atmospheric pressure and room temperature. The solutions soaked completely within 1–2 h, depending on the substrate type. The dispensers were then aged for 12 h in a closed vessel, and the solvent was evaporated on exposure to air.

Pheromone Analysis. All the analyses were performed with dispensers exposed in the laboratory at room temperature. The pheromone, released from individual dispensers, was quantitatively analyzed using the relative static method according to Baker et al. (1980). The dispenser was hung in a 250-ml Erlenmeyer flask, stoppered with a ground joint stopper (29/32) with a hanger, and the flask was kept at 25° ± 0.2°C for 2 h. After taking out the dispenser, the pheromone adsorbed on the flask walls was washed out with hexane (5 ml; for residue analysis, Merck, Darmstadt, F.R.G.), and a defined amount of tetradecanol was added as internal standard. The solution was concentrated to 10 μl, and the whole residue was injected into a gas chromatograph.

The gas–liquid chromatography was carried out on an HP 5880 Hewlett-Packard (Mountain View, California) chromatograph equipped with a FID, on a 25-m × 0.3-mm-ID fused silica column with cross-linked 5% phenyl methyl silicone (HP-5, Hewlett-Packard); splitless injection. The oven program for analysis was as follows: (A) 50°C, 30 sec; (B) 30°C/min; (C) 190°C, 20 min; a 10-min purge at 250°C. Quantitative analyses were done using the ISTD method. Each analysis was repeated three to five times. For all the substrates analyzed, blank analyses without pheromones were run. No substances of retention times similar to those of the analyzed pheromone isomers evaporated from the substrates. The identity of all four isomers, formed from the individual pure pheromones, was proved by GC-MS analysis (Hewlett-Packard, model 5985A).

RESULTS

Since isomerization of aliphatic pheromones containing a conjugated diene system results in equilibrium mixtures of about 65–69% *E,E* isomer, 12–23% *E,Z* isomer, 9–11% of *Z,E* isomer, and 3% *Z,Z* isomer, the substrates were preliminarily selected using the isomerization of the more sensitive *E*7,*Z*9–12:Ac. The above-mentioned composition is not the same for all conjugated dienes; our values agree with those published by Ideses et al. (1982) and Davis et al. (1984). First, the degree of isomerization of *E*7, *Z*9–12:Ac with 10.7% of the *E,E*-isomer in substrates Aa—Af was estimated at 24 hr and then 22 days after impregnation (Table 1). In spite of the good results in the laboratory test, polyethylene tubes were excluded since these corresponding dispensers do not protect the pheromones from sunlight and gave the worst results in the field tests. Substrates with lowest degree of isomerization were used in the second

experiment in which the evaporation rate and degree of isomerization were determined during the first, 13th, and 29th day after impregnation (Table 2).

According to the laboratory experiments, the substrate Ab is suited best for manufacturing pheromone dispensers. In the field tests during the 1984 season, these dispensers proved to be better for monitoring the codling moth, *Cydia pomonella* (L.), than the commercial dispensers CM (Zoecon, U.S.A.) and CP (Chemica, Czechoslovakia) (Hrdý et al., 1986). Dispensers, made from a different batch of the same substrate, were again field-tested in 1985. Since the biological effectiveness of these dispensers in the field test with *Cydia pomonella* was substantially lower than in 1984, a new batch of the substrate was prepared by the manufacturer. With this material the same results were obtained as in 1984. Therefore, we concluded that the difference in quality was due to either manufacturing and/or quality control problems. We therefore decided to prepare our own substrates of as simple composition as possible, in which the presence of sulfur would be excluded or at least minimized (Vrkoč et al., 1986) because we regarded sulfur as one of the possible isomerizing factors.

The degree of isomerization of *E*7,*Z*9–12 : Ac with 6.3% of the *E,E* isomer in substrates Cb–Cd is given in Table 3. Table 4 contains the isomerization data for *E*8, *E*10–12 : Ac. The isomerization data for *E*8,*E*10–12 : OH (0.5 mg) also demonstrated better stability on the same substrates as compared with the sulfur-cured substrate Af.

The amounts of the individual isomers, evaporated during 2 hr at 25 ± 0.2°C from selected substrates up to 47 days after their preparation and exposure in the laboratory, are compared in Figures 1 and 2. Figure 1 compares the release rate and degree of isomerization of *E*7,*Z*9–12 : Ac in sulfur-cured sub-

DISCUSSION

The isomerization of conjugated dienes in the dispensers during storage and application can be influenced mainly by the substrate used and by variable weather conditions, primarily the sunlight intensity (Shani and Klug, 1980; Nesterova et al., 1984; Brown and McDonough, 1986). The substrate itself affects weather-induced isomerizations, thus influencing the biological utilizability of the dispenser.

Rubber substrates, suitable for the preparation of insect monitoring systems, should be selected not only according to their physicochemical properties, but also according to the components used in their manufacturing. From the data presented above, rubbers cured with elemental sulfur should be avoided; better results were obtained with rubbers cured with organic sulfur accelerators, but rubbers cured with organic peroxides are best. Although organic peroxides readily isomerize double bonds, they are thermally decomposed during the curing and, moreover, their residues can be removed by an additional thermal treatment of the final products. Our conclusions agree with those of Brown and McDonough (1986), who report that the absence of sulfur is the most important factor for minimizing isomerization of conjugated dienes in rubber septa and suggest substrates based on phenolic resin-cured halobutyl elastomer.

Since rubber septa for the monitoring systems are used only for a short time, no stabilization is necessary. The substrates, however, must have an appropriate degree of cross-linking to enable a relatively uniform release during a sufficiently long time period. Because of possible unfavorable effects of additives, their number as well as amount should be minimized. The possible sta-

[a]Percentage of *Z,E*, *E,E*, and *E,Z* + *Z,Z* isomers, $N = 5$, median; 1 mg per dispenser.

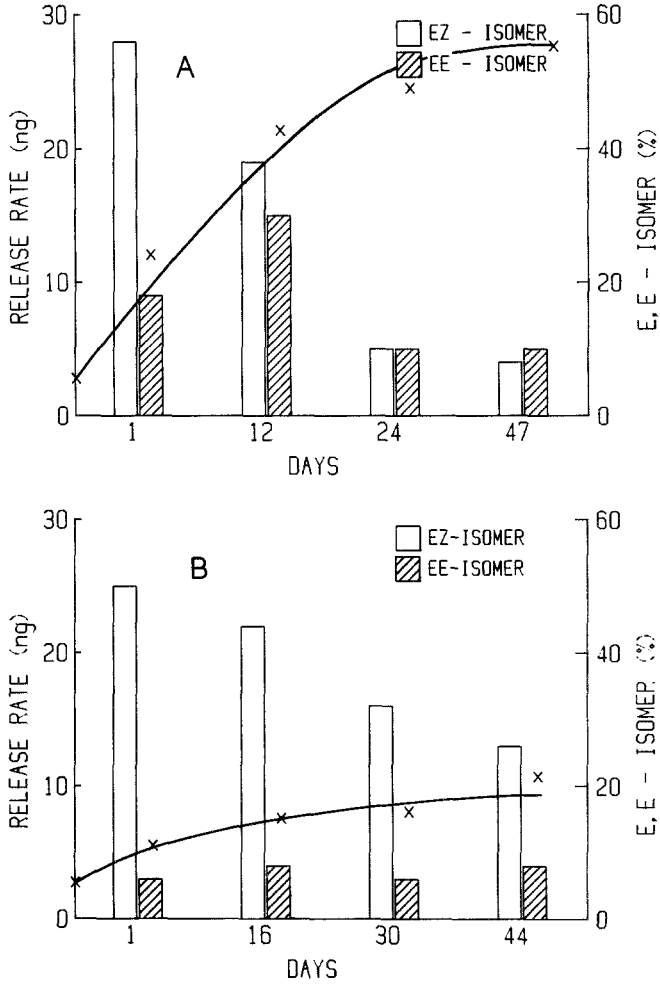

FIG. 1. Isomerization and release rate (ng) of *E*7,*Z*9–12 : Ac (containing 6.3% of *E*,*E* isomer; 2 mg per dispenser) in pheromone dispensers made from substrate Af (A) and substrate Cd (B) and dynamics of pheromone release during 47 and 44 days, respectively, at room temperature. x——x: % unwanted isomer formed.

bilization of the pheromones by some antioxidants (Greenway and Wall, 1981; Reed and Chisholm, 1985) can be achieved by their application together with the pheromones.

It follows unequivocally from the data presented that the isomerization of conjugated dienes takes place in freshly prepared dispensers. The degree of isomerization depends on the type of the substrate, increases during storage and

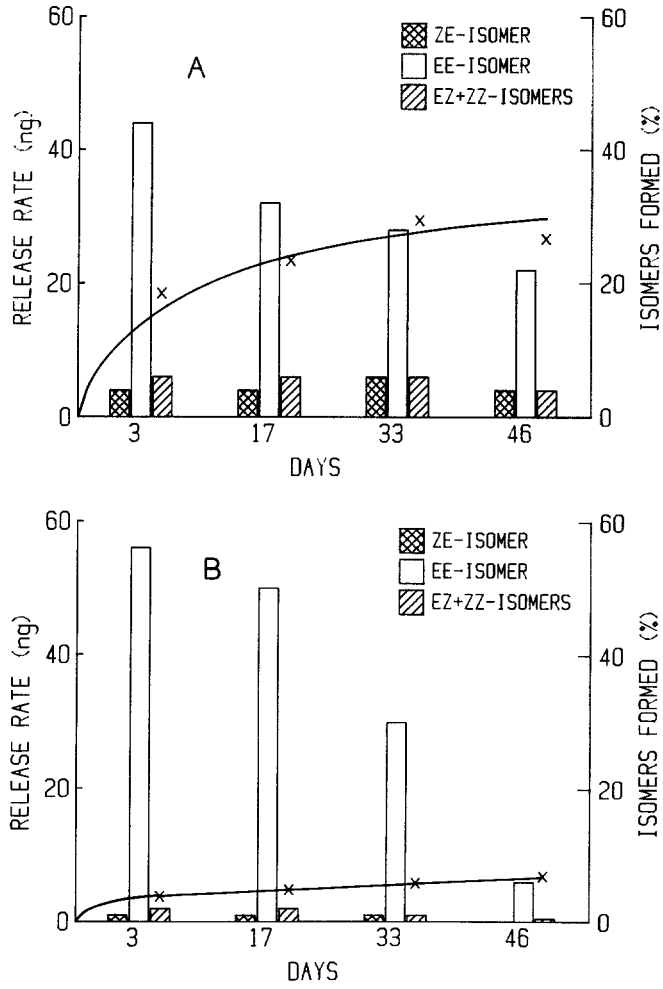

FIG. 2. Isomerization and release rate (ng) of *E*8,*E*10–12:Ac in pheromone dispensers (1 mg per dispenser) made from substrate Af (A) and substrate Cc (B) and dynamics of pheromone release during 46 days at room temperature. x——x: % unwanted isomers formed.

application, and can substantially affect the biological activity of the dispensers. Individual insect species obviously differ in sensitivity towards the presence of other isomers. Further data about the isomerization of *E*8, *E*10–12:OH and its effect on the catch of the codling moth (*Cydia pomonella*), and isomerization of *E*8,*E*10–12:Ac and the effect on the pea moth (*Cydia nigricana*), lucerne moth (*Cydia medicaginis*), and European grapevine moth (*Lobesia botrana*)

catch will be reported elsewhere. The pea moth males are very sensitive to the presence of isomers with different configurations of the conjugated double bonds and only substrates with the lowest degree of isomerization can give sufficiently active formulations. Also the preparation of active formulations for the European grapevine moth is difficult because the *E,Z* isomer is very susceptible to isomerization.

Steck et al. (1982) have recently reviewed the field test screening and recommend a careful interpretation of the results. According to these authors, the great majority of the chemical lure components used are of a purity less than 99.9% even before they are deteriorated by weather conditions or by the substrate. Many pheromone blends of noctuids have optional minor component contents of 1% or less; contents of 0.1% or even 0.01% are quite sufficient for biological activity. Thus, the good results with impure (or at least undefined) lures may result from the main component as well as from one of the impurities or even from a fortuitous effect of the multicomponent mixture. Further complications arise from degradation of pure compounds by weather conditions and/or various carriers. Consequently, interpretation of such results may be misleading.

The preparation of standard dispensers, allowing objective and qualified interpretation of the biological activity, requires (in addition to the usually published amount and ratio of the active compounds): (1) data on purity of the active compounds used, (2) identification of the possible impurities, (3) chemical characterization of the formulation substrates and, particularly, for pheromones containing conjugated double bonds, (4) an isomerization test in the formulation substrate.

(Received March 27, 1987; accepted July 20, 1987)

Abstract—Sex gland extracts of *Ostrinia nubilalis* females collected in the wild or laboratory-reared from Switzerland, Italy, and Hungary were analyzed. Individuals collected in the north of Switzerland contained (*Z*)- and (*E*)-11-tetradecenyl acetate at the approximate ratio of 97:3 (*Z* type), in accordance with field responses of males and previous findings. On the other hand, females from a laboratory culture derived from field collections made in the same area and reared for four to five generations contained the *Z* and *E* isomers at ratios of ca. 3:97 and 35:65, respectively. In the south, one of the eight wild females analyzed was of the *Z* type and the rest intermediate, whereas males were predominantly trapped with blends of the two isomers containing 60 to 97 *E*. In a laboratory culture reared for one to two generations from corn borers collected in Hungary, three of nine females were of the intermediate type and the rest *Z*. Small amounts of (*Z*)-11-hexadecenyl acetate were detected in female glands of the *E* strain; however, no effect of this compound could be observed in the field.

Key Words—Sex pheromone, European corn borer, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, (*Z*)-11-tetradecenyl acetate, (*E*)-11-tetradecenyl acetate, (*Z*)-11-hexadecenyl acetate.

INTRODUCTION

The European corn borer, *Ostrinia nubilalis*, represents a classical case of pheromone polymorphism. Klun and Brindley (1970) identified (*Z*)-11-tetradecenyl acetate (*Z*11–14:Ac) as the main pheromone component. Kochansky et al. (1975) verified the existence of two strains in North America, one in New York (*E* strain) with a ratio of 4:96 *Z*11–14Ac and (*E*)-11-tetradecenyl acetate (*E*11-14Ac), and one in Ontario (*Z* strain) at a 97:3 ratio; the latter resembled the population in Iowa (Klun and Robinson, 1971). Hybridization of the two was accomplished in the laboratory (Liebherr and Roelofs, 1975); males responding to blends of the two isomers were trapped in Pennsylvania (Cardé et al., 1975) and elsewhere.

In Europe, a survey by Klun and cooperators (1975) revealed the prevalence of the *Z* type; catches with 3:97 and 1:1 blends of *Z*:*E* were made in the north of Italy. Analyses and field tests by Maini et al. (1978), Büchi et al. (1982), Anglade et al. (1984), and Barbattini et al. (1985) confirmed that the *E* strain is present south of the Alps and occasionally hybridizes with the *Z* strain. However, there have been reports of occurrence of the *E* strain as far north as the Ruhr region in northern Germany (Langenbruch et al., 1985).

Additional components have been identified in the sex gland of *O. nubilalis*. Tetradecyl acetate (14:Ac) occurs in both *Z* and *E* strains (Kochansky et al., 1975) and was found synergistic at high levels (Stockel, 1980). (*E*)-9-Tetradecenyl acetate (*E*9–14:Ac), a compound detected in small amounts in the *Z* strain (Klun and Junk, 1977), inhibits male response (Klun et al., 1979). Attygalle et al. (1987) found (*Z*)-11-tetradecen-1-ol (*Z*11–14:OH) in the *Z* strain using solid sample injection of female gland material; this compound had no effect on male catch in North America (McLeod and Starrat, 1978).

For the European corn borer, a reliable monitoring technique would be desirable in integrated control programs, e.g., when using the parasite *Trichogramma maidis* (Bigler, 1986). In Europe, pheromone traps are not routinely used for that purpose, possibly due to general uncertainty about the suitable composition of the attractant. We therefore decided to reinvestigate the sex pheromone of *O. nubilalis* in Europe, by chemical analysis and field tests.

METHODS AND MATERIALS

Insects. Collections were made as diapausing larvae, unless noted. In laboratory cultures adults from the same origin were allowed to mate freely. The following sources were investigated: (1) Fricktal wild: collection made in the autumn of 1985 at Elfingen near Basel (north of Switzerland); (2) Fricktal culture: a collection made in the same location reared on an artificial diet (Bathon, 1978; diet 2), analyses were made from the fourth and fifth generations; (3) Ticino wild: nondiapausing larvae of the first generation collected at Giubiasco

(south of Switzerland) at the end of July 1986; (4) Bologna wild: a field collection made in the fall of 1985 in northern Italy; (5) Hungary culture: field collection made at Hódmezövásárhely in the southeast of Hungary in September 1985 and reared on an artificial diet (Nagy, 1970). Analyses were made on females of the first and second generations.

Insects were sexed as pupae and held at 80% relative humidity in a 18:6 hr photoperiod with 3000–6000 lux, 26°C in the photophase and 18°C in the scotophase (Loughner and Bringley, 1971; Maini et al., 1978).

Extraction and Cleanup. Extracts were made by severing the everted ovipositor tips of 2- to 3-day-old calling females and collecting them in hexane (Merck, for residue analysis) for 5–10 min. Batches of 20–25 females were extracted using 2–3 μl/female. Individual gland extracts required between 7 and 10 μl. The crude preparations were sealed in 50-μl micropipets and kept at −18°C.

To prevent interference from cuticular hydrocarbons, the pooled extracts used to detect minor components were chromatographed through a 1.2-mm × 4-cm silica column (Merck, 70–230 mesh). After removing nonpolar components with 3× 35 μl hexane, the sample eluting with 4× 35 μl methylene chloride (Merck, for residue analysis) was concentrated with a gentle stream of N_2 to ca. 2 μl and injected. Analysis for alcohols, which could be retained by silica, was done on a crude extract.

Gas Chromatography–Mass Spectrometry (GC-MS). Analyses were carried out on a SP-2340 fused silica capillary column (30 m, 0.32 mm ID) coupled via fused silica capillary interface to a Finnigan 4000 quadrupole instrument (EI, 70 eV, 240°C, *m/z* (35–750). Samples were introduced by splitless injection and the carrier gas (He) set at 1.5 bar.

Extracts of individual females were analyzed without previous cleanup by selected ion monitoring of the *m/z* values 61 ($CH_3COOH_2^+$, for acetates), 194, and 222 (M^+-CH_3COOH and M^+-H_2O for both monounsaturated acetates and alcohols of 14 and 16 carbons, respectively). A typical temperature program was: 50°C for 2 min, 20°C/min to 100°C, and 5°C/min to 170°C, heating out to 240°C. Elution temperatures ranged from 110 to 170°C for dodecenyl to octadecenyl acetates.

About 50% of the Fricktal culture and Hungary individuals were analyzed with GC-flame ionization detection, under the same conditions as above. The electroantennographic detector (EAD) with a male antenna of *Mythimna unipuncta* Hw. was used for detection of (*Z*)-11-hexadecenyl acetate (Z11–16:Ac) (Guerin et al., 1985).

Field Tests. Tests were carried out to determine the occurrence of males responding to different blends of the two isomers and to establish the importance of the minor components at proportions similar to those found in the female glands (Table 1). Unsaturated compounds were purchased from Farchan Chem-

icals, Willoughby, Ohio, and purified by HPLC on silver nitrate–silica gel (Heath et al., 1975) to an isomeric purity of better than 99.9%; 14:Ac was purchased from NuChekPrep, Elysian, Minnesota. Overall purity of chemicals was >99.0% by GC. Compounds were applied to rubber caps which were suspended above the sticky surface of tetra traps; treatments were tested in 10 replicates in an experimental design used by Arn et al. (1986).

Traps were placed in maize fields at Trasadingen and Hornussen (north of Switzerland), the latter being located ca. 5 km from the "Fricktal wild" collection site and, during the second flight only, at Giubiasco (south). Treatments were placed 2.8 m, replicates 25–50 m apart; trap height was adjusted to plant growth, starting at the upper level of the crop up to a maximum of ca. 2 m.

RESULTS

Analysis of Z11-14:Ac and E11-14:Ac. Results of female extract analyses are given in Figure 1. Individuals can be classified into three types: one containing between 1 and 20 ng *E* and ca. 2% *Z* (*E* type), another with 1–10 ng *Z* and ca. 3% *E* (*Z* type), and one with a more or less constant blend of 65 *E* and 35 *Z* (hybrid).

The 10 females collected in the wild in Fricktal were all of the *Z* strain. However, individuals of a culture derived from material collected at the same location and reared for five generations were, in six cases, of the *E* type and in the two remaining hybrids. Batch analyses of 20 and 25 females of the fourth generation gave similar results (60 and 73% *E*).

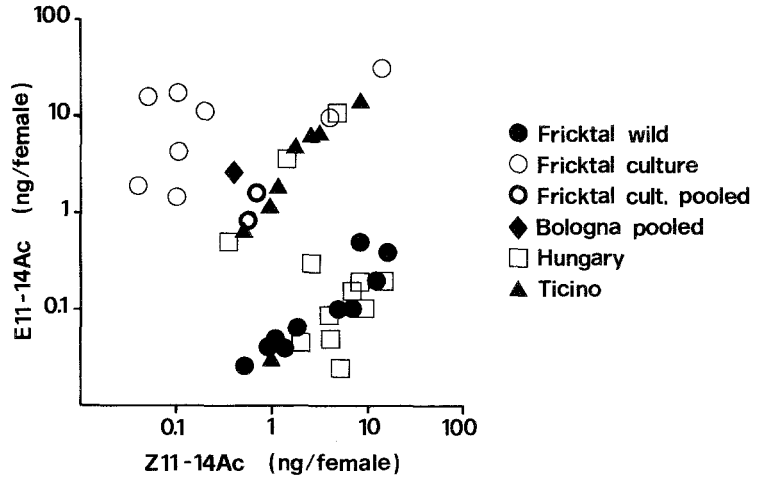

FIG. 1. (*Z*)- and (*E*)-11-tetradecenyl acetate content of *Ostrinia nubilalis* female glands of various sources.

In Giubiasco where we expected to find some *E* types, seven of eight were hybrids and one was *Z*. A batch of 22 wild females from Bologna contained ca. 87% *E*. Of the Hungarian culture, eight of 10 females from the first generation and one of two from the second were *Z*, while the remaining three were hybrids.

Other Components. Tetradecyl acetate was found in all samples, confirming earlier reports (Kochansky et al., 1975). It was generally associated with *Z*11–14:Ac. Samples with more than 50% of this isomer contained between 5 and 15% saturated acetate, the others 2–5%.

A hexadecenyl acetate was detected in all samples with a high proportion of *E*11–14:Ac, at 5–10% of this compound. Based on retention time and fragmentation patterns of standards, it was identified as *Z*11–16:Ac. The compound gave a response on the *Mythimna unipuncta* EAD equivalent to that elicited by synthetic *Z*11–16:Ac. None of the Δ5 to Δ13 hexadecenyl acetates, tested at a similar dose, gave a response with the male antenna. In most samples containing *Z*11–16:Ac, an amount 10 times lower of a second compound was observed which, on the basis of retention time and the typical fragments *m/z* 61 and 222, was tentatively identified as (*E*)-11-hexadecenyl acetate (*E*11–16:Ac).

No tetradecenyl alcohol could be detected in the female material; detection limit for *Z*11–14:OH was 50 pg per female. Similarly, we were unable to find *E*9–14:Ac (limit of detection ca. 30 pg per female), as reported by Klun and Junk (1977). No dodecenyl acetates (detection limit 10–20 pg) or additional saturated acetates were present.

Field Tests. Results of trapping tests confirmed previous reports from Switzerland (Büchi et al., 1982). At Hornussen and Trasadingen, near the northern border of the country, the population is entirely *Z*, and only sporadic catches were made with mixtures containing 20% or more *E* (Table 1). South of the Alps, on the other hand, highest catches were obtained with mixtures containing 60–97% *E*, with no significant differences between the three blends. Even lures with a lower percentage of *E* were still quite attractive; the trap baited with 97% *Z* made 3% of all catches.

The presence of additional compounds, at levels similar to those found in the females, had no effect on male attraction. *Z*11–16:Ac, which was associated with the *E* strain in female analysis, did not significantly enhance or suppress catches on either strain. The same holds true for 14:Ac which has been found synergistic at high doses (Stockel, 1980).

DISCUSSION

The results of this study generally confirm previous reports of the simultaneous presence of *E*, *Z* and hybrid corn borers south of the Alps and of pure *Z* in the north. However, some divergences were observed.

In Ticino, most of the males were trapped with a high proportion of *E* isomer, while females collected just 1 km away were hybrids or, in one case, *Z*. Similar differences were observed by Maini et al. (1978) in Bologna and Cardé et al. (1975) in Pennsylvania. Since our traps were placed in the middle of a large maize-growing area, it is unlikely that the males responding to *E* came from another host.

In the north, all females collected from the wild (Fricktal) were of the *Z* type, and male catches, with almost no exceptions, were made with 97% *Z*. More surprising was the presence of only *E* and hybrid types in the Fricktal culture. This raises the question of whether interbreeding occurred with Ticino types reared in the same laboratory, or if both strains are inherently present in most field populations. The results obtained in Hungary might be an indication for the latter: while previous records indicated presence of only *Z* corn borers (Anglade et al., 1984), a few hybrid females were found in a population kept for one to two generations in the laboratory. Pheromone types of *O. nubilalis* have been correlated with voltinism (Roelofs et al., 1985), and laboratory conditions are known to select out the nondiapausing part of the population (Stengel and Schubert, 1982). Furthermore, the *E* strain, as the more polyphagous (Langenbruch et al., 1985; Straub et al., 1986) might be better suited to survive on the artificial diet.

With the heterogeneity of the corn borer in Europe, we would recommend that at least three types of attractants be used throughout: blends of *E*11–14 : Ac and *Z*11–14 : Ac in the approximate ratios of 97 : 3, 60 : 40, and 3 : 97.

Acknowledgments—A.P. is grateful to the Spanish Ministerio de Educación y Ciencia for a fellowship. P. Cordillot is acknowledged for collecting the wild pupae in the north of Switzerland. We thank Dr. R. Bues, INRA Montfavet, for supplying a batch of *M. unipuncta* for electroantennographic detection.

(Received April 15, 1987; accepted July 20, 1987)

Abstract—The first chemical analysis of the volatile components of scent material from the cotton-top tamarin, *Saguinus o. oedipus* is presented. In contrast to our previous findings in saddle-back tamarins (*Saguinus fuscicollis*), the chemical composition of the scent marks is quite variable. Analysis of secretion expressed manually from different areas of the scent pads of sedated animals shows individual and regional variability. Only three components (squalene, cholesterol, and *p*-methoxybenzaldehyde) were found in all scent mark samples analyzed. However, suprapubic secretions obtained from one sedated female contained, in addition, 12 butyrate esters as well as five acetate esters which were homologous to the butyrates. The butyrate esters have been previously identified in scent material from *Saguinus fuscicollis*. The variability of the composition of the scent material is discussed in relation to the scent-marking behavior of the cotton-top tamarins. Behavioral studies tested the ability of the cotton-top tamarins to discriminate between scent marks from conspecifics and scent marks from saddle-back tamarins. The group of 12 subjects discriminated between the scent marks from both species in choice tests during which they could freely contact the scent samples. However, when scent marks were presented under a screen, so that the subjects could smell but not contact the stimuli, no discrimination was shown. Four individuals displayed more interest in the screened scent stimuli than all other subjects. When these animals were tested in a second experiment for their ability to discriminate between material from the two species on the basis of only volatile cues, it became evident that they were able to do so. These results indicate that volatile cues alone enable the tamarins to recognize scent marks from conspecifics, but that additional cues per-

ceived during contact with the scent are important for its full attractiveness and/or informational content.

Key Words—Primate, callitrichids, *Saguinus o. oedipus*, chemical communication, scent marking, chemical analysis, GC-MS, volatile composition.

INTRODUCTION

Communication by means of chemical signals is known to be important to the New World callitrichid monkeys. These small marmosets and tamarins possess specialized skin glands located in the circumgenital region and on the midchest. The glands secrete material which, together with urine and possibly genital discharge, is applied to substrates in the environment using specialized scent marking behavior patterns (Epple et al., 1986).

Much of our research over the years has been concerned with the behavioral functions of scent marking and with the chemical composition of the scent marks in the saddle-back tamarin (*Saguinus fuscicollis*). Recently our studies have been extended to include another *Saguinus* species, the highly endangered cotton-top tamarin, *Saguinus o. oedipus*. Cotton-top and saddle-back tamarins have large scent glands in the circumgenital–suprapubic region, which are similar in morphological appearance and in histological structure (Perkins, 1966, 1969).

The scent glands of both species consists of apocrine and holocrine components and are sexually dimorphic, being larger in the female (Perkins, 1966, 1969; Zeller et al., 1988). The sexual dimorphism is particularly pronounced in the cotton-top tamarin. Females possess much larger scent glands than males and exhibit scent marking behavior to a much greater degree (French and Snowdon, 1981; Perkins, 1969; Wolters, 1978). Two distinct patterns of scent marking have been described for *Saguinus o. oedipus* by French and Snowdon (1981). Anogenital marking is performed in a sitting position and results in the application of glandular secretion, urine, and perhaps genital discharge and fecal residues. Suprapubic marking results in the application of skin secretions and other material adhering to the suprapubic part of the glands as the animals, assuming a sprawling position, rub this portion of the gland across the substrate.

Behavioral studies have shown that scent marks produced by the saddle-back tamarin contain a number of communicatory messages, among them the identity of gender, species, subspecies, and individual (Belcher et al., 1986; Epple et al., 1979). At least some of this information appears to be transmitted via volatile cues (Epple, 1978). Chemical analysis by means of gas chromatography–mass spectrometry (GC-MS) has demonstrated that the major volatile components (>90% by weight) of the scent marks of saddle-back tamarins consist of squalene and 15 esters of butyric acid (Yarger et al., 1977). Recent

studies on cotton-tops suggest that the scent marks of this species also convey information to conspecifics which is similar to that of saddle-back tamarins (Epple et al., 1988a).

In this study we present the results of the first chemical analysis of the volatile components of scent material from *Saguinus o. oedipus*. Concurrent behavioral studies, evaluating some of the signal content of volatile cues from scent marks of this species, are also presented. These studies have been undertaken to compare the behavioral and chemical nature of scent communication in these two closely related primate species.

METHODS AND MATERIALS

Maintenance of Experimental Animals and Performance Sites

The cotton-top tamarin is a highly endangered species (Mittermeier et al., 1986), and its availability for laboratory studies is quite limited. For this study six permanently cohabiting male–female pairs were available. The pairs were housed in small colony rooms which they shared with one or two groups of saddle-back tamarins. The rooms were maintained at a temperature of 26°C and 50% relative humidity and were lighted by means of fluorescent light for 12 hr a day. All tamarins were housed in stainless-steel cages consisting of several compartments, each measuring 50 × 80 × 130 cm. The cages were equipped with natural branches, resting shelves, and sleeping boxes. All compartments were available to the pairs most of the time. By inserting a sliding door it was possible to divide each cage into subunits and temporarily separate an animal from its mate for testing or scent collection without causing alarm or stress responses.

The monkeys received a mixed diet consisting of fruits, vegetables, small amounts of cooked meat, dairy products, monkey chow, and several types of cereal, supplemented with vitamins and minerals. The animals were maintained at the German Primate Center, and all behavioral testing was performed there. Chemical analyses were performed at both the Primate Center and the Monell Chemical Senses Center.

Behavioral Studies

Collection of Scent Material. Behavioral studies were performed to determine whether the tamarins could discriminate between natural scent marks from conspecifics and from saddle-back tamarins under two conditions. Under one condition the scent material could be freely contacted, under the second condition it could only be smelled, but not contacted.

The stimulus object on which scent was presented consisted of a glass rod

and a cover tube (Figure 1). The glass rods were closed on one end to form a smooth top. The cover was made from a perforated plastic centrifuge tube which could be placed over the rod, covering it completely. The rounded top of the glass rod was located just underneath the holes in the centrifuge tube. The entire assembly or the centrifuge tube or glass rod alone could be inserted into a hole drilled into a wooden sample carrier which was part of the permanent cage equipment. This made it possible to present scent marks directly on the centrifuge tube, in such a way that the subjects could contact them. Alternatively, scent material could be presented on the glass rod covered by a clean centrifuge tube, a condition under which the animals could sniff but not contact the scent material. Marks were collected on both types of objects by inserting the objects

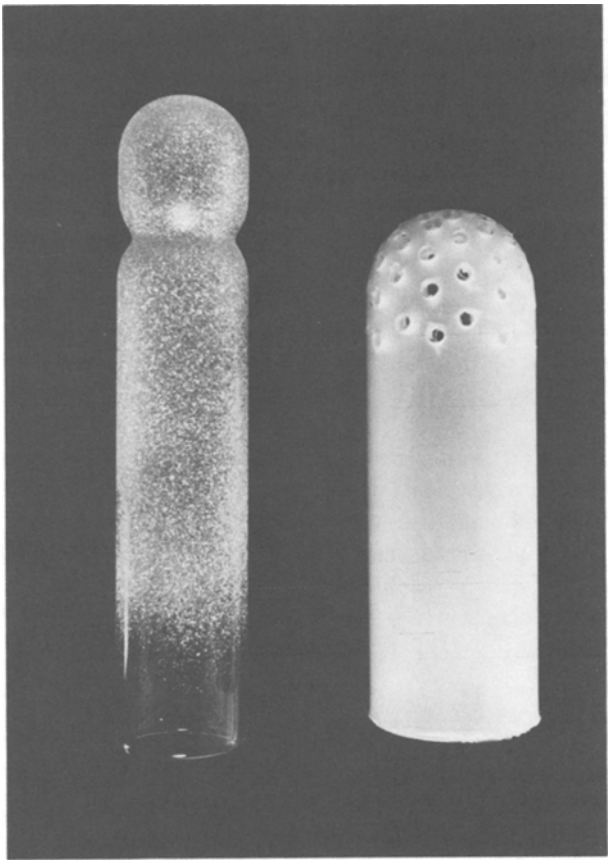

FIG. 1. Glass rod and plastic cover used as the stimulus assembly for behavioral testing of scent material.

into holes in the sample carriers and allowing the donor monkeys to scent mark them. Before use, the plastic tubes were cleaned by soaking them in a soap solution for a few hours or overnight. They were then scrubbed thoroughly with a hand brush to remove all contaminants and rinsed with water, distilled water, and methanol and then air dried. Before using the glass rods, they were thoroughly cleaned using a chromic–sulfuric acid solution, followed by rinses of distilled water, nanograde methanol, and finally, nanograde methylene chloride.

Scent Discrimination Tests. The ability of the tamarins to discriminate between scent marks from conspecifics and scent marks from saddle-back tamarins under the conditions described below was determined by means of choice tests. During each choice test, the subjects were presented with two stimulus objects, each carrying natural scent marks from one of the two donor species. Statistically significant differences in the responses of the tamarins to the two scent types were interpreted as proof that the animals could discriminate between them. All subjects were housed and tested in cages consisting of five compartments. Three of the compartments served as a testing area. In the right and left compartments of this testing area, level wooden shelves ($7 \times 7 \times 80$ cm), which served as sample carriers, were suspended between the back and front of the cages at a height of 65 cm above the cage floor. Each shelf was equipped with a hole into which the glass rod covered by the centrifuge tube could be inserted. The center compartment did not contain a carrier. The wooden sample carriers were part of the permanent cage equipment which also included natural branches. The cages and their equipment were washed in a cage washer at least once a month using hot water but no detergent.

The tamarins were allowed to use all five compartments when no tests were performed. During each test, the subject was confined to the three testing compartments while its mate remained in the other part of the home cage. The duration of each test was 10 min. The total testing time was divided into intervals of 5 sec, indicated by an audible signal. For each 5-sec interval the subject received a score of 1 per stimulus object for each of three behavioral responses if this response was shown.

The following behavioral responses (described in more detail by Epple et al., 1988a) were recorded: (1) contacting the wooden sample carriers; (2) sniffing the stimulus objects containing the samples; and (3) scent marking the stimulus objects. (Anogenital marking was the only marking response recorded. Suprapubic marking was very rare and is not included in this category.)

All animals were tested repeatedly in the course of each experiment (see below). The right–left position of the scent stimuli was counterbalanced across tests and across subjects. The order of testing of the subjects was determined at random. The observer recorded the behavioral responses while sitting approximately 2 m from the cage.

Experiment 1. This experiment tested the ability of the cotton-top tamarins

to discriminate between scent marks from conspecifics and saddle-back tamarins when the animals had full access to the stimulus material and when the animals could only smell but not contact the stimulus material. Six male and six female subjects were given choices between scent marks from conspecifics and from saddle-back tamarins under two conditions. Under the first condition, the plastic centrifuge tubes carried the scent marks from both donor species. The glass rods underneath the centrifuge tubes were clean. Under this condition the tamarins could contact, sniff, lick, and handle the stimulus material.

Under the second condition, the perforated centrifuge tubes were clean while the glass rods located underneath these screens had been scent marked by the donor monkeys. Under this condition the animals could bring their noses within 2–3 mm of the stimulus material but could not contact it directly.

Two cotton-top and two saddle-back females served as donors for each subject. However, due to the limited number of animals available, not all subjects were tested with the scent of the same donor females. All scent marks obtained from the cotton-top donors were anogenital marks. Saddle-back tamarins do not show two distinct marking patterns involving different parts of the circumgenital gland. Donors of this species use labial and suprapubic parts of the glandular pad to varying degrees without an obvious functional distinction.

Each subject received two choice tests under each condition, offering scent marks from the same donors. The succession of conditions was randomized. All subjects were tested only once a day. Mean behavior scores were computed for each subject under each condition. Scores were analyzed by means of a two-tailed paired t test for each condition. A significance level of $P \leq 0.05$ was accepted.

Experiment 2. This experiment tested the ability of four individual cotton-top tamarins to discriminate between scent marks from conspecifics and scent marks from saddle-backs solely on the basis of volatile cues. The four subjects also participated in experiment 1, which preceded experiment 2. Each of the four subjects received six tests offering a choice between scent marks from a female cotton-top and a female saddle-back. Scent marks were presented on glass rods covered by clean, perforated centrifuge tubes as described for experiment 1. Two females from each species served as scent donors. The response scores of each subject were analyzed individually by means of a two-tailed paired t test, accepting a significance level of $P \leq 0.05$.

Chemical Studies

Collection of Scent Material. The chemical studies are based on scent material collected from three adult females (Ri, Ma, and Em) using two different methods of collection. All glass used for collection was acid-cleaned as described for the glass rods in the behavioral methods.

Natural anogenital scent marks were collected by allowing the donor females to mark frosted glass rods. These were inserted into holes drilled into the wooden sample carriers making up the cage equipment. Marks collected in this way were applied by the donors almost exclusively with the labial part of the scent gland and consisted of gland secretions, urine, and perhaps genital discharge.

The scent-marked glass rods were rinsed in 30 ml nanograde methanol–methylene chloride (1 : 3, v/v). Scent-mark collections contained an average of 16 ± 3 SEM individual scent marks. Six collections of pooled scent marks were used for analysis. One individual (Ri) donated material for three collections (50, 20, and 11 marks); a second individual (Ma) donated material for two collections (4 and 6 marks), and the third individual (Em) donated material for one collection (5 marks).

Clean glandular secretion was collected from the suprapubic part of the scent glands of sedated females. For this purpose, the gland was washed thoroughly under running warm water, dried, cleaned with 70% ethanol, and secretion gently expressed several times by hand. Each time, the expressed material was taken up by rolling a frosted glass stopper across the gland, using a clean stopper for each wipe. Clean secretion from the labial part of the scent gland was obtained in a similar manner. The secretion was taken up in 30 ml nanograde methanol–methylene chloride (1 : 3, v/v) by immersing the glass stoppers in the solvent. Each secretion collection contained material from two to three manual expressions of the gland. Gland secretion was collected from two of the three females who donated scent marks (Ri and Em). One secretion sample was collected from female Em. Six samples, including one from the labia, were collected from female Ri. In addition, a control sample was obtained by rinsing a clean glass rod in methanol–methylene chloride using the same procedure as in scent material collection. Samples of natural scent marks and secretion were stored at −80°C until used for analysis.

Preparation of Scent Material for Analysis. Prior to analysis, each solution was carefully reduced in volume to about 0.5 ml using a rotary evaporator under reduced pressure, followed by final evaporation to 30 μl under a stream of nitrogen. The samples were then sealed in small glass vials for air transport from the German Primate Center (Göttingen) to the Monell Chemical Senses Center (Philadelphia). Analysis by gas chromatography at the Primate Center and after air shipment to the Monell Center using conditions identical to those employed for subsequent GC-MS analysis (see below) gave the same results.

Chemical Analysis. Gas chromatography–mass spectrometry (GC-MS) analysis was performed using a Finnigan 4510 GC-MS. The chromatography utilized a Chrompack Sil 8 fused silica column with helium carrier gas in a temperature programmed mode (100°C for 2 min, 4°C/min to 300°C). Mass spectrometry was performed using electron impact (EI) with a 1-sec scan rate.

Data Processing. The data were analyzed using the Nova 3 computer system for all runs in the following manner. The 25–30 largest peaks in each run were compiled into a scan list. Each scan list was processed to yield raw and enhanced spectra and area integration of each peak. Relative retention times of each peak were calculated, using a known component peak, squalene, as the reference. From these data, individual peaks could be compared among all sample runs. Using this procedure, a total of 144 different peaks were found among the 13 different samples analyzed. Those compounds which were identified as silicones or phthalates were assumed to be contaminants and were eliminated from consideration. Additional peaks were disregarded if they appeared in the control sample in comparable amounts. Finally, peaks were disregarded if they did not appear in at least half the samples of natural scent marks or $\frac{3}{5}$ of the samples of gland secretion. A final total of 36 peaks was compiled for analysis (see Table 1). Each mass chromatogram was then searched carefully using selected mass ions to determine if trace amounts of any of these compounds could be detected in any of the other samples.

Two aids to chemical identification were used: a computerized library search using the National Bureau of Standards (NBS) library, and comparison of spectra obtained from scent samples from cotton-top tamarins with spectra of previously identified components of the scent marks of saddle-back tamarins taken under comparable conditions. Positive identifications were made by comparing mass spectra and relative retention times. Identification of previously unknown compounds was confirmed by comparison with mass spectra and retention times of authentic samples. These samples were obtained from the following sources: Sigma Chemical Company, St. Louis, Missouri; Aldrich Chemical Co., and synthesis in our laboratory (Golob et al., 1979).

RESULTS

Behavioral Studies

Figure 2 illustrates the results of experiment 1. When the 12 subjects were presented with a choice between scent marks from cotton-top and saddle-back tamarins under conditions which allowed them to contact the scent marked object directly, they investigated scent from conspecifics significantly more frequently than scent from saddle-backs. Contacting of the sample carriers ($P \leq 0.003$) and sniffing of the samples ($P \leq 0.001$) were significantly more frequent in response to cotton-top scent. No discrimination was made in terms of scent marking. However, when both scent samples were presented under the condition in which the subjects could only sniff but not contact the stimulus material, no discrimination between the scent material was made. Moreover, the mean

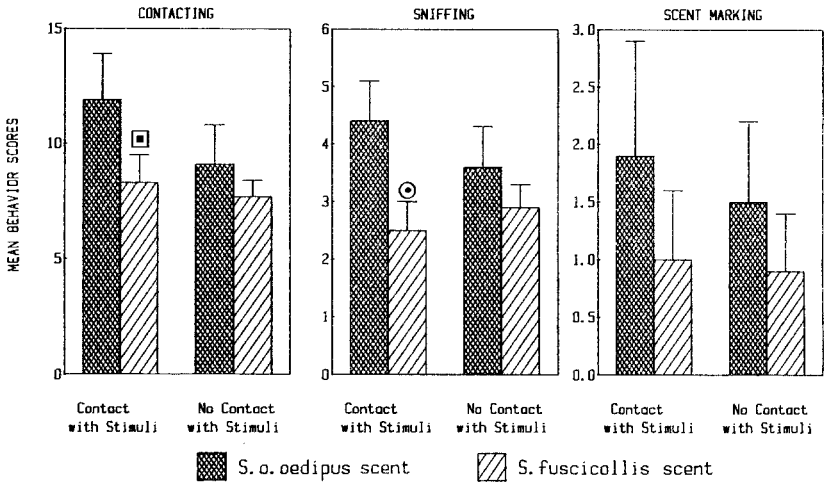

FIG. 2. Mean scores ± SEM for contacting, sniffing, and scent marking in response to scent marks from *Saguinus oedipus oedipus* and *Saguinus fuscicollis*. Scores for tests during which the subjects could contact the stimuli and for tests during which they could not contact the stimuli are shown separately. Significant difference, *t* test. P = ⊙, 0.0002; ▣, 0.003.

scores of contacting, sniffing, and scent marking were lower when the animals could not contact the material.

The results of experiment 1 suggest that the tamarins require direct contact with the stimulus material in order to discriminate between scent from conspecifics and from a related species. It was noted however, that two of the six subject pairs consistently showed more interest in the testing situation than the other pairs and had done so in previous choice tests. Because of this high motivation to investigate scent from conspecifics, it was decided to determine whether any of these four individuals would consistently discriminate between scent samples from the two species on the basis of volatiles alone.

Figure 3 illustrates the results of experiment 2. It shows the behavioral responses of each of the four individuals when presented repeatedly with choices between scent marks from cotton-tops and saddle-backs under conditions where they could smell but not contact the material. All four individuals sniffed scent from cotton-tops significantly more frequently than scent from saddle-backs (Em, $P \leq 0.004$; Ri, $P \leq 0.05$; Hu, $P \leq 0.02$; Rt, $P \leq 0.03$). Three of the subjects also contacted the shelf carrying cotton-top scent significantly more frequently than the shelf carrying saddle-back scent (Em, $P \leq 0.004$; Hu, $P \leq 0.03$; Rt, $P \leq 0.02$), and one female scent marked more on top of samples from conspecifics (Ri, $P \leq 0.01$).

FIG. 3. Chemical Studies

Scent Marks. Thirteen different peaks were found in the scent-mark samples after processing the data as described above. Of these 13 peaks, only three appeared in all six samples. These three components have been identified as *p*-methoxybenzaldehyde, squalene, and cholest-5-en-3β-ol. These three compounds account for approximately 36% of the total volatile material in the scent marks. Figure 4 shows a mass chromatogram of a typical scent mark analysis from female Ri.

The 10 other peaks were found in very low concentrations. They were found in three to five of the six collections analyzed. Identification has been made for four of these compounds. They are *p*-methoxyphenylacetic acid, hexadecyl acetate, hexadecanoic acid, and cholest-7-en-3β-ol. These four compounds together account for approximately 25% of the total volatile material. Hexadecyl acetate was detected only in trace amounts mixed with hexadecanoic acid. The remaining six components have not been positively identified, although all but one appear to be aromatic compounds as evidenced by characteristic ions at *m/z* 91 and 77. See Table 1 for a summary of the data.

Difficulties were encountered in the identification of many of the components due to the low concentration of volatile material contained in the scent marks. Even large collections of scent mark material (up to 50 marks per collection) did not produce high peak intensities on analysis by GC-MS. Many of

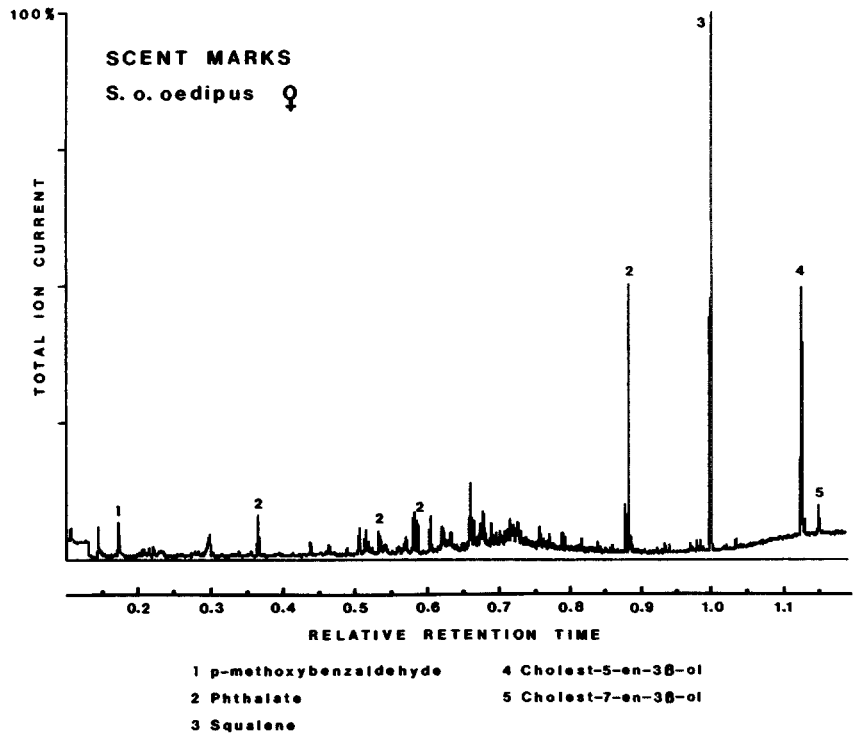

FIG. 4. A mass chromatogram of the volatile components of scent marks from a cotton-top tamarin female (Ri). Numbers refer to specifically identified components. Temperature program: 100°C for 2 min, 4°/min to 300°C.

the peaks are therefore at a very low signal-to-noise ratio and are often mixtures of components. In contrast, the intensity level of peaks in analyses of scent material from the saddle-back tamarins is much larger. It is estimated that one scent mark from the cotton-top tamarin contains approximately 400 ng of volatile material and that squalene and cholesterol account for approximately 150–200 ng of that material. One scent mark from the saddle-back tamarin, on the other hand, is estimated to contain approximately 1000–1500 ng of volatile material, i.e., three to four times as much, and only 15% of that is accounted for by squalene and cholesterol.

Gland Secretion. Chemical analysis of the volatile components of gland secretion manually expressed from the suprapubic glands of two sedated cotton-top females (Ri and Em) gave rather surprising results. Although both had well-developed scent glands, the secretion obtained from these two animals produced extremely different analytical results. The scent profile of suprapubic secretion

from female Em was similar to profiles obtained from the scent-mark samples. The composition of secretion from the labia of female Ri was also similar to that of scent marks; however, the composition of secretion obtained from the suprapubic area of her gland was not.

Analysis by GC-MS of the five suprapubic gland secretion samples from female Ri showed a much different profile than that obtained for any of the other samples. Figure 5 shows a mass chromatogram of a suprapubic gland secretion analysis from female Ri. Thirty different peaks were found in these five samples after processing the sample runs as described previously. Eighteen of these peaks appeared in all five of the secretion samples. Most of these components have now been identified and include, in addition to squalene and cholest-5-en-3β-ol, nine butyrate esters. Three additional butyrate esters were detected in smaller amounts in three or four of these samples. Squalene and cholesterol (cholest-5-en-3β-ol) account for approximately 48% of the total volatile material. The butyrate esters account for an additional 20%. *p*-Methoxybenzaldehyde, one of the three compounds found in all scent mark samples,

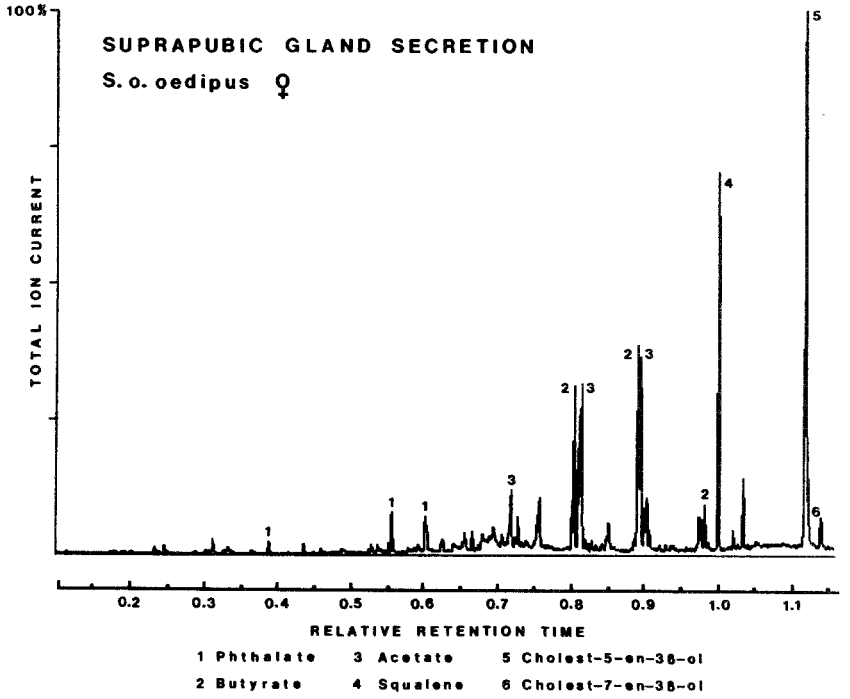

FIG. 5. A mass chromatogram of the volatile components of suprapubic gland secretion from a cotton-top tamarin female (Ri). Numbers refer to specifically identified components. Temperature program: 100°C for 2 min, 4°/min to 300°C.

was detected in only three of five secretion samples and appeared in these in low concentration (<0.5%).

Several additional components have been identified. Five of these compounds are acetate esters, including hexadecyl and octadecyl acetate as well as three monounsaturated esters. These esters, characterized by *m/z* ions of [61] and [M^+-60], account for approximately 15% of the total volatile material. Two of these unsaturated acetates have a 20-carbon alcohol moiety (C20:1), the other has a 22 (C22:1) carbon alcohol unit. Although the position and stereochemistry of the double bond has not yet been established, tentative identification of these unsaturated acetates suggest that they are analogous to three of the butyrates (i.e., C20:1Δ11, C20:1Δ13, and C22:1Δ13 or Δ15).

DISCUSSION

Our present behavioral studies as well as some of our earlier work (Epple et al., 1988a) show that cotton-top tamarins can discriminate between scent marks from conspecifics and from a related tamarin species. This discrimination is shown when the animals can contact the scent material directly. When they can only smell but not contact the stimulus material, their response is decreased and scent from conspecifics is no longer investigated preferentially. These results indicate that the full stimulus qualities of scent marks are available only when the animals can contact the material. The fact that the group of 12 subjects did not discriminate between the marks of the two species on the basis of volatiles alone suggests that the volatile components do not convey the full attractiveness and/or signal content of the mark. However, volatile cues alone appear to provide sufficient information to allow species discrimination by animals who are highly motivated to investigate the material. It is currently unknown which sensory systems are involved in perception of these scents. Olfaction, however, is clearly implicated by the results of this study. In addition the vomeronasal system, which appears to be well developed in callitrichids (Epple, 1986), and other chemosensory systems may be involved.

Similar to cotton-tops, saddle-back tamarins are able to discriminate between scent marks from conspecifics and other callitrichids (Epple et al., 1979, 1988b). Taken together, these results indicate that within the family Callitrichidae different species produce species-specific scents. Under natural conditions such signals may be important in controlling a wide variety of interactions among conspecifics as well as among different species. It is important to document the structural basis for species specificity in any communicatory signal. In the case of chemical communication, comparative chemical analytical studies on scent in related species are indicated.

Previous studies on *Saguinus fuscicollis* have shown that the major volatile

constituents of the scent marks of this species are squalene and a number of butyrate esters. Figure 6 shows, for comparative purposes, a mass chromatogram of scent marks from a female saddle-back tamarin. These compounds are present in relatively consistent concentrations in scent material from males and females of two subspecies. In fact, the sex and subspecies identity of the donor can be accurately predicted solely from these scent profiles (Yarger et al., 1977; Smith et al., 1985; Belcher et al., 1986). In addition, we have documented that methanol–methylene chloride fractions of the scent material from saddle-back tamarins contain sufficient information for the identity of both gender and subspecies. Squalene and the butyrate esters are also present in the same relative concentrations in secretions obtained from both the suprapubic glandular pads and the anogenital glands of sedated saddle-back males and females under conditions identical to those described in the present paper (Belcher, unpublished results).

Based on the studies on the saddle-back tamarin, it was expected that scent material from cotton-tops would be similar. In particular one might expect a

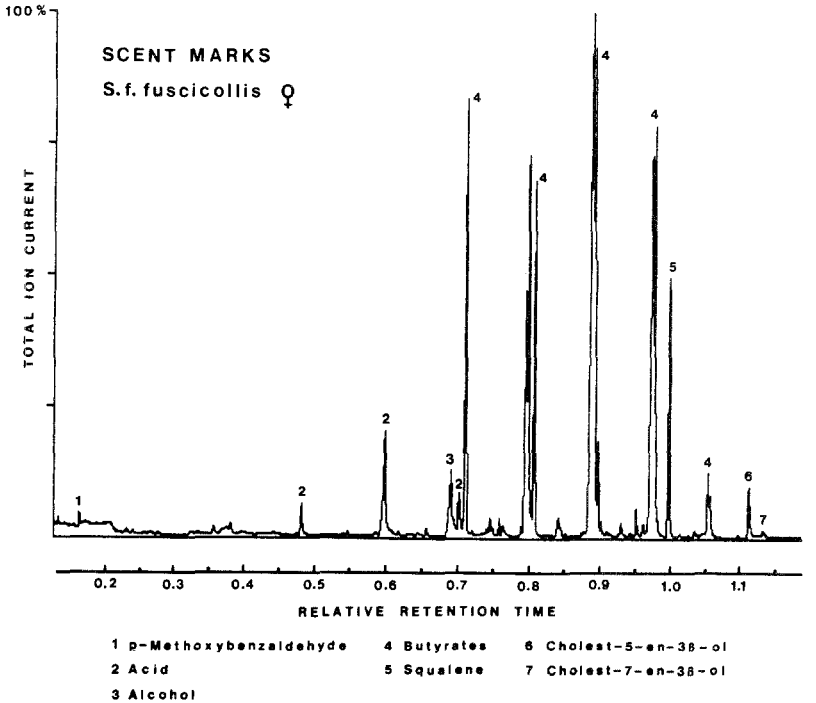

FIG. 6. A mass chromatogram of the volatile components of scent marks from a saddle-back tamarin female. Numbers refer to specifically identified components. Temperature program: 100°C for 2 min, 4°/min to 300°C.

homologous series of compounds, such as the butyrate esters, to be present, perhaps in concentrations different from those seen in the saddle-back species. Chemical analysis of the volatile components of the scent marks of cotton-top tamarins, however, reveals a much different, albeit also complex, profile from that found in saddle-backs. The scent marks of the saddle-back tamarin contain a relatively large number of compounds (16) which appear consistently in all samples. In contrast, the relative concentrations of the major volatile components in the scent marks of cotton-top tamarins do not show a consistent pattern. Only three components (squalene, cholesterol, and *p*-methoxybenzaldehyde) were found in all scent mark samples from cotton-top tamarins. All three are also present in the scent marks of the saddle-back, although only one, squalene, has been previously reported (Yarger et al.; 1977, Belcher, unpublished results). In contrast to our findings in saddle-back tamarins, the chemical composition of glandular secretion from cotton-tops differed from that of their scent marks. In addition, individual and regional variability were apparent. The copious amount of suprapubic secretion obtained from one female (Ri), contained 12 butyrate esters as well as five acetates which were analogous to the butyrates. These acetates were the only components not found in scent material of the saddle-back tamarin.

The chemical composition of secretion obtained from the labial part of the gland of this female (Ri), however, did not differ from that of the scent marks. Furthermore, no evidence of butyrates could be found in the suprapubic secretion of the other female (Em) or in any of the scent-mark samples. Nevertheless, the detection of the butyrates in the suprapubic secretion from one individual demonstrates that these compounds can be produced by this species as well.

The detection of acetates, as well as butyrates, in the suprapubic gland secretion from female Ri is of interest. However, only one of these, hexadecyl acetate, was detected in any of the scent-mark samples, and it was found there only in trace amounts. These acetates have been tentatively identified as analogous to several of the previously identified butyrate esters, including three of the monounsaturated types. Although positive identification has not been made for the unsaturated acetates, we tentatively assume them to be *cis* isomers, as has been previously determined for all of the unsaturated butyrates found in scent material from the saddle-back tamarin. Collection of large amounts of scent material will be necessary for complete structural identification.

It is difficult to explain the considerable variability in the chemical composition of the different scent materials from cotton-top tamarins. It is conceivable that this species can control the release of glandular secretions during scent marking and by doing so produces scent marks which are different in composition from material obtained by manual expression of the gland. Moreover, it is also possible that the suprapubic area of the glandular pad produces secretions different from those produced in the labial part. Cotton-top females appear to use the suprapubic and labial gland areas in two separate and distinct scent

marking patterns (French and Snowdon, 1981). While anogenital marking may be involved in sexual communication, suprapubic marking is used primarily in situations of aggressive arousal. Indeed, French and Snowdon (1981) have suggested that the two signals may differ in chemical composition.

In contrast to cotton-top tamarins, saddle-backs show much less pronounced sex differences in the size of the scent glands and in scent-marking frequency. Moreover, they do not appear to show a functional distinction between anogenital and suprapubic marking. Thus it appears that the two species have developed somewhat different mechanisms for the communication of information via chemical cues and that some of the cues may play different roles in behavior.

Clearly, more work is needed to evaluate the significance of the differences between the two species and the factors that may cause the variability in the chemical composition of the scent samples in *Saguinus o. oedipus*. Unfortunately a more detailed comparison of the composition of scent secretions with that of the scent marks is difficult. Large amounts of both scent marks and expressed secretion must be collected for chemical analysis. The frequent handling and sedation necessary for collecting these secretions, however, is strongly contraindicated in these endangered primates, since it often causes females to lose their pregnancies.

At this stage we cannot determine which of the volatile components of the scent of the two species are involved in encoding species specificity. Indeed, the behavioral studies reported here, as well as some unpublished work in *Saguinus fuscicollis* (Epple, unpublished results) suggest that, in addition to the known constituents, other components which do not lend themselves to chemical analysis by gas chromatography, such as high-molecular-weight, nonvolatile compounds, are necessary to complete the chemical messages. Our ongoing studies of chemical communication in both species are currently addressing this question.

Acknowledgments—We thank Dr. George Preti for assistance in interpretation of mass spectral data, and Dr. Kay Greenfield for constructive criticism and suggestions in the preparation of this manuscript.

COMPUTATION OF RESPONSE FACTORS FOR QUANTITATIVE ANALYSIS OF MONOTERPENES BY GAS–LIQUID CHROMATOGRAPHY

KENNETH F. RAFFA and ROBERT J. STEFFECK

Department of Entomology
University of Wisconsin
Madison, Wisconsin 53706

(Received April 28, 1987; accepted July 20, 1987)

Abstract—Response factors for quantitative analysis by gas–liquid chromatography were computed for 10 monoterpenes using *p*-cymene as an internal standard. The results show that there is no significant variation in our estimates due to sample concentration, and very low variation due to the compound. The most significant deviation from $RF_c = 1.0$ occurred with myrcene. We conclude that the underlying assumptions of quantitative analysis are met using *p*-cymene as an internal standard for most plant or animal monoterpenes, and for total monoterpene content.

Key Words—Monoterpenes, gas chromatography, response factors, internal standards.

INTRODUCTION

Monoterpenes and their related compounds comprise one of the largest groups of secondary compounds in plants (Goodwin and Mercer, 1983). They also exhibit an extremely broad range of biological activities, including insect deterrents, attractants, pheromone precursors, and sequestered defensive agents, microbial inhibitors, allelopathic agents, and mammalian toxins, behavior modifers, and hormone precursors (e.g., Harborne, 1982; Brattsten, 1983). They are also widely used for chemotaxonomic classification. (e.g., von Rudloff, 1975).

In many systems, particularly in plant–animal interactions, qualitative descriptions of monoterpene composition are not sufficient to characterize behavioral or ecological effects. There can be critical differences in the ability

0098-0331/88/0500-1385$06.00/0

of an herbivore to utilize a host plant due to quantitative variation (e.g., Raffa and Berryman, 1982; Cates et al., 1983; and others).

The most reliable way of analyzing monoterpenes is by gas–liquid chromatography (GLC) (Harborne, 1984). Quantification is typically achieved by the internal standard technique, in which the peak area is normalized to the response of a known quantity of a chemical that does not occur in the sample of interest. This method assumes that the detector responds uniformly to all components, and where this assumption is not met corrections must be made using the appropriate response factor (Debbrecht, 1977). Although there have been numerous reports dealing with quantitative variation in monoterpene content, we are not aware of any studies in which this assumption was critically tested. Response factors for other groups can sometimes show high variation (Edwards, 1978; Scanlon and Willis, 1985).

We describe in this paper an analytical system in which the internal standard method can be applied to the quantitative estimation of monoterpene content.

METHODS AND MATERIALS

Instrumentation. GLC was performed using a Shimadzu GC-9A with FID and a CR3A digital integrator. The column was 25 m × 0.25 mm bonded fused silica open tubular polyethylene glycol Superox® (= Carbowax 20 M) (Alltech Assoc., Deerfield, Illinois). Previous experiments demonstrated optimal separation of monoterpenes by this column.

Conditions. The injector and detector temperatures were at 220°C. The oven temperature was at 60°C for 10 min and rose at 10°C/min to 160°C. The carrier gas was helium at 30 cm/sec, with a methane retention time of 83.8 sec.

Monoterpenes were obtained from Aldrich Chemical Co. (Milwaukee Wisconsin). Beta-phellandrene was obtained from Duane Zinkel, USDA Forest Products Laboratory, Madison, Wisconsin. They were dissolved in analytical grade pentane before injection.

Calculation of Response Factor. The response factor is defined as the area ratio to weight ratio of the two constituents (Dietz, 1967): $RF_c = (A_c/A_a)/(W_c/W_a)$; where RF_c is the response factor for C; A_c and A_a are the peak areas of component C and internal standard A, respectively; and W_c and W_a are the corresponding weights.

p-Cymene was used as the internal standard because it is structurally similar to the other monoterpenes of interest, and does not occur at detectable levels in many conifer samples, in which we are particularly interested. *p*-Cymene is frequently used as an internal standard for studies on conifer–herbivore interactions (e.g., Wright et al., 1979; and others).

Each monoterpene was dissolved in pentane at a series of concentrations

to span the proportions we typically find in conifer oleoresin. These included 0.01, 0.1, 1.0, and 5.0%, with 15μl *p*-cymene. The weights of the monoterpene of interest and *p*-cymene in each sample were determined. The sample was injected, the resulting peak areas observed, and RF_c values were computed.

Statistical Analysis. The variation within monoterpenes due to concentra-

tion was estimated by one-way analysis of variance (Steel and Torrie, 1980). The mean response factors for each monoterpene were compared by Duncan's multiple-range test at $P = 0.05$ using SAS (1982).

RESULTS AND DISCUSSION

The retention times and response factors of the various monoterpenes are shown in Table 1. None of the monoterpenes showed any significant variation in response factor due to concentration. Likewise, when all of the monoterpenes were combined, as would be the basis for computing total monoterpenes for example, there was no relationship between concentration and RF_c (Table 2). Therefore, we conclude that *p*-cymene is a suitable internal standard for the quantitative analysis of monoterpenes, at least within the concentration range shown in Table 1. For means-comparison analyses, therefore, we pooled all concentrations for each monoterpene.

The means-comparison analysis is shown in Table 3. There are no significant differences in response factors, except for myrcene vs. all other monoterpenes, and for the (+)-limonene vs. sabinene comparison. Underestimates of myrcene concentrations may be due to its tendency to polymerize at detector temperatures above 200°C. Therefore corrections must be made for estimates of myrcene concentrations in biological samples. For the other compounds tested, the assumption that the response factor for monoterpenes, relative to the

EFFECTS OF DIETARY PROTEIN AND LUPINE ALKALOIDS ON GROWTH AND SURVIVORSHIP OF *Spodoptera eridania*

NELSON D. JOHNSON and BARBARA L. BENTLEY

Department of Ecology and Evolution
SUNY Stony Brook
Stony Brook, New York 11794

(Received April 13, 1987; accepted August 5, 1987)

Abstract—Toxic chemicals and nutrients are often positively correlated within and among plants. We studied how such correlations affect the suitability of plants as food for herbivores by assessing the growth and survivorship of *Spodoptera eridania* (army worm) on artificial diets containing lupine alkaloids and casein. We found that (1) the effects of casein were determined by other dietary components: increased dietary casein led to increased larval growth only when the diet was also high in wheat germ. (2) Dietary alkaloids were effective at very low concentrations, reducing both growth and survivorship. The alkaloids lupanine and sparteine were not synergistic in their effects, and the interaction between alkaloids and casein was significant only in the low-wheat-germ diets. (3) The effects of casein and alkaloids were generally apparent only in the first instar, and the growth of fifth-instar larvae was unaffected by diet. (4) Using these artificial diet experiments, we can make simple predictions about the food quality of plants grown under various nutrient regimes. These predictions are consistant with recent ideas about optimal plant defenses.

Key Words—*Lupinus*, Fabaceae, lupines, *Spodoptera eridania*, Lepidoptera, Noctuidae, southern army worm, sparteine, lupanine, alkaloids.

INTRODUCTION

Herbivores can use plants for food, water, and protection from enemies, but only after overcoming barriers such as poisonous hairs, toxic chemicals, and dry, slippery leaves (Scriber, 1977; Tingey and Laubengayer, 1981; Edwards, 1982; Lawton, 1983). Thus, the suitability of a particular plant as food for

0098-0331/88/0500-1391$06.00/0

herbivores depends on the balance between factors with positive and negative effects. In this paper we focus on two such factors: nitrogen and the quinolizidine alkaloids. Nitrogen is one of the most important nutrients for herbivorous insects (Slansky and Feeny, 1977; White, 1978; Mattson, 1980), while the quinolizidine alkaloids are toxic chemicals in the large genus *Lupinus* (Fabaceae) (Smolenski et al., 1981).

Because the food value of plants is controlled by the interaction between variable plant nutrients and variable antiherbivore agents, predicting the food value of a plant can be a complex task. This task is especially complicated for alkaloid-producing plants, which often have positive correlations between toxic alkaloids and protein (Rhoades and Cates, 1976; Waller and Nowacki, 1978; Johnson et al., 1987). In these cases the relative food value of high-protein and low-protein plants depends on whether increased protein offsets the increases in alkaloid levels. Consequently, experiments with controlled diets are usually required to understand how protein and alkaloids affect the food quality of plants for herbivores (Duffey et al., 1986).

Although the biochemistry of nutrient–toxic chemical interactions has been studied (Reese, 1979), few experiments have used controlled diets to test how nutrient levels affect the toxicity of plant secondary chemicals, and these suggest that more research on nutrient and toxic chemical interaction is needed. Studies of a lepidopteran herbivore (Lincoln et al., 1982) and of rats (Morcos, 1970) found that high protein levels can reduce the negative effects of toxic chemicals. A third study found that the chrysomelid *Trirhabda diducta* had constant growth regardless of the levels of protein and leaf resin (Johnson et al., 1985). Finally, a fourth study found that rutin and tomatine were most effective when incorporated into high protein diets at reducing the growth rates of *Spodoptera exigua* and *Heliothis zea* (Duffey et al., 1986).

In this study we report the effects of dietary protein and the quinolizidine alkaloids sparteine and lupanine on the polyphagous herbivore, *Spodoptera eridania* (Soo Hoo and Fraenkel, 1966). In particular, we ask: (1) Do alkaloid and protein levels interact to affect larval growth? (2) Do different alkaloids interact (e.g., are alkaloids synergistic)? (3) What can we predict about the effects of natural levels of protein and alkaloids on larval growth and consumption? (4) At what developmental stage are larvae most vulnerable to the effects of dietary composition?

The two alkaloids that we have chosen for our study, lupanine and sparteine, are common in the genus *Lupinus* (Kinghorn et al., 1980). They have previously been shown to have antiherbivore activity against generalists, but not against lupine specialists (Smith, 1966; Wink et al., 1982; Wink, 1984). We therefore chose the generalist *Spodoptera eridania* as a convenient model for investigating the toxicity of these alkaloids.

METHODS AND MATERIALS

Larvae and Diets. All *Spodoptera eridania* were obtained as eggs from a laboratory colony maintained for several years by Dr. T. Anderson, Boyce Thompson Institute, Cornell University. Protein sources for diets were casein (ICN Biochemicals) and raw wheat germ. Sparteine was obtained from Sigma Chemical Co. (St. Louis, Missouri), and lupanine was extracted from pods of locally collected *Lupinus perennis*.

Protein and alkaloid concentrations were varied within two basic diets designated diet C (high casein) and diet Wg (high wheat germ). In diet C, each diet contained 6% wheat germ (dry weight) with an additional 16.7% and 33% casein added to the low- and high-protein diets, respectively. In the Wg diets, wheat germ was added to 33% of each diet with the high-protein diets having an additional 16.7% casein. The weight of casein + cellulose (alphacel nonnutritive bulk) was constant within each set of diets, totaling 40% in the C diets and 20% in the Wg diets. All other constituents are as in the artificial diet of Lincoln et al. (1982).

We refer to larval diets in the discussion below using a short-hand code with the first part of the code describing the diet type, the second part denoting the protein level, and the subscript giving the alkaloid concentration. For example, diet $WgL_{.02}$ is a high-wheat-germ diet with low protein levels and 0.02% dry weight alkaloids. This code is varied slightly to designate the two diets containing lupanine, with $CL\text{-}L_{.60}$ containing only lupanine and $CL\text{-}LS_{.60}$ containing lupanine + sparteine. The protein and alkaloid contents of our experimental diets are shown in Table 1, with the protein content including both wheat germ protein and casein using the conversion: wheat germ = 50% protein.

Experimental Procedures. Larvae were reared in 30-ml plastic cups containing small squares of diet and moist paper towels, and diets were changed 3× each week. Cups with larvae were placed in plastic containers lined with damp towels and kept in a growth chamber with a 16-hr photoperiod, 25°C day : 16°C night, and 70% relative humidity. Experiments with the two basic diets (i.e., diets C and Wg) used slightly different protocols. For experiments with diet C, newly hatched larvae were fed an alkaloid-free C diet for 24 hr and then 120 larvae were placed on each of the C diets in Table 1 except diets $CL_{.60}$ and $CH_{.60}$, which began with only 60 larvae. Larvae were initially stocked at 12/cup and then subcultured into new cups at two per cup after five days, and larvae were weighed on day 14. For diet Wg, 40 newly hatched larvae were reared on each of the 18 Wg diets shown in Table 1 at a stocking density of four larvae per cup. Larval instar and survivorship were censused at five 2- to 3-day intervals over the first 11 days, and all larvae were weighed on the 11th day after hatching. Larvae began molting into the fifth instar 14 days after

hatching, and newly molted fifth-instar larvae were kept without food overnight and then used for short-term feeding studies (described below). Because we expected no survivors on the 1.2% sparteine diets and low survivorship on the 0.6% sparteine diets, we kept an additional stock of 50 larvae on the $WgL_{.60}$ and $WgH_{.60}$ diets for use in the short-term feeding studies.

For our short-term feeding studies, larvae were allowed to feed on their original diets during one 16-hr photoperiod. Measurements were performed as in Waldbauer (1968). Briefly, we measured initial food and larval wet weights, both of which were converted to initial dry weights (larva = W_0, food = F_0) using measurements of larval and food percent dry weight; and we measured final food (F_f), larva (W_f), and frass dry weight (E).

Calculations and Statistical Analyses. We assessed the effects of diet on larval performance by calculating growth rates and survivorship over the first 11 (Wg diets) or 14 days (C diets), by estimating the time between instars, and by calculating short-term feeding indices. Because larval performance differed among cups within the same diet, the mean squares among cups was used as the error term in analyses of variance rather than the mean squares among larvae. All analyses of variance were done using type III sums of squares of the General Linear Models procedure of SAS (SAS Institute Inc, Cary, North Carolina).

Exponential growth rates were calculated as $R = \ln (A_T/0.074)/T$, where 0.074 mg = average larval weight at hatching, and A_T = the average weight of larvae in a cup at day T (T = 14 for C diets, T = 11 for Wg diets). We did not use data for 1.2% sparteine, because the $WgL_{1.2}$ estimate was based on only one surviving larva, compared to 4–40 larvae surviving on the other diets. The variates for testing the effects of diet on survivorships were the mean survivorship of each group of four larvae.

The overall effects of protein and sparteine on growth rates and survivorship were tested in a two-way analysis of variance (ANOVA) of protein (discrete) and sparteine (continuous) effects. Individual diets were contrasted using Sidak's correction for multiple comparisons (Sidak, 1967) and the error mean squares from the appropriate ANOVA. Thus, the effects of protein on larval survivorship were tested with high-to-low protein comparisons for each alkaloid concentration (nine comparisons) and the error mean squares of a two-way ANOVA (protein and sparteine, both discrete). The effects of alkaloids on 11-day survivorship and on 11-day larval weights were tested by comparing diets lacking alkaloids to diets with alkaloids (eight comparisons) for each protein concentration, using the error mean squares of an ANOVA of sparteine concentration (discrete).

The duration of the first-instar period was estimated using linear interpolation from our measurements of instar number. The total time spent as second to fourth instars was estimated by subtracting the duration of the first-instar

period from the time from hatch to fifth instar. The effects of protein and sparteine on first and second to fourth instars were tested in a two-way ANOVA of protein and sparteine (continuous).

Short-term feeding indices were calculated as in Waldbauer (1968) and Gordon (1968). Thus, for $t = 1$ day, we calculated relative growth rate: $RGR = \ln(W_f/W_0)$; average weight: $W_{av} = (W_f - W_0)/RGR$; relative consumption rate: $RCR = (F_0 - F_f)/W_{av}$; approximate digestibility: $AD = (F_0 - F_f - E)/(F_0 - F_f)$; efficiency of conversion of ingested food into biomass: $ECI = RGR/RCR$; and efficiency of conversion of digested food into biomass: $ECD = RGR/(RCR \times AD)$.

Feeding indices and fifth-instar weight were analyzed using a three-way ANOVA, with the eight-day period during which larvae reached the fifth instar as a random blocking factor. The main effects for the ANOVA were thus sparteine level (continuous), protein (discrete), and date of reaching fifth instar (random discrete).

RESULTS AND DISCUSSION

Effects of Protein on Larval Growth and Survivorship. The effects of added protein on larval growth were strikingly different in the C diets and the Wg diets. Larvae fed C diets grew more slowly on high-casein than on low-casein diets (Table 2), whereas added casein increased both the growth and survivorship of larvae fed the Wg diets (Figure 1).

We presume that our Wg diets mimic leaves more accurately than do our C diets, because plants with high protein levels are generally more nutritious than those with low protein, all other things being equal (White, 1978; Mattson, 1980). The protein levels in the C and Wg diets are not unusual for the leaves of herbaceous plants, but a heterogeneous protein source, such as leaves or the

TABLE 2. EFFECTS OF DIETARY SPARTEINE AND CASEIN: DIET C[a]

Alkaloid content	Mean larval wt at 15 days, mg (SE, N)	
	20% Protein	36% Protein
0.01% sparteine	439a (10.8, 60)	182b (5.4, 59)
0.06% sparteine	265a (9.8, 58)	146b (5.1, 55)

0.63% lupanine	162 (6.6, 28)	—
0.32% lupanine/0.30% sparteine	118 (7.8, 37)	—

[a] N = number of cups, each of which contains one to three larvae. Values within each row followed by the same letter do not differ significantly ($P > 0.05$).

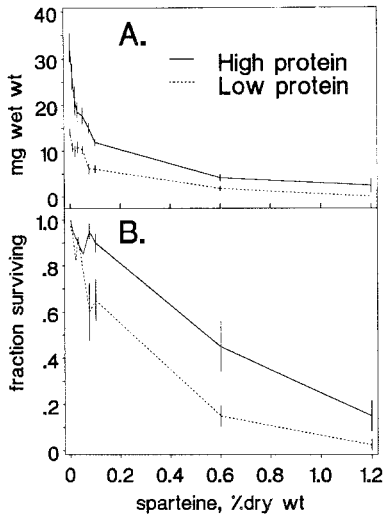

FIG. 1. Larval weight and survivorship of 11-day-old larvae fed Wg diets. (A) Mean weight of larvae; error bars indicate standard errors. High vs. low casein: $F_{1,154} = 42.8$, $P < 0.0001$. $N = 10$ cups/diet, except as follows: $WgL_{.05} = 9$; $WgL_{.60} = 3$; $WgL_{1.20} = 1$. (B) Mean survivorship with standard errors. High- and low-protein diets differ significantly at the following sparteine levels: 0.075%, $t_s = 3.6$, $df = 162$, $P < 0.005$; 0.1%, $t_s = 2.6$, $df = 162$, $P < 0.1$; and 0.6%, $t_s = 3.0$, $df = 162$, $P < 0.05$. $N = 10$. Error bars are omitted at low sparteine levels for clarity.

Wg diets, may be less toxic or may provide a more appropriate amino acid mixture than a homogeneous source such as casein. Alternatively, the differences between the C and Wg diets may be due to important nutrients found in wheat germ that are limiting in the low-wheat germ C diets. Because larvae feeding on low-protein diets have higher relative consumption rates (see below), they may consume adequate amounts of some dietary nutrients from wheat germ in the low-protein C diets that would otherwise be growth-limiting.

Effects of Alkaloids on Larval Growth and Survivorship. Dietary alkaloids decreased both larval weight and survivorship (Table 2, Figure 1). Larval size at 11-days was significantly reduced by as little as 0.02% sparteine in both high- and low-protein diets ($P < 0.05$ and $P < 0.005$, respectively). Larval survivorship, on the other hand, did not decrease until dietary sparteine was >0.05% at low protein and >0.1% at high protein (WgL_0 vs. $WgL_{.10}$, $t = 3.5$, $df = 81$, $P < 0.01$; WgH_0 vs. $WgH_{.60}$, $t = 7.6$, $df = 81$, $P < 0.001$).

Because alkaloids and protein are both quite variable in lupine plants (Johnson et al., 1987), it is important to determine whether the toxicity of alkaloids is affected by protein content. One effect of low protein content is simply

to cause increased alkaloid consumption, since larvae have greater consumption rates on low-protein diets (see below). Thus, we might expect to see a significant interaction between protein and alkaloid content, with alkaloids being more toxic in low-protein diets. However, our two diets gave conflicting results: the Wg diets showed no significant interaction between sparteine and protein, but sparteine was more active at lower protein concentrations in the C diets ($F_{1,247} = 27.2$, $P < 0.0001$). This difference between the C and Wg diets may be due to dietary constituents other than protein and sparteine, since larvae feeding on low-protein diets will have higher consumption rates of all diet components (see below). Neither of our two diets gave results similar to those of Duffey et al. (1986), however. These workers found that rutin and tomatine depressed *Spodoptera exigua* and *Heliothis zea* growth rates more strongly at higher protein concentrations.

We assessed the toxicities of lupanine and sparteine both alone and in combination because both lupanine and sparteine are often produced in a single lupine plant (Kinghorn et al., 1980). When tested individually in diets with 0.6% alkaloid, sparteine retarded larval growth significantly more than lupanine (Table 2, $P < 0.001$). This difference in the toxicities of lupanine and sparteine can be shown to be about twofold using linear interpolation: 0.63% lupanine was equivalent to about 33% sparteine. Wink (1984), using mollusks, also found lupanine to be less toxic than sparteine.

When tested in combination, lupanine and sparteine were not synergistic, since the toxicity of the 0.30% sparteine–0.32% lupanine diet was intermediate between those of the 0.60% sparteine and 0.63% lupanine diets. This lack of synergism can also be shown by using linear interpolation: the 0.32% lupanine–0.30% sparteine diet is equivalent to about 0.45% sparteine, and therefore 0.32% lupanine = 0.15% sparteine. Thus, lupanine seems to be about half as toxic as sparteine, as noted above. Because the plot of larval weight vs. sparteine is concave (Figure 1A), linear interpolation yields a maximum estimate of lupanine toxicity.

Effects of Protein and Alkaloids on Short-Term Feeding Indices and Fifth-Instar Weight. Dietary sparteine had no significant effects on any of the short-term feeding indices (Figure 2A–E), and protein levels did not affect growth or digestion efficiency (Figure 2A,E). In addition, neither sparteine nor protein significantly affected the weight of larvae upon reaching the fifth instar (protein: $F_{1,7} = 0.25$, $P = 0.64$; sparteine: $F_{1,7} = 0.26$, $P = 0.63$).

Thus, *S. eridania* larvae either died before reaching the fifth instar or adjusted to utilize their diets effectively. Larvae adjusted to diets with low protein by consuming more food with lower digestibility and efficiency (Figure 2C–E, all $P < 0.001$), similar to the results of others (Slansky and Feeny, 1977; Johnson et al., 1985).

Suceptibility of Young Larvae to High Sparteine and Low Protein Levels.

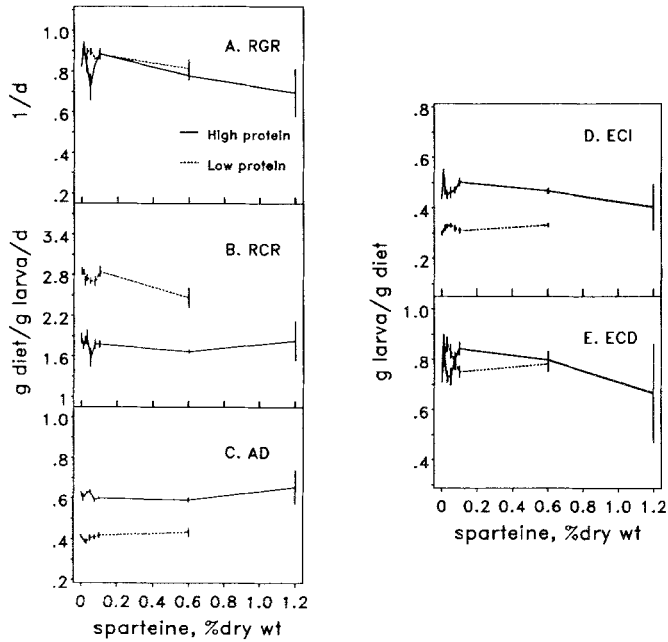

FIG. 2. The effects of dietary protein and alkaloid content on short-term feeding indices. Error bars have been omitted for clarity from some plotted points in A and E. Sample sizes (cups): $WgL_0 = 9$, $WgL_{.01} = 10$, $WgL_{.02} = 9$, $WgL_{.03} = 9$, $WgL_{.05} = 9$, $WgL_{.075} = 7$, $WgL_{.10} = 8$, $WgL_{.60} = 2$, $WgH_0 = 5$, $WgH_{.01} = 5$, $WgH_{.02} = 7$, $WgH_{.03} = 5$, $WgH_{.05} = 7$, $WgH_{.075} = 9$, $WgH_{.10} = 8$, $WgH_{.60} = 6$, $WgH_{1.20} = 3$.

Although surviving larvae had acquired resistance to high sparteine and low protein levels by the fifth instar (Figure 2), sparteine and low protein clearly affected growth at an earlier stage (Figure 1A). To determine when larvae were most affected by diet, we estimated the duration of the first-instar period and the total time that larvae spent as second to fourth instars. The durations of first and second to fourth instars were then tested in a two-way ANOVA of sparteine level and protein (Figure 3, Table 3).

Dietary sparteine had a strong effect on larval development rate only for first-instar larvae, while protein affected the durations of both first and subsequent instars (Figure 3, Table 3). However, the effects of protein on the duration of later stages were primarily evident in the high-sparteine diets, and protein had no significant effect if diets with $>0.6\%$ sparteine were excluded from the analysis.

Larval Growth on Diets with Natural Levels of Sparteine and Protein. Artificial diets can be used to predict the relative performance of herbivores on

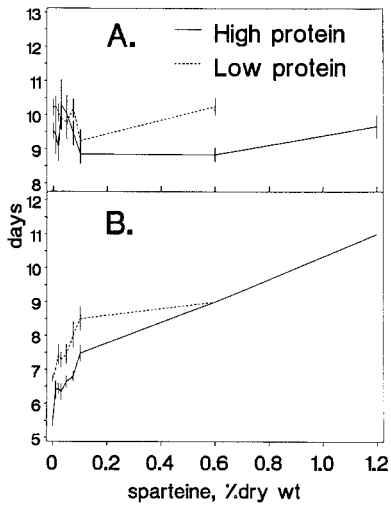

FIG. 3. The duration of larval developmental stages. (A) Duration of 2nd + 3rd + 4th instars. (B) Duration of 1st instar. Error bars indicate standard errors. Sample sizes as in Figure 2.

leaves with various protein and toxic chemical compositions (Berenbaum, 1981; Lincoln et al., 1982). We therefore designed our diets so that our results could be directly applied to recent experiments with *Lupinus succulentus* (Johnson et al., 1987).

The protein and alkaloid levels of *Lupinus succulentus* are strongly affected by available soil nitrogen, and thus soil nitrogen may also affect herbivores of

TABLE 3. EFFECTS OF ALKALOIDS AND PROTEIN ON 1st AND 2nd–4th INSTARS[a]

	df	*SS*	$F_{1,111}$	*P*

Error	111	113.2		

[a] Data from diet $WgH_{1.2}$ were not used because no larvae from $WgL_{1.2}$ survived to the 5th instar.

L. succulentus. We can use our artificial diet data to examine this idea because the different soil nitrogen treatments of Johnson et al. (1987) yielded *L. succulentus* foliage that resembled two of our diets. The mature foliage from low-nitrogen soils had about 17% protein and 0.01% alkaloids (similar to $WgL_{.01}$), while foliage from plants in high-nitrogen soils had about 30% protein and 0.03% alkaloids (similar to $WgH_{.03}$). Since larvae grew over 80% faster on $WgH_{.03}$ than on $WgL_{.01}$ (Figure 1A), despite the threefold difference in alkaloids, we suggest that the foliage from high-nitrogen soils will be a better food for *Spodoptera eridania* than the foliage from low-nitrogen soils (Figure 1). These results are consistant with preliminary experiments using foliage from lupines grown in high- and low-nitrogen soils (N. Johnson, unpublished).

Plants from high-nitrogen soils generally have high growth rates, and it has recently been suggested that plants with high growth rates should have lower levels of defenses (Coley et al., 1985). Our data are consistant with this idea, since we predict that lupines from high-nitrogen soils will be more suitable as food for herbivores than lupines from low-nitrogen soils. Thus high-nitrogen lupines may produce more alkaloids than low-nitrogen lupines, but these defenses are not enough to offset the benefits to herbivores from higher protein levels.

Conclusions. We chose a nutrient and toxic chemicals that are positively correlated in plants and used controlled diets to study the effects of variability in both nutrients and toxins on larval growth and feeding. In particular we conclude that:

1. Protein and sparteine had relatively simple effects on the growth of *Spodoptera eridania* larvae, each altering the growth rate by a constant amount regardless of the content of the other. This lack of interaction between protein and toxins has practical value because it simplifies the assessment of the food quality of plant tissues. However, this result is complicated by the effects of diet composition, since growth on our C diets was affected by sparteine more strongly at low protein levels. Although we presume that the effects of dietary protein in our high-wheat-germ diets mimicked those of plant proteins, the appropriateness of various protein sources and diet compositions clearly deserves more study.

2. We found no evidence of synergism between sparteine and lupanine, two lupine alkaloids that often occur together (Kinghorn et al., 1980). Many lupine species make more than one kind of alkaloid, but our data suggest that such an alkaloid mixture may not be any more toxic than would be expected from the sum of the toxicities of its components.

3. Larvae responded to poor diets by either dying or prolonging the time spent as first instars. However, larval performance beyond the first instar was unaffected by dietary sparteine. These results are similar to those of Larsson et al. (1986), who concluded that *Neodiprion sertifer* larvae were only vulnerable as early instars to the resin acids of Scots pine.

4. We predict that larvae will grow more quickly on *Lupinus succulentus* plants growing in nitrogen-rich soils than on plants in low-nitrogen soils, despite the higher alkaloid levels of plants from nitrogen-rich soils. This prediction is consistant with the idea that the suitability of plants as food for herbivores will be positively correlated with plant growth rate (Coley et al., 1985).

Acknowledgments—We gratefully acknowledge Joanne Labate for her excellent technical assistance, and Thomas Gush, David Lincoln, and two anonymous reviewers for their comments on this manuscript. We also thank H. Siegfried (Bioserve, Frenchtown, New Jersey) for his valuable insights on the effects of casein and wheat germ on larval growth. This research was supported by NSF grant BSR84-19438 and is contribution 667 from the Program in Ecology and Evolution at SUNY Stony Brook.

(Received June 8, 1987; accepted August 5, 1987)

Abstract—Methanol extracts of the green alga *Ulva pertusa* contain four kinds of glycerolipids that are active as feeding-stimulants for marine herbivorous gastropods. These compounds are digalactosyldiacylglycerol (DGDG), 1,2-diacylglycerly-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (DGTH), 1-monoacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (MGTH), and 6-sulfoquinovosyldiacylglycerol (SQDG). The various gastropods exhibit marked specificity, however, as young abalone *Haliotis discus* respond to DGDG and DGTH at minute dosages of 20–30 μg/sample zone, but do not respond to 300 μg of SQDG, which is a phagostimulant for two other kinds of gastropods, *Turbo cornutus* and *Omphalius pfeifferi*.

Key Words—Phagostimulants, feeding stimulants, herbivorous gastropods, abalone, *Haliotis discus, Aplysia juliana, Turbo cornutus*, digalactosyldiacylglycerol, phosphatidylcholine, 6-sulfoquinovosyldiacylglycerol, 1,2-diacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine, 1-monoacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-monoserine, *Ulva pertusa*, alga, glycerolipids.

INTRODUCTION

Gastropods are know to have olfactory and gustatory receptors and are considered to find their foods by chemoreception (Kohn, 1961; Croll, 1983). Such behavior provides a chemical basis to help understand the feeding preferences

[1] Chemical Studies on Phagostimulants for Marine Gastropods. Part VI. For Part V, see Sakata et al. (1986b).

0098-0331/88/0500-1405$06.00/0

of marine herbivorous gastropods for particular species of seaweeds (Frings and Frings, 1965; Uki et al., 1986). Few chemical studies, however, have included the feeding behavior of such important gastropods as the abalone species of *Haliotis* that is now expected to provide a substantial harvest of about 18,000,000 seedlings for liberation a year in Japan (Uki, 1979). There is accordingly a clear need to establish the identity of the feeding attractants[4] for juvenile abalone *H. discus* (Harada et al., 1986) and the phagostimulatory responses of sea hares *Aplysia* spp. (Carefoot, 1986; Jahan-Parwar, 1972). Recently developed artificial diets for juvenile abalone could be improved by the addition of these chemicals, as current practice is to add powdered seaweed as a feeding stimulant.

Observation of the feeding behavior of juvenile abalone *H. discus* in aquaria led to the development of a simple and reliable bioassay for chemical study of their feeding behavior (Sakata et al., 1984). Recently this unique bioassay was found to be equally useful for studies of feeding behavior of other marine herbivorous gastropods including the turban shell *Turbo cornutus*, and the top shell *Omphalius pfeifferi* (Sakata et al., 1986a), both of which are also important seafoods in Japan.

We also established a similar bioassay using filter paper for isolation of the active principles in an ether extract of *Ulva* sp., which contains a feeding stimulant for a Japanese sea hare *A. juliana* (Sakata et al., 1986b). Presumably, a comparable feeding stimulant is involved in the feeding behavior of the Hawaiian sea hare *Aplysia* spp., which respond to a water extract of *Ulva* sp. (Frings and Frings, 1965).

Thus the isolation and purification of the active substances in preferred seaweeds can be monitored at each step for the presence or absence of activity against four kinds of gastropods described above. Following these preliminary trials, methanol extracts of several kinds of seaweeds were subjected to this bioassay, but while most extracts showed feeding-stimulatory activity to varying degrees, the extracts of the green alga *Ulva pertusa* were the most active for all gastropods tested. Accordingly, *U. pertusa* is the one source of algal material used in the present investigation.

METHODS AND MATERIALS

Bioassay Procedure for Phagostimulants for Gastropods. For abalone, *Haliotis discus*, the bioassay procedure was previously reported in detail together with collection and maintenance of the test animals (Sakata et al., 1984). Typical bioassay results are shown in Figure 1.

[4]The various activators of feeding behavior are defined as feeding attractants, arrestant, stimulants, and so on (Mackie, 1982). This paper follows his definition. "Phagostimulants" means feeding stimulants in this paper.

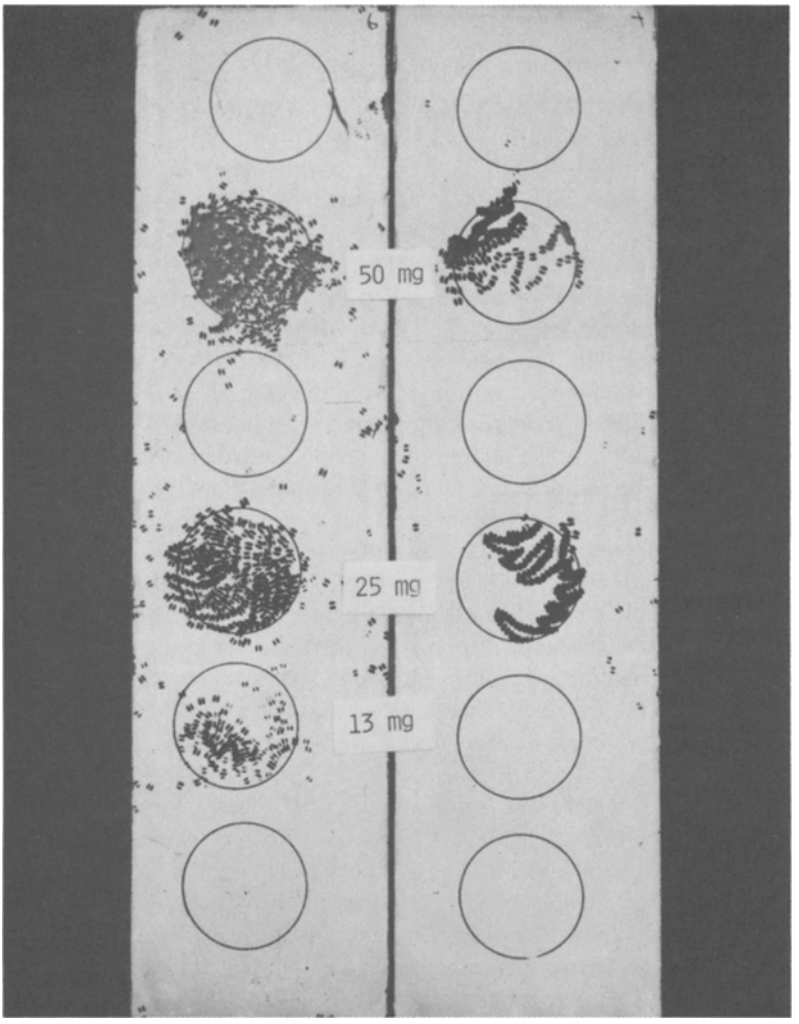

FIG. 1. Typical assay results obtained by using young abalone *H. discus*. The MeOH extracts equivalent to 13, 25, and 50 mg of air-dried brown alga *Eisenia bicyclis* were absorbed in each sample zone (2.5 cm in diameter) on the Avicel plate (0.25 mm thick, 5 × 10 cm). After evaporation of the solvent, each test plate was set, after sunset, at the bottom of each test aquarium which contains 10–20 young abalones (2–2.5 cm in shell length). Next morning, the plates were taken out of the aquarium and the activity was judged as ++, +, and −, according to the ratio of the feeding traces (a pair of characteristic feeding traces) inside the sample zone to those outside. Details of the assay procedure have been reported (Sakata et al., 1984).

For sea hare, *Aplysia juliana*, the assay was performed following the procedure reported previously (Sakata et al., 1986b).

For turban shell, *Turbo cornutus* (Sakata et al., 1986a), the test animals (average diameter of their operculam, 20–25 mm) were bought at a fish market and kept in a plastic aquarium (32 × 61 × 18 cm) into which the seawater filtered through sand was introduced, keeping the depth of the water about 5 cm with a drain. They were fed on dried brown alga *Eisenia bicyclis* as a maintenance food. They were starved for at least a day before the assay. Test sample solutions (50–100 μl) were applied on the sample zone (35–40 mm in diameter) made on an Avicel plate by a compass in the same manner as reported in the assay for the abalone (Sakata et al., 1984). The assay duration was determined for 3–4 hr after sunset. The assay was repeated at least twice. Judgment of the activity of each sample was performed as in the case of the abalone (Sakata et al., 1984): ++, the characteristic biting traces similar to those of abalones are observed almost all over the sample zone, and the activity can be judged clearly; +, many more biting traces are found in the sample zone than those outside in a unit area, but the judgment is not very clear; ±, a few more biting traces are observed in the sample zone than outside; and −, none or nearly the same number of the biting traces are left inside of the sample zone as those outside.

For top shell, *Omphalius pfeifferi*, the test animals (10–15 mm diameter of the opercula) were obtained from a fish market, kept in the same test aquarium as the one used for the abalone bioassay. The assay was carried out exactly the same way as in the case of the abalone (Sakata et al., 1984).

Isolation of Phagostimulants from Green Alga. The isolation procedure is outlined in Figure 2. Fresh *U. pertusa* (900 g), harvested in March 1984, was washed with tap water. The damp-dry alga was finely cut and soaked in a mixture of chloroform–methanol (1 : 3, 2.4 liters) to give the crude extract. Repetition of the extraction yielded ca. 12 liters of the extract. After evaporation of the solvent, the aqueous phase was taken up to ca. 1.5 liters, extracted with hexane (400 ml ×3) and then ethyl acetate (400 ml ×4). Half the combined organic extracts was fractionated by silica gel column chromatography [Wako gel C-300, 4 × 30 cm; 400 ml each of $CHCl_3$–MeOH (2, 5, 20, 30, 50, and 100% MeOH), 5 and 10% aq. MeOH] into six fractions as shown in Figure 2 as suggested by preliminary thin-layer chromatographic analyses (silica gel GF_{254}; BuOH–AcOH–H_2O = 4 : 1 : 2 and $CHCl_3$–EtOAc–MeOH–H_2O = 50 : 25 : 25 : 2) and bioassay of the eluates.

The sample amount of each fraction subjected to the bioassay was determined depending on each assay procedure as follows: 0.5 g equivalent amount of fresh *Ulva* for *Aplysia*, 0.05–0.1 g equivalent for *Haliotis* and *Turbo*, and 0.05 g equivalent for *Omphalius*. The crude algal extracts equivalent to those shown above always showed ++ activity in each bioassay. As the separation

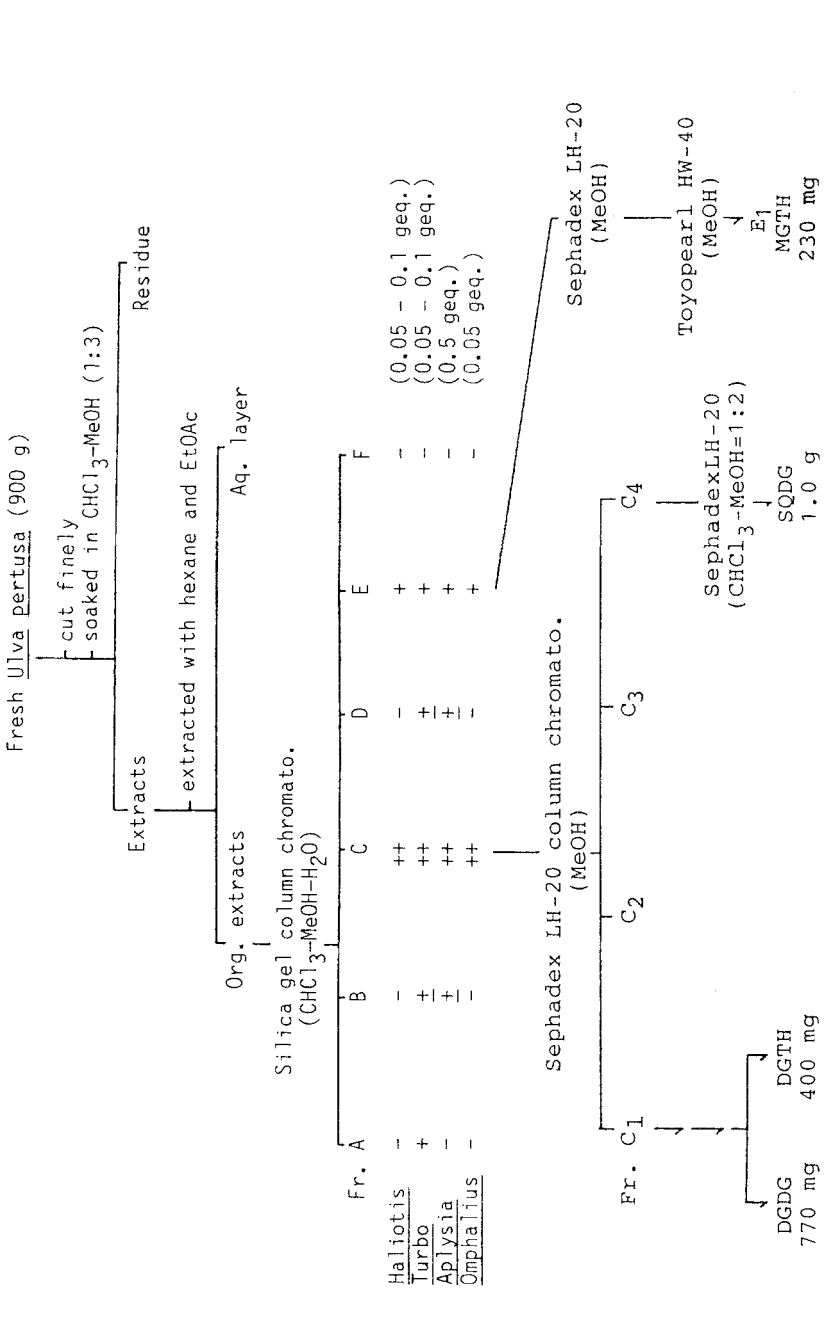

FIG. 2. Outline of the isolation procedure of phagostimulants for the herbivorous gastropods from the green alga *Ulva pertusa*.

of active principles proceeds, the sample amount applied was increased twice or three times more because the activity of the crude extract proved to be based on a few stimulants in it.

The most active fraction (Fr. C) was further fractionated by Sephadex LH-20 (MeOH) column chromatography. Fr. C_1, active against all test animals, was further purified by column chromatography using silica gel (Wako gel C-300, $CHCl_3$–MeOH), Toyopearl HW-40 (MeOH), Wako gel C-300 ($CHCl_3$–EtOH), and Sephadex LH-20 (MeOH) to finally give two active components: the earlier eluting one (770 mg) and the later eluting one (400 mg). Spectroscopic studies established that they were digalactosyldiacylglycerol (DGDG) (Sakata and Ina, 1985) and 1,2-diacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (DGTH), (Sakata et al., 1985), respectively.

The activity of Fr. C_4 was restricted to *Turbo* and *Omphalius*. Further purification by Sephadex LH-20 ($CHCl_3$–MeOH = 1:2) column chromatography yielded an active compound S (1.0 g): [^{13}C]NMR (22.5 MHz, $CDCl_3$–MeOH-d_4 = 4:1) δ 174.4, 173.5, 131.0, 130.3, 100.1, 74.9, 71.7, 69.7, 64.2, 54.3, 35.6, 35.3, 30.9, 30.5, 30.4, 28.4, 26.1, 23.9, 15.1. This was identified as 3-*O*-(6′-deoxy-6′-sulfo-α-D-quinovopyanosyl)-1,2-di-*O*-acyl-glycerol (6-sulfoquinovosyldiacylglycerol, SQDG) as shown below

Fraction E was purified by Sephadex LH-20 (MeOH) and then Toyopearl HW-40 (MeOH) column chromatography, yielding an active component E_1 (230 mg): [^{1}H]NMR (400 MHz, $CDCl_3$) (Figure 3); relative R_f to R_f of PC, 1.17, silica gel GF_{254}, $CHCl_3$–MeOH–AcOH–H_2O = 100:25:12:5. This was identified as 1-monoacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (MGTH) as shown below.

Methanolysis of Compound S. Compound S (62 mg) in methanol (10 ml) was treated with 0.1 ml of N methanolic KOH at 35°C for 1 hr. After neutralization with N HCl, 2 ml of water was added to the reaction mixture, and extracted with hexane (10 ml ×3). The hexane extract was analyzed by capillary GLC.

The residual aqueous solution was concentrated and chromatographed on Sephadex G10 (10% methanol). The fractions showing a single spot (R_f 0.51) on TLC (silica gel G, BuOH–AcOH–H_2O = 2:1:1) were combined, concentrated, and lyophilized to yield 1-glyceryl-α-D-6′-sulfoquinovoside: $[\alpha]_D^{23}$ + 80.4° (c = 1.96, H_2O); [^{1}H]NMR (400 MHz, D_2O) δ 2.89 (H-6′a, dd, 14.3, 9.8), 3.08 (H-4′, dd, 9.8, 9.0), 3.20 (H-6′b, dd, 14.3, 1.3), 3.26 (H-1a, dd, 10.0, 7.1), 3.40 (H-2′, dd, 10.0, 3.7), 3.42 (H-3a, dd, 11.5, 6.1), 3.51 (H-3b, dd, 11.5, 3.7), 3.55 (H-3′, dd, 10.0, 9.0), 3.76 (H-1b, dd, 10.0, 3.7), 3.80 (H-2, m), 3.87 (H-5′, dt, 9.8, 1.3), 4.71 (H-1′, d, 3.7); [^{13}C]NMR (22.5 MHz, H_2O) δ 99.2, 73.9, 73.4, 72.3, 71.7, 69.9, 69.0, 63.6, 53.1). The [^{13}C]NMR spectrum was identical with that previously reported (Johns et al., 1978).

Methanolysis of Compound E_1. Methanol solution of E_1 (38 mg/25 ml)

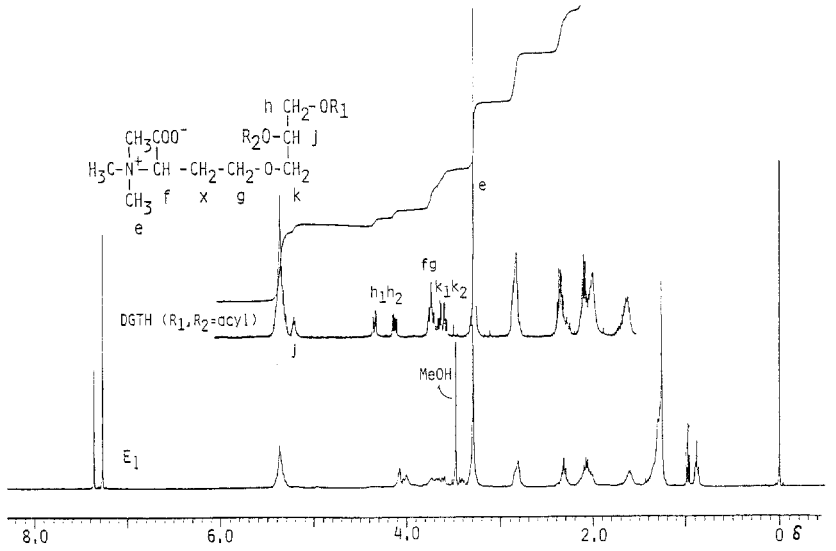

FIG. 3. [^{1}H]NMR spectra of the active component E_1 (MGTH: R_1 = acyl, R_2 = H) and DGTH (R_1, R_2 = acyl) ($CDCl_3$, 400 MHz).

containing about 50 μg of BHT was treated with 10 drops of methanolic N KOH at 40°C for 30 min and neutralized with ^{d}HCl. After addition of 1 ml of water, the reaction mixture was extracted with hexane (5 ml ×3). The hexane extract was washed with NaCl saturated water, dried with anhydrous Na_2SO_4, and subjected to capillary GLC analysis.

The aqueous layer was subjected to carbon column chromatography (Wako activated charcoal, ϕ1.8 × 5 cm). Elution was made by gradient elution between water and methanol (100 ml each). Fractions showing a single spot (R_f 0.25) on TLC (silica gel G, BuOH–AcOH–H_2O = 2:1:2) were combined, concentrated, and lyophilized to yield l-glycerly-4′-O-(*N*,*N*,*N*-trimethyl)-homoserine: [^{13}C]NMR (22.5 MHz, MeOH-d_4) δ 29.04 (t), 52.50 (q), 64.31 (t), 68.48 (t), 72.28 (d), 73.58 (t), 78.06 (d), 171.8 (s). The spectrum was identical with that obtained from DGTH (Sakata et al., 1985).

Capillary GLC Analysis of Fatty Acid Methyl Esters Obtained from Complex Lipids from U. pertusa. Analyses were carried out on a Hitachi gas chromatograph model 163 (FID) under the following conditions: column, PEG-HT G-SCOTT fused silica capillary column, ID 0.25 mm × 50 m; oven temperature 210°C; carrier gas, N_2, 1.5 ml/min; injection and detection temperature 240°C. Analytical data are shown in Table 1.

RESULTS AND DISCUSSION

We have already established a simple and reliable bioassay procedure for phagostimulants for abalone, *H. discus* (Sakata et al., 1984). Figure 1 illustrates how the pattern of feeding traces provides a good semiquantitative bioassay of their feeding activity. Recently we applied this unique bioassay method to the other marine herbivorous gastropods including the turban shell *Turbo cornutus*, and the top shell *Omphalius pfeifferi*. On the test plate, they left pairs of typical feeding traces made by their radula. The traces were very similar to those left by the abalone. Judgment of the activity of each sample was performed exactly as in the case of the abalone (Sakata et al., 1984).

In the case of the turban shell, their feeding is often so active, especially in summer, that the Avicel on the test plate has been totally eaten not only inside of the sample zone but also outside, when the test plate was left in a test aquarium overnight as in the case of abalone. In such a case, judgment of the activity was impossible. We found, however, that good results could be obtained when the assay duration was for 3–4 hr after sunset. As we have already estab-

lished an assay method for *Aplysia* (Sakata et al., 1986b), bioassays for feeding stimulants for four kinds of marine herbivorous gastropods, therefore, are available now.

Isolation of phagostimulants for the gastropods from fresh *U. pertusa* was guided by the results of the four kinds of bioassays we established and is outlined in Figure 2. The combined organic extracts were separated by silica gel column chromatography using a mixture of $CHCl_3$–MeOH and aqueous MeOH into six fractions.

All four of the test animals, responsed to Fr. C (strong) and Fr. E (moderate) but not at all or weakly to Fr. A, Fr. B, Fr. D, and Fr. F. Fr. C was further fractionated by Sephadex LH-20 (MeOH) column chromatography. All test animals responded strongly to Fr. C_1. Further chromatographic purification finally gave two active components, which were identified as digalactosyldiacylglycerol (DGDG) and 1,2-diacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (DGTH), respectively.

These results thus confirm the activity of DGDG (extracted from the brown alga *Undarai pinnatifida*) as a feeding stimulant together with phosphatidylcholine (PC) for the young abalone *H. discus* (Sakata and Ina, 1985) and for the sea hare *A. juliana* (from the green alga *U. pertusa*) (Sakata et al., 1985). The activity of DGTH (from the green alga *U. pertusa*) (Sakata et al., 1985) as a phagostimulant was confirmed for the sea hare *A. juliana* (Sakata et al. 1985).

The activity of Fr. C_4 was restricted to *Turbo* and *Omphalius*. Further purification by Sephadex LH-20 ($CHCl_3$–MeOH = 1:2) column chromatography yielded an active compound S (1.0 g). Its [^{13}C]NMR spectrum suggests that it is 6-sulfoquinovosyldiacylglycerol (SQDG) (Johns et al., 1978). This identification was confirmed by comparison of the [^{13}C]NMR spectrum of its methanolysis product with that previously reported (Johns et al., 1978). The fatty acid composition of SQDG is rather simple ($C_{16:0}$, 58.3%; $C_{18:1}$, 11.8%; $C_{18:3}$, 25.9%) compared with that of DGTH (Sakata et al., 1985), DGDG, and PC (Sakata and Ina, 1985) (Table 1).

From the other active fraction, Fr. E, was isolated an active component E_1 (230 mg). Thin-layer chromatographic mobility of compound E_1 is very similar to that of PC, but it did not react to the Dittmer-Lester reagent. The similarity of the [^{1}H]NMR spectrum of compound E_1 to that of DGTH (Sakata et al., 1985) suggests that E_1 is a lyso form of DGTH (Figure 3).

The polar part of the methanolysis product of E_1 was shown to be identical with that obtained from DGTH (Sakata et al., 1985) by direct comparison of their [^{1}H]- and [^{13}C]NMR spectra. In the 400 MHz [^{1}H]NMR spectrum of E_1 (Figure 3), the H-2′ signal, which was observed at δ 5.21 (m) in the spectrum of DGTH, shifted up field ($\delta < 4.1$), implying the C-2′ hydroxyl of the glycerol moiety is not acylated. Accordingly, the structure of E_1 was determined to be 1-monoacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (MGTH) having a

fatty acid composition very similar to that of DGTH (Table 1). The phagostimulatory activity of the organic extracts of this green alga can, therefore, be attributed to the glycerolipids DGDG, DGTH, MGTH, and SQDG (Figure 4).

One very interesting point is that while DGDG, DGTH, MGTH, and PC were found to be effective for all the gastropods being tested, SQDG was active only for *T. cornutus* and *O. pfeifferi*. The abalone *H. discus* did not respond to SQDG even at dosages as high as 300 μg (Table 2). The young abalone was, however, very responsive to amounts of DGDG and DGTH as low as 20–30 μg (Table 2).

Another interesting point is that these glycerolipids are the first examples of lipophilic feeding stimulants for marine organisms. All the feeding attractants and stimulants for fish so far elucidated are water-soluble compounds like amino acids, nucleosides, etc. (Mackie, 1982; Carr and Derby, 1986). The feeding stimulants thus appear to be of great potential use for the culture of marine herbivorous gastropods that could feed on artificial diets, provided that a suitable feeding stimulant was added.

The wide occurrence of DGDG and PC in the plant kingdom strongly suggests that marine herbivorous gastropods could feed on not only any algae but also on terrestrial plants. The abalone *H. discus hannai* is, however, reported to show quite different feeding preferences, and some algal species are not eaten by them (Uki et al., 1986). Some feeding deterrants may be present in these particular species of algae. Our new bioassay methods for feeding stimulants for herbivorous gastropods are now being applied to study this interesting phenomenon.

The sea urchin is another marine herbivore that is an important seafood in Japan. Indeed, the sea urchin *Strongylocentrotus intermedius* is now easily cul-

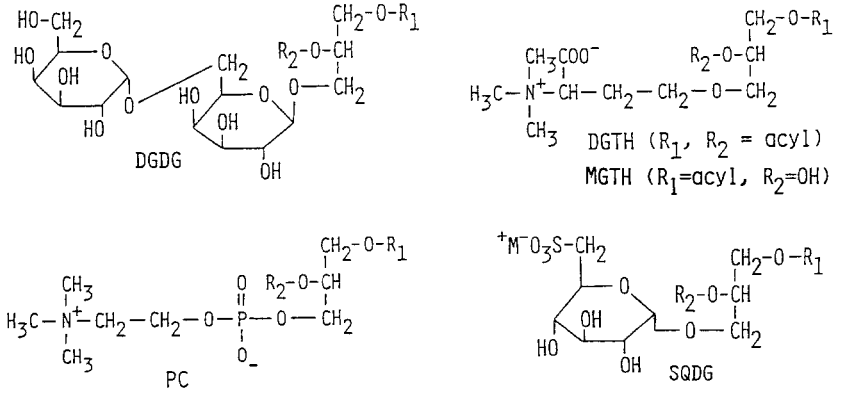

FIG. 4. Glycerolipid structures.

TABLE 2. FEEDING STIMULATION ACTIVITY OF GLYCEROLIPIDS ISOLATED FROM THE ALGA *Ulva pertusa*

	Minimum effective dose (μg)[a]			
	Haliotis discus	*Turbo cornutus*	*Omphalius pfeifferi*	*Aplysia juliana*
DGDG	14–28	15–25	18–23	800[b]
DGTH	10–20	24	<10	100
MGTH	23–50	25–50	<23	
SGDG	>300	20–40	<20	>1000
PC[c]	<10	15	<15	>50

[a] Minimum effective dose value expresses minimum sample amount/sample zone necessary to show + activity. These values are preliminary.
[b] In the case of *Aplysia* minimum sample amount/filter paper (Toyo filter paper No. 2, 5.5 cm in diameter).
[c] Isolated from the brown alga *Undaria pinnatifida*.

tured on a diet of the terrestrial plant, *Reynoutria sachalinensis* ("ooitadori" in Japanese). This technique has been extended to seedling production of the sea urchin in the Hokkaido district in Japan (Department of Mariculture, 1984).

Acknowledgments—The authors wish to thank Drs. A. Sakurai and J. Uzawa of RIKEN (The Institute of Physical and Chemical Research) for 400 MHz [^{1}H]NMR spectra measurements. They are indebted to Mr. T. Nonaka, Director of the Shizuoka Prefecture Fish Farming Center, for his generous gift of the young abalone.

(Received January 20, 1987; accepted August 6, 1987)

Abstract—The analyses of virgin female sex pheromone gland extracts and gland volatiles by GC, GC-EAD and GC-MS, followed by field trapping experiments, have identified (*E*)-9-dodecenyl acetate (*E*9-12 : Ac) as the primary sex pheromone component of the purplestriped shootworm, *Zeiraphera unfortunana*. Dosages of 1.0–10.0 μg of *E*9-12 : Ac impregnated in rubber septa provide an effective trap bait and can be used for monitoring purposes.

Key Words—*Zeiraphera unfortunana*, purplestriped shootworm, *Zeiraphera destitutana*, sex pheromone, (*E*)-9-dodecenyl acetate, electroantennograms, Lepidoptera, Tortricidae.

INTRODUCTION

There are many species of Lepidoptera in North America in the budmoth group found on spruce foliage (Martineau, 1984). Of particular economic importance in New Brunswick are two sympatric species: the spruce budmoth *Zeiraphera canadensis* Mutuura and Freeman and the purplestriped shootworm *Zeiraphera unfortunana* Powell [= *Z. destitutana* (Wlk.)]. These insects are considered important pests because their feeding activity deforms and/or kills new shoots and leaders, thus stunting tree growth (Magasi, 1983, 1984).

[1] Lepidoptera: Tortricidae.

0098-0331/88/0500-1417$06.00/0

We report the identification of the primary sex pheromone component for *Z. unfortunana*. Identification was by GC-EAD and GC-MS analyses of female sex pheromone gland extracts and gland volatiles, and effects on males were verified in field trapping experiments.

METHODS AND MATERIALS

Insects. Zeiraphera unfortunana larvae were collected in 1984 and 1986 from a J.D. Irving, Limited, plantation in St. Leonard, New Brunswick. Branch tips (45 cm) were collected from white spruce [*Picea glauca* (Moench) Voss.] that had a high proportion of budcaps secured in place, apparently by feeding *Zeiraphera* larvae. In the laboratory, these branches were placed on 0.64-cm mesh hardware cloth trays in constant-temperature rooms at 25°C ± 2°C and high relative humidity (>80%). Subsequently, larvae dropped from the trays onto moist vermiculite where pupation occurred. Pupae were separated from the vermiculite by washing in a bleach solution (ca. 1% sodium hypochlorite in demineralized water) for ca. 10 min. They were rinsed in cold tap water for 30 min and then air-dried on paper towels. Pupae were separated by sex and maintained at ca. 25°C, 70% relative humidity on a 16:8 light–dark cycle until emergence. Adults were collected daily and held in cylindrical window-screen cages, misted with water twice daily, and allowed to mature under the same temperature, humidity, and photoperiod regime as were pupae.

Instrumental Analysis. GC analyses were performed using either an SPB-5 (30 m × 0.32 mm) or an SP2330 (30 m × 0.32 mm) fused-silica capillary column (Supelco) on a Varian 3700 gas chromatograph equipped with a flame ionization detector (FID); hydrogen was used as the carrier gas at an inlet pressue of 0.5 kg/cm^2. Injections were made in the splitless mode. The splitter was opened after 30 sec, and the column temperature programmed either at 8°C/min from 50°C to 210°C or 15°C/min from 50°C to 200°C as noted. GC-MS analysis was performed on a Finnigan 4021 EI-CI-INCOS system using the SPB-5 capillary column. Helium was used as the carrier gas with injections made in the splitless mode, with the column at ambient temperature, and then programmed as above.

EI mass spectra were generated at 70 eV, such that 1–5 ng of the synthetics produced excellent full-scan mass spectra with adequate resolution. We examined the respective *E*- and *Z*-monounsaturated isomers of Δ9- and Δ11-dodecenyl acetates (Δ9–12:Ac, Δ11–12:Ac), dodecenols (Δ9–12:OH, Δ11–12:OH), dodecenals (Δ9–12:Ald, Δ11–12:Ald), as well as Δ9- and Δ11-tetradecenyl acetates, alcohols, and aldehydes (Δ9–14:Ac, Δ11–14:Ac, Δ9–14:OH, Δ11–14:OH, Δ9–14:Ald, Δ11–14:Ald) and the saturated compounds dodecyl acetate (12:Ac) and tetradecyl acetate (14:Ac).

Chemicals. Chemicals were obtained from Chemical Samples Company, Columbus, Ohio; Koken Fine and Aromatic Chemicals, Tokyo, Japan; or were synthesized and purified in our laboratory. All chemicals were >99% pure as determined by capillary GC analysis and were used without further purification.

Preparation of Pheromone Gland Extracts and Volatiles. Sex pheromone glands from 2- to 3-day-old females were manually everted and excised during the first 3 hr of scotophase, placed in hexane (Spectrograde) and held at −10°C prior to analyses. Subsequently, glands were sonicated for ca. 1 hr, filtered through precleaned glass wool, and the extract was used for GC, GC-EAD, and GC-MS analyses. Volatiles from extruded virgin female sex pheromone glands of *Z. unfortunana* (2–4 days old; 3–4 hr into scotophase) were collected on glass wool by the method of Baker et al. (1981). Gland volatiles (240 female minutes) were eluted from the glass wool with hexane and were analyzed by GC-EAD using a male (2–4 days old) *Z. unfortunana* antenna.

GC-EAD Analysis. Sex pheromone gland extracts were analyzed by a capillary GC-EAD system (modified after Struble and Arn, 1984). Briefly, effluent from the GC column in a Varian 3700 GC was split 50/50 with a Varian glass-lined splitter. Half of the effluent (ca. 1 ml/min) was delivered to a conventional FID detector while the other half was delivered to the antennal detector. A male *Z. unfortunana* antenna was severed near its base, then the last few segments were excised, and the antenna was placed between the tips of two glass capillaries filled with a saline solution (Roelofs, 1977). Chloridized silver wire electrodes were placed in the solution in each capillary and connected to a 10× EAG amplifier. GC effluent was flushed over the antennal preparation by a water-condenser-cooled air stream passing at right angles over the splitter outlet at a flow rate of ca. 100 ml/min and ca. 100% relative humidity. EAD and GC responses were simultaneous [calibrated with male *Choristoneura fumiferana* (Clem.) antennae for EAD and the primary sex pheromone components 95:5 (*E/Z*)-11-tetradecenal (Silk et al., 1980) as the stimulus]. EAD responses of male *Z. unfortunana* were recorded to GC-separated extracts (sex pheromone glands and gland volatiles) and synthetic standards on both SPB-5 and SP2330 capillary columns.

Field Tests. Field trapping studies were conducted in 1984 and 1986 in the same J.D. Irving, Limited, property where larvae were collected (as above) near St. Leonard, New Brunswick. In 1984, two sites were used; each was comprised of white spruce planted in 1970 (plot 1) and in 1976 (plot 2). In 1986, plot 2 was used again. Red-rubber septa (Arthur H. Thomas Co., Ltd.) impregnated with 10 μl hexane solutions of synthetic chemicals were used as trap baits. Traps (Pherocon 1C) were placed out in a randomized complete block design (8 treatments × 7 blocks × 2 sites, 1984; 6 treatments × 9 blocks, 1986) with 25-m intertrap spacings within and between blocks. All traps were suspended from white spruce foliage at ca. 1.5 m from the ground. In 1984,

traps were placed out for six nights, then brought back to the laboratory for counting. Specimens were randomly selected from traps and sent to the Biosystematics Research Institute (P.T. Dang) in Ottawa for confirmation of species identification. In 1986, trap bottoms were changed daily, or as necessary (>5 moths captured), and the entire array was rerandomized after the third night. All moths were removed from trap bottoms and genitalia examined to confirm species identification. Traps were placed in the field between July 17 and July 23, 1984, and from July 19 to July 25, 1986. Trap capture data were analyzed by two-way analysis of variance and means separated using Tukey's multiple comparison test.

RESULTS

GC and GC-EAD Analysis. A total of 80 sex pheromone glands were available for analysis. Approximately five female gland equivalents (5 FE) in hexane were injected onto the SPB-5 capillary column for GC-EAD analysis (Figure 1; $N = 2$). Although several small EAD responses were noted, only one FID

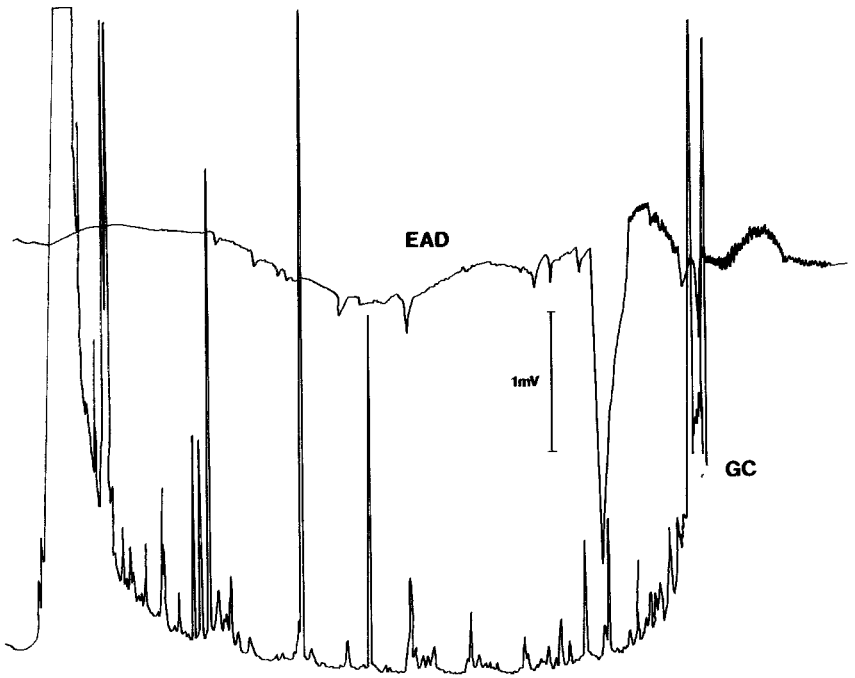

FIG. 1. GC-FID [30 m SPB-5 (0.32 mm) fused silica capillary column; see Methods and Materials] response (lower line) and EAD response (upper line) of a male *Z. unfortunana* antenna to five female pheromone-gland equivalents (equal time scales).

peak corresponded to a large EAD response. The synthetic Δ9–12 : Ac's, Δ9–14 : Ac's, and their saturated analogs (12 : Ac and 14 : Ac) gave noticeable EAD responses (Table 1). The GC retention time and large EAD response of the gland-derived material closely matched that of Δ9–12 : Ac with the retention time, suggesting the *E*-configuration of the double bond (Table 1). GC-EAD analysis of gland extracts (30 FE) on the SP2330 capillary column, which baseline-resolved *E*- and *Z*9–12 : Ac, confirmed the *E* configuration of the double bond (retention times of synthetic *E*9–12 : Ac, 9.90 min; *Z*9–12 : Ac, 10.10 min; gland-derived compound, 9.85 min; 50°C to 200°C at 10°/min). Under these conditions, *Z*9–12 : Ac (< 1% *E*9–12 : Ac) could not be detected in gland extracts. GC-MS analysis was then carried out with the remaining gland extract (40 FE). Although phthalate and other interferences were present, the GC peak of high EAD response had mass spectral (EI) and retention time characteristics of Δ9–12 : Ac [*m/e* 166 (M^+-60) and 61 ($CH_3COOH_2^+$) and fragments at *m/e* 68 and 82] which matched those of synthetic *E*9–12 : Ac. Insufficient material was available to confirm the double-bond position by ozonolysis or other derivatization techniques.

TABLE 1. MEAN EAD RESPONSES OF MALE *Z. unfortunana* ANTENNAE TO SOME SYNTHETICS AND PHEROMONE GLAND EXTRACT

Component	EAD response (mV)[a]
*E*11–14 : Ac	0[b]
*E*9–14 : Ac	1.6 ± 1.3 (N = 6)

14 : Ac	0.6
12 : OH	0.4
14 : OH	0
Major component[c,d]	2.3 (5 FE)

[a] 1 ng stimulus, i.e., 2 ng injected on GC.
[b] Not distinguishable from background response (ca. 0.05 mV).
[c] See Figure 1; five female equivalents.
[d] On SPB-5 capillary column, 50°C–210°C at 8°C/min; synthetic *E*9–12 : Ac retention time = 16.3 min, gland component 16.25 min.

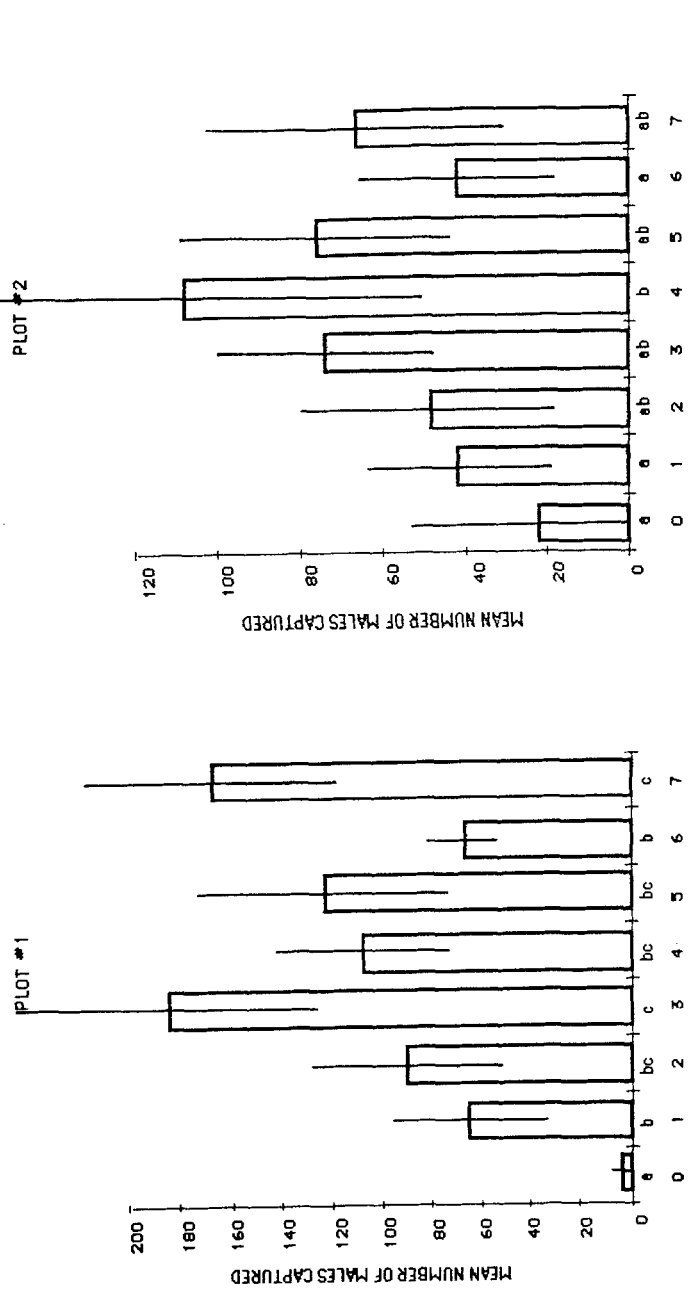

FIG. 2. Mean trap capture of male *Z. unfortunana* in white spruce stands, 1984. Plot 1 (planted in 1970); plot 2 (planted in 1976). Traps were baited with rubber septa impregnated with the following treatments: 0, unbaited trap; 1, 0.1 μg *E*9–12:Ac; 2, 0.3 μg *E*9–12:Ac; 3, 1.0 μg *E*9–12:Ac; 4, 3.0 μg *E*9–12:Ac; 5, 10.0 μg *E*9–12:Ac; 6, 100 μg *E*9–12:Ac; 7, 3.0 μg *E*9–12:Ac + 0.3 μg *Z*9–12:Ac. Means ($\pm$1 SD) followed by the same letter are not significantly different ($P < 0.05$).

GC-EAD analysis of sex pheromone gland volatiles indicated only one EAD-active region with the retention time (SPB-5, 50°C to 200°C at 15°/min; EAD-active peak, 10.10 min, synthetic *E*9–12:Ac, 10.15 min) corresponding to *E*9–12:Ac, confirming the emission of this compound from the sex pheromone gland.

The evidence from GC, GC-EAD, and GC-MS analyses, therefore, supported the assignment of *E*9–12:Ac as the major EAD-active gland component and as the EAD-active component volatilized from the sex pheromone gland surface. An approximate pheromone-gland titer of 100–200 pg/female was computed from the comparison of the magnitude of EAD responses to gland extract vs. synthetic *E*9–12:Ac.

Field Tests. In 1984 in plot 1, all baited traps captured significantly more moths than unbaited controls (Figure 2; $P < 0.05$). In both field plots, a dosage–response relationship was evident, with the 1- to 3-μg dosage apparently producing the highest trap capture rates. The admixture of 10% *Z*9–12:Ac to the 3-μg dosage of *E*9–12:Ac appears to have no effect on mean trap capture. In 1986 (Figure 3), all treatments were significantly different than the control (unbaited trap) but not significantly different from each other ($P < 0.05$). The addition of 10% of either *Z*9–12:Ac or 12:Ac did not appear to affect mean

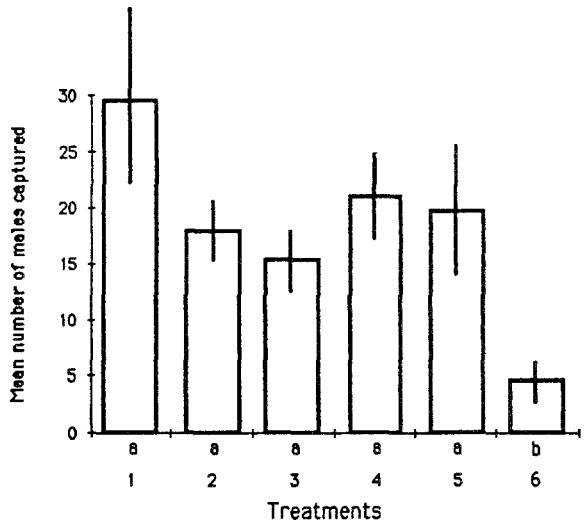

FIG. 3. Mean trap capture of male *Z. unfortunana* in a white spruce stand, 1986: plot 2 (as in 1984). Traps were baited with rubber septa impregnated with the following treatments: 1, 1 μg *E*9–12:Ac; 2, 10 μg *E*9–12:Ac; 3, 100 μg *E*9–12:Ac; 4, 1 μg *E*9–12:Ac; + 0.1 μg *Z*9–12:Ac; 5, 1 μg *E*9–12:Ac + 0.1 μg 12:Ac; 6, unbaited trap. Means ($\pm$1 SD) followed by the same letter are not significantly different ($P < 0.05$).

trap capture at the 1-μg dosage of *E*9–12 : Ac; both these compounds produced noticeable EAD activity but were not detected in the sex pheromone gland extracts of *Z. unfortunana*.

In plot 2 (1984), only the 3-μg dosage was significantly higher than the blank traps. However, one blank trap contained 101 moths and, if eliminated from the analysis, then all baited traps were significantly different from the control traps ($N = 7$; mean $= 22 \pm 35.6$; $N = 6$; mean $= 8.3 \pm 7.9$).

DISCUSSION

GC, GC-MS and GC-EAD analyses have identified *E*9–12 : Ac as the primary sex pheromone component of *Z. unfortunana*. In addition, field trapping studies indicate that *E*9–12 : Ac, impregnated in rubber septa in the 1- to 10-μg range, effectively traps *Z. unfortunana* males. This represents the first chemical identification of a sex pheromone for a North American *Zeiraphera* sp. The *Z* isomer and the saturated analog, at the dosage tested, do not appear to affect mean trap capture rates. Wind-tunnel studies are underway to determine whether *E*9–12 : Ac can elicit upwind flight responses from *Z. unfortunana* males.

At present, few additional data are available on the sex pheromones of North American *Zeiraphera* spp.; however, several European *Zeiraphera* spp. pheromones have been identified. In particular, some Swiss populations of *Zeiraphera diniana* (larch form) utilize *E*11–14 : Ac as their primary sex pheromone component (Roelofs et al., 1971; Guerin et al., 1984), while other *Z. diniana* populations (cembran pine form) utilize *E*9–12 : Ac as their primary component (Baltensweiler et al., 1978; Guerin et al., 1984).

Acknowledgments—We thank Rory McIntosh, Azza Seif el Nasr, and Michael Chandra (RPC) for technical assistance; Sharon Knox and Charles Weaver (CFS) for insect maintenance; and J.D. Irving, Limited (Woodlands Division), for the use of their property and their assistance. Financial support for this project was provided through the Canada/New Brunswick Forest Renewal Agreement.

(Received May 28, 1987; accepted August 10, 1987)

Abstract—Analogs of the two geometrical isomers of the dimethylcyclohexylidene acetaldehyde component of the pheromone of the boll weevil *Anthonomus grandis* were synthesized in which the α-vinylic proton or the aldehydic proton were replaced by fluorine. These isosteric substitutions substantially alter charge distribution and reactivity of the enal system, as documented by spectroscopic changes and changes in reactivity. The electrophysiological activity of the (*E*)- and (*Z*)-acyl fluorides is two orders of magnitude lower than that of the natural aldehyde. In contrast, the EAG response of female antennae to the (*E*)- and (*Z*)-α-fluoro compounds show that the thresholds are quite similar to (and in one isomer lower than) those of the natural aldehyde isomers.

Key Words—*Anthonomus grandis*, boll weevil, Coleoptera, Curculionidae, pheromone analog, fluorinated analogs, acyl fluoride, olfaction, electrophysiology, isosteric replacement.

INTRODUCTION

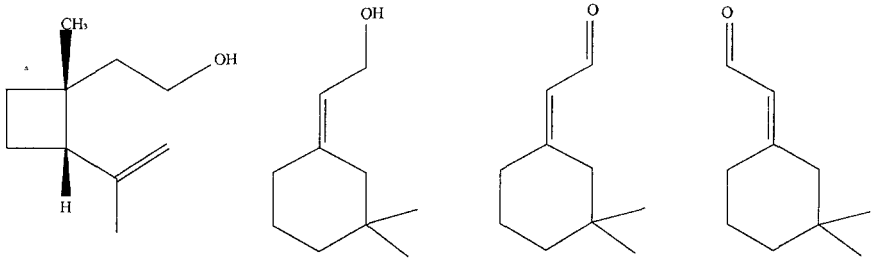
The shape and charge distribution of odorant molecules are important in their interaction with odorant binding sites in receptive tissues. In our efforts to describe the molecular properties of insect pheromone reception systems, we have focused on the design of pheromone analogs with altered chemical reactivity and charge distribution. These analogs can serve as potential affinity labels

0098-0331/88/0500-1427$06.00/0

for pheromone binding proteins (Vogt *et al.*, 1988) or as inhibitors of the catabolic proteins which degrade pheromones (Prestwich, 1987). Current efforts have focused on the bioorganic chemistry of the catabolism and reception of moth pheromones (Prestwich et al., 1987), including the use of fluorinated analogs of pheromones (Prestwich, 1986, 1987; Prestwich and Streinz, 1988; Ding, 1987; Camps et al., 1984a,b). In this paper, we extend our studies to include fluorinated analogs of an aggregation pheromone component from a coleopteran, the boll weevil *Anthonomus grandis*, for which detailed electrophysiological results have been recently reported for the four components I–IV of "grandlure" (Figure 1) (Dickens, 1984). We describe the synthesis of fluorinated analogs of the (*E*)- and (*Z*)-isomers of the dimethylcyclohexylidene acetaldehyde component of the pheromone, and electroantennogram (EAG) studies elucidating their biological activity.

METHODS AND MATERIALS

General Synthesis. 3-Methyl-2-cyclohexene-1-one (V) was purchased from Aldrich and ethyl bromofluoroacetate was purchased from SCM. Solvents were distilled before use. Anhydrous tetrahydrofuran (THF) and diethyl ether were distilled from sodium benzophenone ketyl prior to use. Flash column chromatography and medium-pressure liquid chromatography (MPLC) were carried out using Woelm silica gel (32–63 μm). Thin-layer chromatography (TLC) was performed using MN Polygram Sil G/UV_{254} silica gel plates (4 cm × 8 cm × 0.25 mm). The developed TLC plates were visualized by staining with 3% vanillin (w/v) in ethanol or with UV light. Proton nuclear magnetic resonance ([^{1}H]NMR) spectra were obtained on a Varian FT-80 spectrometer using 0.03% tetramethylsilane (TMS) as an internal standard in chloroform-d_3. Chemical shifts (δ) are expressed as parts per million downfield from TMS. [^{19}F]NMR spectra were obtained on a Nicolet NT-300 spectrometer using trichlorofluoromethane ($CFCl_3$) as an internal standard in acetone-d_6. Chemical shifts (ϕ) are



I II III IV

FIG. 1 Structures of four boll weevil pheromone components.

expressed as parts per million upfield from $CFCl_3$ (ϕ = 0 ppm). Mass spectra (MS), as well as high-resolution mass spectra (HR-MS), (70 eV, electron impact) were obtained using a Spectros MS 30 spectrometer with a DS 50 data system. Gas chromatography was carried out on a Varian 3700 equipped with a fused silica capillary column (DB-5, 30 m × 0.263 mm). All glassware, syringes, and needles were dried in an oven at 110°C before use. The glassware was assembled hot and cooled under a flow of dry nitrogen. All of the reactions were carried out under a small positive pressure of dry nitrogen, using a mercury bubbler as a pressure relief valve.

(E)- *and* (Z)- *Methyl 3,3-dimethylcyclohexane-*$\Delta^{1,\alpha}$*-acetate (VII).* Sodium hydride (490 mg, 60% dispersion in mineral oil, 12.3 mmol) was washed with dry hexane (2× 4 ml) and suspended in 5 ml of anhydrous THF. A solution of trimethyl phosphonoacetate (2.17 g, 11.9 mmol) in 15 ml of anhydrous THF was added dropwise to this suspension at room temperature over 0.5 hr. The mixture was stirred for an additional 0.5 hr, then placed in an ice-water bath. A solution of 3,3-dimethylcyclohexanone VI (495 mg, 3.9 mmol), prepared from enone V as described by Pelletier and Mody (1976), was dissolved in 12 ml of anhydrous THF and added dropwise over 0.5 hr to the above mixture. The cooling bath was removed, and the reaction mixture was then refluxed for 4 hr. After cooling the reaction mixture down to room temperature, 250 ml of water was added to decompose the excess hydride. The aqueous phase was extracted with ether (3× 50 ml) and the combined ether extracts were washed with brine (1× 10 ml), dried ($MgSO_4$), and concentrated in vacuo. The crude product was purified by flash column chromatography (hexane–ethyl acetate, 10:1) to yield 680 mg (94%) of methyl 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-acetate VII as a mixture of *E* and *Z* isomers (*E*:*Z* = 3:2). The isomers could be only poorly resolved by MPLC. [^{1}H]NMR (*E*)-(VII), δ 5.57 (1H, s), 3.68 (3H, s), 2.75 (2H, t), 1.97 (2H, s), 1.0–1.6 (4H, m), 0.90 (6H, s); (*Z*)-(VII), δ 5.68 (1H, s), 3.67 (3H, s), 2.63 (2H, s), 2.13 (2H, t), 1.0–1.6 (4H, m), 0.92 (6H, s).

(E)- *and* (Z)-*3,3-Dimethylcyclohexane-*$\Delta^{1,\alpha}$*-acetic acid (VIII).* The unresolved methyl ester isomers VII (374 mg, 2.1 mmol) were dissolved in 24 ml methanolic KOH (0.25 N, methanol–water, 1:1). The solution was gently refluxed for 3 hr. After cooling, the solution was diluted with 120 ml of water, washed with ether (1× 50 ml), and acidified with 2 N HCl to litmus red. The aqueous phase was extracted with ether (3× 10 ml), and the combined ether extracts were washed with brine (1× 10 ml), dried ($MgSO_4$) and concentrated in vacuo to yield 320 mg (92%) of the acid VIII as a white needle crystals. The *E* and *Z* isomers were separated by MPLC using two consecutive silica gel columns (2.2 cm ID × 30 cm each) eluting with hexane–ethyl acetate (20:1). [^{1}H]NMR (*E*)-VIII, δ 5.58 (1H, s), 2.77 (2H, t), 1.99 (2H, s), 1.2–1.6 (4H, m), 0.90 (6H, s); (*Z*)-VIII, δ 5.70 (1H, s), 2.65 (2H, s), 2.15 (2H, t), 1.2–1.6 (4H, m), 0.92 (6H, s).

(E)-*3,3-Dimethylcyclohexane-*$\Delta^{1,\alpha}$*-acetyl fluoride* [(E)-*IX*]. To a solution of the (*E*)-acid (*E*)-VIII (20 mg, 0.12 mmol) in 1 ml of anhydrous ether at 0°C was added dimethylaminosulfur trifluoride (DAST) (19 mg, 0.12 mmol). The mixture was warmed to room temperature and stirred for 20 min. The solvent was removed in vacuo, and the crude product was purified by flash column chromatography (hexane–ethyl acetate, 20:1) to yield 9 mg (48%) of the (*E*)-acyl fluoride (*E*)-IX. [^{1}H]NMR δ 5.54 (1H, s), 2.76 (2H, t), 2.04 (2H, s), 1.0–1.6 (4H, m), 0.92 (6H, s).

(Z)-*3,3-Dimethylcyclohexane-*$\Delta^{1,\alpha}$*-acetyl fluoride* [(Z)-*IX*]. The (*Z*)-acetyl fluoride (*Z*)-IX was prepared according to the procedure described above starting with the (*Z*)-acid (*Z*)-VIII. [^{1}H]NMR δ 5.69 (1H, s), 2.63 (2H, s), 2.18 (2H, t), 1.0–1.6 (4H, m), 0.92 (6H, s).

Ethyl 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$*-*α*-fluoroacetate (X).* Sodium hydride (165 mg, 60% dispersion in mineral oil, 4.1 mmol) was washed with dry hexane (2× 4 ml) and suspended in 2 ml of anhydrous ether. A solution of triethyl 2-fluorophosphonoacetate (998 mg, 4.1 mmol), prepared from ethyl bromofluoroacetate (Machleidt and Wessendorf, 1964), was dissolved in 5 ml of anhydrous THF and added dropwise to this suspension at room temperature over 0.5 hr. The mixture was stirred for an additional 30 min and then placed in an ice-water bath. A solution of ketone VI (189 mg, 1.5 mmol) in 3 ml of anhydrous ether was added dropwise to the above mixture over 0.5 hr. The cooling bath was removed and the reaction mixture was refluxed for 5 hr. After cooling down to room temperature, 15 ml of water was slowly added to decompose the excess hydride. The aqueous phase was extracted with ether (3× 10 ml) and the combined ether extracts were washed with brine (1× 10 ml), dried ($MgSO_4$), and concentrated in vacuo. The crude product was purified by flash column chromatography (hexane–ethyl acetate, 20:1) to yield 275 mg (86%) of ethyl 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetate X as a mixture of *E* and *Z* isomers (*E*:*Z* = 2:3). The *E* and *Z* isomers could not be separated by MPLC. [^{1}H]NMR, δ 4.26 (2H, q), 2.52 (CH_2-2, d, J_{HF} = 0.9 Hz), 2.14 (CH_2-2, d, J_{HF} = 2.6 Hz), 1.33 (3H, t), 0.92 (6H, s). [^{19}F]NMR, ϕ 131.56(s), 133.26(s).

3,3-Dimethylcyclohexane-$\Delta^{1,\beta}$*-*β*-fluoroethanol (XI).* The unresolved fluoroacetate isomers X (260 mg, 1.2 mmol) and lithium aluminum (51 mg, 1.3 mmol) were dissolved in 5 ml of anhydrous THF and refluxed for 6 hr. Upon cooling to room temperature, the excess hydride was slowly decomposed with 1 ml of ethanol, followed by 10 ml of water. The aqueous phase was extracted with ether (3× 10 ml) and the combined ether extracts were washed with brine (1× 10 ml), dried ($MgSO_4$), and concentrated in vacuo. The crude product was purified by flash column chromatography (hexane–ethyl acetate gradient, 25:1 to 6:1) to yield 180 mg (86%) of the incompletely separated *E* and *Z* isomers XI. [^{1}H]NMR *E* isomer δ 4.22 (2H, dd, J_{HF} = 22.7 Hz, J_{HH} = 6.0 Hz), 1.88 (2H, s), 0.89 (6H, s); *Z* isomer δ 4.26 (2H, dd, J_{HF} = 22.5 Hz, J_{HH} = 6.0

Hz), 2.1–1.9 (4H, m), 0.90 (6H, s). [^{19}F]NMR *E* isomer ϕ 122.09 (t, J_{HF} = 23.7 Hz); *Z* isomer, ϕ 123.70 (t, J_{HF} = 22.0 Hz).

3,3-Dimethylcyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetaldehyde (XII). The unresolved β-fluoro ethanol isomers XI (52 mg, 0.3 mmol) were combined with manganese dioxide (300 mg, 3.5 mmol) in 3 ml of anhydrous CH_2Cl_2 and stirred for 18 hr at room temperature. TLC showed a considerable amount of the starting β-fluoroethanol still present. Additional manganese dioxide (200 mg, 2.3 mmol) was added, and the stirring was continued for another 12 hr. The reaction was quenched with 15 ml of ether, and the dark brown solution was filtered through Florisil. The precipitate was washed with ether (2× 10 ml), and the combined either filtrates were concentrated in vacuo. The crude product was purified by flash column chromatography (hexane–ethyl acetate, 20:1) to yield 32 mg (62%) of the incompletely separated (*E*)- and (*Z*)-α-fluoroacetaldehyde. [^{1}H]NMR *E* isomer of XII δ 9.74 (1H, d, J_{HF} = 18.4 Hz), 2.3–2.5 (4H, m), 0.97 (6H, s); [^{1}H]NMR *Z* isomer of XII δ 9.80 (1H, d, J_{HF} = 18.4 Hz), 2.56 (2H, t), 2.21 (2H, s), 0.96 (6H, s). [^{19}F]NMR *E*-isomer ϕ 135.95 (d, J_{HF} = 19.4 Hz); *Z* isomer ϕ 137.71 (d, J_{HF} = 19.2 Hz).

Electrophysiology. Adult female boll weevils used in this study emerged from a small laboratory colony annually infused with feral insects. Upon emergence, groups of five females were held in separate Petri dishes on moist filter paper (Whatman No. 1) at ca. 26°C on a photoregimen of 16 hr of light (ca. 600 lux) and 8 hr of darkness. Each group of five females was fed daily two fresh cotton squares. Only virgin females four to six days postemergence were used for recordings.

Methods used in recording electroantennograms (EAGs) were modified after previous methodologies (Schneider, 1957; Payne, 1970; Dickens, 1979; Dickens and Payne, 1977) and are detailed elsewhere (Dickens, 1984). Briefly stated, following insertion of Ag–AgCl capillary electrodes in the distal tip of the antennal club (recording electrode) and scape (indifferent electrode), electrical activity was amplified 10 times by a Grass P-16 DC preamplifier. EAG waveforms were displayed on a storage oscilloscope and their amplitudes were registered with a strip-chart recorder.

Dosage–response curves were constructed from serial dilutions (0.01–1.0 μg) of the *E* and *Z* isomers of both the α-fluoro analogs and acyl fluorides. Stimulus compounds diluted in hexane were delivered as 1-μl aliquots placed on filter paper (8 × 18 mm) inserted into glass odor cartridges (80 mm × 5 mm ID). A 10-μl aliquot was used to obtain the 10-μg dosage. Once these cartridges were oriented toward the antennal preparation at a distance of 1 cm, hydrocarbon-free air (filtered and dried) carried molecules evaporating from the filter paper over the preparation.

As in several previous EAG studies of the boll weevil (Dickens, 1984) and other insects (Dickens and Boldt, 1985; Dickens 1986; Light et al., 1988), 1-

hexanol at the 100-μg dosage was used as a standard for the normalization of all responses so that responses from different preparations could be compared. Odorous stimuli were presented from the lowest to the highest dosage; all compounds at one dosage were presented, followed by all compounds at the next higher dosage. Stimulation with the standard preceded and followed response to the series of compounds at each dosage. Responses to the compounds at each dosage were represented as a percent of the mean of the two nearest responses to the standard (Dickens, 1978, 1979, 1981). Three replicates were recorded for each dosage of each compound.

The magnitude of the negative transient of the EAG following stimulation was considered to be a measure of the relative number of responding acceptors (Payne, 1975; Dickens and Payne, 1977). The threshold of response was defined as the dosage at which the lower standard error of the mean was greater than zero. Saturation level was defined as that dosage at which the standard error of the response elicited overlapped with the standard error of the response at the highest dosage. Responses were compared for significant differences using the *t* test for two means (Ostle, 1969).

RESULTS AND DISCUSSION

The four sex pheromone components produced by male boll weevils, *Anthonomus grandis* Boheman, were isolated, identified, and first synthesized by Tumlinson et al. (1969). The four components are oxygenated monoterpenoids: (+)-*cis*-2-isopropenyl-1-methyl-cyclobutaneethanol (I), (*Z*)-3,3-dimethylcyclohexane-$\Delta^{1,\beta}$-ethanol (II), (*Z*)-3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-acetaldehyde (III), and (*E*)-3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-acetaldehyde (IV) (Figure 1). Several efficient syntheses of these compounds have been reported (Babler and Mortell, 1972; Pelletier and Mody, 1976; Wolinsky and Bedoukian, 1975), including synthesis of optically active grandisol I (Hobbs and Magnus, 1976; Mori et al., 1978; Webster and Silverstein, 1986). Laboratory bioassays and field tests (Cross, 1973; Hedin et al., 1973; Dickens, 1984, 1986) of the synthetic and chemically related compounds have also been reported.

Our effort in the boll weevil pheromone receptor system was to synthesize fluorinated isosteric analogs of II, III, and IV. Our target molecules were *E* and *Z* isomers of 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-acetyl fluoride, (*E*)-IX and (*Z*)-IX, and the *Z* and *E* isomers of 3,3-dimethyl-cyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetate, (*Z*)-XI and (*E*)-XII. Note that the change in nomenclature priorities (H < C < F) means that the α-fluoro analog with the *E* geometry is in reality an analog of the *Z* aldehyde.

We have chosen components III and IV as our parent compounds, because EAG studies have shown that both male and female weevils were significantly

more responsive to II and a mixture of III + IV (1 : 1) than to I, but the difference between II and III + IV was not significant (Dickens, 1984). Furthermore, geometrically pure III and IV are difficult to obtain, and the EAGs had not been described in earlier work.

Starting from commercially available 3-methyl-2-cyclohexen-1-one V, the (*E*) and (*Z*)-acyl fluorides (*E*)-IX and (*Z*)-IX could be synthesized in four steps as outlined in Figure 2, in 37% overall yield. A conjugate addition of lithium dimethylcuprate to the starting material V gave 3,3-dimethylcyclohexanone VI in 90% yield (Pelletier and Mody, 1976). Condensation of the resultant ketone with trimethyl phosphonoacetate in THF afforded, methyl 3,3-dimethyl-cyclohexane-$\Delta^{1,\alpha}$-acetate VII, in 94% yield as a mixture of *E* and *Z* isomers (*E*:*Z* = 3:2, GC). Subsequent hydrolysis of the esters in methanolic KOH solution gave the corresponding acids VIII in 92% yield. Separation of the *E* and *Z* isomers was then carried out by using medium-pressure liquid chromatography (MPLC) with two consecutive silica gel columns (2.2 ID × 30.0 cm, each), eluting with hexane–ethyl acetate (20 : 1). Selected fractions were analyzed by gas chromatography (DB-5, fused silica capillary column, 30 m × 0.263 mm). Fractions containing a single component and like retention times were then combined. The assignment of double-bond geometry to these acids was made

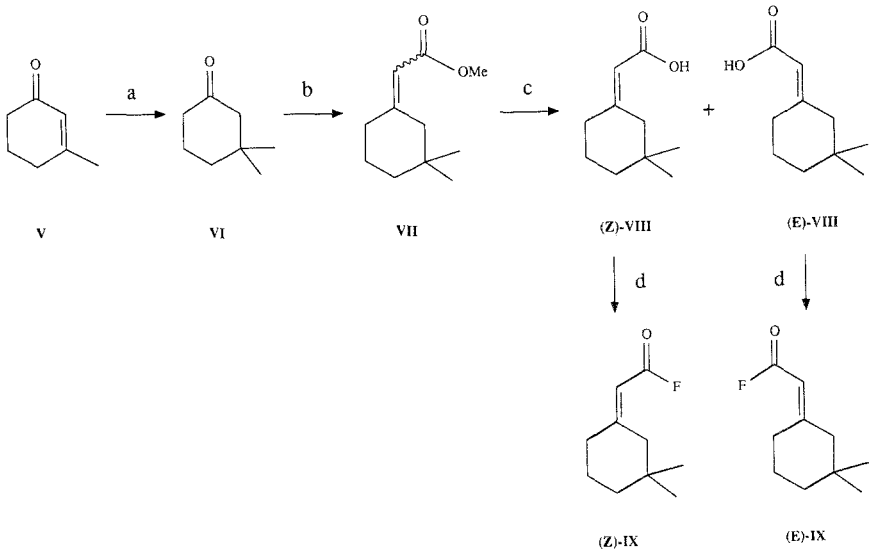


FIG. 2. Syntheses of acyl fluorides. Reagents: (a) CH_3Li, CuI, ether, 20°C, 20 min (90%); (b) NaH, $(CH_3O)_2P(O)CH_2CO_2CH_3$, THF, reflux, 4 hr (94%); (c) KOH, CH_3OH–H_2O (1 : 1), reflux, 3 hr (92%), and then MPLC separation; (d) DAST, ether, 20°C, 20 min (48%).

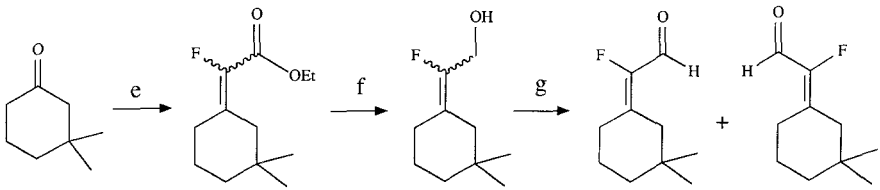
by converting the acids to the corresponding methyl esters with diazomethane and comparing spectra data with literature values (Tumlinson et al., 1971). The isomerically pure acids thus obtained were each reacted with diethylaminosulfur trifluoride (DAST) to give the acyl fluorides (*E*)-IX and (*Z*)-IX in 48% yield. These α,β-unsaturated acyl fluorides were stable and could be purified by flash chromatography without decomposition back to the starting acids. Acyl fluorides lacking the conjugated olefin (e.g., Z9–14:Acf) are readily hydrolyzed in air and do not survive chromatography (Prestwich et al., 1986; Ding, 1987).

The (*E*)- and (*Z*)-α-fluoroacetates (*E*)-XII and (*Z*)-XII could be synthesized in four steps also starting from V, as outlined in Figure 3, in 28% overall yield. To generate the α-fluoroacetate, triethyl 2-fluorophosphonoacetate was first obtained by reacting triethyl phosphite with ethyl bromofluoroacetate (Machleidt and Wessendorf, 1964). The triethyl 2-fluorophosphonoacetate was then added to ketone VI, giving the ethyl 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetate X in 86% yield, as a mixture of *E* and *Z* isomers (*E*:*Z* = 2:3, GC). Reduction of the resulting acetate with lithium aluminum hydride (LAH) gave 3,3-dimethylcyclohexane-$\Delta^{1,\beta}$-β-fluoroethanol XI. Unlike the usual ester reductions with LAH in refluxing ether solution, the presence of the α-fluoro group reduced the rate of reaction significantly. In order to overcome this problem, a higher boiling solvent (THF) and longer reaction time (6 hr) was used. The yield of this reaction was 86%. The same problem was also encountered upon oxidation of the β-fluoroethanol with active manganese dioxide to the target molecules, 3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetaldehydes XII. The reaction time was 30 hr at room temperature and the yield was 62%. Surprisingly, these α-fluoroacetaldehydes, (*E*)-XII and (*Z*)-XII, have quite distinct R_f values: they showed up as two spots on TLC. They could be separated by flash column chromatography easily, as could the β-fluoroethanol compounds



VI X XI (E)-XII (Z)-XII

FIG. 3 Syntheses of α-fluoroacetates. Reagents: (e) NaH, $(C_2H_5O)_2P(O)CHFCO_2C_2H_5$, ether, reflux, 5 hr (86%); (f)$LiAlH_4$, THF, reflux, 6 hr (86%); (g) MnO_2, CH_2Cl_2, 20°C, 30 hr (62%), and then flash column chromatography separation. NOTE: The F atom changes the nomenclature priorities; that is, the α-fluoro compound (*Z*)-XII is a structural analog of the (*E*)-aldehyde IV.

(*E*)-XI and (*Z*)-XI. In contrast, separation of III and IV by flash column chromatography was not possible; even MPLC gave only low yields of pure III and IV, with the bulk remaining as III + IV.

Dosage–response curves constructed from EAGs of female *A. grandis* to the acyl fluorides and the α-fluoro analogs of III and IV revealed striking differences in the reactivity of these compounds with antennal olfactory acceptors (Figure 4). The EAG threshold for the α-fluoro analogs of both III and IV was at least 100-fold to 1000-fold lower for these compounds when compared to their acyl fluoride counterparts. Furthermore, the threshold for α-fluoro-IV [i.e., compound (*E*)-XII] was similar to that obtained for the natural pheromone IV. Antennal acceptors were somewhat more sensitive to the α-fluoro analog of III [i.e., compound (*Z*)-XII] than to III itself at lower concentrations.

Replacement of hydrogen by fluorine is a common strategy in producing biologically active compounds with modified binding properties and having different metabolic stabilities. Fluorinated pheromone analogs are able to effect behavioral responses and electrophysiological responses of insects by several modes of action. They can function as antagonists, blocking access of the pheromone to the receptor and thus inhibiting responses, or as agonists, mimicking the pheromone and producing a modified response. By judicious placement of the fluorine in a chemically reactive position, one can obtain an irreversible antagonist or agonist effect. Finally, a fluorinated analog may be active in disrupting the catabolism of a pheromone, thereby producing aberrant responses due to sensory adaptation to unremoved pheromone.

Camps and his co-workers (Camps et al., 1984a,b) have indicated that vinylic fluorines in olefinic pheromones act as agonists and do not cause major changes in responses of moths to their own pheromone. Our efforts to produce 2-fluorovinyl analogs of the aldehydes of two moth species have revealed a poor mimicry of the aldehyde by this functionality (Prestwich, 1987; Ding, 1987). Similarly, Mason et al. (1987) found that 2-fluoro-1-heptene was a poor analog of heptanal in conditioning experiments with tiger salamanders. When the fluorine is in the terminal ω position, we have observed trail-following activity by *Reticulitermes* to 12-fluoro analogs of dodecadienols similar to that of the unfluorinated compounds (cf. Prestwich, 1986; 1987). In addition, these ω-fluorofatty acid derivatives are potent toxicants by virtue of their in vivo conversion to fluoroacetate and then to fluorocitrate (cf. Prestwich, 1986, 1987).

Fluorination adjacent to carbonyl groups has not been extensively explored in pheromone biochemistry. Ding (1987) has prepared 2-fluoro- and 2,2-difluoroaldehydes analogous to Z11–16:Al, a pheromone component of several moths including *Heliothis virescens*. These aldehydes are so strongly hydrated that they appear unable to stimulate antennal responses; moreover, they are only moderately effective as inhibitors of the antennal aldehyde dehydrogenase of *H. virescens* (Ding, 1987; Prestwich, 1987; Prestwich et al., 1987). The boll

weevil system offered an opportunity to make α-fluoroaldehydes that would not be strongly hydrated, thus allowing us to observe the effects of a *less* electrophilic carbonyl carbon on pheromone response.

The effects of trifluoromethyl ketones as good mimics of acetates for binding or for enzymatic hydrolysis have also been explored in *Trichoplusia ni* (B.D.

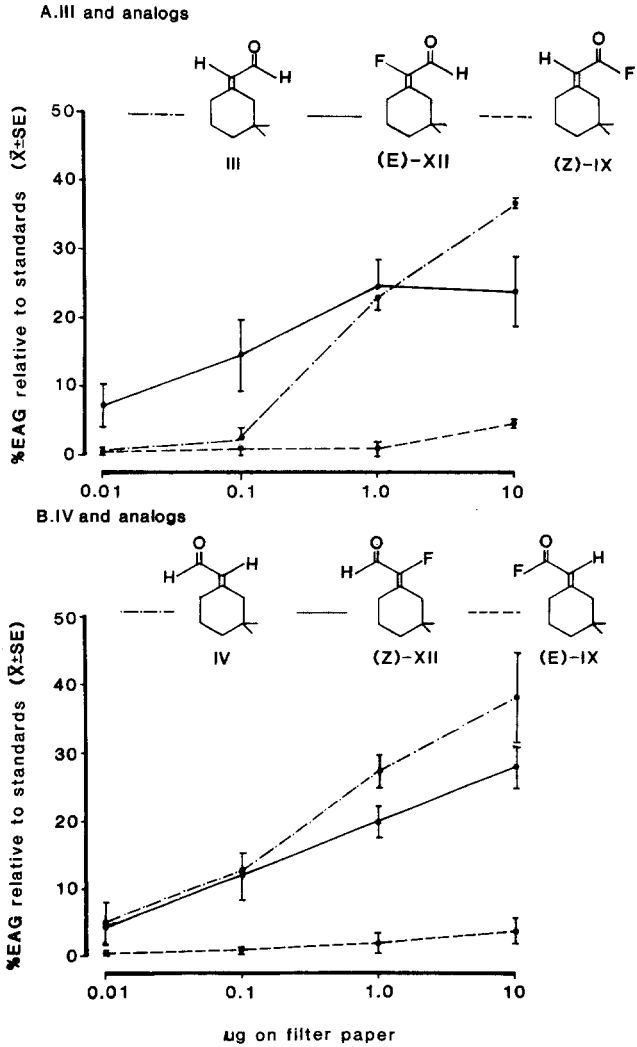


FIG. 4 EAG response ($\bar{X} \pm$ SE) of female antennae relative to 1-hexanol standard. (A) Responses to III (-·-·-·) and to analogs of III: acyl fluoride analog (*Z*)-IX (------) and α-fluoro analog (*E*)-XII (———). (B) Responses to IV (-·-·-·) and to analogs of IV: acyl fluoride analog (*E*)-IX (-----) and α-fluoro analog (*Z*)-XII (———).

Hammock, unpublished, cited in Prestwich, 1987) and in *Plutella xylostella* (Prestwich and Streinz, 1988). Finally, the sequential replacement of acetate hydrogens by halogens in Z11–16:Ac (Prestwich and Streinz, 1988) clearly showed that for *P. xylostella*, mono-, di-, and trifluoroacetates were moderately good stimulants (ca. 50% of acetate in EAG). Other halogens, while not changing the polarity, greatly affected the steric bulk of the acetate and resulted in haloacetate analogs with lower potency in both EAG and enzyme competition assays.

To date, the most striking example of a reactive pheromone mimic has been the Z9–14:Acf and Z11–16:Acf acyl fluoride analogs of the *H. virescens* aldehydes (Prestwich et al., 1986). Irreversible agonist activity was observed in treated males; disorientation and irreversible extrusion of the genitalia and hair-pencils resulted from in vivo exposure to 5 mg of the mixed acyl fluorides. Unfortunately, at low levels this acyl fluoride is quite labile to hydrolysis in the air. EAG assays and flight-tunnel experiments have been uniformly disappointing, because at low levels, hydrolysis, attachment to the substrate (e.g., paper), and release, all occur at competitive rates. Thus, the opportunity to evaluate a more stable α,β-unsaturated acyl fluoride in the boll weevil system offered a route to observe the low-level, longer-term effects of this isosteric replacement to give a *more* electrophilic carbonyl carbon.

The results of the EAG experiments clearly show that enhancing the reactivity of the carbonyl group as the acyl fluoride dramatically reduces its ability to stimulate the aldehyde receptor. In contrast, decreasing the electrophilicity with α fluoro substitution of the vinylic hydrogen produces a potent agonist. Further studies with the α-fluoro compounds will be reported in due course.

CHEMICALLY MEDIATED HABITAT RECOGNITION IN SHORE INSECTS (Coleoptera: Carabidae; Hemiptera: Saldidae)

W.G. EVANS

Department of Entomology
University of Alberta
Edmonton, Alberta, Canada T6G 2E3

(Received April 15, 1987; accepted August 15, 1987)

Abstract—Adults of 14 species of Carabidae and mixed nymphs and adults of two species of Saldidae, collected in habitats associated with a saline lakeshore, sedge fen, vernal pond, stream mud flat, salt spring, mud and sand river bank, pebble river bank, and a marine sand beach, aggregated in choice chambers above volatiles (allelochemics) collected from their habitats. In other tests adults of some carabid species responded to volatiles from habitats other than their own, and to arbitrarily selected individual components and mixtures of components of saline lakeshore volatiles. These results suggest that shore insects recognize habitat allelochemics and aggregate in areas where these compounds are emitted by resident microflora. It is proposed that some habitat allelochemics are short-range signals that indicate locations of microhabitats used by shore insects for behaviors such as feeding, mating, and resting; in contrast, long-range allelochemics allow these insects to select their habitats from a distance. This hypothesis provides a mechanism for explaining how different shore habitats are partitioned among different species of shore insects.

Key Words—Habitat selection, habitat allelochemics, chemical cues, volatiles, shore habitats, arrestants, short-range cues, long-range cues, Coleoptera, Carabidae, Hemiptera, Saldidae.

INTRODUCTION

Even though they straddle the land–water interphase, shore environments are often named after the aquatic component of these ecotones because they are strongly influenced by the nature of the nearby water. Currents and wave action can erode or build up shorelines, and water temperature, pH, salinity, and other

0098-0331/88/0500-1441$06.00/0

such factors determine the composition and structure of the biota of shore as well as aquatic communities (Úlehlová and Přibil, 1978). Yet, except for the intensively studied intertidal zone, little attention has been given to athalassic shore habitats such as those found adjacent to ponds, streams, lakes, springs, and rivers. When these places are examined, a distinct insect fauna is evident (Obrtel, 1972, 1978; Stehr and Branson, 1938; Holeski and Graves, 1978; Shelford, 1978; Richardson, 1921; Andersen, 1968, 1970, 1978, 1985; Lindroth, 1963). The most conspicuous are beetles of the families Carabidae (particularly bembidiines, agonines, and elaphrines), Staphylinidae, and Heteroceridae. Shore bugs (Saldidae) are also common as are scavenging, predatory, or algae-feeding flies (Ephydridae, Chironomidae, Canaceidae, Anthomyiidae, and Dolichopodidae). Collembolans and mites are abundant in some shore habitats, and hunting spiders (Lycosidae, Linyphiidae), normally associated with terrestrial vegetation, frequently forage in the same general areas as ground beetles and staphylinids. Similar insect communities live on some marine beaches and rocky shores (Evans, 1980). In western Canada the shore biota consists invariably of shore insects and an algal flora growing in wet substrates close to the water or in damp depressions on beaches.

Shore habitats vary in extent from narrow zones, scarcely more than 20 cm wide on the edges of meadow pools to vast beaches on gradually sloping shores of large lakes; because they are neither terrestrial nor aquatic, both flooding and desiccation are major hazards. Periodically, shore habitats are inundated by floodwaters or higher than normal tides and, after these subside, they leave deposits that completely blanket the habitats of the resident organisms. Wind-driven algal blooms are often deposited on beaches of large eutrophic lakes and these masses of decaying algae radically alter trophic pathways of the shore communities. Other shore habitats are endangered when lake and river levels subside, and small bodies of water dry out during droughts. However, shore organisms are adapted to these cyclic (intertidal) or intermittent (streams, rivers, ponds, springs, and lakes) fluctuations of water levels (Andersen, 1968; Thiele, 1977). The biota is soon reestablished in suitable sites due to rapid recolonization by pioneering microorganisms, particularly blue-green algae and diatoms, and the subsequent influx of shore insects and other animals. At some sites the successional transition from aquatic to terrestrial communities involves shore communities as early seral stages (Hefley, 1937).

Many shore insects overwinter in more sheltered places than exposed shorelines. Although short distances are involved in some localities, such as from a river bank to a nearby wood, for small insects these movements constitute migrations. Also, individuals of some species, particularly those from river banks prone to flooding or from ponds that dry out in late spring, have to migrate at other times as well. Movements of these insects between habitats require them to locate the general habitat area, the habitat itself, and the microhabitat;

or, in a broad sense (Prokopy, 1986), the habitat, patch, and resource, respectively (Hassell and Southwood, 1978).

Obviously, habitat recognition is an essential component of these kinds of activities. Recognition occurs when perception of certain signals or cues that are congruent with neural cognitive processes invokes specific behavioral responses (Dethier, 1982). The kind of response depends on the nature of the signal: Long-range signals may elicit anemotaxes that enable insects to find general habitat areas from a distance by flying upwind towards the signal source (Evans, 1983); intermediate-range signals may invoke some form of searching behavior; short-range signals induce orthokinetic and klinokinetic movements in relation to the boundaries of the microhabitat, resulting in increased time spent in the area (arrestment) (Jones, 1986).

During migrations, shore insects must distinguish their own habitats from a diverse array of similar habitats by recognizing specific habitat cues. These signals are token stimuli since they represent an integration of the physical, chemical, and biological nature of the habitat (Evans, 1983). Presumably, the species composition of communities differs because members of a particular habitat collectively recognize similar cues such as specific chemical compounds (allelochemics) or specific proportions of chemicals in a multicomponent allelochemic mixture. Components of volatile algal or other microbial metabolites have been implicated as sources of habitat recognition signals for some shore insects (Evans, 1982). These results prompted this investigation on whether other shore insects (from a broad range of shore habitats) also respond to habitat volatiles, the extent of recognition of other habitat volatiles, and whether components of allelochemic mixtures elicit responses.

METHODS AND MATERIALS

Ground beetles (Carabidae) and shore bugs (Saldidae) were chosen as experimental shore insects because they are common, conspicuous, and relatively easy to collect in most shore environments. These two groups of insects are primarily predaceous, their members feeding on smaller insects and mites, and, according to Silvey (1935), on freshly stranded zooplankton. A wide range of habitat types (8) in western Canada, from Saskatchewan to British Columbia, was selected for study. These sites were associated with a pond, salt spring, floating fen, stream, two kinds of river banks, a saline lake, and a marine sand beach. From among these sites adults of 14 carabid species and mixed nymphs and adults of two saldid species were collected, then kept in a laboratory incubator at 10°C until needed for tests. Groups of 10 individuals were placed in plastic boxes provided with damp filter paper and cotton-stoppered vials of water. All insects were fed weekly on vestigial-winged adults of *Drosophila*

melanogaster. Most of the carabids were *Bembidion* spp. along with *Elaphrus* (two species) and *Diplous aterrimus* Dejean and *Opisthius richardsoni* Kirby. The shore bugs consisted of *Saldula comatula* Parshley and *S. pallipes* (Fabr.). However, *S. pallipes* is actually a group of species that has not yet been differentiated taxonomically (Polhemus, personal communication); hence, their designation here as *S. pallipes* complex.

To test responses of the insects to habitat volatiles, they were allowed to choose, in still air, between half filter paper disks (Whatman No. 2, 5.5 cm diameter) treated with volatiles (from their own habitats or, in some experiments, from other habitats) or untreated filter papers, in choice chambers. The papers were positioned 2 mm below circular fine-mesh stainless-steel screens holding the insects, thus exposing them only to volatiles (see Evans, 1982, for details). Aggregation of insects on the sides containing the treated papers was considered evidence that the volatiles act as arrestants. All filter papers were initially rinsed in a mixture of 10% methanol and 90% acetone in a Soxhlet apparatus to remove residual chemicals. In each microhabitat, 50–100 filter papers were treated by pressing them onto the surface of damp soil or exposed algae, or by placing them under logs or stones in the habitats (see next section), and leaving them there for seven days or more. This allowed enough time for adsorption of volatile or contact chemical substances directly from the surface of substrates upon which insects walked. Papers collected in the field were transported to the laboratory in a cooler, then stored in a freezer until needed, and air dried before use. The papers from some habitats were eluted with carbon tetrachloride (four 5-ml aliquots per 20 papers), and the combined eluants were concentrated to about 4 ml with an N_2 gas stream. The concentrates were then applied with a syringe to fresh papers. Other papers from the habitats were used directly in the choice chambers. Groups of up to 10 insects were tested in each choice chamber, with each replicate consisting of between 5 and 10 counts of the insects on each side of the choice chambers at a count rate of one every 2 min.

Insects collected from one of the habitats (saline lakeshore) were tested for responses to individual components of habitat volatiles as well as to mixtures. These components were extracted from filter papers left in the habitat for 14 days and identified using gas chromatography and mass spectrometry. About 100 papers that had been left in the habitat for 14 days were crumpled with forceps and put in two glass tubes 20 cm long × 5.5 cm ID. A male 55/50 ground glass joint on the end of one tube connected with a female joint on the other tube, forming a sealed tube. The other ends of these tubes tapered to 8 mm OD × 7 cm tubing. Using Swagelok fittings, one end of the sample holder was connected to an N_2 source and the other end to a 9 cm long × 5 mm ID stainless tube containing 0.3 g of Tenax-GC stoppered with glass wool. The volatiles were flushed from the sample holder with N_2 at 50 ml/min for 2 hr

and adsorbed on the Tenax-GC, which was then eluted with three 0.5-ml aliquots of acetone.

Prior to injection into a gas chromatograph (Varian Vista 6000 connected to a VG Analytical 70E mass spectrometer), the acetone was concentrated with an N_2 stream to about 10 μl in a 15 mm long $\times$ 10 mm diameter screw-capped vial tapered at the bottom to a 10 mm long $\times$ 1 mm ID capillary tube. Separation of the components in extracted volatiles was performed on 1-μl injections with the use of two columns: a polar OV 351 programmed for 2 min at 35°C then 7°C/min to 200°C; and a nonpolar DB-1 which also started at 35°C for 2 min but continued to 290°C at 7°C/min. The resultant chromatograms and mass spectra showed that sulfur compounds, alkanes, alkenes, and saturated and unsaturated methyl esters of C_{16} to C_{18} acids were common. Therefore, acetone solutions of some of these chemicals (synthetic) were applied to half filter paper disks to serve as the treated side of the choice chambers, with acetone alone applied to the papers on the untreated sides. Three saline lakeshore species (*B. obtusidens* Fall, *B. scudderi* Lec., *B. versicolor* Lec.) and a river species (*B. interventor* Lindr.) were tested with these solutions.

Data were analyzed using replicated goodness of fit tests for observed ratios to expected ratios of 1:1 (G test; Sokal and Rohlf, 1969). The statistic "G pooled" considers all replicates as though they were a single large replicate and tests it for goodness of fit, whereas G heterogeneity indicates whether the trend in any direction is uniform; however, the magnitudes of G pooled and G heterogeneity are proportional to the number of replicates (*N* in tables), other factors being equal. Preliminary control tests using either solvent-treated or untreated papers on both sides of the choice chambers showed no preference by the insects for any side.

Habitats

Vernal Pond. Victoria, British Columbia. This habitat consists of mud flats left by receding water of a pond surrounded by couch grass *Agropyron repens* (L.) Beauv. The surface of the mud, particularly near and among the grass shoots, is covered with a layer of algae consisting mainly of chlorophytes *Oedogonium* spp., *Closterium* spp., *Protoderma* spp.; xanthophytes *Tribonema* spp.; euglenophytes *Trachelomonas* spp.; and cyanophytes *Anabaena* spp. Of the insect predators active in this habitat the carabids *Elaphrus americanus sylvanus* Goulet, *Bembidion coloradense* Hayward, and *B. versicolor* LeConte are the most abundant. Usually, by midsummer the water in the pond has dried out. Filter papers were pressed onto the algal layer.

Sedge Fen. Saltspring Island, British Columbia. This floating fen habitat differs from the vernal pond habitat in being a permanent body of water, although levels fluctuate seasonally, as do the kind of vascular plants present. The insect

predators are similar to those in the vernal pond habitat even though the algal complex overlaps only slightly. Algal aggregations are found on decomposing vascular plants and among stands of bulrush *Scirpus lacustris*. Dominant algae include the chlorophytes *Closterium* spp., *Klebsormidium* spp., and *Gloeocystis* spp.; species of the diatom genera *Pinnularia*, *Rhoicosphenia*, *Nitzschia*, *Eunotia*, *Fragilaria*, and *Hannea*, and the xanthophyte *Heterothrix* (*Tribonema*). Insects collected for testing were the same as those collected in the vernal pond habitat with the addition of *Saldula comatula*. Filter papers were placed on the algal mats.

Stream; Mud Flats. Amisk Creek, Tofield, Alberta. The algal mats on mud surfaces exposed by receding waters of this habitat consist mainly of members of the diatom genera *Nitzschia*, *Bacillaria*, *Navicula*, and *Pinnularia* along with the euglenophyte *Euglena* spp. and the cyanophyte *Chroococcus* spp. The carabids *Bembidion versicolor*, *B. graphicum* Casey, and *Elaphrus californicus* Mannerheim, and the saldid *Saldula pallipes* complex are common. Filter papers were pressed onto the algal layers.

Riverbank; Shingle. Goldstream River, Victoria, British Columbia. This clear, fast-flowing small river flows over a cobbled bottom forming numerous riffles and eddies. The pebbly substrate directly next to the water is the habitat of the patrobine carabid beetle, *Diplous aterrimus*. Both larvae and adults live in the spaces between pebbles, preying and scavenging on aquatic animals, including fingerling salmon stranded on the shore. Surfaces of pebbles in this habitat were coated with diatoms, *Eunotia* probably *lunaris* (Ehrenberg) Grunow. Filter papers were placed close to the water under stones large enough to cover them.

Riverbank; Mud and Sand. Pembina River, Barrhead, Alberta. This microhabitat is located up to 2 m away from the water and debris such as stones, twigs, and leaves serve as shelters for numerous shore insects, with *Bembidion interventor* Lindroth, *B. inequale* Say, *B. timidum* LeConte, and *Opisthius richardsoni* being dominant during the tenure of this study. A faint greenish color on the surface of the caked muds and sands is due to diatoms (*Eunotia*, *Nitzschia*, and *Pinnularia* spp.), so filter papers were placed directly on this substrate.

Saline Lakeshore. Wells Lake, Marsden, Saskatchewan. This sulfate-dominated, 5 × 1 km, saline lake is connected by a stream to Manito Lake [salinity = 19.3 g/liter; (Hammer, 1978)] and is typical of many such lakes in western Saskatchewan and eastern Alberta in having salt-encrusted sandy-loam beaches that provide habitats for many shore insects. One kind of habitat consists of shallow depressions containing 0.5- to 1.5-cm-thick mats of salt crystals, sand, and dense growths of blue-green algae (*Oscillatoria animalis* Agardh and *O. subbrevis* Schmidle). Diatoms, brineflies (*Ephydra* sp.), springtails, mites, and other organisms occupy this habitat as well as the carabids *Bembidion obtusi-*

dens, *B. scudderi*, *B. diligens* Casey, *B. versicolor*, and *B. henshawi* Hayward. On the open areas of the beach *Elaphrus lecontei* Crotch is occasionally present, whereas *Saldula pallipes* complex is very abundant. The wetter parts of the beach, especially near the water, are usually covered by sheets of *Cladophora*, which attract many brineflies but few carabids or saldids. *Salicornia rubra* (A. Nels) is common on the upper shore. Filter papers were placed directly on the salt-encrusted *Oscillatoria* mats.

Marine Sand Beach. This high intertidal habitat is situated on the southwest side of a protected sand spit (Sidney Spit) facing Sidney channel on Sidney Island, British Columbia. Spaces under cast-up logs at the base of sand dunes provide daytime resting sites for adults of the carabid beetle *Bembidion indistinctum* (Dej.) along with amphipods (*Orchestia* spp.), marine weevils (*Elassoptes marinus* Horn), and grapsid crabs [*Hemigrapsus oregonensis* (Dana)]. During nocturnal low tides, these animals forage over the surface in company with other sand-burrowing intertidal insects such as *Thinopinus pictus* LeConte (Staphylinidae), *Phycocoetes testaceous* LeConte (Curculionidae), *Endeodes collaris* (LeConte) (Melyridae); and *Dyschirius obesus* LeConte (Carabidae). The filamentous marine green alga *Percursaria percursa* (Agardh) Rosenvinge grows under those logs that are stranded near the high-tide mark. Filter papers were treated by placing them under logs for seven days.

Salt Spring. Saltspring Island, British Columbia. Sodium chloride is the major salt in this hypersaline spring (salinity = 73.1 g/liter) which oozes from the side of a low hill over an area of about 6 m^2. Collembolans (*Anurida* spp.), brineflies (*Ephydra* spp.), saldids (*Saldula comatula*), intertidal chironomids [*Thalassosmittia marinus* (Saunders)], (Saunders, 1928), and carabid beetles (*Bembidion indistinctum*) are fairly common here. *Salicornia rubra* and *S. virginica* L. dominate the areas downhill of the spring. Dense growths of *Percursaria percursa* give the general area of the spring a bright green color. Thus this marine alga and *B. indistinctum* occur together in two very different kinds of habitats. Filter papers were pressed onto the surface of *P. percursa* mats.

RESULTS

Dominant Microflora of Habitats. The eight shore habitats are readily segregated into four groups by algal composition: (1) The marine sand beach and salt spring are distinct because of the green alga *P. percusa*, which is dependent on the NaCl-dominated waters of these habitats. (2) Blue-green algae, *O. animalis* and *O. subbrevis*, associated with saline waters high in sulfates, characterizes the saline lakeshore habitat. (3) Diatoms encrusted on stones or growing in sand are characteristic of the microflora of riverbanks. (4) Fens, ponds, and

mudflats next to lentic waters, including quiet backwaters of streams, showed the greatest variety of algae such as greens, blue-greens, euglenophytes, xanthophytes, and diatoms growing on surfaces of wet substrates near water.

Responses to Habitat Volatiles. In all tests the total numbers on the treated side of the choice chambers exceeded those on the untreated and the pooled G tests show these differences to be real (Table 1). The treated–untreated ratios varied from 1.4 : 1 for *B. inequale* (river bank) to 4.3 : 1 for *S. pallipes* complex (saline lakeshore), indicating variability in magnitude of responses of species from different habitats. These results suggest that shore carabids and saldids recognize microhabitat signals and tend to aggregate in places that emit them. In more than two thirds of the tests, G heterogeneity was significant; the reasons for this are not known, but habituation of the insects to repeated disturbances when counts were taken cannot be discounted.

The volatiles are produced by the floral constituents of the habitats, as suggested by Evans (1982, 1986) and by a consideration of the *B. indistinctum*/*P. percursa* relationship. The hypersaline environment of the salt spring must have been conducive to *P. percursa* development (after colonization by windblown spores), even though the soils, slope, aspect, and general appearance of the surroundings are very different from marine shores. The common denominator of the salt spring and the sand beach habitats is the alga, indicating that chemical cues emitted by this plant have a significant role in guiding adults of *B. indistinctum* to both habitats.

Responses to Volatiles from Other Habitats. The results (Table 2) show that the insects that were tested can be grouped into those species (*B. coloradense*, *B. obtusidens*, *B. versicolor*) that tolerate a wide range of environmental conditions (eurytopic) and those species (*B. indistinctum*, *B. inequale*, *E. a. sylvanus*, *O. richardsoni*) that tolerate narrower ranges (stenotopic). Although *B. indistinctum* also responded to saline lakeshore volatiles, when given a choice between those and salt spring volatiles individuals of this species chose the latter. *E. a. sylvanus* appears to be restricted to nonsaline environments. Curiously, *B. coloradense*, a nonhalophile from the sedge fen responded to salt spring volatiles, although not to those from the sea shore habitat.

Because of the great contrast between river bank and lake shore environments, as well as the differences in salinity of the waters, river bank insects (*B. inequale* and *O. richardsoni*) did not aggregate above saline lakeshore volatiles. An exception was *B. versicolor*. This is a well-documented eurytopic species (Lindroth, 1963); in this study, individuals were collected at the sedge fen, river bank (sand and mud), and the saline lakeshore (Table 3) habitats. Thus responses of these beetles collected from the sedge fen to volatiles from the vernal pond and from the stream mud flats were not unexpected.

Individuals of *B. obtusidens* are usually found in highly saline environments where salts are precipitated on soil surfaces, but there are collection rec-

ords of this species from hyposaline areas near Edmonton (Lindroth, 1963). Nevertheless, although responses of these insects to salt spring volatiles are expected (even if this habitat is outside their geographical range), it is not clear why they responded to the vernal pond volatiles but not to those from the stream mud flat.

Responses to Components of Saline Lakeshore Volatiles. Individuals of three species (*B. obtusidens*, *B. scudderi*, *B. versicolor*) aggregated above the filter papers treated with components alone or mixtures of these chemicals (Table 3). The ester mixture was shown previously to invoke responses of *B. obtusidens* adults in choice chambers (Evans, 1982) as well as anemotactic responses in a wind tunnel (Evans, 1984). This ester mixture is much more effective in eliciting aggregation of the insects than either of the individual components alone. The results of the methyl 9-octadecenoate tests were barely significant (G pooled), whereas the distribution in response to methyl hexadecanoate did not differ from that occurring by chance.

Although the mass spectra did not positively pinpoint the sulfur compounds, tests using both dimethyl sulfide and dimethyl disulfide [volatiles associated with anaerobic decomposition of organic sulfur (McLaren, 1963)] also induced responses as did the combination of 1-undecene with dimethyl disulfide. The C15:0, C15:1, C17:0, and C17:1 hydrocarbon mixture invoked responses in saline lakeshore species (*B. obtusidens*, *B. scudderi*) and in a river bank species (*B. interventor*). The responses of shore insects to arbitrarily selected concentrations and mixtures (Table 3) indicate that specific blends of volatiles are not required as habitat recognition cues.

DISCUSSION

The behavior of shore insects in choice chambers (Table 1) in response to habitat allelochemics demonstrates that they recognize these chemical signals. Recognition of these cues provides them with a means of monitoring varying degrees of habitat quality in relation to spatial aspects (although it does not explain how the habitat is selected initially by flying insects). The integration of this information with that provided by visual and tactile cues can then enable them to recognize microsites within the habitat for feeding, mating, resting, ovipositing, and other resource-related activities. This mechanism of habitat recognition can help to explain why shore insects appear to be restricted to specific areas of shore environments. *D. aterrimus*, for instance, is found only in a very narrow zone of moist pebbles next to the water. Chemical cues associated with diatoms growing on these stones may be more important than other cues in this process. Adults of *Elaphrus a. sylvanus* lurk in spaces between grass stems bordering ponds and dash out to catch prey on exposed areas next to the water. In one locality, the foraging distance from grass to water was only

about 40 cm. Although visual stimuli probably have a large role in the orientation behavior of these predatory insects, allelochemics also must have been involved (Table 1). Evans (1986) also records the role of these chemicals in habitat recognition in an intertidal carabid beetle inhabiting rock crevices.

These examples represent responses of insects to chemical cues that are short-range signals, i.e., arrestants. Specific concentrations or blends of these chemicals appear to be unnecessary to obtain arrestant responses in the laboratory (Table 3), explaining the responses of shore insects to volatiles from other habitats (Table 2). Perhaps a wide range of habitats produces some chemicals that are common to all of them. Preliminary unpublished results suggest that this may be so, at least in the case of volatiles of river bank soils and saline lakeshore sands. Data on the attraction of a river bank species (*Bembidion interventor*) to mixtures of saline lakeshore hydrocarbons (Table 3) support this idea.

Some shore insects fly readily when disturbed. Even if they are displaced a short distance away from the habitat, intermediate-range cues could keep them informed of their spatial relationship with the habitat, enabling them to fly back to the area. However, the localized effectiveness of short and intermediate range cues precludes their use in habitat selection by migrating insects at considerable distances from the habitat (several kilometers). Therefore, it is postulated that long-distance chemical cues must serve to bring migrants into the general area of the appropriate habitat and that partitioning of shore insect species among the many kinds of shore habitats is thus a function of recognition by these insects of long-range habitat cues. This proposed mechanism of habitat selection further supports the suggestion that components of short-range (microhabitat) signals may occur in more than one kind of habitat, resulting in bioassays that show responses to other habitat volatiles (Table 2) and apparent lack of specificity of responses to particular blends, mixtures, or concentrations of these allelochemics (Table 3).

Acknowledgments—I am grateful for the kindness extended to me by the following for allowing me to conduct field studies on their properties: the Harkema family (sedge fen), G.L. Young (salt spring) the Palmer ranch (saline lakeshore), and the Swan Lake Nature Reserve (vernal pond). I also gratefully acknowledge the generosity of R.A. Ring for providing me with information on the salt spring. For help in identifications, I thank J. Stein (algae), G.E. Ball (carabids), and J.T. Polhemus (saldids); and for help in the field work, P. Hohn and D. Mulyk. Finally I thank J.E. Evans and G.E. Ball for their critical reviews of the manuscript. This research was supported by a Natural Sciences and Engineering Research Council of Canada grant (A-1409).

ANTINUTRITIONAL EFFECTS AND ECOLOGICAL SIGNIFICANCE OF DIETARY CONDENSED TANNINS MAY NOT BE DUE TO BINDING AND INHIBITING DIGESTIVE ENZYMES

HAROLD J. BLYTT, TIMOTHY K. GUSCAR, and LARRY G. BUTLER

(Received June 29, 1987; accepted August 17, 1987)

Abstract—The digestive enzymes alkaline phosphatase and 5′-nucleotide phosphodiesterase, solubilized from bovine intestinal mucosa and purified to homogeneity, were found to be strongly inhibited in vitro by condensed tannins (proanthocyanidins) purified from sorghum seeds and from quebracho. Tannin inhibition was prevented and reversed by the detergent Triton X-100 (protein-binding agent), by soluble polyvinylpyrrolidone (tannin-binding agent), or by phosphatidylcholine (membrane component). When tested as a crude particulate membrane fraction more characteristic of their in vivo condition, both enzymes were inhibited much less than either purified enzyme at the same tannin concentration. Because the enzymes appear to be relatively insensitive to inhibition by tannin in conditions which mimic in vivo conditions, and because the proportion of the dietary tannin which is available to interact with these enzymes in the digestive tract is likely to be rather small, we suggest that the antinutritional effects and ecological significance of dietary tannins are not due to tannin inhibition of these or other digestive enzymes by direct binding to them.

Key Words—Dietary tannins, digestive enzymes, phosphatase, 5′-nucleotide phosphodiesterase, enzyme inhibition.

INTRODUCTION

Tannins are plant polyphenols capable of forming strong complexes with proteins. Tannins are generally beneficial to the plants that produce them, func-

0098-0331/88/0600-1455$06.00

tioning as part of the plants' chemical defense system against herbivores and/or microorganisms (Fellows, 1980). Tannins are effective antifeedants, but the mechanism of this effect has not been established (Mole and Waterman, 1987a). In animal diets tannins generally show antinutritional effects such as diminished weight gains and poor feed efficiency (Blair and Mitaru, 1983).

The growth-depressing effect of dietary tannins has been attributed, in part, to a decrease in protein digestibility (Vohra et al., 1966), possibly due to formation of a complex between the tannin and endogenous proteins such as digestive enzymes (Glick and Joslyn, 1970). Digestive enzymes such as trypsin and α-amylase have been reported to be inhibited in vitro by tannins (Griffith and Moseley, 1980). The digestive enzyme enterokinase, which plays a crucial role in the activation of digestive proteases (Maroux et al., 1971), has also been reported to be inhibited in vitro by (dietary) tannins (Oh and Hoff, 1986). These investigators also reported that tannin may either inhibit or stimulate in vitro digestion by intestinal proteases, depending upon the reaction conditions. Mole and Waterman (1985, 1987b) have also questioned the assumption that the effects of dietary tannins are due to their inhibition of digestive enzymes, and several observations inconsistent with inhibition of digestion as the sole or primary mechanism of the antinutritional effects of dietary tannin in mammals have been summarized (Butler et al., 1986). It has recently been concluded that dietary tannins do not reduce the nutritional value of insect foods by inhibiting digestion (Martin et al., 1987).

Condensed tannins (proanthocyanidins) have been shown to be highly selective in their binding; large, conformationally loose, proline-rich proteins are bound several orders of magnitude more strongly than small, compact proteins (Hagerman and Butler, 1981). Dietary tannin has opportunities for complexing with a wide variety of dietary proteins and other proteins of the digestive tract which have a very high affinity for tannin (Mehansho et al., 1983) before it is exposed to the major digestive enzymes. Tannin may therefore not be free to bind digestive enzymes when it encounters them. Moreover, some digestive enzymes occur in membrane-bound forms, which may be less susceptible to inhibition by tannin than the soluble forms purified and tested in vitro. In an attempt to assess the nutritional significance of the inhibition of digestive enzymes in vitro, we have investigated the inhibition, by condensed tannin purified from sorghum seeds and from quebracho, of two digestive enzymes as they occur in a particulate, membrane-bound form as well as the soluble form which has been purified and characterized in vitro. Because the effects of tannin on proteolytic enzymes are complicated by tannin binding to both the protease and the protein substrate, we have chosen to study phosphohydrolases, for which tannin binds only to the enzymes and not to the substrates. These enzymes, alkaline phosphatase (APase) and 5′-nucleotide phosphodiesterase (PDase), are from mucosal cells of the bovine intestinal brush border.

METHODS AND MATERIALS

Materials. The soluble forms of APase (Landt et al., 1978) and PDase (Landt and Butler, 1978) were purified from bovine intestine as previously described. Purified soluble enzymes were used in all experiments in which particulate enzyme is not specified. To prepare particulate enzymes (all steps carried out at 0–5°C), 2 g frozen bovine intestinal mucosa was suspended in 18 ml of buffer A (100 mM Tris HCl, 12 μM $ZnSO_4$, pH 8.0) using a ground glass homogenizer. The homogenate was centrifuged 20 min at 35,000*g* and the supernatant discarded. The pellet was suspended in 18 ml of buffer, and centrifuged again. The pellet from the second centrifugation was resuspended in buffer A and homogenized on a Brinkmann Polytron equipped with a PT-10 head, at full power for five bursts of 12 sec each, with 2-min intervals for chilling to 0°C. In order to show that Polytron treatment did not convert the enzyme to a soluble form, a sample of the homogenate was centrifuged 90 min at 200,000*g*. Most of the enzyme activity sedimented; only 3.5% of the APase activity and 4.5% of the PDase activity remained in the supernatant.

Substrates (4-nitrophenyl phosphate and 4-nitrophenyl phenylphosphonate), bovine liver phosphatidylcholine, soluble polyvinylpyrrolidone (PVP), average mol wt 10,000, and Triton X-100, average mol wt 625, were from Sigma (St. Louis, Missouri). Sorghum tannin was purified from the seed of the bird-resistant sorghum hybrid, BR 64, by the method of Hagerman and Butler (1980a). Quebracho tannin was purified from quebracho extract (Trask Chemical Corp., Marietta, Georgia) as previously described (Asquith and Butler, 1985).

Enzyme Assays. APase and PDase activities were determined as previously described (Landt and Butler, 1978) using 1 mM 4-nitrophenyl phosphate and 4-nitrophenyl phenylphosphonate, respectively, as substrates at pH 8.0.

RESULTS

Soluble highly purified PDase is strongly inhibited by tannin (Figure 1). Under the conditions used in these assays, no precipitation of the enzymes by tannin is observed; both PDase and APase are glycoproteins, which may account for the solubility of their complexes with tannin (Asquith et al., 1987). Inhibition is not instantaneous, but it is essentially complete in 15 min. Tannins purified from sorghum seeds or quebracho are equally effective as inhibitors, with 50% inhibition at about 20 μg/ml in the subsequent assay. The experiment shown in Figure 1 was carried out at pH 8.0. Similar effects were observed when the enzyme was incubated with tannin at pH 6.0 and assayed at pH 8.0; physiological pH in the small intestine should be between pH 6 and pH 8.

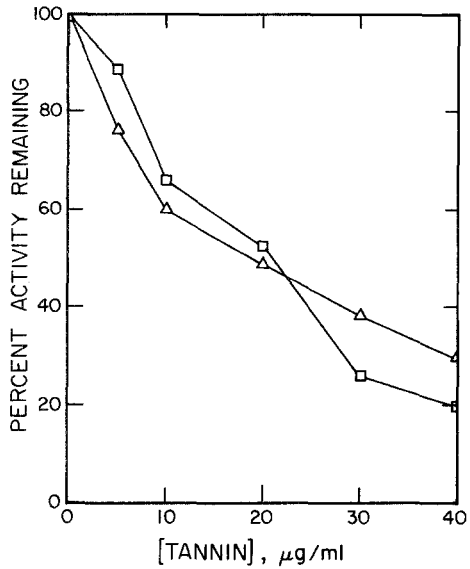

FIG. 1. PDase inhibition by sorghum and quebracho tannin. PDase was incubated for 15 min at 30°C in 0.1 M Tris (HCl), 10 μM $ZnSO_4$, pH 8.0 (buffer A) containing the indicated concentration of sorghum (squares) or quebracho (triangles) tannin. The mixture was then diluted 3.3-fold into assay mix and the activity measured as described in Methods and Materials.

Purified APase is somewhat less sensitive to inhibition by tannin (Figure 2). In contrast to PDase, the two sources of tannin are not equivalent for APase; up to eight times more quebracho tannin is required to obtain the same degree of inhibition observed with sorghum tannin. Sorghum tannin is likewise more effective than quebracho tannin in protein binding and precipitation assays (Asquith and Butler, 1985).

Effect of Triton X-100, Phospholipid, and PVP. Figure 3 shows the pronounced effect of 10 mM Triton X-100 on inhibition of PDase by tannin. Tannin concentrations, which otherwise produce 80% inhibition of PDase, are not inhibitory in the presence of Triton X-100. Tannin even slightly stimulates PDase when 10 mM Triton X-100 is present. Tannin likewise does not inhibit APase in the presence of 10 mM Triton X-100 (Butler et al., 1984). Similarly, in the presence of phosphatidylethanolamine, a prominent membrane component, tannin inhibition of PDase (Figure 4) and APase (not shown) is greatly reduced.

When Triton X-100 is added to tannin-inhibited APase, inhibition is completely reversed (Figure 5). The inhibitory effect of tannin, therefore, does not

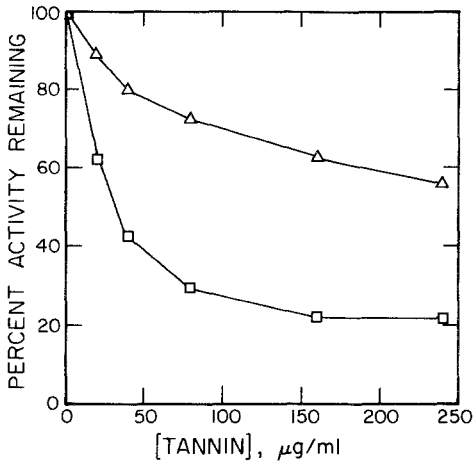

FIG. 2. APase inhibition by sorghum and quebracho tannin. APase was incubated for 15 min at 30°C in Buffer A containing the indicated concentration of sorghum (squares) or quebracho (triangles) tannin and assayed as in Figure 1.

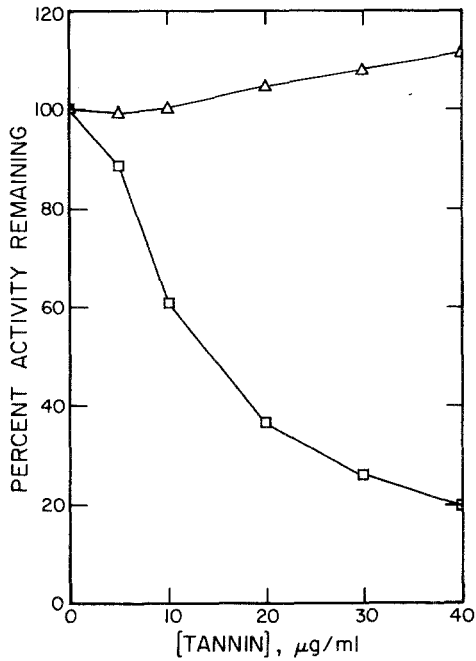

FIG. 3. Effect of Triton X-100 on tannin inhibition of PDase. PDase was incubated for 15 min in buffer A (squares) or in buffer A containing 10 mM Triton X-100 (triangles) in the presence of the indicated concentrations of sorghum tannin.

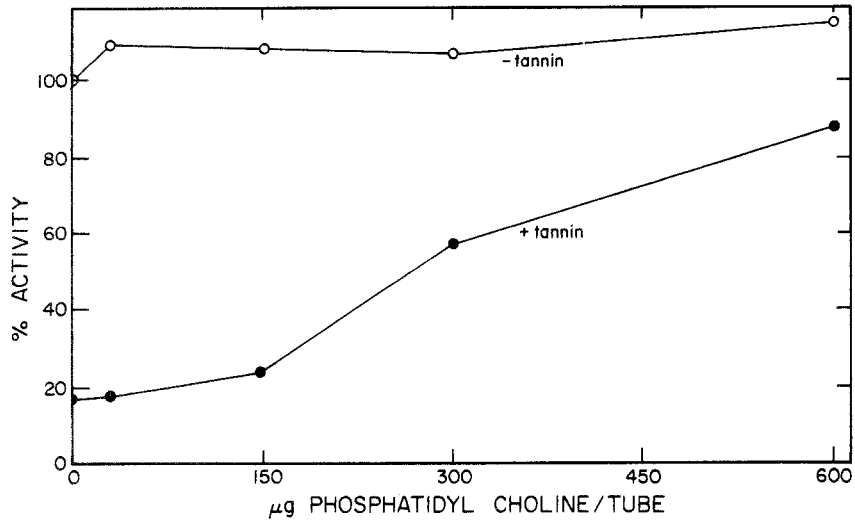

FIG. 4. Effect of phosphatidylcholine on tannin inhibition of PDase. PDase, 1.1 μg protein, was incubated for 30 min at 30°C with the indicated amount of phosphatidylcholine in buffer A after which 30 μg of sorghum tannin was added for a final volume of 0.5 ml another 30 min before assay.

depend on irreversible denaturation or modification of the enzyme. Triton X-100 also reactivated PDase after tannin inhibition (data not shown).

Addition of soluble PVP to tannin-inhibited PDase leads to complete reactivation (Figure 6). Tannin-inhibited APase was also reactivated by PVP, but the recovery of activity after PVP addition was not quite as complete as with PDase. Thus, the inhibition of these enzymes by tannin can be reversed by addition of agents that bind either protein (Triton X-100) or tannin (PVP). On the other hand, 10% (v/v) methanol, which enhances protein precipitation by tannin (Hagerman and Butler, 1980b), did not have a significant effect on tannin inhibition of PDase (data not shown).

When the enzyme sample is a particulate fraction instead of the purified soluble enzyme, the effect of tannin is much smaller. As shown in Figure 7, 50 μg/ml tannin only inhibits the particulate PDase by 11%, whereas the soluble purified PDase is inhibited 45% at this tannin concentration. The particulate enzyme preparation contained about the same level of enzyme activity as the soluble purified PDase, but it had approximately 200 times as much protein. In a previous study (Butler et al., 1984) a higher concentration of the crude particulate enzyme was used, and 50 μg/ml tannin caused only 3% inhibition of the PDase activity. APase activity of the particulate fraction is likewise less

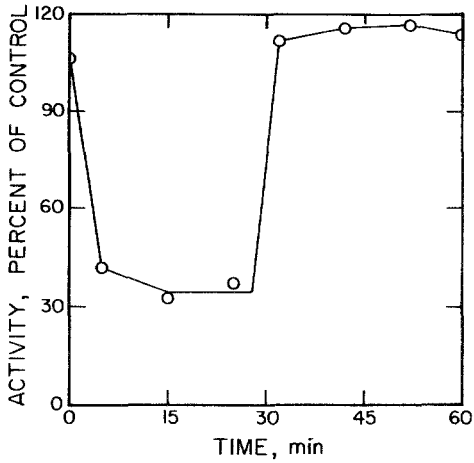

FIG. 5. Reversal of tannin inhibition of APase by Triton X-100. APase was incubated for the time shown at 30°C in buffer A containing 200 μg/ml sorghum tannin and 8 mg/ml methanol. A control sample contained methanol without tannin. At 28 min, both samples were made 12 mM in Triton X-100.

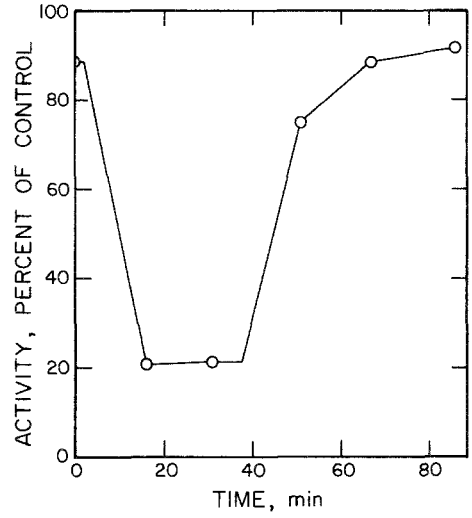

FIG. 6. Reversal of tannin inhibition of PDase by PVP. PDase was incubated for the time shown at 30°C in buffer A. At 2 min, the experimental sample, but not the control, was made 31.2 μg/ml in sorghum tannin. At 38 min, both samples were made 3.85 mg/ml in soluble PVP.

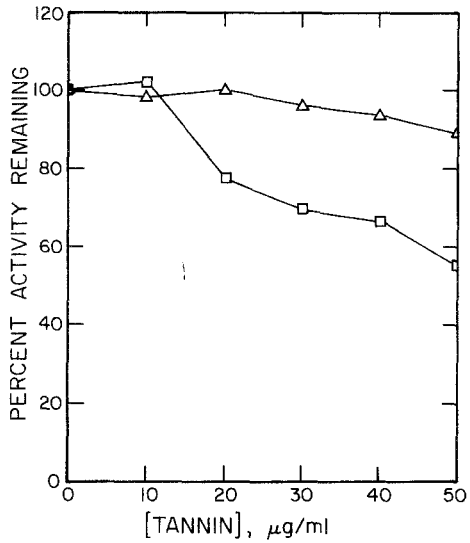

FIG. 7. Comparison of the tannin inhibition of soluble versus particulate PDase. Soluble purified PDase (squares) or the washed particulate fraction from bovine intestinal mucosa (triangles) was incubated for 30 min at 30°C in buffer A containing the indicated concentrations of sorghum tannin.

inhibited by 250 μg/ml tannin (44% inhibition) than is the purified soluble enzyme (79% inhibition).

DISCUSSION

Our results demonstrate, as expected, that in their purified soluble form these digestive enzymes are strongly inhibited by purified condensed tannins. This in vitro inhibition of digestive enzymes may not, however, account for the reported lower digestibility in ruminants (McBrayer et al., 1983; Kumar and Singh, 1984) and nonruminants (Featherston and Rogler, 1975; Martin-Tanguy et al., 1976) of diets containing tannin.

Both APase and PDase occur predominantly in a particulate, membrane-bound form is freshly prepared homogenates of intestinal mucosa; in the rat intestine, brush border membrane the binding of APase has been shown to be hydrophobic in nature (Seetharam et al., 1985). These enzymes in the washed particulate fraction proved to be less susceptible than the soluble form to inhibition by tannins at comparable tannin concentrations. This diminished susceptibility is likely due to the presence in the particulate form of other proteins

which compete for binding the tannin; the specific activity (units of activity per milligram of protein) of the particulate enzymes was approximately 0.5% that of the corresponding soluble purified enzymes. The membrane-bound enzymes may also be protected by bound phospholipids which, like Triton X-100, diminish tannin inhibition of the soluble form of the enzymes. In our early attempts to solubilize and purify PDase (Kelly et al., 1975), phospholipids were found to be strongly associated with this enzyme.

In addition to the diminished susceptibility to tannin of the enzymes in their predominant in vivo form, under physiological conditions dietary tannin is probably not accessible to digestive enzymes. Dietary proteins (Butler et al., 1984) or specialized tannin-binding proteins of the saliva (Mehansho et al., 1983) are available to form complexes with dietary tannin before it is exposed to digestive enzymes. Even if digestive enzymes are subject to inhibition by dietary tannins, the effect is likely to be reversed by detergents (Figure 5) (Oh and Hoff, 1986) such as bile acids or by various tannin-binding materials (Figure 6) encountered in the digestive tract. Our observations are consistent with those of Armstrong (1983), who found other digestive enzymes to exhibit full activity in the intestines of rats fed diets containing tannins from sorghum and other sources.

We conclude that the antinutritional effects (and ecological significance) of dietary tannin are probably not due to binding and inhibition of digestive enzymes by tannin, especially those which predominantly occur in a membrane-bound form. The relative insensitivity to tannin of membrane-bound enzymes suggests that other membrane-associated processes such as absorption may be little affected by dietary tannin. The antinutritional effects of dietary tannin that result in reduced protein digestibility may be due to formation of less-digestible complexes of dietary proteins with tannins (Butler et al., 1984). Other antinutritional effects are unrelated to digestibility (Rogler et al., 1985; Mehansho et al., 1985).

CASTANOSPERMINE—A PLANT GROWTH REGULATOR

K.L. STEVENS and R.J. MOLYNEUX

Western Regional Research Center, USDA-ARS
800 Buchanan Street
Albany, California 94710

(Received May 27, 1987; accepted August 17, 1987)

Abstract—Castanospermine, 1,6,7,8-tetrahydroxyoctahydroindolizine, has been shown to be a potent dicot phytotoxin. The effective concentration to inhibit root length elongation of dicot roots by 50% is 300 ppb, while the effective concentration against monocot roots is 200 ppm, i.e., 10^3 times less effective. In contrast swainsonine, 1,2,8-trihydroxyoctahydroindolizidine, is ineffective as an inhibitor of root length elongation.

Key Words—Castanospermine, phytotoxin, glucosidase inhibitor, swainsonine.

INTRODUCTION

The indolizidine alkaloid, castanospermine (Scheme 1, **1**), 1,6,7,8-tetrahydroxyoctahydroindolizine, isolated from the seeds of the Australian legume *Castanospermum australe* (Hohenschutz et al., 1981), is a potent inhibitor of fibroblast α- and β-glucosidases and almond emulsion β-glucosidase (Saul et al., 1983). In addition, it inhibits the processing of the oligosaccharide portion of the influenza viral hemagglutinin (Pan et al., 1983) as well as the processing of plant *N*-linked oligosaccharides in soybean cells (Hori et al., 1984). Nojirimycin (**2**) (Inouye et al., 1968), an antibiotic structurally related to castanospermine, is a potent inhibitor of α- and β-glucosidases and amylases (Reese and Parrish, 1971) and of plant auxin-induced cell extension, while castanospermine itself is an effective inhibitor of cell-wall associated β-glucosidase from corn roots (Nagahashi et al., 1986). In view of these results, we felt that it would be of interest to determine whether castanospermine was phytotoxic by a test system previously found successful to delineate phytotoxicity (Stevens,

0098-0331/88/0600-1467$06.00

SCHEME 1.

1986). The involvement of glucosidases in cell-wall degradation and synthesis (Inouhe, 1984; Koyama et al., 1983; Nevins, 1970, 1975; Nishitani and Masuda, 1983; Sakurai and Masuda, 1977) further suggests the potential utilization of castanospermine as a probe into the biochemical mechanism of cell growth.

METHODS AND MATERIALS

Isolation of Castanospermine. Castanospermine (1,6,7,8-tetrahydroxyoctahydroindolizine), mp 218–220°C, was obtained (0.3% yield) from mature seeds of *Castanospermum australe* by water extraction and purified by ion-exchange chromatography on Dowex 50W-X8 (Hohenschutz et al., 1981).

Isolation of Swainsonine. Swainsonine (1,2,8-trihydroxyoctahydroindolizidine, mp 144–146, was obtained from *Astragalus lentiginosus* as previously described (Molyneux and James, 1982).

Bioassay. The effect of castanospermine on root length elongation of lettuce (*Lactuca sativa*, black-seeded Simpson), alfalfa (*Medicago sativa*), barnyard grass (*Echinochloa crusgalli*), and red millet (*Panicum miliaceum*) was tested at 0, 10, 20, 40, 80, 100, 200, 400, 800, and 1000 ppb (or ppm in the case of monocots) in 40 ml of 0.5% agar (Bacto-Agar, Difco Laboratories, Detroit, Michigan) in 9-cm Petri dishes. All test seeds were first germinated in Petri dishes on 0.5% agar in a growth chamber (58°F, 8-hr nights; 68°F, 16-hr days). Twelve germinated seedlings were transferred to Petri dishes containing castanospermine and incubated in the dark (21–23°C, 45–72 hr). The lengths of the roots of the 12 seedlings were measured to the nearest millimeter and the

highest and lowest values were discarded. The remaining 10 root length measurements were subjected to statistical analyses. Two replicates were run for each test species. A parallel series of experiments was run using swainsonine (**3**) rather than castanospermine (**1**).

Data Analysis. Seedling growth assay results were statistically analyzed separately at the Washington, D.C., Computing Center facilities and Statistical Analysis System (SAS Institute, Inc., Cary, North Carolina, 1982). The transformed data were subjected to Cochran's test for homogeneity of variances of all treatments and the least significant difference (LSD) test for differences between all treatment means.

RESULTS

The effect of castanospermine (**1**) on lettuce root (*Lactuca sativa*) elongation is shown in Figure 1. At 300 ppb (1.6×10^{-6} M), castanospermine inhibits root elongation by approximately 50%. Addition of 10^{-10} M indole acetic acid (IAA), a concentration determined to promote root elongation, did not nullify the inhibiting effects of castanospermine. Although many plant growth inhibitors exhibit "auxin-like" characteristics, i.e., they display a growth-promoting activity at lower concentrations, castanospermine showed no such activity down to 10^{-10} M. The effects of castanospermine on alfalfa (*Medicago sativa*) was similar to that of lettuce, i.e., a 50% inhibition of root length elongation was observed at 250 ppb. Again the addition of IAA at a concentra-

[b] Number of roots measured.

tion that promotes elongation did not nullify the inhibitory effects of castanospermine.

Monocotyledons, such as red millet (*Panicum miliaceum*) and barnyard grass (*Echinochloa crusgalli*), were also inhibited by castanospermine (Table 1) but at a much higher concentration than for the dicots. For instance, red millet root elongation was inhibited 50% at 200 ppm (8×10^{-4} M) castanospermine. Barnyard grass gave similar results (not shown). Again, the addition of IAA had no apparent effect on nullifying the effects of castanospermine on these grasses.

DISCUSSION

The differential effect of castanospermine on the root length elongation (or inhibition) of dicots and monocots may well reflect the preferential inhibition of enzymes present in living plant tissue needed to degrade primary cell-wall structures. Evidence is substantial (Inouhe et al., 1984; Koyama et al., 1983; Nevins, 1970, 1975; Nishitani and Masuda, 1983; Sakurai and Masuda, 1977) that the auxin-induced elongation of cells is correlated with the degradation or depolymerization of cell-wall xyloglucans which lead to cell wall loosening and therefore cell extension growth. Studies with *Vigna angularis* (azuki bean) (Nishitani and Masuda, 1983) offer evidence that IAA-induced changes in the xyloglucans are related to the degree of cell-wall loosening rather than cell extension growth.

Substantial structural differences exist in the xyloglucans of monocots and dicots (Kato and Matsuda, 1976; Kato et al., 1981; Masuda, 1980), which may account for the differences in the inhibition of the root elongation of these plants by castanospermine. In addition, monocots have β-1,3- and 1,4-linked glucans, hemicelluloses not generally found in dicots. Furthermore, monocots have substantial amounts of glucuronoarabinoxylan (Burke et al., 1974), another hemicellulosic component. These differences could readily account for the observed differences in the effectiveness of castanospermine since it is an effective inhibitor of glucosidases (Saul et al., 1983), enzymes necessary for the degradation of dicot hemicelluloses. Since the structurally related compound, nojirimycin, is a much weaker inhibitor (by a factor of 1000) of glucanases vs. glucosidases (Reese and Parrish, 1971), enzymes necessary for the degradation of monocot hemicelluloses, castanospermine would be expected to have similar inhibitory activity against glucanases. Therefore, dicots would be expected to be inhibited more effectively than monocots by castanospermine. The specific enzyme inhibitory activity of castanospermine thus would interfere with primary cell-wall degradation, a step necessary to cell-wall elongation. Castanospermine does inhibit glucanases; however, a much higher concentration is required than for glucosidases. The effective concentration of castanospermine to inhibit root length elongation of monocots is about 900 times higher than that for dicots, approximately the difference in effectiveness of nojirimycin toward glucanases and glucosidases (Reese and Parrish, 1971).

Analogous experiments with swainsonine (**3**), a known inhibitor of α-mannosidase (Colegate et al., 1979; Kang and Elbein, 1983) but having little effect on glucosidases, showed no effect on the root length elongation or inhibition of either monocots or dicots. These data are consistent with the fact that the cell wall contains little mannose, hence α-mannosidase is not involved in the degradation of cell walls leading to cell elongation.

It has been observed that mannitol inhibits auxin-induced cell elongation by osomosis (Nevins, 1975). Since castanospermine may be considered to have many structural features analogous to carbohydrates, the possibility exists that its effect on monocots is a result of the same phenomenom as mannitol. Mannitol is effective at about 250 mM which is about 10^3 less active than castanospermine. Hence, it seems unlikely that castanospermine is decreasing the turgor of the cells by osmosis, thus interferring with growth.

A closer look at the specific enzymes inhibited by castanospermine and the relative amounts necessary to induce inhibition will lead to a better understanding of cell growth of both monocots and dicots. Castanospermine thus may be used as a probe to precisely define and understand the various polymers that make up the primary cell wall and the mechanisms of depolymerization and/or polymerization leading to cell growth.

We have observed that in order for *C. australe* seeds to germinate they

must be irrigated with water for a considerable period of time. It appears possible that the castanospermine present may therefore be self-inhibitory to germination and growth of the seeds, perhaps until rainfall is sufficient to support further growth. In addition to its effect upon root elongation, castanospermine is a powerful antifeedant to the pea aphid (Dreyer et al., 1985) and has been shown to differentially inhibit disaccharide-hydrolyzing enzymes in a broad taxonomic spectrum of insects (Campbell et al., 1987). Castanospermine may therefore serve a multiple ecological role in conferring an advantage to *C. australe* in competition with other plants and insect predators.

HOST EGG KAIROMONES ESSENTIAL FOR EGG-LARVAL PARASITOID, *Ascogaster reticulatus* WATANABE (HYMENOPTERA: BRACONIDAE) I. Internal and External Kairomones

Y. KAINOH and S. TATSUKI

Institute of Agriculture and Forestry
University of Tsukuba
Tsukuba, Ibaraki 305, Japan

(Received June 1, 1987; accepted August 17, 1987)

Abstract—An artificial egg with a Parafilm membrane was devised for the oviposition of *Ascogaster reticulatus* Watanabe (Hymenoptera: Braconidae), an egg-larval parasitoid of the smaller tea tortrix, *Adoxophyes* sp. (Lepidoptera: Tortricidae). Both external and internal kairomones were essential. The external kairomone, needed for host location and acceptance, was extracted with 70% ethanol, and the internal kairomone, needed for oviposition, was extracted with water. Female parasitoids responded to the external kairomone and oviposited through the membrane into the artificial egg when the supernatant of host egg-mass homogenate was inside, whereas they did not when water or saline solutions were inside. Thus an internal kairomone is responsible for the oviposition in the host egg. The internal kairomone apparently was not specific for the host egg mass because oviposition activity was found not only in egg, larval, and pupal stages of the host, but also in larvae of other species of Lepidoptera and Coleoptera.

Key Words—Kairomone, oviposition, parasitoid, *Ascogaster reticulatus*, Hymenoptera, Braconidae, smaller tea tortrix, *Adoxophyes* sp., Lepidoptera, Tortricidae.

INTRODUCTION

Ascogaster reticulatus, Watanabe (Hymenoptera, Braconidae) is an egg-larval endoparasitoid of the smaller tea tortrix, *Adoxophyes* sp. (Lepidoptera: Tortri-

0098-0331/88/0600-1475$06.00/0

cidae). The female parasitoid responded to a filter paper disk treated with 70% ethanol extract of host egg masses (Kainoh et al., 1982). They performed antennal host searching and ovipositor host searching in response to the extract; however, they did not deposit eggs on the disks and left them in less than a minute. They were present on the egg mass for ca. 1 hr, during which time they laid eggs (Kainoh and Tamaki, 1982). This indicates that other stimuli inside the host egg are responsible for oviposition. Parafilm tubes containing host hemolymph were used to bioassay and identify amino acids and other chemicals as ovipositional stimulants for the ichneumonid parasitoid, *Itoplectis conquisitor* (Say) (Arthur et al., 1969, 1972; Hegdekar and Arthur, 1973). Yamaguchi (1987) used a Parafilm-based artificial egg for the bioassay of marking pheromone which is injected inside the host eggs at oviposition by female *A. reticulatus*.

In this study, an improved artificial egg was used to establish the bioassay of the internal kairomone as the oviposition stimulant. Additionally, the internal kairomone was examined for host specificity with various insects.

METHODS AND MATERIALS

Insects. All insects used were from our stock culture. Rearing was modified from Kainoh and Tamaki (1982). Females (10–20) were kept in a clear plastic container (15 cm diam., 12 cm high) with wet cotton on the bottom and honey on the wall. Virgin females were used for oviposition experiments. The conditions for the experiments were 25 ± 1°C, 60 ± 20% relative humidity, and a 16:8 light–dark photoperiod. Oviposition experiments were conducted in the latter half of a light period, when the activity of females is high (Kainoh, 1986).

Bioassay. An artificial egg was devised with a Petri dish and two sheets of Parafilm (Figure 1). The lid of a Petri dish (5.2 cm diam.) was covered with a sheet of Parafilm and either 30 μl of test solution for the internal kairomone activity or the supernatant of the host egg-mass homogenate was placed at the center. A polyethylene ring (1.9 cm OD, 1.5 cm ID, 1 mm thick) was placed on the Parafilm with the sample in the center. It was then covered with a Parafilm sheet to hold the sample. Host egg-mass extract (20 μl) containing the external kairomone (Kainoh et al., 1982) was placed on the outer Parafilm sheet and was air-dried at room temperature. Another dish (4.6 cm diam.) was used as a cover, and a virgin female parasitoid was introduced to the arena. She was allowed to remain for 30 min (Figure 2), and the number of eggs deposited into the solution was counted using a dark-field stereomicroscope.

Extraction of External Kairomone. The egg masses (15,360; ca. 68g) of

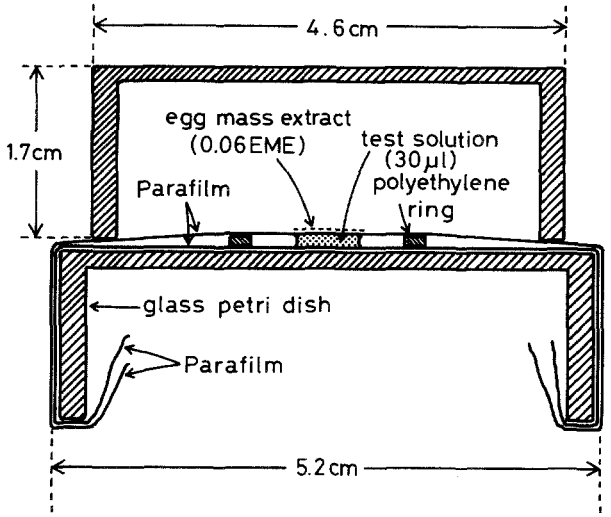

FIG. 1. An artificial egg for the bioassay of internal kairomone. A female *A. reticulatus* was introduced into the arena covered with a Petridish (4.6 cm diam.).

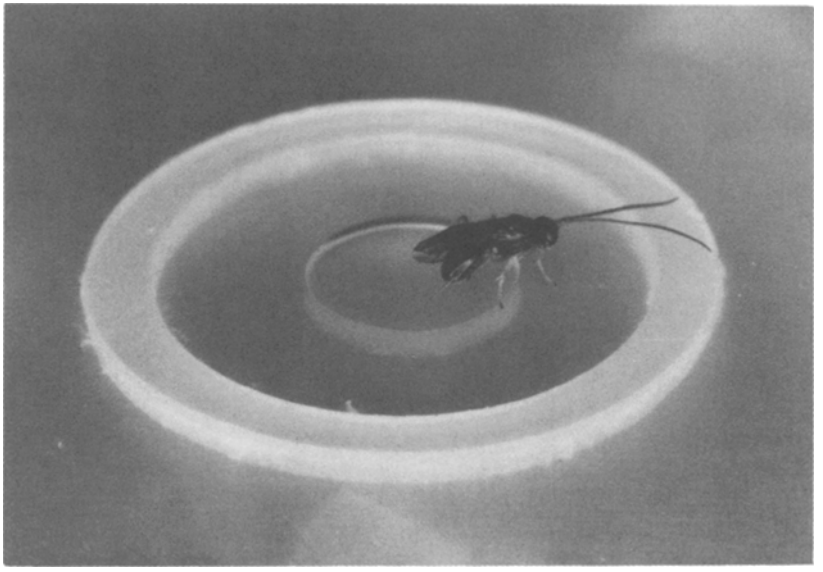

FIG. 2. *A. reticulatus* ovipositing on an artificial egg.

Adoxophyes sp. deposited on paraffin paper were collected according to Tamaki (1966) and soaked in 70% aqueous ethanol (3800 ml) for 1–9 months. The extract, filtered and concentrated to dryness under reduced pressure, was dissolved with 50 ml 70% ethanol. It was then filtered and refrigerated (5°C) until needed. The standard extract concentration for all experiments was set at 6.1×10^{-2} EME (egg mass equivalent)/20 μl, since higher concentrations with oily substances, applied to the Parafilm, affected the antennal response of female parasitoids when they palpated the treated part with their antennae.

Preparation of Physiological Salines. Table 1 shows the chemical composition of various physiological salines used for the homogenization of *Adoxophyes* sp. egg masses. Fifty egg masses on paraffin paper were homogenized with 1 ml of each saline or distilled water (Table 1) in a glass mortar with a pestle. The supernatant resulting from centrifuging the homogenate at 7000*g* for 10 min was used as the test solution. The control was either distilled water or one of the saline solutions without egg components.

Dilution of External Kairomone. Host egg-mass homogenate (50 egg masses in 1 ml distilled water) was centrifuged (7000*g*, 10 min) and 30 μl of the supernatant was used for the artificial egg as an internal kairomone. The egg-mass extract including external kairomone was serially diluted with 70% ethanol (6.1×10^{-7}–10^{-2} EME/20 μl) and 20 μl of each solution was placed on the outer Parafilm membrane. Artificial eggs treated with 70% ethanol (20 μl) were prepared as controls. A virgin female was allowed to remain with each artificial egg for 30 min after the extract or solvent was air-dried at room temperature.

Host Specificity Test. Whole bodies of various insects were homogenized in distilled water (ca. 0.4 g in 1 ml distilled water except the silkworm, *Bombyx mori* L.) with a glass mortar and a pestle, and centrifuged (7000*g*, 10 min): (1) egg masses of *Adoxophyes* sp.,; (2) final instar larvae of Adoxophyes sp.,; (3)

female and male pupae of Adoxophyes sp.,; (4) final instar larvae of the small white butterfly, *Pieris rapae crucivora* Boisduval; (5) final instar larvae of *B. mori* (4 g in 10-ml distilled water); and (6) final instar larvae of the mealworm, *Tenebrio molitor* L. The artificial egg was prepared with 30 μl of each supernatant inside. A parasitoid was allowed to remain with each artificial egg for 30 min.

Probing Behavior and Oviposition. Two types of inner contents were used to prepare artificial eggs. One was the supernatant of the host egg-mass homogenate (50 egg masses in 1 ml distilled water) and the other was distilled water. A female parasitoid was allowed to oviposit in each artificial egg, and the duration and number of probes with an ovipositor were counted for 10 min. One probe was defined as one bout of continuous ovipositor host searching on the kairomone-treated part.

RESULTS

Bioassay. When a female parasitoid was introduced into the arena of an artificial egg, she groomed or walked inside the arena. If she encountered the area containing the external kairomone, she performed antennal host searching and ovipositor host searching (Kainoh et al., 1982) on the treated area. Most of the females released into the arena encountered and responded to the external kairomone within a few minutes. When the inner test solution was active, she began to oviposit, and ovipositor host searching lasted continuously throughout the bioassay. When the solution was inactive, ovipositor host searching was intermittent, and the female soon became indifferent to the treated part (cf. Table 4).

Effect of Physiological Salines. The rate of oviposition and the mean number of parasitoid eggs deposited in the supernatant of egg-mass homogenates were significantly higher when the solvent was distilled water (Table 2). Ovipositional activity was lowest in the case of the NaCl solution ($\bar{X} = 10.3$ eggs). There was no significant difference in ovipositional activity between the *Drosophila* and Neisenheimer's salines used as solvents. There was no ovipositional activity ($N = 10$) in the physiological salines devoid of homogenized egg masses.

Effect of External Kairomone. As the concentration of the egg-mass extract increased, ovipositional activity increased (Figure 3). More than 60 parasitoid eggs were deposited into artificial eggs at 6.1×10^{-4}–10^{-2} EME. No oviposition was detected in the artificial egg in the absence of the external kairomone ($N = 10$).

Host Specificity. Ovipositional activity was found not only in host insects but also in various nonhost insects (Table 3). Among the stages of *Adoxophyes*

DISCUSSION

The bioassay of internal kairomone of *A. reticulatus* was established. The simple structure with two sheets of Parafilm membrane makes it easier to evaluate the activity of samples. The external kairomone, in amounts ranging from 6×10^{-4} to 6×10^{-2} EME is necessary to elicit appropriate ovipositional response.

The physiological salines used in this experiment adversely affected the ovipositional activity of the egg-mass homogenate (Table 2), which indicates that these salines are not suitable for the homogenizing solvent. Instead, distilled water is enough for the homogenization. Neisenheimer's saline was active by itself for the oviposition of *Trichogramma californicum* Nagaraja & Nagarkatti (Rajendram and Hagen, 1974) but was not active at all for the *A. reticulatus*. In *T. pretiosum* and *T. minutum* dilute solution of a mixture of KCl and $MgSO_4$ was an active stimulant for oviposition in the artificial egg (Nettles et al., 1982). This mixture was not active for *A. reticulatus* (Kainoh, unpublished).

The concentration of external kaironome critically affected the oviposition into the artificial egg (Figure 3). Although both the external and internal kairomone(s) were necessary for *A. reticulatus* to oviposit into the host, this differs from the case in *I. conquisitor* (Arthur et al., 1969) and *T. californicum* (Rajendram and Hagen, 1974). External kairomone may not be necessary, but physical properties of host may be more important for oviposition in these two species.

The activity of the internal kairomone for *A. reticulatus* was not specific for the host egg mass, since ovipositional activity was found not only in larval and pupal stages of *Adoxophyes* sp., but also in larval stages of other Lepidoptera and Coleoptera (Table 3). Also, in *I. conquisitor*, oviposition occurred in the serum of species of Lepidoptera, Hymenoptera, Coleoptera, and Trichoptera (Hegdekar and Arthur, 1973). The internal kairomone must not necessarily be specific, since the external kairomone for *A. reticulatus* was specific for some tortricids (Kawakami and Kainoh, 1986).

There was no activity as external kairomone for *A. reticulatus* in the larvae and just a little in the pupae of *Adoxophyes* sp. by the filter paper disk bioassay (Kainoh et al., 1982); however, they were both active in the Parafilm bioassay (Table 3). Furthermore, the diluted water solution of external kairomone (70% ethanol extract of host egg masses) was not active as internal kairomone by the Parafilm bioassay (Kainoh, unpublished). These results indicate that the external and internal kairomones were different chemicals.

Ovipositor host searching was important for detecting the internal contents of the host, since *A. reticulatus* females responded to the external kairomone and probed with their ovipositors even in the artificial egg with inactive internal

contents (Table 4). There may be some chemoreceptors on the tip of the ovipositor to detect the internal kairomone, as can be seen in other parasitoids (Gutierrez, 1970; Ganesalingam, 1972; Hawke et al., 1973; Greany et al., 1977) Dethier (1947) proved the response of an ovipositor to salt and acid solutions by the use of isolated abdomen of *Nemeritis canescens* (Grav.), and suggested the common mechanism of action for contact chemoreceptors. Morphological and electrophysiological studies will be necessary in *A. reticulatus* to understand the physiological aspects of oviposition.

Acknowledgments—The authors wish to express their thanks to Prof. T. Kusano, University of Tsukuba, for his comments and encouragement; and to Dr. Y. Tamaki, National Institute of Agro-Environmental Sciences, for his suggestions and reading of the manuscript. We are also grateful to Dr. W. C. Nettles, Jr., USDA, for reading the manuscript.

(Received February 17, 1987; accepted August 24, 1987)

Abstract—Cuticular components of the green leaves of the Repandae section of the *Nicotiana* species contain compounds that have been shown to be toxic to larvae of the tobacco hornworm larvae, *Manduca sexta*. The surface constituents of leaves of greenhouse-grown *N. repanda*, *N. stocktonii*, and *N. nesophila* were extracted with methylene chloride in order to isolate the active compounds. Solvent partitioning and gel chromatography was used to isolate a series of hydroxyacylnornicotines (HOAcylNN). The major component was identified as *N'*-(3-hydroxy-12-methyltridecanoyl)nornicotine. A number of minor 3-hydroxyacylnornicotines, with the acyl group containing C_{13}–C_{15}, were also identified. The HOAcylNN mixture in ethanol was topically applied to first-instar tobacco hornworm larvae at rates of 10, 50, 100, and 200 μg. Mortalities after 48 hr were 33, 44, 78, and 100% respectively.

Key Words—*Nicotiana repanda, Nicotiana stocktonii, Nicotiana nesophila*, nicotine alkaloids, hydroxyacylnornicotines, *Manduca sexta*, tobacco hornworm, Lepidoptera, Sphingidae, antibiosis.

INTRODUCTION

Several studies on the alkaloid contents of the species of the genus *Nicotiana*, particularly *Nicotiana tabacum*, have been performed (Jeffrey, 1959; Smith and

0098-0331/88/0600-1485$06.00/0

Abashian, 1963). These reports generally examined the commonly occurring nicotine-related alkaloids, nicotine, nornicotine, anabasine, and anatabine, which generally comprise about 95% of the leaf alkaloids (Saitoh et al., 1985). Little work has been done, however, on the so-called minor or secondary alkaloid constituents and that which has been done was generally qualitative and lacking in biological activity data (Matsushita et al., 1979; Bolt, 1972; Miyano et al., 1979). Some investigators have found that the wild species of *Nicotiana*, in the section Repandae, contain "minor" nicotine alkaloids in the leaf exudates. These materials, in fact, impart a high level of resistance against certain phytophagous insects (Huesing and Jones, 1984). Therefore, it was the purpose of this study to identify the biologically active component(s) in the leaf exudate of the wild species, *N. nesophila*, *N. repanda*, and *N. stocktonii*, of the section Repandae.

METHODS AND MATERIALS

Extraction of Cuticular Leaf Components. Young leaves (30–60 g fresh wt.) were removed from greenhouse-grown plants at full-flower. Each leaf was dipped eight times into 170 ml of methylene chloride, in an 8-oz wide-mouth bottle, as described for the removal of cuticular components from *Nicotiana tabacum* (Severson et al., 1984). Leaf surface areas of the washed leaves were measured by a Licor model LI-3000[4] portable area meter.

Glass Capillary Gas Chromatography (GC-2). A portion of the extract, equivalent to about 20 cm^2 of surface area, was transferred to a test tube, and the solution volume was reduced under a stream of nitrogen. The residual solution was transferred to a micro-auto analyzer vial, the solvent was removed under nitrogen, and a 50-μl portion of 1:1 *N,O*-bis(trimethylsilyl)trifluoroacetamide–dimethylformamide (BSTFA/DMF, Pierce Chemical Company) was added. The vial was capped and heated for 30 min at 76°C. After cooling, a 50-μl portion of 1:1 BSA–pyridine was added and the sample was analyzed with a HP 5840 gas chromatograph, modified for GC-2 as described by Severson et al. (1982) and equipped with an HP 7672 autosampler and a 0.3 mm ID × 25 m thin-film SE-54 fused silica capillary column. The temperature program was 150–280°C at 4°/min with a 20-min hold at 280°C, hydrogen flow was 35 cm/sec, and flame ionization detection was used. Fraction isolates were analyzed in a similar manner.

Isolation of N'*-(3-Hydroxyacyl)nornicotines (HOAcylNN).* The isolation scheme for the hydroxyacylnornicotines is given in Figure 1. About 43 mg of combined cuticular extracts from *N. nesophila*, *N. repanda*, and *N. stocktonii*

[4] Names of products are included for the benefit of the reader and do not imply endorsement or preferential treatment by USDA.

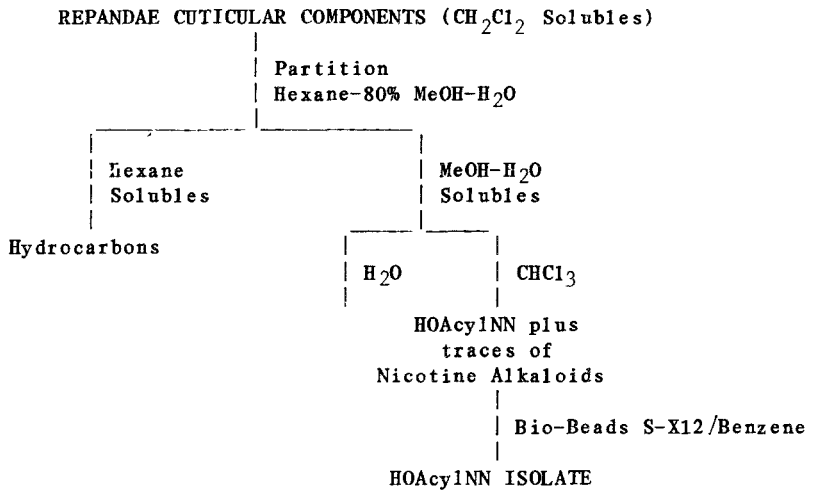

FIG. 1. Chromatographic isolation procedure for the cuticular hydroxyacylnornicotines (HOAcyNN).

were partitioned between hexane (5 ml) and 80% methanol–water (3 ml). The hexane and methanol–water fractions were then back-extracted with methanol–water (1× 2 ml) and hexane (3× 2 ml), respectively. After the addition of water (1 ml) and saturated KCl (1 ml) to the methanol–water-soluble fraction, it was extracted with chloroform (3× 2 ml), which yielded about 16 mg of the HOAcylNN mixture (95+% by GC-2). GC-2 analyses indicated the presence of the unknown compounds as well as a small amount of normal nicotine alkaloids and hydrocarbons. This chloroform extract was then separated by gel filtration chromatography on S-X12 Bio-Beads. The gel system consisted of four 1.25 × 109-cm Chromatronix LC columns, connected in series. The columns were packed with S-X12 Bio-Beads in benzene (Severson et al., 1976) and were eluted with benzene at a rate of 2 ml/min; 8-ml fractions were collected. The HOAcylNN eluted in fractions 28–33. Fractions 29–32 were combined to yield 10.3 mg of the HOAcylNN mixture (99+% by GC-2, average of two determinations).

A portion of the HOAcylNN gel isolate was subjected to preparative low-pressure, reverse-phase liquid chromatography on a 1.25 × 60-cm Chromatronix LC column packed with a 50-cm bed of Waters C_{18} reverse-phase packing. The 1:1 acetonitrile–H_2O eluant was pumped at 2 ml/min. A 94% pure (by GC) isolate of the iso-C_{14} HOAcylNN isomer was obtained.

Characterization of HOAcylNN Mixture. About 500 μg of the gel isolate were hydrolyzed in 2 N HCl for 2 hr at 100°C. After cooling, the sample was

extracted with methylene chloride. The methylene chloride extract was concentrated and treated with BSTFA/DMF. GC-2 analysis indicated the presence of fatty acids and unhydrolyzed hydroxyacylnornicotines. The aqueous portion was neutralized with KOH and was analyzed according to the GC-2 conditions for normal nicotine alkaloids (Severson et al., 1981). This analysis showed the presence of nornicotine. The HOAcylNN mixture was subjected to direct insertion probe mass spectrometry (MS) and also, after silylation, to GC-2-MS on a HP 5985B GC-MS system modified for GC-MS analysis, as described by Arrendale et al. (1984).

The iso-C_{14} isolate was subjected to NMR analysis: [^{1}H]NMR ($CDCl_3$)δ 0.93 [d, $J2$ = 6.5, 6H, $CH(C\underline{H}_3)_2$, 1.16–1.30 (m, 15H), 1.30–1.45 (m, 2H, $CHOHC\underline{H}_{2(n)}$, 1.85–2.13 (m, 4H, H-3 and 4 pyrrolidyl), 2.37–2.64 (m, 2H, $COC\underline{H}_2$), 3.64–3.85 (m, 2H, H-5 pyrrolidyl), 4.00–4.15 (m, 1H, $C\underline{H}OH$), 4.32 (s, 1H, OH), 5.02–5.29 (m, 1H, H-2 pyrrolidyl), 7.35 (m, 1H, H-5 pyridyl), 7.52 (m, 1H, H-4 pyridyl), 8.52–8.66 ppm (m, 2H, H-2 and 6 pyridyl).

Bioassay. The HOAcylNN isolate was bioassayed by topical application on first-instar *Manduca sexta* (tobacco hornworm) larvae at application rates of 10, 50, 100, and 200 μg of HOAcylNN in 1 μl of absolute ethanol. Additionally, 500 μg of nicotine (Sigma Corporation) was bioassayed in 1 μl ethanol as a control.

RESULTS

Isolation and Characterization of HOAacylNN. All three of the Repandae section species, *N. nesophila*, *N. repanda*, and *N. stocktonii*, yielded similar gas chromatographic profiles for their cuticular extracts. GC-MS analyses of this mixture indicated the presence of the typical *Nicotiana* aliphatic hydrocarbons and a homologous series of unknown components with one major homolog eluting near *n*-tricontane. These unknown components could be separated from the cuticular hydrocarbons by a simple hexane/80% methanol–water solvent partitioning step (Figure 1). GC-2 analysis of the resulting methanol–water solubles, after extraction with chloroform, showed the presence of a series of components, with one major component, and the presence of small amounts of the normal nicotine alkaloids, nicotine, nornicotine, anabasine, and anatabine. Subsequent chromatography of the above chloroform extract on Bio-Beads S-X12 gels resulted in the isolation of a series of components (Figure 2), free of the nicotine alkaloids.

Acid hydrolysis of the gel isolate yielded nornicotine and a series of hydroxy aliphatic acids, indicating that the unknown components were a series of *N'*-(hydroxyacyl)nornicotines, which are acid amides of nornicotine and β-hydroxy aliphatic acids. As shown in Table 1, probe mass spectral analyses

360	342	432[b]	417	342	C_{13}
374[a]	356	446[a,b]	431	356	C_{14}
388	370	460[a]	445	370	C_{15}

[a] Major component.
[b] Two or more isomers by GC-2.

of the underivatized mixture (neat) indicated a series of components differing by 14 amu, with a major homolog having a mass of 374, which readily lost water to yield an ion at 356. GC-2-MS of the TMS derivatives yielded ions with masses 72 amu higher than the neat sample. In agreement with the hydrolysis data, the mass spectral data showed the presence of HOAcylNN, with carbon chains in the acid groups ranging from C_{12} to C_{15}. The major acid was identified to be a C_{14}-hydroxy-acid, 3-hydroxy-12-methyltridecanoic acid. Previously, acylnornicotines ranging from formylnornicotine to octanoylnornicotine were isolated from *Nicotiana tabacum* leaves and cigarette smoke, and these compounds have been extensively studied by mass spectrometry (Bolt, 1972; Snook et al., 1984).

When the aliphatic chain has three or more carbons, major fragmentation ions are present at *m/e* 147, 175, 189, 190, and 203. The mass spectrum of the major C_{14} isomer, as its TMS derivative, is given in Figure 3, and its proposed fragmentation is given in Figure 4. All components, neat or as TMS derivatives, produced ions at *m/e* 147, 175, 189, and 190. In the neat sample, major fragment ions were at *m/e* 219 and 233. Due to the hydroxyl group on the β-carbon of the acid moiety, the intensive β-cleavage ion, normally observed in the spectra of compounds with an aliphatic chain (*m/e* 203), was now found 16 amu higher at *m/e* 219 (291 for TMS). Except for minor differences in the mass spectral data, due to methyl end-branching on the acid chains, and differences in molecular weight, all components yielded mass spectra with ion intensities similar to that shown in Figure 3.

It is well documented that *Nicotiana* species produce hydrocarbons and fatty acids with normal chains, isomethyl-branched chains, and anteisomethyl-branched chains (Severson et al., 1984; Snook et al., 1984). The mass spectral data from the TMS derivatives indicated that the numerous isomers observed in the isolate were also due to differences in the methyl-substitution on the acid chain. As shown in Figure 3, the iso-branched isomers lose the isopropyl group to give a weak M-43 ion and also a fairly intense 43 ion. The anteiso-branched chains yield weak M-15 and M-29 ions due to the loss of methyl and ethyl groups and the M-43 ion is essentially absent in the spectra of these compounds. Evaluation of the GC-MS data from the TMS derivatives of the isolate indicated that the C_{12} acids consisted of the isomethyl-branched acid, *N'*-(3-hydroxy-10-methylundecanoyl)nornicotine, and the normal-chained acid, from *N'*-(3-hydroxydodecanoyl)nornicotine. The C_{13} acids resulted from the iso-branched *N'*-(3-hydroxy-11-methyldodecanoyl)nornicotine, and from the anteiso-branched *N'*-(3-hydroxy-10-methyldodecanoyl)nornicotine. The C_{14} acids were derived from the iso-branched *N'*-(3-hydroxy-12-methyltridecanoyl)nornicotine and the normal *N'*-(3-hydroxytetradecanoyl)nornicotine. The C_{15} acids were iso-branched, namely *N'*-(3-hydroxy-13-methyltetradeca-

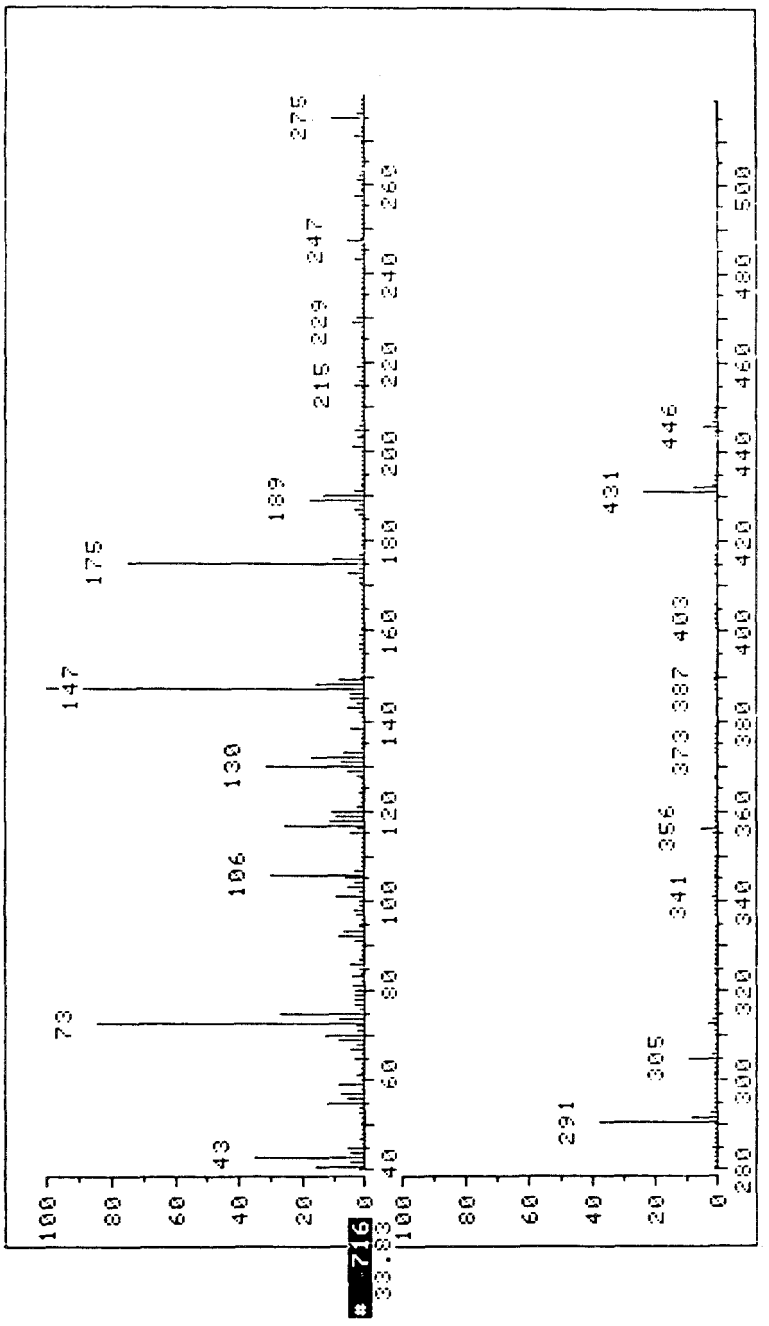

FIG. 3. The mass spectrum of the trimethylsilyl ether of *N'*-(3-hydroxy-12-methyltridecanoyl)normicotine.

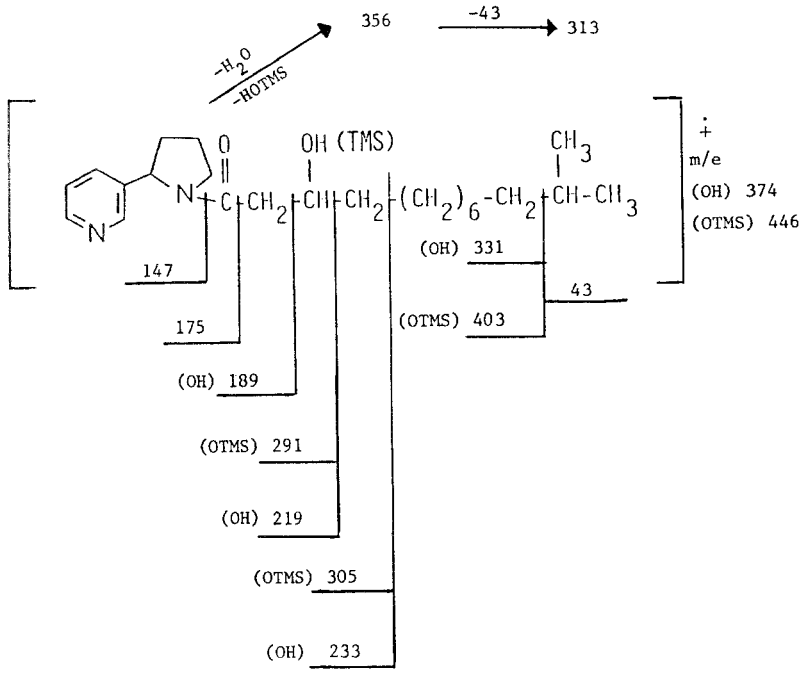

FIG. 4. Proposed MS fragmentation pattern for hydroxyacylnornicotines as shown in the C_{14} acid isomer.

noyl)nornicotine, and anteiso-branched, namely *N'*-(3-hydroxy-12-methyltetradecanoyl)nornicotine.

The NMR spectrum of *N'*-(3-hydroxy-10-methylundecanoyl)nornicotine was consistent with the mass spectral interpretation. The resonances for the pyridyl and pyrrolidyl ring hydrogens were consistent with those reported for acetylnornicotine (Warfield et al., 1972). The chemical shifts for the α-methylene and β-carbon protons were similar to those obtained from other β-hydroxy acid derivatives (Pouchert, 1983) and the presence of the isopropyl group was confirmed by a doublet at 0.93 ppm.

Bioassay. Topical applications of 200 μg of HOAcylNN produced 100% mortality to first-instar *Manduca sexta* within 48 hr (Table 2). Applications at the 50- to 100-μg level produced 80% or greater mortality within 96 hr. Even at the 10-μg level, 40% mortality was observed after 96 hr. This is in marked contrast to the 7% mortality observed when 500 μg of commercial nicotine, the most toxic nicotine alkaloid (Yamamoto et al., 1962), was applied.

TABLE 2. CUMULATIVE PERCENT MORTALITY OF *M. sexta* LARVAE[a] FOLLOWING APPLICATIONS OF HOAcylNN FROM REPANDAE

DISCUSSION

Several polyunsaturated straight-chain acyl derivatives of isobutylamine, tyramine, piperidine, and dihydropiperidine have been isolated from tribus Anthemideae (Bohlman et al., 1974; Burden and Crombie, 1969; LaLonde et al., 1980). Some of these amides, in particular the *N*-isobutylamides of 2,4-decadienoic acid, have demonstrated insecticidal action. However, this study has shown for the first time a class of acylated *Nicotiana* alkaloids produced by plant tissue which, unlike normal nicotine alkaloids, are biologically active against *M. sexta* larva (Bolt, 1972; Matsushita et al., 1979; Miyano et al., 1981). Our results indicate that this class of alkaloids is a major component of the leaf exudates of the Repandae species. It should be noted that these alkaloids have not been investigated from a human health perspective. The possible use of these alkaloids as antibiotic factors in conventional tobacco will make health-related studies mandatory.

MATING STIMULANT OF THE PINE WEEVIL *Hylobius abietis* (L.)

DAVID A. TILLES, HUBERTUS H. EIDMANN, and BERITH SOLBRECK

Swedish University of Agricultural Sciences

Box 7044, S-750 07 Uppsala, Sweden

(Received April 16, 1987; accepted August 24, 1987)

Abstract—Factors eliciting copulatory behavior in mature male *Hylobius abietis* were studied in the laboratory. Dead female weevils were sexually attractive, while dead mature males and pentane-extracted female weevils were not. The sexual attractiveness of dead females declined with time after death. Pentane extracts of whole female weevils or of the anterior or posterior parts of their bodies elicited a copulatory response when applied to decoys. In contrast, extracts of hindgut or frass were inactive. Juvenile males were sexually attractive for about four weeks, after which their attractiveness gradually declined. The results indicate that the mating stimulant is present on the body surface of female and juvenile male weevils, and it can be extracted with pentane.

Key Words—*Hylobius abietis*, Coleoptera, Curculionidae, sex attraction.

INTRODUCTION

The pine weevil *Hylobius abietis* (L.) is a common and widespread Palearctic forest insect. It feeds on conifer bark and causes damage in reforestation areas by killing seedlings. In regions where clear-cutting and reforestation by planting are practiced, *H. abietis* is one of the most harmful insects.

We have been studying the ecology, dispersal, and orientation of the species, with emphasis on host orientation and intraspecific communication. Pine weevils meet and copulate often, and oviposition extends over a long period (May to August, e.g., Lekander et al., 1985). Weevils are strongly attracted by host odors and find food as well as breeding substrate using olfactory ori-

0098-0331/88/0600-1495$06.00/0

entation (e.g., Eidmann, 1974; Nordlander et al., 1986). They may aggregate at the host, but our studies suggest that *H. abietis* adults do not use pheromones to recognize each other over distances greater than a few centimeters (Tilles et al., 1986). On the other hand, at short distances sex-specific recognition does occur.

Selander and Jansson (1977) and Selander (1978) have described courtship and mating behavior in *H. abietis*. Their observations indicated that copulatory attempts by males were induced by a female-produced odor. After freeze-killing weevils, Selander (1978) reported that males attempted to copulate with dead juvenile and mature females but not with dead mature males. The dead weevils elicited this behavior for several hours following their return to room temperature. He also reported that juvenile males were sexually attractive to mature males. According to Selander (1978) the sex pheromone was present in female frass; however, his data do not support this conclusion.

Our goals have been to characterize more thoroughly the mating stimulant and determine some of its properties. In this paper we report on efforts to determine what parts of the body contain the mating stimulant and on the changes over time occurring in the sexual attractiveness of juvenile males.

METHODS AND MATERIALS

General. Weevils were collected during their flight period at a sawmill about 40 km northwest of Uppsala, Sweden. They were stored in total darkness at 10°C, and food was renewed at regular intervals. Weevils were sexed, and the sexes were transferred separately to a 20°C climate chamber with a 20:4 light–dark photoperiod ca. 7–10 days prior to their use. Males were used for six to eight weeks as responders, after which they were replaced with fresh males. Unless otherwise specified, all weevils used in the tests were sexually mature.

All bioassays were conducted under red light at 20°C and ca. 30% relative humidity. In the various tests, counts were made of male copulatory attempts (CA) with either living weevils, freeze-killed weevils, or decoys, i.e., dead weevils extracted in solvent and allowed to dry for 12–24 hr. A copulatory attempt was defined as occurring when a male mounted a living weevil or decoy, using its forelegs to stroke the latter's head while simultaneously attempting to initiate genital contact. Dead weevils and decoys used in the tests were pinned through their prothorax and placed in a 24-cm-diam. circular plastic arena with walls 6 cm high; the floor was covered with a 50-mm layer of moistened sand. When placed in the arena, male weevils tended to walk in circles around its periphery. To exploit this behavior, we placed the treated decoys around the circumference of the arena, 1 cm from the wall. When multiple treatments were

used, they were alternately placed around the arena to ensure that responding weevils had equal chances of contacting each treatment.

Fifty or 100 male weevils were placed in the arena and allowed about 5 min to acclimatize to the experimental setting before initiating a test. Each male attempting to copulate with a pinned specimen was immediately removed from the arena. Another male was then placed in the center of the arena so that the same number of males was present at all times during the tests.

A different method (see below) was used to test the attractiveness of living weevils.

Response to Dead Weevils. The attractiveness of dead female and male weevils was tested according to the procedures described above.

To determine how long dead females remain sexually attractive to males, 10 freeze-killed female weevils were tested in the arena at intervals for up to 97 hr after removal from the freezer.

Effect of Solvent Extraction on Female Attractiveness. Freeze-killed females were screen-tested in the arena with males for 30 min, and, based on these tests, five pairs of female weevils with similar sexual attractiveness were chosen. One weevil in each pair was then extracted in pentane for 60 min while the other was left untreated. The sexual attractiveness of the extracted and unextracted females was then tested.

Response to Extracts of Female and Male Weevils. Extracts of male and female weevils were prepared by extracting freeze-killed weevils in pentane. Approximately 5 ml solvent was used for every 100 weevils extracted, and the extracts were concentrated to about a fifth of the original volume in a water bath at 30°C. A test was then performed to determine whether the male and female extracts would stimulate male copulatory behavior. A 10-μl amount, equivalent to the extract from one weevil, of each pentane extract and a 10-μl pentane control were applied to each of 10 decoys and tested.

Localization of Mating Stimulant. Female weevils were divided into anterior (head and prothorax) and posterior sections, and the hindgut was removed. Each of these parts was then extracted separately. Extract preparation and bioassay methods were similar to those described above. A 10-μl amount, equivalent to the extract from one weevil, of each pentane extract and a 10-μl pentane control were applied to each of 10 decoys.

Freeze-killed females were screen-tested in an arena with males for 30 min, and, based on these tests, five pairs of female weevils with similar sexual attractiveness were chosen. The anterior section of each weevil was then separated from the rest of the body and half of them (one from each pair of weevils) were extracted in pentane for 30 min. These sections were then reconnected to the remainder of the body. The other weevils were also reassembled; however, their anterior sections had not been extracted. The sexual attractiveness of these five pairs of weevils was then estimated as described above. Parallel tests were

also conducted in which the posterior sections were extracted instead of the anterior ones. The tests were repeated twice. The results of the two repetitions were combined for statistical analysis using the Wilcoxon signed rank test.

To test frass, female weevils were placed in 16-cm-diam. glass Petri dishes and provided with small pine branches on which to feed. Their frass was collected daily and stored at −20°C. The frass (10.5 g) was then extracted in 23.5 ml pentane for 30 min. A 2-ml amount of this extract was then concentrated to 130 μl in a water bath at 35°C. Simultaneous comparisons were then made between five decoys treated with 20 μl frass extract, 20 μl concentrated frass extract, or 20 μl pentane. In addition, five unextracted females were included as controls in the test.

Attractiveness of Juvenile Males and Mature Females Compared over Time. The sexual attractiveness of each of 10 juvenile male and 10 mature female weevils (used as controls) was estimated periodically. The juvenile males were removed from their pupal chambers in the field and kept with fresh food at 5°C in total darkness for 36 days until the experiment was begun.

Throughout the experimental period, both juvenile males and adult females were stored at 20°C under a 20:4 light–dark cycle. Each weevil was uniquely color-marked on its elytra. The attractiveness of the weevils was measured during 50-min tests, three times weekly for about two months. During these tests, one juvenile male or mature female was placed in each of 10 open Petri dishes containing five mature males. The sides of the dishes were coated with polytetrafluoroethylene to prevent weevils from escaping, and a thin layer of moist sand was provided for the weevils to walk upon. A notation was made each time a mature male attempted to copulate with a marked animal. The responding male was then removed and replaced with another mature male held in reserve. Every 5 min the marked test animals were systematically moved to adjoining dishes with five males each. Thus, each test animal met at least 50 males per 50-min test.

RESULTS

The main results of the experiment are summarized in Table 1. Dead mature male weevils did not elicit copulatory behavior in the male responders, while all dead females stimulated males to mate (Table 1). The sexual attractiveness of dead females decreased slowly, reaching very low levels three days after death (Table 2).

Females extracted thoroughly in pentane no longer stimulated mating in male responders. When such extracted females (decoys) were treated with concentrated pentane extract of mature females, they became sexually attractive to males. The extract of mature males was inactive.

97	2	2	0–1

[a]The duration of each test was 30 min; 100 male responders. Each of the 10 females elicited copulatory attempts (CA) in one or more tests.

Extraction of either the anterior or the posterior parts of female weevils decreased sexual attractiveness to levels below those of unextracted females. The decrease was statistically significant ($P < 0.05$ for extraction of the anterior part, $P < 0.01$ for extraction of the posterior part). The decrease of attractiveness appeared to be more pronounced in the females with an extracted posterior body.

Pentane extracts of the anterior or posterior part of the body of mature females applied to decoys also elicited copulatory responses, while extracts of hindgut and pentane controls were inactive. The data suggest that the extract of the posterior body was more stimulatory than that of the anterior body.

Extracted females treated with frass extracts or pentane did not elicit mating behavior, while unextracted dead females, serving as controls, elicited numerous copulatory responses.

In the experiment monitoring the sexual attractiveness of juvenile males during their first months of adult life (Figure 1), the male weevils were only slightly attractive on day 1. They subsequently increased in attractiveness to levels comparable to those of the female control weevils and maintained these levels for about four weeks. During the following two weeks, they declined steadily in attractiveness, and by week seven they were unattractive. The female control weevils remained sexually attractive during the entire experimental period. Attractiveness varied between individual males as well as between indi-

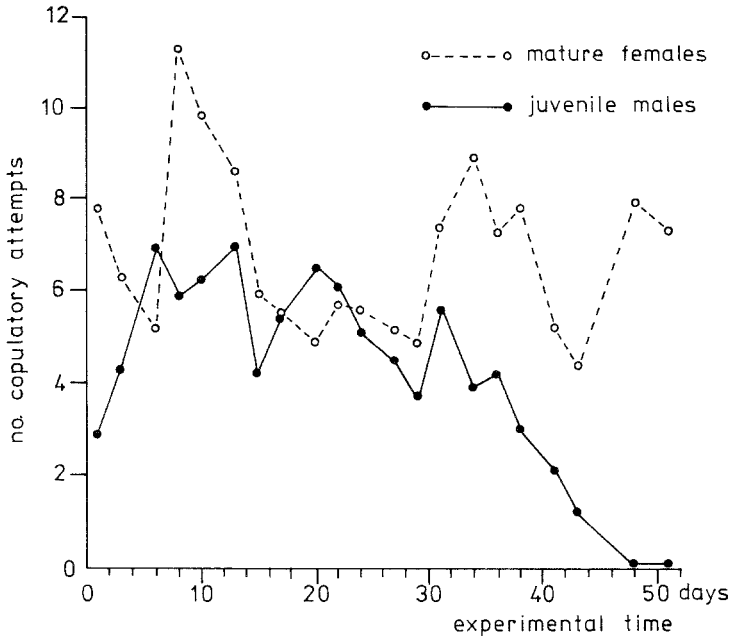

FIG. 1. Sexual attractiveness of 10 juvenile male and 10 mature female pine weevils during a long-term experiment. Attractiveness expressed as number of copulatory attempts per individual during a 50-min test period.

vidual females. The attractiveness of each individual also varied from test to test.

DISCUSSION

Our study substantiates Selander's (1978) observations that *H. abietis* females produce a substance releasing copulatory behavior in male pine weevils. However, we found frass and hindgut extracts lacking in activity. Instead, whole body extracts of female weevils rinsed in solvent elicited strong copulatory responses. These results indicate that the mating stimulant is present on the surface of the weevils.

Kalo and Nederström (1986) reported the existence of sex-specific compounds in the ovaries of female *H. abietis*. However, they were unable to show biological activity in these compounds, nor did we detect activity in hindgut extracts. It is also probable that ovarian tissues contain a variety of compounds—of no special biological interest—not found in other tissues.

The indications that the posterior part of the female body is more attractive than the anterior part may be explained by the fact that the former has a larger surface area than the latter.

Copulation release pheromones have been recovered from whole-body extracts of other Coleoptera, including *Leptinotarsa decemlineata* (Say) (Chrysomelidae) (Levinson et al., 1979), *Aleochara curtula* Goeze (Staphylinidae) (Peschke, 1978), *Cylas formicarius elegantulus* (Summers) (Curculionidae) (Coffelt et al., 1978), and *Callobruchus chinensis* L. (Bruchidae) (Tanaka et al., 1981). Peschke and Metzler (1987) reported that pheromone components of female *A. curtula* include C_{21} and C_{23} alkenes.

Selander and Jansson (1977) observed differences in the ability of female pine weevils to release copulatory behavior in males. We also have shown that the mating response of male weevils to an identical group of females fluctuated irregularly over a period of several weeks. Moreover, the number of mating attempts elicited by each female varied greatly between test periods. We interpret these observations as fluctuations in female sexual attractiveness. These fluctuations could indicate variability in the production or release of mating stimulant, and they could also, to some degree, be due to differences in male responsiveness.

As reported by Selander (1978), and as confirmed in our study, juvenile male weevils are sexually attractive to mature males. Peschke (1985, 1986) reported that juvenile males of *A. curtula* produce the female sex pheromone, which helps juveniles avoid aggressive encounters with adult males. We have not observed aggressive behavior in *H. abietis* males in the laboratory or in the field, nor have we come up with an explanation as to why production of a mating stimulant should be advantageous for juvenile males.

The decline that we observed in the sexual attractiveness of juvenile males after about four weeks could have been due to a cessation of pheromone production or to the production of a male recognition substance. We are addressing these alternatives in our present work.

Acknowledgments—We gratefully acknowledge Fredrika von Sydow for her help in the study, Rune Axelsson for his drafting services, and Birgit Andersson for typing the manuscript. This study was carried out within the Swedish project "Odour Signals for Control of Pest Insects" funded by the Swedish research councils, FRN, NFR, SJFR, and other sources.

(Received June 1, 1987; accepted September 8, 1987)

Abstract—One theory in plant antiherbivore defense predicts that slow growing late succession plants like white spruce (*Picea glauca*) make large investments in antiherbivore defenses. Juvenile stages of white spruce in the Yukon, Canada, are rarely browsed by snowshoe hares (*Lepus americanus*), an abundant herbivore, but mature spruce is a highly preferred food. The hexane-soluble fractions of the methanol extracts from juvenile and mature white spruce contain camphor and bornyl acetate. There is four times as much camphor in juvenile spruce as in mature spruce from GC analysis. Plant extracts were added to rabbit chow. Pairs of extracts were offered to hares in choice tests. These tests demonstrated that camphor in the juvenile spruce extracts deterred feeding. Bornyl acetate did not have a clear antifeeding effect.

Key Words—Camphor, bornyl acetate, antifeedant, *Picea glauca*, snowshoe hare, *Lepus americanus*, herbivore, plant defense.

INTRODUCTION

The boreal forest of North America has a generalist mammal herbivore, the snowshoe hare (*Lepus americanus*) which, when in high numbers, imposes a severe browsing impact on trees and shrubs. One theory on plant antiherbivore defense, synthesized by Coley et al. (1985) from earlier statements of Bryant and Kuropat (1980) and Bryant et al. (1983a), suggests that plants which are slow growing make large investments of their resources in antiherbivore de-

[3] On leave from the Department of Chemistry, University of the South Pacific, Fiji.

0098-0331/88/0600-1505$06.00/0

fenses compared to the investments made by fast-growing plants. There has been much work on the antifeeding deterrents to snowshoe hares found in the fast-growing earlier succession shrubs such as birches, willows, and alders (Bryant, 1981; Bryant et al., 1983b, 1985; Reichardt et al., 1984, 1987; Palo, 1984; Palo et al., 1985; Tahvanainen et al., 1985; Clausen et al., 1986). However, there has been little attention paid to the slow-growing later successional plants such as white spruce (*Picea glauca*). In this species, Coley's hypothesis would predict high amounts of antifeedant chemicals because it is slow growing, it retains its needles, and it cannot resprout from the roots if it is ring-barked, as can the fast-growing angiosperms. Another theory (Bryant and Kuropat, 1980; Bryant et al., 1983a) proposes that the juvenile growth phase of boreal trees and shrubs is more heavily defended than the adult phase. This has been demonstrated by these authors for birches, willows, and shrubs but not yet for conifers.

In the Kluane region of southwest Yukon, white spruce is the dominant tree. It is obvious even to the casual observer that juvenile white spruce in that region are hardly touched by snowshoe hares although the trees are easily accessible. (For operational reasons we define "juvenile" here as plants below an arbitrary height of 2 m. Whether size or age are the relevant variables is the subject of other work. Similarly "mature" trees are those over 5 m.) Occasionally one sees a single sapling that has been almost completely browsed, but most juveniles are rarely browsed. On the other hand, mature trees that have fallen during windstorms in winter are clearly favorite food sources, with hares lining up along the fallen tree to feed side by side. Normally these trees, when upright, are out of reach of hares.

Feeding experiments at Kluane in winter (Sinclair and Smith, 1984) showed that mature white spruce was preferred over mature twigs of birches and willows when they were presented together. However, in similar experiments using mature birches and willows but with juvenile spruce, the latter was the least preferred plant type. In experiments where side branches of mature spruce and tops of juvenile spruce were offered together, there was a 10-fold greater amount of mature spruce eaten compared to the juvenile spruce. Despite these clear preference differences shown by hares for the two stages of white spruce, crude chemical analysis showed little difference: crude protein, total phenols, and protein-complexing phenols showed no significant difference, while total resins (ether extractable product) were higher in juvenile spruce but only by a small amount (Sinclair and Smith, 1984). It appeared, therefore, that a specific compound rather than the total resin or phenol content was affecting hare feeding.

This paper describes the analysis of organic extracts from juvenile and mature white spruce. We show that a major constituent of juvenile spruce is camphor, that this is in much lower quantity in mature spruce, and that in feeding trials it is the camphor that deters feeding by snowshoe hares.

METHODS AND MATERIALS

Sample Collection. The distal 30 cm of mature spruce side branches or the tops and side branches of juvenile spruce were clipped while frozen during winter at Kluane. The samples were shipped by air to the University of British Columbia and kept frozen until analyzed.

Extraction and Purification of Secondary Metabolites. The foliage of juvenile white spruce (660 g wet weight) was soaked in methanol (3 liters) at room temperature. After 24 hr, the methanol was decanted and concentrated in vacuo to near dryness. The resulting suspension was partitioned between water (100 ml) and hexane (3 × 300 ml) in a separatory funnel. The hexane layers were combined, dried over magnesium sulfate, and evaporated in vacuo to give a gum (3.0 g) referred to as the "juvenile hexane extract." Foliage of mature white spruce (660 g wet weight) was treated in an identical manner to generate the "mature hexane extract" (3.2 g).

[^{1}H]NMR spectra of the juvenile hexane extract (Figure 1) and the mature hexane extract (Figure 2) were run in $CDCl_3$, with TMS as an internal standard, on a Varian XL300 spectrometer.

Fractionation of the juvenile hexane extract was achieved by flash chromatography (Still et al., 1978) on silica gel 60 (230–400 mesh) using a step-gradient elution scheme involving mixtures of petroleum ether (40–60°C) and diethyl ether (200 ml each of 0, 10, 20, 50, 70 and 100% of petroleum ether in diethyl ether; 50-ml fractions were collected). The separation was monitored via silica gel thin-layer chromatography (TLC) of the collected fractions.

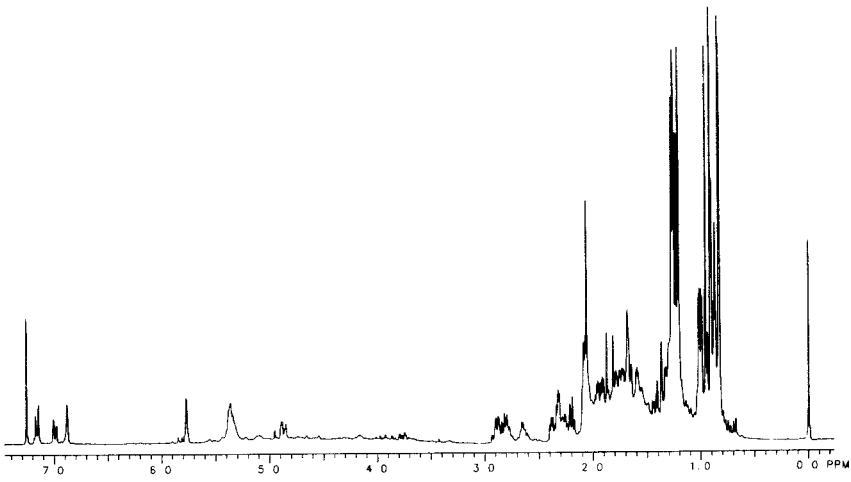

FIG. 1. [^{1}H]NMR (300 MHz) of juvenile hexane extract.

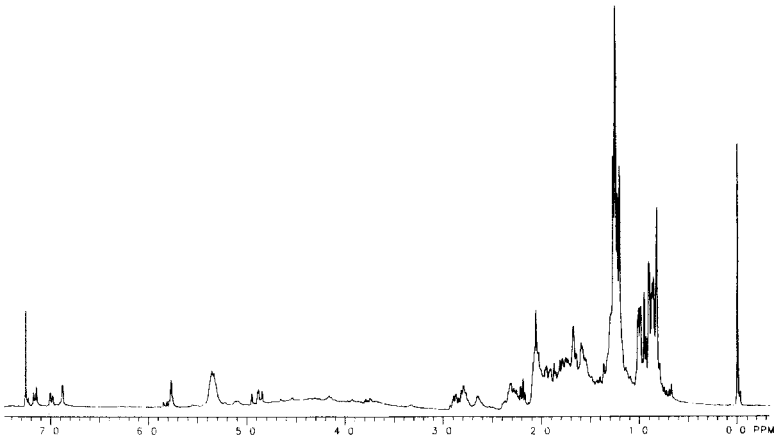

FIG. 2. [^{1}H]NMR (300 MHz) of mature hexane extract.

Preparation of Bioassay Samples. A "juvenile hexane extract with camphor" sample was prepared first by extracting the foliage of juvenile white spruce (660 g wet weight) as described above to get a juvenile hexane extract. This extract was then fractionated via flash chromatography as described above. All the fractions devoid of camphor by TLC analysis were recombined and concentrated in vacuo to give the "juvenile hexane extract without camphor" sample. A second batch of juvenile white spruce (660 g wet weight) was extracted and chromatographed in an identical fashion. All of the fractions from the second batch, including the ones containing camphor, were combined and concentrated in vacuo to give a "juvenile hexane extract with camphor control" sample. Similar procedures were used to prepare "juvenile hexane extract without bornyl acetate" and "juvenile hexane extract with bornyl acetate control" samples.

Samples for bioassay were dissolved in diethyl ether (300 ml) in a 1-liter round bottom flask. Rabbit chow (330 g dry weight) was added to the ether solution, and the solvent was removed in vacuo on a Buchi rotary evaporator to give "treated" chow. White spruce is 50% water, so the amount of rabbit chow used was equivalent to the dry weight of spruce from which the extracts were obtained.

Quantitative Analysis of Camphor and Bornyl Acetate. Quantitative analysis of camphor and bornyl acetate was carried out via analytical gas–liquid chromatography on a Hewlett Packard 5830A gas chromatograph using a 2 m $\times$ 2 mm (ID) stainless-steel column packed with 3% Carbowax 20 M on Chromosorb W. Helium, delivered at a flow rate of 10 ml/min, was used as a carrier

gas. Individual runs were temperature programmed from 100–180°C at a rate of 5°C/min. A known quantity of borneol was added to the methanol extracts of white spruce as an internal standard. The methanol extracts were then treated as described above to get juvenile and mature hexane extracts for GC analysis. Standard calibration curves were prepared for camphor, bornyl acetate, and borneol using weighed samples of authentic material. A Hewlett Packard 18850a computing integrator was used to quantify peak areas. The identity of peaks in the juvenile hexane extract and in the mature hexane extract was confirmed by GC-MS on a Kratos MS80 instrument.

Bioassay of White Spruce Extracts. The general procedure used approximately 80-g amounts of rabbit chow treated with extract. These were offered in bowls to the hares in separate cages overnight. The extracts were offered in pairs so that the animal could make a choice in its feeding. Weights of each chow type were recorded before and after feeding. This procedure was repeated for a minimum of four nights with the location of the two bowls in each cage switched each night to avoid location biases by the hares.

All statistical tests on the amount eaten used the nonparametric Wilcoxon matched-pairs signed ranks test (Siegel, 1956).

RESULTS

Isolation of Secondary Metabolites. The [^{1}H]NMR spectra of juvenile hexane extract (Figure 1) and mature hexane extract (Figure 2) showed significant differences. In particular, there were a series of intense high field methyl resonances present in the juvenile extract spectrum that were not present in the mature extract spectrum. We suspected that the secondary metabolite(s) responsible for the antifeedant activity of the juvenile hexane extract were also responsible for the additional high-field methyl resonances in the [^{1}H]NMR spectrum of the juvenile hexane extract.

The flash chromatography carried out on the juvenile hexane extract gave, in the order of elution, pure bornyl acetate, pure camphor, and a complex mixture of diterpenoic acids, that were only partially characterized. Camphor and bornyl acetate were shown to be identical to authentic samples by [^{1}H]NMR, [^{13}C]NMR, MS, TLC, and GC comparisons. It was possible to attribute all the additional high-field methyl resonances in the [^{1}H]NMR spectrum of juvenile hexane extract (Figure 1) to protons in either camphor or bornyl acetate.

Quantitative Determinations of Camphor and Bornyl Acetate. GC analysis showed that in juvenile white spruce the concentrations of camphor and bornyl acetate were 2.52 and 1.26 g/kg wet weight of foliage, respectively. In mature white spruce, the concentrations of camphor and bornyl acetate were 0.65 and

0.42 g/kg wet weight of foliage, respectively. Thus, we found that there was roughly four times as much camphor in juvenile white spruce foliage as there was in mature foliage.

Bioassay of Secondary Metabolites: Experiment 1. Camphor was added to chow at a concentration of 0.5 g/330 g of chow. This was approximately one fifth the concentration in an equivalent dry weight of juvenile white spruce. The control was ether-treated chow. The results for the amounts eaten are given in Table 1. The animals significantly avoided the camphor-treated chow ($P < 0.001$), and they ate approximately five times as much of the control chow compared with the camphor chow.

Experiment 2. The mature hexane extract was added to chow at the same concentration as that of the camphor chow (0.5 g extract/330 g chow). This concentration of mature hexane extract represented a sixth of that found in the plant. The dilute mature hexane extract was offered to hares with the camphor chow (Table 1). Figure 3A shows that the hares preferred the mature hexane

TABLE 1. AMOUNTS OF RABBIT CHOW TREATED WITH WHITE SPRUCE EXTRACTS EATEN BY SNOWSHOE HARES IN CHOICE TESTS[a]

Extract in chow	Amount eaten	
	Mean weight ± SE/day (g)	% of total

Juvenile hexane extract with bornyl acetate control	23.6 ± 3.1	40.2

[a] Four replicate runs were made for each experiment.

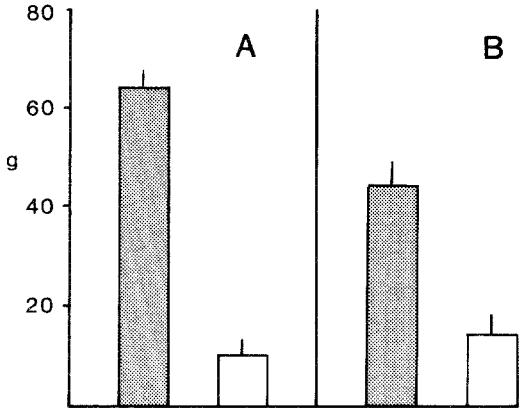

FIG. 3. The mean amounts of rabbit chow eaten per day by snowshoe hares. (A) Chow treated with mature hexane extract (shaded) and camphor (open) both at 0.5 extract/330 g chow. (B) Chow treated with juvenile hexane extract without camphor (shaded) and with camphor (open). Verticle lines are one standard error.

extract over the camphor chow ($P < 0.001$), eating approximately six times as much of the former.

Experiment 3. The mature hexane extract was added to chow at the concentrations found in the natural plant (3.2 g extract/330 g chow). This was offered to hares with the camphor chow. Table 1 shows that the hares did not show a preference between the two, eating similar amounts of both. The mature spruce extract contained 0.43 g camphor in 330 g of chow (from the quantitative analysis above), slightly less than that in the camphor-treated chow. The result of no significant choice is, therefore, to be expected since the camphor concentrations in the two choices were nearly the same.

Experiment 4. In experiment 3 the concentrations of the mature hexane extract and the camphor were markedly different, and the former was noticeably stronger smelling. To balance the secondary metabolites on offer, juvenile hexane extract was offered to hares at the same concentration as that of the mature hexane extract (3.2 g extract/330 g chow). The two hexane extracts were offered together. Table 1 shows that in this situation preference of the mature hexane extract was reestablished ($P < 0.005$).

Experiment 5. To test whether camphor was the major antifeedant in juvenile spruce, camphor was separated from the remainder of the juvenile hexane extract by flash chromatography as described above. In a portion of the remainder, camphor was replaced; in the other portion, camphor was excluded. This procedure controlled for all extraction processes. Juvenile hexane extract with camphor was tested against the same extract without camphor (Table 1). Figure

3B shows that hares preferred the juvenile hexane extract that did not contain the camphor ($P < 0.005$), eating three times as much of this than the extract with camphor.

Experiment 6. The other substance found largely in juvenile spruce was bornyl acetate. The procedure for treating chow with this compound was the same as that for camphor in experiment 5. Thus juvenile hexane extract with bornyl acetate in chow was offered to hares together with chow containing similar extract without bornyl acetate. Although the hares ate more of the extract without bornyl acetate, the result was not significant ($P > 0.05$).

DISCUSSION

The first feeding experiment showed that hares avoided camphor when it was added to chow. But it is possible that hares were simply avoiding any odoriferous substance, so that ether chow was not a proper control. Experiment 2 addresses this aspect by using a concentration of mature spruce extract similar to that of camphor. The avoidance of camphor in this case is more convincing; it appears to be the camphor itself that is being avoided.

The lack of preference shown by hares in experiment 3 could be due to either the similar quantities of camphor present in the two choices or to the higher concentration of other secondary metabolites in mature spruce (2.77 g extract/330 g chow). These other secondary metabolites could counteract the avoidance of camphor (0.5 g camphor/330 g chow). Experiment 4, therefore, was designed to balance the other secondary metabolites in mature and juvenile spruce, leaving only the camphor as the difference between them. Again in this case the animals avoided the juvenile hexane extract containing the camphor. Finally, experiment 5 was designed to show that camphor was the active antifeedant compound by comparing juvenile hexane extract with and without camphor. Extraction procedures were kept identical to avoid hidden biases. The hare preferences confirmed that it was the presence of camphor in the juvenile hexane extract that caused them to avoid it.

Bornyl acetate did not produce a significant antifeeding response in the hares (experiment 6). However, the results suggested there might be some avoidance and further testing is needed. In any case, avoidance of bornyl acetate was much less than avoidance of camphor.

In conclusion, we show that camphor, a specific compound in white spruce, acts as a major antifeedant for snowshoe hares. Camphor occurs at four times the concentration in juvenile spruce (<2 m high) compared to that in mature spruce (>5m high). Another compound, bornyl acetate, did not show significant antifeedant properties. Our results support the hypothesis of Coley et al. (1985) that late-succession slow-growing plants should be strongly defended

against herbivores. The results also support the growth-stage hypothesis of Bryant and Kuropat (1980) that early growth stages are more heavily defended than mature stages.

For these conifers, one evolutionary explanation could be that defense is against smaller mammals such as hares because the presence of camphor is associated with plant height. In addition, Sinclair and Smith (1984) found that preference for spruce tops at 3 m height was intermediate between preferences for spruce at <2 m and >5 m high. Defense against either insects or large mammals (browsing mastodons and giant ground sloths were present in these ecosystems less than 12,000 years ago; Dreimanis, 1968) would not be tied to height.

However, we note that the angiosperms, such as alder, also show a diminution in chemical defense in mature stages, but these stages are usually available to browsing hares. This suggests an alternative explanation that the lower defense of mature twigs is due to fundamental physiological changes in the plant rather than a relaxation of predation. What now remains is to see how camphor content is related to size and age of the spruce plant.

Acknowledgments—We thank Naomi Smith, Joy Snyder, Garth Mowat, Art Rodgers, and Louise Grenier for help with plant samples, chemical analyses, and feeding experiments. This work is part of a long-term boreal ecosystem study funded by the Natural Sciences and Engineering Research Council of Canada as a Co-operative Special project under Dr. C.J. Krebs and others. Other funding was provided by N.S.E.R.C. operating grants to A.R.E. Sinclair and R.J. Andersen.

ARTIFICIAL DEFLORATION AND FURANOCOUMARIN INDUCTION IN *Pastinaca sativa* (UMBELLIFERAE)

JAMES K. NITAO[1]

Department of Entomology
University of Illinois at Urbana-Champaign
320 Morrill Hall, 505 S. Goodwin Avenue, Urbana, Illinois 61801

(Received June 8, 1987; accepted September 8, 1987)

Abstract—Damage simulating herbivory was tested as an inducer of furanocoumarins in the floral parts of the wild parsnip, *Pastinaca sativa* (Umbelliferae). In one experiment, primary umbels of *P. sativa* were partially deflorated over the course of nine days, and higher-order umbels as well as the remaining primary umbel floral parts were sampled. Total furanocoumarin concentration was not significantly affected by defloration, but one furanocoumarin, isopimpinellin, increased in one floral stage of the secondary umbel in damaged plants. In a second experiment, primary umbels were completely deflorated and the higher-order umbels allowed to set seed. No significant effect of defloration on furanocoumarin content was found in the seeds of the higher-order umbels.

Key Words—Wild parsnip, *Pastinaca sativa*, furanocoumarins, induction, defloration, optimal defense, Umbelliferae, allelochemicals, herbivore-plant interactions.

INTRODUCTION

Damage from herbivory can result in the induction of higher levels of plant allelochemicals (reviewed in Kogan and Paxton, 1983; Rhoades, 1983). Because resources are allocated for defense only when required, this flexibility in phytochemical response presumably represents the efficient use of limited materials and energy by the plant (Rhoades, 1979). In theory, induction should be especially important in the reproductive parts of monocarpic plants. For a plant

[1] Current address: Department of Entomology, 243 Natural Sciences Bldg. Michigan State University, East Lansing, Michigan 48824.

0098-0331/88/06-1515$06.00/0

reproducing only once during its lifetime, herbivore damage to any flowers or fruits increases the proportional contribution of the surviving floral units to its overall reproductive success; in other words, the more flowers are eaten, the more important the remaining flowers become to the plant. If levels of defensive chemistry are closely matched with floral value, the defense of surviving floral units should increase accordingly.

Simulated herbivory was tested as an inducer of one class of allelochemicals, the furanocoumarins, in the floral parts of the wild parsnip, *Pastinaca sativa* (Umbelliferae). *P. sativa* is a monocarpic perennial, flowering in its second year only if sufficient root mass has been accumulated (Thompson, 1978; Baskin and Baskin, 1979). Many of the furanocoumarins found in the flowers and seeds of *P. sativa* are either deterrent or toxic to herbivores (Yajima et al., 1977; Berenbaum, 1978; Muckensturm et al., 1981; Berenbaum and Neal, 1985; Ashkenazy et al., 1985), and several are involved in determining resistance of wild parsnip to two specialist insect species (Berenbaum and Feeny, 1981; Berenbaum et al., 1986). The production of furanocoumarins in response to other forms of stress makes it likely that these compounds can be induced by herbivore damage. Xanthotoxin and bergapten are phytoalexins in celery (Wu et al., 1972). Psoralen, bergapten, isopimpinellin, and xanthotoxin are induced in celery by exposure to cold temperatures, ultraviolet light, and sodium hypochlorite (Beier and Oertli, 1983). Xanthotoxin is a phytoalexin in parsnip root in vitro (Johnson et al., 1973), while angelicin, bergapten, psoralen, and xanthotoxin, collectively, can be 25 times higher in concentration in diseased parsnip roots compared to unspoiled roots (Ceska et al., 1986). There have been no studies, however, investigating the inducibility of furanocoumarins by herbivory or injury simulating herbivory.

METHODS AND MATERIALS

Flowers of *P. sativa* are borne on umbels, and initiation of floral development proceeds according to umbel order. The primary umbel terminates the main flowering stalk and develops first. Secondary umbels branch off the main stalk and develop next, while the tertiary umbels arise from the peduncles of the secondary umbels, and so on. The seeds of the primary umbel are therefore the first to mature and those of the highest umbel order the last to mature. This flowering pattern enabled me investigation of furanocoumarin content changes over two different time courses. In one experiment, I tested for chemical induction in developing flowers shortly after defloration of the primary umbel (short-term response). In a second experiment, seeds that had matured several weeks after primary umbel defloration were sampled from the higher order umbels (long-term response). In both experiments, herbivory was simulated by artificial

defloration to assure equal levels of damage among plants. Artificial defloration simulates insect herbivory with respect to compensatory floral growth in *P. sativa* (Hendrix and Trapp, 1981), so that plants may in general respond to artificial primary umbel damage as they would with natural herbivory.

Compensating floral growth in the higher-order umbels can occur after primary umbel damage in *P. sativa*, and the degree of compensatory growth is dependent on umbel order (Hendrix, 1979; Hendrix and Trapp, 1981). Because of this differential umbel order response, the different orders were sampled and analyzed separately for each plant so as to detect any similar differential response in furanocoumarin chemistry.

Test for Short-Term Response. In May 1984, one hundred *P. sativa* plants at the University of Illinois Phillips Tract natural area, Champaign County, were sprayed with acephate insecticide once a week for three weeks to prevent insect damage. Fifty of these plants were randomly assigned to the artificial defloration treatment and the other 50 to the undamaged control treatment. Five umbellets were clipped from the primary umbel of plants in the defloration group every other day from May 27 to June 6 for a total of four removals. This schedule of removal simulates damage as might occur from a flower-feeding insect such as the parsnip webworm, *Depressaria pastinacella* (Lepidoptera: Oecophoridae), a species commonly found on wild parsnips. *P. sativa* is andromonoecious and protandrous, with each hermaphroditic flower passing through bud, male, and female stages. Primary umbel flowers were buds at the time of the first removal and were mostly males and females at the time of the last removal.

Two days after the last defloration, the following floral parts were sampled from each plant for chemical analysis: one umbellet from the periphery of the primary umbel, one umbellet from the periphery of one of the topmost secondary umbels, and an entire tertiary umbel branching off the secondary umbel that was sampled. An unidentified disease manifested itself in some of the plants in the population as flowering progressed. Only plants appearing healthy and showing no signs of stress were sampled, leaving 28 control plants and 37 artificially damaged plants. Plant samples were dried at 60°C, weighed, and extracted in ethyl ether; furanocoumarin content was quantified using high-performance liquid chromatography (Berenbaum et al., 1984). Seven furanocoumarins were detected: angelicin, imperatorin, bergapten, isopimpinellin, xanthotoxin, sphondin, and psoralen.

Plants varied in their degree of development at the time of sampling. Because furanocoumarin content varies with floral development (Nitao and Zangerl, 1987), each umbel order sampled was categorized into one of four floral developmental classes depending on the status of its flowers (bud, male, female, or fruit stage). Statistical comparisons were made within umbel order/floral stage classes to adjust for this developmental variation. Sufficient sample sizes existed

for comparisons between treatments for primary umbel male flowers, primary umbel female flowers, secondary umbel buds, secondary umbel male flowers, and tertiary umbel buds. The *t*-tests were used to test for a treatment effect on total furanocoumarin concentration and the relative amounts of each individual furanocoumarin. Data for proportions of compounds were arc-sine transformed prior to analysis.

Test for Long-Term Response. Nineteen overwintered *P. sativa* plants from Phillips Tract were transplanted as rosettes into pots in May 1985, kept in a greenhouse, and sprayed with acephate to prevent insect herbivore damage. Plants were randomly assigned to three treatment groups: control (no defloration); complete defloration of the primary umbel at the bud stage; and complete defloration of the primary umbel at the female flower stage. Earlier results showed that the timing of defloration affected growth in higher-order umbels (Nitao and Zangerl, 1987), suggesting that stage-dependent effects of defloration on furanocoumarin content in the resulting seeds might occur as well. All flowers in the umbel were clipped off when the primary umbel attained its preassigned stage to create as severe an impact as possible. All higher-order umbels were allowed to set seed.

Ten filled seeds were randomly chosen from the secondary and tertiary umbels of each plant and pooled for chemical analysis. Quaternary and pentanary umbel seeds were present in only a few of the plants and thus were not included in the analysis. Seeds were cut into halves to facilitate solvent penetration and extracted in ethyl acetate. Furanocoumarins were quantified by high-performance liquid chromatography as described earlier. One-way analysis of variance was used to test for a treatment effect on total furanocoumarin concentration and the relative proportions of individual compounds in the seeds. Data for proportions were arc-sine transformed prior to analysis (Sokal and Rohlf, 1981).

RESULTS

Test for Short-Term Response. An overall examination of the data revealed no consistent trends to suggest that total concentration of furanocoumarins increased in response to primary umbel damage; no significant treatment effect on total furanocoumarin concentration was found in any of the umbel orders and floral stages tested (Table 1).

No treatment effects were found on the relative proportions of the individual compounds except for a significant increase of isopimpinellin in the male flowers of secondary umbels; the mean percentage of isopimpinellin in the control group was 11.2 ± 2.68, whereas that of the deflorated group was $16.0 \pm$

TABLE 1. TOTAL FURANOCOUMARIN CONCENTRATION (μg FURANOCOUMARIN/mg DRY PLANT MASS) IN FLOWERS OF *Pastinaca sativa*[a]

Umbel order	Floral stage	Treatment[b]	
		Control	Deflorated
Primary	male	0.513 ± 0.1342 (6)	0.370 ± 0.0494 (6)
	female	0.938 ± 0.1175 (15)	0.949 ± 0.0751 (30)
Secondary	bud	0.420 ± 0.0526 (18)	0.410 ± 0.0578 (23)
	male	0.612 ± 0.0720 (8)	0.631 ± 0.0652 (14)
Tertiary	bud	0.611 ± 0.0720 (28)	0.592 ± 0.0772 (37)

[a] Primary umbels were either undamaged (control) or artificially deflorated. Mean ± SE. Sample size in parentheses.
[b] No significant treatment effects on total concentrations were found ($P > 0.05$, t tests).

1.13 ($P < 0.05$, t test, $t = -2.10$, $df = 20$). Because the mean total concentrations of furanocoumarins for the two treatment groups were not different, this change in relative amount signifies an absolute increase in isopimpinellin concentration as well. The 1.5-fold proportional increase in this compound was approximately equal to a 0.03 μg/mg increase in absolute concentration. Although several other compounds in turn tended to decrease in proportion, these changes were not large enough in any single compound to be significant. Across all umbel orders and floral stages, the range of mean relative proportions for angelicin was <0.01–0.1%, imperatorin 20.9–53.3%, bergapten 9.8–15.4%, isopimpinellin 8.1–21.2%, xanthotoxin 23.4–51.9%, sphondin 1.1–2.4%, and psoralen <0.1–5.3%.

Test for Long-Term Response. As with the experiment examining short-term effects, defloration of the primary umbel at either the bud or female stage failed to alter total furanocoumarin concentration in the seeds (Table 2). The mean total concentration of an umbel for control plants was intermediate to those of plants deflorated at either bud and female stages.

The relative proportions of the individual compounds were not significantly affected by primary umbel defloration. No consistent trend was found to suggest a change in the proportion of isopimpinellin similar to that observed in the secondary umbel/male flowers in the short-term response experiment. Across all umbel orders and treatment groups, the range of mean relative proportions

of angelicin was 1.0–1.7%, imperatorin 27.2–33.0%, bergapten 18.7–22.3%, isompimpinellin 10.7–19.8%, xanthotoxin 29.8–38.0%, and sphondin 1.0–1.8%. No psoralen was detected in these seeds.

DISCUSSION

No significant effect of artificial herbivory was found on total furanocoumarin concentration as either short- or long-term responses. Moreover, no consistent trends occurred to indicate that any true differences in total concentration might have been obscured by large variances. This result runs counter to what might be expected if plants defend tissues according to their value. Even though the value of the remaining floral units are, in theory, higher after defloration of the primary umbel, chemical defense as measured by overall furanocoumarin concentration did not correspondingly increase. Only one significant difference in the qualitative composition of the furanocoumarins was found in either experiment. The relative amount of isopimpinellin was higher in the male flowers of the secondary umbels in plants that had their primary umbel partially deflorated. This finding is in striking contrast to the dramatic 25-fold increase of four furanocoumarins in the presence of pathogens in parsnip roots (Ceska et al., 1986).

The experimental design may account for the absence of significant levels of induction. Insecticides can themselves be inducers of plant secondary compounds (Kogan and Paxton, 1983), so that the acephate used to prevent damage may have induced all plants regardless of defloration treatment. This appears not to have been the case, however, because the furanocoumarin values obtained in these experiments are comparable to those found in *P. sativa* plants of the same population not sprayed with acephate (Berenbaum and Zangerl, 1986; Nitao and Zangerl, 1987). Artificial herbivore damage does not always simulate

actual herbivore injury (Capinera and Roltsch, 1980); thus an unknown chemical stimulus that might occur in herbivore saliva may be required for the induction of furanocoumarins in damaged plants. Although this factor was not taken into account, Hendrix and Trapp (1981) have shown that, at least with respect to compensatory seed set, artificial defloration does simulate herbivory by the parsnip webworm.

Physical injury does not elicit increased production of secondary chemicals in all plant species (e.g., Chapin et al., 1985; Johnson and Brain, 1985), indicating that other ecological and physiological constraints can be important. Because reproductive parts directly determine fitness, there may be a high cost for even slight damage to these tissues; the resource cost for the plant to produce furanocoumarins (Zangerl and Berenbaum, 1987) may be outweighed by this low tolerance for damage. Plants may therefore allocate defenses according to the current value of the reproductive part instead of increasing allocation to defense only after flowers have already been lost.

(Received August 3, 1987; accepted September 8, 1987)

Abstract—Corn seedling volatiles collected cryogenically are highly attractive to western corn rootworm larvae, *Diabrotica virgifera virgifera* LeConte (Coleoptera: Chrysomelidae), in a laboratory bioassay. Carbon dioxide is known as an attractant for western corn rootworm larvae, and the amount of carbon dioxide in the cryogenic collections was measured with an infrared gas analyzer. In a choice test between a source containing carbon dioxide alone and a source containing corn seedling volatiles with an equal amount of carbon dioxide (verified by infrared gas analysis), western corn rootworm larvae chose the corn volatile source significantly more often than the side with carbon dioxide alone. This indicates that carbon dioxide is only one of the volatiles from corn seedlings that is behaviorally important and that other compounds of behavioral importance are present as well.

Key Words—*Diabrotica virgifera virgifera*, Coleoptera, Chrysomelidae, western corn rootworm, rootworm, corn, *Zea mays*, kairomone, volatile substances, attractants, carbon dioxide, semiochemical.

INTRODUCTION

Diabrotica virgifera virgifera LeConte, the western corn rootworm, is an annual threat to corn throughout much of the Midwest. Larval damage to corn roots results in reduced plant height, reduced yield, and lodging of corn, which interferes with harvesting (Branson et al., 1980). Members of the genus *Diabrotica* have been estimated to cause more than $1 billion in damage per year in the United States, mostly to corn (Metcalf, 1986).

Larvae emerge from overwintering eggs in the spring and can feed only

0098-0331/88/0600-1523$06.00/0

on certain species of Gramineae (Branson and Ortman, 1967, 1970). Because the eggs are laid in soil the previous year, the burden of host plant location lies entirely with the newly hatched larvae. The larvae have been reported to crawl through as much as a meter through the soil to find the roots of a suitable host (Short and Luedtke, 1970), although estimates to date have been complicated by a number of experimental difficulties (Branson, 1986). In surface olfactometer choice tests between cut roots of corn and broad-leaved plants, Branson (1982) found that significantly more western corn rootworm larvae were attracted to the roots of corn than to the roots of soybean, squash, or sunflower (no difference was observed between roots of corn and tomato). Behavioral bioassays in a soil olfactometer did not reveal differences in attraction, perhaps due to the difficulty of establishing equal amounts of root tissue for the choice test (Branson, 1982). Roots of a number of grass species were as attractive as corn roots or more so to western corn rootworm larvae in surface olfactometer choice tests, including several grass species that were nonhosts (Branson, 1982).

The only chemical cue known to be involved in the orientation of western corn rootworm larvae to corn roots is carbon dioxide (Strnad et al., 1986, Strnad and Bergman, 1987), which is known to attract a number of other soil insects (Jones and Coaker, 1977; Doane et al., 1975; Pline and Dusenbery, 1987; and references therein). Carbon dioxide is produced by the roots of most plant species, and it does not appear to provide a basis for the ability of the larvae to distinguish the roots of host plants from those of many other plant species. We wished to determine if carbon dioxide was the only attractive compound produced by corn root tissue, or if other semiochemicals may be involved in host selection by western corn rootworm larvae as well. Compounds that affect larval behavior might be expected to include two principal categories: compounds that are volatile and disperse mainly by diffusion in the soil atmosphere, and those that are water-soluble and disperse mainly by diffusion in aqueous solution. Our initial studies have focused on the possible contribution of volatile constituents of corn plants.

Cryogenic collection was used to recover volatile compounds from corn seedlings in the present study. This technique has been used successfully for the recovery of other semiochemicals, such as insect pheromones (Browne et al., 1974; Golub and Weatherston, 1984). Unlike conventional cold trapping, cryogenic collection involves condensing the air itself, along with any volatile organic compounds that the air might contain. Low-temperature distillation allows nitrogen (bp $-196°C$) and oxygen (bp $-183°C$) to be removed after the collection is complete, while volatiles with boiling points higher than $-183°C$ are retained. The principal advantage of cryogenic collection is that compounds with a wide range of volatilities can be recovered. This is important in the present study because the very volatile carbon dioxide is already known as a semiochemical important in host location by western corn rootworm larvae

(Strnad et al., 1986; Strnad and Bergman, 1987), and we wished to evaluate the possible behavioral importance of additional compounds that may have an array of large and small molecular weights. In many other studies of volatile semiochemicals, compounds have been extracted with solid adsorbants such as Tenax or Porapak Q, but these techniques fail to recover compounds with very small molecular weights, such as carbon dioxide (Byrne et al., 1975).

Two behavioral bioassays were developed to determine the role of volatile semiochemicals from corn seedlings in host location by western corn rootworm larvae. A single-choice bioassay was developed to determine if the full complement of corn volatiles collected cryogenically was attractive to the larvae and to verify the conclusion of Strnad et al. (1986) that carbon dioxide alone is attractive to western corn rootworm larvae. A choice test bioassay was also developed, to allow behavioral comparison of carbon dioxide alone with a cryogenic collection of corn volatiles that contained an equal amount of carbon dioxide. Instead of using a choice test bioassay with carbon dioxide levels equal on both sides, the behavioral role of carbon dioxide can alternatively be evaluated by using KOH to remove carbon dioxide from a volatile blend, and using single-choice bioassays to compare the attractiveness of KOH-treated host plant volatiles with untreated host plant volatiles (Doane et al., 1975; Jones and Coaker, 1979). However, there are two problems with this approach: First, semiochemicals that are behaviorally relevant only in the presence of carbon dioxide would be detected in a choice test, but would not be detected in single-choice bioassays of a KOH-treated volatile blend. Second, KOH reacts with many compounds other than carbon dioxide and may remove or chemically alter other semiochemicals in addition to carbon dioxide. A choice test bioassay was adopted in the present study to obviate both these possible problems.

METHODS AND MATERIALS

Insect Colony. Eggs of a nondiapausing strain of *Diabrotica virgifera virgifera* were obtained in June and July of 1986 from Dr. Jan Jackson at the Northern Grain Insects Research Laboratory. The colony was maintained according to methods described by Jackson (1986), with some modifications. Modifications (Jackson, personal communication) included the use of soil in covered, small plastic containers (17 cm diam. $\times$ 10 cm high) in which 75 larvae were reared on corn seedlings for their first six days of growth. Two of these smaller containers (along with the larvae) were then transferred into a larger covered plastic container (18 $\times$ 32 $\times$ 8 cm), which contained sufficient seedling corn in soil for completion of larval development and pupation.

Corn Seedlings. Dried whole kernels of field corn, not treated with insecticide or fungicide, were purchased from a local supplier (variety unspecified).

Dried kernels were washed with detergent solution (Ivory liquid) for 5 min to inhibit fungal contamination, rinsed thoroughly, and soaked in water for 24 hr. Soaked seeds were washed again with detergent solution, rinsed thoroughly, placed on moist germination paper (Anchor Paper Co., St. Paul, Minnesota), covered with moist paper towels, and kept in a closed plastic container. Corn seedlings were removed three to four days later for bioassays.

Cryogenic Volatile Collection. A cryogenic collection technique similar to that described by Browne et al. (1974) was used, based on a simple pump in which a glass sample tube closed at one end (12 mm × 35 cm) was immersed in a liquid nitrogen bath. A boiling chip was placed in a clean sample tube, and a glass seed-holding tube (30 cm × 30 mm, tapering to 12 mm) containing 70 g of 3- to 4-day-old corn seedlings (seeds not treated with insecticide or fungicide) was connected to the sample tube with Teflon tubing. The sample tube was then immersed 20 cm into the liquid nitrogen bath. As air condensed in the sample tube, a vacuum was created that pulled air through the corn seedlings at 300 ml/min (measured with a bubble flowmeter). After 10 min, the sample tube was removed from the liquid nitrogen bath and disconnected from the seed-holding tube. The sample tube was immediately placed into a snugly fitting Styrofoam sheath that had been precooled in liquid nitrogen. The condensed air boiled away within 10 min, allowing liquid nitrogen (bp −196°C) and liquid oxygen (bp −183°C) to escape slowly and leaving compounds that were tested in behavioral bioassays for their importance in western corn rootworm larval orientation.

Single-Tube Bioassay. Plastic Petri dishes (10 cm diam.) were used as arenas for the bioassay. The top of the sample tube was connected with Teflon tubing to a 12-mm hole cut in the bottom of the Petri dish (see Figure 1). Ten larvae (5–6 days old and 4–6 mm long) were placed equidistant in a ring near the wall of the Petri dish, and the cover was replaced. We chose to use second-instar larvae (5–6 days old and 4–6 mm long) for our bioassays because initial bioassays indicated that they behaved similarly to first-instar larvae (the instar that must locate a host), and second-instar larvae were easier to handle for the large numbers of bioassays required. All bioassays were performed in dim light. The number of larvae that entered the tube was recorded at 5-min intervals for 30 min. To prevent possible effects from previous testing, larvae were not reused in the bioassays.

Two treatments were tested in larval behavioral bioassays as controls. Clean sample tubes were tested to verify that the sample tubes themselves were not inherently attractive. Sample tubes containing cryogenic collections of ambient air were tested to determine if the circumstances of the cryogenic collection procedure might influence the bioassay results.

Water was observed to condense in the sample tubes in cryogenic collec-

tions from corn seedlings. Measurement of the weight change in the sample tube before and after the cryogenic collection indicated that 75 ± 5 (SE) mg of water collected in a sample tube during the 10-min collection interval. Sample tubes containing the same amount of water were tested to determine if water alone was attractive to western corn rootworm larvae.

Because carbon dioxide has been reported as an attractant for western corn rootworm larvae (Strnad et al., 1986, Strnad and Bergman, 1987), we wished to verify that carbon dioxide was attractive in our bioassay as well. Carbon dioxide from a gas cylinder was introduced into clean sample tubes for 15 sec, and the tubes were inverted for 30 sec to reduce the concentration of carbon dioxide and disperse it evenly in the tube. An infrared gas analyzer interfaced with a Porapak N gas chromatograph column (GC-IRGA, details below) was used to determine the carbon dioxide concentration in the tubes. The number of larvae attracted into the sample tubes was counted every 5 min for 30 min.

Double-Tube Bioassay. Because carbon dioxide was highly attractive in our single-tube bioassays, the additional influence of other behaviorally important corn volatiles would have been difficult to detect using the single-tube bioassay. In order to test if compounds other than carbon dioxide were involved, a choice test bioassay was designed to give larvae a choice between a sample tube containing carbon dioxide alone and a sample tube containing an equal amount of carbon dioxide in association with other corn volatiles. A bioassay apparatus similar to that described by Branson (1982) was designed, consisting of three plastic Petri dishes (5 cm diam.) connected in series by Teflon tubing (10 mm diam.). Holes (12 mm) were cut into the end dishes to allow connection of sample tubes (see Figure 3). One choice was a sample tube containing 4 mmol/mol of carbon dioxide at bioassay initiation (see Figure 3). The sample tube was prepared by flushing with carbon dioxide from a gas cylinder and inverting it for 30 sec to reduce the concentration of carbon dioxide and disperse it evenly in the tube. The carbon dioxide concentration was verified with the GC-IRGA (details below). For the other choice, a sample tube containing a cryogenic collection of corn seedling volatiles was prepared, the liquid nitrogen and liquid oxygen were removed by low-temperature distillation, the sample tube was raised to room temperature, and the carbon dioxide concentration therein was adjusted to 4 mmol/mol at bioassay initiation (see Figure 3) (by flushing the sample tube with carbon dioxide, inverting it, and verifying the final carbon dioxide concentration with the GC-IRGA). Each sample tube was connected to one of the end dishes of the bioassay apparatus, and a 5-min delay was allowed for volatiles to begin diffusing before larvae were added. Ten larvae were placed in the center of a small Petri dish lid (40 mm diam. with a lip 5 mm high); this was placed in the center chamber of the bioassay apparatus, and the cover to the chamber was replaced. The number of larvae in each of

the three Petri dishes was recorded every 5 min for 30 min. Bioassays were performed in dim light. To prevent possible effects from previous testing, larvae were not reused in the bioassays.

Carbon Dioxide Levels in Bioassays. An infrared gas analyzer (IRGA, Beckman model 865) was used to measure carbon dioxide concentrations. An interface of our own design was constructed to allow the IRGA to be used as the detector for a Porapak N gas chromatograph column (3 mm × 2 m) operated isothermally at 25°C, and the output from the GC-IRGA was analyzed with a HP 3390A integrator-recorder. Gas samples (1 ml) were injected with a Pressure-Lok gas sampling syringe (Precision Sampling Co.) for analysis. A mixture of carbon dioxide in nitrogen equal to the atmospheric concentration was purchased (340 ppm, Union Carbide Corp., Linde Division) and used as a standard for quantitation of carbon dioxide by GC-IRGA analysis. In addition, a 99.9% carbon dioxide source (local welding supplier) was used to make dilutions to generate a calibration curve of GC-IRGA response with respect to carbon dioxide concentration. For the single-tube bioassays, gas samples were taken from the mouth of the sample tube (see Figure 1). For the double-tube bioassays, gas samples were taken from the edges of the middle dish (see Figure 3), because this is the location at which larvae must make a choice to leave the dish. Samples were taken every 5 min for 30 min for analysis with the GC-IRGA.

Statistical Analysis. The statistical package BMDP (BMDP Program Librarian, Department of Biomathematics, University of California, Los Angeles, California 90024) was used for data analysis. Behavioral bioassay data for 30 min were analyzed with one-way analysis of variance for larval attraction in the single-tube and double-tube bioassays, because larvae that entered the sample tubes were usually unable to come back out of the tubes and the bioassay data were therefore essentially cumulative with time. Duncan's multiple-range test (Duncan, 1955) was used to discern differences among treatment means. Data for carbon dioxide levels at all times sampled were compared in a repeated measures design (Anonymous, 1981), because sequential samples for GC-IRGA analysis were taken from each sample tube.

RESULTS

Significantly more ($P \leq 0.01$) western corn rootworm larvae were attracted to sample tubes containing cryogenically collected corn volatiles than to control treatments, which included sample tubes containing ambient air, cryogenic collections of ambient air, or water (Figure 1A). Samples tubes containing cryogenic collections of ambient air attracted more larvae ($P \leq 0.05$) than tubes with ambient air not cryogenically collected.

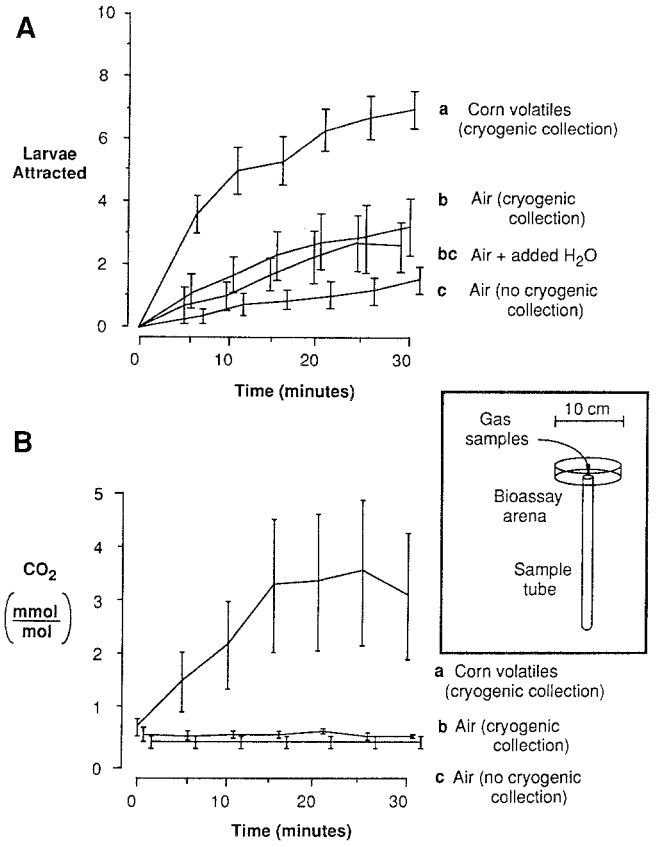

FIG. 1. (A) Single-tube bioassay to evaluate behavioral responses of western corn rootworm larvae to cryogenic collections of corn seedling volatiles and to control treatments. Treatment means at time 30 min were significantly different ($P \leq 0.01$) for curves followed by different letters according to Duncan's NMRT. Error bars represent 95% confidence intervals. (B) Carbon dioxide concentrations at the orifices of the sample tubes. Treatment means of overall carbon dioxide levels were significantly different ($P \leq 0.05$) for curves followed by different letters in a repeated measures analysis of all times according to Duncan's NMRT. Error bars represent 95% confidence intervals.

When a Petri dish with 10 larvae was added to sample tubes containing cryogenic collections of corn seedling volatiles, the first observable larval responses were head-waving, also observed by Strnad et al. (1986), and alignment of their body axes toward the center of the dish. Larvae crawled rapidly and more or less directly toward the source of corn volatiles, similar to the path that larvae took to carbon dioxide in Strnad et al. (1986). This behavioral sequence rarely occurred in response to control treatments (ambient air treat-

ment or water treatment). Larvae that lowered their heads into the sample tube usually crawled in and did not crawl back out.

The cryogenic apparatus for volatile collection provided an efficient vacuum. Air flow past the corn seedlings remained essentially constant throughout the 10-min collection period as indicated by measurement of the volume of liquid air that accumulated in the sample tube (0.35 ± 0.02 SE ml/min) and by measurement with a bubble flowmeter (300 ml/min). Collection rates remained relatively constant for collection periods as long as 30 min. Behavioral bioassay results indicated that it was effective in collecting compounds of interest to larvae, and after distillation of liquid oxygen and nitrogen, the odor of corn was apparent to the human nose as well.

Analysis of carbon dioxide standards with the GC-IRGA indicated a retention time for carbon dioxide of 1.8 min. No other peaks were observed in GC-IRGA analyses of air, cryogenic collections of air, or cryogenic collections of corn seedling volatiles. Calibration with known carbon dioxide concentrations showed the GC-IRGA to be linear in response ($r^2 = 0.995$) for the range of carbon dioxide found in the bioassays (0.34–30 mmol/mol). The use of the IRGA and GC in combination provided a sensitive, semiselective means of detecting carbon dioxide in conjunction with a characteristic retention time for this compound, allowing rigorous determination of carbon dioxide in the volatile samples even at low concentrations. The carbon dioxide concentration in ambient air was easily measurable (0.34 mmol/mol is atmospheric concentration).

The carbon dioxide concentration (Figure 1B) was significantly higher in sample tubes containing cryogenically collected corn seedling volatiles than in sample tubes containing cryogenically collected ambient air or sample tubes containing ambient air without cryogenic collection ($P \leq 0.01$). The concentration of carbon dioxide in sample tubes containing cryogenically collected ambient air (Figure 1B) was slightly higher than that found in ambient air (but significant, $P \leq 0.01$). The cryogenic collection evidently concentrated carbon dioxide from the surrounding air, and the greater carbon dioxide concentration may account for the significantly greater attraction of larvae to sample tubes containing cryogenically collected ambient air than to the sample tubes containing air alone.

Single-tube bioassays with carbon dioxide (Figure 2A) showed that this compound is highly attractive to western corn rootworm larvae ($P \leq 0.01$). The source of carbon dioxide in this experiment was a sample tube from which carbon dioxide emerged by diffusion. The dynamics of carbon dioxide release by the sample tube were determined by analysis with GC-IRGA (Figure 2B). For sample tubes prepared by filling them with carbon dioxide from a gas cylinder and inverting them for 30 sec to adjust the concentration to a low level,

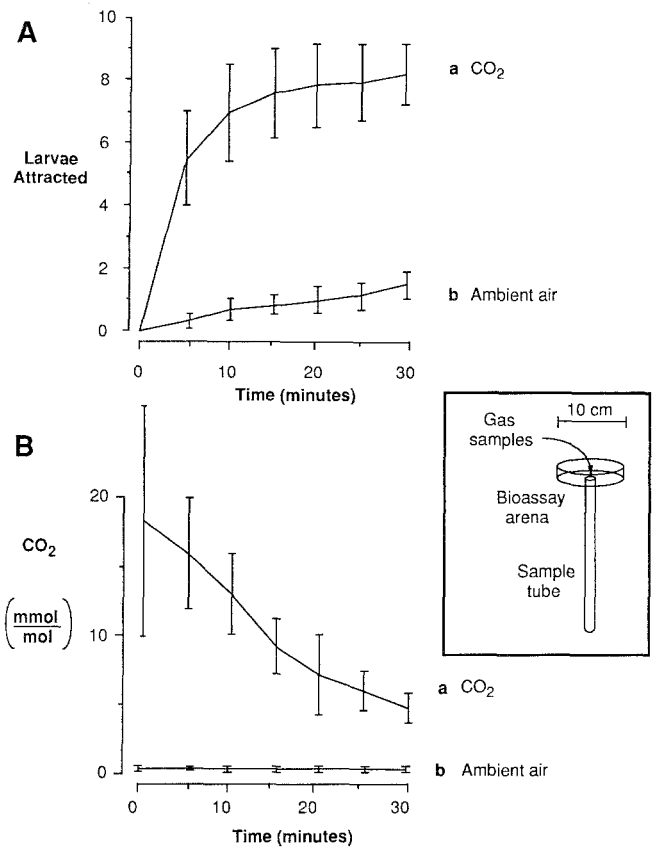

FIG. 2. (A) Single-tube bioassay to evaluate responses of western corn rootworm larvae to carbon dioxide and to ambient air. Treatment means at time 30 min were significantly different ($P \leq 0.01$) for curves followed by different letters according to Duncan's NMRT. Error bars represent 95% confidence intervals.(B) Carbon dioxide concentrations at the orifices of the sample tubes. Treatment means of overall carbon dioxide levels were significantly different ($P \leq 0.01$) for curves followed by different letters in a repeated measures analysis of all times according to Duncan's NMRT. Error bars represent 95% confidence intervals.

the average concentration of carbon dioxide at the orifice of the sample tube was initially 18 $\pm$ 8 (SE) mmol/mol and dropped to a third this value as the gas diffused from the sample tube during the 30 min bioassay (Figure 2B). This source of carbon dioxide was highly attractive to the larvae, in that 82% of the larvae tested entered the sample tube, and more than half of these entered the sample tube within the first 5 min of the bioassay (Figure 2A).

In a choice test between a sample tube containing carbon dioxide (4 mmol/mol at bioassay initiation; Figure 3B) in association with cryogenically collected corn seedling volatiles and a sample tube containing an equal amount of carbon dioxide alone (4 mmol/mol at bioassay initiation; Figure 3B), significantly more ($P \leq 0.01$) western corn rootworm larvae chose the sample tube

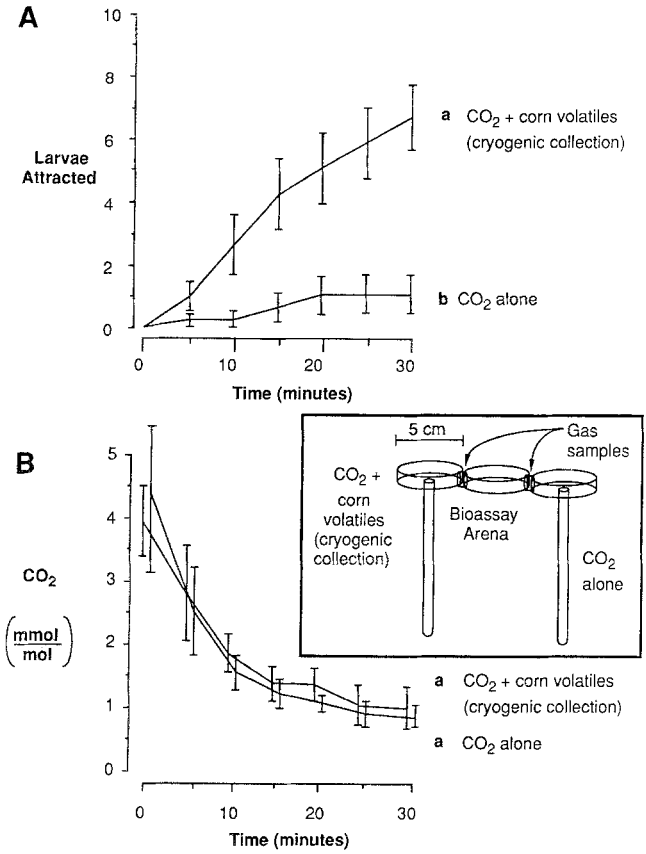

FIG. 3. (A) Double-tube bioassay to evaluate choice of western corn rootworm larvae between a sample tube containing carbon dioxide alone and a sample tube containing an equal concentration of carbon dioxide in conjunction with cryogenically collected corn seedling volatiles. Treatment means at time 30 min were significantly different ($P \leq 0.01$) for curves followed by different letters according to Duncan's NMRT. Error bars represent 95% confidence intervals. (B) Carbon dioxide concentrations at the orifices of the sample tubes. Treatment means of overall carbon dioxide levels were significantly different ($P \leq 0.05$) for curves followed by different letters in a repeated measures analysis of all times according to Duncan's NMRT. Error bars represent 95% confidence intervals.

with corn seedling volatiles (Figure 3A). It was essential that carbon dioxide concentrations be the same in both sample tubes, and GC-IRGA analysis verified that identical concentrations were effectively established by filling both types of sample tubes with carbon dioxide from a gas cylinder and inverting them for 30 sec (Figure 3B). The concentrations of carbon dioxide in each sample tube declined during the bioassay period as carbon dioxide diffused from the tubes, and the time course of carbon dioxide release from the two types of sample tubes was the same throughout the bioassay period (Figure 3B). The strong preference of the larvae for the sample tube containing corn seedling volatiles indicates that carbon dioxide is only one of the corn seedling volatiles attractive to western corn rootworm larvae and that other behaviorally important compounds are also produced by corn seedlings.

DISCUSSION

A central interest in studies in chemical ecology is to establish the complement of chemical compounds involved in a given ecological interaction and to determine how those compounds direct its course. We have shown that volatiles can be cryogenically collected from corn seedlings and that the isolated volatiles are attractive to western corn rootworm larvae. The only compound that has been implicated in host plant interactions with *Diabrotica* larvae is carbon dioxide (Strnad et al., 1986, Strnad and Bergman, 1987), a primary metabolite that is released by the roots of corn plants (Harris and van Bavel, 1957; Massimino et al., 1980). We found by GC-IRGA analysis that carbon dioxide is one of the compounds present in cryogenically collected corn seedling volatiles and verified that this compound was strongly attractive to larvae in our single-tube bioassay. The strong attraction of larvae to carbon dioxide in the single-tube bioassay (Figure 2A) would have made it difficult to determine any additional influence of other semiochemicals produced by corn seedlings. To make this distinction, we developed a choice test bioassay in which equal concentrations of carbon dioxide were present on both sides, and we found that the side containing corn root volatiles attracted significantly more western corn rootworm larvae. This indicates that a blend of volatile compounds from corn seedlings is involved in attraction of western corn rootworm larvae and that carbon dioxide is not the only compound in corn root volatiles of behavioral importance of *Diabrotica virgifera virgifera* larvae. Volatile secondary plant compounds have been shown to be important in location of host root systems by other species of insects that live in the soil but have not yet been implicated in host location by *Diabrotica* larvae (Jones and Coaker, 1978; Hsiao, 1985).

A number of volatiles from corn roots have been identified but have not been tested behaviorally with western corn rootworm larvae. Buttery and Ling

(1985) used the solid adsorbant Tenax to collect volatiles from the roots of young (60 cm high) and mature corn plants (2 m high). The principal volatiles recovered were sesquiterpene hydrocarbons that included beta-caryophyllene, logifolene, bazzanene (tentative), cyclosativene, alpha-ylangene, and a major hydrocarbon that was not identified. Volatile secondary compounds have also been identified from corn leaves (Buttery and Ling, 1984), buds (Thompson et al., 1974), silks (Flath et al., 1978; Cantelo and Jacobson, 1979), tassels (Buttery et al., 1980), and from husks and kernels (Buttery et al., 1978).

A review of the literature on volatile semiochemicals for soil insects indicates that two groups of compounds with very disparate vapor pressures have been considered. One group comprises gases such as carbon dioxide, nitrogen, oxygen, methane, and ethylene (see Jones and Coaker, 1977; Doane et al., 1975, and references therein). Carbon dioxide alone is attractive to a number of soil invertebrates, including insect larvae (Klingler, 1957, 1958, 1965, 1966; Doane et al., 1975; Städler, 1971, 1972; Paim and Beckel, 1963a, b; Meeking et al., 1974; Jones and Coaker, 1977), insect adults (Paim and Beckle, 1963a, b), mites (Moursi, 1962, 1970), chilopods (Moursi, 1970), nematodes (Pline and Dusenbery, 1987; Prot, 1980; Johnson and Viglierchio, 1961; Klingler, 1961, 1963, 1965), and bacteria (Scher et al., 1985). The other group of volatile semiochemicals for soil invertebrates comprises secondary compounds with considerably lower vapor pressures that can easily be collected by tissue extraction, steam distillation, or air extraction with solid adsorbants (Jones and Coaker, 1978; Hsiao, 1985).

Volatile secondary compounds important in underground attraction of larvae have been chemically identified for several insect species (all of them Diptera), including the carrot rust fly, *Psila rosae* (F)., the onion maggot, *Delia antiqua* (Meigen), the turnip maggot, *Delia floralis* (Fallen), and the related species *Delia brassicae* (Wiedemann). For the carrot rust fly *Psila rosae*, an insect that has a high degree of host specificity for certain species of Umbelliferae, carbon dioxide is one of several attractants that have been found for underground larvae (Jones and Coaker, 1977, 1979). Of 45 volatile secondary compounds that have been identified from fresh carrot root, five have been found to be most attractive to carrot rust fly larvae: bornyl acetate, 2,4-dimethyl styrene, alpha-ionone, beta-ionone, and biphenyl (Ryan and Guerin, 1982, Guerin and Ryan, 1984). Underground larvae of the onion maggot *Delia antiqua* are able to orient to onion volatiles (although host selection is primarily made by the ovipositing females). The larvae showed strong attraction to 27 synthetic sulfides, disulfides, and mercaptans in a laboratory bioassay (Matsumoto and Thorsteinson, 1968; Matsumoto, 1970, Soni and Finch, 1979), although only some of these compounds are known to be released from onions (Carson and Wong, 1961. Rotting onions are more attractive to larvae (and to ovipositing females) than are fresh onions, and it has been established that this is due to

the activity of *Klebsiella* bacteria, although it is not yet clear which volatiles of *Klebsiella*-infestated onions are responsible for the enhanced attraction (Ikeshoji et al., 1980, 1982, Yamada et al., 1981). Underground larvae of some *Delia* species feed only on certain species of Cruciferae. Larvae of the turnip maggot *Delia floralis* (Rygg and Somme, 1972) are attracted to allyl isothiocyanate, a characteristic volatile of many Cruciferae. A source of mustard oil glucosides is attractive (perhaps because of volatile degradation products) to the related species *Delia brassicae* (Finch and Skinner, 1974).

Volatiles have been shown to play a role in host location by underground larvae of several other insect species, but the compounds involved have not yet been chemically characterized. The false wireworm *Eleodes suturalis* (Say) was attracted to volatiles in an airstream passed over germinating wheat (Calkins et al., 1967). Sutherland (1972) found that subterranean larvae of the scarab beetle *Costelytra zealandica* (White) were attracted to fresh perennial ryegrass root in a laboratory bioassay. Neonate larvae of the clover root curculio *Sitona hispidulus* (F.) are attracted to roots of alfalfa *Medicago sativa* L. and red clover *Trifolium pratense* L. and are attracted in particular to *Rhizobium* nodules on the root systems (Wolfson, 1987).

Adults of some insect species have also been shown to orient underground to volatile secondary plant compounds, either for feeding or for oviposition. Underground adults of the scolytid *Hylastinus obscurus* Marsham, the clover root borer, feed on the diseased roots of red clover, *Trifolium pratense* (Leath and Byers, 1973), and behavioral bioassays for attraction have been performed with organic extracts of diseased roots and with organic extracts of a solid adsorbant (Tenax) used for air extraction of diseased roots (Kamm and Buttery, 1984). Of the compounds identified from diseased root tissue, the most attractive in a laboratory bioassay were ethyl laurate, ethyl benzoate, estragole, chavicol, pentadecanal, hexadecanal, and hexanoic acid. These compounds were not attractive in the field when presented alone or in combination (Kamm and Buttery, 1984). Adults of the pine weevil *Hylobius abietis* (L.) (Nordlander et al., 1986) and of the scolytid *Hylastes nigrinus* (Mann.) (Rudinsky and Zethner-Moller, 1967) locate conifer roots suitable for oviposition by using host volatiles diffusing through the soil.

The basis for host specificity in western corn rootworm larvae has not yet been determined. *Diabrotica virgifera virgifera* is an oligophagous species, feeding only on certain species of grasses. Branson and Ortman (1967, 1970) made a rigorous survey of the host plants suitable for larval development. Of 44 grass species tested, 18 supported rootworm larval growth for at least 10 days. No larvae survived 10 days on any broad-leaf species tested. In choice tests between cut roots of corn and of nonhost broad-leaved plants in a surface olfactometer, Branson (1982) found that significantly more western corn rootworm larvae were attracted to roots of corn than to roots of soybean, squash,

or sunflower (no difference was found for tomato roots vs. corn roots). In tests with a variety of grass species, many nonhost grass species were as attractive as corn or more so. Even the nonhost grass sorghum was found to be attractive (Branson, 1982) and to elicit feeding from western corn rootworm larvae (Branson et al., 1969), despite the fact that the roots contain cyanogenic glycosides that are lethal to the larvae. These results indicate that the olfactory cues used by western corn rootworm larvae in host location may be restricted to a range of grass species, limiting the amount of searching that must be done in the soil, but are not rigorously restricted to the grass species on which western corn rootworm larvae occur. We have shown that a blend of volatile compounds from corn seedlings is attractive to western corn rootworm larvae, and if these compounds are limited to some members of the Gramineae, this may provide a basis for olfactory discrimination by western corn rootworm larvae between grasses and broad-leaved plants.

Acknowledgments—We would like to thank Dr. Jan Jackson from the Northern Grain Insects Research Laboratory in Brookings, South Dakota, for donating eggs of a nondiapausing strain of *Diabrotica virgifera virgifera* to initiate our colony and for providing advice concerning various aspects of this research. Dr. Deborah Kendall critically reviewed the manuscript and assisted in maintaining the insect colony. We thank the Colorado State University Microservices Lab for assistance in plotting data, and we thank Mr. James Zumbrunnen from the Colorado State University Statistics Laboratory for assistance in data analysis. This research was funded by the Colorado Agricultural Experiment Station.

Book Review

Insect–Plant Interactions. J.R. Miller and T.A. Miller (eds.). New York, Springer Verlag, 1986. $67.00, DM 158.00, xii + 342 pp.

The title of this volume does not indicate that the book deals primarily with methods and techniques. A discussion of this subject is, however, most useful since everyone actively engaged in the field of insect–plant studies encounters experimental problems that arise from dealing with two completely different types of organisms. Insects and plants each have their own peculiar physiological features and their own typical degree of variation. Because of these essential differences, the proper design of experiments is often tremendously complicated.

This book, published within the Springer Series in Experimental Entomology, aims at presenting "approaches and methods at a level useful to nonexpert and expert researchers." Before reading the contents, I made a short list of topics that I would expect in a book of this format. It included: feeding and oviposition behavior under laboratory and field conditions, variability and adaptability of behavior (including learning), orientation, sensory responses (electrophysiological methods), artificial diets, nutritional parameters, plant resistance to insects, expression of plant responses, standardization of insects and plants (including genetic aspects), biological rhythms, insect–flower interactions, marking methods, data analysis and statistical tests, and terminology of insect and plant reactions. All of these subjects (with the notable exception of insect–flower interactions) have been discussed, in several instances in more than one place. Most of the authors selected by the editors have great experience in their fields of study, and all chapters reflect their authoritative position on the topics assigned to them. The format of the book is not that of a cookbook or a manual on techniques and methods. Rather, each chapter presents certain aspects of insect–plant relations, with an emphasis on methods, embedded in a discussion of the present state of understanding of that topic. The advantage of this approach is that the book is very readable, since it gives more than only techniques. Also, the presentation of views and hypotheses within a methodological framework often leads to a rearrangement of known facts, which makes stimulating reading. The disadvantage of this approach is that it often takes some effort by the reader to locate a certain method and the discussion of its ins and outs. However, this problem is to a large extent compensated for by a good index.

0098-0331/88/0600-1541$06.00/0

The opening chapter by S.B. Opp and R. Prokopy is a well-balanced general introduction to the study of insect behavior, its pitfalls, and some of the technical aids available. Two chapters are devoted to behavioral studies in the field situation. The contribution by S. Fich contains a lucid discussion of experimental design and trapping devices, especially applicable to crop vegetations. M. Singer discusses behavioral studies in natural habitats and includes a highly informative case study of a butterfly. A.C. Lewis and H.F. van Emden present an incisive and critical review on feeding assays, historically the most important approach to the analysis of insect–plant relationships and still an extremely fruitful method. Three chapters are devoted to measuring food quality. M. Kogan elaborates on nutritional parameters and thus presents an appreciable extension to G.P. Waldbauer's famous founding paper (1968) on this subject. Postingestive effects of plant allelochemics on insects are authoritatively discussed in two chapters by M. Berenbaum and I. Ishaaya, respectively. Since plant chemicals play an overwhelming role in most insect–plant interactions, it seems appropriate to discuss problems associated with isolating and identifying chemical plant constituents, although this subject as a whole is clearly outside the scope of the present book. To treat this within the framework of one chapter is an unenviable task. I. Kubo and F.J. Hanke have chosen to discuss recent developments in analytical plant chemistry in this area, exemplified by one group of compounds of physiological importance, phytoecdysteroids. A special and very useful chapter (W.M. Tingey) is devoted to evaluating plant resistance to insects, the very heart of agricultural entomology. This is also the place where the effects that insects may induce in the plant receive some attention, thus justifying the term "interactions" in the title of the book. Last but not least comes the electrophysiological analysis of insect chemoreceptory capacities. J.L. Frazier and F.E. Hanson present a clear account of this approach, including its potential for the understanding of insect–plant relationships.

On one hand, the volume is a rich source of available methods and techniques although, as indicated before, one has occasionally to dig a bit to find the information desired. On the other hand, it is more than that. It also presents current lines of thinking in this rapidly expanding area of biology and makes one appreciate once more that scientific advancements are, to a large extent, determined by the techniques available. Clearly there is some dualism in the approach chosen, in which discussions of methods and useful techniques are combined with views on principles underlying insect–plant relationships. I would have preferred that the discussion was restricted to methods.

Of course, a book of this size cannot be expected to give a complete and exhaustive treatment of the subject. For instance Dethier's screen test is not mentioned, nor are Jermy's sandwich test and Saxena's grid test, all of them simple but rewarding methods. Some chapters (e.g., 7 and 9) hardly cite papers published after 1980, whereas others (e.g., 10) contain references up to 1984.

Addition of an author index would have increased its usefulness. The book is produced attractively.

In conclusion, this volume belongs in any library of experimental entomology, and it makes good reading for both advanced and beginning researchers in the field of experimental insect–plant studies. I suspect this volume will have a long half-life value.

Book Review

Pheromone Biochemistry. G.D. Prestwich and G.J. Blomquist (eds.). New York, Academic Press, Inc. 1987. xix + 565 pp.

Pheromones are used throughout the animal kingdom for chemical communication among members of a species, particularly to ensure reproductive success. This book concentrates primarily on the biosynthesis, catabolism, and reception of sex pheromones in insects. Besides providing an excellent overview of this field, many of the chapters include methodological critiques and discuss new approaches for the study of these processes.

At the outset of the first section covering pheromone biosynthesis and its regulation, Tumlinson and Teal give a good overview of insect pheromone biochemistry as detailed in the remainder of the book. Then come technique-oriented chapters on sex pheromone gland ultrastructure and on pheromone biosynthesis in Lepidoptera. These chapters are crammed with specific methodology along with critical assessments, which should be extremely valuable to workers in these areas. Following are reviews of endocrine regulation of pheromone production in Lepidoptera, Coleoptera, Diptera, and in the ixodid ticks. For the Coleoptera and Diptera (primarily the house fly), these include a summary of the pheromones and their biosynthesis. Interestingly, the various groups use different endocrine signals to regulate pheromone production: ecdysteroids in the Diptera and ticks, juvenile hormone in the beetles, and neurosecretory hormones in the Lepidoptera. In beetles many of the pheromones are derived from plant host chemicals either by the beetle itself or by associated microorganisms. Plant-derived pheromones may also be important in sexual selection in Lepidoptera as portrayed in a series of short, thought-provoking vignettes by Eisner and Meinwald. The section ends with a detailed analysis of the terpenoid biosynthetic origin of cantharidin in blister beetles.

The second part of the book discusses reception and catabolism of sex pheromones, beginning with a nicely illustrated review of the functional morphology of the pheromone-sensitive sensilla. These sensillae are very selective, highly sensitive, and able to respond to rapid changes in pheromone concentration. Understanding these properties at both the neurophysiological and the biochemical levels is the basis of two reviews of recent studies that are providing new insights into the mechanisms involved. The study of the biochemical mechanisms of pheromone reception required new chemical approaches that Prestwich discusses in detail. The book closes with a short review of the molecular

0098-0331/88/0600-1545$06.00/0

mechanisms of vertebrate olfaction that shows the many parallels with pheromone reception in insects.

In spite of the omission of the social insect pheromones, this book can be highly recommended to graduate students and postdoctoral and seasoned researchers in pheromone biochemistry. It provides an excellent basis for future research in this field.

POTENTIAL FOR EVOLUTION OF RESISTANCE TO PHEROMONES
Worldwide and Local Variation in Chemical Communication System of Pink Bollworm Moth, *Pectinophora gossypiella*

KENNETH F. HAYNES[1] and THOMAS C. BAKER

Division of Toxicology and Physiology
Department of Entomology,
University of California
Riverside, California 92521

(Received June 15, 1987; accepted September 15, 1987)

Abstract—Female *Pectinophora gossypiella* (Saunders) from most of the desert cotton-growing areas of southern California emitted significantly more pheromone in 1984 and 1985 than in preceding years (1982 and 1983). This increase amounted to almost 20% by 1985. It is unlikely that this small change would represent effective resistance to disruptant pheromones, but this increase could reflect the result of selection pressure imposed by the use of mating disruption for population control. A worldwide survey of emitted pheromone from this species found that there was much more variation in the emission rate than the blend ratio of the two pheromone components. The emitted blend ratio was remarkably consistent over time (in southern California) and throughout the worldwide range of the insect. Small differences in the blend ratio that were detected probably have no major biological significance because of the relatively broad response spectrum of males to changes in the blend of pheromonal components. Populations of males did not consist of several phenotypes, each with a different preference for specific blend ratios. Rather, the broad response spectrum to blend ratios in a population can be attributed to variation in the response of any individual. Therefore, selection for a response phenotype that is narrowly tuned to the blend emitted by females may be difficult.

Key Words—Resistance, mating disruption, sex pheromone, (*Z*,*Z*)-7,11-hexadecadienyl acetate (*Z*,*E*)-7,11-hexadecadienyl acetate, Lepidoptera, Gelechiidae, pink bollworm, *Pectinophora gossypiella*.

INTRODUCTION

Selection imposed by the use of synthetic sex pheromones to disrupt mating of key agricultural insect pests could result in evolutionary changes in their chemical communication systems. The potential for rapid evolution of resistance to these mating disruptants will depend in part on heritable variation in the characteristics of chemical communication such as the emission rate, the emitted blend ratio of pheromone components, or phenotypic variation in the response of males to different blend ratios of pheromone components.

An ideal subject species for studying the potential for evolution of resistance to pheromones is the pink bollworm moth, *Pectinophora gossypiella* (Saunders), because its communication system has been examined extensively and certain populations have been exposed to mating disruptants for many generations. The sex pheromone of *P. gossypiella* consists of two components (*Z*,*Z*)- and (*Z*,*E*)-7,11-hexadecadienyl acetate (*ZZ*7,11-16:Ac and *ZE*7,11-16:Ac, respectively) (Hummel et al., 1973; Bierl et al., 1974). A blend of these components centered about a 1:1 *ZZ*/*ZE* ratio has been used by many cotton growers in the desert Southwest to disrupt mating of this species since the first commercially available mating disruptant was registered by the U.S. Environmental Protection Agency in 1978 (Doane and Brooks, 1981). Recently, Haynes et al. (1984) reported that these components were emitted from the sex pheromone gland in a blend ratio of 61:39 *ZZ*:*ZE*7,11-16:Ac, and Linn and Roelofs (1985) found that male *P. gossypiella* responded optimally to *ZZ*/*ZE* blend ratios between 60–65:40–35 at low emission rates of these components. Haynes et al. (1984) examined populations of *P. gossypiella* throughout southern California for evidence of resistance to sex pheromones used as mating disruptants. No differences in the emission rates or blend ratio of these pheromone components were documented in a comparison of females from fields with a long history of pheromone treatments to females from fields that received principally insecticide treatments. While these results were encouraging for continued effective use of mating disruption to control this species, it was important to expand this study in three critical ways. First, there was a need to continue this sampling for several years in case resistance to sex pheromones could not be detected in local populations because of migration among these populations. This procedure might establish a temporal record of changes in the communication system. Second, by sampling throughout the much broader geographical distribution of this species, in this case the worldwide distribution, one might detect differences between these populations that could correlate to the general pattern of use of mating disruptants in an area. In addition, this study of geographical variation in the emission rate and blend ratio might establish whether changes in the communication system of this species have occurred over the much longer period of time in which the species range has expanded. Third,

since heritable variation in the response of males to blend ratios could accelerate significantly the development of resistance, an analysis of phenotypic variation in the behavioral response to blend ratios was undertaken within a single field population.

METHODS AND MATERIALS

Collection and Handling of Insects from California. Cotton bolls were collected from selected cotton fields in the three major cotton-producing valleys in southern California (Coachella, Imperial, and Palo Verde valleys) during August through October. In each valley an attempt was made to select fields with different histories of use of mating disruptants. When possible, fields with no exposure to disruptant pheromones (called insecticide-treated fields) and fields with three to five years of treatment with disruptant pheromones (called pheromone-treated fields) were selected. Because of prevailing agricultural practices in some valleys (e.g., crop rotation) and changing patterns of disruptant pheromone use, it was not always possible to group fields into these two categories. For example, no pheromone-treated fields were identified in Coachella Valley in 1985, and every cotton field in Imperial Valley was treated with disruptant pheromone in 1982. Between 1000 and 3000 cotton bolls were collected in each field, and the bolls were transported to Riverside, California, where they were stored in screened cages in a lath house. Handling of cotton bolls and emerging insects was identical for all four years of the experiment and followed the protocol detailed by Haynes et al. (1984).

Laboratory *P. gossypiella* were reared on shredded wheat-germ diet in half-gallon cartons (Haynes et al., 1984). The procedure for handling the laboratory-reared pupae and adults was identical to that followed for field-collected insects. The laboratory population originated from insects collected before 1976 from fields in Coachella Valley.

Collection and Handling of Insects from Around the World. Collaborators in Argentina, Brazil, China, Egypt, Mexico, and Pakistan shipped field-collected last-instar larvae or pupae by the quickest practical method to the quarantine facility in the Division of Biological Control, Department of Entomology. At this facility pupae were separated according to sex. Adult females that had emerged within a 24-hr period were taken out of the quarantine facility in individual cages that were then housed in an environmental chamber with laboratory-reared females.

Collection and Quantification of Emitted Pheromone. Pheromone was collected from individual female *P. gossypiella* during their peak period of calling during the last half of the scotophase, following the procedures described by Haynes et al. (1984). The female's wings were folded back over her head and

she was inserted abdomen-first into a 2.0-mm-ID glass tube with a 0.5-mm (diam.) hole at the distal end. This hole was large enough to allow only the ovipositor and associated pheromone gland to emerge when light pressure was applied to the female's head with a pipe cleaner. The glass tube was then inserted through a Teflon-coated GLC septum into the collector. Volatiles emitted from the gland's surface were collected for 10 min (at ca. 25°C). An internal standard [3.0 ng of (*Z*)-7-hexadecenyl acetate (*Z*7–16:Ac) in 5 μl of CS_2] was added to the glass wool before the inside of the collector was rinsed with ca. 200 μl of CS_2. This volume of CS_2 was reduced under a nitrogen stream to ca. 6 μl before it was pulled up into a 10-μl syringe for injection onto the GLC column.

It was critical that the internal standard remained at a constant concentration throughout the four years of the experiment. We ensured this consistency by maintaining several reference standards of *Z*7–16:Ac that were not used as internal standards, but were compared by GC analysis to the internal standard on a daily basis. In this way a change in the concentration of the internal standard of a few percent was easily detected. An increase in concentration occurred during repeated opening of the vial containing the internal standard. An internal standard was discarded as soon as the concentration change was detected. All standards were stored at −20°C. Before each year's collections, a set of new standards were prepared from >98% pure *Z*7–16:Ac and were compared to the previous years'. No changes in concentration of the standards were noticed during storage between years.

Analyses were made on a Varian 3700 gas chromatograph equipped with a hydrogen flame detector, a Hewlett-Packard 3380A integrator, and a Silar 10C packed column (ca. 4 g of 10% Silar 10C on acid-washed 100–120 mesh Chromosorb W; glass column 3 m or 4 m; oven temperature ca. 175°C; N_2 flow rate of 30 ml/min). Over the four-year course of the experiment, several columns were used. Consistency in the ability of the columns to separate the pheromone isomers was checked by analyzing a standard that contained 2 ng *ZZ*7,11–16:Ac and 1.33 ng *ZE*7,11–16:Ac in 5 μl of CS_2 (60% *ZZ*7,11–16:Ac). The column was replaced or repacked if accuracy was lost in determining the blend ratio of this standard.

The amount of each isomer was calculated from a standard curve relating peak to mass. These values were corrected for recovery efficiency by standardizing the measurements relative to the internal standard. The lower analytical limit of our technique was ca. 0.1 ng (0.01 ng/min).

Variation in Males' Responses to Different Blend Ratios. Synthetic *ZZ*- and *ZE*7,11–16:Ac were purchased from Scentry Inc. (Buckeye, Arizona) and were determined to be greater than 93% free of other sex pheromone-like volatiles by GLC analysis. *ZZ*7,11–16:Ac contained as much as 4% *ZE*7,11–16:Ac. *ZE*7,11–16:Ac contained as much as 3% *ZZ*7,11–16:Ac. Hexane solutions of four blend ratios (38:62, 48:52, 58:42, and 68:32 *ZZ*:*ZE*) were

prepared taking into account the cross-contamination of the original materials. Using a pheromone collection device, it was determined that the emitted blend ratios from rubber septa treated with 5 mg of the two acetates were within 1% of the desired 40:60, 50:50, 60:40, and 70:30 blends of *ZZ*- and *ZE*7,11-16:Ac. Interestingly, the emitted blend ratio was always slightly biased towards the *ZZ* isomer relative to the blend loaded onto the rubber septum. The two pheromone components together were emitted at a rate of ca. 1.8 ng/min.

Sixty-four modified traps for marking males with fluorescent powders were deployed in a cotton field in Coachella Valley, California, during September 1984. These marking stations were evenly spaced in an 8 × 8 grid with 20 m between traps, and there was at least 40 m between every trap and the edge of the cotton field. The 64 marking stations consisted of 16 quartets arranged in a square. Each of the four blend ratios was used to bait a single marking station within each quartet.

The marking stations were cylindrical metal traps (height 13.5 cm, diam. 25 cm) with four 12.5-cm (width) by 3.5-cm (height) holes spaced evenly around the midline of the cylindrical surface. Each station contained a paper plate (25 cm diam.) that fit into the trap's bottom below the level of the holes. About 50 ml of fluorescent powder (Day-Glo Color Corp., Cleveland, Ohio) were spread evenly over the plate's surface. Four colors of fluorescent powder were used: Aurora Pink for the 40:60 blend, Horizon Blue for the 50:50 blend, Saturn Yellow for the 60:40 blend, and Blaze Orange for the 70:30 blend of the *ZZ* to *ZE* isomers. A pheromone-impregnated rubber septum was fixed with a color-coded straight pin to a cork that was in turn stapled to the paper plate.

Traps that were used to permanently capture males were similar to the marking stations, except paper plates coated with Stickem Special replaced the plates covered with fluorescent powder. Both marking stations and traps were placed at a height of about 1 m with three 1.2-m-long redwood stakes. Traps were placed at the center of each quartet of marking stations. Marking stations were only baited on the first, third, and sixth nights of the experiment, and traps were baited on the second, fourth, fifth, seventh, and eighth nights; thus marking stations and traps were not baited at the same time. Positions of traps were rerandomized before each trapping night of the experiment.

RESULTS

Comparison of Populations from California Valleys and Laboratory over Four Years. The emission rate of *ZZ*7,11-16:Ac from field-collected females was significantly higher during the last two years of the experiment (1984 and 1985) than during the first two years (1982 and 1983) (Table 1). On average a field-collected female emitted 19.3% more *ZZ*7,11-16:Ac during 1985 (0.117

TABLE 1. EMISSION RATE OF ZZ7,11–16:Ac (ng/min) FROM THREE VALLEYS IN CALIFORNIA AND LABORATORY COLONY FOR 1982–1985

	$\bar{X}$ Emission rate (ng/min) of ZZ7,11–16:Ac + SD (*N*)			
	Coachella	Imperial	Palo Verde	Laboratory
1982	0.086 ± 0.049 (47)cde[a]	0.099 ± 0.054 (145)bc	0.100 ± 0.056 (216)bc	0.094 ± 0.050 (52)cd
1983	0.082 ± 0.033 (76)cde	0.074 ± 0.031 (54)e	0.092 ± 0.042 (227)cde	0.080 ± 0.046 (80)de
1984	0.115 ± 0.041 (90)ab	0.117 ± 0.037 (100)a	0.131 ± 0.046 (77)a	0.085 ± 0.049 (76)cde
1985	0.120 ± 0.034 (35)a	0.119 ± 0.042 (62)a	0.114 ± 0.049 (101)ab	0.090 ± 0.054 (83)cde

[a] Any means followed by the same letter are not significantly different ($P > 0.05$, analysis of variance and Duncan's new multiple-range test).

ng/min) than during 1982 (0.098 ng/min). The difference between field-collected females and the laboratory-reared population was greatest in 1984 when the former (0.120 ng/min) emitted 41.2% more *ZZ*7,11–16:Ac than the latter (0.085 ng/min). Unlike the results of analyses of volatiles from field-collected females, the emission rate of pheromone did not change from year to year in the laboratory population.

The blend ratio of the two pheromonal components showed no significant trend towards increasing or decreasing over the course of our sampling in either the field populations or the laboratory population (Table 2). No valley consistently had females that emitted a higher or lower blend ratio than those from the other valleys or the laboratory. The significant differences that were documented between valleys were small—the range of mean percent *ZZ*7,11–16:Ac was only 60.1–62.9.

For the subsample of fields that could clearly be separated according to their history of pheromone use, there was no relationship between this history and the emission rate or blend ratio of components (Table 3).

Worldwide Variation in Chemical Communication. The highest emission rate of *ZZ*7,11–16:Ac was found in females from Californian populations (0.119 ng/min), followed by a population from Egypt (0.103 ng/min) (Figure 1). The average emission rate from females from a Chinese population was 0.057 ng/min, and was significantly lower than the other populations with the exception of that from Brazil, which was intermediate (0.082 ng/min).

The Chinese population was also unusual in terms of the emitted blend ratio of pheromonal components (Figure 2). Females from this population emitted 57.5% *ZZ*7,11–16:Ac, significantly lower than all other populations sam-

[a] Emission rate is ng of *ZZ*7,11-16:Ac emitted per minute.
[b] Blend ratio is % *ZZ*7,11-16:Ac in two-component blend.
[c] Significantly different pair of means ($P < 0.05$, Analysis of variance).

pled. The overall range in mean percent *ZZ*7,11-16:Ac emitted was small (57.5-63.1).

Variation in Males' Response to Different Blend Ratios. Over the course of this experiment we captured 13,303 male *P. gossypiella*, of which 331 (2.5%) were marked at least once. The 70:30 blend of *ZZ*- to *ZE*7,11-16:Ac captured significantly fewer moths than the 40:60 blend, and there were no other significant difference between blends. Because these traps were approaching their numerical capacity to capture and retain males, the absolute numbers captured are not useful. However, the proportion of males marked with fluorescent powders and subsequently captured should provide an accurate estimate of the proportion of males that actually visited the marking station.

Fluorescent marks were detected in the following proportions: 100 pink, 94 blue, 101 yellow, and 82 orange (pink = 40:60, blue = 50:50, yellow = 60:40, and orange = 70:30 *ZZ*:*ZE*7,11-16:Ac). A 4 × 4 chi-square analysis revealed that there was no significant relationship between marking and recapturing at specific blend ratios ($\chi^2 = 4.2$, 9 *df*). Figure 3 illustrates that some individuals that had responded to specific marking blends were subsequently recaptured in every capture blend. Fourty-two males (0.3% of total number of males captured) were marked with two or more colors. They were captured in the following numbers 10 P/B, 5 P/Y, 5 P/O, 6 B/Y, 7 B/O, 9 Y/O. Of these males, 20 were captured at a blend that was different from any to which they were marked, indicating that they had responded to at least three blends. Two males were marked at three different blend ratios, and one of these had visited every blend ratio that was available when the capture blend was considered.

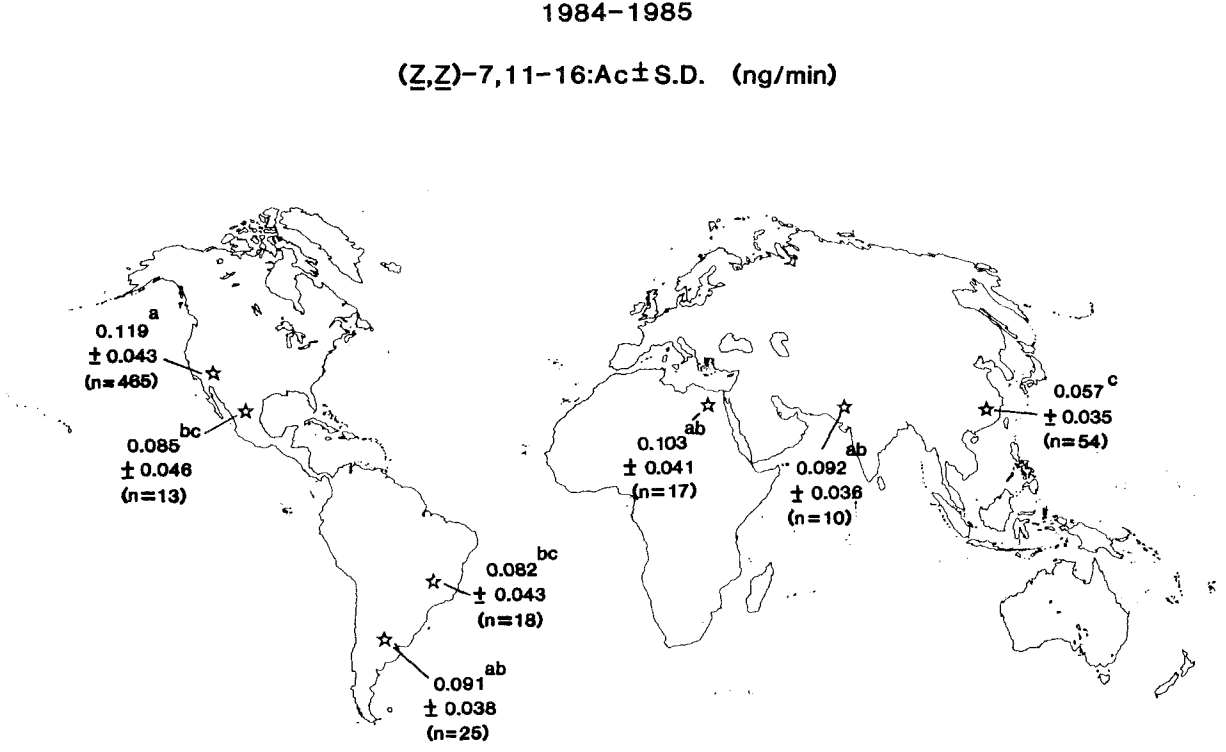

FIG. 1. Worldwide variation in the emission rate of *ZZ*7,11–16:Ac from the sex pheromone glands of female *P. gossypiella*. Means followed by the same letter are not significantly different ($P > 0.05$, analysis of variance and Duncan's new multiple-range test).

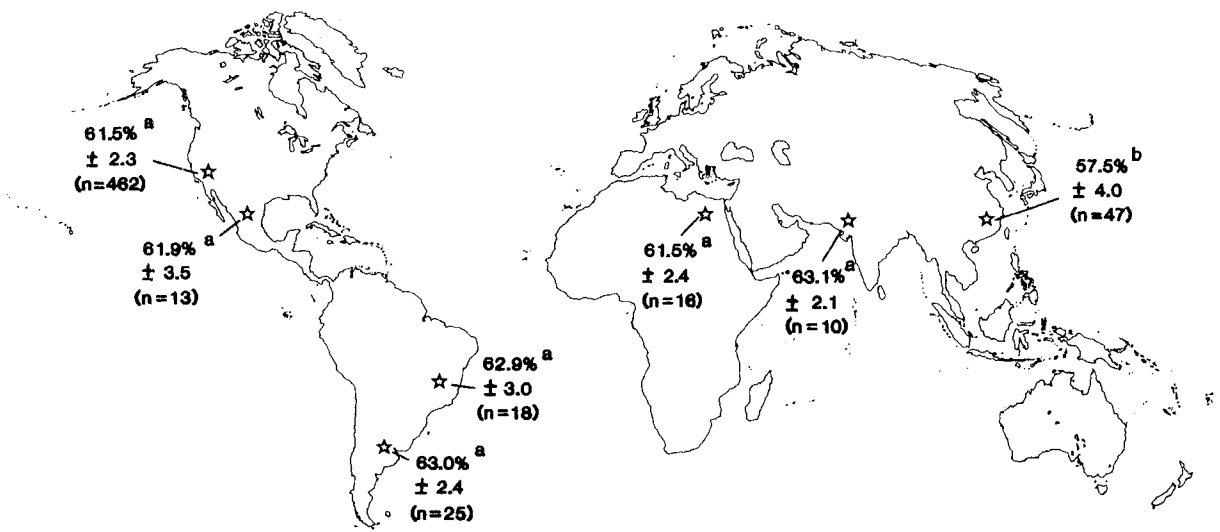

FIG. 2. Worldwide variation in the emitted blend ratio of ZZ7,11-16:Ac and ZE7,11-16:Ac expressed as % ZZ7,11-16:Ac, from female *P. gossypiella*. Means followed by the same letter are not significantly different ($P > 0.05$, analysis of variance of arc sin $\sqrt{\%\ ZZ}$ and Duncan's new multiple-range test).

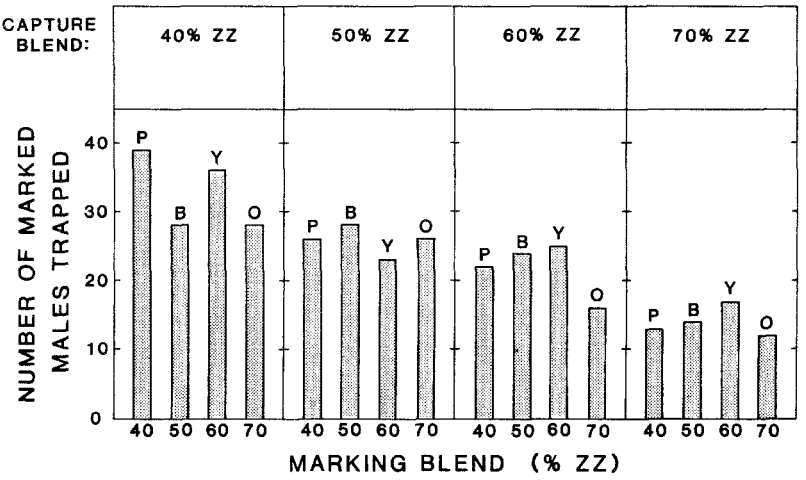

FIG. 3. The number of male *P. gossypiella* captured at indicated blend after being marked with fluorescent powders. Fluorescent marks established record of prior responses to specific blend ratios of pheromone components (P = pink = 40:60; B = blue = 50:50; Y = yellow = 60:40; O = orange = 70:30 *ZZ*- to *ZE*7,11-16:Ac).

DISCUSSION

The present study documents biological (phenotypic) variation in pink bollworm populations from southern California that has occurred over the four-year course of this experiment. Our data are not sufficient to unequivocally support the hypothesis that selection imposed by the use of mating disruption caused these changes. Rather this hypothesis should be considered as but one of a number of viable explanations, including undocumented changes in the environment with no underlying genetic change, selection imposed by some unknown factors that have resulted in the documented phenotypic change, or genetic drift with no underlying selection pressure. Regardless of the cause(s), however, the populations in 1984 and 1985 contained females emitting higher average amounts of pheromone and should have been, at least hypothetically, slightly less susceptible to the effects of synthetic disruptants than populations in previous years. We believe that any such advantage gained by females in these populations would have been too slight to result in significant loss of efficacy of the disruptant pheromone, and thus should not have had any major effect on overall population growth.

There is some indirect support for the idea that the increase in emission rate of pheromone in southern California in 1984 and 1985 could be related to the use of synthetic sex pheromone to disrupt mating. First, pheromones have been used there on a commercial basis for control of the pink bollworm moth

for over eight years. Second, field documentation of a possible selective advantage for a higher emission rate from point sources in disruptant-treated field was supplied by Doane and Brooks (1981), who showed that increasing emission rates of synthetic pheromone (*ZZ*- and *ZE*7,11-16:Ac) from traps lead to increasing captures of male moths in pheromone-treated fields. Third, in the laboratory, Collins and Cardé (1985) showed that the heritability of pheromone quantity was slightly greater than for blend quality, and they have been able to select for a line of *P. gossypiella* in which the females contain almost twice as much *ZZ*- and *ZE*7,11-16:Ac in their sex pheromone glands (personal communication). Thus the potential for a response to selection has been demonstrated in the laboratory.

One observation is not necessarily consistent with the hypothesis of selection for increased emission rate in field populations as a response to use of disruptant pheromone. In 1982 an areawide program was in effect in Imperial Valley in which all cotton growers utilized pheromone applications for control of *P. gossypiella* for part of the growing season. This program represented one of the most extensive uses of disruptant pheromones in agriculture to date, but it did not result in an immediate increase in pheromone emission rate from field-collected females. In fact, the emission rate from females collected in Imperial Valley in 1983 was 0.074 ng/min, the lowest average that was recorded.

Unlike the phenotypic variation in emission rate that was documented in field populations, the emission rate of *ZZ*7,11-16:Ac from laboratory females remained relatively constant throughout the four-year period. This consistency in the laboratory population was expected because of the constancy of environmental conditions and the lack of selection pressure for increased emission rate under laboratory conditions.

Based on our first year of sampling (Haynes et al., 1984), we anticipated that if any change occurred in the blend ratio, it would be an increase in the *ZZ* to *ZE* ratio, because a blend centered about a 50:50 ratio has been used as the standard commercial blend to disrupt mating, whereas females emit ca. a 60:40 blend. This could mean that directional selection might be imposed on the pheromone blend. However, in the present study the blend ratio of *ZZ*- to *ZE*7,11-16:Ac was relatively constant throughout the period of the study (Table 2). Selection on the emitted blend ratio may be more difficult because it would involve changes in both males and females, unless there was close genetic linkage between emission and response.

Our analyses of pheromone components emitted by females from around the world was consistent with greater interpopulational variation in the emission rate than in the blend ratio of components. While the blend ratios emitted by females from China were significantly lower that those from any other locality, the overall difference was small. In contrast, females from China emitted about half as much pheromone as those from southern California. It would be inter-

esting to obtain pink bollworm moths from Australia because *P. gossypiella* and *P. scutigera*, the pink-spotted bollworm, are sympatric in certain areas of this country. The two species respond to different blend ratios of *ZZ*- and *ZE*7,11–16:Ac (Rothschild, 1975), and thus interspecific selection pressure may have led to divergence of their blend ratios or to a narrowing of the broad response spectrum of males to blend ratios of the pheromone isomers. Our initial attempts to obtain sufficient numbers of moths from Australia were not successful because cotton production no longer occurs in areas where *P. gossypiella* occurs on wild plants (S.E. Learmonth and G.H.L. Rothschild, personal communication).

If selection is resulting in the changes in the pheromone communication system of *P. gossypiella*, then why are we unable to detect these differences between pheromone- and insecticide-treated fields in southern California? One possibility is that local differences between populations may be swamped by migration between fields within a valley and possibly between valleys. While the potential impact of migration on gene flow has not been evaluated in any quantitative way, the occurrence of such migration is well documented (Bariola et al., 1973; Flint and Merkle, 1981; Stern, 1979).

Since our marking–capture analysis of variation in the response of males to blend ratios from 40:60 to 70:30 indicated that there was no evidence of phenotypic variation between individuals, the potential for rapid selection for a preadapted phenotype that responds specifically to the blend released by the female and not to the blend used to disrupt mating seems unlikely. The major source of variation in the response of males to blends comes from variation within individuals rather than between individuals. It would seem that in order for resistance involving blend ratios to evolve rapidly, the population would need to begin with males having narrower blend ratio response spectrums than we measured here. Cardé et al. (1976), who first applied this marking–capture technique to the Oriental fruit moth, *Grapholita molesta*, also found no evidence of phenotypic variation in the response of males to different blends of the pheromone components of that species.

Considering the results of our experiments, it is possible that the observed increase in the females' emission rate of pheromone may be an early response to selection imposed by the use of disruptant pheromones, but other undocumented factors may play a role in this biological variation that has been followed for four years. Evolutionary changes in the blend ratio may be inherently more difficult because males have a broad response spectrum to variation in blend ratio (Flint et al., 1979; Linn and Roelofs, 1985) with no detectable phenotypic variation between individuals. Even so, shifts in the emitted blend ratio and the responses of males to blend ratios should continue to be considered as a possibility that may be expressed in individuals in field populations over evolutionary time.

Acknowledgments—The following individuals made the international portion of this study possible by collecting infested cotton bolls in their countries and shipping mature larvae and pupae to us: M. Angst (CIBA-GEIGY, Switzerland, coordinated collections in Egypt); M.R. Attique (Central Cotton Research Institute, Pakistan); S. Barbosa and M.J. Lukefahr (EMBRAPA, Brazil); G.W. Videla (Instituto Nacional de Tecnologia Agropecuaria, Argentina); and Wen-Gu Li (Shanghai Institute of Entomology, P.R.C.). The laboratory and/or field assistance of M. Badgley, E. Charlton, L.K. Gaston, J. Higgs, C.F. Kennedy, W.G. Li, F. North, M.M. Pope, K. Ronning, R.W. Simmons, Jr., C. Taylor, G. Urquizu Jr., and R.S. Vetter is gratefully acknowledged. C. Beasley, R. Staten, and R. Weddle assisted us by locating suitable cotton fields. We are thankful for the cooperation of several pest-control advisors and cotton growers, including: J. Benson, A. Burrell, P. Cooper, C. Harris, J. Percy, C. Shields, K. Shouse, W. Shropshire, G. Stanworth, V. Terran, and K. Wood. We thank R. Collins and R.T. Cardé for allowing us to cite some of their unpublished results. Our research was supported initially by the Cotton Pest Control Board of California and subsequently by the National Science Foundation (NSF grant PCM-8309349 to T.C. Baker).

DEGRADATION OF JUGLONE BY SOIL BACTERIA

S.K. SCHMIDT

Department of Environmental, Population, and Organismic Biology
University of Colorado, Boulder, Colorado 80309

(Received July 27, 1987; accepted September 15, 1987)

Abstract—Bacteria that can degrade juglone (5-hydroxy-1,4-naphthoquinone) were isolated from soil beneath black walnut trees. Autecological studies with one of these bacteria (*Pseudomonas* J1), demonstrated that it could grow rapidly using juglone as its sole source of carbon and energy. Using nonlinear regression analysis and the Monod equation, it was determined that this bacterium had a high affinity for juglone (K_s = 0.95 μg/ml). *Pseudomonas* J1 can also utilize other aromatic compounds from plants as its sole source of carbon and energy. Compounds such as chlorogenic acid, ferulic acid, gallic acid, and 2-hydroxy-1,4-naphthoquinone (Lawson) were rapidly degraded by *Pseudomonas* J1. The rapid degradation of juglone and other suspected allelochemicals by soil bacteria make it unlikely that these compounds are important mediators of plant–plant interactions under natural conditions.

Key Words—Allelopathy, biodegradation, humic acids, *Juglans nigra*, juglone, nonlinear regression, *Pseudomonas putida* biovar A.

INTRODUCTION

Juglone is a toxic chemical produced by *Juglans nigra* L. and other members of the walnut family (Juglandaceae) (Thomson, 1971). It has long been known that juglone is toxic to certain plants, and this toxicity has been invoked to explain the antagonistic effect of black walnut trees on neighboring vegetation (Davis, 1928, Rietveld, 1983). Fisher (1978) presented evidence that the allelopathic potential of juglone was not expressed in well-drained soils, and he attributed this to the aerobic microbial mineralization of juglone in these soils. He went on to reason that, in wet soils, aerobic microorganisms capable of metabolizing juglone were not active, and therefore juglone was able to build up to concentrations high enough to inhibit the growth of red pines. However,

0098-0331/88/0700-1561$06.00/0

no evidence was presented by Fisher (1978) or subsequent workers (Rietveld, 1983; Rietveld et al., 1983) that juglone was metabolized by soil microorganisms. Other hypotheses for the disappearance of juglone from well-drained soils, such as increased leaching, incorporation into soil organic matter (Mathur, 1972; Saiz-Jimenez et al., 1975), or sorption onto the mineral fraction of the soil also have not been explored (Fisher, 1987).

Many studies have demonstrated the microbial breakdown of simple aromatic compounds in soil (Alexander, 1977; Reber, 1975), but very little work has been done on the metabolism of polycyclic quinones such as juglone. Polycyclic quinones are toxic, very reactive, and therefore more likely to be incorporated into the humic fraction of soil than to be completely metabolized by soil microorganisms (Saiz-Jimenez et al., 1975). The present study was undertaken to determine if soil microorganisms are able to breakdown juglone at concentrations likely to occur under field conditions.

METHODS AND MATERIALS

Bacterial Isolate. Soil samples were collected from the top 10 cm of soil beneath a stand of black walnut trees in Boulder County, Colorado. Soil was also collected 20 m from the walnut trees at a site in which no black walnut or other trees were growing. These soils were clay-loams of the Niwot series and are characterized as being somewhat poorly drained and mildly alkaline (Moreland and Moreland, 1975). Five soil samples from each site were used in enrichment studies to determine if juglone-utilizing microorganisms could be isolated. Juglone (98%, Aldrich Chemical Co., Milwaukee, Wisconsin) was added to 3-g soil samples in sterile 20-ml vials at a concentration of 2 μg/g of soil (2 ppm). After seven days, an additional 6 μg of juglone in 0.2 ml of distilled water was added to the soil. This process was repeated twice more, and 0.5 g of soil was then transfered to 100 ml of distilled water containing inorganic salts and 5 μg of juglone per milliliter. The culture was incubated for seven days at 23°C. Serial dilutions were then plated on a medium containing inorganic salts, 5 μg of juglone and 15 mg of Difco Bacto-Agar per milliliter. Isolated colonies were selected and streaked on juglone plates several times successively until pure cultures were obtained.

Identification of the bacteria obtained from each soil was done using standard bacteriological techniques (Palleroni, 1984). Flagella were stained using the technique of Heimbrook et al. (1986), and the capacity of the organisms to metabolize allelopathic compounds other than juglone was tested using the auxanographic technique as described by Parke and Ornston (1984). The inorganic salts solution used in all enrichments and experiments contained 750 μg KH_2PO_4, 480 μg Na_2HPO_4, 40 μg NH_4Cl, 10 μg $MgSO_4 \cdot 7H_2O$, 10 μg $CaCl_2 \cdot 2H_2O$, and 0.02 μg $FeCl_3 \cdot 6H_2O$ per milliliter of distilled–deionized water.

Three of the enrichments from the walnut soil yielded bacteria capable of metabolizing juglone. One of these bacteria was chosen at random for further studies and is henceforth designated as *Pseudomonas* J1. Stock cultures of *Pseudomonas* J1 were grown in the inorganic salts solution containing 5 μg of juglone per milliliter. The inoculum of *Pseudomonas* J1 used in the experiments described below was grown in inorganic salts solution containing 10 μg of juglone per milliliter. Cells were grown to the early stationary phase and were then diluted with inorganic salts solution to obtain the initial cell densities used in the experiments. Experiments were conducted in glass-stoppered 250-ml Erlenmeyer flasks containing 100 ml of the inorganic salts solution and the indicated concentrations of juglone. The flasks were incubated at 23°C without shaking. At regular intervals, the number of cells was determined by using the spread-plate technique. Triplicate 0.1-ml portions of 10-fold dilutions were plated on a medium containing 15 mg of Difco Bacto-agar and 3 mg of Trypticase soy broth with glucose (BBL, Cockeysville, Maryland) per milliliter of deionized water, and colony counts were made after 72 hr of incubation at 23°C. The data represents means of triplicate plate counts from individual flasks.

Juglone concentrations were determined with a spectrophotometer. To obtain a standard curve, juglone was dissolved in the inorganic salts solution at concentrations of 0.25, 0.5, 1.0, 2.5, 5.0, 7.5, 10, 20, and 40 μg/ml. These solutions were acidified with concentrated sulfuric acid to a pH of approximately 0.8 and the absorbance was read at 420 nm. During the experiments, 2-ml samples were removed from the cultures and immediately acidified with one drop of concentrated sulfuric acid to a pH of approximately 0.8 to stop all microbial activity in the sample. The absorbance values for each sample were then determined and the juglone concentration was calculated using the standard curve.

Data Analysis. Nonlinear regression analyses were performed on the curve of juglone disappearance. For this purpose, the MARQFIT computer program was used (Simkins and Alexander, 1984). This program fits nonlinear data by minimizing the square of the differences between the data and the model curve using the Marquardt method (Bard, 1974). Nonlinear regression is a statistical tool that can be used to determine values for ecologically important parameters describing the growth and metabolism of microorganisms (Schmidt et al., 1985b). This information can then be used to help estimate the persistence of organic chemicals in the environment.

RESULTS

Juglone-metabolizing cultures were isolated only from soils collected under black walnut trees. Bacteria that could tolerate juglone were obtained from the other soil samples, but these bacteria could not metabolize juglone even after

three months of incubation in the presence of juglone. In addition, juglone-utilizing cultures did not develop in flasks containing juglone but no soil, when these were left open to the laboratory air for three months. Therefore, it is reasonable to conclude that the bacteria obtained from soils beneath walnut trees were indigenous to those soils.

Pseudomonas J1 is a short (1–2 μm) gram-negative rod with one to four polar flagella, requires no growth factors, reacts positively to the oxidase and catalase tests, and can hydrolyze arginine under anaerobic conditions. In addition, *Pseudomonas* J1 produces a yellow fluorescent pigment when grown under iron limitation. These characteristics warranted placing it in rRNA group I of the genus *Pseudomonas* (Palleroni, 1984). Of the species in rRNA group I, *Pseudomonas* J1 matches almost exactly the characteristics of *P. putida* biovar A (Palleroni, 1984).

Table 1 summarizes the results of tests conducted with a number or organic compounds to determine what compounds could serve as sole carbon and energy sources for *Pseudomonas* J1. Many of the aromatic compounds have been reported to be allelochemicals (Rice, 1984). In addition to these suspected allelochemicals, other compounds such as sugars and amino acids were also tested for their ability to support the growth of *Pseudomonas* J1. Of note in these results was the inability of this organism to utilize most of the simple sugars that were tested. Only glucose and fructose were degraded, and even these sugars were not used as rapidly by *Pseudomonas* J1 as were the aromatic compounds tested.

Pseudomonas J1 was able to metabolize juglone and grow rapidly using this compound as its sole source of carbon and energy (Figure 1). In the inorganic salts solution in absence of juglone, no growth of *Pseudomonas* J1 was detected (Figure 1), and in the inorganic salts solution in the absence of *Pseudomonas* J1, no degradation of juglone was observed (data not shown). The yield of *Pseudomonas* J1 cells was also proportional to the concentration of juglone (1.4×10^7 and 3.1×10^7 cells/ml for 10 and 20 μg of juglone per milliliter, respectively), as would be expected for an organism using a substrate as its sole source of carbon and energy. The cell yields obtained are also close to those for other soil *Pseudomonas* spp. that completely mineralize simple aromatic compounds such as phenol (Schmidt et al., 1985b).

The data presented in Figure 2 show the disappearance of juglone when *Pseudomonas* J1 utilized juglone as its only source of carbon and energy. A similar curve of juglone disappearance was obtained with an initial juglone concentration of 20 μg/ml (data not shown). The data for the mineralization of 10 μg of juglone per milliliter was fit by the Monod equation using nonlinear regression analysis (Simkins and Alexander, 1984). From this analysis, the half saturation constant (K_s) for the growth of this organism on juglone was estimated to be 0.95 ± 0.71 μg/ml ($P = 0.05$). The values for the other parameters

of the Monod equation were $X_0 = 0.53 \pm 0.18$ μg/ml, $\mu_{max} = 0.47 \pm 0.09$/hr, and $S_0 = 9.76 \pm 1.3$ μg/ml. X_0 is the initial population density expressed in terms of juglone concentration, μ_{max} is the maximum specific growth rate for *Pseudomonas* J1 on juglone, and S_0 is the program's estimate for the actual initial concentration of juglone. Independent estimates of these parameters also were determined from the growth data shown in Figure 1 and simply by knowing the concentration of juglone and cells added at the beginning of the experiment. Thus, $X_0 = 0.63$ μg/ml, $\mu_{max} = 0.56$/hr, and $S_0 = 10.0$ μg/ml. These independent parameter estimates all fall within the 95% confidence intervals of the computer-generated estimates from the data presented in Figure 2.

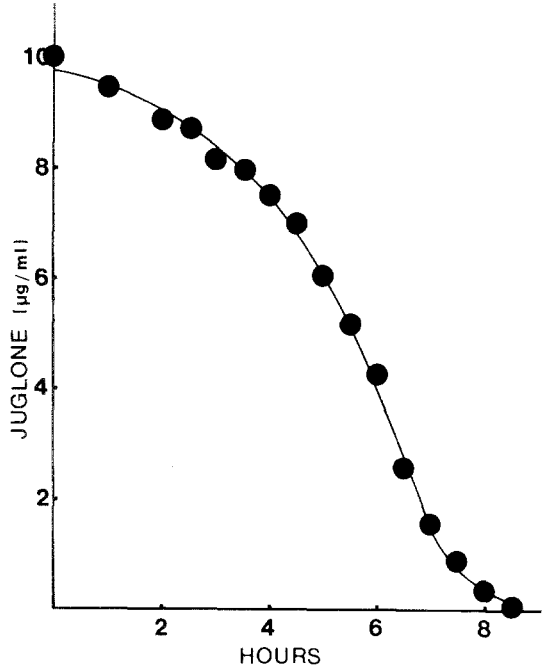

FIG. 2. Mineralization of 10 μg of juglone per milliliter by *Pseudomonas* J1. The curve is the best fit of the Monod equation to the experimental data (●). The curve was fit using nonlinear regression.

DISCUSSION

The presence of juglone-metabolizing bacteria in soils collected from under black walnut trees was confirmed in this study. This finding supports the hypothesis of Fisher (1978) that juglone is degraded and thus not allelopathically active in well-aerated soils. Juglone-mineralizing bacteria were not found in adjacent soils not exposed to black walnut litter or roots, indicating that juglone-utilizing bacteria are selected for in soils beneath black walnut trees. Juglone is structurally dissimilar to many aromatic compounds found in the soil solution (Alexander, 1977), and thus organisms adapted to metabolize simple compounds such as benzoate or phenol would not be expected to metabolize juglone. *Pseudomonas* J1, however, was able to grow on many simple aromatic compounds commonly reported to occur in soil. Compounds such as caffeic, chlorogenic, ferulic, and gallic acids have been reported to be allelochemicals (Rice, 1984), but most of these are readily degraded by a wide range of soil microorganisms (Alexander, 1977; Reber, 1975; Schmidt et al., 1987; Turner and Rice, 1975).

This is the first report of the microbial degradation of juglone. Previous work on the metabolism of polycyclic quinones has shown the fungus *Penicillum notatum* to be able to partially degrade lapachol (Rosazzo, 1982), an antitumor naphthoquinone from the wood of several species in the Bignoniaceae, Proteaceae, and Verbenaceae families (Thomson, 1971). *P. notatum* was able to carry out the partial degradation of lapachol using a monooxygenase enzyme under aerobic conditions (Rosazzo, 1982). Martin and Haider (1979), demonstrated that complexed anthroquinone mixtures were degraded by soil microorganisms, but they did not isolate the responsible organisms from soil.

Saiz-Jimenez et al. (1975) presented evidence for a different fate of polycyclic quinones in soil. In their work, the fungus *Eurotium echinulatum* catalyzed the oxidative linkage of anthroquinones and phenols to form dark-colored pigments similar to humic acids. Other workers have stressed the likelihood of an important role for polycyclic quinones in the formation of humic acids in soil (Mathur, 1972; Steelink and Tollin, 1967). Quinones also are very reactive with amino acids and proteins in the soil solution, forming complex molecules that are resistant to microbial degradation (Smith, 1982). Therefore, under aerobic conditions in soil, a multitude of fates is possible for polycylic quinones such as juglone. The fate of juglone in a particular soil may depend on several factors, such as aeration and the types of microorganisms present, but in any case it seems unlikely that juglone would persist in an unmodified form under aerobic conditions in soil in which black walnut trees are growing.

There is also reason to believe that juglone would not persist in an unmodified form under anaerobic conditions in soil. Recent work has demonstrated the bacterial breakdown of many aromatic compounds in anaerobic soil (Young, 1984). Soil bacteria can degrade aromatic compounds either by anaerobic (nitrate) respiration (Williams and Evans, 1975) or under methanogenic con-

ditions (Balba et al., 1979; Young, 1984). Even recalcitrant compounds such as halogenated benzoates are readily degraded by certain bacteria under anaerobic conditions (Suflita et al., 1982). In addition, 1,4-naphthoquinone and other naphthoquinones, which are structurally very similar to the K vitamins, have been shown to be utilized as growth factors by anaerobic bacteria such as *Succinivibrio dextrinosolvens* (Gomez-Alarcon et al., 1982). Thus, juglone may be subject to anaerobic attack, especially in soils that are repeatedly exposed to prolonged flooding. The persistence of juglone under wet moisture regimes in the lab (Fisher, 1978) may be due to the slower breakdown of juglone under anaerobic conditions, rather than a complete lack of degradation. It is also noteworthy that in his laboratory studies, Fisher (1978) used a soil that is not normally exposed to either anaerobic conditions or juglone. Thus, anaerobic bacteria adapted to metabolize juglone were probably absent from the soil used by Fisher (1978). Controlled studies are needed to determine if the die off of trees in certain soils is caused by juglone or if the effect is simply the result of anaerobiosis itself.

Autecological studies of microorganisms have been greatly enhanced by the use of nonlinear regression analysis and other computer-assisted techniques (Holder-Franklin and Tate, 1986; Simkins and Alexander, 1984). In the present study, the kinetic parameters obtained can be used to estimate the rate at which juglone will be degraded at different concentrations in the soil solution. Using the Monod equation and nonlinear regression techniques, an estimate for the half-saturation constant (K_s) for the utilization of juglone by *Pseudomonas* J1 was determined to be 0.95 μg/ml. K_s is inversely proportional to an organism's affinity for a given organic compound. A low K_s indicates a high affinity for the compound. At juglone concentrations greater than K_s, *Pseudomonas* J1 will be able to metabolize juglone at a rate approaching the maximum possible rate for this bacterium. The implications of this are that free juglone is unlikely to persist for long in the soil solution at concentrations around or above K_s. At concentrations below K_s, *Pseudomonas* J1 will metabolize juglone according to pseudo-first-order kinetics (Schmidt et al., 1985b). That is, juglone will be metabolized at a rate that is directly proportional to both the concentration of juglone and the size of the microbial population mineralizing juglone. The high affinity of *Pseudomonas* J1 for juglone is also evident from the rapid growth rate that this organism exhibited when growing on 10 μg of juglone per milliliter as its only source of carbon and energy.

At a juglone concentration approaching two orders of magnitude below K_s, *Pseudomonas* J1 may degrade juglone very slowly or not at all. Bacteria can exhibit threshold concentrations below which they are unable to mineralize organic compounds (Schmidt et al., 1985a). The threshold concentration for a *Pseudomonas* sp. that mineralizes *p*-nitrophenol (PNP) was approximately 100× lower than its K_s for growth on PNP (Schmidt et al., 1987). If *Pseudomonas*

J1 behaves similarly to this organism, it should be able to mineralize juglone at concentrations as low as 0.0095 μg/ml, a concentration below 10^{-7} molar. This is probably a conservative estimate of the lower limit for the degradation of juglone in soil. Scow et al. (1986) have demonstrated the rapid mineralization of many complex aromatic compounds at concentrations well below 1 ng/g of soil. In any case, *Pseudomonas* J1 is probably capable of mineralizing juglone at concentrations well below the lowest concentration that has elicited phytotoxicity, 10^{-6} molar (Rietveld, 1983), or significant toxicity to nitrogen fixing bacteria, 10^{-4} molar (Dawson and Seymour, 1983).

This study demonstrates the importance of considering the metabolic capabilities of soil microorganisms in studies of allelopathy (cf. Kaminsky, 1981). Soil microorganisms are carbon-limited most of the time (Lockwood and Filonow, 1981), and thus organisms such as *Pseudomonas* J1 are literally waiting to consume compounds such as juglone. The rapid degradation of potential allelochemicals by soil microorganisms should cause researchers to question claims of allelopathic activity if they are based solely on tests conducted in sterilized soil or laboratory media. Tests of the effects of a suspected allelochemical should be conducted using unsterilized soils from field sites where the alleged allelopathy is occurring. This simple procedure would give a more realistic assessment of the potential for a given chemical to cause allelopathic effects in nature.

Abstract—The biological activity of aqueous extracts of velvetleaf (*Abutilon theophrasti* Medik.) seed coats and their flavonoid components against three plant species and five soil fungi was investigated. Aqueous extracts slightly inhibited germination and significantly inhibited radicle growth of all plant species tested. Fungal growth was inhibited or not affected, depending on species, by aqueous extracts. The aqueous extracts were extracted into methanol and separated using paper chromatography for identification of compounds responsible for inhibition of seedling and fungal growth. Six flavonoid compounds were isolated and tentatively identified as delphinidin, cyanidin, quercetin, myricetin, (+)-catechin, and (−)-epicatechin. Bioassays revealed that the flavonoid compounds significantly inhibited germination and radicle growth of all test species at a concentration of 1.0 mM. Individual flavonoids had variable effects on fungi but appeared to inhibit growth and sporulation of potential seed-decomposing fungi rather than "beneficial" fungi. These results indicate that the flavonoid complement of velvetleaf seed coats may function in a dual defensive role against competing seedlings and seed-attacking fungi.

Key Words—*Abutilon theophrasti* Medik., allelopathy, antifungal activity, flavonoids, seed germination, soil fungi, weed biology, weed seeds.

INTRODUCTION

Velvetleaf is a highly competitive annual dicotyledonous plant that is a major weed problem in row crops grown in the United States (Spencer, 1984). Velvetleaf produces large numbers of seeds followed by high dispersability near the parent plant for addition to the seedbank on and in the soil. The majority of the seeds arriving on the soil are dormant (possessing hard and impermeable seed coats) and remain viable in soil for several years during which germination gradually occurs (Egley and Chandler, 1983; Lueschen and Andersen, 1980). The hard-seeded attribute is considered a major factor for the occurrence of velvetleaf as a serious weed of row crops (Egley and Chandler, 1983).

Chemical compounds present in velvetleaf seeds have been reported to have various effects on plant seedlings and microorganisms. Velvetleaf seeds are sources of inhibitors to crop seed germination and seedling elongation (Gressel and Holm, 1964) and of growth regulatory compounds that cause abnormalities in cabbage (*Brassica oleracea* L.) root parenchyma cells (Retig et al., 1972). LaCroix and Staniforth (1964) qualitatively determined phenolic compounds in water extracts of velvetleaf seeds that inhibited velvetleaf seed germination. Elmore (1980) examined the effects of aqueous extracts of velvetleaf seeds on turnip (*Brassica rapa* L.) seed germination and concluded that plant phenolic fractions of the extract likely contributed the most to the observed inhibitory effects and urged further investigation of these compounds. Recent laboratory studies demonstrated considerable inhibition of microbial growth by intact, dormant seeds of velvetleaf placed on agar culture plates (Kremer, 1986). Chemical analyses of the seed diffusates within the inhibition zones around the seeds revealed the presence of phenolic compounds.

The occurrence of allelochemicals and the prolonged persistence in soil of velvetleaf seeds suggests that the seeds may influence the ecological balance of the soil microenvironment. The allelochemicals in the velvetleaf seeds inhabiting niches in the soil environment may be advantageous by reducing the germination and growth of competing plants (Friedman and Waller, 1983) and by inhibiting the growth of potential seed decomposers (Kremer, 1986). However, the simultaneous effects of allelochemicals of dormant seeds on adjacent germinating seeds and soil microorganisms are not well understood. Furthermore, the seed coat of dormant seeds is the only seed structure encountered by germinating seeds and microorganisms in the soil environment and, therefore, these organisms likely respond differently to the seed coats than to the seed contents. It is a common practice to assay alcoholic extracts of intact seeds (seed coat plus seed contents) in studies of allelochemicals of seeds. This may yield misleading information on the potential interaction of organisms with seed coats alone. Also, seed extracts obtained using organic solvents are likely not representative of natural conditions where biologically active chemicals are leached

out of seeds by water. In the present study, flavonoids in aqueous extracts of velvetleaf seed coats were investigated because of their widespread distribution in seeds (Bate-Smith and Ribereau-Gayon, 1958; Feenstra, 1960; Halloin, 1982; Young and Paterson, 1980) and their documented effects on seedling plants (Popovici and Reznik, 1976; Weston et al., 1987) and microorganisms (Byrde, 1963; Flood and Kirkham, 1960; Kraft, 1977; Rubia et al., 1987).

The overall objective of this study was to determine if aqueous extracts of velvetleaf seed coats exert allelochemical influences on other plant species and soil fungi. Specific objectives were to isolate and identify flavonoid compounds present in velvetleaf seed coats that may contribute to allelochemical activity and to assess the biological activity of seed coat extracts and identified compounds on both plant and microbial species.

METHODS AND MATERIALS

Collection and Processing of Velvetleaf Seed Coats. Mature velvetleaf seeds were collected from a plant accession grown at the University of Missouri Agronomy Research Center, Columbia, Missouri, in July 1984. The intact seeds were fractionated into seed coat and embryo components by grinding in a blender for 45 sec and then separating them on a seed blower for 1 min (Kremer et al., 1984). Seed coats were ground in a Wiley mill (mesh screen size 1 mm) and stored in sealed glass containers until used for extraction procedures.

Extraction of Velvetleaf Seed Coats. Seed coats (10 g) were extracted for 48 hr with 100 ml sterile distilled water on a shaker (60 rpm) at 27°C. Five seed lots were extracted to provide enough experimental material. Mixtures were filtered through Whatman No. 4 paper to remove particulate matter. Upon microscopic examination, the aqueous extracts appeared free of microorganisms, indicating that microbial by-products likely would not contribute to toxicity of the extracts detectable under bioassay conditions. Total phenolic content of the aqueous extract was estimated using the Folin-Denis technique (Horowitz, 1980). The aqueous extract was also tested with 10% lead acetate in 10% acetic acid and with 1% ferric chloride to detect the presence of tannins (Robinson, 1980). A 0.1% aqueous solution of tannic acid served as a control for these tests. The vanillin–HCl reaction (Broadhurst and Jones, 1978; Robinson, 1980) was used to detect catechins and leucoanthocyanidins in the aqueous extract. A solution containing 1 mg (+)-catechin per 1 ml methanol was used as a positive control.

Isolation and Characterization of Flavonoids from Extracts of Velvetleaf Seed Coats. The aqueous seed coat extract was evaporated to dryness by rotary evaporation at 45°C after which the dried residues were dissolved in 70% methanol (15 ml). The concentrated extracts were applied (20 μl) to Whatman No.

1 chromatography paper and developed two dimensionally in BAW (*n*-butanol–acetic acid–water, 4:1:5, upper phase) and in Forestal solvent (acetic acid–conc HCl–water, 30:3:10) (Harborne, 1984). After development and drying, the chromatograms were examined visually with and without longwave UV light and the position and color of each spot recorded. Chromatograms were also sprayed with 10% vanillin in conc HCl to detect the presence of catechins (Robinson, 1980). The flavonoid spots on the two-dimensional chromatograms were tentatively identified by direct comparison with authentic flavonoids through cochromatography. Cochromatography with authentic compounds is required to confirm that flavonoids occupying different positions on the chromatogram are different and those occupying similar positions are indeed the same compound (Harborne, 1984; Markham, 1982).

Seed Germination and Seedling Growth Bioassays. Concentrated aqueous extracts were diluted with sterile distilled water to concentrations representing 25, 50, and 100 mg seed coat per milliliter. Individual commercially available compounds, selected on the basis of chromatographic identifications, were initially dissolved in acetone followed by diluting with distilled water to a final concentration of 1 mM. Five milliliters of each test solution was added separately to sterile glass Petri dishes lined with Whatman No. 3 filter paper. A distilled water control was also included. Biological activity of the test solutions was assayed using seeds of cress [*Lepidium sativum* (L.) cv. Curlycress], radish (*Raphanus sativus* L. cv. Sparkler White Tip), and soybean [*Glycine max* (L.) Merr. cv. Williams 82]. Seeds were surface-sterilized by immersion in 70% ethanol for 4 min and then rinsed 10 times with sterile distilled water. Treatments consisted of 20 evenly spaced seeds per dish. Four replicates of each treatment were arranged in a completely randomized design and were repeated twice. Treated seeds were incubated in the dark at 27°C. Germination (radicle protrusion through the seed coat) and radicle lengths of all species were measured at 72 hr. Data were subjected to analyses of variance, and F values and 5% least significant differences were calculated to determine significance of treatment effects in each bioassay.

Fungal Growth Bioassays. Aqueous extracts of velvetleaf seed coats and test compounds at concentrations described previously were added to separate 125-ml Erlenmeyer flasks containing 50 ml sterile mineral salts medium. All test solutions were added through 0.2-μm filter membranes. The medium contained sodium nitrate (2.0 g/liter), dipotassium phosphate (1.0 g/liter), magnesium sulfate (0.5 g/liter), and potassium chloride (0.5 g/liter). Sucrose (15 g/liter) was added to control flasks. The fungi *Aspergillus niger*, *Gliocladium roseum*, *Penicillium diversum*, *Trichoderma viride*, and *Fusarium* sp. previously isolated from soil (Kremer et al., 1984) were used as indicator species. The fungi were cultured for five days on potato dextrose agar (PDA) after which a 5-mm plug of agar and mycelia from the actively growing edge of the fungus

was used as inoculum for each flask. Four replicate flasks were prepared for each test solution–fungus combination. The cultures were incubated in the dark at 27°C. After 14 days, mycelial mats were filtered onto preweighed filter papers and dried for 24 hr at 120°C prior to weighing. Data were analyzed as described previously.

RESULTS AND DISCUSSION

Aqueous extracts prepared from velvetleaf seed coats significantly decreased germination of cress seeds at extract concentrations of 50 and 100 mg seed coat extracted per milliliter of water (Table 1). Germination of radish and soybean seeds was significantly decreased only at 100 mg seed coat extracted per milliliter. Seed coat extracts at all concentrations inhibited radicle growth of all test species. Elmore (1980) reported similar inhibitory activity of aqueous extracts of whole velvetleaf seeds on both germination and radicle growth of turnip. Our results also agree with previous studies concerning bioassays of plant extracts in that seedling growth appears to be more sensitive to the effects of allelochemicals than does germination (Panasiuk et al., 1986; Rasmussen and Einhellig, 1977; Weston et al., 1987). In addition to effects on radicle growth, seedlings growing in seed coat extracts were generally less vigorous with greater occurrences of abnormal development, necroses, and chlorosis.

Seed coat extract concentrations at 25 mg seed coat extracted per milliliter of water had no significant effect on the growth of the test fungal species (Table 2). However, seed coat extract concentrations of 50 and 100 mg/ml inhibited growth of *A. niger*, *P. diversum*, and *Fusarium* sp., while the growth of *G. roseum* and *T. viride* were not affected. It appears that inhibitory activity of seed coat allelochemicals is dependent on both the nature of the fungal test

TABLE 1. EFFECTS OF AQUEOUS EXTRACTS OF VELVETLEAF SEED COATS ON GERMINATION AND SEEDLING GROWTH OF SELECTED PLANT SPECIES

species and the concentration of the allelochemicals in the seed coat extract. Similar differential effects of allelochemical extracts have been observed for fungi associated with intact oat caryopses (Picman et al., 1984) and for soil fungi in contact with *Eupatorium riparium* residues (Rai and Tripathi, 1984). Extracts at concentrations of 50 and 100 mg seed coat per milliliter also inhibited sporulation of *A. niger*, *P. diversum*, and *Fusarium* sp. This is supported by previous reports on the inhibitory properties of seed coats on fungal sporulation (Picman et al., 1984; Kremer, 1986).

The aqueous seed coat extracts reacted positively to lead acetate and ferric chloride reagents and yielded a positive vanillin–HCl test. These reactions are consistent with the presence of phenolic compounds and, regarding the vanillin–HCl test, condensed tannins (Broadhurst and Jones, 1978; Robinson, 1980). The concentration of total phenolic compounds determined by the Folin-Denis method was 0.55 mg tannic acid equivalents per gram seed coats. Although this method does not measure any specific tannin or phenolic compound, a relative measure of phenolic content present can be used to assess the significance of these compounds in the total composition of the seed coat.

Paper chromatography of seed coat extracts revealed six distinct spots visualized under UV light or by the vanillin–HCl reagent (Table 3). The compounds, tentatively identified by cochromatography with authentic compounds, were members of the polyphenolic class of chemicals collectively known as flavonoids (Harborne, 1984). The intensities of the flavonoid spots on the chromatograms indicated that delphinidin was the major component, with catechin, epicatechin, and quercetin appearing as intermediate components. Cyanidin and myricetin were determined to be minor components. To our knowledge, the six flavonoid compounds detected are reported for velvetleaf seed coats for the first time. The classification of flavonoid compounds detected in this study is largely

preliminary and absolute identification using more detailed chemical and spectral techniques (Harborne, 1984; Markham, 1982) is necessary for specific analyses of the total chemical composition of the seed coats. Cyanidin and delphinidin have been shown to be common constituents in seed coats of several plant species (Bate-Smith and Ribereau-Gayon, 1958). However, species of Malvaceae, which include velvetleaf, were not included in previous analyses. Catechin, identified in cottonseed, was shown to be the major precursor of tannins in that malvaceous species (Halloin, 1982).

The flavonoids detected using chromatography were bioassayed to determine if these compounds might contribute to the inhibitory activity of velvetleaf seed coat extracts against plant and fungal species. The compounds were assayed at a concentration of 1.0 mM, a level approximating that occurring in the soil solution for other phenolic compounds (Williams and Hoagland, 1982) and a level that would likely occur in soil microsites adjacent to seeds. Bioassays revealed that flavonoid components had significant inhibitory effects on both germination and radicle growth of all three test species (Table 4). Visual observations included lack of root hair and/or lateral root formation and considerable necrosis of the developing root. Little information is available on the influence of flavonoids on seed germination and seedling growth. Quercetin and myricetin were shown to inhibit protoplasmic streaming in oat root hairs (Popovici and Reznik, 1976). Tricin, a flavonoid isolated from quackgrass [*Agropyron repens* (L.) Beauv.] shoots, inhibited seedling growth of several plant species (Weston et al., 1987).

The overall effects of individual flavonoids on the growth of soil fungi contrasted among fungal species (Table 5). For example, *T. viride* was considerably more tolerant of delphinidin, catechin, and epicatechin than was *Fusar-*

TABLE 4. EFFECTS OF FLAVONOID COMPOUNDS ON GERMINATION AND SEEDLING GROWTH OF SELECTED PLANT SPECIES

ium sp. Quercetin significantly inhibited the growth of *A. niger* and *Fusarium* sp. but had no effect on the other fungi. All fungi were generally tolerant of or were stimulated by cyanidin. Although fungi were able to grow on several of the flavonoids, sporulation was commonly inhibited by these compounds. Previous studies have also shown that catechin and epicatechin may inhibit invading seed fungi (Byrde, 1963; Halloin, 1982). Delphinidin, a major flavonoid

component in the testa of pea (*Pisum sativum* L.) accessions, is fungistatic and inhibits sporulation of the pathogen *Fusarium solani* f.sp. *pisi* (Kraft, 1977).

From the results of this study it may be seen that the flavonoid complement of velvetleaf seed coats shows biological activity in both seed coat extracts and as individual components against each type of test organism, thus suggesting a dual defensive role. This study supports the suggestion of Friedman and Waller (1983) that the allelopathic potential of seeds, produced in large numbers by the parent plant, i.e. velvetleaf, favors seedling establishment by reducing the germination and growth of competing adjacent vegetation. On a similar basis, allelochemicals likely protect weed seeds against microbial attack, as suggested by Halloin (1983). Indeed, these compounds may regulate the composition of organism populations in the seed–soil microenvironment. This is exemplified by the ability of certain seed coat flavonoids to inhibit the growth and/or sporulation of *Fusarium*, a potential seed pathogen, while not detrimentally affecting the activity of more beneficial (to the seed) antibiotic-producing fungi such as *Trichoderma* and *Gliocladium* spp. Elucidation of the presence and types of compounds present in seed coats and their effects on other organisms in vitro provides a basis for future studies aimed at demonstrating their ecological role under natural conditions. The impact of allelochemicals in seed coats of many hard-seeded plant species may be most pronounced in their interactions with other organisms when focused on the soil microsite perspective rather than on the broader soil system.

Abstract—*Heliothis zea* (Boddie) larvae fed cowpea seedlings produced volatile semiochemicals to which *Microplitis demolitor* Wilkinson responded in a wind tunnel. However, most *M. demolitor* females reared from *H. zea* larvae fed an artificial diet were not responsive at emergence to the same volatile semiochemicals. A preflight contact with frass from *H. zea* fed cowpea was needed to stimulate a response of sustained flight in a wind tunnel. The most consistent flight response was 7–10 days postemergence. Response resulting from both antennal and ovipositor contact with host frass during preflight stimulation was no better than from antennal contact alone. Chilling the parasitoid pupae rendered most of the emerging females unresponsive to volatile semiochemicals.

Key Words—*Microplitis demolitor*, Hymenoptera, Braconidae, *Heliothis zea*, Lepidoptera, Noctuidae, Biological control, artificial diet, preflight behavior, wind tunnels, oviposition, age, chemosensory receptors, chilling pupae.

INTRODUCTION

Many authors, of whom we cite only a few, have shown that semiochemicals and other biological communication mediators serve vital roles in the foraging activities of entomophagous insects (Salt, 1935; Monteith, 1955, 1958; Arthur et al., 1964; Carton, 1971; Corbet, 1971; Hendry et al., 1973; Lewis et al., 1975; Lenteren, 1976; Weseloh, 1976, 1977; Prokopy and Webster, 1978; Nordlund et al., 1981a,b; Vet, 1983; Lecomte and Thibout, 1983; Vinson, 1976, 1984a,b; Noldus and Lenteren, 1985). An example is the report of Drost et al. (1986), who conducted wind-tunnel studies with the indigenous *Microplitis croceipes* (Cresson) and showed that responses of the females to volatile semiochemicals required appropriate preflight stimulation.

M. demolitor is an important part of the parasitoid community, which attacks *Heliothis* in several crops, especially soybeans in Australia. It was imported from Australia in 1981 through the Research Quarantine facility in Stoneville, Mississippi. Shepard et al. (1983) found that *M. demolitor* developed successfully in the cotton bollworm, *Heliothis zea* (Boddie); the tobacco budworm, *Heliothis virescens* (F.); the soybean looper, *Pseudoplusia includens* (Walker); and the cabbage looper, *Trichoplusia ni* (Hübner).

The studies reported here were designed to determine the response of the exotic *Microplitis demolitor* Wilkinson reared from *Heliothis zea* (Boddie) fed on artificial diet. Specific objectives were: to determine the effect of age and prior oviposition activity on flight response of *M. demolitor* females to odors emanating from the plant-host complex using a wind tunnel; to determine if a specified part of the plant–host complex was more particularly involved in preflight activation of females; to investigate the role of chemosensory receptors of antennae and ovipositor in integration of messages relative to presence of cues from the plant–host complex; and to test the effect of chilling *M. demolitor* pupae on the quality of females subsequently emerging.

METHODS AND MATERIALS

Culture of M. demolitor *in Hosts Reared on Artificial Diet.* All tests used *M. demolitor* that were reared from larvae of *H. zea* fed on artificial diet. Females prefer first- to third-instar larvae of *H. zea* for parasitization (Shepard et al., 1983). A detailed description of the rearing techniques for this parasitoid is provided by Hérard et al. (1988). Adult parasitoids were paired (1 male and 1 female) 1–15 hr after emergence. Each pair was placed in a 30-ml cup with honey and water until tested.

Preflight Experience. Response to olfaction can be affected by the parasitoid's previous experience (Thorpe and Jones, 1937; Narayanan and Subba Rao,

1955; Arthur, 1971). Drost et al. (1986) conducted wind-tunnel studies with the indigenous *Microplitis croceipes* (Cresson) and showed that responses of the females to volatile semiochemicals required appropriate preflight stimulation. Nordlund and Lewis (1985) observed initiation of host-seeking behavior when *M. demolitor* females contacted frass of *H. zea* and *T. ni* larvae fed pea cotyledons. They verified that 13-methylhentriacontane, a compound earlier identified from *H. zea* larval frass and shown to elicit antennation by *M. croceipes* (Jones et al., 1971), also stimulated the antennation behavior by females of *M. demolitor*.

Prior to these tests in the flight chamber, individual *M. demolitor* females were exposed to the components of plant–host complex in a 150-mm-diameter Petri dish for 2 min. The complete experience consisted of contact with greenhouse-grown, pink-eye, purple-hull cowpea seedlings freshly damaged by *H. zea* larvae; frass from the feeding host larvae; and one or two ovipositions.

Contact was limited to a specified part of the plant–host complex to determine the effect of various preflight stimuli. Twelve treatments were tested. Treatment 1 was the control, i.e., the female was tested without preflight exposures to plant–host-related materials. Treatment 2 was contact with an undamaged plant. Treatment 3 was contact with an artificially damaged cowpea seedling. Treatment 4 was contact with a plant that had been fed upon and then washed with water. Treatment 5 was contact with natural feeding damage and frass. Treatment 6 was contact with frass alone. In treatment 7, the parasitoid was exposed only to the host odor. The experience chamber contained second- and third-instar host larvae isolated in compartments. The female *M. demolitor* was placed above the host larvae in a chamber with a double bottom of organdy. In this way the parasitoid was able to detect the odors of larvae without contacting them. In treatment 8, the female was allowed to oviposit once. Treatment 9 was contact with the complete plant–host complex and one oviposition. Treatment 10 was contact with the same material as in treatment 9 and two ovipositions. Treatment 11 was contact with an artificially damaged seedling and frass. In treatment 12, the source of the odors was a 4-liter jar containing five cowpea seedlings and 25 actively feeding third-instar *H. zea* larvae producing damage to plants and frass. An *M. demolitor* female was placed in a 10-cm^3 cage with a double cover of organdy and the cage placed in the 4-liter jar so that the parasitoid could detect odors from the complete plant–host complex but could not contact the source.

Test in the Wind Tunnel. The wind tunnel provided laminar air flow at 16 cm/sec. The test section of the tunnel was 2 m long with a 75 × 75-cm cross-section. Overhead lighting was provided by four 80-W fluorescent light bulbs.

The source of airborne semiochemicals consisted of a damaged cowpea seedling bearing fresh frass and five second- and third-instar *H. zea* larvae, which were feeding actively at the time of each test. The source was prepared

by allowing the larvae to feed on the seedling, the stem of which was immersed in water, for 2 hr prior to testing. During most of the tests, the source was placed at the center of the upwind end of the flight tunnel.

Each naive female *M. demolitor* was transferred to the experience chamber (Petri dish) and then to the tunnel in clear 3.7-ml vials. The vial was placed 1.3 m downwind from the source with the open end up. When the females walked out of the vial and became exposed to the odor plume, they displayed two principle types of responses. One was a non-target-oriented flight that occurred either immediately or after a brief period of walking while drumming on the release vial with the antennae. The other was a sustained flight to the source of odors, which occurred after a period of upwind orientation on the vial. If a female conducted a non-target-oriented flight in the first trial, we placed her back on the vial and allowed a maximum of four other chances of flight to the source. We recorded which females displayed a sustained flight in the first through fifth trials.

We tested the possible role of vision when *M. demolitor* females approached the source in the flight chamber with the technique developed by Zanen et al. (1988). The source was placed outside the wind tunnel, and semiochemicals were introduced through a simple glass nozzle. Thus, the plant–host complex was not visible to the parasitoid as she flew. Females did not need visual cues because they oriented and flew to this nozzle.

Effect of Parasitoid Age. The level of response to volatile semiochemicals from a plant–host complex varied widely with the ages of *M. demolitor* females. We investigated the effect of age on flight response to plant–host odors by experienced females. Female *M. demolitor* 1–14 days old were separated into seven groups, each with an age range of two days.

Effect of Oviposition Activity. An *M. demolitor* female emerges from its cocoon with some mature eggs available for oviposition during the very first day. The females tested in the above-mentioned experiment were not allowed to oviposit prior to the test. In order to determine if the response to odors from the plant–host complex by 7-day-old females was due to their strong need to lay eggs, we allowed 20 females to deposit five eggs per day and another group of 20 to lay 20 eggs per day for seven days. Their flight responses were compared to 20 females that were not allowed to oviposit during the same period.

Role of Chemosensory Receptors of Antennae and Ovipositor in Integration of Messages Relative to Presence of Cues from Plant–Host Complex. While exploring an area containing some cues from the plant–host complex, a female frequently shows intense antennation activity followed by probing with the abdomen. Occurrence of a necessary information exchange process based on messages received by the chemosensory receptors of these two organs was suspected in the recognition of contact kairomones and sensitization to volatile semiochemicals.

An experiment was set up to observe the flight response of female *M. demolitor* to volatile semiochemicals following contact with host frass, either by the antennae only or by the antennae and ovipositor. These responses were compared with those of inexperienced females. To allow contact only by the antennae, a pellet of frass maintained on the tip of a pin was presented above the substrate to the female until she palpated it with her antennae. Normal behavior of the female was to catch the pellet with her fore tarsae, climb on the pin, and probe the pellet with her ovipositor. To avoid this contact, we moved the pellet back while the female moved forward still palpating the pellet with her antennae. We stopped the contact after 15–20 sec and then tested the female in the wind tunnel.

Effect of Chilling Pupae on Quality of Subsequently Emerging Females. Initially, it was observed from experiments designed for other purposes that *M. demolitor* and *M. croceipes* females emerging from chilled pupae were particularly unsuitable for behavioral bioassays. These females had a strong propensity to show only non-target-oriented flights. Since chilling of pupae is commonly practiced in many entomological laboratories, we suspected a general practical interest in this observation. We tested effect of chilling pupae at 13°C for 4, 7, and 13 days on behavioral and reproductive performance of *M. demolitor*.

Statistical Analysis. The numbers of females tested in each treatment was 20, except for 40 in the seven groups used to study the effect of age, and 30 in the study of the effect of chilling pupae. Incidences of sustained flight in the first trial were compared in the different treatments by using repeated G tests, or replicated goodness-of-fit tests, based on use of the log-likelihood ratio (Sokal and Rohlf, 1969; Zar, 1974). The 0.05 probability level was used for rejection of all null hypotheses.

RESULTS AND DISCUSSION

Description of Response to Contact and Airborne Semiochemicals. Females of *M. demolitor* that contacted material from the plant–host complex in an experience chamber exhibited intense antennation activity, drummed the plant material or frass with their antennae while walking or standing still, and probed at the material with the tips of their ovipositors.

Flight initiation and orientation sequences of *M. demolitor* females to odors from the plant–host complex in the wind tunnel were essentially the same as those described by Drost et al. (1986) for *M. croceipes*: a period of preflight orientation characterized by a sequence of walking while drumming, followed by standing still oriented upwind while holding the antennae in a vertical plane perpendicular to the wind direction, and followed by initiation of the flight pose.

During the flight pose, the female stood on her meta- and mesothoracic legs while making "walking" movements with her prothoracic legs. Takeoff usually was followed by a sequence of wide zigzagging, straight flight, recurrent zigzagging, another straight flight, hovering at about 10 cm downwind from the target, and quick darts toward the target, ending with landing on the target. This characterized sustained flight.

Effect of Age. Figure 1 shows that the response to semiochemicals by 1- to 6-day-old females was low and variable. In the youngest females, only a few responded in the first trial, and some did not fly in five trials. However, the percentage of females responding increased from 1 to 6 days of age.

Response to semiochemicals in 7- to 10-day-old females was much more consistent, with 55–75% of them conducting sustained flights in the first trial. In 11- to 14-day-old females, response to semiochemicals decreased and individual variability increased. Forty-five percent of females showed a sustained flight in the first trial, and 20% did not respond in five trials.

As no statistical difference was observed between the 7- to 8- and 9- to 10-day-old groups, we considered the 7- to 10-day-old group sufficiently homogeneous to be used in experiments where a high responsiveness to semiochem-

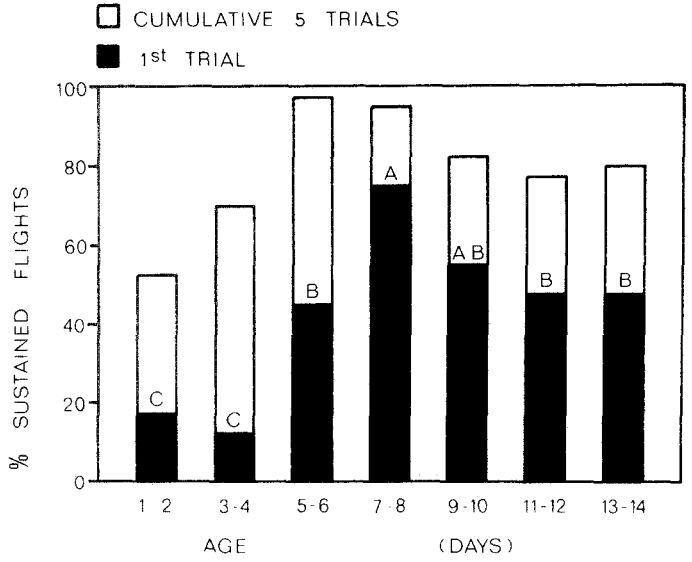

FIG. 1. Effect of age on flight response to odors from cowpea–*Heliothis zea* complex by experienced *Microplitis demolitor* females. The black portion of the bars represents the percentage of females flying in the first trial, and the white plus black bars those flying at least once in five trials. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

icals was needed. This also suggests that age of the female is an important consideration when releasing parasitoids in the field.

Effect of Oviposition Activity. There were no significant differences among the percentages of flight responses by the experienced females which had laid 0, 35, and 140 eggs, respectively, prior to the test (Figure 2).

These results show that previous egg depositions did not diminish the responsiveness of the females to volatile semiochemicals. On the other hand, the younger females did possess eggs and were capable of ovipositing. Therefore, it appears that the characteristics of possessing mature eggs and being held away from hosts is not sufficient of itself to induce the host-searching process by a female *M. demolitor*.

These results suggest that we cannot expect effective field performance by released *M. demolitor* merely because the females are inseminated and possess mature eggs.

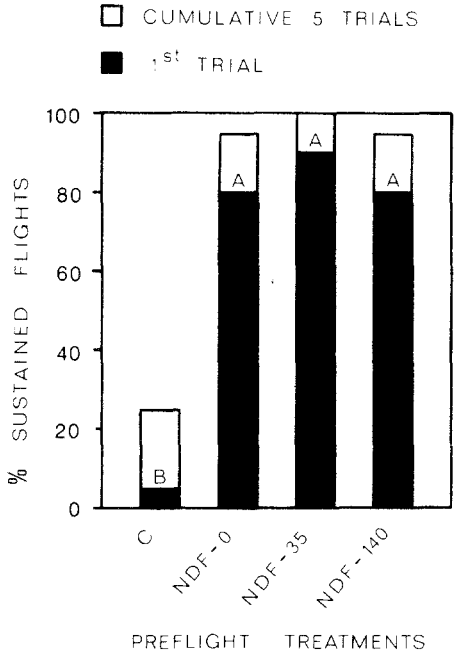

FIG. 2. Effect of preliminary egg deposition on flight response to odors from cowpea–*Heliothis zea* complex by 7- to 8-day-old experienced *Microplitis demolitor* females. C: no egg laid, no preflight experience; NDF-0: no egg laid, natural damage + frass; NDF-35: 35 eggs laid, natural damage + frass; NDF-140: 140 eggs laid, natural damage + frass. The black portion of the bars represents the percentage of females flying in the first trial, and the white plus black bars those flying at least once in five trials. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

Effect of Varying Preflight Stimuli. Data for the 12 preflight experience designs are shown in Figure 3. Treatments 2, 3, 4, 7, 8, 11, and 12 gave results not significantly different from the control. Contact with the complete plant-host complex (treatment 5) induced a sustained flight in the first trial in 75% of the females. When components of the plant-host complex were used separately in the experience chamber (treatments 2, 3, 4, 6, and 7), only frass (treatment 6) induced a stimulation (in 70% of the females) which was as good as the complete complex (treatment 5). Three other treatments containing the frass component induced a good sustained flight in the first trial: natural damage + frass (treatment 5), and complete plant-host complex with oviposition (treatments 9 and 10). The additional contact with natural feeding damage and the experience of one or two ovipositions did not significantly increase the degree

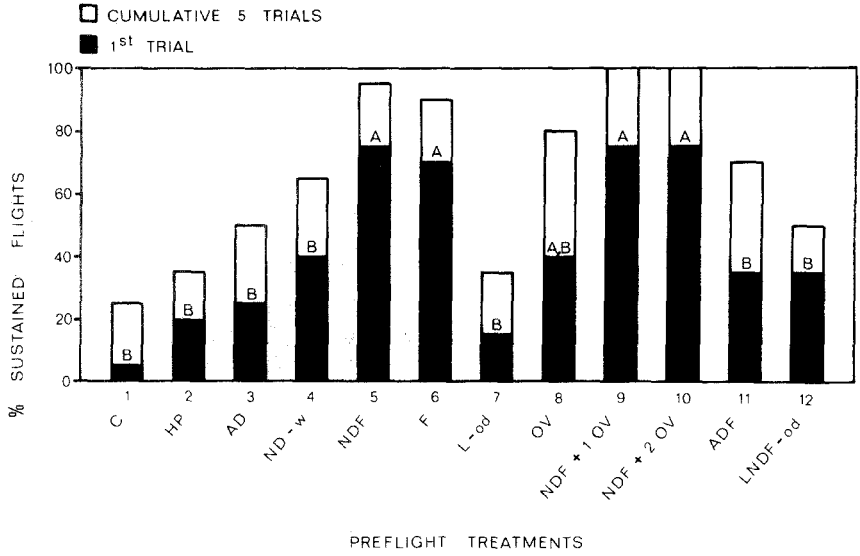

FIG. 3. Effect of varying preflight stimuli on flight response to odors from cowpea-*Heliothis zea* complex by 7- to 8-day-old experienced *Microplitis demolitor* females. Treatment 1 (C): no preflight experience; treatment 2 (HP): undamaged host plant; treatment 3 (AD): artificial damage; treatment 4 (ND-w): natural damage, water washed; treatment 5 (NDF): natural damage + frass; treatment 6 (F): frass; treatment 7 (L-od): larval odor; treatment 8 (OV): 1 oviposition; treatment 9 (NDF + 1 OV): natural damage + frass + 1 oviposition; treatment 10 (NDF + 2 OV): natural damage + frass + 2 ovipositions; treatment 11 (ADF): artificial damage + frass; treatment 12 (LNDF-od): odor of larvae, natural damage and frass. The black portion of the bars represents the percentage of females flying in the first trial, and the white plus black bars those flying at least once in five trials. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

of response observed with frass alone. Only the combination of preflight contact with frass and artificial damage (treatment 11) gave a response as poor as other treatments lacking frass. This suggests the possibility of a masking or repulsive effect of chemicals emitted by cowpea leaves damaged artificially.

A leaf from which the frass was removed was then washed (treatment 4) and did not induce host-seeking behavior in most of the females. Exposure to odors of larvae (treatment 7) or of the complete plant–host complex with no contact with the material (treatment 12) were not valuable preflight experiences. Even a brief contact with a host, limited to a fraction of a second, during which an egg was laid (treatment 8), did not render most of the females tested responsive to volatile semiochemicals. Contact with undamaged or artificially damaged plants (treatments 2 and 3, respectively) had no effect on responses to plant–host odors in most of the *M. demolitor* females. However, very few females (5%), with no preflight experience at all (treatment 1), showed a sustained flight in the first trial. This indicates that a few females have a sufficiently low inherent threshold of response to volatile semiochemicals such that no prior experience is required. This experiment showed that: (1) most of the *M. demolitor* females reared from hosts fed artificial diet needed a preflight experience to become responsive to volatile semiochemicals emitted by a target plant–host complex; (2) frass from the host was the most effective source for preflight stimulation and only a brief contact with the source was necessary; and (3) the act of oviposition alone did not increase responses nor did it enhance the effect of contact with the frass.

Role of Chemosensory Receptors of Antennae and Ovipositor in Integration of Messages Relative to Presence of Cues from Plant–Host Complex. Figure 4 indicates that there is no significant difference in percentages of females showing a sustained flight in the first trial after experience by contact with frass with only the antennae or with antennae and ovipositor. This indicates that the antennae are the necessary and sufficient olfactory organs involved in: (1) recognition of significant cues from the plant–host complex, (2) detecting host presence in the vicinity and continuation of active search for it, and (3) the threshold level necessary for flight response to volatile semiochemicals.

Contact with frass elicits responses of antennation, a short running, and subsequent probing with the abdomen by the female *M. demolitor*. As soon as the ovipositor touches the frass, running stops and antennation is resumed. Consequently, we assume that when the frass is touched with the antennae, it triggers a stereotypical behavior of oviposition, which ceases when the chemoreceptors of the ovipositor encounter a substance that is not a suitable host.

Very likely, an information exchange process occurs when the stimulation is received alternatively by antennae and ovipositor. Whereas the former would induce activation of search for the host by lowering the threshold of sensitivity

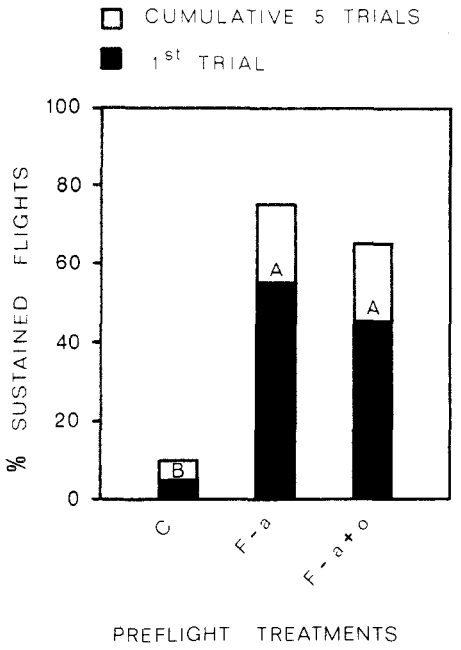

FIG. 4. Role of chemosensory receptors of antennae and ovipositor in establishing experience of frass, and effect on flight response to odors from cowpea-*Heliothis zea* complex by 7- to 8-day-old *Microplitis demolitor* females. C: no preflight experience; F-a: experience with frass by the antennae only; F-a + o: experience with frass with both the antennae and ovipositor. The black portion of the bars represents the percentage of females flying in the first trial, and the white plus black bars those flying at least once in five trials. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

to airborne semiochemicals and by initiating the reflex of oviposition, the latter would have a regulatory effect on this reflex and would act mainly in host recognition and host acceptance. Many parasitoids are guided to the host by volatile odors and are stimulated to accept it or reject it by chemotactile stimuli on the cuticle or in the body, perceived through receptors on the antennae, tarsi, or ovipositor (Herrebout, 1969; Vinson and Lewis, 1965; Weseloh and Bartlett, 1971; Corbet, 1971; Wilson et al., 1974; Weseloh, 1974; Prokopy and Webster, 1978).

Effect of Chilling Pupae on Quality of Subsequently Emerging Females. The percentage of experienced females that performed a sustained flight to the odor source in the first trial in each of the three chilled groups was significantly lower than in the nonchilled group (Figure 5). Even a four-day period of chilling led to a decrease in the response of subsequently emerging adults. Experienced

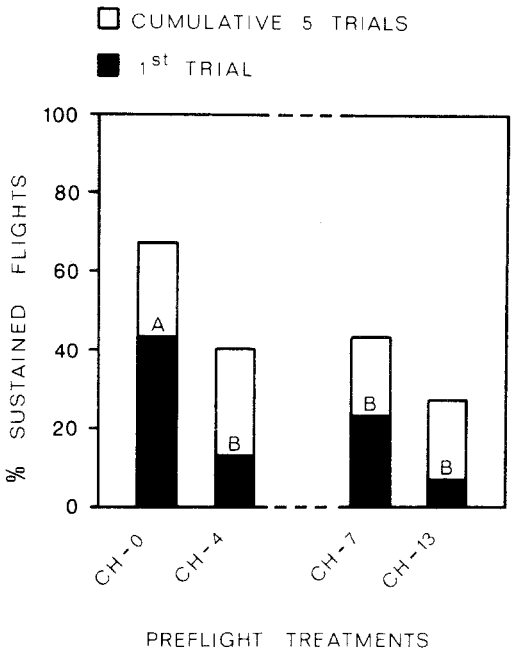

FIG. 5. Effect of chilling pupae on flight response to odors from cowpea–*Heliothis zea* complex by 7- to 8-day-old experienced *Microplitis demolitor* females, subsequently emerged from this pupae. CH-0: not chilled; CH-4: 4-day chilling; CH-7: 7-day chilling; CH-13: 13-day chilling. All the females were given a preflight exposure to natural damage + frass. The black portion of the bars represents the percentage of females flying in the first trial, and the white plus black bars those flying at least once in five trials. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

females did not respond to volatile semiochemicals in most cases. It may be that such parasites, released in the field, would be ineffective for biological control.

In addition, reproductive performance of the seven- and 13-day chilled individuals was so altered that 94% of their progeny were males. These data suggest that females were not inseminated because of a misfunctioning of the pheromonal system or because the sperm transfer was altered by the cold. In order to answer this question, we interbred females emerging from seven-day-chilled cocoons with normal males, and seven-day-chilled males with normal females. Observation of the males' response to the female pheromone suggested that chilled females produced the pheromone normally. Both chilled and unchilled males responded positively and chilled males were sensitive to the

female pheromone. Matings were observed in the two groups. The percentage of male progeny in both groups was higher than in typical rearing (60% instead of 40–50%). The results indicate that chilling of pupae altered the reproductive performance of both the females and males. The combination of these effects, when chilled males and females were interbred, led to production of a particularly high percentage of males among the progeny.

These studies demonstrated the importance of airborne semiochemicals in the host-searching behavior of *M. demolitor* and the importance of preflight handling on behavioral performance of the parasitoid. Understanding the process of preflight stimulation has a high practical value. It appears that conditioning of beneficial insects by contact with particular cues from the target plant–host complex before their release results in a much more effective host-searching behavior by them and their retention in the release area. Gross et al. (1975) demonstrated in greenhouse and field studies that stimulation with host-seeking stimuli just prior to release resulted in higher parasitization rates with *M. croceipes*, *Trichogramma pretiosum* (Riley), and *T. achaeae* Nagaraji. Lewis et al. (1975) showed that retention of *Trichogramma* spp. increased when a kairomone (Tricosane) was applied to plant foliage.

Acknowledgments—We are most grateful to Lisa Hill and Joe Spurlin, who maintained insect and plant cultures; to Deryck Perkins and Margaret Wood, who generously provided host larvae and artificial diet; and to Ted Turlings, Fred Eller, Lucas Noldus, Yvonne Drost, and Olivier Zanen for helpful discussions and suggestions. Raymond Moore, Walker Jones, David Perkins, John McLaughlin, John Hamm, and Geneviève Prévost gave valuable suggestions for manuscript revisions.

Abstract—*Microplitis demolitor* Wilkinson were reared from *Heliothis zea* larvae fed either an artificial diet or a diet of cowpea seedlings. Responses of females from these two sources to semiochemicals from the insect host–cowpea complex were compared in a flight tunnel. Very limited responses were obtained from females reared from hosts fed artificial diet unless they first had preflight contact with frass from plant-fed hosts. Female parasitc ls reared from plant-fed hosts were generally responsive without preflight contact. Contact with cocoons containing frass of the plant fed host at the time of emergence was an important source of stimulation. It increased their subsequent responsiveness to the volatile semiochemicals of the insect host–plant complex. The cocoons of females reared from artificial diet-fed hosts were apparently lacking plant chemicals that are vital to their subsequent responsiveness. Imprinting of the adults at time of emergence from the cocoon is strongly indicated.

Key Words—*Microplitis demolitor*, Hymenoptera, Braconidae, *Heliothis zea*, Lepidoptera, Noctuidae, biological control, rearing on plant, wind tunnels, flight response, preflight behavior, imprinting.

[1]Hymenoptera: Braconidae.

INTRODUCTION

Earlier work (Hérard et al., 1988) indicated that, at emergence, most *Microplitis demolitor* Wilkinson females reared from *Heliothis zea* (Boddie) larvae fed artificial diet could not orient and fly upwind to volatile semiochemicals emitted by the cowpea–*H. zea* complex. Optimally, they needed a preflight contact with frass from *H. zea* larvae fed cowpeas to show a sustained flight in a wind tunnel to odors from this plant–host complex. In addition, the most consistent flight responses were performed at 7–10 days of age following emergence (Hérard et al., 1988). Several authors have demonstrated that host frass can be a source of compounds that induce a behavioral change when parasitoids detect them (Kajita and Drake, 1969; Cardona and Oatman, 1971; Lewis and Jones, 1971; Greany and Oatman, 1972; Kennedy and Golford, 1972; Hendry et al., 1973). However, diet can affect the kairomonal content of host frass (Roth et al., 1978; Nordlund and Sauls, 1981). Sauls et al. (1979) and Nordlund and Sauls (1981) found that differences occur in the antennation response of *M. croceipes* (Cresson) females to frass from *H. zea* larvae fed different diets. Nordlund and Lewis (1985) demonstrated that host-selection response of *M. demolitor* to *H. zea* frass is also dependent on the diet on which the larvae fed. These authors observed that antennation behavior was elicited in *M. demolitor* females contacting the frass of *H. zea* and *Trichoplusia ni* (Hübner) larvae fed pea cotyledons, whereas it was not elicited in individuals contacting frass from larvae fed artificial diet. These findings prompted us to evaluate and compare flight responsiveness to volatile semiochemicals by *M. demolitor* females reared from hosts fed plant material and from hosts fed artificial diet.

METHODS AND MATERIALS

H. zea larvae, parasitized by *M. demolitor*, were reared individually on an artificial diet developed by Burton (1969). Following pupation, parasitoid cocoons were isolated in clean 30-ml cups with honey and water. Adults were paired (1 male and 1 female) a few hours after emergence. Each pair was isolated and provided with honey and water until the time behavioral testing. (See Hérard et al., 1987, for more detail on *M. demolitor* rearing techniques.)

The *M. demolitor* were also reared from *H. zea* fed on pink-eye purple-hull cowpea seedlings that had been grown in the greenhouse. Two hundred parasitized first-instar larvae were placed on two pans of cowpea seedlings in 70-liter cages until emergence of the parasitoid larvae from their hosts. The parasitoid cocoons, normally spun on the damaged leaves, were removed from the plant and placed individually in 30 ml cups. Thus, these adults did not have any contact with the damaged plant at emergence.

Those females provided with a preflight experience on the plant–host complex were placed for 2 min into a 150-mm-diameter Petri dish containing a cowpea leaf damaged by *H. zea* and frass from cowpea-fed *H. zea* larvae. The host itself was not presented since we knew from earlier studies (Hérard et al., 1988) that contact with and oviposition in hosts does not increase a parasitoid's stimulation. The wind tunnel used and test procedures were the same as described by Hérard et al. (1988). The odor source placed at the upwind end of the flight tunnel consisted of one cowpea seedling being fed upon by five third-instar *H. zea* larvae and fresh frass. The larvae were confirmed to be actively feeding at the time of each test.

Individual females were released from a vial 130 cm downwind from the odor source. A positive response consisted of sustained oriented flight from the release point to the odor source. A description of various responses by female *M. demolitor* are detailed in Hérard et al. (1988).

Characterization of Varying Response Thresholds to Volatile Semiochemicals. Results obtained in earlier studies (Hérard et al., 1988) showed that in female *M. demolitor* reared from *H. zea* fed artificial diet, 5% of individuals with no experience flew in the first trial to a source of volatile semiochemicals emitted by the cowpea–*H. zea* complex. This observation led us to ask two questions: (1) Do some individuals have an inherently lower response threshold; or (2) have they obtained some experience from inadvertent contaminations? One source of contamination could be from the surface of the cocoon. In the rearing containers that held the artificial diet, the parasite cocoons were spun on a layer of silk from the host and were generally contaminated with fragments of frass. They were removed from these containers before emergence of adults, but inevitably were contaminated with silk and frass from the host. Some contact by the parasitoid with this material could occur and serve as a preflight stimulation.

For this experiment, we used two groups of 20 parasitoid females reared from *H. zea* fed artificial diet. One group of females emerged normally from their cocoons. Females of the second group emerged from pupae that had been separated from their cocoons on the second day of pupal stage, by cutting the cocoon and the cast larval cuticle longitudinally all around in two halves, with a razor blade. The pupae were then removed and placed individually in 30-ml plastic cups on a layer of moist cotton. Proper humidity was crucial during imaginal molting to obtain adults with functional wings. In this manner we isolated 20 female *M. demolitor* that had not contacted a cocoon. We did not provide females of the two groups with any stimulation before testing them in the wind tunnel. Tests were with 7- and 8-day-old females.

Effect of Host Diet on Behavioral Performance of Parasitoid. At the end of the parasitoid larval development, the parasitized host on a cowpea leaf stops moving. The end of its abdomen seems paralyzed and fixed to the substrate.

The host does not feed but is still alive. The anterior part of its body remains free, and it spins a considerable amount of silk around itself. The parasitoid larva emerges from the host and begins to spin a cocoon attached to the leaf just beside the host on the layer of larval silk. At this time, the parasitoid larva and its cocoon are mixed with hemolymph, silk, frass, and larval cuticle which contain chemicals from the plant–host complex. We assumed that these host and plant products on cocoons could be a source of activation for the female at emergence. To test this hypothesis we reared two groups of *M. demolitor*: one from larvae fed on artificial diet and the other from hosts fed on cowpea seedlings at the same temperature (26 ± 1°C). They showed an equal period of development. Cocoons were removed from cups of artificial diet and from cowpea leaves and isolated until emergence of adults which were then fed and paired. Five- and 6-day-old females from the two cultures were tested in the wind tunnel on the same days. Half the females in each group were tested without preflight experience. The other half were exposed to frass and cowpea leaves from feeding *H. zea* larvae and frass.

Effect of Contact with Cocoon when Host Larvae were Reared on Plants. It was assumed that *M. demolitor* females emerging from cocoons spun on plants acquire the experience of the plant–host complex as soon as they palpate their cocoon with their antennae at the moment of emergence. To verify the role of contact with a cocoon, we tested in the wind tunnel three groups of parasitoids reared from hosts fed on cowpeas. In two of them, the females emerged from their cocoons normally. The first group received preflight experience with the natural plant damage and frass, and the second received no preflight experience before the test. In the third group, the cocoons were cut and the pupae isolated as described earlier. The adults emerged without contact with the cocoon. The females received no experience before the test.

RESULTS AND DISCUSSION

Characterization of Varying Response Thresholds to Volatile Semiochemicals. No female of the group removed from the cocoons flew in the first trial, but 15% showed a sustained flight to the source in 5 trials (Figure 1). This confirmed the natural ability of a few females to respond to semiochemicals without any prior stimulation. Several authors have given clear evidence that searching is partly genetically determined, because certain cues evoke an innate fixed searching pattern (Thorpe and Jones, 1937; Jones et al., 1971, 1973; Lewis et al., 1972; Hendry et al., 1973; Vinson et al., 1975; Sandlan, 1980). Among the females emerged from the cocoon of a host fed artificial diet, but given no other experience other than contacting the cocoon, 5% showed a sustained flight to the source in the first trial, and 25% flew in five trials (Figure

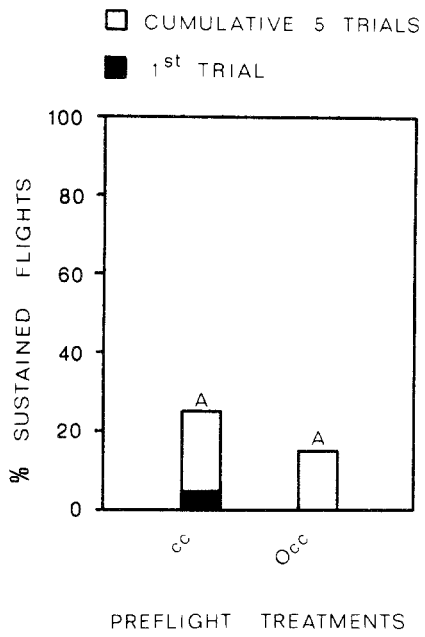

FIG. 1. Flight response to odors from cowpea–*Heliothis zea* complex by 7- to 8-day-old inexperienced *Microplitis demolitor* females reared from hosts fed artificial diet. cc: parasitoid emerged from cocoon. Occ: pupa developed and emerged outside cocoon. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

1, cc). These percentages are not significantly different from the results obtained with similar females emerging without contacting the cocoon (Figure 1, Occ). These results indicate that contact with the cocoon and associated materials from artificial diet was not a sufficient source of activation for *M. demolitor* females.

These data indicate that, from a practical standpoint, if *M. demolitor* is to have an effective host-selection behavior when reared in large numbers from hosts fed on artificial diet, it should have contact with appropriate semiochemicals from the target plant-host complex before release in the field. Most of them would disperse immediately and would be ineffective for biological control without this preflight stimulation. This may apply to other beneficial insects.

Effect of Host Diet on Behavioral Performance of Parasitoid. Percentages of females flying in the first trial to the source were significantly higher in the group obtained from hosts reared on plants, even when they did not receive preflight experience (Figure 2, p-0exp), than in the group obtained from hosts reared on artificial diet (Figure 2, a-0exp and a-NDF). Among the females

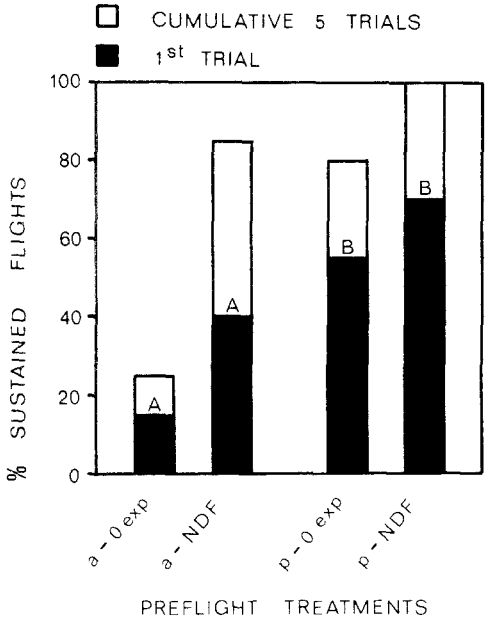

FIG. 2. Flight response to odors from cowpea-*Heliothis zea* complex by 5- to 6-day-old female *Microplitis demolitor* reared from hosts fed plant material or artificial diet. a-0exp: host reared on artificial diet, no preflight experience. a-NDF: host reared on artificial diet, preflight exposure to natural damage + frass. p-0exp: host reared on plant, no preflight experience. p-NDF: host reared on plant, preflight exposure to natural damage + frass. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

obtained from hosts reared on plants, the occurrence of an additional preflight experience (Figure 2, p-NDF) did not increase significantly the percentage of positive responses. Thus, parasitoids from hosts fed on the natural plant apparently receive valuable experience from the plant–host complex before or at time of emergence from the cocoon. Arthur (1966, 1971) gave evidence that the searching pattern can be influenced by previous experience in the ichneumonids *Itoplectis conquisitor* (Say) and *Venturia canescens* (Gravenhorst). Learning in insects has been shown to occur (Thorpe, 1956; Alloway, 1972, 1973) and takes different forms: habituation (Thorpe, 1938; Waage, 1979), preimaginal conditioning (Thorpe and Jones, 1937; Monteith, 1955; Waage, 1979; Kudon and Berisford, 1980), postimaginal latent learning (Thorpe and Jones, 1937; Thorpe, 1938), and associative learning (Monteith, 1963; Vinson et al., 1977). The ecological significance of the learning process was discussed by Vet (1983). The function of learning in search behavior would be to "optimize the discovery and utilization of resources which fluctuate in abundance and time" (Vet, 1983).

Our results confirmed that females obtained from hosts reared on artificial diet were not naturally experienced at emergence. Perhaps some essential compound existing in the plant is lacking in the artificial diet. Accordingly, the frass of hosts fed on this diet would not contain the kairomone(s) that contaminate the parasitoid's cocoons, activate the host-seeking behavior of emerging females, and lower the threshold response to volatile semiochemicals. Observations by Nordlund and Lewis (1985) showed that contact of *M. demolitor* females with frass of *H. zea* larvae fed artificial diet did not elicit host-seeking antennation behavior by the parasitoids.

Effect of Contact with Cocoon when Host Larvae were Reared on Plants. As shown in Figure 3 by the two first bars, a high percentage of experienced (cc-NDF) and inexperienced (cc-0exp) females that had emerged from their cocoons responded to odors from the plant–host complex in the first trial. Most

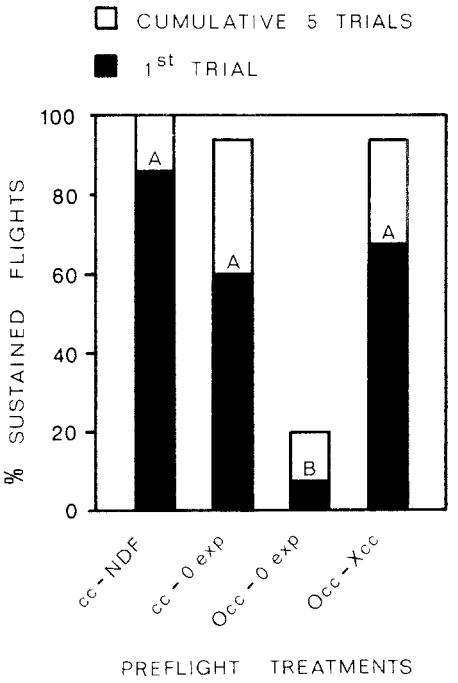

FIG. 3. Effect of contact with the cocoon on flight response to odors from cowpea–*Heliothis zea* complex by 7- to 8-day-old female *Microplitis demolitor* reared from hosts fed plant material. cc-NDF: parasitoid emerged from coccon, preflight exposure to natural damage + frass. cc-0exp: parasitoid emerged from cocoon, no preflight experience. Occ-0exp: parasitoid emerged outside cocoon, no preflight experience. Occ-Xcc: parasitoid emerged outside cocoon, preflight exposure to cut cocoons. Bars topped by the same letter do not differ significantly; $P = 0.05$; repeated G tests.

of the females that had emerged separated from the cocoons (Occ-0exp) did not fly to the target.

The females of this third group, which showed only negative responses in five trials, were later exposed for 2 min to the cut cocoons. They became very active at the surface of the cocoons, showing intense antennal activity and abdominal probing. They were tested again in the wind tunnel. A high percentage of them then flew to the odor source, as shown in Figure 3 (Occ-Xcc). Thus the cocoon of individuals reared from hosts fed on plants is a natural source of substances important for preparation of *M. demolitor* females for later host-finding performance.

In fact, cocoons spun in contact with damaged plants and dying hosts are likely to be contaminated by a complete set of cues from the plant–host complex (sap from the damaged plant, and silk, saliva, hemolymph, and frass from the host). These data show that the first preflight stimulation occurs naturally at the time of emergence through contact with the cocoon and surrounding substrates and that this contact is sufficient to obtain responsiveness by most females. It is a durable activation, since the females respond positively for at least seven days after the contact with a cocoon. Accordingly, true imprinting of emerging *M. demolitor* females from hosts fed plant material is strongly indicated.

CONCLUSIONS

These studies showed that when the parasitoids were reared from host fed artificial diet, the foraging behavior of female *M. demolitor* response to the insect–host plant contact was not activated by contact with its cocoon at emergence. When hosts were reared on plants, parasitoid cocoons were mixed with frass and semiochemicals from the plant–host complex. It was demonstrated in this case that simple contact of a *M. demolitor* female with its cocoon at emergence served as a necessary, valuable, and durable preflight stimulation in its subsequent search for a host.

These studies show that when parasitoids are reared from hosts fed artificial diet, they are missing vital experience necessary for their most effective performance. A few other questions arise at this point. Is imprinting on a host reared on a particular host plant specific to that plant–insect host association? What would be the responsiveness of a parasitoid to semiochemicals of the same host species reared on another host plant? From a practical standpoint, is it necessary to give the parasitoids a preconditioning on the target plant–insect host complex before release in the field in order to achieve the highest rate of parasitism? The validity of these ideas was not tested in the present study and requires experimental proof, as the results have significant implications concerning the effectiveness of the parasitoids in biocontrol programs. Thus, parasitoids reared from hosts fed cowpeas may not respond to semiochemical cues

from host feeding on cotton and vice versa. The specificity of the imprinting to semiochemicals from the plant–host complex is an important question that arises from this research. Studies designed to better understand the roles and mechanisms of these factors could greatly enhance biological control programs.

Acknowledgments—We are most grateful to Lisa Hill and Joe Spurlin, who maintained insect and plant cultures; to Deryck Perkins and Margaret Wood, who generously provided host larvae and artificial diet; and to Ted Turlings, Fred Eller, Lucas Noldus, Yvonne Drost, and Olivier Zanen for helpful discussions and suggestions. Raymond Moore, Walker Jones, David Perkins, John McLaughlin, John Hamm, and Geneviève Prévost gave valuable suggestions for manuscript revisions.

(Received April 9, 1987; accepted August 25, 1987)

Abstract—Rearing the parasitoid *M. croceipes* on hosts fed cowpea-seedling leaves instead of artificial diet increased the percentage of oriented flights to odors of a cowpea seedling–*H. zea* complex in a flight tunnel. However, the increase in response was much stronger after adult females had searched a fresh plant-host complex just prior to a test. The host plant appears to be of major importance in the parasitoid–host relationship: host-plant species, growth phase, and part of the host plant influence the parasitoid's response in the flight tunnel. The percentage of inexperienced females responding to infested leaves was higher for 4- to 5-day-old females than for 0- to 1-day-old females, while the response to uninfested flowers was equally high for both age groups. Olfactory experience with odors of an attractive plant–host complex increased the response to an unattractive plant–host complex. Possible implications of the results are discussed.

Key Words—*Microplitis croceipes*, Braconidae, Hymenoptera, *Heliothis zea*, Lepidoptera, Noctuidae, olfaction, flight, olfactory experience, rearing.

INTRODUCTION

Host specialists may be more likely to have an innate response to stimuli that are directly related to the host or to the host habitat than are host generalists (Vet, 1983; Waage, 1979). Females of the host specialist *Microplitis croceipes* (Cresson), an important larval endoparasitoid of *Heliothis zea*, show an innate host-searching response when they make contact with feces of the host. They restrict the host-searching area by drumming the surrounding substratum with their antennae (Lewis and Jones, 1971). Yet, in a flight tunnel the females do not fly upwind to *H. zea* feeding on cowpea-seedling leaves unless they had previously contacted feces (Drost et al., 1986). Contact with feces may often be followed by oviposition once the host is found; however, oviposition was not required for obtaining increased flight responses. Thus, contact with feces induces a change in the behavior of the parasitoid. We will use the term "experienced" for adult females that had searched a plant–host complex and oviposited once and "inexperienced" for females that had no oviposition experience and no contact with host- or host-plant related cues since emergence.

Parasitoids used by Drost et al. (1986) were reared on *H. zea* larvae feeding on an artificial pinto-bean diet (Burton, 1969). Perhaps this rearing method has influenced the responsiveness of the adult females. Sauls et al. (1979) reported that feces from hosts fed artificial diet elicit less antennation in adult female *M. croceipes* than do feces from hosts fed cowpea-seedling leaves. During the development of the parasitoid in the host larvae, the parasitoid perhaps perceives chemical cues derived from the host's diet that are required as a later reference in the host-finding process.

Another factor that may cause low responsiveness of the parasitoids may relate to the quality of the source emitting the odors in the flight tunnel, which is determined by the host and the host plant. The host-plant species of *H. zea* influences the parasitization rates by *M. croceipes* in the field, as was reported by Danks et al. (1979). The likelihood of attack and the probability of successful parasitism is correlated with the host-plant species (Mueller, 1983). The influence of the host-plant species on host-searching behavior by inexperienced *M. croceipes* has not been determined previously. In addition to host-plant species, the growth phase and part of the plant might influence the response by *M. croceipes*. One might expect the parasitoid to fly more frequently to plant species, plant growth phases, and plant parts on which hosts are most likely to occur, such as fruits and young leaves on which third-instar *H. zea* larvae prefer to feed (Schmidt, 1985). For example, Elzen et al. (1987) found *M. croceipes* females responding to odors of uninfested cotton.

The age of the adult parasitoid may influence its response to host-related odors. Although Drost et al. (1986) found that the age of the adult female does not influence the flight response of experienced females, this might not be true

for inexperienced females. Influences on the responsiveness due to the age of the parasitoid female may have been overridden by the effect of experience.

We discovered that odors of a plant–host complex attractive to inexperienced females had an effect on the subsequent response to other plant–host complexes. This means that besides experience with cues perceived while searching a plant–host complex, olfactory experience might play a role in the host-searching process.

In the present paper, we show how the responsiveness of *M. croceipes* in a flight tunnel is influenced by the rearing method, host-plant species, host-plant growth phase, part of the host plant, presence of host larvae, age of the parasitoid, and experience of the adult with odors from a plant–host complex.

METHODS AND MATERIALS

Insects. Heliothis zea larvae were reared on artificial diet (Burton, 1969). *Microplitis croceipes* were reared using the method of Lewis and Burton (1970) (see also Drost et al., 1986). Oviposition experience was given just prior to a flight test with one host.

Flight Tunnel. For a complete description of the flight tunnel, see Drost et al. (1986), and for the odor supply system, see Zanen et al. (1988). Odors were injected into the flight tunnel (50 × 50 × 120 cm) through nozzles made of Pasteur pipets. Four separate flasks were connected to one nozzle outside the flight tunnel, which allowed individual separation of the four larvae that formed one odor source. This was necessary because the larvae are cannibalistic and odors emanating from cannibalism reduce the response by *M. croceipes*. The system allows shut-off of odor sources when they are not needed, which makes it possible to switch between odor sources without contaminating the flight tunnel. Wind speed was maintained at 50 cm/sec.

Odor Sources. Cowpea-seedling leaves (*Vigna unguiculata* L.) and mature leaves and squares (i.e., flower buds) of cotton (*Gossypium hirsitum*) were obtained from plants grown in a greenhouse. Mature leaves and flowers of cowpea and hyacinth bean (*Lablab purpureus* L.) were collected in the field. One day prior to an experiment, recently molted fourth-instar *H. zea* larvae were placed in 1-oz cups with limited food (1-cm^2 piece of leaf on the plant to be evaluated). On the test day, odor sources were prepared with one larva and 1–2 g of plant material per flask and four flasks per odor source. To ensure saturated adsorption of materials inside the glass tubing and nozzles and to remove volatiles emanating from the cutting wounds of the plant material (Zanen et al., 1988), we turned on the dispersing system for 60 min prior to testing.

Test Procedure. The parasitoid females were placed in the experiment room under an exhaust hood and supplied with fresh honey and water 30 min prior

to a test. A single female was introduced into the flight tunnel in a 1-dram vial while the wind speed was set on maximum (140 cm/sec) and the odor source shut off. Subsequently, the door of the tunnel was closed, the odor source opened, and the wind speed set on 50 cm/sec. By keeping the wind speed high until a test started, we could prevent pretest flight of the parasitoid. The occurrence of a sustained flight (i.e., a nonstop flight followed by a landing on the odor source; see Drost et al., 1986) was recorded for each female. All females were used once, and the percentage of sustained flights was calculated as the quotient of the number of females making a sustained flight and the total number of females tested, unless otherwise noted. All tests were single choice tests and were carried out on at least three different days. Homogeneity among days of number of sustained flights to a certain odor source was tested with a chi-square test with alpha = 0.05.

RESULTS

Experiment 1: Influence on Rearing Method on Responsiveness of Adult Female. To test the hypothesis that the rearing method influences the response to infested cowpea seedlings, we compared two groups of females: one group reared on hosts fed artificial diet and one group reared on hosts fed cowpea-seedling leaves. For parasitization, 20 third-instar *H. zea* larvae were confined with two 3-day-old *M. croceipes* females in a 16-oz cup for one night. Subsequently, the larvae were split into two groups and transferred to 1-oz cups, one larva/cup, with artificial diet or cowpea-seedling leaves. The larvae were kept at 28°C, 50–70% relative humidity, and a 16-hr photophase. The cowpea-seedling leaves were replaced every other day by fresh ones. We collected the parasitoid pupae and transferred them to clean 1-oz cups for emergence. Adults were collected from the cups before 10 AM each day and transferred to 16-oz cups, one female and one male per cup, until they were 4-5 days old. The females were released in acrylic cages (30 × 30 × 17 cm) the night prior to a test and provided with water and honey. We tested the responsiveness of the females in both groups (58 females reared on artificial-diet-fed hosts and 50 females reared on cowpea-seedlings-fed hosts) to odors of hosts feeding on cowpea-seedling leaves. All parasitoids were inexperienced when tests started. Females that made a sustained flight in either one of the first two trials were scored as responsive. Females that did not respond in the first two trials were given oviposition experience, which increases the probability of flight, and tested twice more to ensure that the alternative rearing methods had not diminished the flight capabilities of the parasitoids.

Females that were reared on hosts fed cowpea seedlings made more sustained flights to odors of hosts feeding on cowpea seedlings than females that

were reared on hosts fed artificial diet (Figure 1, open bars). For both groups, many of the nonresponding females would respond after oviposition experience and the total (inexperienced + experienced) number of responding females for both groups was not significantly different (Figure 1, solid bars). This indicates that the rearing method influences the olfactory response of adult females but does not change the flight capabilities of the females.

*Experiment 2: Influence of Odors from Different Plant–*H. zea *Complexes on Flight Response by Inexperienced Females.* In order to avoid possible conditioning to the host diet (Vet, 1983), we reared the parasitoids in this and all following experiments on hosts fed artificial diet. Responsiveness of 4- to 5-day-old inexperienced females was tested for three different odor sources in single-source experiments: (1) hosts feeding on mature cowpea leaves (N = 26), (2) hosts feeding on mature cotton leaves (N = 62), and (3) hosts feeding on mature hyacinth-bean leaves (N = 55). All plants were bearing flowers or flower buds when leaves were picked.

Odors from a hyacinth bean–*H. zea* complex elicited significantly more sustained flights in inexperienced females than did odor from cowpea leaves–*H. zea* or cotton–*H. zea* complexes (Figure 2). The three odor sources all elicited sustained flights in at least 40% of the females, which means that inexperienced females, even when reared on hosts feeding on artificial diet, are able to respond to volatile stimuli. Comparison of the results for cowpea with the results of experiment 1 for inexperienced females reared on hosts fed artificial diet suggested that the age of the host plant is another important factor determining the number of sustained flights. We verified this with the next experiment.

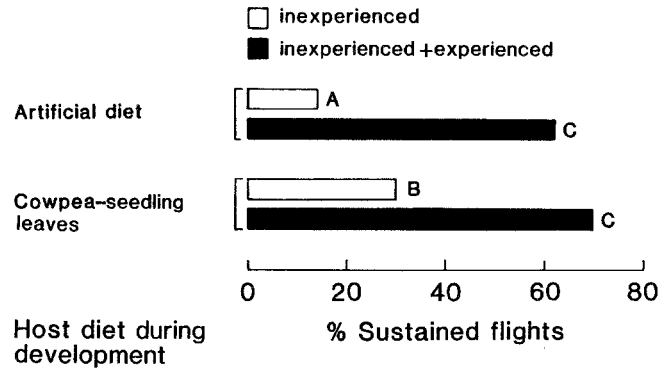

FIG. 1. Influence of rearing method on the flight response of adult females to odors of a cowpea seedling–*H. zea* complex. Similarly patterned bars with different letter indicate significant difference (G test, $P < 0.05$).

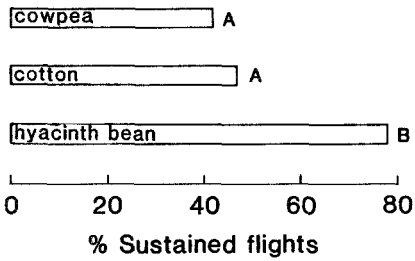

FIG. 2. Effect of host-plant species of *H. zea* on the flight response by *M. croceipes*. Bars with different letters indicate significant difference (G test, $P < 0.05$).

Experiment 3: Influence of Growth Phase of Host Plant on Flight Response. Inexperienced 4- to 5-day-old females were tested for their response toward plant–host complexes containing either cowpea-seedling leaves or mature cowpea leaves. The percentage females making a sustained flight toward a mature cowpea leaves–*H. zea* complex (42%, $N = 26$) was significantly (G test, $P < 0.05$) higher than that toward a cowpea seedling–*H. zea* complex (17%, $N = 34$).

Experiment 4: Flight Responses toward Different Parts of Plant in Relation to Presence of Hosts. We determined the responsiveness of inexperienced 4- to 5-day-old females toward infested leaves ($N = 55$), infested flowers ($N = 40$), uninfested leaves ($N = 44$), and uninfested flowers ($N = 50$) of hyacinth bean, all in single-source experiments. Both leaves and flowers were attractive without hosts present. Females did not respond differently to infested than to uninfested flowers although they did respond more frequently to infested leaves than uninfested leaves (Figure 3). Infestation significantly reversed the response lev-

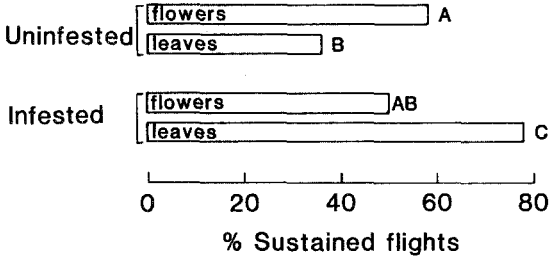

FIG. 3. Influence of the part of the host plant and *H. zea* infestation of the flight response. The host plant was hyacinth bean in all cases. Bars without same letters indicate significant difference (G test, $P < 0.05$).

els to flowers compared to leaves (G test, $P < 0.05$). We expected that infested flowers would be more attractive than uninfested flowers because they contain both hosts and food for the parasitoid. One explanation might be that the odor of the flowers masks the odor of the larvae.

Experiment 5: Influence of Age of Parasitoid on Flight Response. We tested 0- to 1-day-old females for their response toward infested hyacinth-bean leaves and uninfested flowers, again in single-source tests, and compared the responses with those of 4- to 5-day-old females from experiment 4. Comparison between experiments 4 and 5 was justified, because both experiments were carried out at the same days with parasitoids taken from the same populations. The age of the parasitoid is of significant (G test, $P < 0.05$) importance for the flight response when the parasitoid is inexperienced. While 78% ($N = 55$) of 4- to 5-day-old females respond to odor of a hyacinth bean leaves–*H. zea* complex, only 29% ($N = 41$) of 0- to 1-day-old females respond to the same odor source. In contrast, the response to host-free flowers was not significantly different for both age groups: 55% ($N = 20$) for the 0- to 1-day-old females and 58% ($N = 50$) for the 4- to 5-day-old females.

Experiment 6: Influence of Odors Encountered Previously on Flight Response. In the previous experiments, the percentage of females responding to a cowpea seedling–*H. zea* complex was consistently lower than to the hyacinth bean–*H. zea* complex. In this experiment, parasitoids were tested for their response to both these plant–host complexes in each of three sequences: cowpea/cowpea ($N = 19$), cowpea/hyacinth bean ($N = 25$), and hyacinth bean/cowpea ($N = 23$). One female was allowed to have no more than two trials and no more than one sustained flight to each odor source. This resulted in differences in the number of trials per female (minimum 2, maximum 4), but we thought it was more important to keep the flight experience to each source constant because flight experience may increase the level of response. However, when both odor sources contained infested cowpea seedlings, none of the females responded twice (Figure 4). Apparently, in females without preflight exposure to a plant–host complex, flight experience by itself does not increase the level of response as was the case for parasitoids with preflight exposure to a plant–host complex (Drost et al., 1986). When the first odor source contained infested cowpea seedlings and the second contained infested hyacinth bean leaves most of the females responded only to the odor of the hyacinth bean–*H. zea* complex. When the first odor source contained infested hyacinth bean and the second contained infested cowpea seedlings, most females responded to the hyacinth bean complex as well as to the cowpea seedling complex and less than 10% did not respond at all. Thus the encounter with the odors of an attractive odor source increases the response to odors of a less attractive odor source.

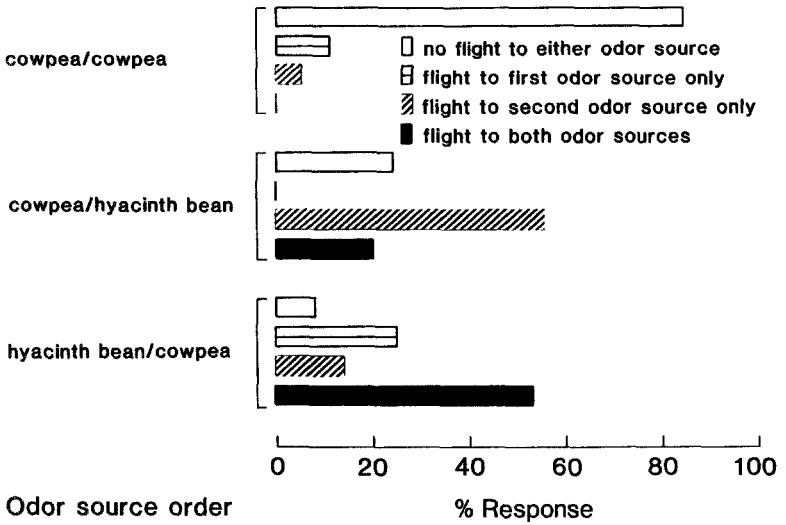

FIG. 4. Effect of previous encounter with odors on subsequent flight response. Odor sources were either a cowpea seedling–*H. zea* complex or a hyacinth bean–*H. zea* complex that were presented in different order to one female according to the treatment. The distributions of responses are significantly different between the three treatments with a repeated G test ($P < 0.05$).

DISCUSSION

The diet of the host larva during development of *M. croceipes* influences the responsiveness of the females toward odors of a plant–host complex in the flight tunnel. This may be caused by stimuli perceived either prior to eclosion or shortly after eclosion. During parallel studies in our lab on *M. demolitor*, Hérard et al. (1988) found that this parasitoid, which also parasitizes *H. zea* larvae, obtained the stimuli causing the increased responsiveness by contact with the cocoon. *M. demolitor* females reared on hosts fed cowpea seedlings and dissected from their cocoons had a low responsiveness. When these females were allowed to contact the cocoons, the responsiveness to a cowpea seedling–*H. zea* complex increased significantly compared to the initial response. A similar phenomenon may occur in *M. croceipes*. It is unclear whether stimuli perceived during development or upon eclosion condition the parasitoid, i.e., females reared on larvae fed artificial diet may be conditioned to respond to an artificial diet–*H. zea* complex, or decrease the response threshold to any plant–host complex. Whatever the mechanism, contact experience of the adult female with a fresh plant–host complex seems to be far more important for the respon-

siveness to host-related odors than the rearing method. Vet (1983) reported similar findings for the parasitoid *Leptopilina claviceps*, a larval parasitoid of fungivorous Drosophilidae.

The host plant of the *H. zea* larvae appears to be an important factor in the host-searching process of the parasitoid. The innate response of *M. croceipes* females differed with the host-plant species on which *H. zea* was feeding, and odors of an attractive plant–host complex increased the response to a less attractive plant–host complex. Hence, a less attractive host plant may benefit from being planted between more attractive host plants because the response threshold of the parasitoid is at least temporarily decreased by the more attractive host plants.

Flowers and extrafloral nectaries may influence the distribution of both pest and beneficial arthropod populations (Adjei-Maafo and Wilson, 1983; Maxwell et al., 1976). The presence of floral and extrafloral nectaries increases both the survival of the parasitoid and rates of parasitization in *Campoletis sonorensis*, another larval endoparasitoid of *H. zea* (Lingren and Lukefahr, 1977). Although we found only a small percentage of inexperienced recently emerged *M. croceipes* females responding to host-related odors, a much larger percentage was responding to host-free flowers. Upon visiting flowers, the prefered plant part by *H. zea*, a female might by chance encounter host feces or a host and thus become experienced, which increases her response level to subsequently perceived host-related odors.

The work reported here shows that different factors in the environment of the parasitoid as well as in the parasitoid itself affect the behavioral response in *M. croceipes*. It still remains to be investigated in what way the different factors interact with each other.

Acknowledgments—We thank Michael Keller, Daniel Papaj, Douglas Whitman, and Olivier Zanen for their critical comments on the paper; J. D. Miller for providing the *Lablab purpureus* seeds; and Lisa Hill for maintaining the insect cultures. (Received June 1, 1987; accepted September 24, 1987)

Abstract—The effects of nine methyl ketones previously identified in the mixture of volatiles released by *Amaranthus palmeri* (AMAPA) residues upon onion, carrot, AMAPA, and tomato seed germination were determined. Three-day exposures to these volatiles significantly inhibited germination of all assay seeds, and the degree of inhibition was dependent upon seed species, exposure time, and concentration. Based on the degree of inhibition observed in both time- and concentration-dependent assays, the following activity series was obtained: 2-octanone, 2-nonanone > 2-undecanone > 2-heptanone > 2-hexanone, 3-methyl-2-butanone, 2-pentanone, 3-hydroxy-2-butanone > 2-butanone. The activities of these compounds appear to be additive and dependent on relative volatility and hydrophilicity.

Key Words—Allelopathy, volatile allelochemicals, methyl ketones, germination inhibitors, onion, *Allium cepa*, carrot, *Daucus carota*, Palmer amaranth, *Amaranthus palmeri*, tomato, *Lycopersicon esculentum*.

INTRODUCTION

The presence of *Amaranthus palmeri* (AMAPA) residues in the soil reduces fresh weight accumulation in onions and carrots and markedly decreases seedling field establishment in carrots (Menges, 1985). Classic natural products iso-

[1] Name of companies or commercial products are given solely for the purpose of providing specific information; their mention does not imply recommendation or endorsement by the U.S. Department of Agriculture over others not mentioned.

lation techniques (Bradow, 1985, Fischer and Quijano, 1985) and solid-phase separation techniques applied to water extracts of soil containing AMAPA residues (Bradow and Connick, 1987) failed to isolate any inhibitory factors from either AMAPA residues or soil containing such residues.

However, volatiles emitted both by AMAPA residues and soil containing the residues were highly inhibitory of germination in onion, carrot, AMAPA, and tomato (Bradow and Connick, 1987). A number of volatile organic compounds associated with AMAPA seedhead, stem, and root residues were subsequently identified (Connick et al., 1987), and two of these volatiles, 2-heptanone and 2-heptanol, were shown to be potent inhibitors of seed germination. The high bioactivity of 2-heptanone and the detection of six other methyl ketones in the volatile mixtures associated with AMAPA residues led to the present examination of the seed germination effects produced by the identified methyl ketones (plus 2-hexanone and 2-octanone detected under anaerobic conditions), tested individually and in selected binary combinations. This paper describes the concentration and exposure-time dependence of these effects observed with nine C_4–C_{11} methyl ketones associated with AMAPA residues.

METHODS AND MATERIALS

All chemicals used in these assays were purchased from Aldrich Chemical Company (Milwaukee, Wisconsin). Assay seeds were either purchased from commercial sources or were gifts of Dr. R.M. Menges, USDA, Weslaco, Texas.

Time-Dependent Seed-Germination Bioassays. The desiccator seed-germination assay technique has been previously described (Bradow and Connick, 1987; Connick et al., 1987). Briefly, seeds of onion, carrot, AMAPA, or tomato were spread on double sheets of deionized water-saturated Whatman No. 1 filter paper placed on the porcelain plates of separate 2.5-liter (160-mm-ID) glass desiccators. Circles (22 mm diam.) had been removed from the filter paper sheets to facilitate diffusion of volatiles, and the filter paper circles were divided into eight equal segments (replicates) containing the same number of seeds (25 AMAPA, or 20 of the other species). Each desiccator well contained a 10-ml glass beaker resting on 50 g of pure sand in a crystallizing dish (100 × 50 mm). The sand was moistened with 10 ml of deionized water. The central beakers were left empty in the controls. In the time-dependence study, a volume equivalent to 34.4 μM of a volatile test compound was placed in the central beaker, and the separate seed species were incubated for 72 hr before germination evaluation (3-day data). Radicle protrusion was the germination criterion. All evaluations were made in dim light under an exhaust safety hood. The volatile

source beaker was then either removed (3 + 4-day data) or the test volatile was renewed by the addition of a second 34.4 μM equivalent (7-day data). All seeds were then incubated an additional four days before final evaluation. Controls (deionized water) was repeated at three-month intervals throughout the duration of the experiments.

Concentration-Dependent Seed-Germination Bioassays. The central beaker of the desiccator apparatus contained the appropriate volume of a single test compound to give a nominal volatile concentration of 3.4, 6.9, 17.2, or 34.4, μM, assuming total volatilization and negligible adsorption. The actual volumes of neat ketone placed by microsyringe in the central beakers were adjusted on the basis of compound density to produce equal initial volatile molarities, e.g., 0.8, 1.8, 4.5, and 8.0 μl 2-butanone compared to 1.8, 3.5, 8.9, and 17.8 μl 2-undecanone. The seeds were then incubated three days in the presence of the test volatile, germination was evaluated, the volatile source was removed, and the seeds were incubated an additional four days. In both assays humidity within the desiccators was maintained by the addition of 10 ml deionized water after germination evaluation at three days.

2-Heptanone × 3-Hydroxy-2-butanone Interaction Assays. The standard 3-day exposure seed-germination assay was repeated using total ketone concentrations of 34.4, 25.8, or 17.2 μM in ratios of 2-heptanone to 3-hydroxy-2-butanone of 4:0, 3:1, 2:2, 1:3, or 0:4.

Statistical Analysis. After normalization by the transformation $[(x + 0.5)^{0.5}]$, germination count data from the concentration-dependent bioassays and the 7-day and 3 + 4-day time-dependent data were compared separately for each seed species by two-way analyses of variance with 16 replicates. One-way analyses of variance were used to determine significant differences between the effects of the methyl ketones and appropriately incubated deionized water controls within the 3-day, 7-day, and 3 + 4-day data, using Tukey's Honestly Significant Difference procedure (significance level, $P = 0.01$); and concentration-dependent data were examined by regression analysis. Chi-square test and G-test goodness of fit procedures were used to test the hypothesized additive relationships between the activities of 2-heptanone and 3-hydroxy-2-butanone (Sokal and Rohlf, 1981).

RESULTS AND DISCUSSION

All of the nine methyl ketones listed in the figures and tables were detected in the volatile mixtures above AMAPA residues (Connick et al., 1987 and unpublished data). 2-Hepatonone was a major component of these mixtures,

but 2-nonanone and 2-undecanone were observed only in trace amounts and principally in volatiles emitted by AMAPA root tissue. 2-Octanone and 2-hexanone were observed only when the residues were incubated anaerobically under nitrogen. Since plant residue decomposition frequently occurs under low oxygen conditions in the soil (Parr and Reuszer, 1959) and since volatiles from both AMAPA roots and seedheads inhibited germination in at least one test seed (Bradow and Connick, 1987), the homologous C_4–C_9 methyl ketone series plus 2-undecanone, 3-hydroxy-2-butanone, and 3-methyl-2-butanone were tested for effects on the germination of onion, carrot, AMAPA, and tomato seeds. Germination of seeds exposed only to deionized water vapor (control) showed no significant changes throughout the duration of these experiments.

Effects of Exposure to 34.4 μM Methyl Ketones upon Onion Seed Germination. After a 3-day exposure, all nine methyl ketones significantly inhibited onion seed germination in comparison to the control (Figure 1). 2-Butanone was the least inhibitory (39% reduction, compared to control), and 2-heptanone and 2-octanone were the most inhibitory (85% and 88% reductions, respectively). When the volatile source was removed after three days and the seeds were incubated for an additional four days, the germination of onion seeds exposed to 2-heptanone, 2-octanone, 3-methyl-3-butanone, 3-hydroxy-2-butanone was no longer significantly inhibited. The significant inhibitors induced by a 3-day exposure to 2-butanone and 2-pentanone persisted unchanged, regardless of whether the ketone source was removed or renewed before the additional 4-day incubation. Continuous 7-day exposure to 2-hexanone, 2-nonanone, and 3-methyl-2-butanone was necessary to maintain the degree of inhibition observed with these compounds at three days. Continuous exposure to 2-heptanone and 3-hydroxy-2-butanone retarded, but did not prevent, onion seed germination. 2-Undecanone produced the largest residual effect (67% reduction) after the ketone source was removed, and 2-octanone and 3-methyl-3-butanone produced the largest inhibition (76% reduction) after 7-day exposure. The significant differences observed among the activities of these methyl ketones correlate most closely with carbon chain length.

The effects of 2-butanone, the two substituted 2-butanones, and 2-pentanone were not significantly different in the 3-day or the 3 + 4-day results. 3-Methyl-2-butanone was more inhibitory than these compounds in the 7-day continuous exposure assays.

Effects of Exposure to 34.4 μM Methyl Ketones upon Carrot Seed Germination. Carrot seed germination was also significantly inhibited by 3-day exposure to all the methyl ketones tested (Figure 2). The level of inhibition ranged from the minimums observed with 3-hydroxy-2-butanone (29% reduction, compared to control) and 2-butanone (33% reduction) to elimination of

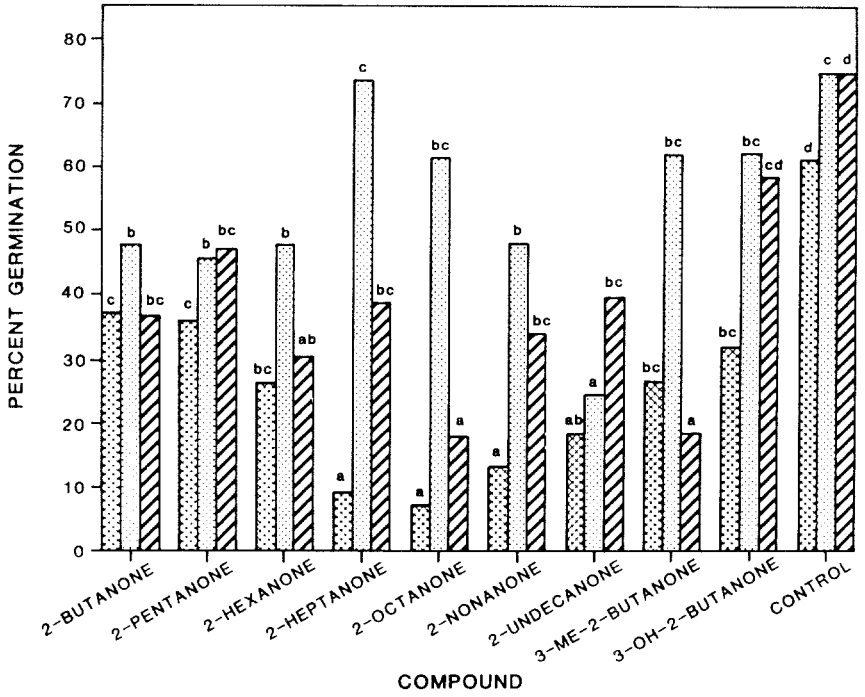

FIG. 1. Percent germination of onion (*Allium cepa* L.) seed exposed to 34.4 μM methyl ketones for three (first, crosshatched bar) and seven (third, diagonally striped bar) days or three days followed by four days' incubation after removal of ketone source (second, dotted bar). Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $< 1.8\%$.

germination in the presence of 2-heptanone, 2-octanone, and 2-nonanone. The C_7-C_9 methyl ketones, which were the most inhibitory after three days, were the only test compounds to produce significant residual effects after removal of the ketone source. Continuous 7-day exposure to these same ketones also prevented germination, 2-undecanone decreased (22% reduction) germination under the same conditions. Although carrot seeds exposed for three days to 3-methyl-2-butanone and 3-hydroxy-2-butanone exceeded the germination percentages observed in the controls after seven days' total incubation, the increases in germination were not significant. In the carrot seed assays, activity differences were again correlated with carbon chain length. The activities of 2-butanone,

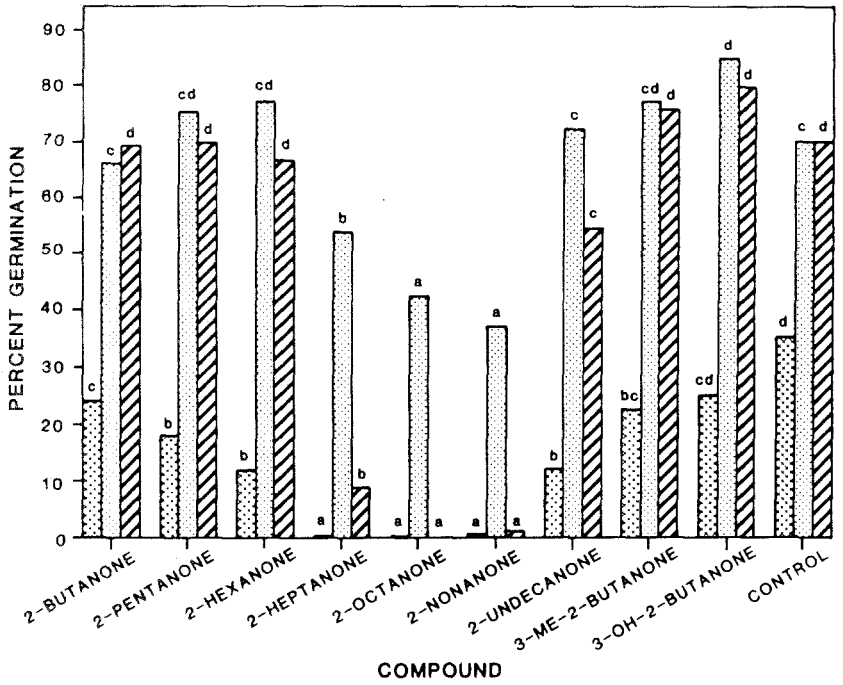

FIG. 2. Percent germination of carrot (*Daucus carota* L.) seed exposed to 34.4 μM methyl ketones for three (first, crosshatched bar) and seven (third, diagonally striped bar) days or three days followed by four days' incubation after removal of ketone source (second, dotted bar). Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $< 1.5\%$.

3-methyl-2-butanone, 3-hydroxy-2-butanone, and 2-pentanone were not significantly different after either the 3-day or 7-day exposures.

Effects of Exposure to 34.4 μM Methyl Ketones upon AMAPA Seed Germination. All the methyl ketones profoundly inhibited AMAPA seed germination after a 3-day exposure (minimum inhibitory activity: 2-butanone, 86% reduction, compared to control) (Figure 3). When the ketone source was removed, the inhibitory effects of 2-butanone, 2-pentanone, and 2-heptanone disappeared by the end of the 7-day incubation. Residual inhibitory effects ranged from the minimum observed with 3-hydroxy-2-butanone (50% reduction) to the maximum induced by 2-nonanone (74% reduction). When exposure

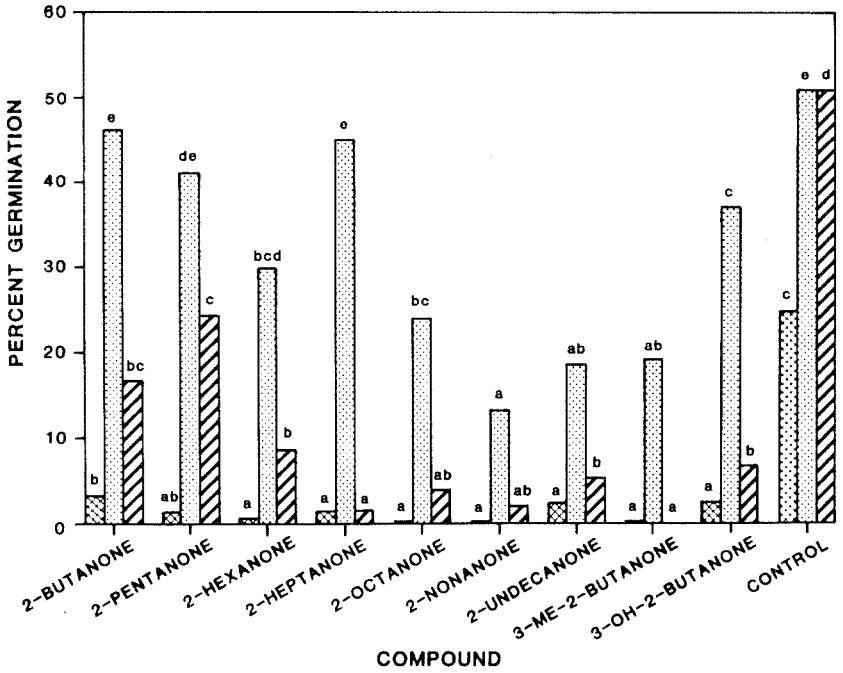

FIG. 3. Percent germination of AMAPA (*Amaranthus palmeri* S. Wats.) seed exposed to 34.4 μM methyl ketones for three (first, crosshatched bar) and seven (third, diagonally striped bar) days or three days followed by four days' incubation after removal of ketone source (second, dotted bar). Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $<2.1\%$.

to the ketones was continuous throughout the incubation, the 3-day levels of inhibition were maintained in the presence of all but 2-butanone and 2-pentanone. 3-Methyl-2-butanone essentially prevented AMAPA germination as long as it remained present. Germination of AMAPA after a 3-day exposure to any of the tested methyl ketones was extremely low, but comparison of the effects of 2-butanone, 3-methyl-2-butanone, 3-hydroxy-2-butanone, and 2-pentanone after a 7-day exposure shows the following decreasing order of inhibition, 3-methyl-2-butanone > 3-hydroxy-2-butanone $\geq$ 2-butanone $\geq$ 2-pentanone. The correlation between carbon chain length and inhibitory activity observed in the other assay seeds was not apparent in the AMAPA data.

Effects of Exposure to 34.4 μM Methyl Ketones upon Tomato Seed Ger-

mination. A 3-day exposure to the C_5–C_9 methyl ketones, 2-undecanone, and 3-methyl-2-butanone prevented (<2% germination) tomato seed germination (Figure 4). 2-Butanone and 3-hydroxy-2-butanone were also highly inhibitory (70% and 75% reductions, respectively, compared to control). This length of exposure to 2-undecanone and 3-hydroxy-2-butanone, however, produced no significant residual inhibition in tomato seeds after the ketone source was removed. With the exception of 2-octanone (70% reduction), the residual inhibitory effects of the other methyl ketones were in the 26–33% reduction range. Even when the ketones were renewed before the second 4-day incubation period, the inhibitions initially caused by 2-butanone, 3-methyl-2-butanone, and 3-hydroxy-2-butanone did not persist, and the inhibitory effects of 2-pentanone, 2-undecanone, and 2-hexanone decreased. Only 2-heptanone, 2-octanone, and

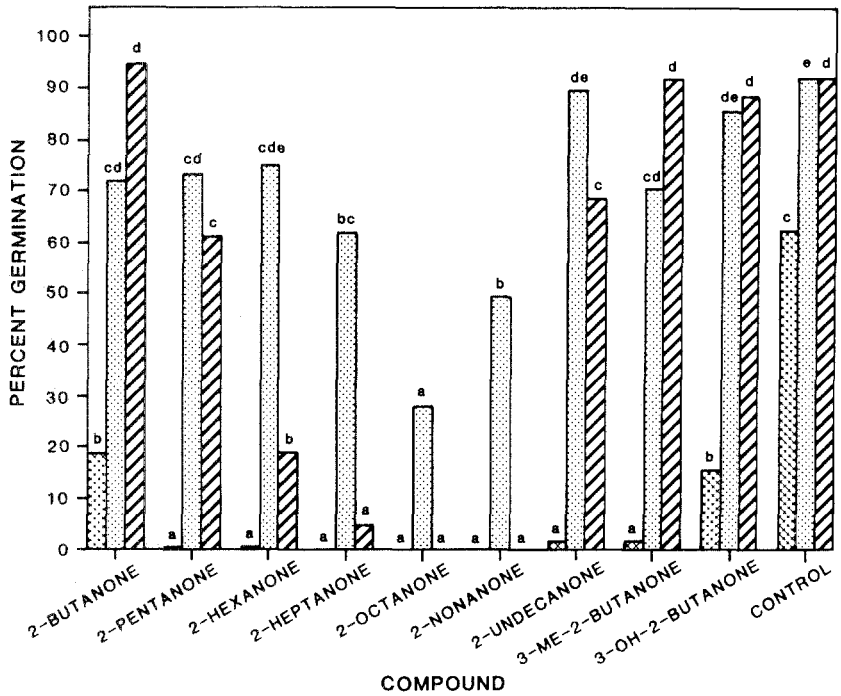

FIG. 4. Percent germination of tomato (*Lycopersicon esculentum* Mill.) seed exposed to 34.4 μM methyl ketones for three (first, crosshatched bar) and seven (third, diagonally striped bar) days or three days followed by four days' incubation after removal of ketone source (second, dotted bar). Percentage represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was <1.4%.

2-nonanone were profoundly inhibitory during the continuous 7-day exposure. The correlation between carbon chain length and inhibitory activity was apparent in both the 3-day and 7-day exposure data and, to a lesser degree, in the 3 + 4-day data for tomato seeds.

When the composite activities of these methyl ketones are considered across seed species and exposure time, the following approximate activity ranking is obtained: 2-octanone, 2-nonanone, 2-heptanone, 2-undecanone, 2-hexanone, 3-methyl-2-butanone, 2-pentanone, 2-butanone, 3-hydroxy-2-butanone. The two most active methyl ketones were observed as traces under aerobic conditions and were formed in increasing amounts when the AMAPA residues were incubated under nitrogen. 2-Heptanone, the third most active methyl ketone in these time-dependent experiments, was a major component in all AMAPA residue volatiles mixtures examined.

Although 34.4 μM of most of these methyl ketones inhibited all four assay seeds after the first 3-day exposure, the inhibition usually did not persist after the ketone source was removed. Residual inhibition was most often observed in seeds exposed to 2-undecanone, 2-nonanone, and 2-octanone, the latter two compounds having no significant residual effect on onion seeds. Continuous exposure to the methyl ketones for seven days was much more inhibitory, particularly in the case of the more inhibitory C_7–C_9 methyl ketones.

Concentration Effects of Exposure to Methyl Ketones. When the four species of assay seeds were exposed to 3.4, 6.9, 17.7, or 34.4 μM of each of the methyl ketones, the results shown in Table 1 were obtained. Two-way analyses of variance of the 3-day exposure data showed that concentration, compound, and the concentration $\times$ compound interaction were significant for all four species of seeds. When the appropriate control germination data were used as null concentration, direct plots of percent germination yielded hyperbolic curves, but transformation $[(x + 0.5)^{0.5}]$ of both x and y axes yield significant ($P > 0.10$) linear regression lines for all compounds and seeds. The slopes shown in Table 1 are for the transformed data.

Compared to the control, all concentration levels of the methyl ketones significantly inhibited onion seed germination, but not all these inhibitory effects were concentration dependent. 2-Octanone and 2-heptanone induced the most concentration-sensitive effects, while the inhibitory activity of 3-hydroxy-2-butanone did not change over the range of concentrations used. In comparison to the control, 2-butanone and 2-pentanone were inhibitory at all concentrations, but the degree of inhibition decreased as the concentration increased.

On the basis of analysis of variance ($P = 0.01$), carrot seed germination was insensitive to 3.4 μM levels of the methyl ketones. However, 3.4 μM 2-butanone and 2-undecanone induced inhibition that was significant ($P = 0.05$). All but 3-methyl-2-butanone and 3-hydroxy-2-butanone inhibited significantly

[a] Percentages are the means of 16 replications. Values in columns followed by the same letter and associated with a given seed species are not significantly different ($P = 0.01$). Standard errors of the means were $< 2\%$.

[b] Slopes were obtained using transformed $(X + 0.5)^{0.5}$ germination count data.

at 6.9 μM. Higher levels of 2-heptanone, 2-octanone, and 2-nonanone essentially eliminated carrot seed germination. The relatively low inhibitory effects of 2-butanone, 2-pentanone, 3-methyl-2-butanone, and 3-hydroxy-2-butanone were not concentration dependent, while those of 2-heptanone, 2-octanone, and 2-nonanone increased significantly as the concentration increased.

All levels of the methyl ketones dramatically decreased AMAPA seed germination, and there was no significant difference in the concentration effects of the test compounds on these seeds. Tomato seed germination was not significantly affected by 3.4 μM 2-butanone, 2-pentanone, 3-methyl-2-butanone, and 3-hydroxy-2-butanone; however, 2-hexanone, 2-heptanone, and 2-undecanone were highly inhibitory at all concentrations tested. 2-Octanone and 2-nonanone inhibition was highly significant at concentrations above 3.4 μM. 2-Butanone inhibited tomato seed germination only at 34.4 μM.

A summary of the results based on the degree of inhibition at all assay concentrations and the relative concentration dependence as shown by the regression line slopes for each methyl ketone yields the following activity series: 2-octanone, 2-nonanone, 2-heptanone, 2-undecanone, 2-hexanone, 3-methyl-2-butanone, 2-pentanone, 3-hydroxy-2-butanone, 2-butanone. This series is essentially the same as that observed in the time-dependent studies.

Two-way analyses of variance of the 3 + 4-day data showed no significant ($P = 0.01$) concentration effects on carrot seed germination, and no methyl ketone induced a residual inhibition of 50% at 34.4 μM (Figure 2) or less (data not shown). There was no significant residual concentration effect on onion seed germination, and only 34.4 μM 2-undecanone inhibited more than 50% (Figure 1). There was also no significant difference between the residual effects of different concentrations of the test compounds on tomato seed germination, and no residual inhibition above 50% was observed, except after exposure to 34.4 μM 2-octanone (Figure 4).

Concentration, test compounds, and concentration $\times$ compound interaction effects were all significant in the 3 + 4-day AMAPA data. Exposure to 34.4 μM 2-octanone, 2-nonanone, 3-methyl-2-butanone, and 2-undecanone residually inhibited AMAPA 50% or more (Figure 3). In addition, under the 3 + 4-day exposure protocol, 6.9 and 17.7 μM 3-methyl-2-butanone reduced AMAPA seed germination, in comparison to the control at seven days, by 52 and 61% respectively.

2-Heptanone $\times$ 3-Hydroxy-2-butanone Interaction. All of the results discussed above were obtained by exposing the assay seeds to one methyl ketone at a time at differing concentrations or for varying lengths of time. Since the AMAPA residues give off mixtures of volatiles, assay seeds were exposed for three days to varying ratios of 2-heptanone and 3-hydroxy-2-butanone, the two major methyl ketone peaks in stem and root chromatograms (Connick et al., 1987). The effects of these mixtures and the pure compounds are shown in Table 2. Goodness-of-fit analysis permits the assumption of additivity in the

[a] Observed percentages are means of 16 replications and values in a given column and associated with a particular seed species followed by the same letter are not significantly different ($P = 0.01$).

combined effects of 2-heptanone and 2-hydroxy-1-butanone at all combined concentration levels ($P = 0.01$). Since the concentration-dependence curves for these compounds are nonlinear, inhibitions observed at the three different total concentrations are not proportional. In all cases, the differences between observed and expected values were within experimental error for the germination assays.

The results of both the time- and concentration-dependent seed-germination studies show that the inhibitory activity of the methyl ketones is related to carbon chain length. The C_7–C_9 ketones were more inhibitory of all four seed species, the activity decreasing as the chain length increased or decreased out-

side this range. Branched-chain molecules (i.e., 3-methyl-2-butanone and 3-hydroxy-2-butanone) were no more inhibitory than the straight-chain ketones of similar molecular weight. The observed methyl ketone activity series may arise from differing, structure-related physiological activity, but the volatility of the individual compounds is probably also a significant factor. In all assays, the individual test compounds were allowed to vaporize from a dry glass beaker to equilibrate with the water-saturated interior of the desiccator. Thus, both the vapor pressures and the air–water partition coefficients of the test compounds would determine the effective concentrations within the desiccator. The vapor pressures of the methyl ketones show an approximately 100-fold decrease at the assay temperature over the C_4–C_{11} molecular weight range. At the micromolar levels assayed here, however, it can be assumed that the methyl ketones volatilize 100% after initial application to the beaker. The effective concentrations, with respect to the germinating seeds, would then be determined by the relative volatilities of the methyl ketones in dilute water solution. Under aqueous conditions, the higher-molecular-weight homologs in the methyl ketone series, up to C_9, are more volatile than the lower-molecular-weight homologs (Buttery et al., 1969). The air–water partition coefficient of 2-nonanone is approximately eight times greater than that of 2-butanone. However, this coefficient for 2-undecanone, which is less inhibitory than 2-nonanone, is 10 times that of 2-butanone, which is significantly less inhibitory.

The lower-molecular-weight compounds are more water soluble (Amoore and Hautala, 1983) and are also more likely to hydrogen bond with water, resulting in lower volatilization fluxes (Rathbun and Tai, 1984). Thus the air–water partitioning characteristics of the methyl ketones serve to increase the effective volatile concentrations of the compounds found most inhibitory in the bioassays. These same differences in hydrophilicity would also cause differential partitioning of the methyl ketones between membranes and cytoplasm within the germinating seeds. The various partitioning effects add weight to our current hypothesis which relates the physiological activity of these compounds to membrane disruption during seed rehydration and early stages of germination. This partitioning phenomenon may also explain the reciprocal relationship between molecular weight and seed-germination inhibition observed with millimolar aqueous solutions of acetone and the C_4–C_9 methyl ketones (Reynolds, 1977).

In most cases continual exposure to the methyl ketones was necessary for significant germination suppression. However, dried AMAPA residues, upon rehydration, emit inhibitory volatile mixtures for more than four months (Bradow and Connick, 1987). Thus, significant amounts of volatiles would be added to the soil atmosphere as long as these residues persist in the soil. Since the inhibitory activities of these methyl ketones appear to be additive, volatile mixtures, such as those arising from AMAPA residues, must be important, but relatively uninvestigated, factors in the soil atmosphere.

Volatile substances in the soil atmosphere, such as the methyl ketones and other compounds associated with AMAPA residues, probably have a decisive role in other cases of allelopathy besides the observed inhibitions of onion and carrot field establishment and growth which prompted this and earlier studies (Koller, 1972; Lill et al., 1979). In addition to decreasing or retarding seed germination, methyl ketones have been shown to stimulate the germination of competitive weeds (French and Leather, 1979; French et al., 1986) and of spores of pathogenic fungi (French, 1984, French et al., 1986). In the soil, other mixtures of volatile substances stimulate sclerotial (King and Coley-Smith, 1968; Linderman and Gilbert, 1969) and mycelial growth (Menzies and Gilbert, 1967). The components of these and other biologically active mixtures of volatiles (Afifi, 1975; Lill et al., 1979) have not been identified, but the inhibitory C_7–C_9 methyl ketones have been reported to be emitted by other plant residues (Buttery et al,, 1978, 1985; Flath et al., 1978). The broad distribution and biological activity of plant residue volatiles make them important factors, not only in allelopathy, but in phytopathology and agronomy, particularly in reduced tillage situations.

(Received June 1, 1987; accepted September 24, 1987)

Abstract—Effects of 3-pentanone and eight low molecular weight aliphatic alcohols and aldehydes identifed in the mixtures of volatiles released by *Amaranthus palmeri* S. Wats. (AMAPA) residues were determined on germination of onion, carrot, AMAPA, and tomato seeds. Three-day exposures to these volatiles significantly inhibited germination of these assay seeds, and the inhibition was dependent upon exposure time and concentration. Based on the degree of inhibition observed in both time- and concentration-dependent assays, the following activity series was obtained: 2-heptanol > 3-methyl-1-butanol, 1-hexanol > hexanal, 1-pentanol, 3-pentanone, acetaldehyde > ethanol, 2-methyl-1-propanol. The activities of this group of compounds with that of 2-heptanone appear to be additive and related to test compound volatility and hydrophilicity. 2-Heptanol and 2-heptanone also significantly inhibited the germination of other species, including shepherds-purse, soybean, lettuce, alfalfa, common purslane, oats, and lovegrass.

Key Words—Allelopathy, volatile allelochemicals, alcohols, aldehydes, germination inhibitors, onion, *Allium cepa*, carrots, *Daucus carota*, Palmer amaranth, *Amaranthus palmeri*, tomato, *Lycopersicon esculentum*.

INTRODUCTION

The presence of *Amaranthus palmeri* (AMAPA) residues in the soil reduces fresh weight accumulation in onions and carrots and markedly decreases seed-

ling field establishment in carrots (Menges, 1985). Classic natural products isolation techniques (Bradow, 1985; Fischer and Quijano, 1985) and solid-phase separation techniques applied to water extracts of soil containing AMAPA residues (Bradow and Connick, 1987) failed to isolate inhibitory factors from either AMAPA residues or soil containing such residues.

However, volatiles emitted by AMAPA residues and soil containing the residues were highly inhibitory of seed germination in onion, carrot, AMAPA, and tomato (Bradow and Connick, 1987). A number of the volatile allelochemicals associated with AMAPA seedhead, stem, and root residues were identifed (Connick et al., 1987) and have been tested individually and in selected binary ratios for seed germination effects. This paper describes the effects on seed germination induced by the vapors of 3-pentanone, six alcohols, and two aldehydes, all associated with AMAPA residues.

METHODS AND MATERIALS

All chemicals used in these assays were purchased from Aldrich Chemical Company (Milwaukee, Wisconsin). Assay seeds were either purchased from commercial sources or were gifts of Dr. R.M. Menges, USDA, Weslaco, Texas.

Time-Dependent Seed-Germination Bioassays. The desiccator seed-germination assay technique has been previously described (Bradow and Connick, 1987, 1988; Connick et al., 1987). Controls (deionized water) were repeated at three-month intervals throughout the duration of the experiments, and no significant changes were observed during the term of these experiments. In the time-dependence study, 34.4 μM of a volatile test compound were placed in the central beaker, and the separate seed species were incubated for 72 hr before germination evaluation (3-day data). The volatile source beaker was then either removed (3+4-day data) or the test volatile was renewed by the addition of a second 34.4 μM volume (7-day data). All seeds were then incubated an additional four days before final evaluation.

Concentration-Dependent Seed-Germination Bioassays. The concentration-dependent assays were performed as previously described (Connick et al., 1987, Bradow and Connick, 1988), using 3.4, 6.9, 17.2, or 34.4 μM of each test volatile. The seeds were incubated for three days in the presence of the test compound, germination was evaluated, the volatile source was removed, and the seeds were incubated an additional four days.

Assays of Binary Mixtures of 2-Heptanone × Alcohol. The standard 3-day exposure seed-germination assay was repeated using ratios of 2-heptanone × 2-heptanol or 2-heptanone × 3-methyl-1-butanol of 4:0, 3:1, 2:2, 1:3, or 0:4 to give total assay volatile concentrations of 34.4, 25.8, or 17.2 μM.

Multiseed Assays of 2-Heptanone and 2-Heptanol Activity. Under environmental conditions similar to those used in the desiccator studies, seeds of the species listed in Table 4 were germinated separately in an apparatus consisting of a sealed one-pint (0.473-liter) dome-lidded Mason jar in the mouth of which was suspended a perforated aluminum weighing dish (5.7 cm diam., Fisher Scientific). The bottom of the dish was perforated with a 1-cm central hole surrounded by six 4-mm holes, all made with a cork borer. A paper punch (6 mm diam.) was used to make six additional holes around the side of each dish to facilitate vapor phase movement. Each dish was lined with two sheets of 5.5-cm-diam. Whatman No. 1 filter paper, each sheet having a 1-cm central perforation. Depending on seed size, 30 or 40 seeds were placed on the filter paper sheets which had been moistened with 2 ml deionized water. To emulate the desiccator assays on the smaller scale of the Mason jar apparatus, all parameters were reduced by a factor of 0.19 based on the ratio of the relative volumes of the Mason jars and the desiccators. A Wheaton bottle (8 ml) that contained 9.5 g sand moinstened with 1.9 ml deionized water was placed in the bottom of each jar, and a microsyringe was used to place either 34.4 or 68.9 μM (2.3 μl or 4.6 μl) of 2-heptanol or 2 heptanone in the Wheaton bottle.

Statistical Analysis. After normalization by the transformation $[(x+0.5)^{0.5}]$, germination count data from the concentration-dependent bioassays and the 7-day and 3+4-day time dependent data were compared separately for each seed species by two-way analyses of variance with 16 replicates. One-way analyses of variance were used to determine significant differences between the effects of the test volatiles and appropriately incubated deionized water controls within the 3-day, 7-day, and 3+4-day data, using Tukey's Honestly Significant Difference procedure with a significance level of $P = 0.01$. Concentration dependent data were also examined by regression analysis, and the chi-square test and *G*-test goodness-of-fit procedures were used to test hypothesized additive relationships between the activities of selected pairs of volatile compounds (Sokal and Rohlf, 1981). To permit comparisons between these volatiles and the methyl ketones discussed in the preceding paper (Bardow and Connick, 1988), all analyses of variance were repeated on the combined data for the 18 volatile compounds.

RESULTS AND DISCUSSION

Prior work had shown that all the compounds listed in the figures and tables were detected in the volatile mixtures associated with AMAPA residues (Connick et al., 1987). 2-Pentanol and 1-hexanol were observed in atmospheres associated only with AMAPA roots. 3-Methyl-1-butanol was a major compo-

nent of the volatile mixtures, and 2-heptanol was always associated with 2-heptanone in the GC-MS analyses. Ethanol and traces of acetaldehyde were ubiquitous.

Effects of Exposure to 34.4 μM Test Volatiles upon Onion Seed Germination. After a 3-day exposure, all test compounds, except 3-pentanone, inhibited onion seed germination more than 50% with respect to the deionized water control (Figure 1). 2-Heptanol, 3-methyl-1-butanol, acetaldehyde, and hexanal were the most inhibitory. When the volatile source was removed after three days and the seeds were allowed to incubate an additional four days, seeds initially exposed to 3-methyl-1-butanol were still greatly inhibited (>80%), essentially the same degree of inhibition observed if the volatile concentration were maintained throughout the 7-day duration of the assay. Onion seeds exposed to 2-heptanol and hexanal were still significantly inhibited after seven days, regardless of whether the volatile sources were removed; but seeds inhib-

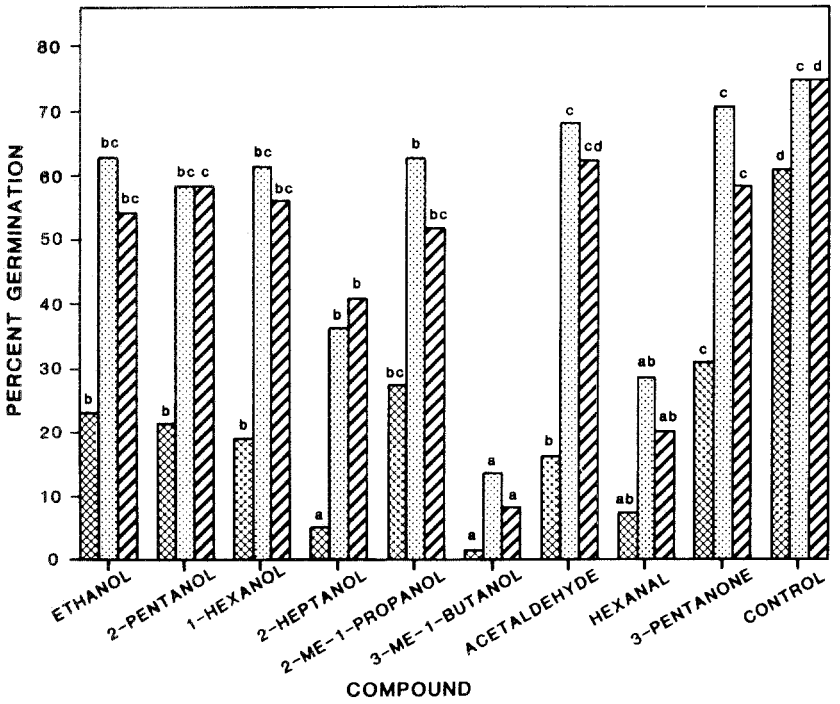

FIG. 1. Percent germination of onion (*Allium cepa* L.) seeds exposed to 34.4 μM test volatiles for three (first, crosshatched bar) and seven (third, striped bar) days or three days followed by a four-day (second, dotted bar) incubation after removal of ketone source. Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was <2.0%.

ited by a 3-day exposure to acetaldehyde germinated to the same extent as the control after seven days, both in the presence and the absence of this aldehyde. None of the other test compounds inhibited onion seed germination more than 30% after the initial 3-day exposure period.

On the basis of the analyses of variance combining data for this group of nine volatile compounds with data previously reported (Bradow and Connick, 1988) for nine methyl ketones, 3-methyl-1-butanol, hexanal, and 2-heptanol were more inhibitory of onion seed germination than the most active methyl ketones, i.e., 2-undecanone and 2-octanane.

Effects of Exposure to 34.4 μM Test Volatiles upon Carrot Seed Germination. 1-Hexanol, 2-heptanol, 3-methyl-1-propanol, 3-methyl-1-butanol, acetaldehyde, and hexanal all inhibited carrot seed germination more than 50% after the 3-day exposure (Figure 2). None of the test compounds had any significant inhibitory residual effect when the volatile source was removed after three days,

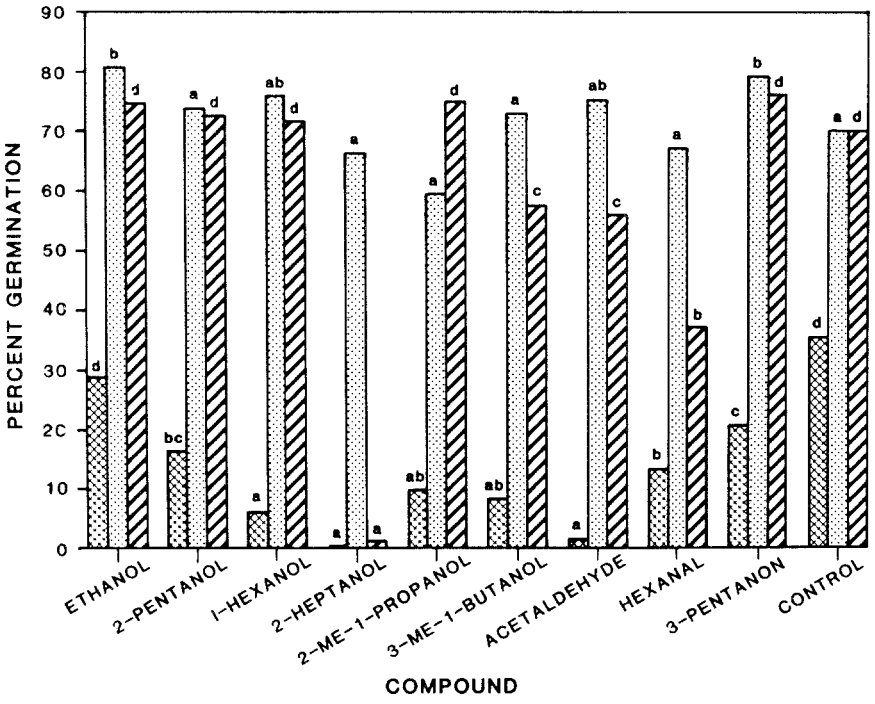

FIG. 2. Percent germination of carrot (*Daucus carota* L.) seeds exposed to 34.4 μM test volatiles for three (first, crosshatched bar) and seven (third, striped bar) days or three days followed by a four-day (second, dotted bar) incubation after removal of ketone source. Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $< 1.4\%$.

and germination was slightly promoted in carrot seeds initially exposed to ethanol and 3-pentanone. A 7-day exposure to 2-heptanol eliminated carrot seed germination, and continuous exposure to 3-methyl-1-butanol, acetaldehyde, and hexanal also significantly inhibited germination.

The composite analysis of variance including the methyl ketone data shows that, in general, 2-heptanol was as inhibitory as the most potent methyl ketones, and the activities of hexanal, acetaldehyde, 1-hexanol, and 3-methyl-1-butanol were comparable to that of 2-undecanone in the carrot seed assays (Bradow and Connick, 1988).

Effects of Exposure to 34.4 μM Test Volatiles upon AMAPA Seed Germination. Again, a 3-day exposure to any of the test compounds inhibited AMAPA seed germination (Figure 3). 2-Methyl-1-propanol was the least inhibitory. Only low residual effects were observed when the sources of 1-pentanol, 2-heptanol, and 3-pentanone were removed. After a 7-day exposure, all test compounds

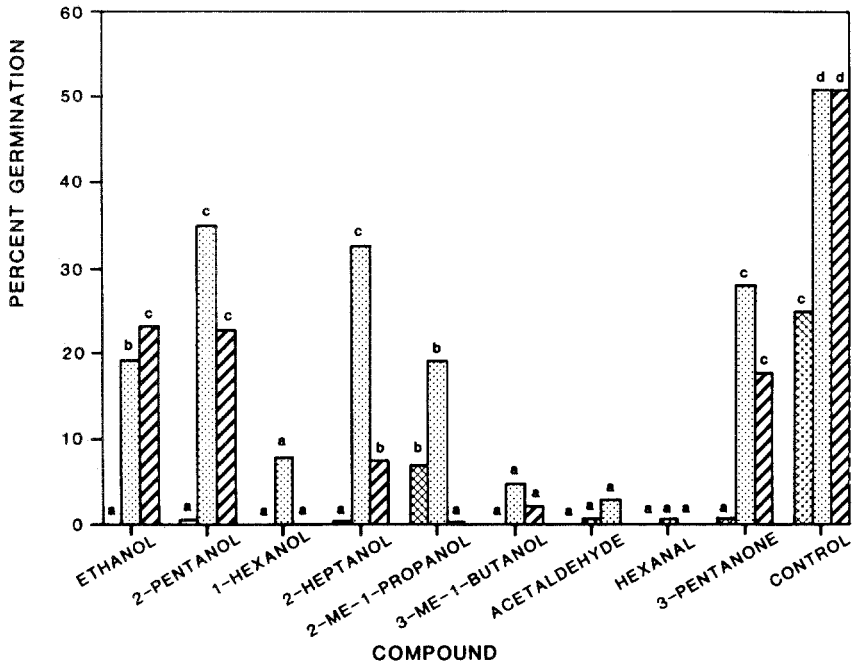

FIG. 3. Percent germination of AMAPA (*Amaranthus palmeri* S. Wats.) seeds exposed to 34.4 μM test volatiles for three (first, crosshatched bar) and seven (third, striped bar) days or three days followed by a four-day (second, dotted bar) incubation after removal of ketone source. Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $<2.0\%$.

inhibited AMAPA seed germination more than 50%, in comparison to the appropriate control. Ethanol, 1-pentanol, and 3-pentanone were the least inhibitory under these conditions.

Acetaldehyde, hexanal, 3-methyl-1-butanol, and 1-hexanol had greater residual effects on AMAPA seed germination than all the methyl ketones (Bradow and Connick, 1988). Continuous exposure to 1-hexanol, hexanal, 2-methyl-1-propanol, 3-methyl-1-butanol, acetaldehyde, and 2-heptanol was as effective in suppressing AMAPA seed germination as similar exposure to the most inhibitory methyl ketones, 3-methyl-2-butanone, the C_6–C_9 methyl ketones, 2-undecanone, and 3-hydroxy-2-butanone.

Effects of Exposure to 34.4 μM Test Volatiles upon Tomato Seed Germination. Ethanol was the only test compound that did not inhibit tomato seed germination more than 70% after a 3-day exposure (Figure 4). Seeds exposed

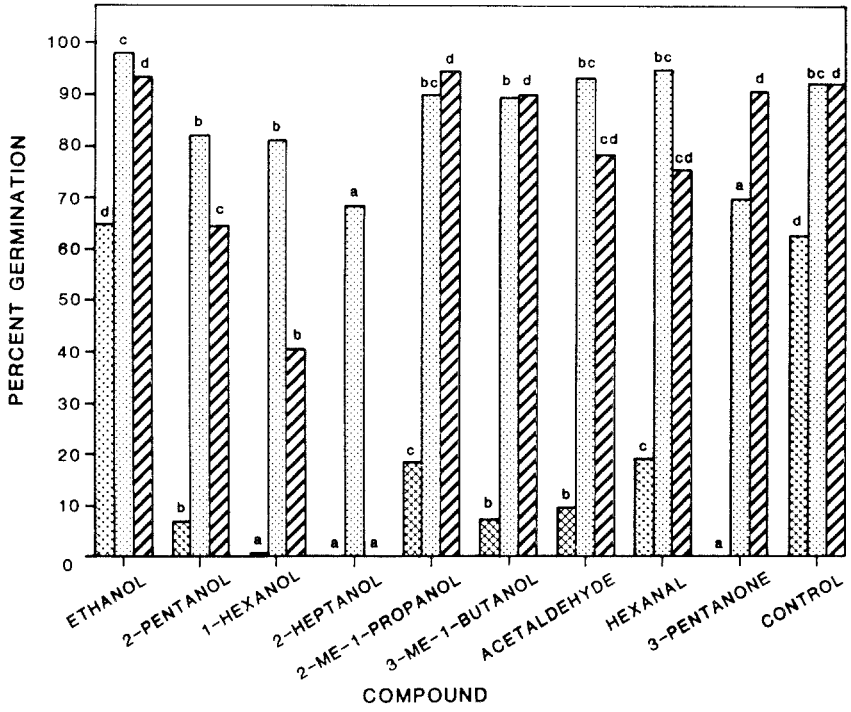

FIG. 4. Percent germination of tomato (*Lycopersicon esculentum* Mill.) seeds exposed to 34.4 μM test volatiles for three (first, crosshatched bar) and seven (third, striped bar) days or three days followed by a four-day (second, dotted bar) incubation after removal of ketone source. Percentages represented by bars with the same shading and lower case letter do not differ significantly ($P = 0.01$ with $N = 16$). Standard error of all means was $< 1.5\%$.

to all the test compounds, except 2-heptanol and 3-pentanone, germinated normally when the volatile sources were removed after the initial exposure period. During a 7-day exposure, 2-heptanol prevented tomato seed germination and 1-hexanol inhibited germination of tomato seeds more than 50%.

After the 3-day exposure, 2-heptanol, 3-pentanone, 2-pentanol, 3-methyl-1-butanol, and acetaldehyde were as inhibitory of tomato seed germination as the highly active C_5–C_9 methyl ketones and 2-undecanone (Bardow and Connick, 1988). Only 2-heptanol and 3-pentanone had residual effects equivalent to those observed with the more inhibitory methyl ketones, but continuous exposure to 2-heptanol was as effective in preventing tomato seed germination as exposure to the highly inhibitory C_6–C_9 methyl ketones. The effects of 2-heptanol were equivalent to those observed after exposure to 2-heptanone.

Overall, the most inhibitory compounds in these exposure-time-dependent studies were 3-methyl-1-butanol, hexanal, and 2-heptanol. The inhibitory activities of these nine compounds could be ranked 3-methyl-1-butanol, hexanal, 2-heptanol > 1-hexanol, acetaldehyde, 2-pentanol > 2-methyl-1-propanol, 3-pentanone >> ethanol. In comparsion to the activities of the methyl ketones discussed in the preceding paper (Bradow and Connick, 1988), the germination reductions caused by exposure to 3-methyl-1-butanol, hexanal, and 2-heptanol were equivalent to those produced by 2-heptanone. 1-Hexanol, 2-pentanol, and acetaldehyde inhibited to the same degree as 2-hexanone, 3-methyl-2-butanone, and undecanone; while the activities of 2-methyl-1-propanol and 3-pentanone were not significantly different from those of 2-pentanone and 2-butanone. Both 3-hydroxy-2-butanone and ethanol induced relatively little inhibition, compared to the other test compounds in the combined series. [Refer to Figures 1–4, in Bradow and Connick (1988) for corresponding methyl ketone results.]

Concentration Effects of Exposure to Volatile Test Compounds. When the four species of assay seeds were exposed for three days to 3.4, 6.9, 17.2, or 34.4 μM of each of the nine test compounds, the results shown in Table 1 were obtained. Two-way analysis of variance of the data showed that concentration, compound and the concentration × compound interaction were significant for all four species of seeds. When the appropriate control germination data were used as null concentration, direct plots of percent germination yielded hyperbolic curves, but transformation $[(x + 0.5)^{05}]$ of both x and y axes yields significant ($P < 0.01$) linear regression lines for all compounds and seeds. The slopes shown in Table 1 are for the transformed data and include null concentration data from the appropriate controls.

After a 3-day exposure, all of the test compounds significantly inhibited onion seed germination of all four assay concentrations. The most pronounced concentration-dependent effects were observed in onion seeds exposed to 3-methyl-1-butanol and 2-heptanol. The concentration-dependent effects of 2-heptanol and 3-methyl-1-butanol approximated to those observed with 2-octanone, and hexanal and acetaldehyde were as inhibitory as 2-nonanone. The

[a] Percentages are the means of sixteen replications. Values in column and associated with a given seed and followed by the same letter are not significantly different ($P = 0.01$). Standard errors of the means were <2%.

[b] Slopes were obtained using transformed $[(x + 0.5)^{0.5}]$ germination count data.

methyl ketone results are shown in Table 1 of the preceding paper (Bradow and Connick, 1988).

At the lowest assay concentration following a 3-day exposure, only 3-pentanone had a significant inhibitory effect on carrot seed germination. Significant inhibition was observed after exposure to 6.9 μM 2-heptanol, 3-methyl-1-butanol, and 3-pentanone and to 17.2 μM 1-hexanol and acetaldehyde. The effects produced by 3-methyl-1-butanol and 2-heptanol were the most concentration dependent in the carrot seed assays. The inhibitory effects of 2-heptanol approximated those of 2-nonanone, and those of 3-methyl-1-butanol approximated the inhibitory effects caused by exposure to 2-octanone and 2-heptanone.

All test compounds except 2-methyl-1-propanol essentially prevented AMAPA seed germination after a 3-day exposure. 2-Heptanol, 2-pentanol, 1-hexanol, 3-methyl-1-butanol, and 3-pentanone all significantly inhibited tomato seed germination after a 3-day exposure at 3.4 μM. When the concentrations of the test compounds were doubled, all test compounds but ethanol, 2-methyl-1-propanol, acetaldehyde and 2-methyl-1-propanol inhibited tomato seed germination more than 50%. Only ethanol was not inhibitory at 34.4 μM. The responses of tomato seeds to 1-hexanol and to 2-heptanol were most concentration dependent. Tomato seeds were insensitive to hexanal and acetaldehyde at concentrations below 34.4 μM.

A summary of the results based on the degree of inhibition at all assay concentrations and after an exposure of three days yields to the following activity series: 2-heptanol > 3-methyl-1-butanol, 1-hexanol > 2-pentanol, 3-pentanone, acetaldehyde > hexanal > ethanol, 2-methyl-1-propanol. Due to the insensitivity of seeds to hexanal and acetaldehyde at concentrations below 34.4 μM, this activity series differs from that obtained in the time-dependent studies. When the overall activities of these compounds are compared with those of the methyl ketones the series becomes: 2-nonanone, 2-heptanol, 2-octanone > 2-undecanone > 3-methyl-1-butanol, 1-hexanol > 2-heptanone > 2-hexanone > 3-methyl-2-butanone, hexanal, 2-pentanol, 3-pentanone, 2-pentanone, acetaldehyde, 3-hydroxy-2-butanone > ethanol, 2-butanone, 2-methyl-1-propanol.

Two-way analyses of variance of the 3+4-day data showed no significant ($P = 0.01$) residual germination effects in carrot and tomato seeds (data not shown). Overall, 3+4-day concentration effects were insignificant in onion seed germination, but 2-heptanol inhibited onion seed more than 50% at all but the lowest concentration. Concentration, compound, and concentration × compound interactions were significant in the AMAPA seed data. All concentrations of ethanol residually inhibited AMAPA germination more than 60%. At 17.2 and 34.4 μM, 1-hexanol inhibited AMAPA seeds more than 80%, 3-methyl-1-butanol more than 90%, and 2-methyl-1-propanol more than 70%. Even after the volatile source had been removed, acetaldehyde and hexanal were highly inhibitory at all concentrations, and an initial 3-day exposure to

34.4 μM of both aldehydes prevented AMAPA seed germination after the four-day recovery period.

2-Heptanone × 2-Heptanol Interaction. All of the results discussed above were obtained by exposing the assay seeds to a single test compound at differing concentrations or for varying lengths of time. The AMAPA residues, however, give off mixtures of volatiles, and 2-heptanone and 2-heptanol have been identified as the components of a major peak in the gas chromatograms of volatile mixtures from AMAPA residues (Connick et al., 1987). Therefore, assay seeds were exposed for three days to varying ratios of 2-heptanone and 2-heptanol at three concentrations (Table 2). When the observed germination percentages are compared with "expected" values calculated from results obtained for the pure

compounds, goodness-of-fit testing permits the assumption of an additive relationship in the inhibition of all four species of assay seed exposed to 34.4 μM total 2-heptanone + 2-heptanol. Tomato seed germination was too low at 25.8 μM total concentration for the interaction to be characterized. Inhibition was lower than expected in onion seeds exposed to 25.8 and 17.2 μM mixed volatiles, and the null hypothesis of additive inhibition due to exposure to mixed 2-heptanol and 2-heptanone was rejected ($P = 0.01$). However, exposure to the mixtures did reduce onion seed germination significantly below that observed of onion seed controls (Table 1), and no antagonistic relationship was apparent.

2-Heptanone × 3-Methyl-1-Butanol Interaction. Two major chromatogram peaks observed in analyses of volatile mixtures from AMAPA residues were those representing 2-heptanone and 3-methyl-1-butanol (Connick et al., 1987). When the assay seeds were exposed to different ratios of these two compounds, the results shown in Table 3 were obtained. Germination of all four assay species was essentially eliminated by exposure to 34.4 μM volatiles, and AMAPA seeds did not germinate when exposed to the 25.8 or 17.2 μM binary volatile mixtures. Goodness of fit analysis permits the assumption of additivity in the combined effects of 2-heptanone and 3-methyl-1-butanol on onion, carrot, and tomato seeds exposed to the 25.8 μM mixtures. Again, onion and carrot seeds exposed to 17.2 μM mixtures of these two compounds were inhibited less than the activities of the individual compounds would indicate, but the mixtures significantly inhibited both species of seed, compared to the controls (Table 1). Germination was lower than expected in tomato seeds exposed to 17.2 μM mixtures of these two major components of the AMAPA residues volatiles mixtures.

Effects of 2-Heptanone and 2-Heptanol on Seed Germination of Weed and Crop Species. Using the Mason jar apparatus, seeds of 17 dicot and six monocot weed and crop species were exposed to 34.4 μM or 68.8 μM 2-heptanone or 2-heptanol in the dark under the same alternating temperature conditions used in the desiccator assays (Table 4). In comparison to the controls, 68.8 μM 2-heptanone or 2-heptanol significantly inhibited seed germination in several dicots, i.e., *Capsella bursa-pastoris*, *Daucus carota* cv. Imperator, *Glycine max*, light-sensitive and light-insensitive *Lactuca sativa*, *Portulaca oleracea*, *Rumex acetosella*, and *Sida spinosa*. The lower concentration of the two C_7 compounds inhibited *Capsella*, light-sensitive and light-insensitive *Lactuca*, *Medicago sativa*, *R. acetosella*, and *Sida* seed germination. Among the sensitive monocot species, *Avena sativa* and *Eragrostis curvula* were inhibited by both concentrations of the two compounds; and 68.8 μM of both compounds significantly inhibited *Lolium* seed germination. *Sorghum bicolor* seed germination was promoted by 68.8 μM of either 2-heptanol or 2-heptanone. The effects of the vapors of 2-heptanone and 2-heptanol upon the sensitive species of seeds did not differ significantly at either concentration. At five- and tenfold

higher concentrations and under different germination conditions than used in these studies, 2-heptanone vapors have previously been reported to produce >50% inhibition of seed germination in *Amaranthus retroflexus* (light or dark germination) and to stimulate *R. acetosella* germination (French and Leather, 1979). In aqueous solution 0.57 mM 2-heptanol and 1.1 mM 2-heptanone, 50% germination was reported for Great Lakes lettuce seed (Reynolds, 1977).

There was no apparent correlation between carbon chain length and inhibitory activity. This is in contrast to the chain-length effect observed in the C_4–C_{11} methyl ketones (Bradow and Connick, in 1988). The branched-chain alcohol, 3-methyl-1-butanol, was more inhibitory than the straight-chain ketones and alcohol of the same molecular weight. The vapor pressures of the test com-

pounds decrease as the inhibitory activity increases, ethanol and acetaldehyde having the highest vapor pressures and 2-heptanone the lowest. When attempting to compare the inhibitory effects produced by vapors of analogous methyl ketones, methyl alcohols, and aldehydes, the relative activities do not appear to be related to the air–water partition coefficients, since the less inhibitory but less water-soluble hexanal is approximately 12 times more concentrated in the vapor phase than 1-hexanol (Buttery et al., 1969). In the presence of water, the highly inhibitory alcohols are significantly less volatile than the analogous methyl ketones which, in turn, are less volatile than aldehydes. High water solubility could account for the low activities of acetaldehyde and ethanol vapors. There were also clear species differences in seed germination sensitivity to alcohols, ketones, and aldehydes. Further examination of the relative activities of analogous aldehydes, alcohols, and ketones is necessary before the modes of action and the relationships between molecular structure, functional group, volatility, and water solubility can be understood.

Both the C_4–C_{11} methyl ketones discussed in the preceding paper (Bradow and Connick, 1988) and the AMAPA residue volatiles discussed in this paper have been detected in volatiles emitted by a number of plant materials (Buttery et al., 1985; Flath et al., 1978; Johnson et al., 1971a,b; Lundgren et al., 1985; Ninnemann and Jüttner, 1981). The broad distribution of these volatile compounds suggests that plant residue volatiles may be active in selective regulation of seed germination and growth of annual weeds (Purvis, et al., 1985), as well as in observed cultivar and species specificity of insect attractants (Buttery et al., 1978, 1985; Flath et al., 1978). The species specificity of the volatile profiles from plant material has already been applied in the identification of somatic hybrids (Ninneman and Juttner, 1981) and chemotaxonomy (Lundgren et al., 1985), and the differing responses of plant species to the group of volatile compounds considered in this and the preceding paper indicate that the volatiles released from plant residues must be an important factor in the various detritus food webs encountered in both conventional and no-tillage ecosystems (Hendrix et al., 1986).

FEEDING PREFERENCES OF EASTERN SPRUCE BUDWORM LARVAE IN TWO-CHOICE TESTS WITH EXTRACTS OF MATURE FOLIAGE AND WITH PURE AMINO ACIDS

P.J. ALBERT and S. PARISELLA

Department of Biology, Concordia University
1455 De Maisonneuve Blvd W.
Montreal, Quebec, Canada H3G 1M8

(Received June 25, 1987; accepted September 27, 1987)

Abstract—The feeding preferences and feeding rates of eastern spruce budworm on extracts from mature foliage normally avoided by larvae indicate that the chemical composition of four major host plants does not account for this avoidance. Other factors such as the degree of lignification and/or moisture content of the older foliage may play a more important role. Of 14 amino acids tested, alanine, lysine, proline, and serine stimulated feeding. The interactions of amino acids and sucrose were studied, and the results are discussed in relation to feeding preferences and feeding rates.

Key Words—Eastern spruce budworm, *Choristoneura fumiferana*, Lepidoptera, Tortricidae, amino acids, proline, sucrose, extracts, host plants, feeding behavior.

INTRODUCTION

Eastern spruce budworm larvae, *Choristoneura fumiferana* Clem. (Lepidoptera: Tortricidae), normally feed on balsam fir [*Abies balsamea* (L.) Mill.], white spruce [*Picea glauca* (Moench) Voss.], red spruce (*Picea rubens* Sarg.), and black spruce [*Picea mariana* (Mill., B.S.P.)] in eastern North America. Sixth-instar larvae confine themselves to the newly developed shoots of these hosts; however, in cases of severe defoliation, larvae may be forced to feed on the older, mature foliage. In so doing, their pupal weight and adult fecundity are reduced (Blais, 1952; Miller, 1963).

In behavioral tests using extracts from new shoots of its four hosts, feeding

0098-0331/88/0800-1649$06.00/0

was highly stimulated by sugars/glycosides, slightly stimulated by amino acids/bases, and organic acids had no effect or deterred feeding. The chloroform fractions (lipids, etc.) of white and red spruces stimulated feeding, while those of balsam fir and black spruce had no effect (Albert, 1982). Subsequent studies emphasized the importance of the sugars/glycosides (Albert and Parisella, 1985) and of sucrose in particular on the feeding behavior of the spruce budworm larva (Albert et al., 1982).

Since larvae normally avoid the older foliage from their host plants, we wished to determine whether this was due to their chemical composition. Does mature foliage have the ability to stimulate larval feeding, or is it actually deterrent?

The effects of amino acids on the feeding behavior of insects have been studied in Coleoptera (Wensler and Dudzinski, 1972; Mitchell, 1985), Lepidoptera (Schoonhoven, 1969; Dethier and Kuch, 1971; Ma, 1972; Ascher et al., 1976; Cobbinah et al., 1982), Diptera (Shiraishi and Kuwabara, 1970), Hemiptera (Hatfield et al., 1982), Homoptera (Srivastava and Auclair, 1974; Srivastava et al., 1983), and Orthoptera (Sugarman and Jakinovich, 1986), to cite a few. The amino acid compositions of balsam fir and of white spruce were described by Kimmins (1971). Heron (1965) showed that *l*-proline stimulated eastern spruce budworm larvae to feed. Results of experiments with pure amino acids are presented in the second part of this paper to illustrate the potential hazards in the interpretation of different types of feeding behavior data and to supplement our knowledge of the feeding behavior of the spruce budworm larva toward host-plant chemicals.

METHODS AND MATERIALS

Insects. Larvae were obtained from the Forest Pest Management Institute, Sault Ste Marie, Ontario. They were reared on the artificial diet developed by McMorran (1965) and supplied by the Maritimes Forest Research Centre, Fredericton, New Brunswick. Sixth-instar larvae, <1 day post molt and starved for 24 h, were used in feeding tests.

Plant Extracts and Amino Acids. Collections of foliage from all four host species coincided with the time of year (mid-June, 1982) when larvae in the field were actively feeding as sixth instars, at the Acadia Forest Experiment Station, New Brunswick. Plant material was freeze-dried and extracted with hot methanol, then separated by column chromatography on Amberlite resins as described previously (Albert and Jerrett, 1981). We obtained four fractions from each host species: sugars/glycosides, amino acids/bases, organic acids, and chloroform (lipids, esters, alcohols, aldehydes, waxes, etc.). All fractions were evaporated to dryness. Polar extracts were redissolved in distilled water to bring

their concentration to 1.0×, which was the equivalent of their concentration in the host plant at the time of its collection. Chloroform fractions were redissolved in hexane to bring their concentration to 1.0×.

Amino acids were obtained from Sigma Chemical Co. (St. Louis, Missouri). The concentrations of amino acids used in our experiments were based on those found in balsam fir and white spruce, as determined from the work of Kimmins (1971).

Two-Choice Feeding Tests. Two-choice feeding tests modified after Jermy et al. (1968) for spruce budworm larvae (Albert et al., 1982) were used. Results are presented as mean percent consumption (± SE) of test disks vs. control disks, and feeding rates: $FR = [(T + C)/H]$, where T = area eaten of test disks, C = area eaten of control disks, and H = time in hours. Multiplying the *FR* by 33.183 (the surface area of one disk) gives the total amount of feeding (mm^2) on the combined test and control disks per hour. Mean percent consumption data were analyzed using Wilcoxon's signed-ranks test (Sokal and Rohlf, 1969) and feeding rate data were analyzed with condescriptive statistics (Nie et al., 1975) to obtain means and 95% confidence limits.

RESULTS AND DISCUSSION

Extracts. The amounts of chemicals recovered in extracts from each of the four hosts are shown in Table 1. Feeding preferences for the extracts from 1-year-old foliage (Table 2) are similar to those described for new foliage (Albert, 1982). Sugars/glycosides are the preferred extracts. The most notable differences in the response are that the organic acids of balsam fir and red spruce are

TABLE 1. WEIGHTS OF CHEMICALS RECOVERED IN EACH FRACTION FROM FOUR HOST PLANTS' ONE-YEAR-OLD FOLIAGE

Chemical fraction	Weight (mg/g of freeze-dried needles)			
	Balsam fir	White spruce	Red spruce	Black spruce
SG[a]	103.9 (53.6)[b]	184.1 (73.8)	116.5 (37.1)	101.7 (48.5)

actually preferred to the water controls, whereas for white and black spruces there was no preference. Feeding rates on red and black spruce extracts from old foliage are more than double those using new foliage. Feeding rates on organic acids from white spruce, on the other hand, are 60% lower.

There is an increase in the preference for the balsam fir chloroform extract over the corresponding extract from new foliage, with no change in the feeding rate. Animals show the same preference for chloroform extracts from red and white spruce, but the feeding rates are reduced by one half compared to those on new foliage extracts. The only other notable difference is in the lowered preference for sugars from black spruce, with a 40% reduction in feeding rate, and a reduced preference compared to data from new foliage.

Feeding preference and feeding rate data suggest that the chemical composition of mature foliage is adequate to stimulate larval feeding. With the exceptions noted above, the responses to these extracts are remarkably similar to those previously reported for new foliage (Albert, 1982).

The actual chemical composition of the extracts from mature foliage is obviously expected to differ from that of new growth. If a feeding deterrent

such as pungenin is present in the mature foliage (Heron, 1965), it could account for the reduced preference and feeding rate for black spruce sugars/glycosides, although it does not explain the high preference for white spruce sugars/glycosides, which should also contain this same chemical since it has been identified in this host (Neisch, 1957). In a recent study, Strunz et al. (1986) found that pungenin was, at best, a modest feeding deterrent for spruce budworm larvae.

Larvae may avoid old foliage because it is tougher, as was suggested by Heron (1965). Another contributing factor could be the reduction in moisture content of old vs. new foliage. The moisture content of mature foliage in our collections was as follows: balsam fir, 51%; white spruce, 52%; red spruce, 42%; black spruce, 52%. These values are lower than those for new foliage, which are about 75–80%. Mattson and Haack (1987) discussed the effects of drought (moisture stress) on phytophagous insects. Since larvae fed readily on the extracts at the concentrations found in the host plants, we assume that leaf toughness is the most likely factor that discourages feeding on older foliage.

Amino Acids. Pure alanine, lysine, proline, and serine stimulate feeding (Table 3); valine deters feeding, and the remainder have no effect. The strongest

preference is for proline, which was described as a feeding stimulant by Heron (1965). Feeding rates are similar to those in experiments with amino acid extracts (Table 2).

To determine the possible effect of synergism between amino acids and sucrose, experiments were repeated using 25 mM sucrose on control disks, and the same amino acids dissolved in 25 mM sucrose on test disks. Under these conditions, alanine and lysine had no effect; glutamic acid and serine deterred feeding; and valine glycine, and proline stimulated feeding (Table 4). The most significant changes are seen in the feeding rates, which are increased by the addition of 25 mM sucrose. Serine, by itself, for example, is stimulating (Table 3), but when mixed with sucrose, it appears to deter feeding (Table 4, mean percent consumption data). However, the feeding rate of larvae in the latter experiment is 3.6× greater than in the comparable experiment without sucrose. The same is true for alanine, where the feeding rate is doubled, indicating a possible synergism. Similar effects were noted by Cobbinah et al. (1982) for the gum leaf skeletonizer *Uraba lugens*, where amino acids showed a low phagostimulatory activity that increased upon combination of the acids with sucrose.

[c] Saturated solution.
[d] NS, not significant.

A possible synergistic effect occurred with a combination of sucrose and arginine in their experiments.

Feeding Preference vs. Feeding Rate. An interesting phenomenon is observed in comparing the mean percent consumption data with the data on feeding rates in all experiments. Clearly, there is no direct correlation between the two measures of feeding behavior. The highest feeding rates were found in experiments with sugars/glycosides, as was also shown for new foliage (Albert, 1982). Feeding rates with pure amino acids are comparable to those for amino acid extracts. When combined with sucrose, however, feeding rates for eight of the 14 amino acids increased substantially. Glutamic acid and serine would be considered deterrents as judged from mean percent consumption data; yet, they obviously did not interfere with the actual ingestion of cellulose disks. Feeding rates for six of the amino acids increased only slightly, indicating that they suppressed the positive effect of sucrose. This information would not be gleaned from observing the mean percent consumption data alone; thus care must be taken in interpreting the results of feeding preference tests, as discussed by Dethier (1982). Evidence from electrophysiological experiments on the chemosensilla responsible for the reception of sucrose and amino acid stimuli may prove useful in explaining the above phenomena.

Acknowledgments—The authors are grateful for the supplies of larvae from the Forest Pest Management Institute, Sault Ste Marie, Ontario, and for supplies of artificial diet from the Maritimes Forest Research Center, Fredericton, New Brunswick. We also thank Paul Widden and Jim Frazier for their criticism of the manuscript. Support was from Natural Sciences and Engineering Research of Canada grant A9723 to P.J.A.

CHEMICAL PROTECTION OF PHEROMONES CONTAINING AN INTERNAL CONJUGATED DIENE SYSTEM FROM ISOMERIZATION AND OXIDATION

RUT IDESES and ARNON SHANI

Department of Chemistry, Ben-Gurion University of the Negev
Be'er-Sheva 84105, Israel

(Received June 1, 1987; accepted September 28, 1987)

Abstract—Conjugated diene systems are common in natural products, including pheromones. The systems are sensitive to heat, light, and oxygen, among other things. They can be protected by antioxidants and UV absorbers, which slow down *cis–trans* isomerization and oxidation. Three sex pheromones (one as an analog) containing *Z,E*, *E,Z*, and *E,E* units were studied: (*Z,E*)-9,11-C_{14}OAc, (*E,Z*)-7,9-C_{12}OAc, and (*E,E*)-10,12-C_{16}OAc. The UV absorber 2-hydroxy-4-methoxybenzophenone and the antioxidants BHT and BHA were found to be effective in solution. The protective effect of the UV absorber against photoisomerization on paper carriers was not as good as that in solution. Preliminary studies on the utilization of formulations containing these compounds and (*Z,E*)-9,11-C_{14}OAc in the mass trapping of Egyptian cotton leafworm male in cotton fields showed the new combinations to be as good as a previously used formulation with UOP 688, a compound which is unpleasant to handle.

Key Words—*Lobesia botrana*, *Spodoptera littoralis*, *Earias insulana*, conjugated dienes, sex pheromone, photoisomerization, UV absorbers, antioxidants, protection of pheromones.

INTRODUCTION

As integrated pest management (IPM) becomes more sophisticated, the main role played by pheromones will be that of monitoring and disruption of communication (confusion) via controlled release of the active ingredients in the field. The longer the desired field life of the pheromones, the greater the quantity of pheromones that will be degraded by chemical and physical processes. Evaporation is known to be a major cause of the loss of material in short-lived

0098-0331/88/0800-1657$06.00/0

devices, but not much is known about chemical degradation under field and/or laboratory conditions. The few studies that have been performed have dealt mainly with the oxidation and isomerization of double bonds (Goto et al., 1974; Bruce and Lum, 1976, 1981; Fujiwara et al., 1977; Shani and Klug, 1980a, b; Ideses et al., 1982b, c; Shani et al., 1982; Vaintraub et al., 1983; Davis et al., 1984; Vylegzhanina et al. 1984; Guerin et al., 1984; Nesterova, 1985; Nesterova et al., 1985; Chisholm et al., 1985; Brown and McDonough, 1986; Sychev et al., 1987), with transformations of aldehydes (Weatherston et al., 1981; Shaver and Ivie, 1982; Dunkelblum et al., 1984), and with hydrolysis of acetates in the field (Shani and Klug, 1980b).

Our group (Shani and Klug, 1980a, b; Shani et al., 1982; Ideses et al., 1982b, c) has already shown that the conjugated diene systems in several sex pheromones of moths are isomerized into a mixture of the four possible geometric isomers and oxidized in the field (or under simulated field conditions in the laboratory) to a furan system (Scheme 1, structure I), via a peroxide.

V

Scheme 1.

With the aim of finding means of protecting these sensitive chemicals and prolonging their biologically active period in the field, we studied the effect of antioxidants and UV absorbers on pheromone stability both in the laboratory and under field conditions. Three internal conjugated diene systems known to be present in moth sex pheromones were studied: *Z,E* dienes as found in (*Z,E*)-9,11-tetradecadien-1-yl acetate (TDDA) (II), the main component of the sex pheromone of the female Egyptian cotton leafworm (*Spodoptera littoralis*) (Nesbitt et al., 1973; Tamaki et al., 1973); *E,Z* dienes as found in (*E,Z*)-7,9-dodecadien-1-yl acetate (DDA) (III), the sex pheromone of the female European grapevine moth (*Lobesia botrana*) (Roelofs et al., 1973; Buser et al., 1974); and *E,E* dienes, as found in (*E,E*)-*10,12*-hexadecadienal (HDAL) (IV) [studied as the corresponding ester (*E,E*)-10,12-hexadecadien-1-yl acetate (HDDA) (V)], the sex pheromone of the female spiny bollworm (*Earias insulana*) (Hall et al., 1980).

We report here the results of these studies and a preliminary study of the efficiency of protected pheromone carriers in cotton fields in Israel in mass trapping of Egyptian cotton leafworm males.

METHODS AND MATERIALS

Chemicals. The purity of the pheromones and the pheromone analog was determined by GLC: (*Z,E*)-9,11-C_{14}OAc 98%, 2% *E,E*-isomer; (*E,Z*)-7,9-C_{12}OAc 92%, 8% *E, E*-isomer; (*E,E*)-10,12-C_{16}OAc 100%. Antioxidants 3(2)-*tert*-butyl-4-hydroxyanoisole (BHA) and 2,6-di-*tert*-butyl-4-methylphenol [butylated hydroxytoluene (BHT)] were purchased from Sigma. UV absorbers 2-hydroxy-4-methoxybenzophenone [$\lambda_{max}^{C_6H_{12}}$ 288, 360 nm (ϵ = 14,770, 9,090); $\lambda_{max}^{t\text{-BuOH}}$ 286, 340 nm (12,860, 7,750)] (trade name Eusolex 4360), and a eutectic mixture of 4-isopropyldibenzoylmethane and 3-(4-methylbenzylidene)camphor [$\lambda_{max}^{C_6H_{12}}$ 312, 342 nm (ϵ = 15,790, 18,420); $\lambda_{max}^{t\text{-BuOH}}$ 299, 350 (22,470, 19,720)] (trade name Eusolex 8021) were purchased from Merck. UV spectra were determined with a Bausch & Lomb Spectronic 2000 in spectroscopic grade cyclohexane or in *tert*-butanol.

GLC analyses were performed on a Packard GLC model 417 fitted with a flame ionization detector and with either a fused silica capillary column of SP 2340 30 m × 0.25 mm, flow rate (He) 0.4 ml/min at 130–160°C or a WCOT Silar 9 25 m × 0.5 mm, flow rate (He) 2.7 ml/min at 130–160°C, depending on the pheromone studied.

All solutions contained 100 mg of a pheromone in 5 ml cyclohexane or *tert*-butanol in a corked Pyrex flask, and 50 μl were withdrawn and diluted to 0.5 ml with cyclohexane and then injected twice ($\pm$1%) into the GLC (1–2 μl).

Flasks were refilled to 5 ml every day to compensate for evaporation. Solid carriers (two replicates of each sample) were extracted with hexane (2 × 2 ml), evaporated and then diluted to 1 ml and injected into the GLC. All formulations (solutions or solids carriers) were subjected to diffused sunlight on the roof of the building for the greater part of the experiment, although for some of the time they were placed in direct sunlight. (Details of the light regime are given in the tables or in the text.) Samples were usually withdrawn every two to four days until no pheromone (or its isomers) could be detected by GLC; this period usually lasted five to six weeks. Thus, samples analyzed up to the third or fourth week contained enough material for detection (in general 20–40% of the starting material and isomers were present). In the absence of antioxidant, the pheromone decomposed much faster, and the last sample that contained measurable amounts is documented in the Tables.

RESULTS AND DISCUSSION

It has already been established that heat (50°C in the laboratory hood) causes thermal oxidation via $^3O_2$ and that the process can be slowed down by antioxidants such as BHA or BHT (Shani et al., 1982).

The effect of light seems to be more complicated. In the field, both direct and scattered sunlight may be present, a situation that may affect both pheromone carriers in traps and slow-release devices that are covered by leaves and other objects in the field. Moreover, the excitation of the diene system could be through direct absorption of light by its end absorption (Shani and Klug, 1980b; Shani et al., 1982) or via energy transfer from a sensitizer. In addition, in tropical or subtropical regions, exposure during the summer means that the pheromones are subjected to a combination of high-intensity sunlight and temperatures of 40°C or more. We have already found (Shani and Klug, 1980b) that the rate of direct photoisomerization in sunlight is two to three times faster in summer than in winter. These results are in keeping with the summer and winter figures for total solar energy in Be'er-Sheva (5500–6900 vs. 2300–3500 kcal/m^2/day)[1]. Therefore, in all the experiments described below, the pheromones were, in fact, exposed to a combination of heat, light, and oxygen. Thus, the protective effect of the antioxidant is crucial. The set of experiments performed by us was designed, therefore, to include all possible factors that also play a role in any study on the effect of light on isomerization of pheromones.

Effect of Antioxidants. When pheromones are subjected to heat and light, two competing chemical processes take place—thermal decomposition (oxida-

[1]We thank A. I. Kudish, Department of Chemical Engineering, Ben-Gurion University for the data.

tion) and photoisomerization. Heating alone (in the hood) caused decomposition of the pheromone within a few days (Shani et al., 1982), as was the situation in this experiment with pheromones exposed to sunlight and not protected by an antioxidant. In this case, very little isomerization took place (entries 1, 4, and 7 in Table 1). Pheromones protected by an antioxidant and hence exposed to longer periods of sunlight underwent more extensive isomerization, almost reaching the equilibrium composition, which was found to be 68–75% of the *E,E* isomer, 12–16% of each of the *Z,E* and *E,Z* isomers, and 1–3% of the *Z,Z* isomer (Shani et al., 1982; Ideses and Shaní, 1986). In an earlier study (Shani and Klug, 1980b), we observed that the rate of photoisomerization is somewhat slower in the presence of the antioxidant, as compared to the process in its absence. After 11 days of sunlight, 17% of (*E,E*)-9,11-TDDA was found when

[a] Each sample contained 100 mg of pheromone, 100 mg of antioxidant, and 100 mg of UV absorber (when mentioned) in 5 ml cyclohexane.

[b] Due to fast decomposition, the last sample withdrawn which gave measurable results is presented. Without antioxidant, the oxidation product I was formed in some cases (Ideses et al., 1982c).

[c] Last sample withdrawn when some 20–40% of starting material and isomers were still present in solution.

BHT was added to the pheromone solution as opposed to 30% of the *E,E* isomer when it was not present. After 16 days of sunlight exposure, both solutions contained 35% of the *E,E* isomer. That study was performed during May 1979, when the total sunlight energy is very high (6000–6900 kcal/m^2/day), but temperatures in Be'er-Sheva are still moderate.[2] This might explain why we could still detect the isomers of TDDA after 16 days in sunlight while in the current study, which was performed in August 1985, decomposition was much faster, being complete within seven days (Table 1, entry 1). The first experiment with (*E,Z*)-7,9-C_{12}OAc (entry 4) was done in July 1981 and repeated in July–August 1985.

Effect of UV Absorbers. We studied the effect of two UV absorbers that have their main absorption bands in the region of 300 nm (see Methods and Materials). The photoisomerization of the three diene systems was followed in solution, and the results are summarized in Table 1.

The effect of the antioxidant is again demonstrated in that less pheromone is decomposed in the solution, and exposure period to sunlight is thus lengthened. The effect of the UV absorber is dramatic, as can be seen by comparing the composition in entries 2, 3, 5, 6, 8, and 9 with entries 1, 4, and 7 of Table 1. Exposure to sunlight for three to four weeks brings the isomeric mixture closer to equilibrium (see above), except in the presence of UV absorbers which slow down this process, allowing very little isomerization to take place (entries 2, 5, and 8 of Table 1). The difference between E-4360 and E-8021 (entries, 2, 5, 8 and 3, 6, 9 in Table 1) is clear. We attribute the protective effect to the intense absorption of E-4360 at 288 nm, which exactly covers the end absorption of the conjugated diene system (Shani and Klug, 1980a, b, Shani et al., 1982). The other UV absorbers (E-8021) is less effective, as its main absorption bands are at longer wavelengths, which do not mask the diene absorption. We may also assume that E-8021 does not act as a photosensitizer, since its components have essentially the same chromophor system as that of E-4360. As aromatic ketones, these chemicals probably possess a very high quantum yield for intersystem crossing in solution ($S_1 \rightarrow T_1$) (ΦISC 0.9–1.0) and, when excited, contain about the same triplet energy (ca. 70 kcal/mol) (Calvert and Pitts, 1966).

In order to learn more about the efficacy of both the antioxidant and the UV absorber on the photoisomerization process, we prepared solutions with different amounts of these two essential additives, as shown in Table 2. It is clear that a pheromone solution containing 10% of the antioxidant and 10% of the UV absorber is well protected from both thermal oxidation and photo-

[2] The average daily maximum temperatures (°C) in Be'er-Sheva during different periods of study were as follows: 1979, May 28.7, December 17.0; 1981, July 33.1; 1985, July 32.9, August 34.0. We thank Dov Mills of the Regional Meteorological Station in Be'er Sheva for the data.

isomerization of the internal conjugated diene system under sunlight (compare entries 2 and 4 in Table 2).

Effect of Photosensitizer. In the presence of a photosensitizer (in our case rose bengal) the photoisomerization is very fast, yielding an equilibrium mixture, and the process can be accomplished within 90 min (Shani et al., 1982) as compared with direct illumination for several weeks in sunlight without photosensitizer. The question whether the UV absorber could slow down this energy transfer and excitation was investigated, and the results are summarized in Table 3.

The effect of E-4360 in slowing down the sensitized photoisomerization is impressive, as compared with that of E-8021, the latter compound being completely ineffective (compare entries 3 and 4 in Table 3). These results are in keeping with the findings for these two UV absorbers in direct sunlight (Table 1). The photosensitizer (rose bengal) probably transfers its energy to E-4360,

TABLE 3. EFFECT OF UV ABSORBER ON PHOTOISOMERIZATION OF TDDA IN PRESENCE OF PHOTOSENSITIZER[a]

Entry	UV absorber	Exposure time (min)	Composition (%)			
			Z,E	*E,Z*	*Z,Z*	*E,E*
1		45	16	13	1	70
2		75	15	12	1	72
3	E-4360	60	65	10		25
4	E-8021	60	13	16	3	68

[a] Each sample contained 100 mg of (*Z,E*)-9,11-C_{14}OAc, 10 mg of rose bengal, and 100 mg of UV absorber in 5 ml *tert*-butanol.

which, having absorption bands at 288 and 360 nm, does not take part in energy transfer to the diene system. We thus may consider E-4360 as a good "filter."

It was interesting that the antioxidant (BHA) was also effective in slowing down the sensitized photoisomerization. As noted above (entries 1 and 2 in Table 3) and as has already been published (Shani et al., 1982), sensitized photoisomerization towards equilibration of the four isomers is fast, being accomplished in 30–100 min. However, when a solution of 100 mg of pheromone (TDDA or DDA) containing 10 mg of rose bengal and 100 mg of BHA was left in the sunlight, the rate of isomerization was much slower, and more than 50% of the starting isomer was detected in the tested solution after 4 hr. When the UV spectrum of an admixture of rose bengal and BHA was studied, two separate and unchanged spectra of the components were clearly observed. Still, energy transfer from rose bengal to BHA can take place since the absorption band of BHA is wide and intense at this concentration (100 mg in 5 ml solution) even beyond the 300 nm. Another explanation could be that the phenoxy radical reacts with the photosensitizer and thus decreased its efficacy as a photosensitizer. More experiments should be undertaken in order to determine the preferred mechanism.

The effect of radicals (I_2, C_6H_5SH) on the isomerization was also studied, and we found that the process with I_2, but not with the thiophenol, is slowed down by antioxidants as radical scavengers. The reaction is temperature dependent and can be considered as a catalytic process in 5–10% of iodine in solution (Ideses and Shani, in preparation).

Simulated and Real Field Conditions. The effect of the binary mixture of the antioxidants and the UV absorber was also checked in pheromone carriers, which are usually applied in the field in traps. We selected to study (*Z,E*)-9,11-$C_{14}OAc$, since this compound is used extensively in mass trapping of males of the Egyptian cotton leafworm in cotton fields in Israel. The pheromone is usually applied into the carrier as a solution of the active ingredients (the solvent evaporates in a short time and then the carriers are stored in a refrigerator until used). These carriers are installed into traps under a "cover" that protects them from direct sunlight. We thus investigated these carriers on the roof of our building in diffused sunlight. The results are shown in Table 4.

We found that the photoisomerization of pheromones in solution takes place at a slower rate than that in pheromones impregnated on a carrier. This phenomenon may be explained in terms of the observation that upon application of solution, "paper chromatography" took place and two or three zones appeared on the carrier. We cannot determine how much of overlapping of the components is effective, but it is interesting that the UV absorber is not as effective on the carrier as it is in solution, especially on the cigarette filter (entries 2 and 6 in Table 4). In fact, it seems that the antioxidant alone is almost as good as the binary mixture of antioxidant and UV absorber. This finding could be

[a] Each carrier was loaded with cyclohexane solution containing 2 mg of pheromone, 0.2 mg of BHA, and 0.2 mg of E-4360 (when mentioned). The solution contained 100 mg of pheromone in 5 ml cyclohexane. The carriers (two of each sample) were kept in a Pyrex dish, covered with a watch glass. All samples were kept on the roof of the building in diffused sunlight.

[b] The amount of the starting isomer was 20–40% of its original quantity. For technical reasons, analyses of samples were performed on different days.

[c] The flask was broken.

explained by the protective effect of the solid support of the carrier, which may furnish better masking from sunlight than is available in a clear solution. It is also possible that some additives in the paper act as either UV absorbers or quenchers, as the antioxidant acts in the presence of a photosensitizer (see above). Such a phenomenon was found in carriers made of rubber septa (Fujiwara et al., 1977; Brown and McDonough, 1986; Teich and Shani, unpublished results). It is important to remember that without an antioxidant, the pheromone decomposed on the carriers in a few days and could not be detected on the GLC.

The real test of the biological activity of the pheromone carriers loaded with the binary protecting mixture was conducted in kibbutz cotton fields. The usual pheromone carrier on a cigarette filter was loaded with 2 mg of (*Z*,*E*)-9,11-C_{14}OAc and 8 mg of UOP 688 (*N*-phenyl-*N'*-(1-methylheptyl)-*p*-phenylenediamine). The latter compound is a dark, viscous, and unpleasant material that may act as a protecting "solvent" for the pheromone and also for slowing down evaporation. Preliminary results of catching efficacy of different preparations are summarized in Table 5. No significant difference ($P = 0.05$, Student's *t* test) was found between each of the five experimental preparations and the standard (UOP), or among the five compounds themselves, except for two

6	UOP 688 (standard)	0.2	6.7	9.3	6.2

[a] Each carrier was loaded with a cyclohexane solution of 2 mg of (*Z*,*E*)-9,11-C_{14}OAc, 0.2 mg of BAH or BHT, and 0.2 mg of E-4360 (when mentioned). With UOP 688, 8 mg of the material was loaded on each carrier with 2 mg of pheromone.

[b] Dry traps with long sleeves were erected at random, 50 m apart, six replicates of each sample. Catches were monitored twice a week.

[c] Significantly different from UOP 688 at $P = 0.10$ (Student's t test).

formulations (entries 1 and 4 in Table 5) in the experiment carried out at Kibbutz Reshafim, which were significantly different from UOP 688 (entry 6) ($P = 0.10$, Student's t test). These results strengthen previous observations (Teich, Shani, and Klug, unpublished results) made during the 1981–1982 seasons, which showed not only that BHA and BHT were better protecting chemicals for (*Z*,*E*)-9,11-C_{14}OAc than UOP 688, but also that they increased catching efficacy. Therefore, it should be desirable to replace UOP 688 as an antioxidant in pheromone protections with BHA and BHT, at least for technical and handling reasons.

It is interesting that both the UV absorber and the antioxidant as a single additive prolonged the trapping efficacy of the pheromone. This fact may be in keeping with our earlier findings (see Table 4) that the behavior of the solid carriers was very much like that of one (antioxidant) or two additives and not to the positive effect observed for the UV absorber in solution (Tables 1, 2, and 4). The exact quantity of the pheromone and the relative composition of its geometrical isomers remaining on the solid carriers in the field can indicate the

correlation between the chemical processes and the biological activity (Shani and Klug, 1980b). At this stage we should remember that, when analyzing the results from the field study and comparing them with the chemical transformations of the pheromone, either in solution or on solid carriers, we are comparing two different processes and results. It could be, and we indeed found earlier in two cases, that not much of the real pheromone is needed for attraction, and the other geometric isomers do not interfere with trapping (Shani and Klug, 1980b; Ideses et al., 1982a). Therefore, the chemical results obtained in the laboratory do not necessarily reflect the biological findings in the field and vice versa. As long as enough active pheromone is present on the carrier and the other isomers are inactive and do not interfere, there may be high activity in the field despite the fact that isomerization and/or oxidation has destroyed much of the pheromone. In solutions studies, the pheromones and their isomers could be detected by GLC for up to six weeks afer the start of the experiment, while in the field the carriers attracted the Egyptian cotton leafworm for up to two months. The results in Table 5 show that, in the first experiment at Kibbutz Mefalsim, trapping in the second month (24.7–28.8) was almost as high as that in the first month of the second experiment.

We may summarize the results as follows:

Thermal Decomposition–Oxidation. Addition of an antioxidant prolonged the life-span of the diene system both in solution and in the carrier from several days to 2 weeks to six to eight weeks (Shani and Klug, 1980b; Ideses et al., 1982b; this work).

Isomerization. Addition of a UV absorber effectively slowed down isomerization in the diene system in solution and was less effective on the solid carrier. Both additives are crucial in solution, but the effect of the UV absorber becomes less important on the solid carriers.

Biological Activity. We have found that (*Z*,*E*)-9,11-C_{14}OAc attracts the Egyptian cotton leafworm in the field up to two months. The (*E*,*Z*)-7,9-C_{12}OAc isomer was found to attract the European grapevine moth in the field for up to seven weeks (Ideses et al., 1982a), which time is in the range of the chemical stability. The (*E*,*E*)-10,12-C_{16}Ald isomer is active in catching the spiny bollworm for four to five weeks (Kehat et al., 1981). The chemical behavior of this isomer was studied on the corresponding acetate, as the sensitive group is the aldehyde. The isomerization was very slow as the *E*,*E* isomer is the most stable one in the mixture.

Israeli entomologists and farmers usually change the carriers in traps for all three once in four to six weeks, although from scattered observations in the fields, some traps were found to be active for two months or more.

All these findings lead to the conclusion that results of laboratory studies and experimentation cannot necessarily be extrapolated to the real-life situation

in the field: the ultimate test of pheromone efficacy is the biological activity on the field, when all factors come into full expression and the weighted system is the governing power.

Acknowledgments—We wish to thank Miss Ofra Gerstein, Dr. Reuven Or, and Mr. Ya'acov Barkai for the cotton field study.

(Received May 18, 1987; accepted September 28, 1987)

Abstract—The responses of the goldenrod leaf beetle *Trirhabda canadensis* to host and nonhost volatile odors were tested in a Y-tube olfactometer in the laboratory. Beetles preferred host to nonhost odors and were sensitive to concentrations of host odor. Beetles distinguished between host and nonhost volatiles of only one of the two nonhost *Solidago* species; host volatiles were preferred to all nonhost volatiles at the family and order levels. In other words, all nonhosts above the genus level had similar effects on beetle responses. Although the odors of most nonhosts were neutral (i.e., neither attractive nor repellent) to the beetles as tested against air, this neutrality disappeared if the odors of two or more nonhosts were added to the host odor and beetles were given a choice between this mixture and pure host odor. Given this choice, they strongly preferred pure host odor, which suggests that diversity of odors per se is unattractive to the beetles. Beetles walked rather than flew to locate their hosts in the field, and their movements suggest that they used olfactory cues to locate hosts.

Key Words—*Trirhabda canadensis*, Coleoptera, Chrysomelidae, *Solidago*, plant volatiles, host finding, olfaction.

INTRODUCTION

Host selection by insect herbivores comprises a number of behavioral responses to various stimuli associated with the host plant; stimuli may be olfactory, gustatory, visual, or mechanical (Visser, 1986). In particular, the orientation of phytophagous insects to chemical stimuli has been most extensively studied in agricultural systems (Finch, 1980; Visser, 1986). In these, it has been shown

0098-0331/88/0800-1671$06.00/0

that volatile plant odors are important stimuli that aid specialist insects in short- and long-distance discovery of suitable host-plant patches and in selecting individual host plants. Since host-plant patches may vary in size, density, and the diversity of non-host-plant species associated with them, the volatile odors emanating from different patches may also vary. The concentration of host odor and the presence of nonhost odors may affect the ability of insects to find host plants in various ways (Root, 1973; Tahvanainen and Root, 1972; Kareiva, 1983; Stanton, 1983; Visser, 1986). Thiery and Visser (1986), for example, have shown experimentally that mixing nonhost odor with host odor neutralizes the normal response of the Colorado potato beetle, *Leptinotarsa decemlineata*, to host odor. They describe this effect as masking of the host odor by the nonhost odor.

The work described in this paper is part of a larger study that examined the responses of a specialized herbivorous beetle to patches of host plants in the field, and, in particular, how the density of the host and the presence of associated nonhost species influenced beetle responses. Here we present data from field and laboratory experiments on the responses of beetles to odors from host and nonhost species. These plant species are in the same genus or same family as the host or in different orders. All species are naturally cooccurring herbaceous perennials native to the tall grass prairie of North America (Table 1). We tested four hypotheses: (1) beetles prefer host volatiles to nonhost volatiles; (2) beetles detect differences in concentration of volatiles from the host plant; (3) volatiles from plants in the same genus as the host are more acceptable

TABLE 1. ARRAY OF PLANT SPECIES TESTED IN THREE SETS OF OLFACTOMETER EXPERIMENTS, AND THEIR TAXONOMIC AFFILIATIONS

Species	Order	Family	Tribe	Subtribe
Solidago altissima L. *Solidago nemoralis* Ait. *Solidago missouriensis* Nutt. *Solidago rigida* L.	Asterales	Asteraceae	Astereae	
S. altissima L.	Asterales	Asteraceae	Astereae	Solidaginae

Lespedeza capitata Michx.	Fabales	Fabaceae		
Monarda fistulosa L.	Lamiales	Lamiaceae		

to beetles since they are closely related and are therefore expected to have some of the same volatile chemicals, while species that are more distantly related are less acceptable since these produce volatiles that are less similar; and (4) beetles prefer pure host volatiles to volatiles from host + non-host combinations.

METHODS AND MATERIALS

Goldenrod Leaf Beetle. Trirhabda canadensis Kirby (Coleoptera: Chrysomelidae) feeds on a narrow range of goldenrod *Solidago* species (Hogue, 1970). At Cedar Creek Natural History Area in Anoka and Isanti counties, Minnesota, the beetles feed on *S. altissima* L. and *S. missouriensis* Nutt. In May, larvae hatch from eggs that have overwintered in the soil at the base of goldenrod plants. They crawl up host plants to feed, complete three instars by mid-June, and drop to the ground to pupate in the soil. Adults 8–10 mm long emerge in early July and recolonize host plants, sometimes dispersing to new goldenrod clones. Beetles mate repeatedly and feed on the host until the end of the summer, usually early September.

Experimental Beetles and Plant Material. Adult beetles were obtained from Cedar Creek at intervals from July 21 to August 26, 1986. They were collected from *Solidago altissima* and *S. missouriensis* in the early morning and air-freighted to Boston the same day. They were maintained at Northeastern University on locally collected *S. canadensis* (which belongs to the *S. canadensis–S. altissima* polyploid complex) under controlled conditions (18°:15°C and 16:8 hr light–dark), and used for olfactometer tests within seven days of collection. Beetles were deprived of food for 2 hr before testing and were used only once in 75% of the tests. Because their number was limited, we used some beetles a second time. However, in those tests we ensured that: (1) the plant material in the second test was as different as possible from that used in the first (for example Air vs. *S. altissima* and then Air vs. the mint *Monarda fistulosa* L.); and (2) at least three days elapsed between the first and second tests. A preliminary trial showed that male and female responses did not differ, so beetles of both sexes were used for the tests.

Plant material was also obtained from Cedar Creek, where it was collected in the early morning, stored in a cooler with individual stems in Water-pics, and air-freighted to Boston the same day. Material was refrigerated and used for olfactometer tests within three days; preliminary trials showed that beetles did not respond in a reproducible manner to plant material after three days.

Experimental Procedures. The olfactometer was modeled after one described by Ascoli and Albert (1985), with minor modifications (Figure 1). A compressed-air cylinder provided the airstream, and a pipecleaner rather than copper wire was provided for beetles to climb. Plant material was placed in

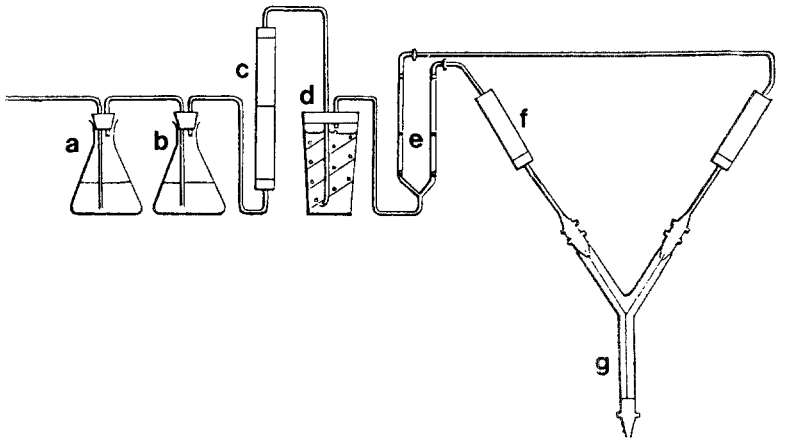

FIG. 1. Schematic diagram of the Y-tube olfactometer apparatus (after Ascoli and Albert, 1985): (a) drierite, (b) charcoal, (c) molecular sieve, (d) water, (e) flowmeters, (f) tube for plant material, and (g) Y tube.

polypropylene sample tubes, connected by polypropylene joints at either end to Tygon tubing, so that the airstream passed over the plant material in the sample tubes at a flow rate of 80 ml/min. We tested air flow in the olfactometer with smoke prior to using it, and determined that flow was smooth, with very little turbulence at the Y junction. The apparatus was positioned in a fume hood in which fluorescent lights provided illumination. Experiments were conducted at room temperature (25°C). The Y tube and pipecleaner were rinsed with acetone after each trial.

Plant material used in the tests was replaced every 30 min. Five to eight leaves were used at a time, except where indicated. In interspecific comparisons, the number of leaves was adjusted so that the amount of leaf material per species was the same.

Between 50 and 80 beetles were used for each test. For each trial, a beetle was placed on the pipecleaner 1 cm from the bottom of the Y tube and allowed to crawl up the pipecleaner. The trial ended when the beetle was within 1 cm of the top of either arm of the Y. A beetle was recorded as not having made a choice if it had not done so in 300 sec. Data were analyzed using chi-square tests for goodness of fit to an even distribution.

To establish whether beetles found a particular plant odor, or combination of odors, attractive, neutral, or repellent, the plant(s) in question were run against air. Then nonhost plants were individually tested against the host, *S. altissima*. Finally, we tested whether beetles distinguished between pure host odor and host odor plus odors from different taxonomic groupings of nonhost species. The nonhost groups were: (1) two species in the same genus, (2) three

species in different tribes or subtribes of the family Asteraceae, or (3) three species in different orders.

Individual Beetle Movements. We recorded movements of individually marked female beetles in the field to determine whether they typically move by walking and/or flying and to see whether their paths were directed or random with respect to host and nonhost plants. Eight observers recorded the movements of eight and seven female *T. canadensis* placed 4 m downwind of cut stems of *S. altissima* or *Helianthus* sp. (Asteraceae), respectively. A curved, open "fence" of stems, approximately 40 cm deep, 70 cm high, and 6 m long, was made from cut stems placed in buckets and jars that were dug into a lawn so that stems were at ground level. The *Helianthus* sp. was chosen because its leaves are similar in shape to *S. altissima*. Wind speed varied from 1.8 to 2.7 m/sec during the experiment. We released each beetle onto a 30-cm bamboo skewer and recorded her path across the lawn with numbered skewers.

RESULTS

Olfactometer Tests. In 85% of the olfactometer tests, beetles walked straight up the pipecleaner with their antennae moving as if to test the airstream, and they did not pause before choosing and walking up one of the arms. In 11% of the tests, beetles walked up one branch of the olfactometer for 10–15 mm before returning to the Y junction and walking up the other to make their final choice; these were included in the final sample as having made a choice. Beetles took 44.3 $\pm$ 9.3 sec ($\pm$SD) to complete a trial. Beetles made no choice in the remaining 4% of the olfactometer tests. These results were included in the calculation of χ^2 values (Siegel, 1956); they did not alter the significance of any of the tests.

Beetles were attracted (as shown by testing against air) to their host plants *S. altissima* and *S. missouriensis* in significant numbers (Figure 2a). They were not significantly attracted to or repelled by *S. nemoralis* Ait. and *S. rigida* L., two closely related nonhosts, although they showed a slight attraction to *S. nemoralis*. Beetles did not distinguish between their two hosts, *S. altissima* and *S. missouriensis*, when offered a choice (Figure 2b). However, when given a choice between *S. altissima* and the two nonhost goldenrods, the beetles did not distinguish significantly between *S. altissima* and *S. nemoralis*, although they did show a slight preference for *S. altissima*. They did significantly prefer *S. altissima* to *S. rigida* (Figure 2b). In short, *T. canadensis* did not distinguish among the *Solidago* species with the exception of *S. rigida*. *S. nemoralis* has been shown to contain a diterpene which is strongly antifeedant to *T. canadensis* (Cooper-Driver et al., 1986), but the volatile chemicals released by this species were not deterrent to the beetles.

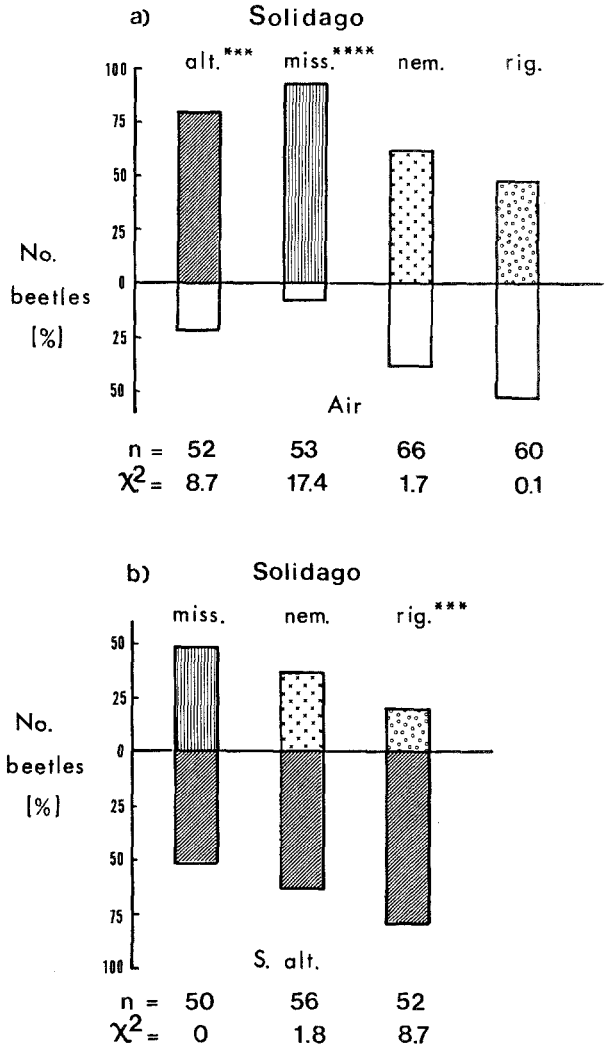

FIG. 2. The choices of adult *Trirhabda canadensis* of plant odors in a Y-tube olfactometer. Choices among plants of the genus *Solidago* were offered against (a) air and (b) the host, *S. altissima*. *S. altissima* = diagonal lines, *S. missouriensis* = vertical lines, *S. nemoralis* = crosses, *S. rigida* = open circles, air = white. ***$P < 0.01$, ****$P < 0.001$.

To test whether beetles responded to differences in odor concentration of the host, they were offered volatiles from one small leaf vs. two small leaves and five leaves vs. 20 leaves of *S. altissima* in two different tests. Beetles did not distinguish between volatiles from five leaves and 20 leaves, but showed a

5 Sm	20 Sm	25	27	1	53	0.04	NS

[a] Sa = *S. altissima*, Sm = *S. missouriensis*. Numbers preceding host species refer to the number of leaves offered.

[b] The first two columns indicate the number of beetles choosing each host odor, the third the number of trials in which beetles made no choice.

significant preference for two leaves over one leaf (Table 2). Thus, it appeared that a threshold concentration existed above which the odor was strong enough to elicit a positive response no matter what the concentration.

All three confamilial species tested [*Liatris aspersa* (Michx.) Greene, *Aster ericoides* L. and *Helianthus laetiflorus* Pers.] were neutral to *T. canadensis*, as shown by testing against air, although beetles appeared slightly to prefer air in all three tests (Figure 3a). However, they showed a significant preference for *S. altissima* to all three of these species (Figure 3b). In the orders group, *Monarda fistulosa* was highly repellent to *T. canadensis*, as tested against air, while the other two species were not (Figure 4a), and beetles significantly preferred the host plant to any of the three (Figure 4b). Thus, in the family and orders comparisons, one of the six species tested was repellent to the beetles; the other five appeared to be neutral, although there was a slight (but statistically nonsignificant) tendency for beetles to prefer air in all five tests. Beetles significantly preferred the host, *S. altissima*, to all six species.

Four of the six comparisons of beetle preference given *S. altissima* alone versus *S. altissima* plus one nonhost species showed that the nonhost species was neutral (Figure 5). Of the family group, *Helianthus* was the only species the odor of which caused the beetles to choose *S. altissima* alone over *S. altissima* + nonhost, in spite of being neutral to the beetles on its own; neither the odor of *Liatris* nor of *Aster* had this effect (Figure 5a). Of the three species in the orders group, *Monarda* was the only one that caused the beetles to prefer *S. altissima* on its own to *S. altissima* + nonhost (Figure 5b).

Equal numbers of beetles chose the odor from a "genus bouquet" (a mixture of *S. altissima*, *S. nemoralis*, *S. missouriensis*, and *S. rigida*) and odor from pure *S. altissima*, that is, beetles did not distinguish between the odor from pure *S. altissima* and that from the bouquet (Figure 6). When a larger amount of pure *S. altissima* (20 leaves) was offered equal to the total amount of leaf material in the genus bouquet, beetles only slightly preferred the odor

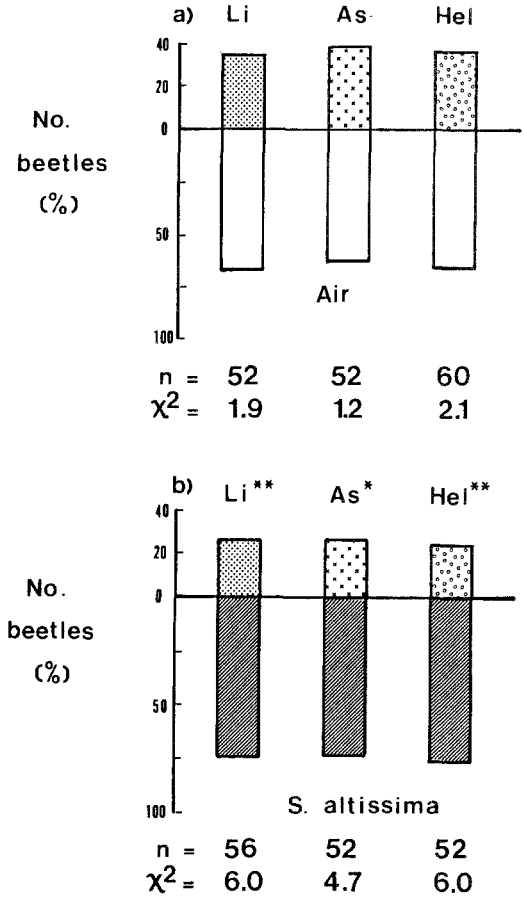

FIG. 3. The choices of adult *Trirhabda canadensis* of plant odors in a Y-tube olfactometer. Choices among different nonhost species in the family Asteraceae were offered against (a) air and (b) the host, *S. altissima*. *S. altissima* = diagonal lines, *Liatris aspersa* = dots, *Aster ericoides* = crosses, *Helianthus laetiflorus* = open circles, air = white. $*P < 0.05$, $**P < 0.02$.

of pure *S. altissima* (32 beetles vs. 19, $\chi^2 = 1.63$, 1 *df*, NS), but this result was not statistically significant.

S. altissima plus the three species from the family array was neutral to the beetles (as shown by testing against air) (Table 3). Interestingly, when *S. altissima* was removed from the family array, the number of beetles preferring air increased (Table 3), although the preference was not significant. However, beetles significantly preferred pure *S. altissima* to *S. altissima* plus the three non-

host species in the family array (Figure 6). The "order bouquet" was repellent to the beetles when tested against air even though it had *S. altissima* present (Table 3), and this was most likely due to the presence of *Monarda*. Given the repellency of *Monarda* (Figure 4), it was not surprising that the beetles pre-

same way as they did in the olfactometer tests. One beetle flew after walking for 58 min. On average, beetles moved 5.5 ± 2.0 m/hr (±SD) and walked 4–12.9 m before finding a goldenrod stem (Figure 7). Of the eight beetles released downwind of *S. altissima*, seven moved upwind and six of these found a goldenrod stem. Of the seven beetles released downwind of *Helianthus*, two went downwind from their starting points and both eventually found *S. altissima* stems. The other five initially moved upwind: two reversed direction and one

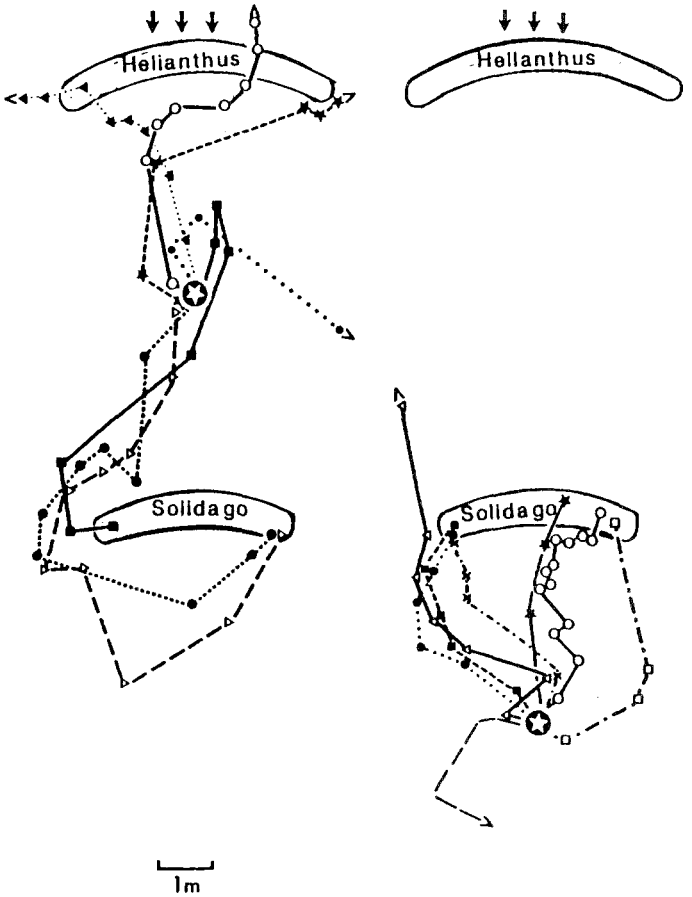

FIG. 7. Paths walked by 15 *Trirhabda canadensis* placed downwind of *Helianthus* sp. (left) or downwind of *S. altissima* (right). White stars indicate release points. Arrows at top indicate wind direction.

of these located an *S. altissima* stem, while the other three passed around or through the *Helianthus*. The circuitous paths walked by the beetles suggested that they found goldenrod stems using olfactory rather than visual cues (Figure 7).

DISCUSSION

The behavior of goldenrod leaf beetles in the laboratory showed that beetles responded to olfactory cues from host and nonhost plants and preferred host to nonhost odors. In addition, beetles were sensitive to concentrations of host odor. Beetles distinguished between host and nonhost volatiles of only one of the two nonhost *Solidago* species; host volatiles were preferred to all nonhost volatiles at the family and order levels. In other words, all nonhosts above the genus level had similar effects on beetle responses. Although the odors of most nonhosts at the family or order levels were neutral (i.e., neither attractive nor repellent) to the beetles as tested against air, this neutrality disappeared if the odors of two or more nonhosts were added to the host odor and beetles were given a choice between this mixture and pure host odor. Given this choice, they strongly preferred pure host odor, which suggested that diversity of odors per se (or odors emanating from a diversity of species) was unattractive to the beetles. Beetles walked rather than flew to locate their hosts in the field, and their movements suggested that they used olfactory cues to locate hosts.

Beetle preference in these experiments largely supported the results of several experiments conducted in the field at Cedar Creek, testing the responses of goldenrod leaf beetles to the same set of host and nonhost species. In colonization experiments, beetles preferred monospecific plots to plots with *S. altissima* interplanted either with three species in the same genus or with three species in the same family or with three species in different orders (Morrow, Tonkyn, and Goldburg, unpublished data). It is likely that the final distribution of beetles in the colonization experiments was the result of beetle response to the different volatile "profiles" of the different plots.

The movements of individual beetles in the field experiment (Figure 7) also suggested that beetles were responding to host-plant odor. The likely mechanism was by means of odor-conditioned positive anemotaxis (Kennedy, 1977; Visser and Nielsen 1977; Visser, 1986). The general orientation of insects to chemical stimuli has been studied extensively (Shorey and McElvey, 1977; Visser, 1986, and references therein). Orientation may occur by means of chemotaxis, which comprises a response directed towards or away from a chemical stimulus and depends on a steep odor gradient. Therefore, chemotaxis can occur only at short distances from an odor source. The effective distance for chemotaxis in insect larvae ranges from 0.5 to 4 cm (Visser, 1986), while chemotaxis

occurs over slightly longer distances than this in adult insects since adults are more sensitive to odors than larvae (Baker, 1985). For longer distances, insects are thought to orient by means of odor-conditioned positive anemotaxis. This taxis comprises mechanical stimulation by wind which primes the insect; when it then perceives an attractive odor, it turns upwind (Visser, 1986). The concentration of the odor needs to be only just above the threshold of detection to bring this taxis into operation. Thus, it is thought to be effective over long distances, although the exact distance has not been determined experimentally (Baker, 1985).

The hypothesis that beetles would show a graded response to volatiles from plants that were closely to distantly related to the host (hypothesis 3 above), was only partly supported by our results, since we found that all nonhosts above the genus level had similar effects on beetle responses. This suggests that beetles recognize specific volatile components or profiles associated with *Solidago* species. Visser and Avé (1978) found that the specificity of potato plant odor in eliciting a positive response from Colorado potato beetles depended on the ratios of the individual volatiles present rather than the presence of any particular volatile. On the other hand, the importance of all non-*Solidago* volatiles appeared to depend on the total diversity present rather than on the recognition of specific volatiles.

Experimental methods for testing insect orientation to chemical stimuli have been reviewed (Kennedy, 1977). Although Y-tube olfactometers have many advantages, they have the disadvantage of not enabling the actual mechanism of attraction to be unequivocally assayed since chemoklinotaxis cannot be distinguished from odor-conditioned positive anemotaxis. This ambiguity in ability to attribute the behavioral mechanism responsible for beetle choices in this study was not a problem since we were interested in actual beetle responses to plant odors rather than in determining the mechanism by which beetles responded.

Of the plant volatiles so far isolated, over 40% are derived from either terpenes or glucosides (Finch, 1980). Visser and Avé (1978) found that leaf alcohols, aldehydes, and derivatives, which they called "green leaf" volatiles, induced positive anemotaxis by the Colorado potato beetle. We are currently isolating volatiles from the plant species used in the present study and testing these to determine which are responsible for observed beetle behavior.

It is possible that attractiveness, neutrality, or repellency of the volatiles of a given plant species or mixture of species is strictly a function of the chemical structure of these volatiles, as determined, for example, by the presence of a particular functional group, although Harborne (1982) cautions that the relationship between chemical structure and odor is not likely to be a straightforward one. Whatever the mechanism, the varied responses of beetles to host, nonhost and host + nonhost volatiles suggest that in natural systems beetles

may respond not only to host odors but may also use nonhost odors to gain additional information about their environment. For example, given the same concentration of host plant volatiles, the presence either of increasing concentrations of the volatiles from one nonhost species or of increasing numbers of volatiles from a larger number of nonhost species may signal a host plant patch with higher total plant density. In such a patch, the host might be less vigorous and therefore a poor-quality source of food.

This study is the first to our knowledge that has focused on insect odor perception in a natural system where plants and insects have been associated over long periods of time. We have shown the effects of plant diversity (as represented by volatile diversity) on the responses of a specialist phytophagous insect at a fairly close range in the laboratory. In future field and laboratory experiments, we plan to test the effects of plant diversity on long-distance attraction of these beetles. More experiments such as these are needed, since such effects have not been tested for any insect species to date (Thiery and Visser, 1986).

Acknowledgments—This study was funded by NSF grants BSR-8307580 to P.A.M. and BSR-8307596 to P.W.L. The comments of J. Glyphis and F. Chew improved the manuscript. We thank the undergraduate students who helped us track beetles to determine individual beetle movement in the field.

CHEMOSENSORY RESPONSES IN TWO SPECIES OF ELEPHANTS TO CONSTITUENTS OF TEMPORAL GLAND SECRETION AND MUSTH URINE

L.E. LITTLE RASMUSSEN

Oregon Graduate Center for Study & Research
Beaverton, Oregon

(Received May 26, 1987; accepted September 30, 1987)

Abstract—This report discusses three areas of investigation: (1) The chemical components in the temporal gland secretion (TGS) of Asian (*Elephas maximus*) and African (*Loxodonta africana*) elephants were characterized by radioimmunoassay (RIA) for testosterone (T) and dihydrotestosterone (DHT) levels and by on-column capillary column gas chromatographic analysis of volatiles. An inverse relationship between TGS testosterone levels and (*E*)-farnesol levels was observed. (2). African elephants responded preferentially toward a particular constituent of African elephant TGS. (3) Urine from Asian bull elephants in musth was partially fractionated by high-performance liquid chromatography. Specific chromatographic regions elicited dramatic avoidance responses from female African elephants. These results support the suggestion that the TGS plays multiple chemocommunicative roles.

Key Words—Temporal gland secretion, *Elephas maximus*, *Loxodonta africana*, testosterone, urine, flehmen, palatal pits, (*E*)-farnesol.

INTRODUCTION

Elephants utilize a variety of sensory systems to communicate with each other: auditory (Heffner and Heffner, 1980; Berg, 1983; Payne et al., 1986; Buss, personal communication 1980), visual (Rensch, 1959; Kuhme, 1962; Markowitz et al., 1975), and tactile (Eisenberg, 1980; Gadgil and Nair, 1984). Especially important in communication are the olfactory (Eisenberg et al., 1971; McKay, 1973) and other chemosensory systems, including the vomeronasal organ (VNO) (Rasmussen et al., 1982, 1986). Chemicals from certain glands, body secretions, and/or excretions apparently convey information to other ele-

0098-0331/88/0800-1687$06.00/0

phants on sex (Schmidt, 1978), sexual status (Hess et al., 1983; Rasmussen et al., 1982, 1984), individuality (Rasmussen et al., 1986), status within groupings (Schmidt, personal communication), and familial relationships (Rasmussen, unpublished).

Urine and secretions from the temporal gland (Rasmussen et al., 1982, 1984; Buss et al., 1976) are intimately involved in chemocommunication among elephants. The temporal gland is a modified sebaceous–apocrine skin gland, uniquely possessed by elephants (Perrault, 1734; Estes and Buss, 1976). The gland is located on the side of the head in the temporal fossa about midway between the eye and ear and opens to the surface by a duct near the center of its lower border. Various functions have been proposed for the gland in African elephants (Sikes, 1971, McKay, 1973; Buss et al., 1976; Wheeler et al., 1982) and in Asian elephants (Eisenberg et al., 1971; Rasmussen et al., 1984). Current thinking favors a multifunctionality for the gland.

Three probably chemosensory responses are distinguishable in both species of elephants (*Elephas maximus*, Asian elephant, and *Loxodonta africana*, African elephant). First, olfactory responses have been observed for centuries (Strabo, 63 BC–21 AD; Estes, 1972; McKay, 1973; Eisenberg et al., 1971; Buss et al., 1976). Systematic studies documenting specific olfactory responses such as sniffing (the trunk tip may be several centimeters to kilometers distant from the odor source) and checking (extreme tip of the trunk touches sampling area), their frequencies, and resulting behavioral responses are few (Eisenberg et al., 1971; Rasmussen et al., 1982; Rapaport et al., 1986). Second, flehmen responses have been documented for both sexes of Asian and African elephants (Rasmussen et al., 1982, 1984, 1986; Rapaport et al., 1986). The flehmen response by elephants apparently occurs directly after olfactory investigation, although it is possible that there may be involvement by as yet undescribed contact or tactile receptors in the trunk tip. Specifically, the flehmen response in elephants involves the contact of the trunk tip with a wet spot, e.g., urine or temporal gland secretion (TGS), followed by placement of the tip directly on the orifices of the paired ducts which connect with the VNO (Rasmussen and Hultgren, 1988). Highest flehmen frequencies exhibited by the Asian bull toward female urine correlate with ovulation and are inversely related to serum progesterone levels (Hess et al., 1983). Third, a response involving placement of the trunk tip on the palatal pit region of the inner upper lip has been observed among Asian elephants at the Washington Park Zoo (WPZ) (Rasmussen et al., 1986; Haight and Rasmussen, in preparation). These three behavioral responses by the elephants served as the basis of the response data recorded during the bioassay sessions.

The present study has (1) compared the chemical composition of temporal gland secretions (TGS) from two species of elephants (with careful attention to age, sex, diet, and physiological condition), (2) recorded the three described chemosensory responses in Asian and African elephants to both whole secre-

tions (TGS and urine) and subfractions derived from these secretions, and to specific compounds previously identified as present in temporal gland secretions, and (3) noted a behavioral response to yet unidentified molecules excreted in urine by male Asian elephants during musth.

METHODS AND MATERIALS

Bioassay Procedure

Bioassay procedures utilizing the three described responses have been developed for both African and Asian elephant groups in moderately sized enclosures involving free-roaming animals (Rasmussen et al., 1986).

Sites. Cooperative relationships have been established with three zoos—Washington Park Zoo (WPZ), Portland, Oregon; Wildlife Safari Park (WLSP), Winston, Oregon; and Point Defiance Zoo (PtDZ), Tacoma, Washington. Each has good facilities for bioassaying. Each zoo maintains small groups of free-roaming elephants in enclosures composed of sand and grass substrates varying in area from 0.25 to 5 hectares. The test enclosures contained several areas of concrete slabs. These slabs were rigorously cleaned with organic cleansers and hosed with hard streams of water prior to every bioassay session. The unique elephant facility, especially the elephant restraining crush, at the WPZ made possible the frequent collection of serum and TGS samples.

Test Animals. Twenty-two elephants in six separate groups of elephants (entirely Asian or African, and mixed species groups) were available for response monitoring (Table 1) either as groups or as individual animals.

TABLE 1. ELEPHANTS PARTICIPATING IN BIOASSAYS

Location	Sex	Status	Age (years)	Origin[a]
Elephas maximus				
Washington Park Zoo (WPZ)	3 bulls	mature and breeding	21–25	2 wc,1 cb
	7 cows	mature and cycling	22–38	5 wc,2 cb
	1 female	intermediate	3	1cb
Point Defiance Zoo (PtDZ)	1 male	intermediate	3	1cb
Loxodonta africana				
PtD2	3 females	maturing	9–12	3wc
Wildlife Safari Park (WLSP)	6 cows	mature	13–35	6wc
	1 male	maturing	12	1wc

[a]cb = captive born; wc = wild caught.

Sample Preparation and Placement. Intact urine samples or fractions thereof in 250 ml buffer were placed on the slabs. Physiological concentrations and their percentages were estimated for specific compounds using analytical data. Substances of limited water solubility were first dissolved in acetone or methanol and subsequently added to buffer. Controls included buffers, heterospecific urine, selected novel substances, and organic solvents in concentrations equivalent to levels used in separation procedures.

Samples of 250 ml volume were poured directly on level areas of concrete slabs. Three to nine samples (two to six test preparations and one to three controls) were placed at random positions prior to each bioassay session. Intervals between bioassay sessions, unless for special experiments described later, were at least 24 hr and usually 48 hr to five days. Samples were placed in the absence of the test animal(s). All bioassays were conducted with the observer uninformed of the test solution composition. Unlike the constant interactions observed between the elephants and their keepers, our experience demonstrated no interactions between the elephants and the observer during the bioassay sessions. The observer watched from a regular visitor viewing area, standing, visible to the test animal, about 30 feet from the samples with an unobstructed view of all the samples. Bioassay sessions lasted 1–4 hr.

Each sample was tested in duplicate during the first bioassay presentation and at least eight additional times during subsequent bioassay sessions, for a total of at least 10 tests. Depending on the purpose of the test, three to five discrete, successive bioassay test sessions were separated by 1–3 hr, at least 24 hr, or 6 months to 1 year. Habituation by the elephants to samples was a concern. The criterion for bioactivity (and lact of habituation) was a response of nondiminishing intensity elicited during five successive (intervals between 1 and 3 hr and/or 24 hr) tests on the same elephant. Selected compounds, especially single compounds testing positively, were also retested after periods of 6 months and 1 year. An earlier study in Asian bull elephants demonstrated that about one third of the chemical substances tested elicited responses upon initial presentation (Rasmussen et al., 1986). Subsequent retesting of these initial response-provoking substances demonstrated loss of response by the fourth bioassay except for selected natural substances from the elephant secretions (Rasmussen et al., 1986).

Responses. The responses monitored included three distinct responses: (1) olfactory responses [number of sniff (trunk tip not touching sample) responses per unit time, duration of sniff episodes, number of check (trunk tip touching sample) responses and duration of checks]; (2) the flehmen response; and (3) the palatal pit area contact response (PPAC). The latter response was described a "sideways tasting response (STR)" in Asian bull elephants (Rasmussen et al., 1986). Examination of recent videotapes clearly showed the trunk tip is actually placed on the area of the palatal pits. Histological examination has not

demonstrated any taste buds in this region (Haight, unpublished results). The response is identical to the palatal pit area contact respone (PPAC) described in female Asian elephants (Haight and Rasmussen, in preparation). The characteristics of these three responses are outlined in Table 2.

Data Collection

Scoring Procedures—Behaviors. We recorded the frequencies of these three responses (Table 2) during bioassay time periods of 1–4 hr (Hutt and Hutt, 1974, "event sampling"; Slater, 1978, "complete record").

Observers. Each person observed one or two elephants. During multiple animal bioassays, a focal animal was chosen at random. The number of elephants present during a bioassay session varied from 1 to 6 animals (always randomly selected). Only the principal investigator and three other trained personnel served as observers (see Acknowledgments).

Observers recorded the type of initial detection of test samples (a sniff or a check), its duration (in seconds), any repetitiveness or sequence, the number of flehmen responses and their duration, the number of palatal pit responses and their duration, and unusual responses, especially responses indicating agitation or avoidance. Records indicated whether scored responses were those of a single animal or if two or more animals were involved.

Recording Procedures. We utilized video taping as an accurate, supplemental recording technique. Video recordings were cross checked with both written and auditory observer records and with rapid sequence (3/sec) still photography substantiating both intraobserver and interobserver reliabilities. During multiple animal bioassays, the entire session was filmed by a preset automatically recording videocamera.

Sequential Scoring on Focal Animals. One set of experiments emphasized the recording of sequence of responses. The video recordings were an especially valuable check on accuracy of sequencing records (see Table 6).

Data Handling Procedures. The range of response durations was tabulated (Table 2), and average durations of responses were calculated. Frequencies (number per unit time) of flehmen and palatal pit responses were calculated, and these frequencies were compared. Interobserver reliability rate was determined both by the videotape methodology of Lehner (1979) and calculated from simultaneous data sheets by the Kappa method of Cohen (1960).

Procurement of Secretion Samples

Female Asian Elephant TGS. Ten samples of TGS from Asian females were collected during the 4-year period 1981–1985. Infrequent secretion occurred predominantly at stressful times such as changing of cow association groups and calving. Samples were collected by gently placing specially designed

TABLE 2. PROBABLE CHEMOSENSORY RESPONSES IN ELEPHANTS

Response	Description	Duration*		Occurrence	Behavior may be indicative of
		Range	Mean		
Olfactory		1 sec to 5 min.	15 sec		
Sniff	Trunk tip several cms to several meters distant from odor source				
Check	Extreme tip of trunk touches sampling area			solitary event or prior to flehmen	mating greeting offspring recognition
Flehmen	Contact of trunk tip with wet spot followed by placement of the tip directly on orifices of incisive ducts.	1–3 sec	1 sec	After prior olfactory investigation	male–female interactions: recognition of estrus/ nonestrus female–female interactions male–male interactions: musth/nonmusth female–maleinteractions maternal recognition

widemouth collecting flasks to washed areas beneath the orifice of the temporal gland, or, for very viscous secretions, using special wide-bore Teflon needles connected to a glass syringe.

Male Asian Musth Secretion. Asian bull elephants experience an annual "musth" period characterized by radical behavioral changes including an increase in aggressiveness and dominance displays (Schmidt, 1978), a 10-fold increase in serum testosterone levels, and copious secretion from the temporal glands. Testosterone is extremely high in most TGS samples from musth bulls (Rasmussen et al., 1984). Between 2 and 101 TGS samples per bull were obtained from three Asian bull elephants in musth at intervals during entire musth periods (Rasmussen et al., in preparation) during the years 1981–1986. Twenty samples have been analyzed for this report. During light musth, some gland secretion and some aggressive behavior occur. During heavy musth, copious, odoriferous gland secretions, intermittent uncontrolled urine dribbling, lack of appetite, inability to lower the penis, and very aggressive, unpredictable behavior occur (Schmidt, 1978; Rasmussen et al., 1984). The procurement of the TGS was dangerous, but possible because of WPZ's restraining crush, which prevented bull movement during sample collection (Rasmussen et al., 1984). Samples were frozen in liquid nitrogen and stored at −20°C. Whenever possible, concurrent serum samples were obtained by the method described in Hess et al. (1983). Both the serum and TGS samples from both elephant species, in the wild and in zoos, were obtained consistently between 9 and 11 AM.

African Elephants. TGS samples were obtained from three young female elephants at PtDZ. Samples from wild culled African adult male and female elephants were collected and frozen by the method described in Rasmussen et al., (1984). Some TGS and serum samples were obtained from several African males observed to exhibit certain behaviors similar to those of Asian bulls in musth (Hall-Martin, personal communication, 1980; Poole and Moss, 1981; Hall-Martin and Van der Walt, 1986).

Collected samples were subdivided into six aliquots before being frozen; duplicate aliquots were used for radioimmunoassay. Three samples per group were analyzed by both capillary column gas chromatographic (gc) analyses and gas chromatographic–mass spectrometric (GC-MS) analyses. The GC analyses are based on 20 replicate GC runs of each of the three aliquots. Other aliquots were fractionated by HPLC, used for bioassay presentations, or assessed for freeze–thaw stability and stability during chemical manipulations.

Chemical Characterization of Components of TGS

Samples were analyzed for testosterone (T) and dihydrotestosterone (DHT) by the method of Resko et al. (1980) as described in Rasmussen et al. (1984).

Samples were prepared for gas chromatographic separation by three suc-

cessive extractions of 1 ml of TGS with dichloromethane using a secretion–solvent ratio of 1:3. Extractions were combined and dried by filtration through anhydrous sodium sulfate. An aliquot (0.5 μl) was chromatographed using a capillary column (J&W DB-5 fused silica column, 60 m, 0.32 μm, film thickness 0.25 mm), with helium as the carrier gas, and temperature programed from 35°C to 300°C at 6°/min using a Hewlett-Packard 5790 gas chromatograph. Flame ionization detection was used. Reference standards of the five previously identified compounds from African elephant temporal gland secretions—phenol (P), 4-methylphenol, (*E*)-farnesol, farnesol monohydrate (FMH), and farnesol dihydrate (FDH)—were used to identify those components in samples (Wheeler et al., 1982). These compounds were also used as internal standards. Identification was made on the basis of retention times relative to those of these standards, and by GC/MS (using a Hewlett-Packard 5790 GC coupled to a Finnigan mass spectrometer #4000 and/or a VG 7070 E-HF double-focusing mass spectrometer system with FD-EI and FAB ion source system and a 11/250 data system).

Identification of additional, new compounds (such as 4-ethylphenol, 2-propylphenol, 4-propylphenol, and 1-benzoylpyrrole) were tentatively made by GC/MS analyses and confirmed by additional on-column capillary column GC analyses in comparison to standards, both external and internal, and by analyses on a 90-MHZ NMR spectrometer. Other categories of compounds were only tentatively suggested, not postively identified, such as hydrocarbons and steroids.

Preparative high-performance liquid chromatography (HPLC) was employed to separate the organic-extracted, aqueous-soluble components of musth urine. Selective fractions, separated by HPLC on a semipreparative C-18 Bondpak reverse-phase column using a gradient elution system of 20:80, methanol–water to 90% methanol, were prepared for bioassay.

RESULTS

Chemical Analyses: Characterization of TGS Components

Testosterone. Testosterone (T) and dihydrotestosterone (DHT) levels were measured in 20 TGS samples from three Asian bull elephants in musth (Table 3). Bull #2 samples were taken serially during two different musth periods. Several concurrent serum samples were obtained (Table 3). TGS testosterone values were high, ranging from 17.5 to 2113.8 ng/ml. The wide range was apparent even when androgen levels were equated per TGS protein. Especially to be noted are the testosterone levels in the TGS extracts analyzed by GC (Figure 1). Testosterone values for serum and TGS are given for the samples analyzed (Figure 1, legend).

phant (dashed line indicates female captive African elephant); #4, Asian male elephant, estrone injected; and #5, African bull elephant with high serum and TGS testosterone. The TGS volatiles GC patterns from Asian male elephants in musth (#1) and African bulls with high serum testosterone (#5) are especially noteworthy to compare. The similarities between the TGS volatiles of an estrone-injected in-musth Asian bull (#4) and a African bull with normal serum T levels (#3) are equally remarkable.

Five volatiles [previously identified in the TGS of both sexes of culled African elephants (Wheeler et al., 1982)]—phenol (P), 4-methylphenol, (*E*)-farnesol (3,7,11-trimethyl-2,6,10-dodecatrien-l-ol), farnesol monohydrate (FMH, 3,7,11-trimethyl-2,10-dodecadien-l, 7-diol), and farnesol dihydrate (FDH, 3,7,11-trimethyl-2-dodecen-l,7,11-triol)—were identified in TGS samples from several captive African females and one male African elephant (Figure 1, #3).

Variable concentrations of either or both phenol and 4-methylphenol were detected in all TGS samples from both elephant species, including Asian bulls in musth.

(*E*)-Farnesol was a component of the TGS from most African elephants of both sexes. (*E*)-Farnesol was present in low concentration in TGS of Asian female elephants (Table 4). In only five of 101 TGS samples from Asian bulls in musth were low levels (< 1%) of (*E*)-farnesol detected (Table 4) (Rasmussen et al., in preparation). However, (*E*)-farnesol was readily identified in the single TGS sample from an estrone-injected Asian bull in musth (Table 4; Figure 1, #4).

Other notable differences in volatiles from TGS included the presence in

FIG. 1. On -column capillary GC separation of volatiles in dichloromethane extracts of temporal gland secretions (TGS) from following indicated elephants: Chromatogram #1, captive Asian bull at WPZ, serum T = 73.8 ng/ml, TGS T = 247.00 ng/ml, F = 1%. Chromatogram #2 Asian female elephant sample obtained shortly after parturition, serum T = 0.05 ng/ml, TGS T = 0.05 ng/ml. Chromatogram #3, African female or male with low serum T 0.05–0.5 ng/ml, TGS -T = 1.45 ng/ml. Dashed lines indicate farnesol peak from captive female African elephant TGS, serum T = 0.02 ng/ml, TGS T = 0.75 ng/ml. Chromatogram 4, estrone treated Asian male elephant, TGS T = 2.50 ng/ml. Chromatogram #5, African male elephant (wild) serum T = 6.64 ng/ml, TGS T = 78.06 ng/ml. Compound codes: P = phenol, propylphenol = mixture of 2- and 4-propylphenol, T = testosterone, S = nontestosterone steroid, HC = hydrocarbons including triacontanes, pentatriacontanes; other compounds identified in this region included 2-benzothiazole, *n*-propylbenzamide and other benzoic acid derivatives. FMH = farnesol monohydrate, FDH = farnesol dihydrate, I = 1-benzoylpyrrole, 4-nonylphenol (contains other isomers).

female Asian elephant secretion of a number of high-molecular-weight hydrocarbons (tentative identifications include various substituted pentatriacontanes, tetratriacontanes, and tritetracontanes of undetermined substitutions), benzoic acid derivatives, and at least one nontestosterone steriod (S) (Figure 1, #2). A high level of (*E*)-farnesol was present in the TGS of a young zoo female African elephant as indicated by the dashed line in Figure 1, #3 and Table 4.

The GC pattern of volatiles from the male Asian elephant TGS "musth" was distinctive. The majority of identified peaks, including 1-benzoylpyrrole (I), 4-methylphenol, 4-ethylphenol, 2-propylphenol, and 4-propylphenol, eluted before the farnesols (Table 4, Figure 1). By GC/MS analysis on Finnigan #4000 under the particular GC conditions, 2-propylphenol and 4-propylphenol co-eluted (Figure 1, propylphenol). GC separation of extended times resulted in the elution of 2-propylphenol (bp 224–226°C) several minutes prior to 4-propylphenol (bp 232°C. Identifications were confirmed by high-resolution GC/MS (VG 7070), internal standards, and NMR. A similar protocol was followed for 1-benzoylpyrrole. GC-MS and internal standard data established the retention time of testosterone (T) as indicated in Figure 1. The testosterone peak, varying quantitatively, was detected in all Asian musth bull and several African bull TGS samples. The volatiles from the TGS of the male African elephant with high testosterone (Figure 1, #5) bear an interesting resemblance to the volatiles from the TGS of an Asian bull in musth (Figure 1, #1 and Table 4). Noteworthy similarities were the presence of various phenols, the reduced farnesol content, and the high levels of testosterone. Further identifications will be presented in Rasmussen et al., in preparation.

HPLC Analyses. The indicated eluting region on the HPLC chromatogram of fractionated Asian male musth urine (Figure 2) elicited a characteristic response from female African elephants (both at PtDZ and WLSP). Upon initial detection of the test sample, there was a high frequency of flehmen and PPAC responses, immediately followed by a dramatic avoidance alarm response. The ears were held in an erect position characteristic of alarm (Buss, personal communication). Trumpeting and roaring occurred. Both at PtDZ and WLSP, the elephants herded together, ran to the other end of yard, and thereafter avoided the sample. Further fractionation of this chromatographic region is currently in progress.

Bioassay Results: Natural Substances

The interobserver reliability was calculated to be 0.81. Three responses were recorded independently. Comparisons between them are expressed primarily as frequency. The *y* axis scale of response frequency differs in Figures 3 and 4. Data on response duration are contained in Tables 2 and 5.

Asian Elephant Responses. The bioassays were conducted several times a week at WPZ for a total of 1351 samples tested. Each sample was bioassayed by each bull 10 or more times and by each cow 5–10 times.

Among females, the highest flehmen frequencies were to male musth urine and male nonmusth urine with no significant differences between these two samples (Figure 3). All six samples, including male musth TGS and female conspecific TGS (Figure 3, top), elicited significantly higher responses than the controls.

Both self and sequential palatal pit responses were observed toward musth urine and less frequently toward female urine. Within our study group of samples, female Asian elephants performed more PPAC responses than male Asian elephants.

Several of the eight female Asian elephants tested at WPZ exhibited a less dramatic, less intense avoidance response than that demonstrated by African females to Asian musth urine. Cow behavioral responses observed anecdotally, after introduction into enclosures previously occupied by bulls in musth and

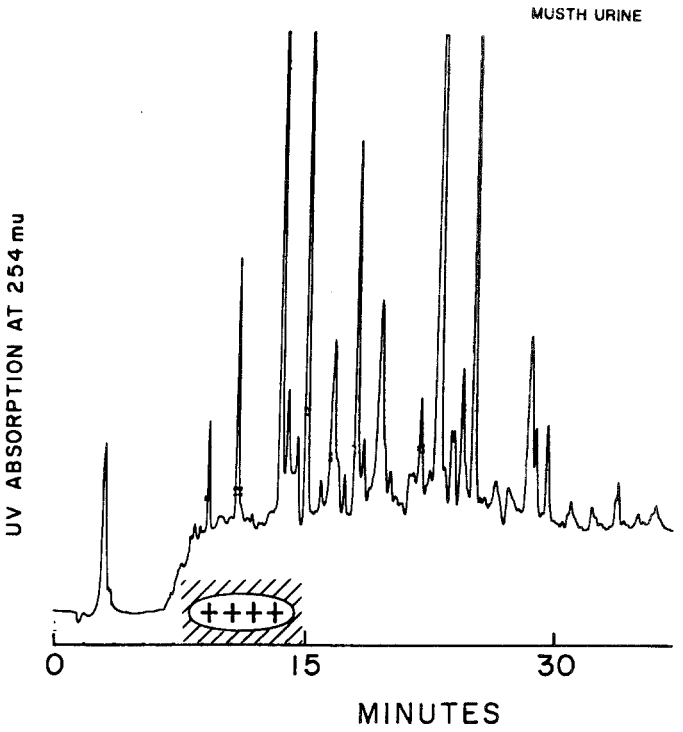

FIG. 2. HPLC chromatogram of "musth" urine fraction from male Asian elephant. Bioassay animals: African female elephants. Biologically active region: Sample: concentrated sonicated aqueous fraction from desiccated dichloromethane extract. Code: ++++ response, especially avoidance reaction, trumpeting. Separation conditions: reverse-phase C-18 bonded silica column, 30 min separation time, linear gradient 20 : 80 methanol–water to 90 : 10 methanol–water.

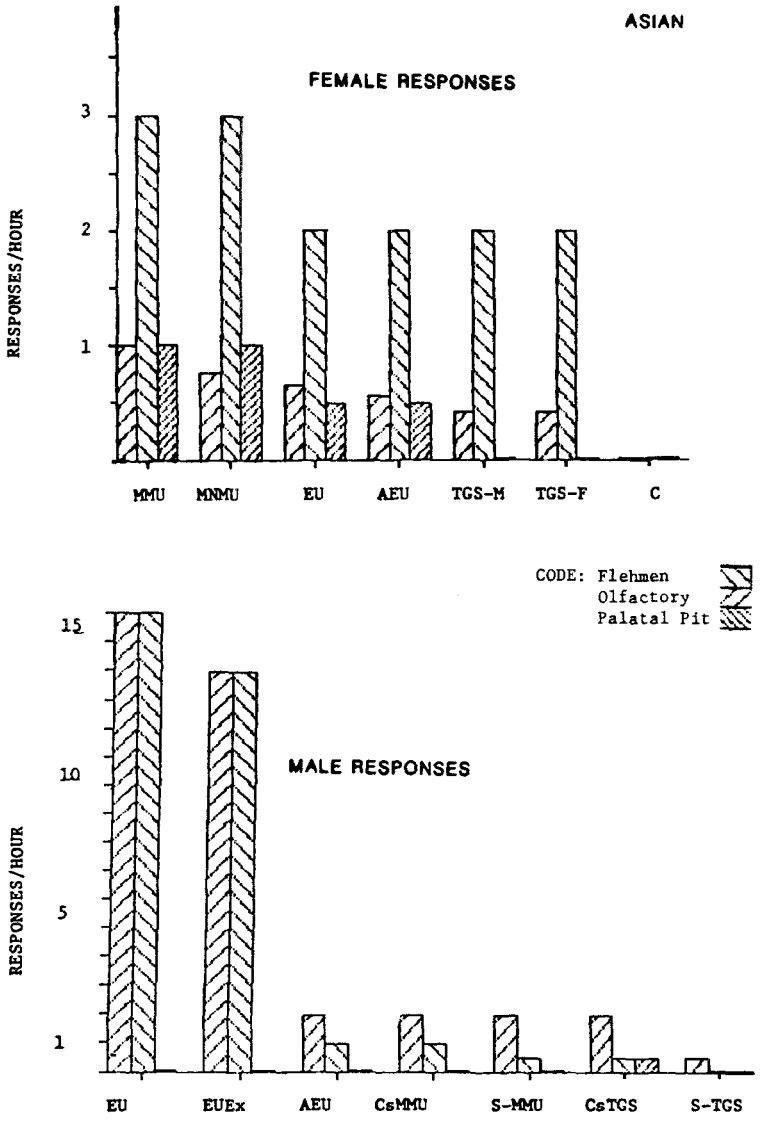

FIG. 3. Responses by Asian elephants to urine and temporal gland secretions. Sample size: TGS, 0.5 ml; urine, 500.0 ml. Each female tested 10 times; each male tested 25 times, at intervals of at least 24 hr MMU = male nonmusth urine, MNME = male nonmusth urine, EU = estrous urine, AEU = anestrous urine, TGS-M = conspecific temporal gland secretion (male), TGS-F = conspecific temporal gland secretion (female), EUEx = estrous urine extract, CSMMU = conspecific male musth urine, S-MMU = self male must urine, CsTGS = conspecific temporal gland secretion, S-TGS = self temporal gland secretions, C = controls all samples were from *Elephas maximus*. The calculated standard error (SE) for flehmen data: 0.125–0.175 [standard deviations (SD) 0.392–0.553]; for PPAC data, 0.115–0.145 (SD 0.284–0.601); and met the criteria for 0.05% confidence limit. The *t* test was used to test for significant differences, $P < 0.05$.

containing voided musth urine, included agitation. The familarity of the cows with the particular bulls, the normally maintained physical separation of bulls and cows, and the stage of musth at which the urine is obtained may be contributing factors affecting their behavioral responses. Studies employing musth urine from bulls whose serum T levels have been measured are currently in progress.

In regard to responses by males, previous studies demonstrated a high flehmen frequency by Asian bulls to estrous urine and estrous urine extract (Rasmussen et al., 1982). This high response was significantly different in frequency (10-fold) than flehmens to other urines (Rasmussen et al., 1984). The second-rank flehmen frequencies exhibited by Asian bull elephants were to conspecific male musth urine and to anestrous urine (Figure 3, bottom). Nonmusth urine, either self or conspecific, elicited no responses.

Among bulls, musth TGS also elicited detectable flehmen responses. The initial positive responses toward testosterone, a single and major component of Asian elephant TGS, were novel substance responses that diminished on successive bioassays (Rasmussen et al., 1986).

Olfactory response frequencies and flehmen frequencies appeared complementary. However, as the frequency of flehmen and olfactory checks increased with approaching ovulation, the duration of olfactory investigations did not lengthen.

Palatal pit area responses were only observed to the following samples: conspecific TGS, acidified artificial samples, and selected purified fractions from estrous urine.

African Elephant Responses. Bioassays were carried out on 10 occasions at PtDZ and five times at WLSP.

The frequencies of the three responses by female African elephants to selected urine and TGS samples are depicted in Figure 4 (top). The samples tested included male musth urine (MMU), temporal gland secretions (TGS) from conspecifics and Asian elephants, and four categories of Asian elephant urine, including one extract of female Asian elephant estrous urine. Data are from 10 tests at PtDZ on three young African female elephants and five tests at WLSP on six adult female elephants (see Table 6). Standard deviation between the two data sets at two locations were within the 0.05% confidence limit; the data were summarized together.

Among the African female elephants, the flehmen response frequencies were greatest toward male musth urine. After sample detection, high-intensity responses occurred, samples were avoided subsequently. The olfactory response frequencies were highest toward estrous urine. The frequencies of palatal pit responses were greatest to female urine, both estrous and nonestrous.

Female African elephants showed a low, but detectable, response to both male and female conspecific TGS. None of the TGS samples tested were from African bulls with high serum testosterone.

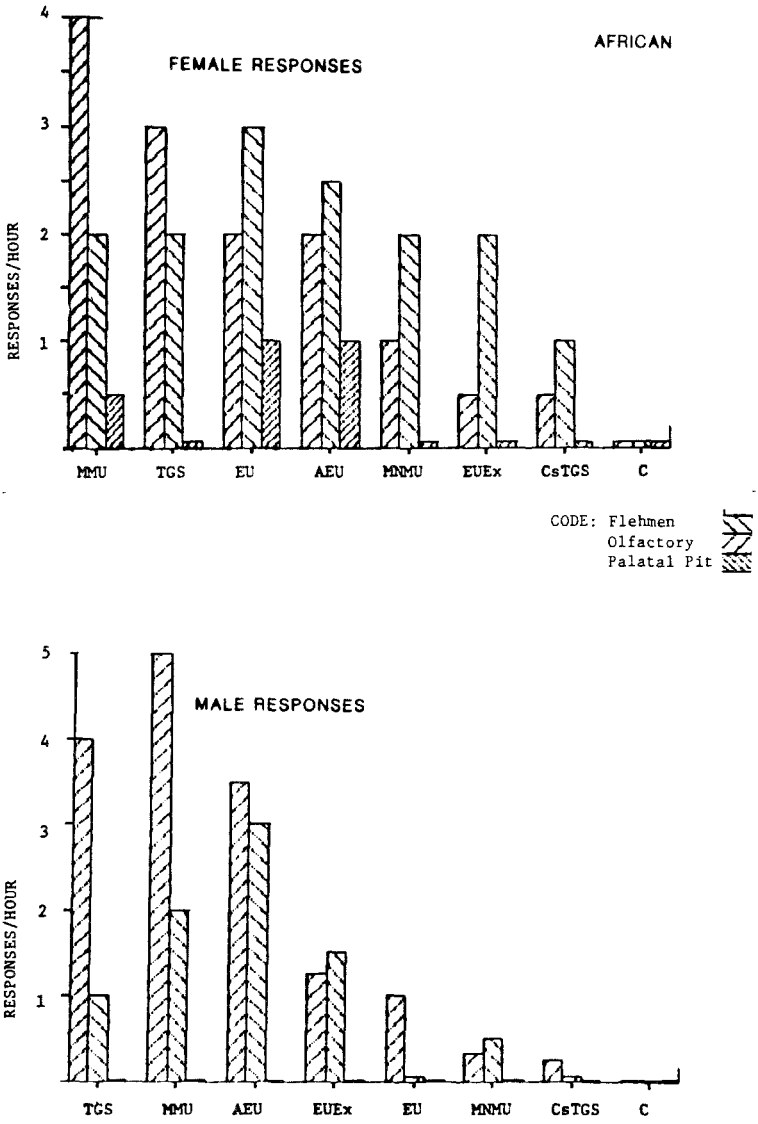

FIG. 4. Responses by African elephants to urine and temporal gland secretions Sample size: TGS, 0.5 ml; urine, 500.0 ml. Females were tested 10 times at 24-hr and 6-month intervals. Sites: PtDZ, 3 females; WLSP, 6 females. Avoidance reactions (trumpeting, herding of young elephant by older elephants, ears in laid back position, and agitated running) were observed. Males were tested 12 times at 24-hr and 6-month intervals; two successive tests per time; WLSP- 1 male MMU = male musth urine, TGS = temporal gland secretion, EU = estrous urine, AEU = anestrous urine, EUEx = estrous urine extract, MNMU = male non-musth urine, CsTGS = conspecific temporal gland secretion, C = controls. All samples were from *Elephas maximus*, except CsTGS which was from *Loxodonta africana*. The SE for flehmen and PPAC data was within the 0.05% confidence limit. Olfactory data was less rigorous. The *t* test was used as criteria of significant differences, $P < 0.05$.

The most striking responses exhibited by female African elephants to male musth urine were the high-frequency flehmen response (4/hr), trumpeting, roaring, erectile ears, and persistence of avoidance. The response by the African female elephants to male Asian musth urine was similar to the reactions to the fractions previously described. A response of four flehmen per hour is a high flehmen frequency for female elephants. Olfactory investigation times of musth urine were long (Table 5). TGS from heterospecifics also elicited interest (Figure 4, top).

In regard to the response by males, the only bull available for bioassay testing exhibited the highest flehmen frequency to Asian musth urine and the greatest frequency of olfactory responses to anestrous urine. Few palatal pit area responses were observed. Urine from African female elephants with hormonally well-characterized estrous cycles was not available.

Bioassay of Synthetic Mixtures of Identified Components of African TGS. Figure 5 and Table 6 show the responses of one maturing African bull and 10 African females (ages 9–35 years) at two locations to the three available (of five) volatile components identified in African TGS and of selected biological secretions. Each sample was tested at least 10 times. Three bioassays were done in immediate (1–3 hr) succession; three bioassays were separated by 24 hr; three bioassays were separated by 6 months to 1 year. The maximum response obtained from a variety of controls was a cursory olfactory check (Table 6). Responses were observed to several concentrations of (*E*)-farnesol and to mixtures of farnesol with 4-methylphenol and cholesterol. The greatest response was elicited by a low farnesol concentration (0.033%). The response to 0.033% (*E*)-farnesol was 50% the response level seen to musth urine. The response frequency to single components was not of the magnitude of the response by the Asian bull to estrous urine; rather it was the order of magnitude of the detectable response of the bull to anestrous urine. Its repeatability in successive bioassays was remarkable.

FMH and FDH were used as standards during GC analyses, but sufficient quantities were not available to allow the bioassay of these two components. No funds were available for their synthesis during this study.

Of the male Asian elephant responses, three Asian bull elephants demonstrated individual variability in response to components from African GS. One bull with former associations with African elephants responded to all three tested components [phenol, 4-methylphenol and (*E*)-farnesol] and their mixtures from African TGS, whereas the responses of the other two bulls were negative.

Proportional Use of Three Responses. The complete record of three responses to four investigator-placed samples in a single experiment are listed in Table 5. As listed in Table 5, the total number of olfactory responses and their duration was higher than the number or duration of flehmen responses. The flehmen responses were greater in number and total duration than palatal pit responses.

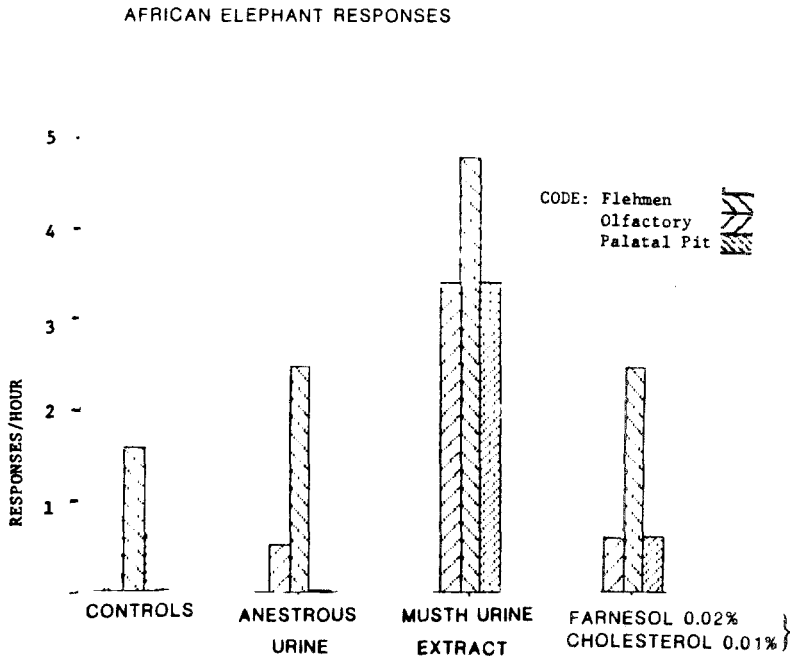

FIG. 5. Female African elephant responses to four biological samples. Sample size: TGS, 0.5 ml; anestrous urine, 500.0 ml; musth urine Extract, 500.0 ml equivalent. Controls: all solvents used in preparations various urines. TGS was from *Loxodonta africana*; the other samples were from *Elephas maximus*. The *t* test for significant differences was set at $P < 0.05$.

The data from one female are depicted in Figure 5. The high response of African elephants to Asian musth urine (Figure 4) is also seen in Figure 5. Olfactory responses tabulated were threefold higher toward musth urine samples than to controls and twofold higher toward musth urine than to 0.02% farnesol and 0.02% cholesterol mixture or to anestrous urine. Flehmen responses were fivefold higher to musth urine than to the other two samples. The number and duration of sequential palatal pit responses were greatest when musth urine was tested.

DISCUSSION

The response frequencies observed to whole secretions and urines, to unpurified fractions, and to single components were greater than expected from earlier investigations. Bioassay procedures, using aerosol spraying or air blowing for sample dispersion followed by subsequent monitoring of olfactory

responses, did not reveal any responses by African or Asian elephants to African TGS components (Buss, personal communication; Gorman, 1986a, b). However, Asian bull elephants were observed to flehmen both to their own

urine and TGS and that of conspecifics (Rasmussen et al., 1984). In the current study, presentations of natural secretions and appropriate synthetic compounds in liquid media resulted in measurable olfactory, palatal pit, and flehmen responses in a variety of contexts in both species.

The flehmen response in elephants is seen only after prior olfactory investigations. The trunk tip physically transports liquids to the openings of the vomeronasal passages during flehmen. The flehmen response in elephants, used with dramatic intensity by Asian bull elephants in response to estrous urine (Rasmussen et al., 1982), is seen in both sexes during a variety of situations, which include not only sex identification and sex state information but also the establishment and maintenance of mother–young recognition, in female–female interactions, and in the mediation of male–male interactions. In the wild, certain African bulls have been observed to flehmen to the penile area and urine of other more dominant, more aggressive bulls (Rasmussen et al., 1986; Hall-Martin and Rasmussen, in preparation). Current observations show that flehmen is used in sequence with prior olfactory responses and often with successive palatal pit responses. (The possibility that these three responses represent different intensities of a similar response is currently under investigation.) Such sequences involving the PPAC response were most evident in the premating sequences and alarm–avoidance reactions. Moderately high frequencies of palatal pit response and high frequencies of flehmen responses by female African elephants occurred during initial response to Asian male musth urine. After evidencing alarm by trumpeting, roaring, and positioning ears, the animals did not return to the test sample.

Positive responses to novel substances could be sorted out from real meaningful responses by successive, repetitive testing. Habituation was not evident during frequent testing of Asian bulls with biologically active compounds (Rasmussen et al., 1986). In the present study, the lack of habituation for selected compounds in successive tests may indicate that elephants recognize, innately or through learning, meaningful compounds. These molecules elicit responses, consistently and repetitively, if presented in appropriate concentrations and presentation media.

Factors such as age, sex, diet, physiological condition, and season might affect gc, GC/MS, and HPLC results. Some of these factors are not controllable, but with the WPZ bulls these factors remained relatively constant. The consistency of triplicate samples and samples from successive days (within groupings of animals), the reproducibility of bioassays in repetitive sample testing, and the demonstration of similar GC patterns of TGS from animals with similar testosterone levels support the validity of the GC analyses.

The dramatic reaction by African female elephants to male Asian musth urine (and specific fractions), in contrast to female Asian elephants' lower

response to Asian musth secretion and Asian TGS, raises several questions. Which chemicals or combinations are meaningful to each species? Is a spectrum necessary? Do the species' repertoires gradate into each other? Maybe a clue exists in the chemical similarity between Asian musth TGS and the TGS from African bulls exhibiting a behavioral musth (Hall-Martin and Rasmussen, in preparation) and having high serum and TGS testosterone.

Figure 1 and Table 3 show an inverse relationship between farnesol and testosterone levels in TGS. Especially noteworthy to compare are the estrone-injected Asian bull in musth with the normal African bull and the high testosterone African bull with an Asian bull in musth. The TGS sample from an African male elephant with high serum and TGS testosterone does not have the proportion of (*E*)-farnesol normally resolved from African male and female TGS.

Such observations as this inverse relationship between testosterone levels and farnesol levels in TGS, and an avoidance reaction by female African elephants to Asian male musth urine, and an earlier description of the triggering of TGS secretion release in Asian bulls (Rasmussen et al., 1984), suggest definitive chemocommunicative functions for this unique gland.

Acknowledgments—sincere appreciation is expressed to the Point Defiance Zoo, Tacoma, Washington (especially to Mr. Roland Smith, Assistant Director, Mr. Gary Miller, and Mr. Jeff Zimmermann); Wildlife Safari Park, Winston, Oregon (especially Mr. Dan Black); and the Washington Park Zoo, Portland, Oregon (especially to Dr. Michael Schmidt, Mr. Roger Henneous, and Mr. Jay Haight, who obtained most of the TGS samples). The volunteer observers (Patrica Ashley, Bonnie Comegys, and Anna Michel) were arranged for with the help of Ms. Jill Mellen, Behavioral Research Director, WPZ. Without the encouragement and help of these persons and generous use of elephants of the three facilities, this study would not have been possible. I thank Dr. David L. Hess, Oregon Regional Primate Center ORPC #RR-00163, for his assistance in the testosterone and dihydrotestosterone assays. This research was supported in part by the Friends of the Washington Park Zoo, by the Portland Branch of the American Association of Zookeepers, and by Biospherics Research Corporation.

Announcements

INTERNATIONAL SYMPOSIUM ON INSECT-PLANT RELATIONS

The 7th International Symposium on Insect-Plant Relationships will be held in Budapest, Hungary, July 3–8, 1989. Its organizers, Drs. T. Jermy, Chairman, and A. Szentesi, Secretary, have grouped sessions according to the special fields of physiology, behavior, ecology, phytochemistry, evolution, and applied aspects. Interested scientists may acquire more details by writing to A. Szentesi, 7th International Symposium on Insect-Plant Relationships, Plant Protection Institute, Department of Zoology, Budapest, Pf. 102, H-1525, Hungary.

CURRENT AND FUTURE TRENDS IN BIOLOGICAL CONTROL OF INSECTS

To honor the retirement and many contributions of Professor Harry C. Coppel to the field of biological control, the University of Wisconsin Entomology Department is sponsoring a symposium entitled Current and Future Trends in Biological Control of Insects, to be held on the university campus September 27–29, 1988. The agenda includes presentations by nationally recognized leaders in biological control and a poster session for contributed papers. For more information contact: D. L. Mahr, Department of Entomology, University of Wisconsin, Madison, Wisconsin 53706 (608–262–3228) or N. E. Beckage (608–263–7924).

BEHAVIORAL RESPONSES OF FEMALE MEXICAN FRUIT FLIES, *Anastrepha ludens*,[1] TO COMPONENTS OF MALE-PRODUCED SEX PHEROMONE

D.C. ROBACKER

Subtropical Fruit Insects Research
USDA-ARS, Weslaco, Texas 78596

(Received July 6, 1987; accepted September 28, 1987)

Abstract—The behavioral responses of virgin female Mexican fruit flies elicited by components and combinations of the components of male-produced pheromone were measured in a laboratory wind-tunnel bioassay where test chemicals were applied to the undersides of some leaves on a treated tree but to none of the leaves of a control tree. Only treatments containing at least (*Z*)-3-nonenol and/or (*Z,Z*)-3,6-nonadienol in combination with (*S,S*)-(−)-epianastrephin elicited strong behavioral responses. Responses included attraction to the vicinity of the pheromone but not to point sources, increased searching rate, changes in searching strategy, and agonism. The results support a model of pheromone-component function in which components act as a unit to stimulate all behaviors of the pheromone-mediated behavioral repertoire.

Key Words—Sex pheromones, Mexican fruit fly, Diptera, Tephritidae, *Anastrepha ludens*.

INTRODUCTION

Extracts of male Mexican fruit flies (*Anastrepha ludens* Loew) elicit a repertoire of behaviors from conspecific virgin females (Robacker and Hart, 1986). Behaviors include attraction to pheromone, stimulation of searching activity, changes in searching strategy, and an increase in female–female agonism. Robacker and Hart (1985b) demonstrated biological activity for several chemicals previously identified from male extract (Esponda-Gaxiola, 1977; Battiste

[1] Diptera: Tephritidae.

et al., 1983; Stokes et al., 1983; Nation, 1983). Robacker and Hart (1985b) showed that (*Z*)-3-nonenol, (*Z*,*Z*)-3,6-nonadienol and (*S*,*S*)-(−)-epianastrephin each elicited weak but significant attraction and/or locomotor arrest in combinations containing the components (*R*,*R*)-(+)-epianastrephin and (*R*,*R*)-(+)-and (*S*,*S*)-(−)-anastrephin, and that combinations containing either alcohol with (*S*,*S*)-(−)-epianastrephin elicited synergistically enhanced activity. However, effects of chemicals on specific behaviors of the behavioral repertoire were not tested.

The purpose of this work was to test components of male extract, singly and in combinations, shown to be important by earlier research (Robacker and Hart, 1985b) for their effects on attraction, searching, agonism, and other behaviors from the behavioral repertoire of virgin female *A. ludens*. This research also addresses the broader question: do pheromone components in multicomponent systems function individually to elicit distinct behaviors or do all components of a blend act as a unit to elicit any and all behaviors of a pheromone-mediated behavioral repertoire?

METHODS AND MATERIALS

General. All flies were from a laboratory culture maintained for at least 50 generations with no wild-fly introductions. Experiments were conducted in the laboratory. Temperatures varied between 20 and 30°C and relative humidity between 40 and 70%. Photoperiod (14 : 10 light–dark) was shifted so that lights came on at 0230 hr and went off at 1630 hr.

Preparation of Chemical Treatments. Chemical treatments per 10 μl of hexane were: (*Z*)-3-nonenol (Z3N), 100 ng; (*Z*,*Z*)-3,6-nonadienol (ZZ36N), 40 ng; (*R*,*R*)-(+)-anastrephin (RRANA), 100 ng; (*S*,*S*)-(−)-anastrephin (SSANA), 100 ng;(*R*,*R*)-(+)-epianastrephin (RREPI), 350 ng; (*S*,*S*)-(−)-epianastrephin (SSEPI), 350 ng; Z3N/SSEPI combination, 100/350 ng; ZZ36N/SSEPI combination, 40/350 ng; the six-chemical combination, 100/40/100/100/350/350 ng; and extract of male *A. ludens* abdomens. These amounts equal 1.0 male equivalent (ME) per chemical (Robacker and Hart, 1985b).

Each chemical was at least 97% free of contamination from the other five chemicals (J.L. Nation, University of Florida, Gainesville; M. Jacobson, USDA-ARS, Beltsville, Maryland; and gas chromatography by author when possible). Male extract was prepared by grinding abdomens of sexually mature, virgin male *A. ludens* in hexane. Extract was filtered through glass wool, concentrated under nitrogen, and stored at −20°C.

Bioassay. The bioassay cage was a simple wind tunnel consisting of an aluminum-framed cage (2.0 m long × 0.7 m wide × 1.3 m high) with aluminum window screening covering the top and all sides. An airflow of about 1 m/

sec was directed through the length of the cage by fans on the upwind and downwind ends. The downwind fan exhausted the chemical-laden air to outdoors. A bank of four fluorescent lights on top of the downwind half of the cage attracted the test insects away from the upwind end when they were not responding to pheromone. A vertically placed aluminum sheet completely divided the upwind end of the cage into two compartments to prevent flies entering one compartment from detecting chemicals in the other. A 1-m-tall, potted, grapefruit tree (*Citrus paradisi* MacFad.) with about 30 leaves occupied the center of each compartment. Canopy diameters were ca. 0.4 m. Twenty filter-paper squares were attached to the undersides of leaves of both trees as in Robacker and Hart (1986). Thus, the treated (T) tree had 10 T leaves and 10 control (C) leaves and the C tree had 20 C leaves.

We conducted one test each day beginning at 1500 hr when flies were sexually active. One ME of one of the chemical treatments was applied to each T leaf and 10 μl of hexane were applied to each C leaf. Fifty sexually mature, virgin females of the same age were then released into the downwind end of the cage about 1.5 m from the tree canopies. Cohort females were used to test each of the 10 treatments within a replication, when possible. Thus female age increased during testing of the 10 treatments. Previous work (Robacker et al., 1985) showed the age-range (9–30 days posteclosion) had little effect on response to pheromone. Behavior observations and bioassay procedures were conducted as in Robacker and Hart (1986) with the following exceptions. Arrivals of flies to trees were monitored for 4 min per tree instead of 2 min during the last arrival-monitoring period of each half test. Also, we did not monitor arrivals to T and C leaves during this time. Instead, we monitored the numbers of within-leaf flights on T and C leaves of the T tree and on C leaves of the C tree for 4 min per tree. A within-leaf flight is a flight which originates and ends on the same leaf. Total observation time (all behaviors combined) following each of the two pheromone applications in each test was 21 min.

We investigated the following aspects of behavior: attraction to the vicinity of test chemicals, leaf visitation rate and searching strategy in the vicinity of the chemicals, attraction directly to chemical point sources, searching strategy after arrival to point sources, and agonistic behavior near and at chemical sources. The methods used to quantify these behaviors were described previously (Robacker and Hart, 1986), except that searching strategy after arrival to point sources was determined from within-leaf flights as well as from time spent by females on point sources.

After each test we cleaned the wind tunnel with acetone and the trees with soap and water. Ten trees were used to test the 10 chemical treatments, with the same tree always used for the same treatment. Further, the same tree served as the C tree in all tests and the same leaves served as T and C leaves. The experiment was conducted in this way to prevent problems from residual chem-

icals on leaves. We kept trees as identical in appearance as possible to minimize tree and leaf effects arising from factors other than those imposed by the treatments. Nine replications of each chemical treatment were conducted.

Statistical Analyses. Data for arrivals to trees (T and C), arrivals to leaves (T leaves, C leaves of T tree, C leaves of C tree), within-tree flights, within-leaf flights, agonistic behavior on trees, agonistic behavior on leaves, fly density on trees, and fly density on leaves were analyzed as separate randomized complete-block analyses of variance (ANOVA). All eight ANOVAs included the 10 chemical treatments and contained nine replications. Analyses of variance comparing trees had 20 treatments (2 tree types $\times$ 10 chemical treatments), and those comparing leaves had 30 treatments (3 leaf types $\times$ 10 chemical treatments). Operations performed on data such as converting to a per-fly basis were done before analyses. Within ANOVAs, means were compared by t tests (LSD). When results for a particular chemical departed from overall data trends, we conducted t tests or ANOVAs using only behavioral data from that chemical. Tendencies for behaviors to vary either with fly density or with other behaviors were measured by regression. Data for time spent by flies on trees and leaves fitted bimodal distributions and were analyzed by chi square (2×2 contingency tables) comparisons of the proportion of flies spending less than 2 min with the proportion that spent greater than 2 min on T and C treatments.

RESULTS AND DISCUSSION

Chemical combinations containing Z3N and/or ZZ36N with SSEPI elicited significantly greater responses ($P < 0.05$) to T than to C locations for the behaviors: arrivals to trees (Table 1); within-tree flights (Table 2); and agonism on trees and leaves (Table 3). These treatments also stimulated greater ($P < 0.05$) fly density on T than on C trees (Table 4). Fly density is a positive function of arrival rate and locomotor arrest. The ZZ36N/SSEPI combination elicted more attraction to trees ($P < 0.05$) (Table 1) and greater fly density on trees ($P < 0.05$) (Table 4) than the Z3N/SSEPI combination, but this pattern did not hold for all behaviors. Male extract and the six-chemical combination did not generally elicit greater behavioral responses than the alcohol/SSEPI combinations. However, extract and the six-chemical combination were the only treatments that consistently elicited significantly greater time spent on T trees than on C trees ($P < 0.01$) and on T leaves than on C leaves ($P < 0.05$) (Table 5). Futhermore, they both stimulated greater fly density on trees ($P < 0.05$) than either of the alcohol/SSEPI combinations (Table 4). Individual chemicals did not elicit behavioral responses greater than controls (blanks) with one exception. The number of arrivals to the ZZ36N T tree was significantly higher ($P < 0.05$) than to the C tree (Table 1) according to a paired t test of the data for

this individual chemical (conducted in addition to the ANOVA shown in the table). Conversely, the amount of agonistic behavior on the RREPI T tree was not significantly greater than on its C tree (Table 3), also according to an additional paired *t* test.

We conducted regressions of within-tree flights per female, within-leaf flights per female, and agonistic behavior per female on fly density and on other behaviors to determine if the tendencies of females to perform these behaviors were related to and perhaps caused by either fly density or to tendencies to perform other behaviors. All regression coefficients calculated were too small to account for the large differences in behavior between T and C locations. For example, the coefficient from the regression of agonistic interactions per female on the number of females on the male-extract T tree was 0.02 ($F = 0.7$).

These results generally agree with the data from the bioassay of all 64 possible combinations of the six chemicals (Robacker and Hart, 1985b). Both experiments showed that individual components had little effect on any of the behaviors. However, in both experiments ZZ36N elicited a weak behavioral

response by itself. The present work shows that ZZ36N attracts virgin females to the vicinity of the chemical source. Combinations containing either Z3N or ZZ36N with SSEPI elicited much stronger responses in both experiments, and combinations of the six components elicited stronger responses than the minimal alcohol/SSEPI treatments. Also, combinations containing ZZ36N outperformed those with Z3N in both experiments.

Robacker and Hart (1986) studied the effects of *A. ludens* male extract on essentially the same behaviors of conspecific females as in the present work. The results of the two experiments were similar, but some differences occurred, possibly due to procedural differences. Three major modifications were: bioassays were conducted in a pheromone-free room; the bioassay cage was used as a wind tunnel; and flight activity ending on leaves was partitioned into arrivals and within-leaf flights.

Conducting the tests in a pheromone-free room apparently increased overall response to pheromone treatments. This is evident in many of the behaviors. For example, compare within-tree flights (per female) on the male-extract T tree in Table 2 (12.5) with the same from Table 1 in Robacker and Hart (1986) (5.6). On average most behavioral responses were two to three times higher in the present work. The increase in pheromone sensitivity may have triggered some undesirable effects not evident in Robacker and Hart (1986). Crowding caused by the greater attractiveness may have caused an overflow of flies from preferred T leaves to C leaves, where they performed behaviors normally associated with T leaves. Also, time spent on T leaves may have been reduced. Although we recorded time spent only for "undisturbed" flies, premature departures due to activity on nearby leaves may have occurred.

Converting the bioassay cage into a wind tunnel was done to better evaluate attraction from a distance. The change was apparently successful as can

be seen by comparing the ratio of arrivals to the male-extract T and C trees in Table 1 (37/9) to the same in Table 1 of Robacker and Hart (1986) (6.2/3.8). The aluminum-sheet partition also may have affected behavior by preventing flies on C trees from perceiving pheromone on T trees. Thus, flies on C trees performed relatively less pheromone-mediated behavior than in Robacker and Hart (1986) in which no partition was placed between T and C trees: Compare the ratio of agonism (per female) on male-extract T and C trees in Table 3 (2.6/0.5) to the same in Table 1 of Robacker and Hart (1986) (0.28/0.088).

Partitioning behavior on leaves into arrivals and within-leaf flights resulted in a different interpretation of attraction behavior than was reported previously. Robacker and Hart (1986) reported that pheromone probably attracts females directly onto T leaves, based on a ratio of arrivals (per female) to T and C leaves of 0.25/0.098 ($P < 0.05$) (Table 1). This conclusion is challenged by the present work in which the ratio was 0.22/0.18 (not significantly different from a ratio of 1) for T and C leaves (Table 1). The discrepancy arose because

[a] Percentages in a horizontal row in the same group (trees or leaves) followed by the same letter are not significantly different from each other at the 5% level by 2 × 2 chi-square contingency tests. Each value is the percentage summed over all observations in all replications. The number of observations is in parenthesis.

[b] Z3N = (*Z*)-3-nonenol; ZZ36N = (*Z*,*Z*)-3,6-nonadienol; RRANA = (R,R)-(+)-anastrephin; SSANA = (*S*,*S*)-(−)-anastrephin; RREPI = (*R*,*R*)-(+)-epianastrephin; SSEPI = (*S*,*S*)-(−)-epianastrephin.

in Robacker and Hart (1986) we recorded all flights ending on a leaf as arrivals to that leaf, whereas in the present work we counted as arrivals only those flights that originated at some place other than the observed leaf. We recorded flights that began and ended on the same leaf as within-leaf flights. Table 2 shows that the ratio of within-leaf flights (per female on leaf of type) on T vs. C leaves for the male-extract T tree was also not significantly different from 1 (12.4/11.2). However, multiplying these values by the number of females on each leaf type and dividing the results by the number of minutes of observation time shows the ratio of within-leaf flights (summed over females) on the T tree is ca. 12/3. The arrival's ratio after similar operations is 2.2/1.7. Adding numerators and denominators yields an arrival ratio, as defined in Robacker and Hart (1986) of 14.2/4.7 or about 3/1. This is similar to the ratio from Robacker and Hart (1986) of 0.25/0.098 or about 2.6/1. Thus, flies behaved similarly in both experiments but behavior partitioning showed that flies did not arrive at higher rates to T than to C leaves. The apparently higher rate in Robacker and Hart

(1986) was probably due to greater numbers of flies performing within-leaf flights on T leaves. This suggests that females are attracted to the vicinity of males by pheromone but are attracted to male-held leaves by other stimuli, possibly by visual and/or acoustical signals from males (Robacker and Hart, 1985a; Sivinski et al., 1984).

Do within-leaf fights really constitute different behavior from arrivals to leaves, or is it just a matter of the experimenter's point of view as to where a fly alights? Assuming the null hypothesis that they represent just two different outcomes of the same behavior, a fly taking off from a leaf should land on a different leaf more often than on the leaf of flight origin, since there are many different leaves available compared to only one that it left. From the above paragraph, the number of arrivals to T and C leaves on the male-extract T tree was ca. 3.9 per minute (2.2 + 1.7) compared to ca. 15 within-leaf flights per minute (12 + 3). Thus, flies performed about four times as many within-leaf flights as arrivals. This contradicts the null hypothesis and demonstrates that within-leaf flights and arrivals to leaves are distinct behaviors. Possibly, females perform arrivals when they are searching for pheromone sources (males), whereas they perform within-leaf flights at or near pheromone sources to increase their visibility to males.

Do females alter their searching strategy at or near pheromone sources by performing within-leaf flights, as suggested in the above scenario? Table 2 shows little difference in within-leaf flights per female on T and C leaves of T trees, with the exception of the Z3N/SSEPI treatment. Reanalysis of the Z3N/SSEPI data by a paired t test found this difference nonsignificant also. Table 2 also shows that more within-leaf flights per female took place on both T and C leaves of the T tree than on C leaves of the C tree ($P < 0.05$) for Z3N/SSEPI, ZZ36N/SSEPI, the six-chemical combination and male extract. These results show that females do alter their searching strategy in the vicinity of pheromone but not on individual leaves (pheromone point sources), at least with respect to within-leaf flights.

Data for time spent by females on various locations were bimodally distributed, suggesting that at least two different behaviors were involved. Most flies spent either less than 1 min or more than 3 min at any location. Flies spending less than 1 min were probably engaged in searching activity. This could include searching for food as well as mates and searching by visual and acoustical as well as by olfactory modes. Some flies spending greater amounts of time were preening and possibly resting. This was especially evident on C leaves of the C tree where females often exhibited these behaviors for a half hour or more. Finally, some females spent more time where they perceived pheromone, as reported earlier (male extract and six-chemical combination). We interpret this as an altered searching strategy in response to pheromone (Robacker and Hart, 1986), but not necessarily locomotor arrest since time spent

included time that females performed within-tree and/or within leaf flights. Unfortunately, data from behaviors other than response to pheromone diluted the searching strategy alteration and probably increased variability. This variability is evident as large differences in responses to C locations from one treatment to another (Table 5). Because of the different behaviors involved in "time-spent" data, differences within columns of Table 5 (among chemical treatments) could not be compared meaningfully. Thus, only comparisons between T and C locations within a chemical-treatment test were conducted.

Pheromone Component Functions. A major aim of this research was to evaluate two models of pheromone component function in multicomponent systems using the *A. ludens* pheromone as a test system. One model, proposed by Jacobson et al. (1970), is that each component functions to elicit a different behavior from the pheromone-mediated behavior repertoire. Cases that fit this model have been reported (Baker et al., 1976; Nakamura, 1980; Linn and Gaston, 1981). The alternate model is that pheromone components function as a unit to elicit each and all behaviors (Baker and Cardé, 1979).

Our results fit the unit-function model. For all behaviors, individual pheromone components stimulated little or no response. The only exception was that ZZ36N elicited weak attraction (Table 1, $P < 0.05$ by a paired t test). Because the effect was weak compared to that elicited by blends such as ZZ36N/SSEPI, this does not fit the model in which individual components elicit specific behaviors out of a repertoire of behaviors. We interpret the effect as partial stimulation of behavior, complete stimulation requiring all critical components.

Further evidence for the "unit" model is that pheromone blends elicited most behaviors either greatly or not at all. Also, adding more components to the blend did not generally elicit additional behaviors, just higher levels of the same behaviors. One exception was that the two alcohol/SSEPI combinations did not stimulate females to spend more time on T than C locations, whereas the six-chemical combination and male extract did (Table 5). Fly density data in Table 4 also reflect this behavior, since fly density depends in part on time spent. Since no individual components increased time spent, one possible explanation is that several, perhaps all, components are necessary to elicit locomotor arrest, which translates into greater time spent. This result is consistent with the "unit-function" model, although it suggests that some behaviors may require the unit to be more complete than others. These conclusions do not rule out the possibility that other as yet unknown pheromone-mediated behaviors of this species may be controlled by the individual components studied here or by other unknown components.

Acknowledgments—I thank Bianca Chapa and Reyes Garcia for technical assistance; Sammy Ingle, Ruben Garcia, and Julia Olivarez for insects; and J.L. Nation (University of Florida, Gainesville) and M. Jacobson (USDA-ARS, Beltsville, Maryland) for laboratory-synthesized pheromones. I also thank W.G. Hart for support.

(Received July 29, 1985; accepted September 30, 1987)

Abstract—The morphology and chemical content analysis of Hagen's glands of the braconid wasps *Biosteres longicaudatus*, *B. tryoni*, and *B. arisanus* were shown to be useful taxonomic markers. *B. longicaudatus* glands contain two components tentatively identified as (3aα,5β,6aα)-5-butyltetrahydrofuro[3,2-b]furan-2(3H)-one and a corresponding 5-hexyl derivative, while *B. tryoni* glands contained dodecan-4-olide and *B. arisanus* glands contained ethyl octanoate, ethyl Z-4-octenoate, and octan-4-olide.

Key Words—*Biosteres longicaudatus*, *Biosteries tryoni*, *Biosteres arisanus*, Hymenoptera, Braconidae, Hagen's gland, ethyl octanoate, ethyl octenoate, octan-4-olide, dodecan-4-olide, (3aα,5β,6aα)-5-butyltetrahydrofuro[3,2-b]furan-2(3H)-one, (3aα,5β,6aα)-5-hexyltetrahydrofuro[3,2-b]furan-2(3H)-one.

INTRODUCTION

Glands originating near the tip of the abdomen in males of various opiine braconid parasitoids have been implicated in the production of fragrant substances (Hagen, 1953; Buckingham, 1968, 1975). Both Hagen (1953) and Buckingham (1968) discussed these glands in connection with mating or courtship behavior but were unwilling to attribute a function to the gland because of insufficient data. Haramoto (1957) suggested a possible role in protection against natural

[1]Approved as TAES 20830 by the Director of the Texas Agricultural Experiment Station.

0098-0331/88/0900-1727$06.00/0

enemies, but presented no quantitative data. Buckingham (1975) later presented evidence for the role of gland secretions in defense against predators in one opiine species, *Opius concolor siculus* Monastero, and one alysiine braconid species, *Alysia alticola* (Ashmead). He also noted that the glands did not originate on the true pygidium in some species and suggested that they be called Hagen's glands rather than pygidial glands. As far as we can determine, no other purpose for these glandular secretions has been brought forward.

In the work presented here, we describe the glands and identify volatile chemicals found in them for three species of opiine Braconidae: *Biosteres longicaudatus* Ashmead, *B. arisanus* (Sonan), and *B. tryoni* (Cameron). *B. arisanus* has recently been treated as a senior synonym of *B. oophilus* (Fullaway) (Wharton and Gilstrap, 1983).

METHODS AND MATERIALS

Parasitoid wasps examined during this study all belong to the braconid subfamily Opiinae. They include the three *Biosteres* species listed above, and two *Opius* species, *O. incisi* Silvestri and *O. fletcheri* Silvestri. All insects were laboratory reared in Honolulu, Hawaii, from fruit samples originally collected on the island of Maui. Adult parasitoids were shipped to College Station, Texas, soon after emergence from their tephritid hosts *Ceratitis capitata* (Wiedemann), *Dacus cucurbitae* (Coquillett), and *Dacus dorsalis* Hendel.

Glands were dissected from the males immediately after their arrival in Texas. Glands were removed in a small drop of distilled water, blotted, placed in vials containing a minimum amount of glass-distilled diethyl ether, and crushed prior to analysis. GC analysis was performed on a Tracor 550 FID instrument equipped with a 105–0 : 1 variable ratio all-glass splitter system and a Brownlee-Silverstein thermal gradient collector (Brownlee and Silverstein, 1968). A 1.83-m × 4-mm-ID glass column packed with 3% OV-101 on Chromosorb 750 100–125 mesh was used, with an N_2 flow rate of 60 ml/min, temperature programmed from 80 to 270°C at 10°/min. Fractions were collected in 1.3-mm-OD glass capillary tubes cooled by liquid nitrogen and were flame sealed until used. Comparisons with standards and analyses of purity were performed on a Varian 3700 GC equipped with a 25-m × 0.33-mm-ID vitreous silica BP1 capillary column with helium carrier gas at 15 psig head pressure, temperature programmed at 60°C for 1 min, then to 220°C at 10°/min, using flame ionization detection. Mass spectral data were obtained on Hewlett Packard 5993A and Finnigan 1020 OWA quadrupole instruments in electron impact mode. The former was equipped with a 1.83-m × 2-mm-ID OV-1 on Supelcoport 100–125 mesh column, He flow rate 30 ml/min, temperature programmed from 120 to 240°C at 10°C min, the latter with a 25-m × 0.33-mm-

ID vitreous silica BP1 capillary column, He head pressure 15 psig, operated at 60°C for 1 min, then temperature programmed to 220°C at 10°/min. NMR spectra were recorded using $CDCl_3$ solvent on a JEOL FX 90Q Fourier transform instrument or using acetone d_6 solvent on a Bruker 500 Fourier transform instrument. NMR shift and coupling assignments for component 6 were made using the fixed decimal PANIC® algorithm on the Bruker instrument. Known compounds for comparison were obtained as gifts from International Flavors and Fragrances or were purchased from Aldrich Chemical Company.

RESULTS AND DISCUSSION

Males of all three *Biosteres* species exuded strong, pleasant fragrances. As first noted by Hagen (1953), there were interspecific differences in the odors produced. Gland extracts exhibited these same aromas, indicating that the glands were their sources. Relative shapes and sizes of the male Hagen's glands for these species are shown in Figure 1. They compare favorably with illustrations of *B. arisanus* (oophilus) and *B. longicaudatus* glands given by Buckingham (1968, 1975). Glands of *O. incisi* and *O. fletcheri,* which were much smaller than those of *Biosteres*, did not produce a detectable aroma, and did not produce peaks on GC analysis.

The gland contents of *B. arisanus* (Table 1) were studied first due to their

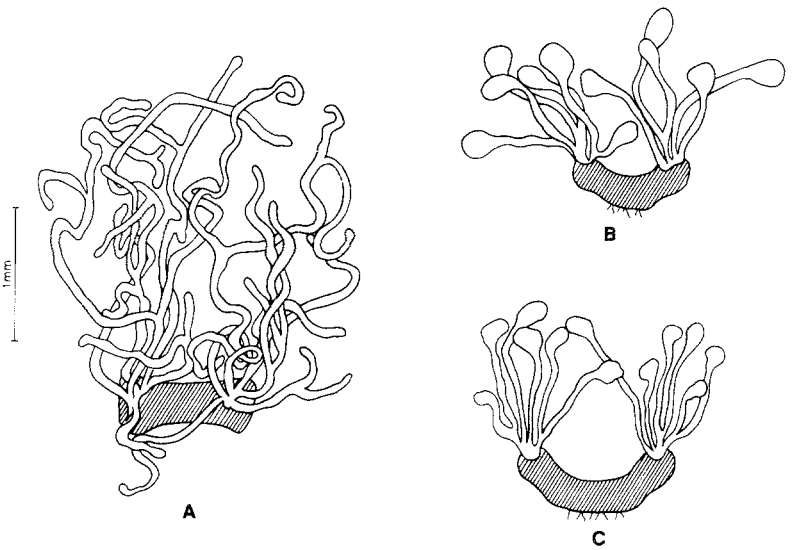

FIG. 1. Hagen's glands of *Biosteres* species showing placement on internal surface of 9th tergum. (A) *B. arisanus*, (B) *B. tryoni*, (C) *B. longicaudatus*.

TABLE 1. GC ANALYSIS OF GLAND VOLATILES[a]

Species	Component	RT	Relative percentage

fragrance, which was highly reminiscent of fresh coconut. GC analysis indicated the presence of two minor components (**1** and **2**) and one major component (**3**) in the gland. Component **3** had the characteristic coconut aroma. The mass spectrum of component **3** showed a base peak at *m/z* 85, characteristic of a γ-lactone (Honkanen et al., 1965). A parent peak at *m/z* 142 indicated a possible molecular formula of $C_8H_{14}O_2$. NMR analysis at 90 MHz showed a 3H distorted triplet at δ0.9, a complex broad 10H multiplet at δ1.2–2.4 and a 1H multiplet at δ4.36, characteristic of an oxygen substituted methine. The spectrum was identical to that of γ-octanoic lactone (octan-4-olide) purchased from Aldrich Chemical Co. GC and MS data also were identical. The structure is therefore as shown in Figure 2, component **3**. This compound is, in fact, a component of coconut oil and is used as artificial coconut flavoring.

The minor components **1** and **2** gave parent MS peaks at *m/z* 170 and 172, indicating possible molecular formulas of $C_{10}H_{18}O_2$ and $C_{10}H_{20}O_2$, respectively. Component **2** exhibited the characteristic *m/z* 88 and 101 fragments of a saturated ethyl ester. This assignment was confirmed by NMR analysis, which showed a 3H triplet at δ1.28 coupled to a 2H quartet at δ4.15. The single 3H distorted triplet at δ0.92 combined with the broad multiplet centered at δ1.3 indicated no branching. Component **2** was therefore ethyl octanoate (Figure 2).

The NMR spectrum of component **1** showed a δ1.28 3H triplet and a δ4.15 2H quartet, indicating that it too was an ethyl ester. The molecular formula indicated one unit of unsaturation in an eight-carbon acid unit, which was also indicated by the presence of two broad 1H doublets at δ5.32 and 5.42, with a 4Hz *cis* coupling constant. One of these was coupled to a broad δ2.05 2H triplet which in turn was coupled to a δ2.33 2H triplet, the methylene next to the carbonyl, indicating that the double bond is in the 4 position. A single methyl triplet at δ0.98 indicated that no branching occurred. The compound is therefore ethyl (*Z*)-4-octenoate (component **1**, Figure 2). NMR and mass spectra are in

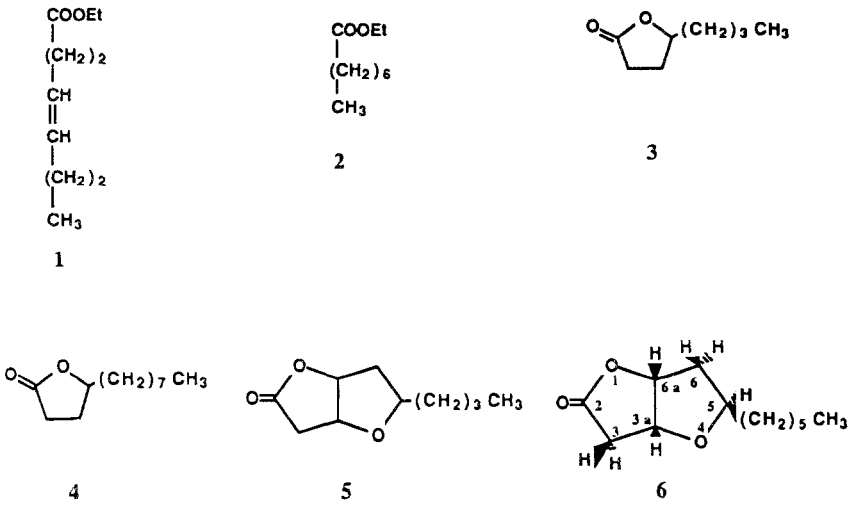

FIG. 2. Volatile chemicals identified from *Biosteres* spp. Hagen's gland extracts.

good agreement with those of Naf and Degen (1971). Naf-Muller and Willhalm (1971) identified this compound as a component of pineapple essential oil.

GC analysis of *B. tryoni* gland contents showed that it consisted of a single component of greater than 99% purity (Table 1). Its sweet, lingering fragrance is very similar to that of the blacktail deer lactone (*Z*)-6-dodecen-4-olide (Ravid et al., 1978). The mass spectrum again showed a base peak at *m/z* 85 characteristic of a γ-lactone (Honkanen et al., 1965), but the parent peak was at *m/z* 198, indicating a molecular formula of $C_{12}H_{22}O_2$. The NMR spectrum was almost identical to that of γ-decanolactone purchased from Aldrich Chemical Co., the only difference being that integration of the broad singlet at δ1.3 indicated the presence of two more methylenes in the side chain. The compound is therefore dodecan-4-olide (component **4**, Figure 2).

B. longicaudatus gland contents presented a more difficult analytical problem. The mass spectra of the two components present (Table 2) showed parent peaks at *m/z* 184 and 212 (major compound), respectively, indicating possible molecular formulas of $C_{10}H_{16}O_3$ and $C_{12}H_{20}O_3$. Base peaks in both instances were at *m/z* 127, and the spectra were virtually identical in the *m/z* 35–127 range, indicating the presence of common core fragments of possible molecular formula $C_6H_7O_3$. [^{1}H]NMR at 90 MHz ($CDCl_3$) showed complex patterns, the spectra of the two compounds differing only in the broad multiplet at δ1.0–1.6. Distorted triplets in the spectra of both compounds (**5**, δ0.91, **6**, δ0.90) with broad multiplets at δ1.0–1.6 indicated straight hydrocarbon side chains.

The spectrum of the major component was taken at 500 MHz (acetone d_6,

TABLE 2. MASS SPECTRA.

Figure 3, Table 3). From this spectrum and the mass spectrum, structure **6** is proposed for the major component based on the following analysis. Three 1H multiplets at δ4.01 (complex), 4.80 (d of d), and 5.16 (apparent triplet) indicated the presence of three O—C—H fragments. Decoupling experiments showed that the two lower field signals were coupled to each other (4.7 Hz) but not to the signal at δ4.01. The peak at δ4.80 was also coupled to an AB system at δ2.42 and 2.82 with couplings of <1 Hz and 6.4 Hz, respectively. The strong coupling of the AB hydrogens to each other (18.4 Hz) indicated these were geminal methylene protons with a strong electronegative influence. The peak at δ4.80 was thus assigned to the methine at C-3a and the peaks at δ2.42 and 2.82 are assigned to C-3β and C-3α, respectively. The proton at δ5.16 shows a coupling (5.1 Hz) to a multiplet at δ1.71. This peak shows a geminal coupling (J = 13.7 Hz) to the signal at δ2.28. These peaks are therefore due

to the C-6 methylene protons (C-6β, δ2.28; C-6α, δ1.71). The methine proton at δ4.01 is coupled to both methylene protons on C-6 ($J_{C\text{-}6\alpha}$ = 10.1 Hz; $J_{C\text{-}6\beta}$ = 4.9 Hz) and to the first two side-chain methylene protons, broad multiplets at δ1.48 and δ1.57. Kojima and Kato (1979) studied 5-*t*-butyltetrahydrofuro[2,3-b]furan-2(3H)-one), a compound derived from an antifeedent for *Spodoptera litura* F., which is useful as an NMR model. Their measured geminal couplings of 17.3 and 13.0 Hz and *cis* ring juncture methine coupling of 4.9 Hz are in excellent agreement with those of component **6**.

The configuration of the hydrogen at C-5 was determined using the Karplus equation (Karplus, 1959) and dihedral angles were calculated using computer simulation. For H_5 in the β position, couplings to $H_{6\alpha}$ and $H_{6\beta}$ would be expected to be 6.0 and -0.2 Hz, while with H_5 in the α position, the couplings are calculated to be 7.9 and 6.3 Hz. The measured values of 10.1 and 4.9 Hz are more nearly those calculated for $H_{5\alpha}$. All other couplings calculated were within 3 Hz of the measured values. The [^{13}C]NMR spectrum showed a lactone carbonyl at 175.8 and three H—C—O linkage carbons at δ84.8, 78.1, and 77.2. Component **5** differs from component **6** only in having two fewer carbons in the side chain.

Chemically, the major gland component of *B. tryoni* appears to be more closely related to that of *B. arisanus* than to those of *B. longicaudatus*, but it must be noted that removal of the oxygen bridge in the *B. longicaudatus* furan would produce the *B. tryoni* lactone. *Biosteres tryoni* and *B. longicaudatus* are closely related and are members of a distinct Indo-Pacific species group (the tryoni complex) characterized by the apomorphic possession of a sinuate ovipositor (Fullaway, 1951; Wharton and Gilstrap, 1983). In addition, these two species share wing venation patterns, and propodeal, thoracic, frons, and vertex sculpture patterns that are distinctly different from *B. arisanus* and other members of the persulcatus complex to which *B. arisanus* belongs. Although both *B. arisanus* and *B. longicaudatus* have the second abdominal tergum longitudinally striate, the striations are different (Wharton and Gilstrap, 1983), and probably not homologous. Thus, our preliminary results suggest that gland chemistry may not be useful for studying relationships at higher taxonomic levels. Gland chemistry is sufficiently distinct to discern species, however, and may be useful in solving certain speciation problems. For example, further work on the chemistry of glands of *B. longicaudatus* collected from populations throughout its natural range should help to clarify the status of this species. A number of varieties and species have been described (Fullaway, 1953; Fischer, 1966, 1971), all of which have been treated as synonyms of *B. longicaudatus* (Wharton and Marsh, 1978; Wharton and Gilstrap, 1983).

As suggested by Buckingham (1975), gland morphology may also be useful for elucidating higher taxonomic relationships. *Opius incisi* and the closely related *O. fletcheri* have much smaller glands, with different morphological fea-

tures (Buckingham, 1975, Figure 38), than the glands discussed here. Similarly, the Indo-Pacific species of the tryoni and persulcatus complexes, all of which attack fruit-infesting tephritids, have distinctly different glands from *B. carbonarius* and related species (Buckingham, 1974), which attack leaf-mining Anthomyiidae. Host and gland morphology differences are supported by a number of external morphological differences (e.g., Fischer, 1977), suggesting that these two groups should probably be treated as different genera.

Buckingham (1975) concludes that the primary and possibly sole function of Hagen's glands is defensive. He based his work largely on experiments with *O. concolor siculus*, which has glands similar to *O. incisi* and *O. fletcheri*. We believe that differences in gland morphology and chemistry of species in the present study suggest other functions, which may either be in addition to, or to the exclusion of, defense. While gland secretions of *O. concolor* and related species may be primarily for defense, those of the species treated herein may function during mating or courtship.

Acknowledgments—This study could not have been done without the assistance of Mr. T.T.Y. Wong, USDA/ARS, Honolulu, Hawaii, who kindly supplied the opiines from his laboratory. We would also like to thank Drs. Ian Scott and Paul Fagerness of the Center of Biological NMR at Texas A&M University for help in obtaining and interpreting 500-MHz NMR spectra, and International Flavors and Fragrances, Inc. for the gift of chemical standards.

(Received June 23, 1987; accepted October 1, 1987)

Abstract—The total amounts of, and proportions among, components of the aggregation pheromone produced by *Ips typographus* were found to vary considerably among individuals excised from attacks on standing spruce trees. Chemical analyses of 392 individual male beetles were made by GC-MS. Both unmated and mated males had log-normal frequency distributions in their content of the pheromone components 2-methyl-3-buten-2-ol (MB) and *cis*-verbenol (cV), since a large fraction of males had a low content. The amount of MB in male hindguts varied independently of cV and the other oxygenated monoterpenes, while the amount of cV covaried with the other pinene alcohols and showed a variation between beetles from different spruce trees. Mated males had, on average, lower amounts of MB than unmated, while the average content of cV in mated males varied with the resin content of their host trees. Ipsdienol and ipsenol were only found in mated males, but in less than 40% and 10%, respectively, of these mated males. Even-aged males exposed to α-pinene in the laboratory showed slightly less variation in the amounts of verbenols, and the variations in ratio between cV and tV were similar to those among males attacking the same spruce tree.

Key Words—*Ips typographus*, Coleoptera, Scolytidae, bark beetle, individual variation, 2-methyl-3-buten-2-ol, *cis*-verbenol, *trans*-verbenol, ipsdienol, ipsenol, α-pinene, biosynthesis, principal component analysis, aggregation pheromone.

INTRODUCTION

Until recently bark beetle pheromone systems have been seen primarily from the point of view of the group or the species. However, after Alcock's seminal paper (1982), the evolutionary background of aggregation pheromones is largely seen in a perspective of individual selection (Birgersson et al., 1984; Borden et al., 1986; Schlyter and Birgersson, 1989). An understanding of the importance of individual selection has, together with developments of chemical analysis technology, opened the field of indvidual variation for ecological, physiological, and evolutionary lines of study.

The first study on individual variation in content of pheromone components in bark beetles was done on naturally attacking males of *Ips typographus* L. (Birgersson et al., 1984). Additional studies have been done in laboratory experiments with the North American species *Dendroctonus ponderosae* Hopkins and *Ips pini* (Say) (Slessor et al., 1985; Borden et al., 1986; Hunt et al., 1986). Typical for all these quantitative studies are the large variances among individuals; many are "low producers," while a few have large amounts of pheromone.

What is the reason for these very skewed distributions, and which factors influence it? Apart from the quantification methods, ecological and physiological factors in the attacking bark beetles and in the host trees can be important for the beetles' production of semiochemicals. In the study by Birgersson et al. (1984), the individually analyzed males were all unmated and collected from a spruce tree that had been characterized as having weak resistance to attack. This could have been an atypical tree, due to its low resin content. One question is whether qualitative and quantitative differences in host resistance have an influence on the individual variation between the attacking beetles. Moreover, will beetles from resistant trees include more "high producers" and thus show less skewed distribution in pheromone yield than did the males (Birgersson et al., 1984) from a nonresistant tree? In laboratory experiments with the North American species *Ips paraconfusus* (Lanier), Byers (1981) showed that the production of *cis*- and *trans*-verbenol, and myrtenol increased with the amount of the host precursor, α-pinene, to which they were exposed.

Part of the indvidual variation could also depend on the genotype, which is the only part of the variation subject to natural selection and hence to adaptive evolutionary change. Such genotypically based variation would be indicated by variation in homogeneous groups where variation in external factors (methods of analysis and ecological and physiological factors) are minimal. A large variation in such groups would confirm the view that beetles may differentially employ "strategies" as pioneers, hitchers, or sneakers (Borden et al., 1986; Schlyter and Birgersson, 1989) or that different population levels may give different, alternating selection pressures.

The phenotypic variation in amounts and proportions of the pheromone components is here studied from the following aspects: (1) in relation to tree resin production and composition among trees; (2) in relation to spatial variation of attack within a tree; and (3) in relation to temporal variation between the attack phases of the bark beetles.

We will focus on the pheromone components that are of known behavioral significance and thus are ecologically and evolutionarily relevant: 2-methyl-3--buten-2-ol and *cis*-verbenol, which are essential for attraction of *I. typographus* in the field (Schlyter et al., 1987a), and ipsdienol, ipsenol, and verbenone, which are known to modify the beetles' attraction to methylbutenol and *cis* verbenol (Bakke, 1981; Schlyter et al., 1987b)

To elucidate the nature and reasons for variation in pheromone components, we have quantified the content of volatiles in individually analyzed hindguts from unmated and mated males of the spruce bark beetle, *I. typographus*, in well-defined attack phases originating from six spruce trees with known composition of monoterpene hydrocarbons and different levels of resin production. The naturally attacking males are also compared with males exposed to α-pinene in the laboratory.

METHODS AND MATERIALS

Biological Material

Males from Naturally Infested Trees. Males of *I. typographus* were excised from the bark of four standing (baited) and two windthrown (unbaited) trees of Norway spruce [*Picea abies* (L.) Karst.], north of Torsby, province of Värmland, central Sweden, during the main swarming period June 1–15, 1982 (Table 1). In order to ensure adequate attack, the trees were baited with the commercial attractant for *I. typographus*, Ipslure (Borregaard a/s, Norway). Males from two attack phases (as defined by Birgersson et al., 1984) were collected: phase 3, unmated males with complete nuptial chambers; and phase 6, mated males joined by one or two females, in 2- to 4-cm-long egg galleries (see Figure 5). The beetles were immediately transferred to a cooling box and within 1 hr to a thermos with liquid nitrogen as described by Birgersson et al. (1984).

Fifteen to 20 samples (2 × 3 × 40 mm) of fresh phloem (attacked and brown-stained phloem excluded), evenly distributed over the part of the bole where beetles were collected, were taken from each tree. Samples from each spruce tree were pooled before extraction. The samples contained mainly the phloem and small amounts of adjacent cambium and cork layers, i.e., the layers of bark contacted by the beetles.

Laboratory-Exposed Males. Emerging male brood adults from the 11th generation of laboratory-reared bark beetles, originating from Lardal, southern

Norway (Anderbrant et al., 1985), were separated from the females by their lower bristle density on the pronotum (Schlyter and Cederholm, 1981). The males were initially divided into two groups: (1) one group with 50 males was kept at +4°C and 90–100% relative humidity in a refrigerator after emergence; and (2) the second group, with about 100 males, was given the possibility for flight exercise for 24 hr at +25°C, 95% relative humidity, and 10,000 lux (light : dark = 20 : 4), and then tested in a Y-tube olfactometer (Schlyter and Löfqvist, 1986) at +24°C and 70% relative humidity for 2 hr. Approximately 50% of the males were attracted to a synthetic source of pheromone (5 mg/day of 2-methyl-3-buten-2-ol and 0.1 mg/day of *cis*-verbenol released) as they walked up the Y-tube and were collected at the end of the Y-tube arms (Schlyter and Löfqvist, 1986). The Y-tube tested group of males was, accordingly, divided into responding and not responding groups (2A and 2B, respectively), which were kept dark and cool for 4 hr before α-pinene exposure.

The three groups (1, 2A, and 2B) were exposed simultaneously to α-pinene in separate Petri dishes (ID 9 cm) with moistened filter paper (100% relative humidity at +22°C and 6000 lux for 18 hr). The monoterpene hydrocarbons, (+)-(1*R*, 5*R*)-α-pinene and (−)-(1*S*, 5*S*)-α-pinene (>99%, Fluka, purum) were released from two separate 10-μl glass capillaries attached to the top inside of each Petri dish. Following exposure, release rate was estimated by the amount

of liquid remaining in each capillary. The exposed beetles were kept in liquid nitrogen until dissection and chemical analyses.

Chemical Analyses

The beetle hindguts were dissected (with penis and dorsal abdominal tergite fragments removed) and frozen to the wall of a sharply coned dissection vial (Reacti-Vial, Pierce) chilled on dry ice. Ten microliters of pentane, with an internal standard of 10 ng/μl of heptyl acetate (C_7Ac), was added, and the gut was crushed with a glass rod and left for 10 min at room temperature for extraction. The extract was concentrated, and about 3 μl was injected into a Finnigan 4021 gas chromatograph–mass spectrometer (GC-MS). A 25 m fused silica column, ID 0.20 mm, coated with OV-351 (Supelco, d_f = 0.38 μm, HETP = 0.26 mm, $k'_{C_8\text{-ol}}$ = 4.4) was used in the analyses of the field-collected beetles. The males exposed to α-pinene in the laboratory were analyzed with a 25 m fused silica column, ID 0.15 mm, coated with Superox FA (RSL, d_f = 0.26 μm, HETP = 0.17 mm, $k'_{C_8\text{-ol}}$ = 7.8). Both columns were made at the Department of Chemical Ecology, Göteborg, as described in Lanne et al. (1987), and the temperature program used was 60°C for 4 min, followed by an increase of 8°C per minute to 200°C, and finally isothermal for 7 min. Helium was used as carrier gas (Q = 29 cm/sec) for both columns.

Quantification was done using the extracted ion current profiles (EICP) on characteristic and prominent ions of each substance, relative to the 100 ng of C_7Ac added (Birgersson et al., 1984). To assure the accuracy and precision of the quantifications, each day of analysis was begun with a run of one of the concentrations in the dilution series: 0.1, 0.3, 1.0, 3.0, . . ., 3000, 10,000 ng/3.0 μl plus the internal standard, 100 ng of C_7Ac. The dilution series was made from a stock solution, containing all major compounds found in male hindgut extracts (Birgersson et al., 1984): 2-methyl-3-buten-2-ol (MB), ipsenol (Ie), *cis*-verbenol (cV), ipsdienol (Id), *trans*-verbenol (tV), myrtenol (Mt), *trans*-myrtanol (tM), and 2-phenylethanol (PE), plus verbenone (Vn), in equal amounts. The logarithmic standard curves obtained were essentially linear (r = 0.98–1.00) in the interval from 10^{-1} to 10^4 ng/injection, allowing a conservative estimate of the limit of detection (LOD) as <1 ng/individual gut and of the limit of quantification (LOQ) as <5 ng/individual (Anonymous, 1980). However, using EICP, LOD was better than 0.1 ng and LOQ was 1.0 ng/injection. The dissected beetles were frozen, and dry weight (60°C, 24 hr) and fat content (percent extractable by petroleum ether) were estimated, as described in Anderbrant et al. (1985).

The phloem samples were cut up into millimeter-sized pieces and extracted with 2 ml of pentane (Fluka, p.a.) for 30 min in an ultrasonic cleaning bath.

The extracts were analyzed for the contents of monoterpene hydrocarbons with a Hewlett-Packard 5830A GC. A 50-m glass capillary column, ID 0.32 mm, coated at the Department of Chemical Ecology, Göteborg, as described in Lanne et al. (1987), with Carbowax 40 M (Chrompack, $d_f = 0.66$ μm, HETP = 0.35, $k'_{C_8\text{-ol}} = 6.2$,) was used. The temperature program used was 60°C for 5 min, followed by an increase of 5°C/min for 20 min. Nitrogen was used as carrier gas ($Q = 20$ cm/s). The monoterpene content is expressed in the results as arbitrary integrator units per gram of dried phloem (80°C, 5 hr). For the enantiomeric analyses of α-pinene compare Lindström et al. (1988).

Statistics

The frequency distributions for most of he variables (amounts of hindgut volatiles and percent fat) showed significant skewness and kurtosis. Since ordinary statistics (such as ANOVA, MANOVA, regressions, and correlations) were insufficient to investigate the patterns of variation and covariation among the variables, principal components analysis (PCA) was used. The method employed was SIMCA (soft independent modelling of class analogies), as developed by Wold et al. (1984), which facilitates an analysis of a multivariate data matrix. PCA class models were developed by using 10 individuals from each host tree in attack phase 3. The males were randomly selected, and all or a subset of the variables were used. This method also enabled us to provide an independent check of the "host-tree model," by adding a sample of individuals that had not been used to build the model. The SIMCA method was also used to model phase-3 and phase-6 males from the same tree and to study the separation between the attack phases based on all variables.

The transformation log [amount + 1] was used in both ANOVA, were normality is an essential assumption (Sokal and Rohlf, 1981), and in SIMCA, where log transformation is recommended for GC data (E. Johansson, personal communication).

RESULTS

Naturally Attacking Males

Overall Variation Patterns. In total, 392 male bark beetles, collected during their attack on Norway spruce, were analyzed individually for their content of nine volatiles, using extracted ion current profiles (EICP). The males, all together or separated by attack phase or host tree, showed variation that ranged over three orders of magnitude for most of these compounds (Figures 1 and 2). Representative gas chromatograms (Figure 1) illustrate that the ratios between cV and tV appeared constant in males collected from the same spruce tree,

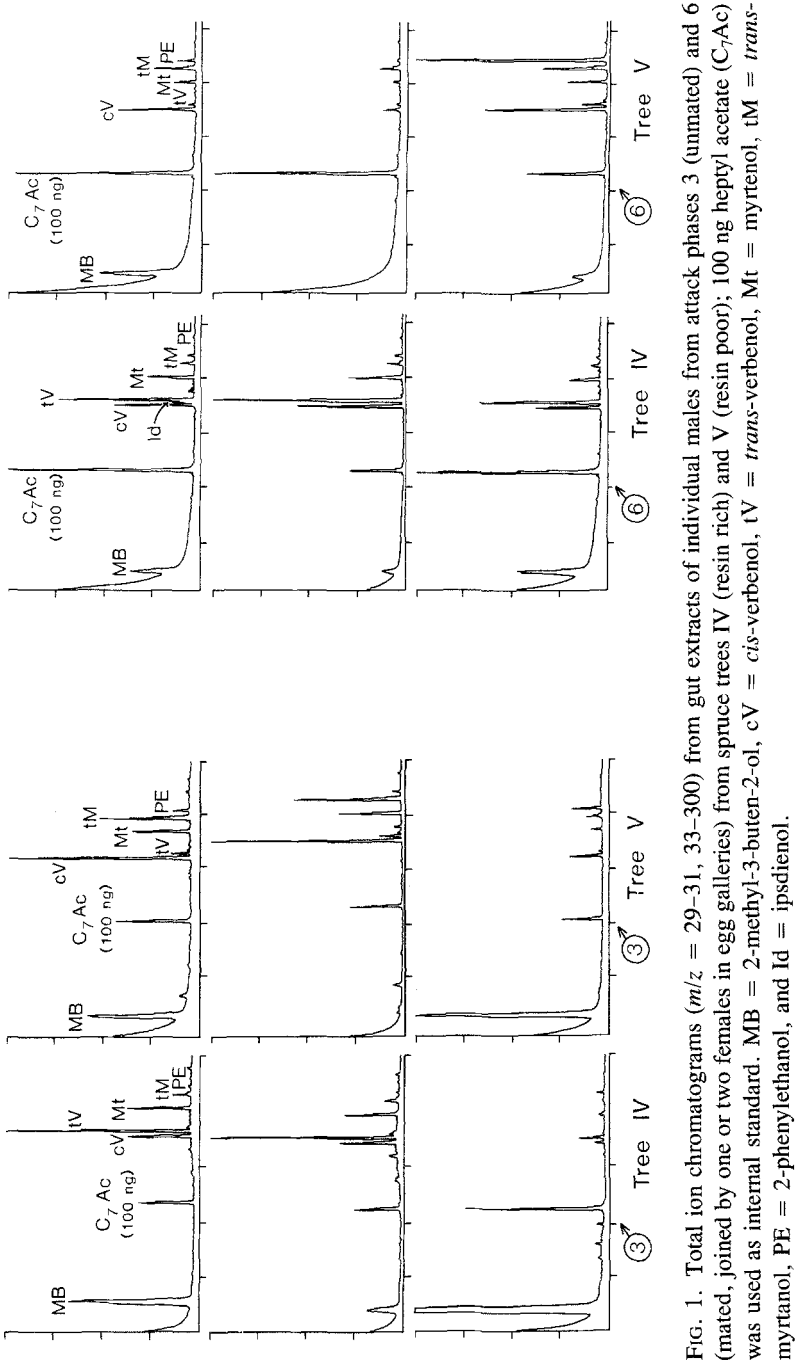

FIG. 1. Total ion chromatograms (m/z = 29–31, 33–300) from gut extracts of individual males from attack phases 3 (unmated) and 6 (mated, joined by one or two females in egg galleries) from spruce trees IV (resin rich) and V (resin poor); 100 ng heptyl acetate (C_7Ac) was used as internal standard. MB = 2-methyl-3-buten-2-ol, cV = *cis*-verbenol, tV = *trans*-verbenol, Mt = myrtenol, tM = *trans*-myrtanol, PE = 2-phenylethanol, and Id = ipsdienol.

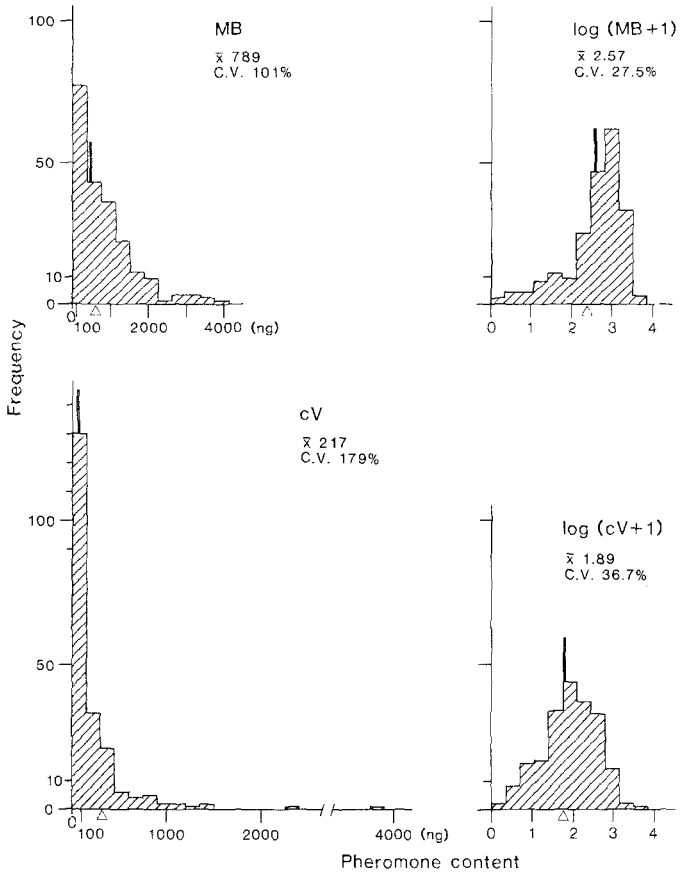

FIG. 2. Frequency histograms of hindgut content in males from attack phase 3 (unmated) from all trees (N = 211) of 2-methyl-3-buten-2-ol, and *cis*-verbenol, untransformed and transformed by log [absolute amount + 1]. Triangles indicate the arithmetic means and vertical lines the medians.

while MB seemed to vary independently of the monoterpene alcohols (cV, tV, Mt, tM, Id, and Ie) and PE.

Many indviduals had low amounts of some or all compounds. However, the sensitivity of the GC-MS method appeared to be sufficient as very few males (< 1% for MB and cV) had amounts below LOD, and less than 3% and 5% for MB and cV, respectively, had amounts too low for a reliable quantification (LOQ).

The large quantitative variation and the high number of individuals with low amounts resulted in very skewed and peaked distributions of both MB and cV, especially in phase-3 males (see Figure 2 and Table 2). This is also indicated by the means being much larger than the medians. A simple logarithmic

[a] Significant departure from normality: $*P < 5\%$, $**P < 1\%$, $***P < 0.1\%$.

transformation, log [amount + 1], gave almost normal distribution of MB and cV with medians very close to the means, but with a left-hand skewness remaining in MB (Figure 2), especially after partition of males for attack phases and host trees. The mean dry weight of unmated males (phase 3) was lower than that for mated males (phase 6) ($P < 0.05$, t test). However, the weight variation for individuals from different trees was small and its distribution was close to normal (Tables 2 and 3). The MB content was weakly correlated with weight ($r = 0.18$, $N = 200$, $P < 0.01$, Spearman rank correlation), but cV content was not ($P > 0.10$). The amounts of MB and cV showed no consistent difference among beetles from the same tree sampled in the morning and in the afternoon or in subsequent days ($P > 0.10$, ANOVA).

Verbenone was never found in amounts exceeding 1 ng in any hindgut extract and in most cases it was below LOD (<0.1 ng, EICP).

Variation among Males from Different Spruce Trees. The ratio between the pinene alcohols (i.e., cV, tV, Mt, tM) was almost constant in the beetles attacking the same spruce tree, independent of absolute amounts of the compounds and of whether the males were mated or not (Figure 3). When ANOVA was used on the total material, the differences among the males from different host trees seemed to be significant for the absolute amounts of MB and cV. However, as many of the amounts of volatiles, after separation of the material by host trees, had heterogeneous variances ($P < 0.05$, Cochrans C and Barlett box tests), we also used principal component analysis (SIMCA) to study the "between tree variation" among males in phase 3. Discrimination among males from different spruce trees based on all variables (i.e., the amounts of MB, cV, tV, Mt, tM, PE, Id, and Ie, and percent fat) was very poor for any pair of "host-tree models" (class models). However, when only the four pinene alcohols (cV, tV, Mt, and tM) were used as variables, a clear separation among males from different host trees was obtained (Figure 4A; cf. Figure 3). The close covariation and the modeling power of the pinene alcohols can be seen in the loading plot for all variables where cV, tV, Mt, and tM form a tight cluster (Figure 4B). MB, PE, and percent fat are widely separated from each other and from the pinene-derived components because they varied independently of each other and of the pinene alcohol group. Id and Ie had no modeling power, as they were never found in phase-3 males.

The amounts of cV, tV, Mt, and tM in males attacking the same spruce tree varied very little in their proportions (Figure 3) and had approximately normal distributions (Tables 2 and 3). However, the proportions of the pinene alcohols varied greatly among males collected from different trees. This "among-tree" difference could be due to the variation in the amounts of monoterpene hydrocarbons present in the phloem from different host trees. The percentage of *cis*-isomer of the verbenols [$\%cis = cV/(cV + tV) \times 100$] was correlated with the percentage of the (−)-enantiomer of host tree α-pinene ($r = 0.92$, $N = 6$, $P < 0.001$; cf. Lindström et al., 1988). However, there is a small difference in the $\%cis$ between males in attack phases 3 and 6, collected

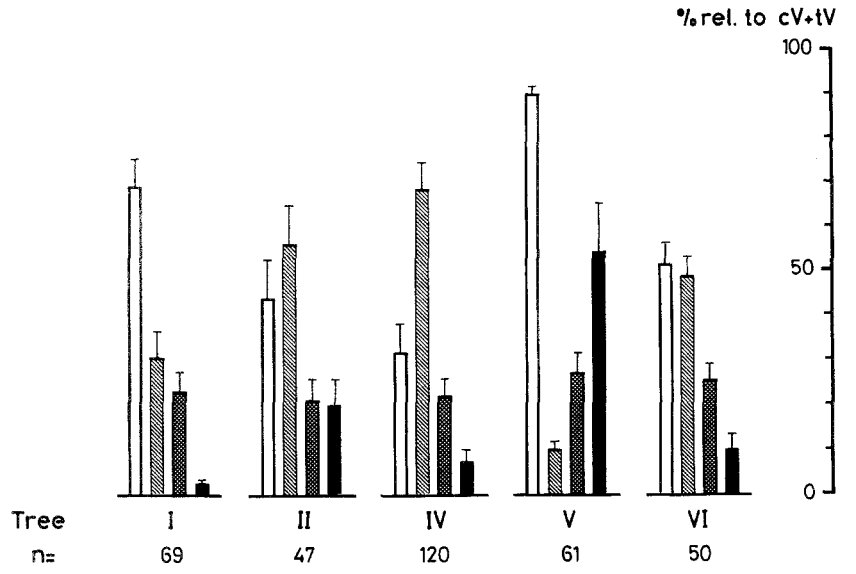

FIG. 3. Differences in relative amounts of pinene alcohols among males collected from different spruce trees. The amounts of *cis*-verbenol, □; *trans*-verbenol, ▨; myrtenol, ▩; and *trans*-myrtanol, ■; are related to the sum of *cis*- and *trans*-verbenol. n = number of beetles analyzed from each tree.

from spruce trees of different resistance. For the males collected from trees IV and V, the difference was significant ($P < 0.05$, t test) while it was not for the males in trees I and II. This shows a tendency for the percentage cV to decline in males from trees fully colonized by the beetles (trees II and V), while it is constant or increases in males attacking resinous and resistent trees (I and IV) (Tables 2 and 3).

To check the validity of the "host-tree separation," we included two randomly selected "test objects" from each of the five trees (Figure 4A). The validity was good, as eight of the 10 test objects were unambiguously assigned to the correct tree (Figure 4C), and none was incorrectly assigned. The two test objects belonging to tree I could not be assigned to tree I or any other tree.

Variation between Males in Different Attack Phases. The males from phase 3 and phase 6 showed the same relative magnitude of variation for all the volatiles, with standard deviations of the same magnitude as the means, which gave very large coefficients of variation [%CV = ($\bar{x}$/SD × 100] (Tables 2 and 3). The differences between attack phases 3 and 6 seemed highly significant for both MB and cV when all males were included in the ANOVA. The amount of MB was much lower in phase 6 than in phase 3 for males from all trees ($P < 0.001$, Wilcoxon signed rank test and Kruskal-Wallis one-way analysis by ranks; Figure 5). For cV and the other pinene alcohols, the picture was more compli-

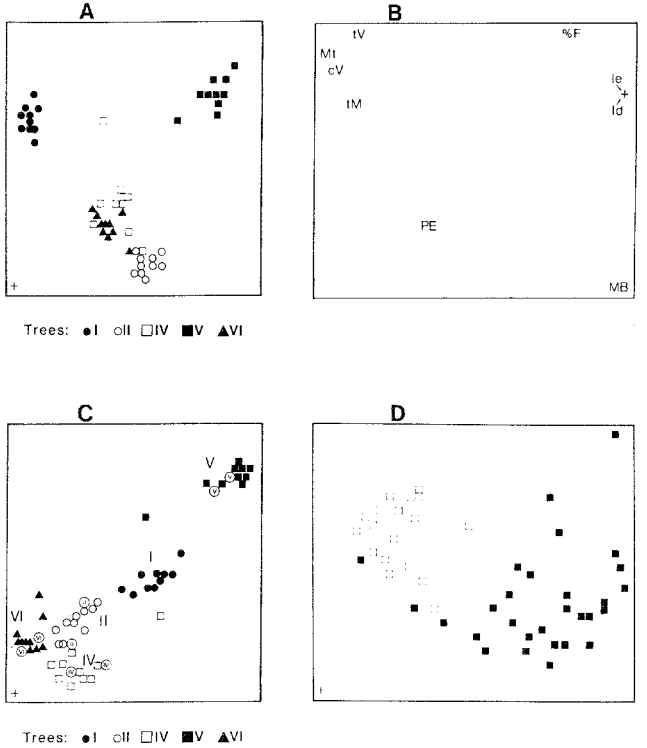

FIG. 4. (A) Plot of the residual standard deviations (SDD plot) from the "host-tree models" of trees I and II for 10 unmated males from each of five trees, where the models were based on the four pinene alcohols (cV, tV, Mt, and tM); + indicates origin. (B) A "loading plot" showing the modeling power of the nine variables orginally used in the classification of males from phase 3 from the five spruce trees. A position far from the origin indicates a high modeling power and a position close to another variable indicates a covariation. Id and Ie had no modeling power as they were never detected in any unmated male. (C) An SDD plot of the same type as in A, but based on the residuals from the class models of trees IV and VI, which gave the best overall resolution. From each tree, two "test objects," which were not used in building of the models and provides a test of the validity of the models, are plotted with the tree number inscribed in a circle. (D) A residual standard deviation plot of phase 3 (■, $N = 29$) against phase 6 (□, $N = 18$) for males from the same spruce tree (No. II) using all variables except Id and Ie and all males of each attack phase to build the "attack-phase model."

cated. The overall arithmetic mean in phase 6 was only slightly lower than in phase 3. Males from trees II and V followed this general pattern ($P < 0.001$, t tests). However, the medians for the pinene alcohols increased in trees I and IV between attack phases 3 and 6 (Figure 5).

Id and Ie were characteristic for phase 6, as none of them were detected

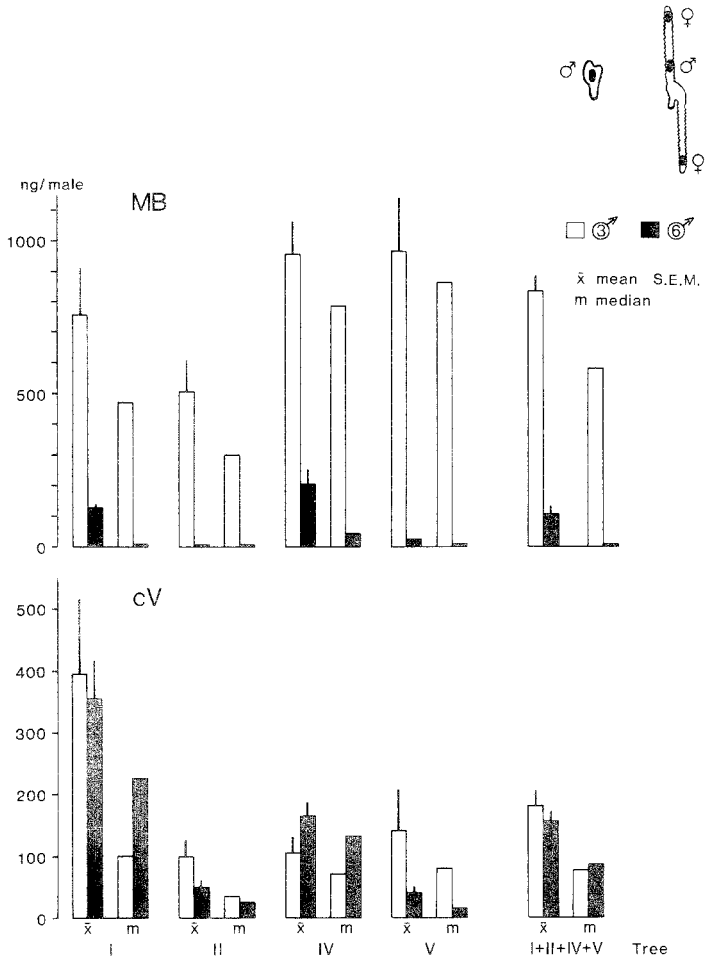

FIG. 5. Mean ($\bar{x}$ + SEM) and median (m) gut content of 2-methyl-3-buten-2-ol (MB) and *cis*-verbenol (cV) in males from attack phases 3 (□) and 6 (■) in the four spruce trees where both attack phases had adequate sample sizes.

(<0.1 ng, EICP) in any individual from phase 3. Still, neither of the two compounds was found in more than 60% of the mated males (Table 4). Two thirds of the males in which Id was detected contained less than 1 ng. Ie was found in fewer than 10% of the phase-6 males in amounts from much less than 1 ng up to 157 ng, but almost all of these males had less than 10 ng.

To evaluate the difference between the attack phases, we class-modeled males from tree II in phase 3 and phase 6 by SIMCA, using all variables except Id and Ie simultaneously. The reason for excluding Id and Ie was that only two males had Id in amounts above LOD, and none had Ie. The classes showed a

certain overlap, mainly due to some individuals in phase 3 having very low amounts of volatiles (Figure 4D).

Terpene-Exposed Unmated Males in the Laboratory.

In order to reduce the variability introduced by external factors such as variation in composition and amounts of monoterpene hydrocarbons (e.g., α-pinene), and phenotypic variance, males as homogeneous as possible (bred in laboratory and bioassayed for pheromone response) were exposed to α-pinene.

Beetles given flight exercise (group 2) had larger amounts of MB present in their hindguts than cold-stored ones (group 1), but still much less than those collected in the field (Figure 6). The differences in mean cV content between males from cold storage responding or not responding to a pheromone source in a Y tube after flight exercise were related only to the amount of (−)-α-pinene released during the exposure ($r = 0.998$, $N = 3$), but the deviation around the

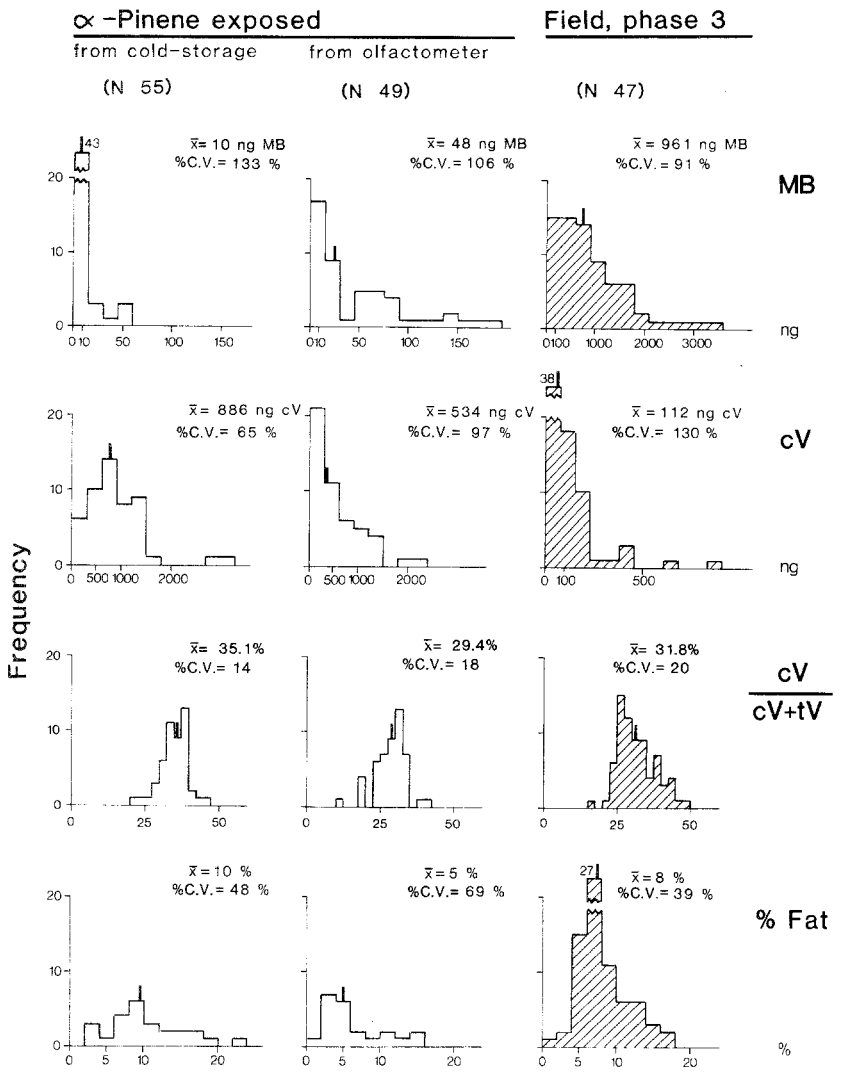

FIG. 6. Frequency histograms of hindgut content of MB, cV, *%cis* [= cV/(cV + tV) × 100], and % Fat in body of males exposed to α-pinene in the laboratory and males in attack phase 3 from spruce tree IV. The left column of diagrams shows beetles kept in refrigerator after emergence. The middle column shows beetles having responded to pheromone in olfactometer after flight exercise before α-pinene exposure. Right column shows males in attack phase 3 sampled from tree IV. Vertical lines indicate the medians, % CV = coefficient of variation [(SD/$\bar{x}$) × 100].

mean of each group was very large (Table 5). The untransformed values of MB and cV were skewed, leptokurtic, and significantly different from a normal distribution. Transformed values of MB and cV (log [amount + 1]) had, together with *%cis*, distributions that were normal or close to normal (Table 5), as was the case with the field-collected material (Tables 2 and 3). The coefficient of variation (%CV) of studied parameters from α-pinene-exposed beetles were generally similar to, or smaller than, those from unmated males collected from tree IV (Figure 6) and other trees (Tables 2 and 3). The fat content was lower

[a] The three groups are: cold storage ($N = 55$), not responding ($N = 42$), and responding ($N = 49$) to pheromone in Y-tube olfactometer after flight exercise.
[b] Significant departure from normality: $*P < 5\%$, $**P < 1\%$, $***P < 0.1\%$.

in the two groups given flight exercise ($P < 0.001$, t test). Comparing only the most relevant laboratory group (2B; flight exercise and pheromone responding) and using only those variables that are at least close to normal distributed, we find that the laboratory group (2B) for log(MB + 1) had 45% CV, while the field groups ranged from 45 to 78% CV; for log(cV + 1) 2B had 22% CV, while the field groups had 17–49% CV; and for *%cis* 2B had 18% and the field groups had between 4 and 32% CV (Tables 2 and 5).

The transformed amounts of cV (log [amount + 1]) were weakly correlated to the dry weight and percent fat for the exposed males in Figure 6 (r = 0.27 and 0 .24, respectively, $P \leq 0.01$), but there were no correlations between the content of MB and the dry weight or the percent fat, for males from any exposure group or all groups combined. However, the amounts of the two pheromone components were significantly intercorrelated ($P \leq 0.001$), especially for the two groups given flight exercise (r = 0.62–0.86).

DISCUSSION

Quantities of the pheromone components in individual male bark beetles appear to be based on a multitude of factors, including external ones and the individual variation in a strict sense. The intrinsic individual variation, i.e., the deviation from the mean of a homogeneous subset of individuals defined by external factors, is in turn composed of phenotypic and genetic factors. Is there a pattern of the quantified compounds that can illuminate these factors?

Variation due to External Factors

Methodology. The sampling regime could possibly have introduced some additional variance in pheromone production among males in the same attack phase, as we sampled beetles throughout and during several days. However, the influence from the time of collection was small in phase 3 as we did not detect any differences among beetles collected in the morning and the afternoon or among different days. This means that males attacking the trees during the first days of swarming did not contain significantly larger amounts of aggregation pheromone components than later attacking ones. Our results do not support the hypothesis put forward by Borden et al. (1986) that the pioneers would have a larger capacity for pheromone production. Another possible factor contributing to the large variation in phase 6 is that most males had only one female, and these were not separated from those with two or more females. An earlier study with batch samples of males with one or two females in attack phases 4 and 5 showed virtually no difference in pheromone content (Birgersson et al., 1984). The individual variation in amounts of volatile in phase 6 is thus most probably not affected by the number of females present.

Monoterpene Composition in Host Trees. The highly significant differences among beetles from different trees are shown by both ANOVA and SIMCA, especially when the analyses were based on the pinene alcohols cV, tV, Mt, and tM (Figures 3 and 4A and B). This result was not unexpected as we earlier found consistent differences in proportions of pinene alcohols among batch samples of males from different spruce trees and were able to correlate the amount of some host monoterpenes and pheromone components in beetle hindguts (Birgersson et al., 1984). It has earlier been shown in laboratory experiments that the production of cV, tV, and Mt depends on the amount and enantiomeric composition of the precursor, α-pinene (Renwick et al., 1976; Klimetzek and Francke, 1980; Byers, 1981).

In our field-collected material, the agreement between the absolute amounts of monoterpene hydrocarbons (MT) in host-tree phloem and pinene alcohols in the beetle hindguts was weak. A possible reason for this is that our analyses of the bark samples measured only the content of MT in constitutive resin present in the phloem, while the beetles interact mostly with the secondary resin produced by the host in response to the bark beetle excavating activity (Wright et al., 1979). The absolute amounts of MT in secondary resin is not correlated with the amounts in primary resin. However, the relative amounts of MT in primary and secondary resin is constant throughout the attack (Leufvén and Birgersson, 1987).

In contrast to the absolute amounts, the relative amounts of cV and tV in the hindguts of both phase-3 and phase-6 males corresponded very closely to the proportions of (−)-(2*S*, 5*S*)- and (+)-(2*R*, 5*R*)-α-pinenes in the phloem, as was reported by Lindström et al. (1988). The relative amount of Mt was very constant among males attacking different spruce trees (Figure 3), while the relative amount of tM was correlated to the amount of β-pinene, relative to α-pinene, in the host-tree phloem (Birgersson, 1989). The enantiomeric composition of Mt, which was not investigated, is probably the same as in the precursor α-pinene, as Mt is produced at a constant percentage independent of the ratios between the produced cV and tV or between (+)- and (−)-α-pinene in the host tree or during the laboratory exposures. The production of tM from β-pinene seems to be of much lower efficiency than that of cV, tV, and Mt from α-pinene; this is probably because tM is not used as a pheromone component (Schlyter et al., 1987a), but is rather, together with Mt, a product of detoxification.

Resin Production in Host Trees. Averaged over all trees, the mated males in phase 6 differed from the unmated phase-3 males mainly in their low content of MB. However, rate of decrease of MB was clearly related to resin flow (Figure 5). While there is a drastic decrease in all medians, the means for males from trees I and IV, which were classified as "resinous," showed a smaller decrease. This means that some males still have a large content of MB, even

almost one week after initiating their attack. On the other hand, there is no clear decrease in cV content of mated males (Figure 5). As in the case of MB, the amount of cV was also greater in beetles from "resinous" trees (I and IV) than in those from "dry/resin poor" (II and V) trees. Additionally, males on "dry" trees (especially tree V) decreased in cV content as attack progressed, while the males in the "resinous" trees clearly increased in their average cV content between attack phases 3 and 6. For males in tree IV, both the mean and the median increased between attack phases 3 and 6. The means of cV content for phase-3 and phase-6 males from tree I is not significantly different, but the median is more than doubled for the mated males. This increased content of cV in males from these resistant trees is probably a result of the continued resin production. Not enough beetles were attracted to the baited standing trees to reach the threshold number of beetles needed to overcome the resin flow (Berryman, 1982) of the resistant trees I and IV. A larger production and release of the aggregative cV, and also MB, by bark beetles attacking a resistant host tree, will increase the number of attracted beetles, which is in agreement with the findings by Raffa and Berryman (1983), where trees with higher resin flow attracted more of the swarming beetles. This continued host resistance probably contributed to the large variation in phase 6, for both the attractants MB and cV and probably also for Id and Ie.

Id and Ie were only found in the mated males, but neither compound was detected in more then 60% of the males in phase 6 (Table 5). The hypothesis by Hughes (1974) and Fish et al. (1979), that Ie is produced from Id, is supported by the fact that Ie was only found together with Id. Both compounds have been shown to influence the attraction of *I. typographus* to synthetic MB and cV; Id slightly increases, while Ie decreases, the attractivity (Bakke, 1976, 1981; Schlyter et al., 1987b). The trace amounts of Id and Ie that were found in the hindguts suggest that their role as natural semiochemicals might be small.

In many bark beetle species, including *I. typographus* and *I. paraconfusus*, Vn is known as an antiaggregation compound (Byers and Wood, 1980; Bakke, 1981). For some *Dendroctonus* species it has been shown that Vn is produced by the beetles themselves (Borden, 1982), even without an apparent precursor (Byers, 1983). However, for the spruce bark beetle, we were only able to detect trace amounts in the hindgut extracts. The quantitative and qualitative variations among cV, tV, and Vn during the colonization part of the attack are discussed by Francke and Vité (1983). It was recently shown that microorganisms isolated from *I. typographus* are able to convert cV and tV to Vn (Leufvén et al., 1984). In a recent study, Leufvén and Birgersson (1987) showed that the amounts of Vn in the phloem surrounding the nuptial chamber and the galleries increased as the attack proceeds, and this compound is also released from the beetles' entrance holes (Birgersson and Bergström 1989).

Variation due to Factors Within the Beetle

A large variation in the natural material remains even in males from the same attack phase and host tree (Figure 6). Unmated males in phase 3 from a certain spruce tree could (except from genetic variation) vary based on two main factors: within-tree variation of resin flow, which was, in fact, observed during the sampling, and variation due to the history of the individual beetle. This intrinsic variation could be due to the fact that an emerging individual faced with severe larval competition will, on the average, have a lower weight, fat content, and pheromone-producing capacity (Anderbrant et al., 1985). Other factors affecting the adults, such as differences in hibernation conditions and flight exercise, might also influence the physiological quality and thereby the pheromone production systems of the beetle.

The different groups of beetles exposed to α-pinene vapors in the laboratory also showed a large variability in content of volatiles, despite virtually identical environmental factors in each Petri dish during the exposure. The reason for the difference in the content of MB between males given flight exercise or not could be that the higher temperature and light levels during the flight exercise prepare the males for MB production, but exposure to α-pinene is neither a sufficient stimulus for this production, nor is α-pinene a precursor (Hackstein and Vité, 1978; Birgersson et al., 1984). The production of MB may be under a stricter hormonal or nervous (CNS) control, stimulated by their excavating behavior, as male spruce bark beetles also produce MB in large amounts after "attacking" spruce logs without a resin flow in the laboratory (unpublished results).

Some swarming bark beetles have to fly until they acquire a low lipid content before they respond to pheromone sources (Atkins, 1969). In the exposure experiments, the males were found to produce cV independent of flight exercise. The average cV content within the different groups was, instead, strongly correlated to the amounts of (−)-α-pinene to which the beetles were exposed. Compared to the different groups of beetles exposed to α-pinene, the males in attack phase 3 collected from tree IV show a distribution of cV content that is more peaked and skewed towards low amounts (Figure 6, Tables 2 and 5). The distribution of the males in each group closely resemble the frequency distributions for tV in *D. ponderosae* females exposed to α-pinene, and Id in *I. pini* males boring in lodgepole pine logs or in *D. ponderosae* males exposed to myrcene (Borden et al., 1986; Hunt et al., 1986).

The variation in *%cis* was almost the same in laboratory exposed and naturally attacking males, as it depends on the enantiomeric composition of the precursor, α-pinene. However, there is still considerable variation (CV up to 15–20%) among the males from the same exposure or host tree. For the attack-

ing males, this variation might be due to spatial or temporal differences of the enantiomeric composition in the host-tree resin.

Is it possible for a single enzyme system to produce cV and tV with this variation, or are the verbenols produced by two separate biosynthetic pathways working in parallel? This latter hypothesis is supported by the fact that *I. typographus* females collected in spruce trees contain very little cV (Birgersson et al., 1984) or none at all after exposure to (−)-α-pinene, although they do produce tV (Anderbrant et al., 1985).

In this study we have measured the content of volatiles in hindguts of male bark beetles at the time of collection. A low amount of compounds can be the result of either a high or normal production followed by a high release, or a low production and release; a large content can be the sum of either a large production and a low release, a very high production and a medium release, or a production without release. If the beetles release their semiochemicals periodically in repetitive bouts of flatulence, the amounts of these compounds in their hindguts may vary according to the production rate and the time after each single release. However, aerations for 3-hr periods outside individual entrance holes (Birgersson and Bergström, 1989) did not show this kind of variation. It is likely that there is a steady state between the amounts of volatiles produced and released, and probably the rate of production is reflected by the content of the hindguts.

Evolutionary Implications

The three species of bark beetles analyzed individually so far (Birgersson et al., 1984; Borden et al., 1986; Hunt et al., 1986) do not only demonstrate a large variance in the content of their pheromone components, but the reason for these high variances is a large positive skewness, corresponding to a large fraction of the population samples from these species that contain very small amounts of pheromone (cf. Figure 2 and Figure 1 in Schlyter and Birgersson, 1989). Such low contents (only a few percent of the mean) would imply a poor signaling capacity and consequently low mating success and low fitness for these individuals.

Variation in pheromone components seems to be higher in bark beetles than in moths (Schlyter and Birgersson, 1989). The reason might be that, while female moths call singly, bark beetles—except for a few "pioneers"—call in groups in which some males mates despite low pheromone production. There is a difference between tree-killing species, with their cooperative component, and those species that breed in windbroken or otherwise severely weakened trees or logging debris. The bark beetle species studied individually so far kill trees in mass attacks either occasionally, at high population levels (*Ips* species), or more often (*D. ponderosae*). In such species, low-producing individuals might "hitch-hike" or "sneak in" on the signal of a large group and hope for

a mate to arrive, more or less by chance, at the gallery entrance where other steps in the mating behavior, such as stridulation or physical contact, may take over. Consequently, at this high population level, selection pressure for high pheromone production will be weaker. Conversely, there should be stronger selection pressure for high pheromone production at lower population levels, when a large proportion of the individuals will find themselves pioneers or members of very small groups. The average genetic structure in a bark beetle population might be the result of alternating periods of selection pressures of different strength operating at different population densities.

Acknowledgments—The field site was suggested and provided by M. Sjölander and G. Barrmyr at Billerud AB. M. Appelgren assisted in the collection of beetles. Capillary columns were skillfully prepared by A.-B. Wassgren. E.V. Jirle performed the fat extractions and maintained the beetle rearing together with L. Reimann-Ericsson. Sex separation and olfactometer bioassay were performed by J. Börnfors. Figures were drawn by B. Hamlet, S. Douwes, and E.V. Jirle. Reviews of the manuscript were made by colleagues at our departments and by J.A. Byers, who also corrected the language. We thank them all for their professional help and support. We acknowledge the generous provision of spruce trees for the beetle rearing by the Björnstorp Estate. This study was made within the Swedish project "Odour Signals for Control of Pest Insects," supported by grants from the Swedish research councils (NFR, FRN, SJFR, and STU).

Rumex obtusifolius L: Release of Allelochemical Agents and Their Influence on Small-Scale Spatial Distribution of Meadow Species

E. CARRAL, M.J. REIGOSA, and A. CARBALLEIRA

Cátedra de Ecología, Facultad de Biología
Universidad de Santiago de Compostela, Spain

(Received May 15, 1987; accepted October 5, 1987)

Abstract—Decomposing *Rumex obtusifolius* L. leaves and their extracts were most toxic for germination and root growth of meadow species *Lolium perenne*, *Trifolium repens*, *Poa pratensis*, and *Dactylis glomerata* after seven days' decomposition, although the toxicity level was, in some cases, still high after 21 days. The hypothesis that *R. obtusifolius* exerts allelopathic control over meadow species is supported by small-scale distribution of meadow species in the neighborhood of *R. obtusifolius* plants. The area affected and the intensity of the effect both increase with the size of the individual *R. obtusifolius* plant.

Key Words—Allelopathy, *Rumex obtusifolius* L., meadow species, bioassays, spatial distribution.

INTRODUCTION

It has long been recognized that plants are not randomly distributed, but exhibit patterns with respect to both their physical environment and other plants (Fowler and Antonovics, 1981). Numerous techniques for sampling and analyzing plant communities have been developed to test distribution models and to investigate the causes of the patterns observed. However, many of these techniques are unsuitable for small-scale studies required for the elucidation of interactions among plants (Turkington et al., 1985). For these purposes, the most sensitive methods are based on point-quadrat sampling procedures (Turkington et al., 1985; Fowler and Antonovics, 1981; Nicolas et al., 1980; Stowe and Wade, 1979).

One of the mechanisms by which interspecies interaction may affect plant

0098-0331/88/0900-1763$06.00/0

distribution in natural or agricultural ecosystems is allelopathy (Rice, 1984; Bhowmik and Doll, 1984; Numata, 1982; Moreira, 1979; Putnam and Duke, 1978). It is nevertheless extremely difficult to distinguish in the field between allelopathy and competition, making it necessary that distribution studies be supported by experimental data (Jong et al., 1983; Carballeira et al., 1988). Conversely, laboratory bioassays are not by themselves sufficient to determine whether allelopathy occurs under natural conditions; most work in this area has consisted of laboratory studies unsupported by small-scale distribution analysis (Stowe, 1979).

This research was designed to determine the extent to which the capacity of *R. obtusifolius* to invade artificial grassland is due to allelochemical mechanisms, and whether such mechanisms are responsible for the poor growth of the major meadow species in the neighborhood of *R. obtusifolius* (Figure 1). Similar repression of meadow species has been observed by Einhellig and Rasmussen (1973) in the neighborhood of *Rumex crispus*; Fowler and Antonovics (1981) found that *Poa pratensis* and *Trifolium dubium* were negatively associated with *Rumex acetosella* in the neighborhood of the latter. Turkington et al. (1985) reported similar negative affinities of *Poa pratensis*, *Trifolium dubium*, *Poa annua*, and *Poa trivialis* for *Rumex acetosa*.

METHODS AND MATERIALS

Site. The site studied was an artificial meadow located in Santiago de Compostela (42°50′N, 80°27′W) at an altitude of 250 m. The meadow faces 218°N with a slope of 26:100. The soil is a humic andosol (FAO) over colluvial deposits, although small variations in depth or density create localized areas of humic cambisol with andic properties. The soil profile is polycyclic. According to Papadakis' classification, the area has a temperate maritime climate with a warm maritime temperature and a humid regime (Carballeira et al., 1983). The mean temperature was 12.9°C, the mean minimum of the coldest month 5.2°C and the mean maximum of the warmest month 23.3°C. Mean summer rainfall was 137 mm and mean annual rainfall 1288 mm. The meadow was established five years ago with a mixture of *L. perenne*, *T. repens*, *P. pratensis*, and *Dactylis glomerata* and was periodically treated with slurry and mineral fertilizer rich in phosphorus and nitrogen.

Bioassays. Juste et al. (1985) found that the main route by which *R. obtusifolius* releases allelochemical agents into the environment is the decomposition of fallen leaves. Accordingly, leaves were picked from *R. obtusifolius* plants at the study site. A sample of these leaves was used to determine the ratio of fresh weight to dry weight at 80°C.

Fresh leaf material was divided into lots equivalent to 30 g dry weight, 30

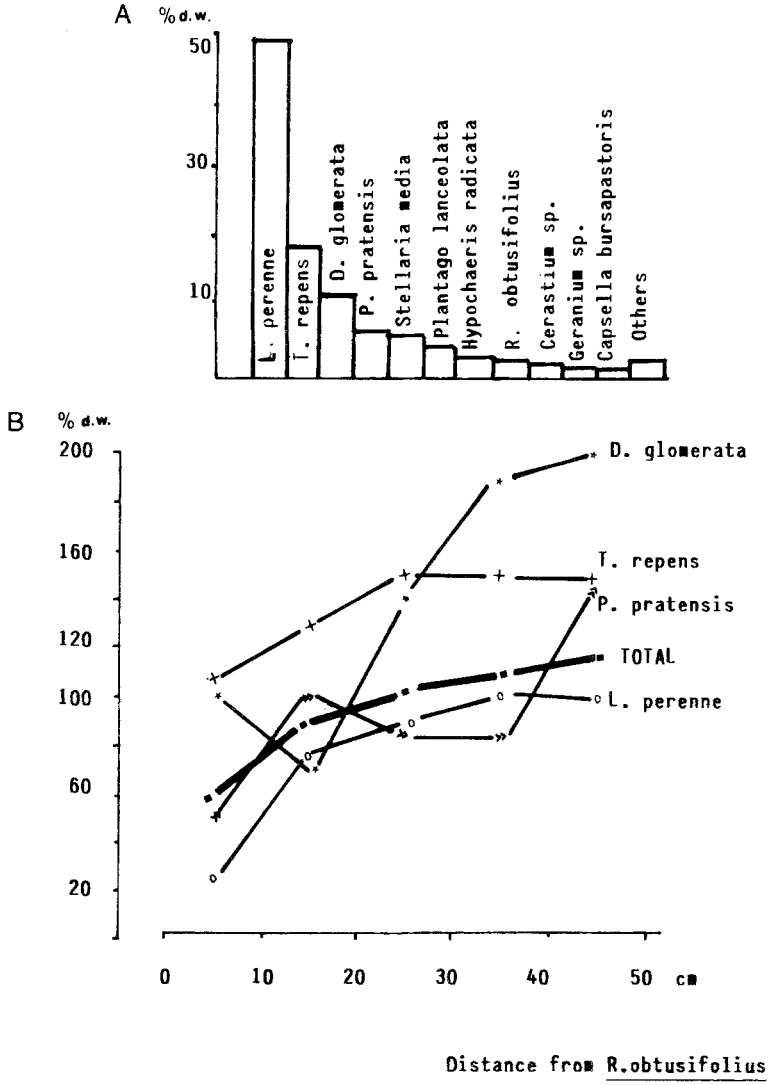

FIG. 1. (a) Composition of the biomass of the study site. (b) Variation of biomass in the neighborhood of *R. obtusifolius*.

of which were placed in 12-mm mesh nylon litter bags. The bags were placed in groups of six at five random points of the study site, and 7, 14, and 21 days later two bags were removed from each group and the contents of each pair pooled. A sample was taken from each pool for dry weight determination, and

the remainder of the material recovered was used for bioassays. Bioassays were also performed on freshly collected leaves (day 0).

Three bioassays were performed, two using leachates (one twice as strong as the other) and one using the leaves as picked or recovered from the litter bags (Woods and Raison, 1982; Kelman and Lang, 1982). For the stronger leachate (1 : 4), leaves saturated with distilled water were left in the dark for 24 hr at 20°C and then gently sprayed with distilled water until the collected drippings amounted to 4 ml/g dry weight. The weaker leachate (1 : 8) was obtained by diluting a portion of the 1 : 4 leachate to twice its volume. For each meadow species whose sensitivity was to be tested, both leachates were bioassayed by sowing 50 seeds on Whatman 3MM paper in a Petri dish and sprinkling them with 4 ml of leachate. For the third bioassay (H), 50 seeds were sown on Whatman 3MM over a layer of leaves on the bottom of a Petri dish and sprinkled with 4 ml of distilled water. In all cases, five replicate dishes were prepared, one from each group of litter bags. Dishes with 50 seeds sown on Whatman 3MM and sprinkled with 4 ml of distilled water were used as controls. All dishes were incubated in the dark at 28 ± 1°C and 80% humidity. Percentage germination and root growth were determined for *T. repens* and *L. perenne* after 144 hr, and for *P. pratensis* and *D. glomerata* after 216 hr.

The data were tested by two- and three-way analysis of variance (Vesereau, 1960).

Spatial Distribution. The spatial distribution of the meadow species considered with respect to *R. obtusifolius* was investigated using a modified form of Stowe and Wade's (1979) "species-region" method. Of the *R. obtusifolius* plants of 20 cm or more in diameter in the study site, 160 were chosen at random. Four 1-m-long transects were drawn radially from the outer edge of each plant's projection area, one in the direction of maximum upward slope and the others at 90° intervals about the plant. A 1-m frame holding a 60-cm sliding needle was placed over each transect. The needle was shifted centimeter by centimeter along the frame, and at each centimeter point the species, if any, in contact with the needle at ground level was recorded, regardless of the organ touched.

The species-region method compares the relative frequencies of occurrence of a secondary species B with respect to the average plant population density inside and outside the region of influence R_1 of a primary species A. Specifically, the tendency of B to associate with A is measured by an association index: $AI = (ad)/(bc)$, where a is the number of occurrences of B within R_1; b is the number of occurrences of species other than B or A in R_1; c is the number of occurrences of B in R_2, a region assumed to be free from A's influence; and d is the number of occurrences of species other than B or A in R_2. $AI < 1$ indicates negative affinity of B for A, $AI > 1$ positive affinity, and $AI \simeq 1$ indif-

ference. A χ^2 test may be used to establish the statistical significance of the observed value of *AI*.

In the present study, the dependence of association on distance was investigated in two ways. In the first (the "accumulative" method), R_1 was defined as a segment of the transect comprising the *r* cm nearest the *R. obtusifolius* plant. In the second (the "annular" method), R_1 was defined as a 10-cm segment centered *r* cm from the *R. obtusifolius* plant. In both cases, the 50 cm furthest from the *R. obtusifolius* plant were used as R_2 (the validity of this was checked in preliminary experiments), and *AI* was plotted against *r*.

RESULTS

Bioassays. The rate of decomposition during the time the picked leaves were exposed in the litter bags was limited only by temperature (Esser et al., 1982). Thermal efficiency was low, and the differences among the three sampling times were small (Figure 2). Heavy rains during the study probably caused leaching of the leaves, thus reducing the concentration of toxins in subsequent bioassays.

Figure 3a shows that whatever the meadow species, germination and root growth averaged over the four sampling times were most depressed in the decomposing leaf bioassay, H. The relative sensitivities of the species were not the same for both germination and root growth in this assay, the rankings of *L. perenne* and *D. glomerata* being interchanged. For all the species, the inhibition averaged over the three kinds of assay was greatest when material exposed for seven days was used (Figure 3b). The extracts from this material were those of lowest pH and highest electrical conductivity (Table 1). In the decomposing

TABLE 1. ACIDITY AND ELECTRICAL CONDUCTIVITY OF LEACHATES USED FOR BIOASSAYS

Bioassay procedure	Day			
	0	7	14	21
pH				
1:4	6.2	5.2	6.5	7.1
1:8	5.9	5.1	6.4	6.9
Conductivity (μmhos)				
1:4	930	3500	1520	1880
1:8	480	1200	840	960

leaf bioassay, germination and root growth averaged over all four meadow species was still inhibited by over 50% by material exposed for 21 days (Figure 4). The two leachates behaved very similarly at all times, in spite of their difference in concentration, and both were inactive when obtained from material exposed for 14 days or more.

The above results suggest that the compounds released by the *R. obtusifolius* leaves are very labile, and their continuous low-level application (as in the decomposing leaf test, the assay closest to natural conditions) is more effective than a large single dose.

Spatial Distributions. The data obtained in the field were initially analyzed

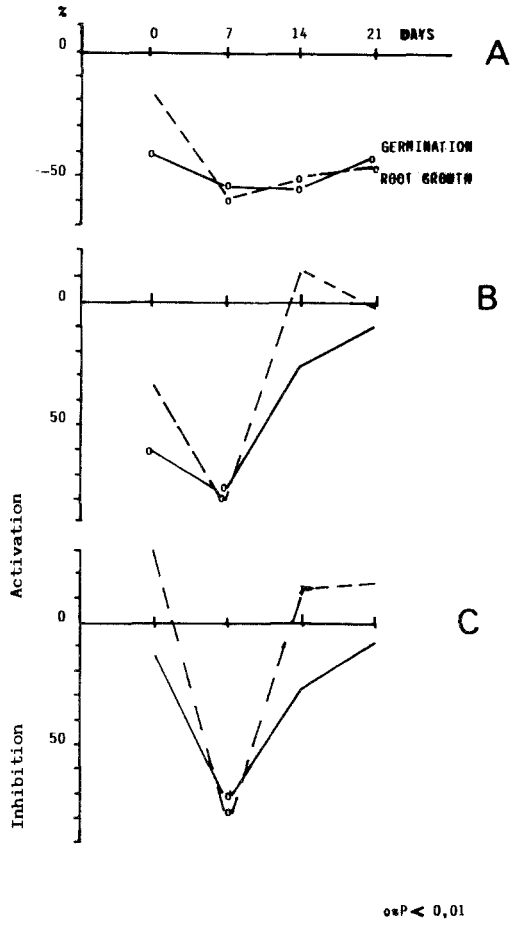

FIG. 4. Effects of decomposition time on the germination and root growth of meadow species (average for the four species studied): (A) in the decomposing leaf assay H; (B) using leachate 1:4; and (C) using leachate 1:8.

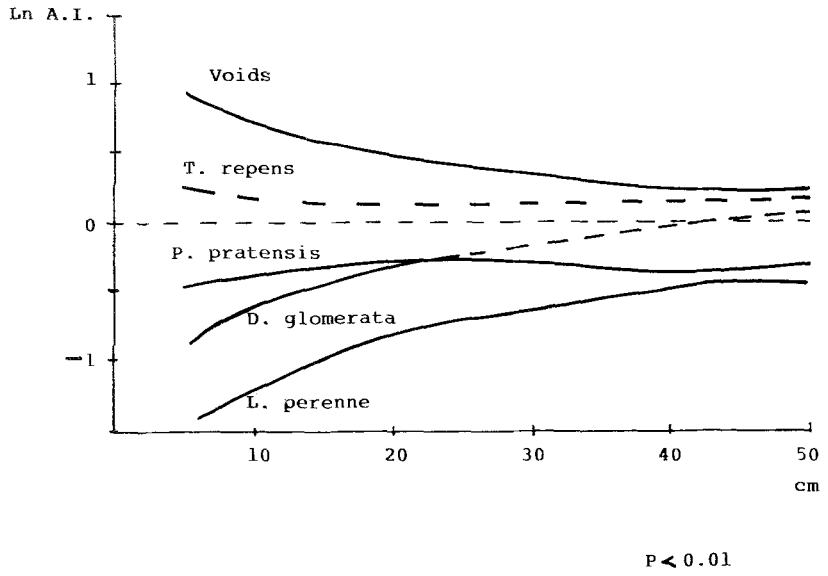

FIG. 5. Dependence of association index, *AI*, on the hypothetical radius of the domain of influence of *R. obtusifolius* as calculated by the accumulative method for four meadow species and voids.

by the "accumulative" method (Figure 5). As the radius of the hypothetical region of influence increased *AI* tended to indifference levels. Except in the case of *D. glomerata*, the weight of the inner few centimeters kept *AI* away from unity, so that it was impossible to determine the radius of the real sphere of influence. To overcome this difficulty, the data were reprocessed using the "annular" method (Figure 6), which showed that voids (absence of any of the four meadow species) were significantly associated with *R. obtusifolius* in the first 20 cm, while *D. glomerata*, *L. perenne*, and *P. pratensis* had negative affinity for *R. obtusifolius* in the inner 15, 35, and 50 cm, respectively. *T. repens* exhibited a slight tendency towards positive affinity.

DISCUSSION

For only one of the four meadow species studied did the spatial distribution results contradict the laboratory findings. *T. repens* was inhibited in the bioassays, but was largely indifferent to the presence of *R. obtusifolius* in the field, with perhaps a slight tendency to positive affinity. This contradiction may be due to the sampling procedure, which recorded all contacts with the sampling

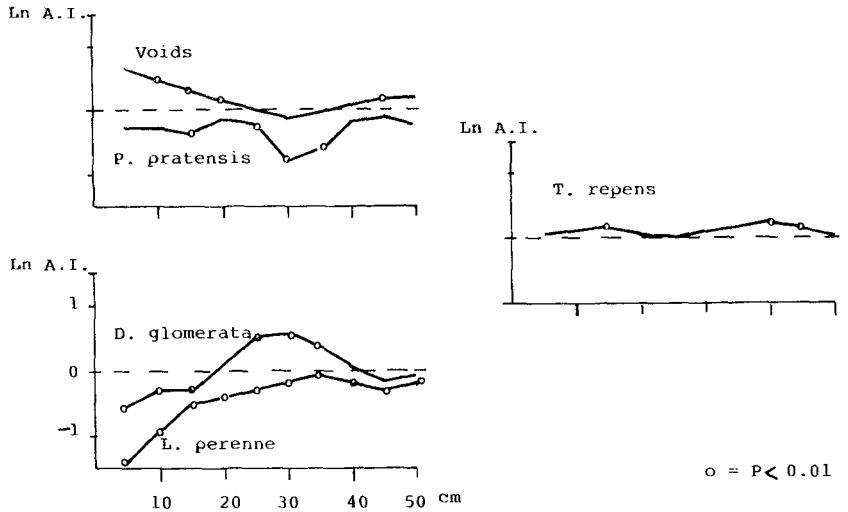

FIG. 6. Dependence of the association index, *AI*, on mean annular radius about *R. obtusifolius* as calculated by the annular method for four meadow species and voids.

needle at ground level, regardless of which part of the plant was touched. Because of the life form of *T. repens*, its aerial structures can lie close to *R. obtusifolius* without there being any competition or allelochemical interaction so long as the clover is rooted outside the influence of the other plant. The life forms of the other meadow species sutdied do not present this complication. With respect to their performance in the decomposing leaves bioassay, H (the assay most similar to natural conditions), they can be ranked by decreasing inhibition of root growth in the order *P. pratensis*, *L. perenne*, and *D. glomerata*, and by decreasing inhibition of germination in the order *P. pratensis*, *D. glomerata*, and *L. perenne*.

The range and degree of these plants' negative affinities for *R. obtusifolius* (as measured by the annular method) exhibit the same ordering as the inhibition of their root growth, which suggests that chemical interference by *R. obtusifolius* is sufficient to reduce their development but not enough to exclude them completely from the neighborhood of *R. obtusifolius* plants. This is in keeping with the current concept of allelopathic interaction, for although these mechanisms are widespread in both natural and agricultural ecosystems, their role should not be exaggerated, but considered merely complementary to other strategies (Muller, 1966). It is clear that even by causing quite small reductions in photosynthetic efficiency or nutrient uptake rates, an allelopathic agent may successfully place a potential competitor at a disadvantage.

Kershaw (1973), in listing the possible causes of patterns in plant com-

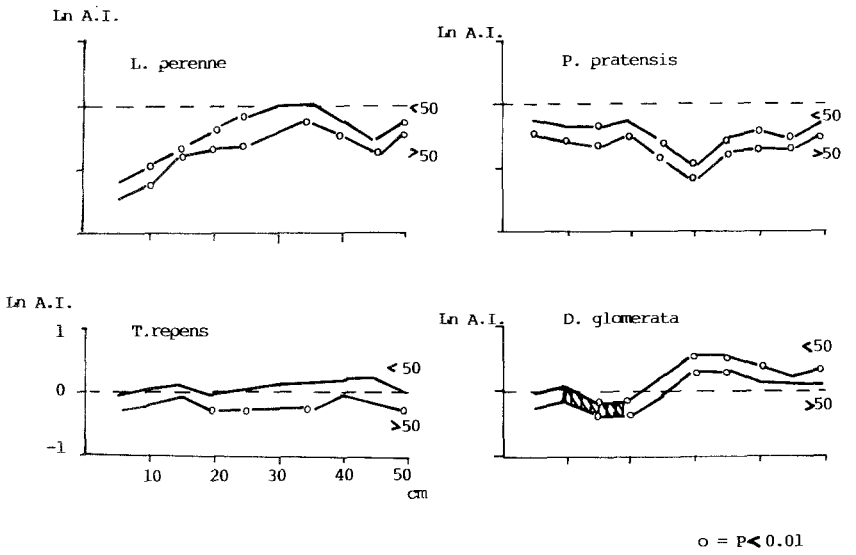

FIG. 7. Variation of association index, *AI*, with distance (annular method) for *R. obtusifolius* plants greater or less than 50 cm in diameter. Shaded area indicates statistically significant differences ($P < 0.01$).

munities as competitive capacity, environmental conditions, and allelopathic interactions, pointed out that the release of toxins may depend on the age of the individual. To investigate this question, we divided *R. obtusifolius* plants studied into two groups according to the diameter of their rosettes (73 plants of 20–50 cm diameter and 87 of 50–74 cm diameter) and performed separate analyses of the spatial distributions of the meadow species studied in the neighborhood of plants of each group (finer classification of diameters produced very unequal class sizes or classes with too few members). The results (Figure 7) confirm that the negative influence of *R. obtusifolius* on the meadow species increases with the size of the *R. obtusifolius* plant, although the difference between the two size classes considered was only statistically significant for the presence of *D. glomerata* between 10 and 20 cm from *R. obtusifolius*.

ASYMMETRIC SMALL-SCALE DISTRIBUTION AND ALLELOPATHY: Interaction between *Rumex obtusifolius* L. and Meadow Species

A. CARBALLEIRA, E. CARRAL, and M.J. REIGOSA

Cátedra de Ecología, Facultad de Biología
Universidad de Santiago de Compostela, Spain

(Received May 15, 1987; accepted October 5, 1987)

Abstract—Analysis of small-scale distribution may allow allelopathic interaction among plant species to be distinguished from competitive interaction. If all environmental factors except slope are uniform, allelopathy produces spatial asymmetry in the association with a hypothetical receptor species and the corresponding hypothetical emitter species in the neighborhood of the latter. The interaction between *Rumex obtusifolius* and the meadow species *Lolium perenne*, *Poa pratensis*, *Dactylis glomerata*, and *Trifolium repens* is analyzed by way of example.

Key Words—Allelopathy, small-scale spatial distribution, slope, *Rumex obtusifolius*, meadow species.

INTRODUCTION

It is well known that in the field it is extremely difficult to distinguish allelopathic interactions among different plant species from competitive relationships. Studies of allelopathy are accordingly usually carried out in the laboratory, and their results are assumed to hold under natural conditions; however, the validity of such a generalization is questionable (Harper, 1977; Stowe, 1979). At what concentrations should extracts be bioassayed? How do the soil microorganisms affect the compounds released by the plants studied? Do laboratory procedures create artifacts?

A necessary condition for the valid extrapolation of laboratory findings to the field is that they be compatible with the spatial microstructure of the vegetation observed under natural conditions. Thus, of all the possible combinations of bioassay response and observed association, all those in the bottom group in

0098-0331/88/0900-1775$06.00/0

Table 1 imply that the laboratory results are probably irrelevant to the processes predominating under natural conditions. However, compatibility is by no means sufficient to guarantee the reliability of bioassay-based conclusions. These will only be valid if the assay conditions adequately reflect natural conditions and, since uncertainty in this regard is the rule, there is a considerable risk of mistaking allelopathic interference for competition or vice versa.

These difficulties would be avoided if it were possible to tell allelopathic from nonallelopathic interactions without recourse to laboratory bioassays. Dekker et al. (1983) suggested that it is sufficient to observe the association between a hypothetical allelopathic species and its hypothetical receptors when they are grown together under conditions which ensure the absence of competition by providing an abundance of all resources. However, this method is often impractical because of costs in time or money or because of technical difficulties associated with the cultivation of noncommercial species. In any case, the results are not necessarily applicable to natural conditions, because it is known that in certain species the release of allelopathic agents is triggered or increased by stress, which may likewise affect the sensitivity of receptors (Rice, 1984).

Here we describe a method for distinguishing allelochemical interactions by analyzing the relative spatial distribution of the hypothetical emitter and receptor under natural conditions. The only limitation to its application is that the site studied should be uniform as to shade, availability of water, depth of soil, etc., but steep enough for gravity to have a significant effect on any allelochemical agent. The ideal location is a hilltop from which shallow slopes descend in all directions. The hypothesis on which the method is based is that under these conditions, gravity should favor downhill flow of aerial leachates, litter, and root exudates. In the neighborhood of the plant from which they

TABLE 1. IMPLICATIONS FOR INTERSPECIES INTERACTIONS OF CORRELATION BETWEEN BIOASSAY RESULTS AND OBSERVED SMALL-SCALE SPATIAL DISTRIBUTION

Response of supposed receptor in bioassay	Observed spatial association	Inferred interaction
Indifference	indifference	no interaction
Activation	positive	allelochemical stimulation
Inhibition	negative	allelopathy
Indifference	negative	competition
Inhibition	positive	bioassay results invalidated
Activation	negative	
Indifference	positive	
Inhibition	indifference	
Activation	indifference	

originate, this may give rise to a difference between uphill and downhill areas as affected by any allelochemical agents produced. Any such uphill–downhill asymmetry in the index of association between a hypothetical receptor and the corresponding hypothetical emitter in the neighborhood of the latter is therefore evidence in favor of the existence of allelochemical interaction (which may, of course, be superimposed upon simultaneous competitive interaction).

ASSOCIATION INDICES

The method used to measure the association between the hypothetical emitter and its receptors is a variant of the "species-region" technique proposed by Stowe and Wade (1979). This technique compares the relative frequencies of occurrence of a secondary species, B, with respect to the average plant population density inside and outside the domain of influence, R_1, of a primary species, A. Specifically, the tendency of B to be associated with A is measured by an association index, $AI = (ad)/(bc)$, where: a is the number of occurrences of B within R_1; b is the number of occurrences of species other than B or A in R_1; c is the number of occurrences of B in R_2, a region assumed to be free of A's influence; and d is the number of occurrences of species other than B or A in $R_2 \cdot AI < 1$ indicates negative affinity of B for A, $AI > 1$ positive affinity, and $AI = 1$ indifference. A χ^2 test may be used to establish the statistical significance of the observed values of AI. The dependence of association on the distance d from the primary species A may be investigated be defining as R_1 an annular region with a central ring of radius d, and plotting AI against d (since the regions R_1 and R_2 are in practice usually segments of transect, the "annulus" is in such cases a segment centered at distance d from A).

SPATIAL ASYMMETRY IN RESPONSE TO ALLELOCHEMICALS

In analyzing natural spatial distributions in accordance with the hypothesis set forth in the Introduction, the substance whose effects are being investigated is, of course, the aggregate of compounds released by the emitter plant. The overall activity of this aggregate may be considered as hormonal if, at some biologically realistic concentration, it stimulates the receptor species, and as toxic if its only action at biologically realistic concentrations is to depress the receptor species. Idealized concentration–response curves for these two types of activity are shown in Figure 1A and B. When the effect of slope in increasing the concentration of the allelochemical downhill from the plant is taken into account, it may be deduced that there are 13 possible kinds of distribution patterns manifesting the difference between uphill and downhill areas. These patterns are illustrated schematically in Figure 2, and the range of hormone or toxin

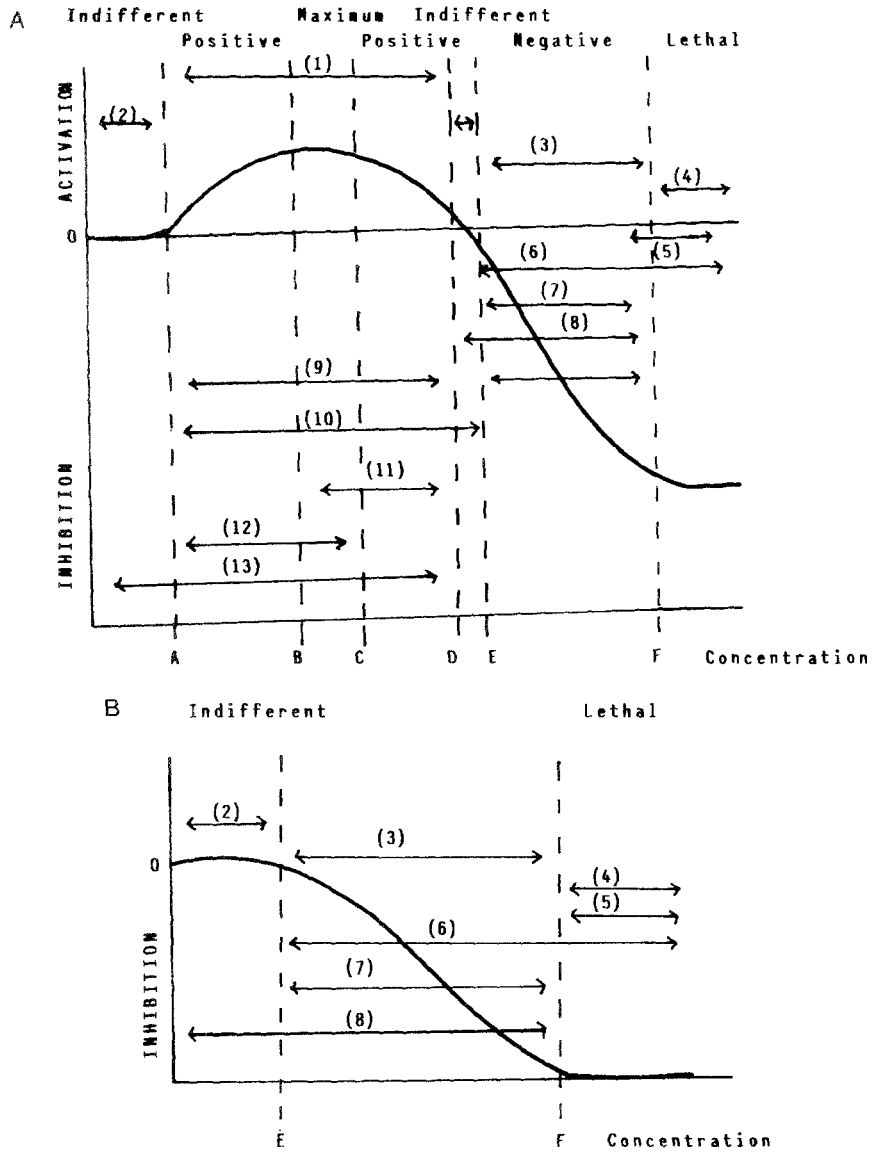

FIG. 1. Idealized response to hormonal (A) and toxic (B) allelochemical agents. Numbers in parentheses indicate the distribution pattern types (Table 2) produced by the corresponding concentration ranges.

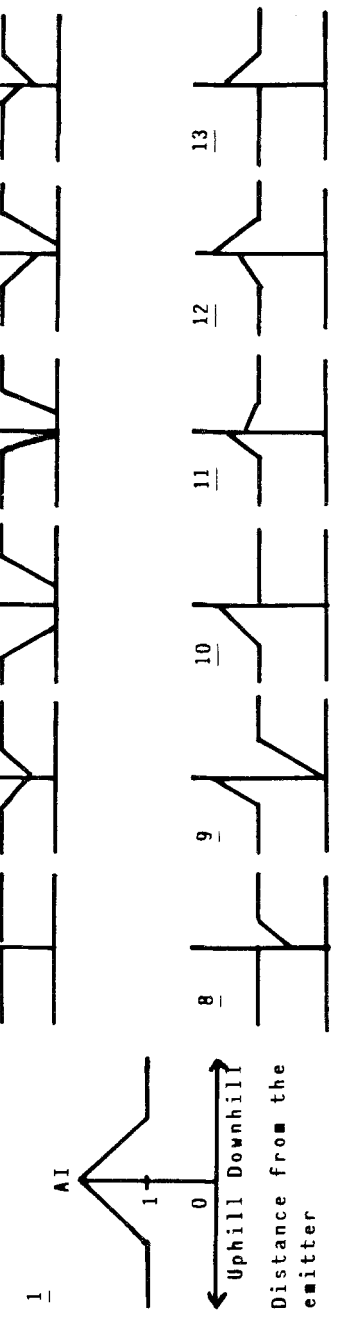

FIG. 2. Schematic representations of the 13 types of interference pattern (Table 2).

concentrations responsible for each is indicated on Figure 1A and B. Pattern 4, for example, may be produced by both hormonal and toxic agents as long as the concentrations in both downhill and uphill directions are greater than those corresponding to level F in Figure 1A and B. Table 2 lists the 13 patterns together with their implications for the type of interspecies interaction (allelopathy, sympathy, competition, or indifference) and, in the case of allelochemical interactions, for the kind of agent (hormonal or toxic). Patterns 2–8 can result from the action of either hormonal or toxic agents, whereas pattern 1 and patterns 9–13 can only be explained as the effect or hormonal allelochemicals.

EFFECT OF DISTANCE ON *AI*

If the interaction between two plant species is mediated by allelochemicals, the intensity of this interaction, and hence of the observed association index, depends not only on the intrinsic affinity of the secondary species for the primary species, but also on the distance between the specimens observed. In the diagrams of Figure 2, for example, it has been tacitly assumed that for a given

TABLE 2. INFERENCE OF INTERSPECIES INTERACTION FROM UPHILL–DOWNHILL ASSOCIATION PATTERN

Type	Association uphill–downhill	Type of interaction	Type of chemical agent
Symmetric			
1	Positive–positive	sympathy[a]	hormonal
2	Indifference–indifference	indifference	
3	Negative–negative	allelopathy or competition	hormonal or toxic
4	Exclusion–exclusion	allelopathy or competition	hormonal or toxic
Asymmetric			
5	Exclusion < exclusion	allelopathy	hormonal or toxic
6	Negative–exclusion	allelopathy	hormonal or toxic
7	Negative > negative	allelopathy	hormonal or toxic
8	Indifference–negative	allelopathy	hormonal or toxic
9	Positive–negative	sympathy–allelopathy	hormonal
10	Positive–indifference	sympathy–allelopathy	hormonal
11	Positive > positive	sympathy	hormonal
12	Positive < positive	sympathy	hormonal
13	Indifference–positive	sympathy	hormonal

[a] Sympathy = allelochemical stimulation.

intrinsic affinity, the observed association depends linearly on distance within the area influenced by the primary species. This is not necessarily so, of course.

Let us consider an emitter plant, the radius of whose projection area is $r = 20$ cm (roughly the radius of the *R. obtusifolius* plants discussed in the next section). Let d be the distance from the receptor plant to the edge of the emitter's projection area, $s = \Pi r^2$, $s' = \Pi[(r + d)^2 - r^2]$, $v = \Pi r^3 2/3$, and $v' = \Pi[(r + d)^3 - r^3]2/3$. Then at distances $d = 4$, 10, 20, and 40 cm the ratio $r/d = 5$, 2, 1, and 0.5, respectively; the ratio $s/s' = 2.27$, 0.8, 0.3, and 0.25; and the ratio $v/v' = 1.37$, 0.43, 0.14, and 0.038. For the purposes of this idealized example, we shall suppose that the biological response to an allelochemical agent is proportional to its concentration, and we shall define the affinity between two species as "intense" when at a distance $d = r/5$, $AI > 10$ (for positive affinity) or $AI < 0.1$ (for negative affinity). Then the AI threshold for intense affinity, which depends on distance, will approach unity at distances $d = 40$, 25, or 20 cm, depending on whether the dispersion of the allelochemical takes place in one, two, or three dimensions. Figure 3 illustrates, for several such arbitrary levels of affinity, the theoretical dependence of the allelochemi-

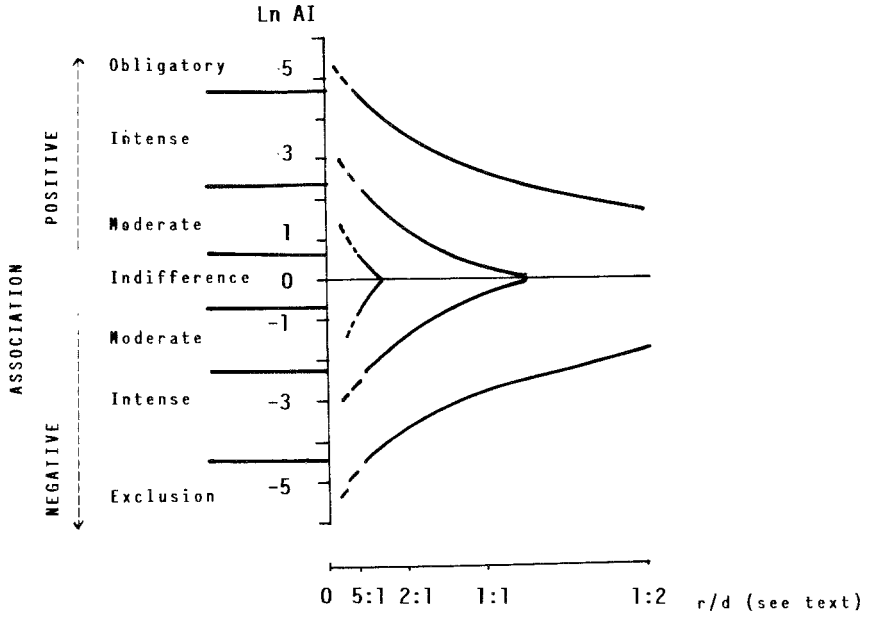

FIG. 3. Theoretical variation of AI with distance from the emitter plant in the case of two-dimensional dispersion at a slope site.

cal's activity on distance under the assumption that dispersion takes place in two dimensions (s/s').

In the idealized model considered in the previous paragraph, the decline in the activity of the allelochemical is due simply to the reduction in its concentration as the area or volume to be impregnated increases. If losses due to infiltration, retention by soil, and degradation by microflora are also taken into account, it seems very unlikely that allelochemical agents transported through the soil can have any appreciable effect at distances greater than one emitter plant radius from the edge of the emitter's projection area. Agents dispersed by other means, such as animals or wind, could of course be effective over much larger areas (Lamont, 1985).

Reasoning along the lines sketched above explains how the association between two species may change sharply within very short distances (Figure 4) and why it is necessary to use sampling intervals of the order of 1 cm in order to analyze the spatial distribution of herbaceous or shrubby vegetation.

INTERACTION BETWEEN *R. obtusifolius* AND MEADOW SPECIES

The theory set forth above was tried out using the field observations of Carral et al. (1988), who, on comparing the results of laboratory bioassays with

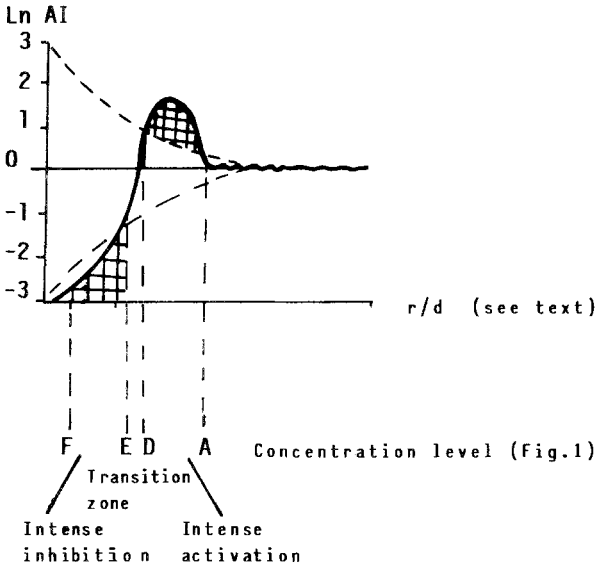

FIG. 4. Illustration of how a radical change in *AI* might be produced over a very short distance (E–D) in response to a hormonal allelochemical.

the observed association between the primary species *R. obtusifolius* and four meadow species, concluded that the invasion of artificial meadow by *R. obtusifolius* and its predominance therein is due to allelopathic mechanisms. The site studied was an artificial meadow located in Santiago de Compostela (42°50′N; 8°27′W) at an altitude of 250 m. According to Papadakis' classification the area has a warm maritime climate with a humid humidity regime. The meadow faces 218°N with a slope of 26 : 100, and its soil is a humic andosol (FAO). Established five years ago with a mixture of *Lolium perenne*, *Trifolium repens*, *Dactylis glomerata*, and *Poa pratensis*, it is periodically treated with slurry and with mineral fertilizer rich in nitrogen and phosphorus.

The spatial distribution of meadow species relative to 160 randomly chosen *R. obtusifolius* plants greater than 20 cm in diameter was studied by considering two 1-m transects drawn radially from the outer edge of each plant's projection area, one in the direction of maximum upward slope and the other diametrically opposite. A 1-m needle frame was placed over the transects, and the vegetation at ground level sampled at 1-cm intervals. The R_1s used to investigate the dependence of *AI* on distance were overlapping 10-cm segments of the transects (0–10, 5–15, 10–20 cm, etc.). R_2 was the segment of the transect comprising the 50 cm furthest from the *R. obtusifolius* plant (the validity of this was checked in preliminary experiments).

Figure 5 shows the ratio between total cover at various distances from *R. obtusifolius* and the mean total cover of the site. *L. perenne* accounts for 48% of the latter figure, *T. repens* for 18%, *D. glomerata* for 13%, and *P. pratensis* for 8%. The remaining 13% is provided by *R. obtusifolius* and the minority species *Stellaria media*, *Plantago lanceolata*, *Hypochaeris radicata*, *Capsella*

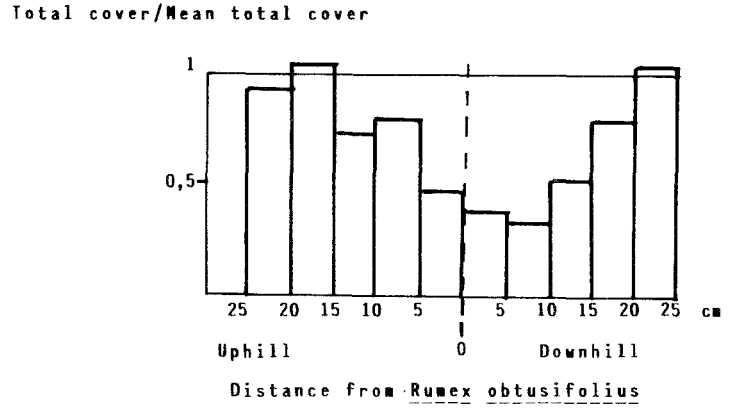

FIG. 5. Variation of relative cover with distance uphill and downhill from *Rumex obtusifolius*.

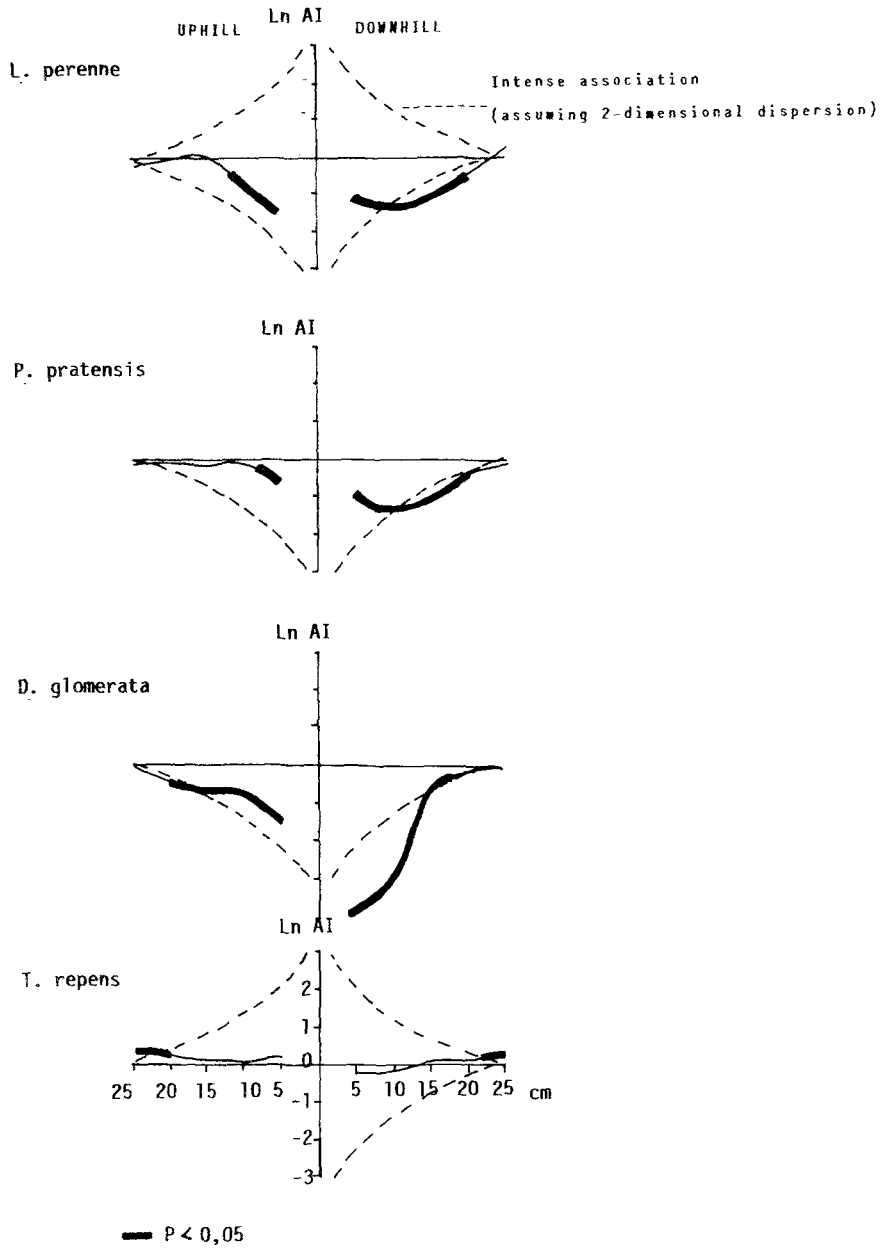

FIG. 6. Influence of distance uphill and downhill from *Rumex obtusifolius* on the *AI* between this primary species and four meadow species. Bold segments indicate that the *AI*s are statistically significant ($P < 0.05$), and dashed curves show the theoretical threshold of intense affinity for two-dimensional dispersion in the absence of slope (see Figure 3).

bursa-pastoris, *Cerastium* sp., and *Geranium* sp. In keeping with the hypothesis being tested, the thinning produced by *R. obtusifolius* can be seen to be of greater intensity and range downhill than uphill and to be limited in either case to a radius of 25 cm (the mean radius of the *R. obtusifolius* plants was 21 cm, with a minimum of 10 cm and a maximum of 36 cm).
