(Received August 18, 1986; accepted December 17, 1986)

Abstract—Levels of phenolic secondary metabolites in the leaves of four west African rain-forest plants, *Acacia pennata*, *Cynometra leonensis*, *Diopyros thomasii*, and *Trema guineensis*, were correlated with incident light intensity at both the inter- and intraindividual level. Enhanced phenolic levels under high light intensity appeared to be due to production of both polyphenolics (condensed and hydrolyzable tannins) and simple phenolics. In *Trema guineensis*, where it is possible to separate leaves in terms of both their age and the light incident upon them, condensed tannin production progressed differently during the development of "sun" and "shade" leaves, suggesting continuing production of new oligomers in the former but not in the latter. The results of this study suggest that the production of phenolics in relation to variation in incident light is a finely tuned process, which must be explained in terms of plant physiology and intermediate metabolism rather than in terms of resource allocation or a direct response to herbivory.

Key Words—Phenolics, tannins, light enhancement, overflow metabolism, *Acacia pennata, Cynometra leonensis, Diopyros thomasii, Trema guineensis.*

INTRODUCTION

Considerable emphasis has been placed on the role of phenolic compounds, particularly polyphenolics (e.g., tannins), in the defense of plants against herbivores (Feeny, 1970; 1976; Rhoades and Cates, 1976; Rhoades, 1979; Baldwin and Schultz, 1983; Zucker, 1983; Harborne, 1985). The mode of action

0098-0331/88/0100-0001$06.00/0

generally associated with tannins has been that of digestibility reduction, providing plants with a quantitative defense (sensu Feeny, 1976) against herbivory by sequestering the protein in herbivore diets as insoluble tannin–protein complexes or by inhibiting digestive enzymes (Rhoades, 1979; Pierpoint, 1985). While there is considerable evidence for avoidance of high levels of tannins in food selection by many mammalian herbivores (Mole and Waterman, 1986), convincing support for digestibility-reducing effects has not generally been forthcoming from in vivo studies (Bernays, 1978; Berenbaum, 1983; Mole and Waterman, 1986), and evidence at the molecular level now indicates that animal digestive systems have evolved ways to counter the potential antinutritional effects of tannins on dietary proteins (Martin and Martin, 1984; Mehansho et al., 1985; Mole and Waterman, 1985). In short, the notion (Feeny, 1976; Rhoades and Cates, 1976) that tannins provide plants with a costly but relatively impregnable defense against herbivores is compromised by currently available evidence. While the production of tannins by a species may be optimized at a constant constitutive level, there is evidence that the quantities produced by an individual are variable and may be under metabolic control (Schultz, 1983; Baldwin and Schultz, 1983). On the assumption that such variation is of adaptive value in terms of plant fitness, then an understanding of the conditions that influence the production of tannins may help us appreciate their role(s).

If it is accepted that tannins have no metabolic or physiologic roles, it is in terms of constraints upon availability of fixed carbon and energy for their metabolism that explanations for their level of production will have to be sought. The starting point for the present work is the report (Waterman et al., 1984) that individuals of the tree *Barteria fistulosa* (Passifloraceae) growing in rainforest clearings respond to the higher light intensity of that environment by an increase in levels of phenolics in their foliage in comparison to individuals growing under the forest canopy. Specifically, the condensed tannin component of foliar total phenolics was shown to be enhanced by high light intensity. Waterman et al. (1984) suggested possible explanations for this phenomenon in terms of passive or active response of biosynthetic processes directly to variation in the light environment or indirectly to variability of herbivore pressure on *B. fistulosa* situated in different light environments. Given the highly effective defense *B. fistulosa* obtains against insect herbivores through an obligate mutualistic association with pseudomyrmicine ants (Janzen, 1972) a direct relationship between light intensity and condensed tannin production was considered the more likely explanation in this case.

A positive association between increasing light intensity and levels of phenolics has been recognized for some time (Hillis and Swain, 1959; McClure, 1985), but only in the last few years has it received attention in the ecological literature. Woodhead (1981) showed that the total phenolic content of *Sorghum*

bicolor increases with high light intensity. Hanley et al. (1986) found that black-tailed deer prefer sympatric shaded conspecifics over their insolated counterparts and that tissues from shaded foliage had lower phenolic concentrations. Waring et al. (1985) and Larsson et al. (1986) both reported decreases in foliar tannin and phenolic glycosides in shaded willow foliage preferred by chrysomelid beetles. Bryant (personal communication) studied the effect of light on the phenol chemistry of *Salix alaxensis* and found that shading contributes to a lowering of phenolics and an increase in palatability, the eventual result of which is the replacement of the willow by less palatable alder (*Alnus* sp.). One plausible explanation for the apparent association between light intensity and phenol production arises from the "resource allocation hypothesis" (Coley et al., 1986; Bryant, 1986). On this basis it can be argued that a reduction in light intensity will lead to a lower level of photosynthesis and consequent decline in carbohydrate production. As nutrient uptake is not similarly influenced, the result is a net decrease in the C/N balance (Bryant et al., 1983) in the shaded leaf, resulting in lower levels of C-based metabolites, including phenolics.

If a plant's light environment does exert a major influence on the output of phenolic metabolites, then the impact of herbivores in determining the level of investment in plant secondary metabolism may not be as great as is generally thought (Bell, 1978; Fraenkel, 1959; Harborne, 1985; McKey, 1979), at least for phenolic compounds. We have sought to test the importance of light intensity in influencing the relative and absolute quantities of phenolic allelochemicals accumulated by plants. The subjects of our study were individuals of four west African rain-forest species: (1) *Acacia pennata* DC (Mimosaceae), a spiny climber found growing in light gaps in recently regenerated secondary forest; (2) *Cynometra leonensis* Hutch. & Dalz. (Caesalpiniaceae), a large forest tree that produces abundant epicormic shoots and thus provides easily accessible foliage; (3) *Diospyros thomasii* Hutch & Dalz. (Ebenaceae), a small understory tree growing 5–10 m high; and (4) *Trema guineensis* (Schum. & Thonn.) Ficalho (Ulmaceae), a small tree found in open secondary regrowth on disused farmland.

Our analysis extends beyond that of Waterman et al. (1984) in two ways. First, we examined responses to light within, as well as between, individuals of a species. The reason for this approach lies in the many reports indicating the adaptive within-plant distribution of chemical defenses (McKey, 1979) which thus make it important to demonstrate a response to the physical environment on a similar scale. Second, we examined the influence of light over a much narrower variation in intensity than the gross insolated–shaded comparison employed for *Barteria fistulosa*. The species chosen for the study were generally restricted to either closed or open canopy vegetation types. Thus, by the criteria adopted for *Barteria*, all individuals of both *D. thomasii* and *C.*

leonensis would be regarded as shaded and all individuals of *T. guineensis* as insolated. *A. pennata* was intermediate, occurring in the widest range of light intensities.

METHODS AND MATERIALS

The study site was located in Sierra Leone, on Tiwai Island (12,000 hectares, 7°33′N 11°21′W) situated in the Moa River, some 60 km inland from the Atlantic Ocean. The island carries no permanent settlement, and about half its area supports 40- to 60-year-old secondary high forest (Cole, 1968), in which leguminous species predominate (e.g., *Cynometra leonensis*, *Piptadeniastrum africanum*, *Pentaclethra macrophylla*). The remaining vegetation is a mosaic of swamp, riverine, and young secondary forest types, together with some recently farmed land. Mean annual rainfall in the area is 3300 mm. Species identifications were made with reference to previously identified specimens growing on site and to Hutchinson and Dalziel (1958) and Savil and Fox (1966).

Measurements of Light Intensity. Individual plants were selected for their possession of branches in relatively sunny and/or shaded positions that could be reached from a 6-m ladder. Once located, suitable groups of leaves were tagged for reference. Whenever possible, shaded and unshaded leaves were chosen from the same plant, but this was not always feasible and single sets of leaves were occasionally taken from individual plants. Tagged leaves were made the object of light-intensity measurements over a period of five days. On each day, measurements of the light incident upon each set of leaves studied were made by placing a piece of white card over them and recording the f-stop and shutter speed required to expose 50 ASA film in a Minolta X300 camera fitted with a 50-mm lens and aimed at the card. These measurements were timed at each set of leaves, and taken at intervals of about 2 hr throughout the daylight period. They were used for comparison with recordings made at 10-min intervals during the day using an identical camera aimed at an identical piece of card placed in a large open clearing. This second set of readings was defined to be a measure of total light incident upon the vegetation. By converting camera settings to foot-candles, using a Weston light meter dial, these data allowed an estimation of the percentage of available light (LIGHT) that reached the leaves under study. This percentage of available light was obviously not constant throughout the day for a given sample of leaves, as it was dependent upon solar movements in relation to openings in the surrounding canopy. However, by averaging all readings taken during each day, for all five days of sampling, an estimate of the percentage of available light reaching each set of leaves was calculated. This is not intended as an absolute measure, or even one linearly

related to solar irradiance, but one that will allow variation in light intensity to be assessed on a continuous scale.

Collection and Preparation of Foliage. On completion of light intensity measurements, leaves were collected and sun dried, the drying process being initiated within 1 h of collection. For *T. guineensis*, which has simple alternate leaves borne on long straight branches with the youngest leaves at the single apex, leaves were separated into the following age classes: "young," the six leaves over 2 cm long closest to the apex; "mature," the next six older leaves; and "old," the remaining older leaves if present. For the other three species, leaf sets were matched for age only to the extent that selection was restricted to visibly mature leaves. Dried leaves were sealed in air-tight bags and returned to the laboratory for chemical analysis. In the laboratory, samples were ground to give a maximum particle size of 1 mm before chemical analysis.

Analysis for Phenolics, Fiber, and Protein. Samples were assayed for their content (% dry wt) of total phenolics (TP), condensed tannins (CT), and nitrogen (N). Total phenolics were estimated using the Folin-Denis method on extracts prepared in 80% aqueous methanol under reflux and are expressed in terms of tannic acid. Condensed tannins were estimated using a sample of the same extract and the proanthocyanidin method, with results expressed in terms of quebracho tannin. The details of the assay procedures have been described by Gartlan et al. (1980). The nitrogen content of the ground samples was measured by the Kjeldahl method with crude protein (PROT) being estimated as N% $\times$ 6.25. Acid detergent fiber was estimated by the standard technique (Waterman et al., 1984).

An additional estimation of CT was made using the vanillin method following Butler et al. (1982). Extracts were prepared by adding 10–20 ml of the milled dry leaf to a 100-ml conical flask containing 25 ml of 70% aqueous acetone to wet the material. Then 25 ml of diethyl ether was added, and the flask was stoppered and set to shake on an orbital mixer for 24 h. At the end of this time, the resulting solution was filtered and then separated with the lower aqueous layer being returned to the flask and freeze dried. The lyophilized powder was then analyzed for CTs by the proanthocyanidin method used above, and also by the vanillin assay using both methanol (Burns, 1971) and glacial acetic acid (Butler, 1982) as solvent.

Chromatography of Extracts. Approximately 100 mg of the powdered extract was added to 4 ml 2 M hydrochloric acid and the mixture heated to 100°C for 30 min. The resulting hydrolysates were cooled and extracted with amyl alcohol (1 ml). The amyl alcohol extract was then chromatographed on cellulose (paper, Whatman No. 3; or thin layer) and developed with Forestal solvent (glacial acetic acid–water–conc. hydrochloric acid, 30:10:3). Red-colored spots that turned blue in daylight when exposed to ammonia vapor were iden-

tified as cyanidin (R_f 0.45–0.55) or delphinidin (R_f 0.30–0.37). Ellagic acid gave a spot intermediate in R_f between cyanidin and delphinidin, which appeared blue under UV light and yellow under UV after brief exposure to ammonia vapor. Gallic acid was identified by its high R_f value and by turning brown on long exposure (30 min) to ammonia vapor. Where gallic acid was detected, a repeat chromatogram was obtained for an unhydrolyzed sample so as to check for the occurrence of free gallic acid in the extract. All named compounds were compared directly with authentic markers obtained from Koch-Light Ltd., Edinburgh.

Estimate for Hydrolyzable Tannin (HT). This estimate of HT levels is described in detail by Mole (1986). It makes use of a blue-colored complex (max. 660 nm) formed between ferric chloride and HTs (cf. green color produced with CTs and the hydrolysis products of HTs). The reduction in absorbance at 660 nm on hydrolysis of an HT-containing extract thus reflects the amount of HT that was present in the original extract. Measuring the absorbance of hydrolyzed and unhydrolyzed extracts at 660 nm in the presence of a standard ferric chloride solution permits an estimation of HT content to be made. A major drawback in the technique is that the green complex formed by HT breakdown products also absorbs at 660 nm at about 10% of the intensity of the blue complex. To compensate, the result of the assay is considered to give a loss of absorbance about 10% less than in fact occurs, and final results are modified accordingly.

The estimate is performed using the following method. An accurately weighed portion of the powdered extract prepared for CT polymer length analysis (see above) was dissolved in water and divided into two equal portions of about 5 ml. To one sample two drops of 4 M sodium hydroxide was added; this mixture was heated in a boiling water bath for 2 hr, and the extract was then cooled and neutralized by the addition of two drops of 4 M hydrochloric acid. Both hydrolyzed and unhydrolyzed samples were then assayed as follows.

At time zero, 500 μl of the extract was added to 3.5 ml of ferric chloride solution (1.62 g anhydrous ferric chloride dissolved in 1 liter 0.001 M hydrochloric acid) in a cuvette. The contents of the cuvette were mixed rapidly and the absorbance read at 660 nm, 15 sec after addition of the extract. Reagent-only blanks were used to zero the spectrophotometer. Readings were only considered valid in the range of 0.05–1.00 absorbance units; all results were duplicated.

RESULTS

The amount of incident light received by leaves of the four species varied from an average of 7% for *D. thomasii* to 81% for the shade leaves and, by definition, 100% for the sun leaves of T. *guineensis*. The data for the shade leaves of *T. guineensis* (sampled exclusively from the basal foliage of the trees)

is approximate as inclement weather prevented a full five-day sampling program. On the available data, a statistical analysis (Mann-Witney U test) revealed that the median values of available light (LIGHT) were significantly different for every possible interspecies comparison ($P < 0.05$). The following is a description by species of the relationships found between light intensity and the chemical measurements made on the samples of whole leaf material. Basic statistics for levels of TP, CT, ADF, PROT, and incident LIGHT are given in Table 1.

Acacia pennata. Samples were taken from a total of 10 individual plants which provided eight paired samples for within plant comparisons of the effect of light intensity on leaf chemical composition. Scatter graph plots for LIGHT versus TP and CT levels are presented in Figure 1a and b. Positive correlations are clearly evident, indicative of phenolic production increasing as light intensity increases. The correlation coefficients among these three variables are (1) LIGHT vs. TP, $r = +0.73$; (2) LIGHT vs. CT, $r = +0.81$; and (3) TP vs. CT, $r = +0.86$; all these being associated with a high degree of statistical confidence ($P < 0.001$). The above analysis could simply reflect gross interplant differences. However, paired samples taken from the same plant (paired sample t test; Campbell, 1974) show that there are significantly more total phenolics and condensed tannins in the leaves receiving the higher light intensity within any given individual ($P < 0.01$). No correlations were found between LIGHT and either PROT or ADF.

Cynometra leonensis. A total of 11 individual trees, which again provided eight paired samples for within plant comparisons, were studied. Scatter graph plots for the whole data set are given in Figure 1c and d, where positive correlations are again evident between LIGHT, TP, and CT (LIGHT vs. TP, $r = +0.69$, $P < 0.01$; LIGHT vs. TP, $r = +0.72$, $P < 0.01$; TP vs. CT, $r = +0.84$, $P < 0.001$). The analysis of the paired data also showed the same within-plant variations as before ($P < 0.01$). However, for this species, significant negative correlations (in the whole data set) were found between PROT and TP ($r = -0.65$, $P < 0.05$) and between PROT and CT ($r = -0.62$, $P < 0.05$) but not between LIGHT and PROT ($r = -0.30$). There was no correlation between LIGHT and ADF.

Diospyros thomasii. Samples were taken from 25 trees with 12 paired samples. The scatter graphs for the data set are presented in Figure 1e and f. Correlations between TP, CT, and LIGHT were: TP vs. LIGHT, $r = +0.65$, $P < 0.001$; CT vs. LIGHT, $r = +0.79$, $P < 0.001$; TP vs. CT, $r = +0.74$, $P < 0.001$; showing the same pattern as *A. pennata* and *C. leonensis*. The analysis of paired samples also confirmed the relationship noted above ($P < 0.01$). No significant correlation was found between PROT or ADF and any other variable.

Trema guineensis. In the absence of light measurements on a continuous

TABLE 1. MEANS (AND RANGES) FOR LEVELS OF TOTAL PHENOLICS (TP), CONDENSED TANNINS (CT), ACID DETERGENT FIBER (ADF), AND PROTEIN (PROT) IN FOUR STUDY SPECIES (AS % DRY WEIGHT) AND INCIDENT LIGHT MEASURED ON THEIR LEAVES

Measure	*Acacia pennata*	*Cynometra leonensis*	*Diospyros thomasii*	*Trema guineensis*
Number of samples	18	15	31	48
TP	5.16 (2.30–8.23)	6.20 (4.91–7.26)	5.81 (2.63–11.54)	1.92 (0.78–3.62)
CT	13.29 (3.83–31.37)	13.16 (6.27–25.59)	5.57 (2.94–12.73)	8.23 (1.59–17.99)
ADF	56.1 (49.9–60.1)	44.7 (38.7–50.8)	51.5 (30.0–64.4)	45.2 (31.8–55.6)
PROT	18.43 (15.18–29.90)	18.43 (16.07–21.39)	13.07 (10.70–15.77)	15.11 (6.92–25.43)
LIGHT	28.10 (4.65–57.93)	14.41 (2.57–39.78)	6.43 (1.03–27.90)	[a]

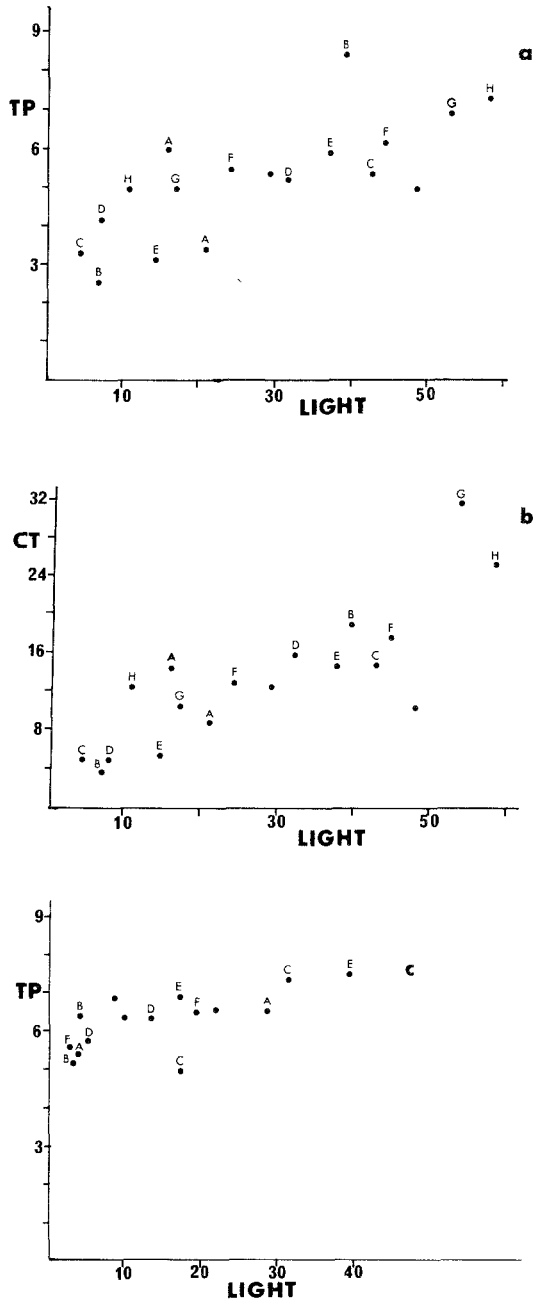

FIG. 1. Scatter graphs of foliar TP and CT (% dry weight) against light intensity (LIGHT) for *Acacia pennata* (a and b), *Cynometra leonensis* (c and d) and *Diospyros thomasii* (e and f). Paired samples, taken from high and low light intensity on an individual tree, are identified by the letter over the point.

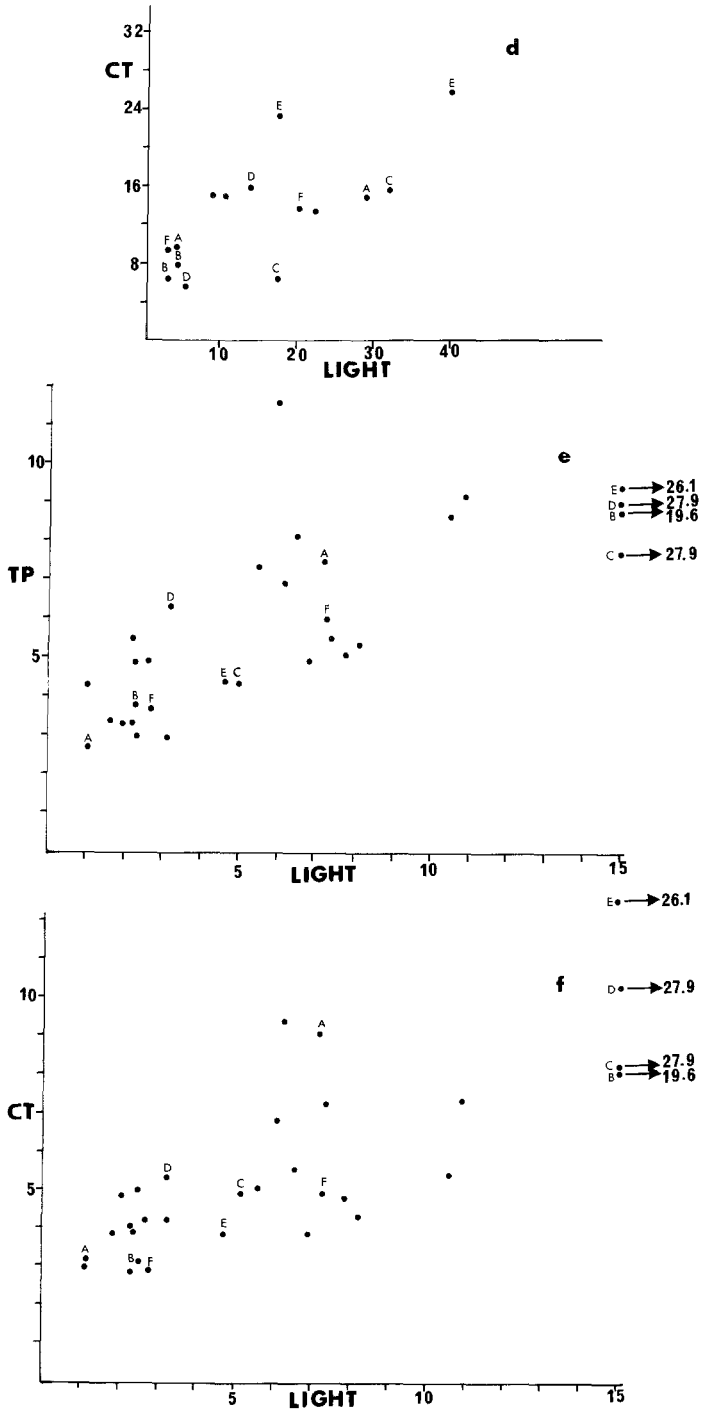

FIG. 1. (*Continued*)

scale, paired samples of leaves were taken from "sun" and "shade" positions on each of eight trees. Table 2 gives summary statistics for leaves in each light environment and for each of the age classes previously defined. Irrespective of leaf age class, "sun" leaves have greater quantities of TP and CT than "shade" leaves. With the single exception of CT in "old" leaves, all these differences are statistically significant ($P < 0.05$). The correlation coefficient between TP and CT was again high ($r = +0.73$, $P < 0.001$) for the whole data set. The correlation coefficients for the age–light classes showed considerable variation (Table 2). ADF levels, as would be anticipated, increase with age.

Identification of Foliar Polyphenolics. The first step in the analysis of the extracts was to examine their acid hydrolysates by chromatography, and a species by species analysis of the results follows.

For *Acacia pennata*, as only 19 extracts were available, each was analyzed. In every case distinctive spots for cyanidin (Pc) and delphinidin (Pd) were evident and typically of an approximately equal color intensity (relative to each other as gauged by eyesight). This means that, for the whole species sample, the CT estimate will be higher than in species where the CT is wholly or predominately Pc, because Pd gives a higher A_1^1 than Pc. Consequently a

TABLE 2. COMPARISON OF LEVELS OF TP, CT, ADF, AND PROT IN "SUN" AND "SHADE" LEAVES OF *Trema guineensis*, BY AGE CLASSES OF LEAVES (EIGHT PAIRED SAMPLES IN EACH AGE/LIGHT CLASS COMPARISON; STANDARD DEVIATIONS IN PARENTHESES)

Measure[a]	Leaf age	"Sun" leaves	"Shade leaves"
TP	young	2.72 (0.39)	1.42 (0.46)
	mature	2.32 (0.22)	1.75 (0.57)
	old	2.03 (0.43)	1.49 (0.20)
CT	young	14.11 (2.73)	5.96 (1.72)
	mature	9.56 (1.30)	5.54 (2.04)
	old	7.99 (2.01)	6.19 (2.05)
r[b]	young	+0.51	+0.72[c]
	medium	−0.25	+0.33
	old	+0.90[d]	+0.35
ADF	young	40.7 (5.66)	41.3 (4.67)
	medium	43.8 (3.61)	46.9 (3.59)
	old	49.2 (3.82)	49.2 (4.17)
PROT	young	18.59 (2.21)	18.03 (1.47)
	medium	14.46 (1.23)	15.30 (2.54)
	old	11.10 (1.53)	12.55 (1.84)

[d] $P < 0.01$.

CT/TP ratio will overestimate the CT contribution. For plant-to-plant comparisons within the species, on the other hand, the CT/TP measure is not greatly biased by the Pd/Pc ratio of the tannins present. However, four extracts yielded an overwhelming predominance of Pd. Two of these were from relatively insolated leaves and two from relatively shaded leaves. Interestingly, these represented collections from four individuals in which the paired collection did not exhibit a corrspondingly high Pd/Pc ratio. Such samples thus constituted a real but unassignable cause of variation. All the extracts also gave a faint spot that was tentatively identified as ellagic acid, suggesting the presence of a trace amount of HT in the extract.

For *Cynometra leonensis*, a random sample of 15 extracts was selected for chromatography, and in each case a distinct spot for Pc was observed together with a very faint spot for Pd. This suggests that Pd does not influence the analysis to any great extent in this species.

For *Diospyros thomasii*, a subset of extracts was analyzed, and all gave the same pattern. A strong spot was observed for Pc, but not Pd could be detected. All samples also gave intense spots for both ellagic acid and gallic acid, indicative of the presence of hydrolyzable tannins. Neither gallic acid nor ellagic acid were observed in chromatograms run prior to hydrolysis.

Trema guineensis gave the same pattern for anthocyanins as *C. leonensis*. The spot indicative of ellagic acid was present in all extracts, both hydrolyzed and unhydrolyzed. *T. guineensis* may therefore contain free ellagic acid rather than hydrolyzable tannin.

Condensed Tannin Polymer Lengths. To complete the analysis of CTs in the extracts, their polymer lengths were estimated by the method of Butler et al. (1982) and by use of the ratio of proanthocyanidin to vanillin (in methanol) assays (Goldstein and Swain, 1963), so as to produce the estimates P1 and P2 (for definition of P1 and P2 see Table 3). Data for mean polymer lengths of the CTs grouped according to species, irrespective of other variables (e.g., light or leaf age) are given in Table 3.

The first point of note is the considerable variability of the data as seen from the standard deviations. While the use of ratios in polymer length estimation will compound errors over individual measurements, their use has been shown to be of practical value, and it is reasonable to assume that the observed variability does reflect the presence of a wide range of polymer lengths within the CTs of each species. As a consequence, interspecific variation is not generally significant, the only exception being for P1 between *A. pennata* and *C. leonensis*. On further inspection of the data, no clear trend in polymer lengths dependent on LIGHT could be found for any species. However, with *T. guineensis*, leaf age was recorded as well as LIGHT and, when the interaction between these two factors was taken into account, a more subtle pattern in polymer length variation was uncovered. Given that the data set was incom-

TABLE 3. ESTIMATES (P1 AND P2) OF CONDENSED TANNIN POLYMER LENGTHS (STANDARD DEVIATIONS IN PARENTHESES[a])

Species	N(P1)	P1	N(P2)	P2
Acacia pennata	18	0.77 (0.09)	18	12.3 (2.99)
Cynometra leonensis	23	14.8 (2.54)	25	16.5 (5.76)
Diospyros thomasii	51	8.8 (1.22)	52	6.9 (9.65)
Trema guineensis	32	8.6 (2.12)	29	29.9 (10.9)

[a] P1 = $CF \times L$, where $CF = A_1^1$ of tannin/A_1^1 of standard CT from *Pinus radiata*, $L = A_1^1$ catechin/A_1^1 of tannin. P2 = A_1^1 of tannin in procyanidin assay/A_1^1 of tannin in vanillin assay.

plete, an ANOVA analysis was not possible, and so differences in polymer length (ΔP1 and ΔP2) were calculated between leaf samples of different age and light classes taken from individual trees. Table 4 shows the mean difference in polymer length between sun and shade leaves with change in leaf age. Also given are the mean differences between sun and shade leaves within the three age classes. From these data, it can be seen that, for both measures, there is a considerable difference in polymer length in relation to leaf age. The other suggestion that emerges from these results is that, in high insolation, polymer length appears to increase consistently with age; in shade, average polymer length, while possibly greater in young leaves, does not increase as much during maturation. This may be interpreted in terms of light-enhanced CT production leading initially to the formation of the greater number of short polymers, which then elongate and surpass the polymer length in shade leaves as higher input of CT occurs in light environments.

Hydrolyzable Tannins. According to the analyses employed, only *D. thomasii* was a significant HT-producer. If HTs were present in the other species, quantities were so small as to be masked by CTs in the assay procedure. As

TABLE 4. CHANGES IN CONDENSED TANNIN POLYMER LENGTHS FOR "SUN"/"SHADE" AND LEAF AGE SUBGROUPS IN *Trema guineensis* (STANDARD DEVIATION IN PARENTHESES)

Leaf type	Comparison	N(P1)	ΔP1	N(P2)	ΔP2
Sun	young to old	15	8.10 (2.63)	13	11.40 (4.98)
Shade	young to old	11	4.55 (2.75)	10	−7.23 (7.99)
Young	sun to shade	7	21.80 (3.45)	5	5.49 (1.59)
Mature	sun to shade	5	1.37 (0.35)	7	3.80 (7.25)
Old	sun to shade	5	−5.04 (1.57)	7	−6.04 (5.69)

[a] ΔP1 and ΔP2 refer to mean change in polymer length value in going from the first to the second variable.

CTs were known to increase as a function of the light intensity incident upon the leaves, and if HTs were to increase in step with this, then the CT/HT ratio should be a constant, independent of LIGHT. The ratio CT/HT was calculated for *D. thomasii* extracts and its dependence on LIGHT investigated. The CT values employed were from measurements made upon the same lyophilized extract as the methanol extract used for the previous CT assays.

The mean CT/HT ratio for extracts from leaves exposed to the lowest light intensities was 4.34 (SD = 1.49, n = 13) and for leaves exposed to the highest light intensity it was 3.20 (SD = 1.58, n = 14). The inference is that under higher levels the quantity of CTs actually decreases in proportion to HTs, suggesting that a greater rise in HT (versus CT) occurs in sun leaves. However, the difference between the means for CT/HT just fails to reach significance at the 5% level, and it can only be concluded that net HT production increases approximately in proportion to CT production as ambient leaf light intensity increases.

DISCUSSION

The results show that for all four species there is, without exception, an increase in levels of TP and CT with increased light intensity. This occurs within and between individual plants. These differences are found in species restricted to near maximal or to relatively low ambient light intensities. Thus, this phenomenon holds within and between individuals that would all be classed as either shaded or insolated by the subjective standards of the *Barteria fistulosa* study (Waterman et al., 1984). As with *B. fistulosa*, there is no comparable relationship apparent between light intensity and fiber levels. Unlike *B. fistulosa*, there is no significant correlation between protein and light intensity. A possible explanation of this is that in these examples differences were examined in terms of light levels in a single environment, while the *B. fistulosa* study used individuals from two distinct environments (light gaps and understory) in which edaphic nutrient levels could be appreciably different.

Waterman et al. (1984) assumed that the response to the light environment by *B. fistulosa* was not due to genetic differences between individual plants. Clearly, for the four species studied here, this assumption is correct because the response has been observed within a single plant. It would thus seem that the induction of phenolics observed in this study is a physiologic response by individual leaves or branches to their position on the plant. Furthermore, the results for *T. guineensis* show that the response occurs for leaves of all ages and that, on a more subtle level, the light environment affects the difference in chemical composition between leaves of different ages.

These findings indicate that light-induced variation in the production of

phenolics is a finely tuned phenomenon. The hypothesis that increased investment in phenolics is a function of resource availability (Coley et al., 1985), while offering a plausible explanation for interplant variation, does not satisfactorily explain the intraplant variability observed here. At this detailed level it seems more appropriate to consider the phenomenon in relation to plant physiology per se, rather than in terms of microenvironment or plant–animal interactions. This is not to discount the resource allocation hypothesis, but rather to view the intraplant variation we observe as taking place within the broader metabolic parameters laid down by that hypothesis.

The significant correlations between LIGHT and CT, and TP and CT are strongly suggestive that the increase in TP is primarily one of increase in CT. However, a first indication that this does not satisfactorily explain all variation is seen in the wide variability in the correlation coefficients between CT and TP for the different light–age classes of *T. guineensis* (Table 2). This suggests changes in other phenolics may well be involved for this species at least. Given that CT is not the only phenolic component of plant material, then if only CT increased with light, the ratio of the two variables (CT/TP) should also increase, as CT becomes a greater proportion of the TP. For the three species where such an analysis is possible, the correlations of LIGHT versus (CT/TP) are as follows: *A. pennata*, $r = +0.77$, $P < 0.001$; *C. leonensis*, $r = +0.66$, $P < 0.01$; *D. thomasii*, $r = +0.12$, NS. In the first two instances, it would indeed seem that the proportion of CT does increase in higher light intensity, but for *D. thomasii* no such correlation occurs. In the latter there is a more general and coordinated increase in the production of phenolics, including HTs. The conlusion that the increase in other phenolics is a coordinated one follows because a disproportionate increase in the other phenolics would have led to a negative value of the correlation coefficient for this species.

Table 5 presents mean values of CT/TP ratios for all four species, and the different age–light classes of *T. guineensis*. By inspection it can be seen that for *T. guineensis* the values for "sun leaves" are not consistently higher than those of "shade leaves." So, applying the arguments used above, other phenolics may be involved in the response to light in this species as well. Of the four species, *T. guineensis* has the greatest proportion of CTs among its phenolics, with the two leguminous species intermediate, and *D. thomasii* with by far the least. On this basis, if other phenolics are involved with *T. guineensis*, then light-dependent changes in other phenolics cannot be ruled out for any of the species.

The hypothesis (Haslam, 1977) that the polymerization of the CTs occurs as an unregulated nonenzymic reaction may be due for review, as Putnam and Butler (personal communication) have found (in vitro) "procyanidin polymerase" activity in *Sorghum* grain. It is thus untimely to attempt a mechanistic interpretation of our results concerning CT polymer lengths. In the present con-

TABLE 5. RATIOS BETWEEN CT AND TP MEASUREMENTS FOR LEAVES FROM EACH SPECIES, WITH DATA FOR *Trema guineensis* FURTHER SUBDIVIDED ACCORDING TO "SUN"/"SHADE" AND LEAF AGE (STANDARD DEVIATIONS IN PARENETHESES)

Species	CT/TP ratio
Acacia pennata	2.44 (0.77)
Cynometra leonensis	2.63 (0.68)
Diospyros thomasii	0.99 (0.26)
Trema guineensis	
All leaves	4.35 (1.46)
Young sun leaves	5.23 (0.99)
Mature sun leaves	4.18 (0.83)
Old sun leaves	3.89 (0.53)
Young shade leaves	4.31 (0.98)
Mature shade leaves	3.42 (1.39)
Old shade leaves	5.06 (1.82)

text, their importance lies in their indication that a plant's light environment affects more than simply the quantity of CT produced. With regard to HTs, this is the first report that light or any other ecological factor affects their production.

At this point it becomes reasonable to consider alternative explanations as to why plants might generally increase their production of phenolics in higher light intensities, particularly as the effect is now established for species in a range of different plant families. The pathways involved in the synthesis of phenolics are related to the three major routes of intermediate metabolism (i.e., the glycolytic and phosphogluconate pathways and the citric acid cycle). The relationships among these processes and the two major types of tannin are slightly different. HTs contain glucose and so may draw directly on the products of primary metabolism (i.e., the Calvin cycle), while their phenolic constituents are derived from an early stage of the shikimate pathway. CTs are produced by the further metabolism of C6–C3 derivatives of the shikimate pathway which consume additional products of intermediate metabolism. About 60% of the carbon in CTs must pass through the reaction catalyzed by the enzyme phenylalanine ammonium lyase (PAL). This reaction is, in metabolic terms, irreversible, and the enzyme is thought to be a point at which metabolic control is exerted (Camm and Towers, 1973).

Hanson and Havir (1981) note that up to 20% of fixed carbon may be subject to metabolism by PAL. Light intensity is included in the factors thought to promote PAL activity either directly or indirectly due to high levels of sugar accumulating in the leaves (McClure, 1985). With respect to the indirect effect,

Margna (1977) provides evidence to suggest that PAL is under substrate level control, which, if it is the case, would explain increased tannin production in high light intensity when there is abundant fixed carbon available. The evidence is therefore favorable to the notion that phenolics, including both types of tannin, could build up in highly insolated plant parts for purely "economic" reasons.

The possible mechanisms involved in the response to light, indicated above, correspond to the hypothesis of Haslam (1985) that secondary metabolites may result from "overflow metabolism" into which excess metabolites may be shunted in times of stress. Haslam (1985) cites evidence that metabolic disorders such as those caused by metal-ion imbalances can result in the accumulation of metabolites, particularly organic acids. An early example was provided by Chesters and Robinson (1951), who regarded the build up of citrate in a zinc-deficient fungal culture as evidence of the organism's inability to completely oxidize carbon to CO_2; this was taken to be a symptom of metabolic malfunction. With regard to tannins, boron deficiency can result in their accumulation (Rajaratnam and Hock, 1975), possibly because this element is involved in the regulation of 6-phosphogluconate dehydrogenase and thus in the regulation of carbon flux into the phsophogluconate, and subsequently into the shikimate pathways (Rajaratnam and Hock, 1975). The similarity of this situation to that reported by Chesters and Robinson (1951) is striking. Further direct evidence that plant nutrient status is important in regulating tannin production is provided by Wilson (1955), Barry and Forss (1983), and Bryant (1987), who have studied tannin production as a function of fertilizer applications. More circumstantially, the evidence that vegetation on poor soils is likely to be rich in phenolics (Janzen, 1974; Waterman, 1983) also supports this case. These effects have been viewed at the level of the whole plant. The intraplant "overflow" observed in this study can be viewed as reflecting a directional stress (rather than a general stress) that leads to the synthesis of compounds that are not readily translocated from the site of formation.

Considering the effects of both light and mineral nutrition on phenol production, a scenario can be envisaged where a plant subject to an external stress that results in imbalances in carbohydrate metabolism might then accumulate an overflowing metabolite (sensu Haslam, 1985). The accumulation of tannin would fit the need for an oxidized product, and, unlike most simple organic acids, tannins may have beneficial effects as allelochemicals. In engineering terminology, tannins are thus viewed as the strain evident as a result of some external stress. Such a view of plant responses to the environment has been proposed by Ayres (1984), and it is one that seems to provide an attractive framework for considering tannins.

Some caution has to be exercised in adopting this position, as metabolic overflow does not necessarily lead to the accumulation of metabolites. For in-

stance, while Haslam (1985) and Hoffman (1985) agree that stress can lead to the citric acid cycle being overloaded by both glycolytic and pentosephosphate pathway metabolites, Hoffman indicates that, due to cyanide-resistant respiration of these metabolites, the accumulation of fixed carbon as phenolics could be prevented. Indeed, not all stresses lead to the accumulation of phenolics or other carbon-rich products, as might be expected from the work of Coley et al. (1985) or Bryant (1987). The accumulation of proline, betaine, or putrescine by water-stressed plants provides a case in point (Treichel et al., 1984).

One final question that should be addressed is why there is no comparable increase in fiber levels related to insolation, particularly in view of the fact that cellulose and lignin formation stems from the carbon-based sector of the nutrient cycle, in the case of lignin via PAL mediation. For the formation of cellulose and related polysaccharides, there appears to be a complex and specific series of control mechanisms (Northcote, 1985), and so there may well be a level of conservatism in these processes that is not seen in simpler PAL-mediated reactions. Lignin production is linked to the process of secondary thickening during cell wall formation, and its rate of synthesis would, therefore, appear to be governed primarily by the formation of the cell wall polysaccharide. In short, cell wall production is a primary process and as such cannot be allowed to exhibit the flexibility afforded to stress metabolic processes.

The arguments presented here are not intended to suggest that all secondary products are overflow metabolites produced in time of stress or that, once produced, phenolics represent a waste of fixed-carbon resources to the plant. Both the possible allelochemical function and possible reentry into metabolism, via turnover, make such assumptions about secondary products unwarranted. Furthermore the production of metabolites as allelochemicals in circumstances of low metabolic stress is not inconsistent with their accumulation as overflow metabolites during stress. The work reported here shows that both HT and CT may be produced for reasons independent of any allelochemical function. The following paper will consider whether these light induced accumulations of polyphenolics are likely to be adaptive at the plant herbivore level.

Acknowledgments—One of us (S.M.) thanks the S.E.R.C. for the award of a scholarship. Dr. J. Bryant, University of Alaska, is thanked for his valuable comments on earlier drafts of this manuscript. The support of Dr. J.F. Oates and Dr. A.G. Davies, Department of Anthropology, City University of New York, during field studies at the Njala University College field station on Tiwai Island is warmly acknowledged.

(Received August 18, 1986; accepted December 23, 1986)

Abstract—The allelochemic activity of the polyphenolics isolated from the leaves of four west African rain-forest plants, *Acacia pennata*, *Cynometra leonensis*, *Diospyros thomasii*, and *Trema guineensis*, was examined by means of protein precipitation experiments to estimate their specific activity as precipitants. Results indicated that light-induced phenol synthesis in the more heavily insolated foliage of a species led to greater protein-precipitating capacity in these leaves. It is considered doubtful that this produced a quantitative difference in protein availability to an herbivore as, on average, even in the most shaded leaves there was sufficient tannin present to precipitate all the foliar protein. However, taking into account the considerable variability inherent in the results obtained and the adaptations herbivores possess to circumvent the antinutritional properties of tannins, it was concluded that shaded foliage was generally likely to present a nutritionally more acceptable food package on a statistical basis but that acceptable leaves could be found from throughout the light continuum encountered in any of the species studied.

Key Words—Foliar phenolics, condensed tannins, light enhancement, protein precipitation, herbivory, variable plant chemistry.

INTRODUCTION

In the preceding paper (Mole et al., 1988) evidence was presented for a positive correlation between the production of phenolic secondary metabolites and incident light intensity in the leaves of four west African plants, *Acacia pennata*, *Cynometra leonensis* (both Leguminosae), *Diospyros thomasii* (Ebenaceae), and

[1] Present address: Department of Biochemistry, Purdue University, West Lafayette, Indiana 47907.

0098-0331/88/0100-0023$06.00/0

Trema guineensis (Ulmaceae). In all four species enhanced phenolic levels in insolated leaves seemed to carry a significant contribution from increased condensed tannin (CT) synthesis; in the case of *D. thomasii* it also included increased production of hydrolyzable tannins (HT).

The ability of tannins to act as antifeedants has been widely considered to occur through their interaction with proteins (Zucker, 1983). The antifeedant activity could be due to astringency of tannins in the mouth (Bate-Smith, 1972; Lea and Arnold, 1978), but most authors assume that tannins exert their activity through inhibiting the action of proteases and other digestive enzymes in the gut and by generally insolubilizing proteins as precipitates (Rhoades, 1979; Mitaru et al., 1984; Sekiya et al., 1984; Beart et al., 1985). Thus it has been widely assumed that animals avoid feeding on tannin-containing plants to avoid inhibiting the processes of digestion.

Martin and Martin (1984) and Mole and Waterman (1985) have shown how tannin-protein precipitates may be solubilized by surfactants naturally present in the gut. While indicating potential adaptations for feeding on tannin-containing plants, this evidence does not show that tannins do not combine with proteins in vivo. Indeed, there is clear evidence that tannins do bind to proteins to form soluble complexes (Van Buren and Robinson, 1969), and so the process of digestion may still be subject to inhibition under conditions where precipitates do not form. Furthermore, evidence indicating that tannins and other phenolics can promote digestion in soluble systems (Neucere et al., 1978; Mole and Waterman, 1985; Oh and Hoff, 1986a) may now need to be reassesssed in light of evidence that tannins have the potential to disrupt sequential proteolytic systems involving inactive zymogen precursors (Oh and Hoff, 1986b).

Thus, none of the available evidence contradicts the notion that tannins will bind to proteins in vivo as they do in vitro, and there is evidence supporting complex formation in vivo (Mitaru et al., 1984). Analysis of feces shows a particular tendency for tannins to prevent digestion of proline-rich proteins ingested in the diet (Eggum and Christensen, 1975; Mole et al., unpublished results). It has recently been proposed (Butler et al., 1986) that mammals might counteract the effects of tannins by means of proline-rich proteins secreted in saliva, binding preferentially with them and so preventing interaction with other proteins.

Recent reviews (Bernays, 1981; Mole, 1986; Mole and Waterman, 1986) suggest that typical insect or mammalian herbivores tend to avoid consuming levels of tannin above an acceptable level for that species. This holds whether the herbivore has a high average intake (tannin specialist) or a low to zero average intake (nonspecialist). There are exceptions, but this generalization holds in the majority of cases.

Thus, despite evidence for counteradaptations (Martin and Martin, 1984; Mole and Waterman, 1985; Butler et al., 1986), the quantitative argument concerning the effects of tannins in vivo still holds true. An excessive intake of

tannin (for a given species) is still liable to overwhelm any endogenous process capable of either nullifying their antinutritional activity or turning tannin–protein binding to the benefit of the herbivore. Given that this is the case, assessment of the concentration of tannins in a food item and its protein-binding capacity remain valuable indicators of their potential as antifeedants.

In this paper we attempt to assess the effects of light-induced variation in tannin levels in the leaves of our four study plants in terms of the potential antifeedant effects of the tannins and the overall value of those leaves as food for a herbivore. To do this we employ in vitro chemical and biochemical assays to illustrate some major variables that, according to present thinking, seem likely to influence selection of food items. The herbivore we consider here could be either vertebrate or invertebrate; the only requirement is that it is deterred from feeding by tannins that are present in food items to a higher extent than they are in the normal diet of that herbivore.

METHODS AND MATERIALS

Experiments were performed on freeze-dried leaf material. The collection and preparation of this material and the assay procedures used for chemical analyses were reported in the previous paper (Mole et al., 1988).

Protein-Precipitating Ability of Extracts. Measurements of the protein-precipitating activity of the extracts followed Hagerman and Butler (1980). Bovine serum albumin (BSA, Sigma fraction V) was prepared as a 5 mg/ml stock solution in a buffer of pH 4.9, which is the protein's isoelectric point. The buffer (170 mM NaCl and 200 mM acetic acid brought to pH 4.9 with NaOH) contained more than sufficient salt to ensure that ionic strength did not limit precipitation.

Measurements of protein-precipitating ability of individual extracts were carried out as follows: A sample of each tannin extract was made up as an aqueous solution in 5 ml of water (concentrations in milligrams per milliliter were uncontrolled and results are expressed in terms of concentration of total phenolics), and 0.5-ml aliquots of this solution were added to each of two centrifuge tubes, one containing 2 ml of "blank" pH 4.9 buffer and the other containing 2 ml of the BSA solution (pH 4.9). The tubes containing the BSA were then centrifuged and the results of total phenolic assays of the supernatant solutions were compared with total phenolic assays (Hagerman and Butler, 1980) of the "blank" buffer so as to calculate the proportion of phenolics present that were not precipitated by BSA. Assays for the proportion of BSA precipitated (%PPT) were also made by the Moore and Stein method (1954, 1968).

After being used for this assay and the HT assay reported in the preceding paper, the aqueous solutions of the extracts for each species that remained unused were bulked and freeze dried again for use in a standard specific activity

assay, where the need to vary the phenolic concentration at will necessitated the use of a powdered extract as starting material.

For each specific activity assay, two sets of 11 test tubes containing 0, 0.5, 1.0, 1.5, ... , 5.0 ml of BSA stock solution were prepared, each tube being made up of 0.5 ml by the addition of "blank" buffer solution. The tannin extract to be assayed was then dissolved in more buffer solution and any insoluble material was removed by decanting or centrifugation. A 0.5-ml aliquot of the clear tannin solution was then added to each of the 22 tubes containing BSA–buffer solution. Fifteen minutes was then allowed for precipitate formation after which the tubes were centrifuged for 5 min at the top speed of a bench centrifuge to pellet the precipitates. The supernatants were assayed for phenolics using the Hagerman and Butler (1980) method and were then discarded. The tube with zero addition of BSA gave no precipitation, and the result obtained from this tube was taken to indicate the total phenolic substances (TPS) present in the assay. The pelleted material was redissolved in 4 ml of 4 M NaOH and heated for 4 hr in a boiling water bath. At the end of this period the hydrolysate produced was neutralized with 4 M HCl and assayed for amino nitrogen by the method of Moore and Stein (1954, 1968). None of the tannin extracts (hydrolyzed or unhydrolyzed) gave detectable reactions for amino nitrogen when tested at the concentrations employed in the experiments.

Experiments were repeated with tannin solutions of an appropriately altered concentration where previously either no precipitation had occurred or where no leveling off in the amount of protein precipitated was seen as the higher BSA concentrations were reached. The 0 to 5 mg/ml concentration range for BSA employed in the experiments was thus used as a "window" through which maximal levels of precipitation of protein by the tannin were found by adjusting the concentration of tannin added to the assays. This resulted in a considerable amount of trial-and-error experimentation.

The specific activity ratio was calculated from the above data following Hagerman and Butler (1980): SA = maximum percentage of BSA precipitated/total phenolics added.

RESULTS AND DISCUSSION

Figure 1 plots the protein-precipitating ability of extracts from the foliage of each of 68 individual collections of *D. thomasii* leaves. This species was chosen for illustration because the extracts showed a considerable range in concentration of phenolics and gave protein precipitation from near zero to a maximum level at which all available protein was precipitated. Total precipitation appeared to be attained with phenolic levels equivalent to about one absorbance unit but variation was considerable. With the assay procedure used, one absorbance unit was equivalent to 0.91% tannic acid, 2.22% *Pinus radiata* CT,

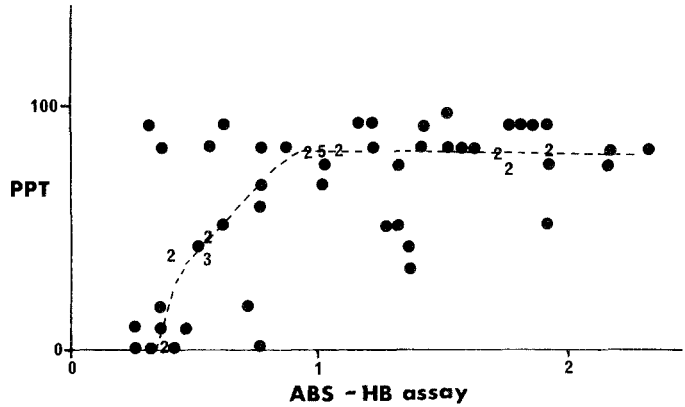

FIG. 1. Precipitation of bovine serum albumin by extracts of *Diospyros thomasii*. The percentage of the maximum recorded amount of protein precipitated (%PPT) is plotted against the phenolic content of the extract as estimated from the Hagerman and Butler (1980) assay for total phenolics (values as absorbance units). Dots represent single results, numbers indicate more than one coincident points.

or 3.3% quebracho CT. Variability in astringency as a function of a single chemical measure is presumably due to intraspecific variation in the qualitative composition of the plant phenolics, which obscures any consistent relationship between the two variables. Within this data set a comparison of high and low light-intensity collections from within an individual tree failed to show any consistent differences other than those anticipated from the relative amounts of phenolics they contained.

Among the other three species, analyses showed a similar pattern in *T. guineensis* but a much narrower range of phenolic levels in the other two species. *A. pennata* samples gave consistently high absorbance values (>0.75) and precipitation values approaching 100%, whereas *C. leonensis* gave low values (<0.75) and generally low but variable levels of precipitation. Table 1 gives average precipitation levels and percentages of phenolics left in solution after precipitation for each species after they had been separated into two groups according to whether the absorbance value in the phenolics assay was greater than 0.75 (sufficient to give near maximum precipitation of protein) or less than 0.75.

Table 2 gives the figures for the specific activity (SA) of the phenolics for each species together with values for the overall level of phenolics present (T/PS) and the percentage of those phenolics that enter into the precipitate (%T). It must be remembered that these results are obtained for bulked extracts for each species and thus represent very crude means. Evidence from the preceding experiments suggest that, at least for *D. thomasii* and *T. guineensis*, the standard deviation in SA values measured for each collection would be very large.

TABLE 1. MEANS AND 95% CONFIDENCE LIMITS (IN PARENTHESES) FOR PHENOLIC CONTENT OF EXTRACT SOLUTIONS; QUANTITIES OF BSA THEY PRECIPITATE (PPT); AND PROPORTION OF NONPRECIPITATING PHENOLICS IN EXTRACTS (NPP)

Species	Phenolics[a]	PPT (%)	NPP (%)
Samples with high levels of phenolics			
Acacia pennata	1.00 (0.32)	71 (26)	41 (8)
Diospyros thomasii	1.00 (0.10)	87 (5)	19 (12)
Trema guineensis	0.87 (0.10)	66 (23)	40 (16)
Samples with low levels of phenolics			
Cynometra leonensis	0.36 (0.09)	11 (18)	57 (53)
Diospyros thomasii	0.34 (0.05)	30 (34)	78 (24)
Trema guineensis	0.38 (0.08)	19 (14)	79 (18)

[a] Phenolics given as terms of absorbance values using the ferric chloride assay of Hagerman and Butler (1980).

However, evidence from experiments on protein precipitation (Figure 1, Table 1) and from *T/P* values (see below) does not indicate that this variability is a function of the light–shade continuum in which these leaves grow.

At an approximate level, the results for SA can be used to estimate the amount of tannin required to precipitate the entire complement of foliar protein (*T/P**). The calculation of *T/P** for a given species assumes that foliar protein is equivalent to the BSA used in the SA assay and that the tannins of the species have the same A_1^1 as quebracho tannin. On this basis *T/P** can be computed from:

$$T/P^* = \left(SA \times \left[\frac{A_1^1}{10}\right]\right)^{-1}$$

TABLE 2. VALUES FOR OVERALL LEVEL OF PHENOLICS PRESENT (TPS), PERCENTAGE OF PHENOLICS ENTERING INTO PRECIPITATION REACTIONS WITH BSA (%T), AND SPECIFIC ACTIVITY (SA) FOR BULKED EXTRACTS FROM EACH SPECIES

Species	TPS[a]	%T	SA
Acacia pennata	0.32	55	8.50
Cynometra leonensis	0.45	13	4.79
Diospyros thomasii	0.36	74	14.42
Trema guineensis	0.24	32	10.67

[a] This value is based on the concentration of the bulked phenolic extract used in the specific activity experiment and does not reflect the actual phenolic content of the bulked leaf samples (Table 1). Values are in absorbance units for the Hagerman and Butler (1980) assay.

TABLE 3. CALCULATED MINIMUM TANNIN–PROTEIN RATIO (T/P*) FOR COMPLETE PROTEIN PRECIPITATION, CALCULATED T/P VALUES (MEAN AND RANGES) FOR INDIVIDUAL LEAF COLLECTIONS FROM EACH SPECIES WITH *Trema Guineensis* SAMPLES SUBDIVIDED ACCORDING TO AGE AND INSOLATION

Species	T/P*	T/P	
		Mean	Range
Acacia pennata	0.026	0.70	0.16–1.57
Cynometra leonensis	0.046	0.74	0.29–1.47
Diospyros thomasii	0.016	0.44	0.20–1.25
Trema guineensis	0.028		
Young sun leaves		0.76	0.36–1.06
Mature sun leaves		0.67	0.30–0.82
Old sun leaves		0.71	0.34–1.31
Young shade leaves		0.33	0.15–0.50
Mature shade leaves		0.36	0.09–0.62
Old shade leaves		0.49	0.19–0.70

where T/P^* = mg tannin/mg BSA required for complete precipitation of the BSA; SA = specific activity of the tannin; A_1^1 for quebracho tannin; and the division by 10 takes account of the different units of SA and A_1^1.

The values for T/P^* based on SA are given in Table 3 and suggest that the phenolics of *D. thomasii* are most effective at protein precipitation and those of *C. leonensis* least effective.

Individual *T/P* values for each extract of *A. pennata*, *C. leonensis* and *D. thomasii*, calculated from the ratio of CT to protein levels are plotted in Figure 2. The tannin element of the *T/P* calculation employed in these figures relates to the procyanidin assay. Similar analyses using the results of Folin-Denis and ferric chloride assay procedures produced comparable plots. Average values and ranges for these *T/P* figures are given in Table 3. Once again there is a large scatter in the results, and in each case these show a significant relationship to the incident light so that as light levels decrease so does the *T/P* value. *T/P* values for sun and shade leaves of *T. guineensis* subdivided into their different age classes are also presented in Table 3. Once again there is a clear distinction between *T/P* levels for sun and shade leaves, this being particularly obvious in the young and mature leaf categories but less so in old leaves. No distinction on the basis of *T/P* can be made for different age classes, except perhaps for the old leaves, in which *T/P* generally rises, presumably due to removal of protein.

Finally, mention should be made of two other measures made by Mole et al. (1987) which are of significance to an assessment of the palatability and food value of a leaf: protein and acid detergent fiber. Neither showed any sig-

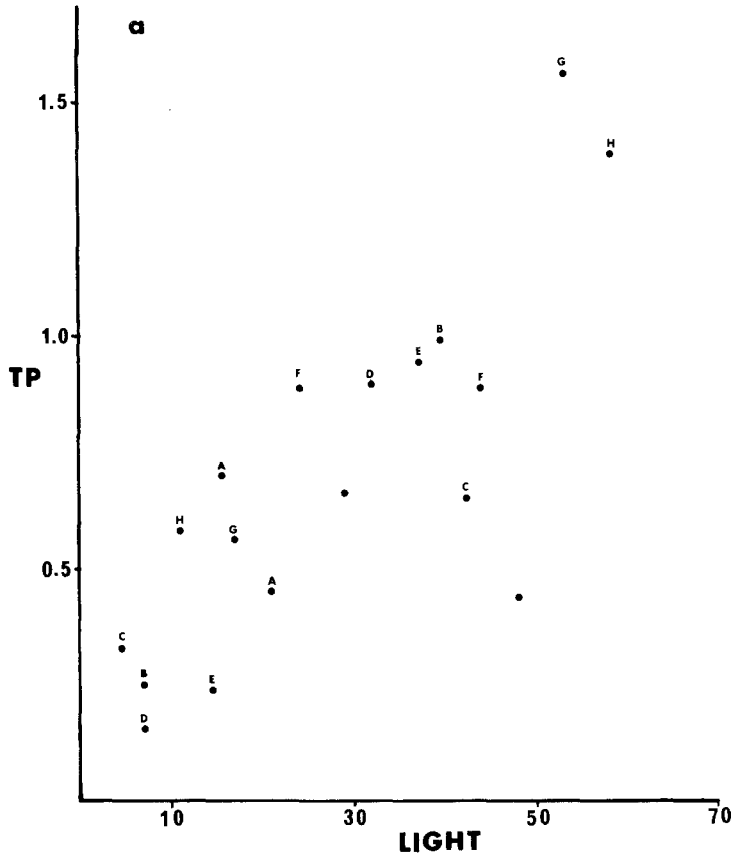

FIG. 2. Plots of tannin–protein ratios (T/P) for individual leaf collections against incident light, estimated as a percentage of the total insolation, on those leaves. Tannin estimates are based on the proanthocyanidin assay for condensed tannins. Plots are for: (a) *Acacia pennata*, (b) *Cynometra leonensis*, and (c) *Diospyros thomasii*. Paired samples taken from high- and low-light environments on a tree are indicated by the same letter.

nificant correlation with light intensity, although in most cases marginally higher protein levels did tend to occur in the more shaded leaves. The coefficients of variation calculated for these measures in relation to all samples from *A. pennata*, *C. leonensis*, *D. thomasii*, and the three age classes of *T. guineensis* were generally low (9–24% for protein and 8–26% for fiber; cf. 13–40% for total phenolics and 36–54% for CTs). By contrast, in *T. guineensis* both measures showed a relationship to leaf age, fiber increasing with age and protein decreasing. Only in *C. leonensis* did there appear to be a significant negative correlation between protein and fiber ($r = -0.66$, $N = 15$, $P < 0.05$).

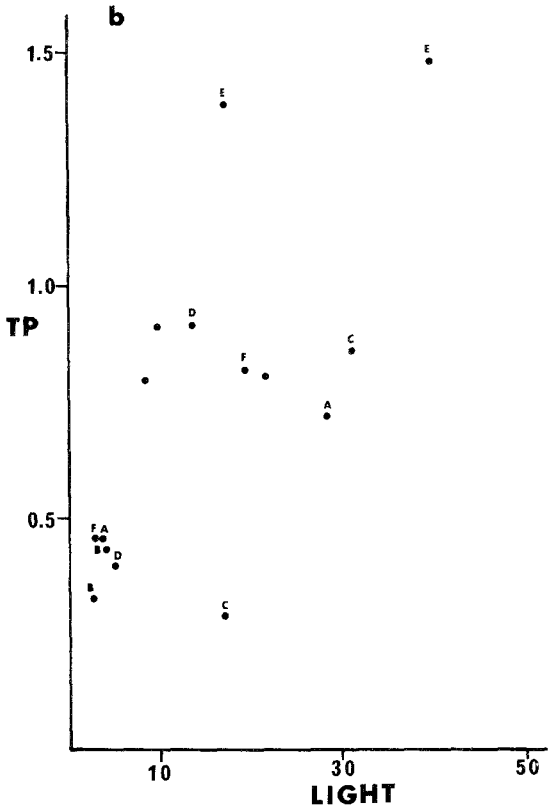

FIG. 2. Continued.

CONCLUSIONS

Because of the approximations necessary in obtaining some of the data reported here, conclusions can only be tentative. What is clear is that in each of the four species *T/P* approaches *T/P** most closely in leaves that come from the more shaded environments and that in an intraspecific comparison these leaves represent a better "nutrient package" than corresponding more insolated leaves. However, taking the computed values for *T/P** and *T/P* for individuals at face value, it would appear that in all situations in each species there is more than sufficient CT present to precipitate all foliar protein. Indeed, in all but a very few cases there is at least an order of magnitude difference between *T/P** and the lowest *T/P* values. One striking feature is that the pattern observed within all four species seems to be very similar, despite their apparent preference for different niches within the light–shade continuum. One possible exception to this argument is *D. thomasii*, which appears comparable to the others

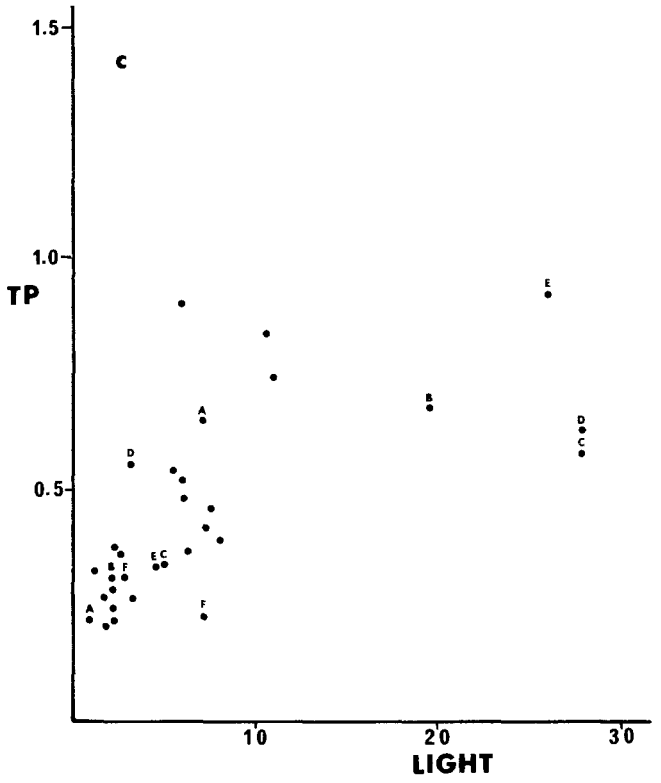

FIG. 2. Continued.

without taking into account the contribution to its phenolics made by HT, which will increase its *T/P* values (Figure 2c) significantly.

Arguments based on the assumption that protein precipitation in vitro reflects on the in vivo process of digestibility reduction are, as we indicated in the Introduction, probably naive. However, choosing as an in vitro assay a procedure optimized to detect protein precipitation does provide a direct measure of tannin–protein binding. Following from this, quantifying the amount of tannin in a leaf by reference to its capacity to bind to the protein complement of that leaf provides a useful framework within which to make predictions concerning allelochemic effects. As *T/P* becomes relatively greater than *T/P**, then if those tannins do bind to the leaf proteins to form soluble or insoluble complexes, there remains an increasing excess of tannin available to bind with other proteins.

What is apparent from this survey is that within each species and within each individual there is appreciable variation in quantitative phenol chemistry that appears to be related to the degree of shading. There is substantial further

variation superimposed on this due to the nonuniformity of qualitative chemical structure and protein-binding activity of the polyphenolic component. On the assumption that the tannin-protein binding mediates the allelochemic activity of tannins, then the biochemical changes that relate to light intensity suggest that more shaded leaves are likely to be preferable to a herbivore as a food source. These data thus lend support to a number of recent reports (Woodhead, 1981; Waring et al., 1985; Hanley et al., 1986; Larsson et al., 1986; Bryant, personal communication) suggesting that shading leads to greater levels of herbivory. On the other hand, the variability in leaf chemistry does indicate that a selective herbivore could obtain an acceptable diet from sun leaves. This, plus the range of herbivore digestive adaptations relating to polyphenolics, allows for the presence of many alternatives for folivores to exploit the variable chemistry of partially insolated/shaded plants.

NOVEL 2-ETHYL-5-ALKYLPYRROLIDINES IN THE VENOM OF AN AUSTRALIAN ANT OF THE GENUS *Monomorium*

(Received October 8, 1986; accepted December 31, 1986)

Abstract—Novel 2-ethyl-5-alkylpyrrolidines and their corresponding 1-pyrrolines have been identified as poison gland products from an unidentified Australian species of *Monomorium*. The major alkaloids present in the venom of this ant are *trans*-2-ethyl-5-undecylpyrrolidine and *trans*-2-ethyl-5-(12-tridecen-1-yl)pyrrolidine. The position of the double bond in the latter was established from its dimethyl-disulfide adduct after the amine function had been protected, and the stereochemistry of the alkyl groups was determined by direct comparison with synthetic compounds. The corresponding 1-pyrrolines were also detected in varying amounts in this venom. The pyrrolidines and 1-pyrrolines possess considerable insecticidal activity when evaluated against termite workers. The alkaloidal venoms of *Monomorium* appear to be an important factor contributing to the success of these small ants both as competitors and as predators.

Key Words—Ants, *Monomorium*, Hymenoptera, Formicidae, venom, 2,5-dialkylpyrrolidines, 2,5-dialkyl-1-pyrrolines, dimethyldisulfide adducts, insecticidal activity, chemical ecology.

INTRODUCTION

A variety of 2,5-dialkylpyrrolidines have been identified in the venoms of ants from the two related myrmicine genera, *Solenopsis* and *Monomorium*. While these compounds have been found in some *Solenopsis* (*Diplorhoptrum*) species (*Solenopsis molesta*, *S. fugax*, and *S. punctaticeps*), they are particularly characteristic of *Monomorium* and have been found in every species of this genus in which alkaloids have been detected (Jones et al., 1982a, and references therein).

This paper reports two novel 2-ethyl-5-alkylpyrrolidines and their pyrrolines identified from an undescribed Australian species of *Monomorium*. This species, henceforth referred to as *Monomorium* sp. #1066, belongs to a major radiation of Australian *Monomorium* that consists of numerous small (1.5–2 mm), dark-colored species, almost all of which are undescribed. They are diurnal, predominantly summer-foraging unspecialized predators and scavengers, most common in semiarid and seasonally arid regions, where they are often among the most abundant ants (e.g., *Monomorium* spp. 1 and 3; Andersen, 1983). Although most *Monomorium* species are quite diminutive ($\sim$2 mm) they are generally effective competitors against any species that are considerably larger (Baroni Urbani and Kannowski, 1974) primarily because of the toxic and repellent activities of their venoms. It thus appears that the great success of *Monomorium* species is in no small way correlated with the evolution of alkaloidal venoms that are effective toxins and deterrents to the wide variety of insect species that constitute both food and competitors for these ants. In order to gain some insights into the chemical ecology of this ant genus, the toxicities of these alkaloids to termite workers, which are common prey of *Monomorium* species, have also been determined. *Monomorium* sp. #1066 were collected near Melton, Victoria, and voucher specimens are deposited under this number in the British Museum (Natural History), London.

METHODS AND MATERIALS

Chemical Analyses. Gas chromatographic analyses were performed on a Gow-Mac model 750P, using a 2-m $\times$ 2-mm-ID glass column packed with 5% SP-1000 on 100–120 mesh Supelcoport. This instrument was programed from 40°C to 200°C at 10°C/min as soon as the solvent had eluted. Retention temperatures were found to be reproducible within one degree on a given day. Preparative gas chromatography was performed on a Varian model 920 using a 2-m $\times$ 5-mm-ID aluminum column packed with either 10% SP-2100 or 10% SP-1000 on 100–120 mesh Supelcoport. Infrared spectra were obtained from neat liquid films with a Perkin-Elmer 1320 grating infrared spectrophotometer.

[^{1}H]NMR spectra were obtained using a Varian FT-80 spectrometer. Mass spectra were obtained using a LKB-9000 GC-MS at an ionizing voltage of 70 eV and fitted with a 2-m × 2-mm-ID glass column packed with 1% SP-1000 on Supelcoport. High-resolution mass spectra were obtained using a VG 7070F in the EI mode at an ionizing voltage of 70 eV. Melting points are uncorrected.

3,6-Heptadecanedione (1). Condensation of 2.9 g of dodecanal (18.4 mmol) and 1.55 g of ethylvinyl ketone in the presence of triethyl amine and 0.5 g of 5-(2′-hydroxyethyl)-4-methyl-3-benzylthiazolium chloride in the usual manner (Jones et al., 1979) gave 4.0 g of the diketone as a waxy solid (75% yield), mp (GC prep) 65–67°C; MS *m/z* (rel. intensity) 268(3, M^+), 239(7), 211(9), 183(14), 141(10), 129(10), 128(100), 113(38), 85(32), 71(25), 57(20), and 43(6). Calculated for $C_{17}H_{32}O_2$ 268.2404 (M^+), observed 268.2411.

cis and trans-2-Ethyl-5-undecylpyrrolidine (2). Reductive amination of 2.0 g (7.2 mmol) of the diketone 1 in the usual manner with sodium cyanoborohydride and ammonium acetate (Jones et al. 1980) gave 1.6 g of a 1 : 1 mixture of *cis* and *trans* isomers that was 90% pure by GLC analysis. The retention times of the isomers on a 5% SP-1000 column were 4.8 min and 5.8 min, respectively, at 190°C. Both isomers had the following mass spectrum: MS *m/z* (rel. intensity) 253(1, M^+), 252(2), 225(9), 224(49), 114(2), 111(4), 99(7), 98(100), 82(2), 74(1), 57(2), and 43(1). Calculated for $C_{17}H_{34}N$ 252.4694 (M^+-1), observed 252.4714; Calculated for $C_{15}H_{30}N$ 224.2378 (M-C_2H_5), observed 224.2380.

2-Ethyl-5-undecyl-1-pyrrolines (5 and 6). A solution containing 0.4 g (1.6 mmol) of 2, and 5 ml of 5% NaOCl solution in 15 ml of methanol was stirred for 1 hr. After the addition of 1.5 g of NaOH, the mixture was heated to reflux for 3 hr. After the solvent was removed, 20 ml of water was added, and the mixture was extracted with ether (3 × 25 ml). The combined ether washings were dried over anhydrous K_2CO_3, and the solvent was removed in vacuo to provide 0.3 g of a mixture of the two 1-pyrrolines that was ca. 90% pure by GLC analysis; IR 1640 cm^{-1}. The two 1-pyrroline isomers could be separated (SP-1000) and had the following mass spectra: First eluting—(5) MS *m/z* 251 (2, M^+), 250(2), 222(6), 208(2), 194(2), 180(2), 166(3), 138(5), 124(35), 111(100), 82(40), 71(5), 70(6), and 57(6); second eluting—(6) MS *m/z* (rel. intensity) 251(22, M^+), 236(7), 222(8), 208(9), 194(9), 180(6), 166(15), 152(30), 138(20), 124(30), 111(90), 110(60), 97(100), 96(75), 82(18), 71(10), and 57(12).

18-Nonadecen-3,6-dione (3). A well-stirred solution containing the Grignard reagent formed from 7.0 g of 4-tetrahydropyranyloxybutyl bromide (Ferdinandi and Just, 1971) and 0.8 g of magnesium in 70 ml of tetrahydrofuran, cooled to 0°C under a nitrogen atmosphere, was treated with 2.0 ml of a freshly prepared 0.2 M solution of Li_2CuCl_4 in tetrahydrofuran (Fouquet and Schlosser,

1974). Subsequently, a solution containing 5.0 g (21 mmol) of 9-decen-1-yl mesylate (from the commercially available alcohol and methanesulfonyl chloride in the usual manner) in 10 ml of tetrahydrofuran was added dropwise to the Grignard solution. The resulting mixture was allowed to warm to 25°C overnight, carefully acidified with 10% HCl and extracted with ether (4 × 50 ml). The combined ether extracts were dried over anhydrous $MgSO_4$, then filtered and distilled to give 3.4 g (75% yield) of colorless 13-tetradecen-1-ol, bp 135–145°C (0.4 mm Hg), having infrared and NMR spectra matching those previously reported (Yamanaka and Imai, 1981). This alcohol (3.0 g) was immediately oxidized with pyridinium chlorochromate (Corey and Suggs, 1975), and after the usual work-up, distillation gave 1.9 g of 13-tetradecenal (63% yield), bp 95–100°C (0.1 mm Hg): IR 3080, 2960, 2720, 1715, 1640, 990, and 910 cm^{-1}; NMR δ 9.76 (1H, t, J = 1.9 Hz), 5.8 (1H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 2.4 (2H, br t, J = 7 Hz), 2.0 (2H, m), 1.3 (18H, br s); MS *m/z* (rel. intensity) 210(2, M^+), 192(4), 181(2), 167(3), 166(8), 135(10), 121(14), 112(12), 111(18), 110(14), 109(13), 98(30), 97(26), 96(26), 95(30), 84(20), 83(38), 82(40), 81(40), 70(24), 69(48), 68(30), 67(30), 67(40), 57(38), 55(100), 43(34), and 41(66). This aldehyde (0.8 g/3.8 mmol) was condensed with ethyl vinyl ketone as described above to give 1.0 g of diketone 3 (83% yield), mp 55–56°C; NMR δ 5.8 (1H, d of d of t, J = 18, 10 and 6Hz, 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 2.7 (4H, s), 2.44 (4H, m), 2.0 (2H, m), 1.26 (18H, br s), 1.1 (3H, t, J = 7Hz); MS *m/z* (rel. intensity) 294(2, M^+), 265(6), 237(5), 209(5), 141(12), 129(10), 128(100), 113(48), 95(14), 85(40), 71(30), 69(20), 67(10), 57(37), 55(33), 43(17), and 41(25). Calculated for $C_{19}H_{34}O_2$ 294.2559 M^+), observed 294.2551.

cis and trans-2-Ethyl-5-(12-tridecen-1-yl)pyrrolidine(4). Reductive amination of diketone 3 (0.735g/2.5 mmol) in the manner described above gave 0.6 g of a 1:1 mixture of *cis* and *trans* isomers that was nearly 80% pure by GLC analysis. Their retention times were 14 min and 17.6 min, respectively, on a 5% SP-1000 column at 190°C. Pure samples of the isomeric mixture were obtained by preparative gas chromatography: NMR δ 5.8 (1H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 2.9 (2H, br m), 2.0 (2H, m), 1.7–1.1 (26H, m), and 0.85 (3H, t, J = 7Hz); MS *m/z* (rel. intensity) 279(2, M^+), 278(2), 277(2), 251(7), 250(37), 152(2), 138(1), 124(5), 111(14), 99(7), 98(100), 97(6), 96(6), 82(10), 69(5), 68(4), 67(3), 55(12), and 41(11). Calculated for $C_{19}H_{27}N$ 279.2928 (M^+), observed 279.2915; calculated for $C_{19}H_{36}N$ 278.2849 (M-1), observed 278.2841; calculated for $C_{17}H_{32}N$ 250.2535 (M-C_2H_5), observed 250.2533.

Derivatization of Pyrrolidine 4. A solution containing 10 mg of pure *cis/trans 4*, 10 mg of 4-dimethylaminopyridine, and 200 mg of trifluoroacetic anhydride in 1 ml of pyridine was stirred under a nitrogen atmosphere for 4 hr at

25°C. The mixture was diluted with pentane and acidified with 10% HCl. The organic phase was separated, dried (anhydrous $MgSO_4$), and concentrated in vacuo to give a solution with two major isomeric components having retention times of 11.2 min and 12 min, respectively, at 200°C on 5% SP-1000 column. MS *m/z* (rel. intensity) 375(4, M^+), 348(6), 347(5), 346(22), 306(2), 262(1), 207(1), 195(11), 194(100), 166(6), 140(6), 95(5), 83(4), 81(14), 69(8), 67(6), 55(5), 44(3), 43(3), and 41(10). This solution was treated with 0.1 ml of dimethyldisulfide and 0.01 ml of an ethereal iodine solution (50 mg in 1 ml of ether) and allowed to stand at 25°C for 48 hr. In a separate experiment, a trace of BF_3 etherate, used as a catalyst instead of iodine, was more efficient. After washing with a 5% $Na_2S_2O_3$ solution, the organic phase was concentrated and gas chromatographic analysis revealed the presence of two major high-molecular-weight isomers (retention times = 32.4 min and 33.6 min, respectively, at 250°C on a 5% SP-2100 column). MS *m/z* (rel. intensity) 469(8, M^+), 422(5), 410(5), 409(10), 408(100), 396(2), 374(5), 373(3), 360(5), 346(2), 295(2), 195(5), 194(38), 95(10), 81(12), 69(8), 67(8), 61(20), 55(20), and 41(10).

Analysis of Monomorium, sp. #1066. Gas chromatographic examination of the methylene chloride extracts of six collections of 50–100 workers of these ants revealed the presence of two components in an 8 : 1 ratio. The mass spectra of these compounds had important ions at *m/z* 253(M^+), 224, and 98(100) and at *m/z* 279(M^+), 250, and 98(100), respectively, and were otherwise identical to those of authentic samples of pyrrolidines 2 and 4. In addition, direct comparison (5% SP-1000 and 5% SP-2100) showed that they had retention times identical to the second eluting isomers of 2 and 4.

GC-MS analysis of the extracts of all of the collections of ants showed two components eluting before 2 whose mass spectra and gas chromatographic retention times were identical to those of an authentic sample of pyrrolines 5 and 6. In addition, there were two analogous compounds eluting before pyrrolidine 4: MS *m/z* (rel. intensity) 277(3, M^+), 276(5), 248(10), 166(10), 152(3), 138(5), 124(30), 112(10), 111(100), 82(35), 71(10), 70(8), and 57(15); and MS *m/z* (rel. intensity) 277(25, M^+), 276(5), 252(10), 268(9), 236(15), 194(15), 180(5), 166(10), 152(20), 148(15), 124(8), 111(70), 110(45), 97(100), 96(50), 82(18), 71(15), and 57(25). In one collection, the total quantity of each isomeric pyrroline mixture was nearly equivalent to the amount of corresponding pyrrolidine present. In the other five collections, all of the pyrrolines combined were not more than 15% of the total alkaloid mixture. As with other collections of ants (Jones et al., 1982b), it was possible to obtain an estimate that each ant contained between 0.5 μg and 2.0 μg of the major pyrrolidine 2 by comparison with standardized solutions of synthetic 2. There were correspondingly less of the other alkaloids present.

Treatment of a sample of one of the extracts first with a drop of trifluora-

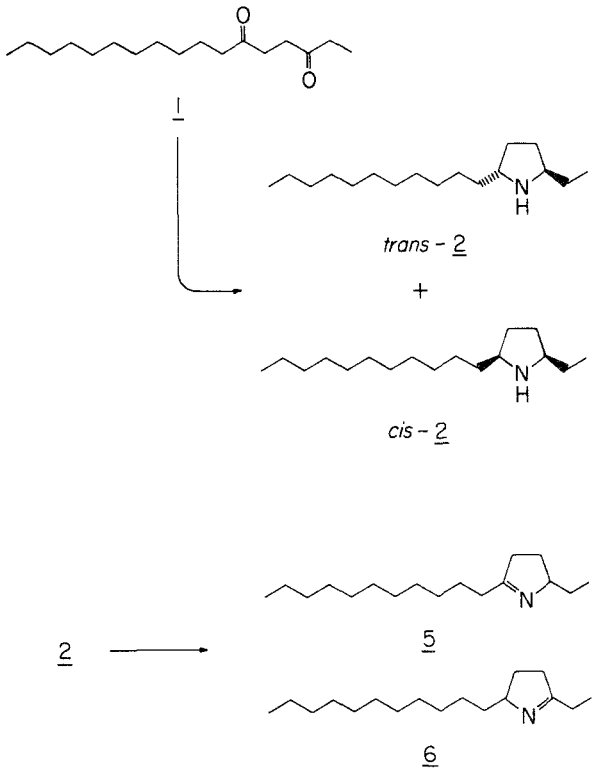
cetic anhydride and three to four drops of pyridine and then, after careful work-up with pentane and 10% HCl, with dimethyldisulfide and iodine gave a complex mixture. GC-MS analysis showed one major high-molecular-weight component (retention time 40 min on a 1% SP-1000 column at 200°C), whose mass spectrum had important ions at m/z = 469(M^+), 408(100), and 194 and was identical to that of the di(thiomethyl)-*N*-trifluoracetyl derivative of 4.

Toxicity Determinations. The toxicities of the alkaloids were determined utilizing workers of an undescribed species of *Reticulitermes* collected from Athens, Georgia. Individual termites (instars 6–8), placed in groups of 10 in 5-cm glass Petri dishes, were each treated with 1 μl of an acetone solution of the test compound. Three replicates per dosage were evaluated, and termite workers treated with acetone served as controls. The treated termites were provided with a moist filter paper and toxicity determinations were made 20 hr later. The resultant sigmoid dosage–mortality curve was linearized by a statistical treatment (Pogits) and the data treated by a computer program in order to obtain the LD_{50} for each compound expressed as micrograms per milligram termite. Values for the insecticides nicotine and methomyl were determined for comparison.

RESULTS

Gas chromatographic analysis of the methylene chloride extracts from all the collections of *Monomorium* sp. #1066 revealed the presence of one major component, whose mass spectrum (m/z = 253 M^+, 224, and 98) indicated that it was 2-ethyl-5-undecylpyrrolidine (2). Comparison with an authentic sample obtained by the reductive amination of the corresponding diketone 1 (Scheme 1) (Jones et al., 1980) confirmed this structure. This synthetic methodology produces the *cis* and *trans* 2,5-disubstituted pyrrolidines in a 1:1 ratio, and these isomers can be separated on a 5% SP-1000 column. It has been shown (Pedder et al., 1976; Jones et al., 1979) that the first eluting isomer has the *cis* configuration. In the case of 2, the natural material had an identical retention time with the second-eluting (*trans*) synthetic isomer.

A second, minor component (present in 10–15% of the amount of *trans*-2) was also found in each of the four samples. This alkaloid had a mass spectrum (m/z = 279 M^+, 250, and 98) indicating a 2-ethyl-5-tridecenylpyrrolidine. The position of the double bond was determined by means of the dimethyl disulfide adduct (Buser et al., 1983). A sample of the extract was first treated with trifluoroacetic anhydride in the presence of pyridine, and then the resulting *N*-trifluoroacetamides were treated with dimethyl disulfide in the presence of iodine. The mass spectrum of the dithiomethyl-*N*-trifluoroacetamide derivative of the minor pyrrolidine (M^+ = 469) had M-61 ($-CH_2SCH_3$) as the base peak

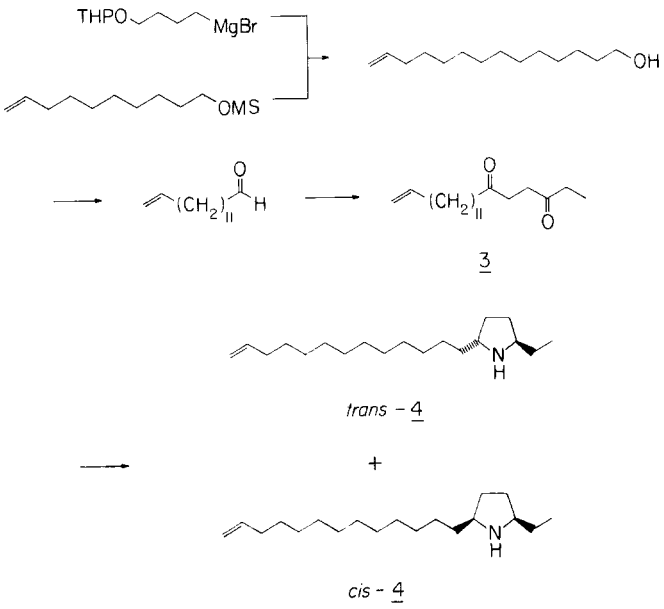


SCHEME 1

(Scheme 2), indicating the presence of a terminal double bond, so that this alkaloid was 2-ethyl-5-(12-tridecen-1-yl)pyrrolidine (4).

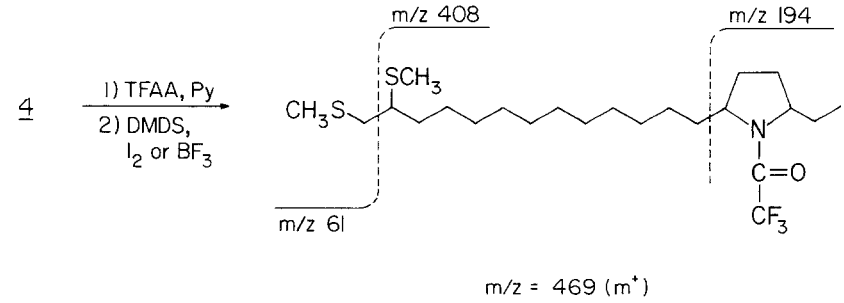
In order to confirm this assignment and to determine its stereochemistry, pyrrolidine 4 was synthesized as shown in Scheme 3. Synthetic 4 is produced as a 1 : 1 mixture of *cis* and *trans* 2,5-disubstituted pyrrolidine isomers by this method, and as before, the second eluting (*trans*) isomer had a retention time and mass spectrum identical to that of the natural alkaloid. A small sample of the purified isomeric mixture was first converted to its *N*-trifluoroacetamide, and then treated with dimethyl disulfide in the presence of iodine to give the dithiomethyl adduct which had a mass spectrum identical to that obtained by derivatizing the ant alkaloid (Scheme 2).

The methylene chloride extracts of the ants contained four additional alkaloidal components. The first two of these components, which eluted before 2, had mass spectra and retention times identical to those of synthetic 5 and 6,



SCHEME 2

prepared from 2 by *N*-chlorination, and subsequent dehydrochlorination (Scheme 1) (Jones et al., 1979). Two similar alkaloids were also present, eluting before 4, and having mass spectra [m/z = 277(M^+), 111(100), and 82; m/z = 277(M^+), 262, 97(100), and 82] indicating the 1-pyrroline homologs of 4. The mass spectra of 2-ethyl-5-alkyl-1-pyrrolines are characterized by important ions at m/z = 96 and m/z = 97, whereas the mass spectra of 2-ethyl-5-alkyl-5-pyrrolines have important fragments at m/z = 82 and m/z = 111 (Pedder et al., 1976).



SCHEME 3

The LD_{50} of 2-ethyl-5-undecylpyrrolidine (2) was 0.17 ± 0.02 μg/mg termite and that of 2-ethyl-5-(12-tridecen-1-yl)pyrrolidine (4) was 0.23 ± 0.07. A mixture of the Δ^1 and Δ^5 pyrrolines of 2-ethyl-5-undecylpyrroline was about half as toxic (0.46 ± 0.03 μg/mg termite) as the corresponding pyrrolidine (2). For comparison, LD_{50s} of the insecticides nicotine and methomyl were 0.5 ± 0.02 and 0.25 ± 0.02, respectively.

DISCUSSION

Although 2-ethyl-5-alkylpyrrolidines have been found in a *Solenopsis* species (Pedder et al., 1976), this is the first report of their occurrence as major venom components in a species of *Monomorium*. The overall carbon–nitrogen skeleta of the 2-ethylpyrrolidines 2 and 4 could be assigned from their mass spectra, and were confirmed by unambiguous syntheses (Schemes 1 and 3). This synthetic methodology also permits the assignment of stereochemistry of the alkyl groups about the pyrrolidine ring, since both *cis* and *trans* isomers are formed (Jones et al., 1980) having identical mass spectra but different gas chromatographic retention times. As has been found to be the case in other ants producing 2,5-dialkypyrrolidines, only the *trans* isomers of the 2-ethyl-5-alkylpyrrolidines 2 and 4 are found in *Monomorium* sp. #1066.

Although terminally unsaturated side chains have also been previously reported in *Monomorium* (Jones et al., 1982a, b), this is the first report of their assignment in an alkaloid by the formation of a dimethyldisulfide adduct. It was found that the trifluoroacetamide derivitive had to be formed before the dithiomethylation reaction (Buser et al., 1983) could be successfully carried out. Although it happens to be irrelevant in this case, an important advantage of forming the dimethyl disulfide adduct for the determination of double-bond location over the previously utilized methoxymercuration–demercuration methodology (Jones et al., 1982b) is the formation of a single derivative for any given vicinally disubstituted double bond.

In the case of pyrrolidine 4 the mass spectrum of the dithiomethyl-*N*-trifluoroamide derivitive shows a parent ion at m/z = 469(M^+), a base peak at m/z = 408(M-61) for the loss of CH_3SCH_2— fragment, and a peak at m/z = 61, which result from C–C bond cleavage between two vicinal thiomethyl groups, and indicate the position of the double bond. Other important ions appear at m/z = 422 (M-CH_3S), m/z = 374 [M-(CH_3S + CH_3SH)], m/z = 360 [M-(CH_3SCH_2— + CH_3SH)], and m/z = 194 [M-$(CH_3S)_2C_{13}H_{25}$] (Scheme 2). Using synthetic 4, it was found the formation of this derivative could be catalyzed by iodine or boron trifluoride etherate (Caserio et al., 1985).

In one of the collections of *Monomorium* sp. #1066, quantities equivalent to those of the pyrrolidines present of the four possible 1-pyrrolines correspond-

ing to 2 and 4 were found, easily identifiable by their mass spectra, in which the important fragmentation and rearrangement ions were the same as those reported for similar ethyl-1-pyrrolines (Pedder et al., 1976). These compounds were also present in much smaller amounts in the other three collections of ants. Although it has been shown that 1-pyrrolines can be formed as artifacts in GC-MS systems (Fales et al., 1980), the fact that there was so great an observable difference in the amounts of these compounds from collections of ants from different nests indicates otherwise. The 1-pyrrolines could be either decomposition products of 2 and 4, or they could have been present in all the extracts initially and were much more subject to decomposition themselves than the concomitant pyrrolidines. The latter seems more likely, since the protonated forms of 1-pyrrolines would be strong electrophiles, subject to attack by a variety of biological and nonbiological nucleophiles.

The 2,5-dialkylpyrrolidines and 2,5-dialkyl-1-pyrrolines present in the venom of *Monomorium* sp. #1066 provide this ant with an insecticidal venom that possesses considerable toxicity when applied topically. Significantly, the tip of the string of *Monomorium* workers is spatulate and adapted for the topical application of venom products (Clement, 1981), rather than being the pointed hypodermic structure characteristic of related ants. Since European species of *Monomorium* commonly utilize termites (*Reticulitermes* spp.) as prey (Clement, 1981), and since we have observed the same thing with *M. minimum* and *Reticulitermes* spp. in the southeastern United States, termites must be considered major food items of these ants. Furthermore, the availability of an alkaloid-rich venom with great topical toxicity appears to be the major evolutionary development that has enabled these diminutive ants to facilely exploit much larger insects such as termites as prey.

In addition to being highly toxic to termites, the dialkylpyrrolidines act very rapidly after topical administration, paralysis of treated termites occurring almost instantaneously. Thus, these alkaloids can enable *Monomorium* workers to speedily immobilize insects with small dosages of topically applied venom. Since dialkylpyrrolidines have been previously demonstrated to be highly effective insect repellents (Blum et al., 1980), these compounds emerge as allomones par excellence.

Monomorium species #1066 belongs to a group of small species, no member of which we have previously examined. Species in this group, which contain a palpal formula of PF 1,2 (Bolton, personal communication) are not uncommon in Australia, although the groupings of Australian *Monomorium* are much more complex than palpal formulae. We are attempting to obtain other members of this group for comparative analyses. The venoms of *Monomorium* species in the PF 3,3 group (*M. latinode*) and species in the PF 2,2 group (*M. minimum*) are qualitatively rich in terms of dialkylpyrrolidines and pyrrolines (Jones et al., 1982a, b) compared to *Monomorium* sp. #1066. Analyses of ad-

ditional species in the PF 1,2 group should demonstrate whether the venom of species #1066 is typical of those of other members of this heretofore unanalyzed group of myrmicine ants.

Acknowledgments—We thank Lewis Pannell and Noel Whittaker of the NIADDK, Bethesda, Maryland, for obtaining the high-resolution mass spectra. We are grateful to Barry Bolton of the British Museum for taxonomic evaluation of *Monomorium* species #1066.

SPECIFICITY OF MALE RESPONSE TO MULTICOMPONENT PHEROMONES IN NOCTUID MOTHS *Trichoplusia ni* AND *Pseudoplusia includens*

(Received October 16, 1986; accepted December 31, 1986)

Abstract—The response of male cabbage looper (CL) and soybean looper (SBL) moths was observed in the flight tunnel and measured in field tests to the six-component CL pheromone, the five-component SBL pheromone, and to Z7-12:OAc, the major component common to each pheromone. In both the flight tunnel and the field, male CL exhibited significantly greater levels of response to their six-component blend than to Z7-12:OAc alone. A low level of cross-attraction of male CL to the SBL pheromone was observed in both the flight tunnel and the field, but it was quantitatively and qualitatively similar to their response to Z7-12:OAc alone. Thus the minor components of the SBL blend did not appear to disrupt the flight behavior of male CL. With respect to SBL, in the flight tunnel males also exhibited a greater level of response to the five-component blend compared to Z7-12:OAc, but in the field their response was not significantly different to either treatment. There was also a low level of cross-attraction of male SBL to the CL blend, but this appeared to involve a significant arrestment effect on the upwind flight of males, as well as a difference in male sensitivity to the blend of components compared with Z7-12:OAc alone. The observed arrestment effect may have been due to male perception of one or more minor components of the CL pheromone. The results show that the multicomponent pheromones of these species function effectively as specific mating signals and that discrimination of odor quality by male moths can occur as the result of minor components affecting male sensitivity or their upwind flight response to the pheromone.

INTRODUCTION

Successful mate location is dependent on a communication channel that is highly efficient and specific. In part, the communication channel is represented by a set of ecological factors, including temporal periodicity of activity (both seasonal and diel), unique microhabitat requirements, energy requirements, and predation (Cardé and Baker, 1984). In many moth species, the communication channel also involves the use of a sex pheromone. Studies have shown that species within a taxonomic group (family or subfamily) often utilize the same chemicals, as a result of common biosynthetic pathways (Roelofs and Brown, 1982). In sympatric species with similar activity patterns, this could lead to significant levels of cross-attraction, decreasing the efficiency of the communication channel. In these cases specificity is presumably effected by the use of unique minor components or similar compounds in different ratios, resulting in different chemical signals for each species.

Within the subfamily Plusiinae of the noctuid moths, there are a number of closely related species that utilize the compound (Z)-7-dodecenyl acetate (Z7–12 : OAc) as the major pheromone component (Tamaki, 1985). Two such species are the cabbage looper (CL), *Trichoplusia ni* (Hubner), (Berger, 1966), and the soybean looper (SBL), *Pseudoplusia includens* (Walker) (Tumlinson et al., 1972). Both the CL and SBL have overlapping seasonal and geographic distributions, similar host plants, and similar circadian rhythms of activity (Mitchell, 1973; Leppla et al., 1979; Leppla, 1983). In field-trapping studies, Mitchell (1972) observed in two of three tests that, whereas females of both species attracted predominantly conspecific males, CL females reduced the capture of SBL males by SBL females or synthetic Z7–12 : OAc. Similarly, Leppla (1983) reported that in release–recapture studies male CL and SBL responded selectively to conspecific females, although there was some cross-attraction. His studies suggested that the SBL and CL are reproductively isolated, in part, by a number of factors related to their chemical communication systems, including long-range attraction, close-range courtship behavior, and male released pheromones.

Recently we identified several new components of the sex pheromone of the cabbage looper (Bjostad et al., 1984) and the soybean looper (Linn et al., 1987). In addition to Z7–12 : OAc as their major, or most abundant, pheromone component, both species produce two common minor components: dodecyl acetate (12 : OAc) and 11-dodecenyl acetate (11–12 : OAc). In addition to these, the sex pheromone of CL includes (Z)-5-dodecenyl acetate (Z5–

12:OAc), (Z)-7-tetradecenyl acetate (Z7–14:OAc), and (Z)-9-tetradecenyl acetate (Z9–14:OAc). Two additional components for the SBL are (Z)-7-dodecenyl propionate (Z7–12:Prop) and (Z)-7-dodecenyl butanoate (Z7–12:But).

With the identification of more complete pheromone blends for these two noctuid species, we initiated behavioral tests in the flight tunnel and in a field situation to compare the response of males to conspecific blends, to Z7–12:OAc, and to heterospecific blends. These tests were designed to show, in two species that share a common major component, how the different complements of minor components affect male sensitivity and specificity of response to the chemical signal.

METHODS AND MATERIALS

Insects. Both species were reared on a semisynthetic medium (Shorey and Hale, 1965) at 25–27°C, 16:8 light–dark photoperiod. For CL the relative humidity was 30–50%; for the SBL 70–80% relative humidity was required for optimal mating, egg laying, and male response (Leppla et al., 1979; see Results). Males were separated from females as pupae and kept under conditions similar to those during rearing. Adults were provided with 8% sucrose solution.

Chemicals. The synthetic chemicals used in this study were the same as those used by Linn et al. (1984, 1987). For CL the proportions of each compound in the six-component blend were: 12:OAc (6.8%), Z5–12:OAc (7.6%), Z7–12:OAc (100%), 11–12:OAc (2.3%), Z7–14:OAc (0.9%), and Z9–14:OAc (0.6%). The proportions of compounds for the five-component SBL blend were: 12:OAc (2.3%), Z7–12:OAc (100%), 11–12:OAc (2.2%), Z7–12:Prop (1.3%), and Z7–12:But (5.0%). These mixtures of compounds, and the relative ratios indicated, represent blends produced by female moths as determined from capillary GLC analysis of female glands. Solutions of these blends were prepared in Skelly B (predominantly *n*-hexanes) and checked on capillary GLC (45-m Carbowax 20 M column) to ensure purity (>99%), with a detection limit of 0.1%. A dilution series was then prepared for each treatment to be applied to polyethylene cap sources. The same solutions were used for both flight tunnel and field tests. Caps (OS-6 closures, American Scientific Products, Rochester, New York) were prepared by adding solutions (10 or 100 $\mu g/\mu l$) to the inside surface of the cap. After 1 hr the caps were closed, and those for the flight tunnel were allowed to sit in a laboratory hood for 36 hr, then placed in glass vials, and held at −10°C when not in use. For the field tests, caps were used within one week of preparation.

Males of both species were tested in the flight tunnel and in the field to 1- and 3-mg dosages of Z7–12:OAc alone and to the same dosages of Z7–12:OAc plus the additional components of the two pheromone blends. These dosages were selected on the basis of previous tests with CL (Linn et al., 1984) and

SBL (Linn et al., 1987) in which dosage–response curves were established for each species to Z7–12:OAc and the female-produced blend.

Flight Tunnel Test Procedures. Individual 3- to 4-day-old males of both species were tested in the sustained-flight tunnel described by Miller and Roelofs (1978), during the fifth and sixth hours of the 8-hr scotophase period (Linn et al., 1984; Leppla, 1983). Males were placed in the room housing the tunnel at the beginning of scotophase to acclimate to scotophase light and temperature conditions: 0.3 lux, 23–25°C. Other flight tunnel conditions were 75–80% relative humidity, and 50–55 cm/sec air velocity. The high relative humidity in the present study was necessary for optimal flight behavior by male SBL. Preliminary tests utilizing flight tunnel conditions that would normally elicit high levels of response from male CL (50% relative humidity or less) failed to elicit significant levels of flight activity in SBL. Subsequent tests revealed that 70% relative humidity or greater was necessary for optimal flight behavior.

Males were handled during testing as previously described (Linn et al., 1984). Males were allowed 1 min to respond and were scored for the following behaviors: taking flight, stationary oriented flight in the odor plume space near the point of release, initiation of upwind flight, source contact, and attempted copulations. Males were used once and then discarded.

Flight tunnel tests were conducted during one 2-hr period each day. During each period five to 10 males of each species were tested to the three treatments at one of the two dosages. For each experiment 100 males were tested to each treatment. Analysis was based on the total response to each treatment according to the method of adjusted significant levels for proportions (Ryan, 1960).

Field Test Procedures. SBL and CL sex pheromones, along with Z7–12:OAc, were field tested during the growing seasons of 1983, 1984, and 1985, at the Louisiana State Penitentiary farm, Angola, Louisiana. Pherocon-IC (Zoecon Corp., Palo Alto, California) traps were baited with the desired treatments and placed 30 m apart on aluminum poles ca. 1.5 m high. Trap height was no greater than 20 cm above the crop canopy. Tests were conducted in a variety of crops, including soybean, cabbage, and broccoli. Each treatment was replicated from three to five times, and treatments were randomized each collection day. Captured specimens were returned to the laboratory and identified to species, using genitalia characteristics described by Eichlin (1975). Data were analyzed by ANOVA, and treatment means were separated using Duncan's multiple-range test (Steel and Torrie, 1960).

RESULTS

Response to Z7–12:OAc and Blends: Flight Tunnel. In the flight tunnel males of both species responded at each dosage in greater percentages to con-

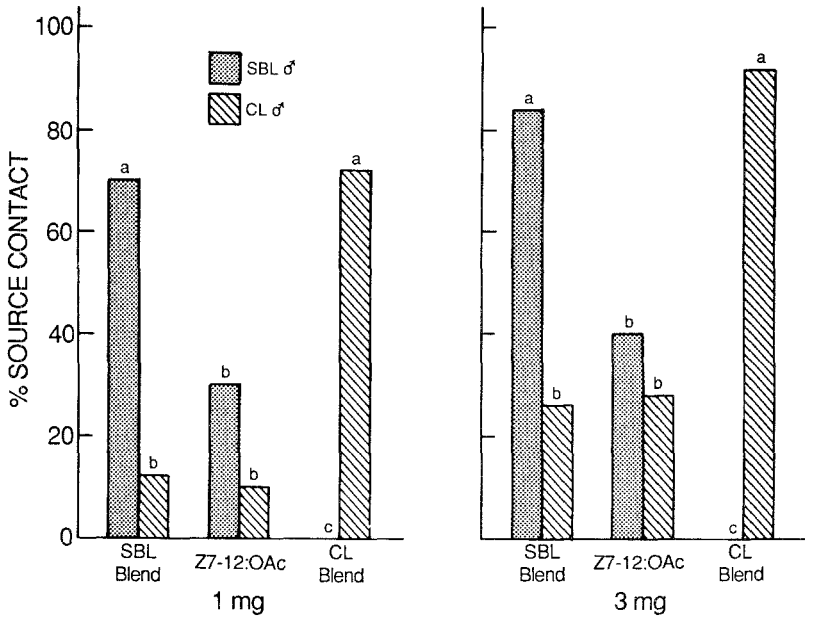

FIG. 1. Response (as percentage of source contacts) of male SBL and CL in the sustained-flight tunnel to the five-component SBL blend, Z7-12:OAc, and the six-component CL blend, at 1- and 3-mg dosages. $N = 100$ for each treatment and dosage. Analysis was performed separately on response values for each species to the three treatments, and the values with different letters are significantly different ($P < 0.05$), according to the method of adjusted significance levels for proportions (Ryan, 1960).

specific blends than to Z7-12:OAc alone (Figure 1). The lower levels of response to Z7-12:OAc were as expected based on earlier dosage–response tests. Male response to heterospecific blends was also much lower than to conspecific blends. Male CL completed flights to the SBL blend in percentages approximating those to Z7-12:OAc. In contrast, none of the SBL males completed flights to the CL blend.

Details of the flight responses of males to the 3-mg treatment in Figure 1 are presented in Figure 2. The lower level of source contacts by male CL to Z7-12:OAc or the SBL blend compared to the six-component blend was due to lowered levels of flight activation, orientation, and initiation of upwind flight. With respect to the SBL, low levels of cross-attraction were also the result of lowered response levels in the initial behaviors of the sequence, but in addition there was significant arrestment of the upwind flight of those males that did initiate this behavior.

Significant differences also were observed in the temporal aspects of the

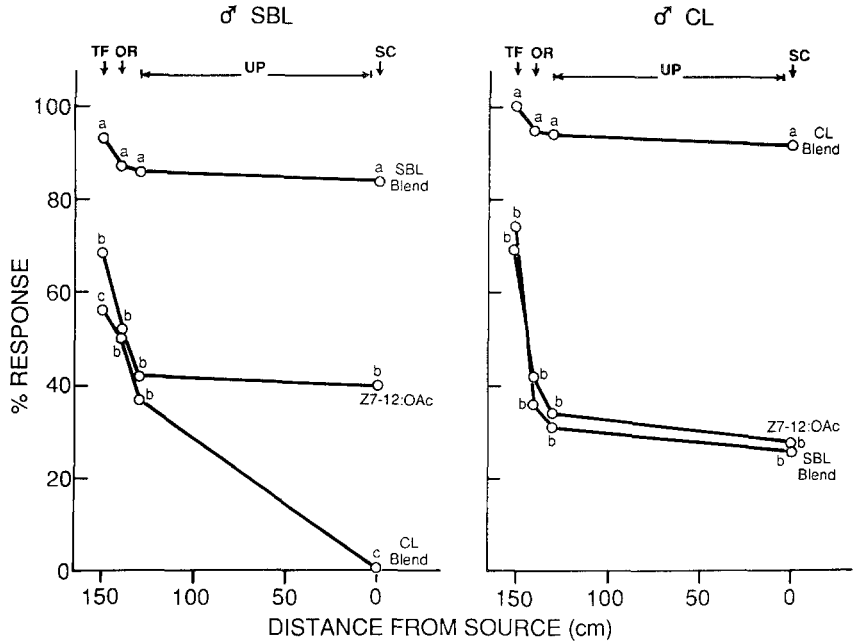

FIG. 2. Details of male SBL and CL response to the 3-mg dosage of the treatments shown in Figure 1. Behaviors are: taking flight (TF), plume orientation (OR), upwind flight (UP), and source contacts (SC). Values with different letters within each behavior are significantly different ($P < 0.05$) according to the method of adjusted significance levels for proportions (Ryan, 1960).

flight responses. The flight of males to Z7-12:OAc was significantly slower than that to their conspecific blends (5 ± 2 SD sec for SBL over the 1.5 m distance to the blend compared to 22 ± 9 SD sec to Z7-12:OAc; 6 ± 2 SD sec, and 28 ± 8 SD sec, respectively, for CL males). Furthermore, the flight of male CL to the SDL blend was not significantly different from that to Z7-12:OAc alone (25 ± 9 SD vs. 28 ± 8 SD sec).

Response of Males to Z7-12:OAc and Blends: Field: In field tests there was no significant difference in the number of SBL males trapped with Z7-12:OAc compared to the five-component blend (Figure 3). Trap capture of SBL males with the CL blend, however, was significantly reduced over that observed to the SBL blend or Z7-12:OAc.

In contrast, male CL were attracted in significantly greater numbers with the six-component blend compared to Z7-12:OAc or the SBL blend. In addition, there was no significant difference in the response of male CL to the SBL blend or to Z7-12:OAc.

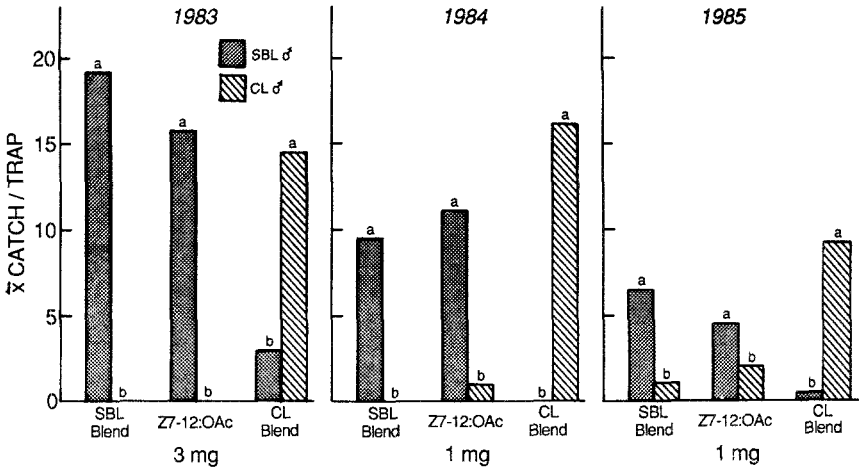

FIG. 3. Trap capture of male SBL and CL to three treatments in Figure 1. Replicates were three in 1983, four in 1984, and five in 1985. Responses for each species within each year were analyzed by one-way ANOVA, and values with different letters are significantly different ($P < 0.05$) according to Duncan's multiple-range test.

DISCUSSION

One of the objectives of the present study was to test the hypothesis that, in species possessing a common major component that is essential for chemically mediated behavior to occur, unique sets of minor components provide the basis for discrimination by males between conspecific and heterospecific females. The results reported here support this hypothesis in that low levels of cross-attraction occurred between male CL and SBL, compared with the response to conspecific blends. The results also show, however, that discrimination of odor quality was the result of two different effects of the minor components on male perception. These involve (1) males possessing a significantly lower threshold for response to the complete blend compared to the major component alone, and (2) male detection of a chemical that is not in the species pheromone blend, but is found in that of the related species, and results in significant arrestment of upwind flight.

In the case of the CL, the data show that a lower proportion of males initiated a response to the SBL blend, compared with the conspecific pheromone. A careful analysis of the flight tunnel results further shows that the response to the SBL blend was both quantitatively and qualitatively like that to Z7–12 : OAc. From this we conclude that (1) the minor components of the SBL

blend did not adversely affect the upwind flight of male CL, and (2) the low level of cross-attraction by male CL to the SBL blend is the result of the majority of the male CL population possessing a higher sensitivity to the six-component blend than to Z7–12:OAc alone.

In the case of the SBL, males took flight, oriented, and initiated upwind flight in the flight tunnel to the CL blend in approximately the same proportions as they did to Z7–12:OAc alone (Figure 2), a result similar to that obtained with CL. However, the level of male SBL response to Z7–12:OAc in the flight tunnel was slightly higher (30% with 1 mg, 40% with 3 mg) than that of CL males (10% with 1 mg, 24% with 3 mg), and in the field it was much higher.

In further contrast to the response of male CL, we observed in flight tunnel tests a significant degree of arrested upwind flight of male SBL responding to the CL blend, suggesting that the upwind flight response of males that initiated a response to Z7–12:OAc was adversely affected by one or more of the CL minor components. Recently, Grant et al. (1987) reported the existence of single olfactory receptor neurons on the antenna of male SBL specifically sensitive to low dosages of Z5–12:OAc, a minor component of the CL blend and one not found in the SBL. They suggested that Z5–12:OAc may be an important element in male SBL discrimination between female SBL and the CL blend.

The types of discrimination exhibited by CL and SBL males are not unique to these species. In a previous study we showed that the sensitivity of male CL, Oriental fruit moths, *Grapholita molesta* Busck, and the red-banded leafroller *Argyrotaenia velutinana* Walker, to the female-produced blend of components was significantly greater than to the major component(s) alone (Linn et al., 1986). Similarly, a number of other species have been reported to be able to detect compounds that are not part of the conspecific pheromone blend but that result in significant reductions in trap catch when presented with the pheromone (Priesner 1980, 1985). This is, in fact, the case with the CL, in which the compound Z7–12:OH causes significant levels of arrested upwind flight when present in the CL blend in amounts as low as 0.5% of the major component (Linn et al., 1984). Interestingly, Z7–12:OH has been proposed as a pheromone component in the related noctuid, *Autographa californica* (Steck et al., 1979).

Our results and conclusions are also in basic agreement with other published studies. Mitchell (1972) found in two of three field tests that CL females caught significantly more CL males than SBL males, and that while SBL females caught approximately equal numbers of male CL and SBL, the number of CL caught was significantly lower than to CL females and was approximately equal to the number caught by Z7–12:OAc alone. This supports our conclusion that minor components of the CL blend reduce the response of SBL males to Z7–12:OAc and that the Cl males responding to the SBL pheromone represent

a small proportion of the population that possess a lower degree of sensitivity to the six-component blend compared to Z7–12 : OAc. In another study, Leppla (1983) also showed, in the laboratory and the greenhouse, that female CL attracted many more male CL than SBL, but also that female SBL caught more SBL than CL. He showed further that when females were placed together male capture was approximately equal. These results suggest that males are able to disciminate between respective blends, a conclusion similar to our flight tunnel results but in disagreement with the study by Mitchell (1972).

Although the selection pressures that have led to the evolution of multicomponent pheromones are not well understood, our results support the idea that both interspecific and intraspecific interactions are important. Male CL, and to a lesser extent male SBL, are clearly more sensitive to the female-produced blend than to Z7–12 : OAc alone. This suggests that there is, or has been, selection for increased male discrimination of pheromone quality, possibly as a result of intraspecific competition between males for unmated females. The increased selectivity of male CL in turn provides a mechanism for discrimination of heterospecific signals, because the majority of the male population requires the complement of minor components for a response to occur. However, a more obvious interspecific effect relates to the perception by males of compounds that are not components of the conspecific female pheromone, but rather are part of the chemical signal of a closely related species. Male SBL exhibited significant levels of arrested upwind flight to the CL blend and, based on the studies of Grant et al. (1987), we would concur with their proposal that Z5–12 : OAc provides the basis for discrimination by male SBL between female SBL and CL. This phenomenon appears to be widespread in the moths and is possibly associated with selection pressures between closely related sympatric species to prevent cross-attraction.

In conclusion, our study demonstrates that the multicomponent pheromones of the CL and SBL serve as effective signals for mate location as well as for discriminating between heterospecific blends. It is also clear that male discrimination can result from at least two processes affecting male perception, one (an intraspecific effect) associated with a heightened sensitivity and specificity for the female-produced blend, and the other (an interspecific effect) involving perception of a component that is not a part of the conspecific pheromone signal but which is a component in a related species blend. The results also indicate that the communication channel is noisy, as in both species a certain proportion of the population did not discriminate betwen the common major component of the two systems and the heterospecific signals. In this regard, Leppla (1983) suggested that close-range courtship behaviors could provide an additional source of information by which discrimination between species can occur. Future studies should elucidate the details of pheromone

composition in other related noctuid moths, as well as the response of males to those pheromones and the effects of related species signals on their behavior.

Acknowledgments—We thank Kathy Poole and Marlene Campbell for rearing the insects, and Geoff Rule for help in preparing the synthetic blends. We gratefully acknowledge Dr. Robert O'Connell and Dr. Alan Grant of the Worcester Foundation for Experimental Biology for their comments on the manuscript and allowing us to refer to the results of their recent studies with the SBL. We also thank Joe Ogrodnick and Rose McMillen-Sticht for preparing the figures. This research was funded by NSF grant BNS 8216752.

Abstract—Four natural products, of varying activity as deterrents of leafcutter attack, were tested for their effects on ant survival and on the growth of the mutualistic attine fungus. The substances were incorporated into an artificial liquid diet for bioassays on the ants or included in an agar culture medium for fungus growth-inhibition studies. Three of the four compounds exhibited deleterious effects on either adult leafcutting ants or their mutualistic fungus, and there appeared to be some correlation between deterrency and activity in these toxicity assays. The implications of these findings for leafcutting ant foraging patterns are discussed.

Key Words—*Atta cephalotes*, Hymenoptera, Formicidae, Attini, leafcutter ants, mutualism.

INTRODUCTION

Leafcutting ants of the genus *Atta* (Formicidae: Attini) are common herbivores in successional forests throughout the Neotropics. A single colony of these ants may harvest many kilograms of leaf material in the course of a year, while attacking 50 or more plant species in the vicinity of the colony (Cherrett, 1968; Lugo et al., 1973; Rockwood, 1976; Haines, 1978). Adult ants are known to imbibe liquid from cut and crushed leaf tissues to satisfy some of their metabolic

0098-0331/88/0100-0059$06.00/0

requirements (Littledyke and Cherrett, 1976; Quinlan and Cherrett, 1979). The ants use solid leaf material to culture a mutualistic fungus, which is believed to be the sole food of the ant larvae (Quinlan and Cherrett, 1979) and the source of proteolytic enzymes which are redistributed in the fungal gardens via the ant's fecal fluid (Boyd and Martin, 1975; Febvay and Kermarrec, 1981). This fungus metabolizes large amounts of cellulose (Martin and Weber, 1969) and may also detoxify some inhibitory or potentially deleterious plant substances (Littledyke and Cherrett, 1976). These characteristics contribute significantly to the abundance of leafcutter ants in neotropical habitats, and to the enormous size of mature ant colonies (in excess of one million workers; Weber, 1972; Schade, 1973).

Although leafcutting ants attack many different plants, at any given time most of the harvested material comes from only a few species (Cherrett, 1968; Rockwood, 1976). Recent laboratory and field studies of the Central American leafcutter *Atta cephalotes* have shown that diet selection is closely related to plant secondary chemistry (Hubbell et al., 1984; Howard, 1987). Numerous terpenoid compounds, isolated from plants unpalatable to *A. cephalotes*, are known to repel these ants or to deter the harvest of otherwise acceptable substrates (Wiemer, 1985). Furthermore, the crude lipid extracts of many other avoided or unpalatable plants are significantly deterrent (Hubbell et al., 1984; Howard, 1987), although specific active compounds have not yet been identified.

Why should terpenoids and other lipids deter or repel leafcutting ants? One possible explanation is that these substances are harmful to the ants, to their mutualistic fungus, or to both; but little evidence currently exists in support of this hypothesis. While lipid extracts of plant tissues have been shown to deter or repel leafcutting ants (Littledyke and Cherrett, 1978; Mudd et al., 1978), the physiological impact of these deterrents on the ants and their fungus has not been investigated. To evaluate the hypothesis that deterrent lipids are generally deleterious to leafcutter ants and/or to their mutualistic fungus, we undertook a preliminary investigation of the effects of several terpenoid deterrents on the survival of the ants and the growth of their fungus.

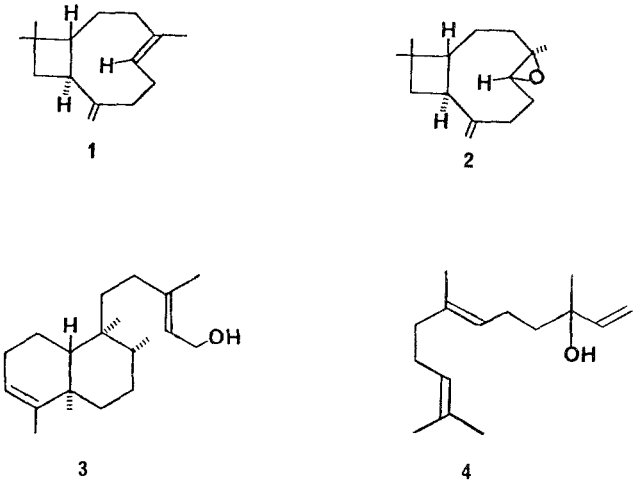
METHODS AND MATERIALS

The leafcutting ants and the fungus used in the study were obtained from a captive colony at the University of Iowa. The colony was originally collected in Santa Rosa National Park, Costa Rica, in August 1982, and was approximately 1 year old at the time of collection. The colony has been maintained in 15 interconnected Plexiglas boxes (12 × 12 × 24 cm), in a temperature- and humidity-controlled room in the Department of Biology, University of Iowa.

Ambient conditions were maintained at 23°C and 40–60% relative humidity. The colony has been fed lilac leaves daily (freshly picked in season, and frozen for use during the winter months), and maintained on a 12 hr: 12 hr light–dark cycle. Under these conditions the colony grew from a Petri dish-sized ball of fungus at the time of collection to completely fill five of the Plexiglas boxes with fungus.

Deterrent Chemicals Tested. Four deterrent terpenoids were tested for potential toxic effects on *A. cephalotes* and its mutualistic fungus: caryophyllene (1), caryophyllene epoxide (2), kolavenol (3), and nerolidol (4) (Scheme 1). All four compounds have been isolated from plants native to the range of *A. cephalotes*, including *Hymenaea courbaril* (1 and 2; Hubbell et al., 1983), *Melampodium divaricatum* (2 and 3; Hubert and Wiemer, 1985), and *Vismea baccifera* (2, 3, and 4; Cancilla, 1985). They were chosen for this study either because they are commercially available or because a large quantity was available from a plant extract. In most cases, natural concentrations of these compounds in plants have not been established; but caryophyllene and caryophyllene epoxide are estimated to occur in leaves of *Hymenaea courbaril* in concentrations of 6.7 mg/g and 8.5 mg/g dry weight, respectively (Hubbell et al., 1983). These concentrations represent approximately 3.0 mg/g and 3.8 mg/g in fresh leaf material, given an average moisture content of 55% for leaves of this species (Howard, 1987).

A laboratory bioassay, which has been described in detail elsewhere (Hubbell and Wiemer, 1983), was used to measure the deterrent activity of these compounds. Bioassays were conducted by placing 60 rye flakes soaked in a



SCHEME 1.

solution of the test compounds on a computer-generated random grid; 60 rye flakes soaked in solvent alone served as controls. Ants were allowed to forage on the grid until half the control flakes were harvested, and the number of test flakes harvested at this time was counted. The significance of the difference between the number of control and test flakes harvested (C − T) was determined using a modified binomial test (Hubbell et al., 1984).

Ant Survivorship Bioassays. Three concentrations of each terpenoid deterrent were tested for their effect on the survivorship of adult ants: 1, 0.1, and 0.01 mM. Each compound was incorporated into an artificial liquid diet consisting of 5% glucose, 1% bacteriological peptone (Nutritional Biochemicals Corp., Cleveland, Ohio), and 0.1% Vanderzant vitamin mixture (Nutritional Biochemicals) (Boyd and Martin, 1975). The diet was autoclaved and then, after it had cooled for 20 min, the test compound was added as an ether solution (1 ml). The ether was removed by heating the diets in a hot water bath (80°C), and the resulting solution was stored in a refrigerator until needed. A control diet was prepared by adding ether (1 ml) to the glucose–peptone–vitamin mixture and then removing the ether in the same manner.

Each concentration of the four deterrents was presented to 60 worker ants in a no-choice bioassay. Worker ants ($\bar{X}$ = 2.2 mm ± 0.14 mm head width) were collected from the colony and assigned to treatment groups using a random number table (Rohlf and Sokal, 1969). Each treatment group of 60 ants was distributed among 10 disposable 100 × 15-mm Petri dishes, and each dish of ants was given the liquid diet in small dishes packed with cotton. Dishes were checked daily and the number of surviving ants noted. Petri dishes and the diet were regularly changed to prevent mold growth on the diet. All dishes were kept in a temperature-controlled incubator, evenly distributed among the shelves.

In addition to tests involving deterrent compounds and the controls, survival under conditions of starvation was measured using 60 ants divided equally among 10 Petri dishes. Ants were collected and assigned to dishes at random, but only a small amount of water was offered in place of food. These dishes also were distributed evenly among the shelves of the incubator.

The effect of each deterrent compound on ant survival was tested using a one-way analysis of variance (ANOVA). The average number of days ants survived in each Petri dish was calculated, and this mean value was used as a single observation in the ANOVA. Each Petri dish was treated as a single observation for the purposes of statistical analysis, yielding 10 observations per treatment.

Fungal Growth Bioassays. Fungus growth bioassays were conducted by comparing the relative inhibition of fungus growth on an agar medium containing deterrent compounds with the amount of growth on control media. A pure culture strain of the mutualistic ant fungus, originally taken from a laboratory colony, was the source of inoculum for these bioassays. The fungus was maintained in culture on potato dextrose agar (PDA) at 25°C. Confirmation that this

fungus isolate was the mutualistic ant fungus was achieved by offering pure cultures to the ants and observing that they readily incorporated the artificial cultures into existing fungus gardens in the colony.

Each of the deterrent compounds was dissolved in diethyl ether at a concentration 10-fold higher than that required for the assay. A 1.0-ml volume of each test solution was added to 10 ml sterile melted PDA contained in a 20 × 150-ml plastic cap-stoppered test tube. Each deterrent compound was tested at final concentrations of approximately 0.1 mg/ml and 0.01 mg/ml medium. The medium was immediately vortexed to distribute the compound evenly throughout, and the tubes were kept in a 50°C water bath for 2 hr to allow evaporation of the diethyl ether. The tubes of media were allowed to cool and solidify to provide agar slants, which were stored for two days at room temperature to allow the last traces of solvent to evaporate. One set of control media was prepared by adding 1 ml ether to each tube of agar and going through the same evaporation procedures as described for the test media. A second set of control media contained only PDA and went through the same evaporation procedures as described for the other media.

Both final concentrations of each of the four test compounds and the control media were inoculated in triplicate with a small center-point inoculum (ca. 1 mm diam.) of the mutualistic ant fungus. The cultures were incubated at room temperature (24°C), and growth readings were made on days 3, 5, 7, 10, 12, 14, 21, and 28. Growth in the two test media and in the solvent control was compared with the amount of growth seen in the PDA controls. The relative growth inhibition by the deterrents was scored as follows: 4+ = no growth; 3+ = growth 25% that of controls; 2+ = growth 50% that of controls; 1+ = growth 75% that of controls; 0 = growth equal to that of controls.

RESULTS

The four compounds tested differed both in their deterrent activity and in their effect on ant survival. Nerolidol and caryophyllene epoxide are highly deterrent to leafcutting ants, even at very low concentrations, while kolavenol is slightly less deterrent, and caryophyllene is deterrent only at relatively high concentrations. Neither caryophyllene nor kolavenol had any consistent effects on the survival of adult ants at the concentrations tested, and ants given a 0.01 mM solution of caryophyllene survived longer than did control ants (Figure 1). In contrast, a 1.0 mM solution of nerolidol significantly decreased the survival of adult ants, and intermediate concentrations of 0.1 and 0.01 mM resulted in lower survival rates, although these were not statistically significant. All concentrations of caryophyllene epoxide tested resulted in significant decreases in survival compared to controls.

In contrast to our observations with caryophyllene epoxide, kolavenol, and

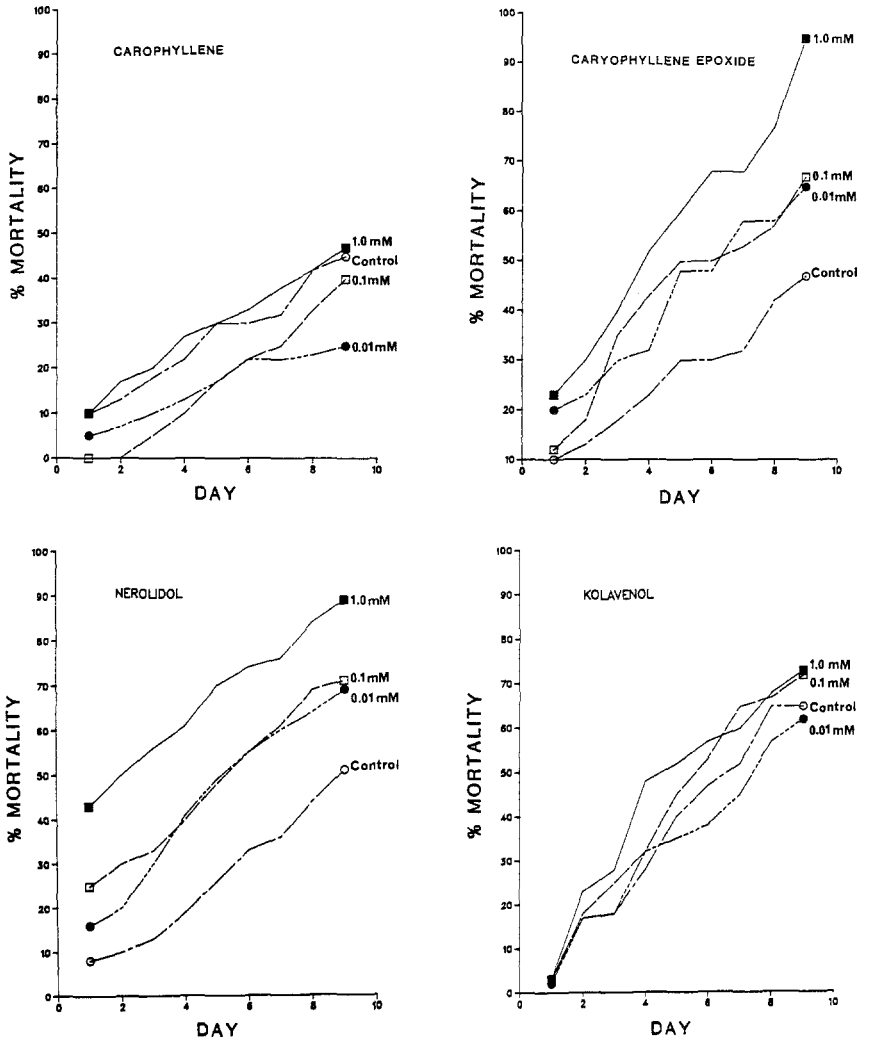


FIG 1. Ant Mortality on artificial diets containing terpenoid deterrents.

nerolidol, the high concentrations of caryophyllene are not completely soluble in the normal assay medium. Therefore a second experiment was conducted in which 2% ethanol was added to both caryophyllene test and control plates. Although caryophyllene is much more soluble in this modified medium, there was still no significant difference in toxicity between the caryophyllene and control experiments.

The decreases in ant survival produced by caryophyllene epoxide and nerolidol were not caused by simple feeding inhibition induced by these com-

TABLE 1. ANT DETERRENT ACTIVITY, ANT TOXICITY, AND FUNGISTATIC ACTIVITY OF FOUR TERPENOID NATURAL PRODUCTS ISOLATED FROM TROPICAL WOODY PLANTS

				0.1	6.1[ab]	0.014	2+
				0.001	6.6[ab]		
				0	8.7[b]		

[a] C/T is the ratio of control flakes to test flakes taken in a deterrency bioassay; at lower concentration caryophyllene is not significantly deterrent.

[b] Mean survival time in days is given for the 60 ants in each ant toxicity assay. Column entries followed by the same superscript letter are not significantly different (Tukey's HSD test, $P < 0.05$).

[c] Relative growth inhibition in the fungal bioassays was scored as follows: 4+ = no growth; 3+ = growth 25% that of controls; 2+ = growth 50% that of controls; 1+ = growth 75% that of controls; 0 = growth equal to that of controls).

pounds. Even with water freely available to prevent desiccation, all ants in a starvation treatment died within two days of the start of the bioassay. Ants given 1.0 mM concentrations of nerolidol and caryophyllene epoxide survived nearly twice as long. These results suggest that ants did ingest some amount of the liquid diet offered, even when this contained deterrent compounds. The effects of caryophyllene epoxide and nerolidol are thus due, at least in part, to direct intoxication of ants rather than simple starvation.

Similar patterns of variation were found in the effects of these compounds on fungal growth. Kolavenol had virtually no effect on fungal growth, but each of the other three compounds produced detectable inhibition of the fungus (Table 1). At the lower concentration tested, caryophyllene and caryophyllene

epoxide reduced fungal growth by about 25% and nerolidol reduced growth by about 50%. At the higher of the two concentrations tested, caryophyllene decreased growth of the ant fungus by as much as 50% compared to controls, and both nerolidol and caryophyllene epoxide completely inhibited ant-fungus growth.

DISCUSSION

The bioassays reported here represent relatively crude methods for determining the impact of plant natural products on leafcutter ants and their mutualistic fungus, measuring only dramatic effects (e.g., ant death or macroscopic evidence of fungal growth inhibition) produced by relatively short-term exposure. In addition, for bioassays on the ants, we used concentrations approximately an order of magnitude lower than those known for caryophyllene and caryophyllene epoxide from fresh leaves of *Hymenaea courbaril*. Nonetheless, three of the four deterrent compounds tested exhibited some degree of deleterious activity against either the leafcutting ants or their fungus. Caryophyllene had no detectable impact on the survival of adult ants but did decrease fungal growth. Both nerolidol and caryophyllene epoxide showed strong deleterious effects on both ant survival and fungal growth.

Among the three compounds that were active against ants and the fungus, there is a rough correlation between deterrency and the magnitude of toxic or inhibitory activity. Nerolidol is the most deterrent of these compounds, and caryophyllene epoxide is almost as deterrent, while caryophyllene is much less active (Table 1). Caryophyllene epoxide showed the strongest activity against adult ants, and nerolidol was also demonstrably active, but no significant effects were produced by caryophyllene on the ants. Nerolidol and caryophyllene epoxide had strong and approximately equal effects on fungal growth, while caryophyllene decreased fungus growth to a lesser extent. Therefore, the two most deterrent compounds had strong effects on ants and fungus, while the less-deterrent compound exhibited only a somewhat weak inhibitory effect on the fungus.

The results also show that all deterrent compounds do not have parallel effects on ants and fungus. Caryophyllene epoxide decreased survival of adult ants at all concentrations tested; it also strongly decreased fungal growth. In contrast, low levels of nerolidol did not significantly reduce survival of adult ants, but it did inhibit fungus growth more than did low levels of caryophyllene epoxide (50% reduction in growth vs. 25%, respectively). Caryophyllene decreased fungus growth but did not significantly affect ant survival.

Why should kolavenol be deterrent to leafcutting ants but show no activity against either the ants or their fungus? It may be that kolavenol is structurally

similar to a substance which does have such effects and evokes similar sensory responses by the ants. Alternatively, or in addition, it is possible that kolavenol does have some deleterious effect on either ants or fungus, either at higher concentrations or on some aspect of ant and/or fungus survival not readily measured by these bioassays. For example, it might be that kolavenol reduces the fecundity of ant queens, interferes with larval development of ants, or inhibits enzyme systems necessary for fungal growth on leaf material. Furthermore, the natural concentration of kolavenol in its source plants is not yet known, and the concentrations used in these experiments may be lower than those typically encountered by leafcutting ants and their fungus.

Overall, these results support the idea that deterrent terpenoids are deleterious to leafcutting ants and their mutualistic fungus. Furthermore, the degree of deterrency bears a rough relationship to the strength of toxic or inhibitory activity. However, deterrent compounds are not necessarily equally harmful to both ants and fungus. It has often been suggested that leafcutting ants prefer leaf material that provides the best substrate for fungal growth and that they avoid leaves containing compounds which inhibit the fungus. Leafcutting ants do discriminate against caryophyllene, which inhibits fungus growth, but both caryophyllene epoxide and nerolidol are harmful to ants as well. Although none of the compounds tested were dramatically more toxic to the ants than to their fungus, there appears to be no reason why such compounds should not exist.

The deleterious effects documented in this study provide significant insights into the consistent finding that plant lipids deter leafcutting ant attack (Littledyke and Cherrett, 1978; Mudd et al., 1978; Hubbell et al., 1984; Howard, 1987; Wiemer, 1985). The harvest of plant material containing these compounds, either for use as fungus substrate or as a source of ant nutrition, may have serious effects on the viability of both ants and fungus. In contrast, other classes of secondary compounds have little systematic effect on diet selection of leafcutting ants (Howard, 1987), and toxic or inhibitory effects of other plant secondary chemicals have yet to be demonstrated. Studies focusing on tannins, alkaloids, and plant aqueous extracts have established no clear relationship between fungal growth rates and ant preferences for plants or the deterrency of specific chemicals (Quinlan and Cherrett, 1978; Mudd and Bateman, 1978). Although tannic acid inhibits the growth of the fungus of the minor attine *Myrmecocrypta buenzlii* (Seaman, 1984), members of this genus are not generally considered to be "leafcutting ants" as they do not consistently use plant material for fungus garden substrate (Weber, 1946). We suggest that further studies of terpenoid and other lipid ant-deterrent compounds, and elucidation of the mechanisms by which they exert toxic effects, may illuminate many details of the ant–fungus symbiosis and may lead to new and valuable insights into natural mechanisms of plant resistance against attack by insects and fungi.

(Received October 28, 1986; accepted January 7, 1987)

Abstract—The effects of the allelopathic compounds of an "ethanolic extract" of corn pollen on growth, respiration, and cellular division of watermelon (*Citrullus lanatus*, var. peacock improved) were studied. Bioassays with the ethanolic extract showed an inhibition of radicle and hypocotyl growth. The effects on respiration were observed in isolated watermelon hypocotyl mitochondria. The ethanolic extract acts as an inhibitor of the electron pathway, decreasing oxygen consumption in state 3, with malate and succinate substrates. The specific inhibition site probably is located before the cytochrome *c*. Ascorbate-TMPD as substrate reversed the inhibitory effect of the ethanolic extract. An evaluation of the mitotic index was made in slide preparations of previously treated meristematic cells. A decrease in mitotic activity of more than 50% was found, as well as irregular and pycnotic nuclei. The data obtained from this study reflect an important mechanism of action of the allelopathic compounds of corn pollen.

Key Words—Allelopathy, corn pollen, respiration, cell division, watermelon.

INTRODUCTION

The allelopathic compounds released into the environment by a "producer plant" sometimes cause deleterious effects on other plants. These effects are revealed in growth, development and vigor, or a delay or absence of flowering

[1]This work was sponsored by Project number 001079, Consejo Nacional de Ciencia y Tecnología.

0098-0331/88/0100-0071$06.00/0

and fruiting. All of these manifestations are a result of alterations in metabolic processes in the affected plant (Horsley, 1977).

Knowledge of the mode of action of allelopathic compounds is rudimentary. However, studies on this subject (Muller, 1965; Muller et al., 1968; Stenlid, 1970; Demos et al., 1975; McCahon, et al., 1973) have shown that allelochemicals can act on several sites within a plant cell, altering processes such as rate of ion uptake, synthesis of proteins, activation or breakdown of hormones, photosynthesis, energy metabolism, and cell division.

Allelopathic compounds can alter the energy metabolism in plant cells, by inhibiting or stimulating respiration. Both actions may be harmful to the energy-producing respiratory process (oxidative phosphorylation) and consequently to other metabolic processes (Horsley, 1977; Putnam, 1983; Rice, 1984).

In a study of the allelopathic potential of corn pollen, Jiménez et al. (1983) confirmed that corn pollen has allelopathic compounds that inhibit the growth of other plants. Peasants from Tabasco, Mexico, assert that fruiting of watermelon is reduced when corn pollen falls over it. This work was undertaken to evaluate the effects of corn pollen on growth, respiration, and cell division of watermelon (*Citrullus lanatus*).

METHODS AND MATERIALS

Bioassays with Corn Pollen and "Ethanolic Extract" of Pollen. Corn pollen was collected from mature male flowers of *Zea mays* L. (Chalquiñocónico, Hernández), in plots located at Mixquic, Mexico City. In an initial bioassay several amounts of pollen (50, 100, and 150 mg) were sprinkled on watermelon seeds (*Citrullus lanatus* (Thunb) Matsum and Nakai, var. peacock improved) in Petri dishes with filter paper as the substrate, and 5 ml of distilled water were added to each dish. The control contained only distilled water. Each treatment was replicated six times. Seeds were germinated at 27°C in the dark. After 168 hr, the radicle length was measured, and data were statistically analyzed as a randomized complete block design.

A second bioassay was carried out with an "ethanolic extract" obtained from corn pollen sonicated in ethanol for 10 min. This extract was filtered and evaporated to dryness in a Buchler flask evaporator under reduced pressure.

The study of Jiménez et al. (1983) shows the preliminary steps to isolate and identify the allelopathic compounds of corn pollen. The authors obtained hexane, ethyl acetate, methanol, and methylene chloride extracts, and also a white and a yellow product from the CH_2Cl_2–MeOH fraction. However, the organic solvents extracted only a small part of the active compounds, and the inhibitory effects of aqueous extract or of remaining pollen were greater than

those of the organic extracts or their products. Considering this result and in order to simplify the process, a new extract was obtained by sonicating pollen with ethanol for 10 min. The ethanolic extract showed a greater inhibitory effect on seeds than that of the methanolic and methylene chloride extracts or of remaining pollen. For this reason, in the present work the ethanolic extract was used for the bioassays; this extract gave a strong positive reaction to preliminary test with phenols.

Five amounts of the ethanolic extract (25, 50, 75, 100, and 125 mg) in a homogeneous suspension with distilled water were tested on the radicle and stem growth of watermelon seedlings. Hereafter, we will call this resuspended ethanolic extract, simply "ethanolic extract" when we refer to these bioassays. Bioassays were conducted in Petri dishes with a filter paper substrate and 11 seeds. The control contained only distilled water. The seeds were germinated under the same conditions as in the first bioassay, with five replicates per treatment. After 168 hr, the radicle and stem length of the seedlings were measured. The data obtained were analyzed using the analysis of variance in a randomized complete block design; $P < 0.01$ and $P < 0.05$ levels of probability were accepted as significant.

Preparation of Mitochondria. The effects of the treatments on cellular respiration were observed on mitochondria isolated from the hypocotyls of 10-day-old watermelon plants grown in the dark in vermiculite at 27°C and a relative humidity of 50%.

The hypocotyls were cut into 1- or 2-cm pieces and placed in a medium containing 0.25 M sucrose–1 mM ethylenediamine tetraacetic acid (EDTA) adjusted to pH 7.3 with Tris base. The tissue was disrupted for 10 sec with a Polytron blender, passed through gauze, and the filtrate was adjusted to pH 7.3 with Tris base. All procedures were conducted at 4°C. The filtrate and supernatant were centrifuged for 10 min at 3000 and 10,000 rpm, respectively. The pellet was resuspended in the same medium with 0.1% (w/v) bovine serum albumin (BSA) and combined to yield a final volume of 50 ml. Two 25-ml aliquots were centrifuged at 10,000 rpm for 10 min, and the pellet was resuspended in 0.5 ml of the medium using a Teflon-tipped tissue grinder. Mitochondrial protein content (mg/ml) was estimated by the method of Lowry et al. (1951) with BSA as the standard.

Oxygen consumption was measured polarographically, with a Clark-type electrode at 25°C. The data obtained were reported as nanoatoms of oxygen consumed per minute per milligram of mitochondrial protein, or as a percent of the control. The reaction medium contained 100 mM KCl, 10 mM phosphate-Tris buffer, pH 7.4, 0.1% w/v BSA, and either 10 mM malate, 10 mM glutamate, or 10 mM succinate. These substrates were adjusted to pH 7.4 with Tris base. At zero time, we added 2 mg of mitochondrial protein. The final volume

was 3 ml. The ethanolic extract used in these experiments with mitochondria was dissolved in ethanol (10 mg/ml); from this stock solution we took the volume necessary for the concentrations tested.

Preparation of Submitochondrial Particles. The mitochondria suspended in 0.25 M sucrose–1 mM EDTA, were adjusted to pH 8.6 with Tris base and subjected to a 60-sec sonication. The small number of unbroken mitochondria were removed by centrifugation at 10,000 rpm for 10 min. The supernatant containing the submitochondrial particles was then centrifuged at 40,000 rpm in an air-driven ultracentrifuge (Beckman, Fullerton, California, Airfuge). The pellet was resuspended in 1 ml of 0.25 M sucrose–1 mM EDTA, pH 7.4. The mitochondrial protein content was estimated using the technique of Lowry et al. (1951), with bovine serum albumin as the standard. We measured the rate of NADH oxidation with the Clark electrode.

Effects on Cell Division. The effects of corn pollen and of the ethanolic extract were observed on meristematic cells from the radicle of dark-grown watermelon seedlings. When the radicle length was 1.5 cm, we randomly chose two seedlings from each Petri dish and from each treatment. The seeds were germinated in the dark, in order to avoid effects of the circadian rhythm.

Root tips 2 mm long were hydrolyzed in 5 N HCl for 15 min, stained with acetorceine, and squashed in a drop of 45% (v/v) acetic acid. Permanent slides were made following the Conger and Fairchild technique (1953).

An evaluation of the mitotic index was carried out on 1000 randomly chosen cells per treatment. The mitotic index (MI) was calculated as the quotient of the total number of dividing cells (DC) with the total number of analyzed cells (AC), ($MI = DC/AC$). The data obtained were statistically analyzed through a test of differences of proportions, in which a Z value is calculated for each treatment vs. control and compared to the Z value of a normal distribution with $P < 0.01$.

RESULTS

Corn pollen had a significant inhibitory effect on the growth of watermelon radicles. Inhibition increased with the amount of pollen sprinkled over the seeds (Figures 1 and 2). Mean contrast test showed no significant difference between 100 and 150 mg of pollen; there was a significant difference between 50 and 150 mg. Fifty milligrams of pollen was enough to reduce radicle growth more than 50%. We also observed swelling and a grayish coloration at the neck base of the root.

The effects of the ethanolic extract of corn pollen on radicle and stem growth of watermelon seedlings are shown in Figures 3 and 4. Significant inhibition was observed with the ethanolic extract. Inhibition increased with in-

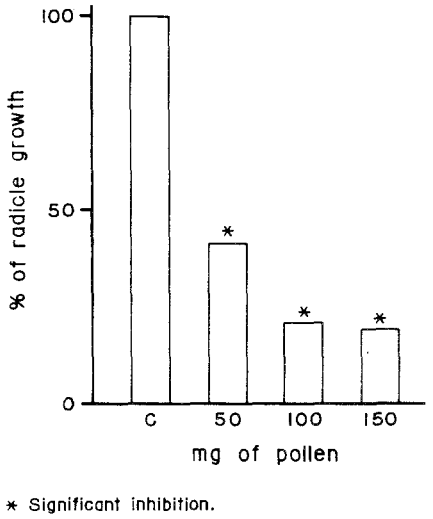

FIG. 1. Radicle growth of watermelon after treatment of seeds with corn pollen ($P < 0.001$).

creasing extract amount. Figure 3 shows that the inhibitory effects on stem growth are greater than those on the radicle. Seventy-five milligrams of extract caused more than 80% inhibition of stem growth.

Effects on Cellular Respiration. Figure 5 shows the traces of oxygen consumption by watermelon mitochondria. Figure 5A shows that ADP stimulated

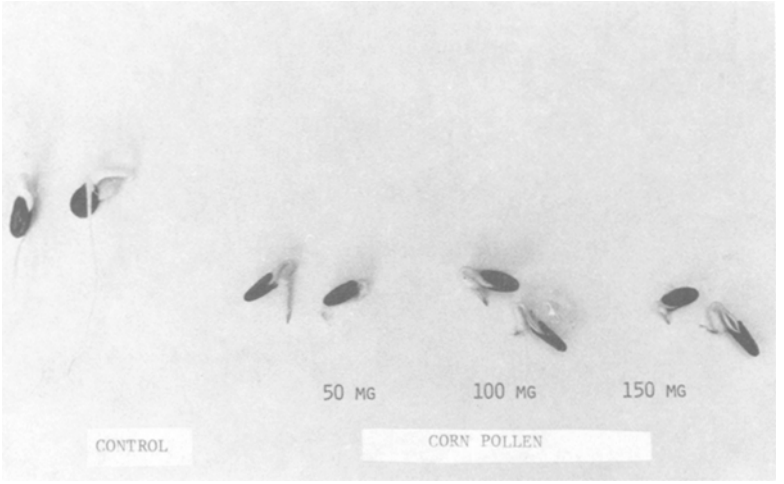

FIG. 2. Radicle growth of watermelon after treatment of seeds with corn pollen.

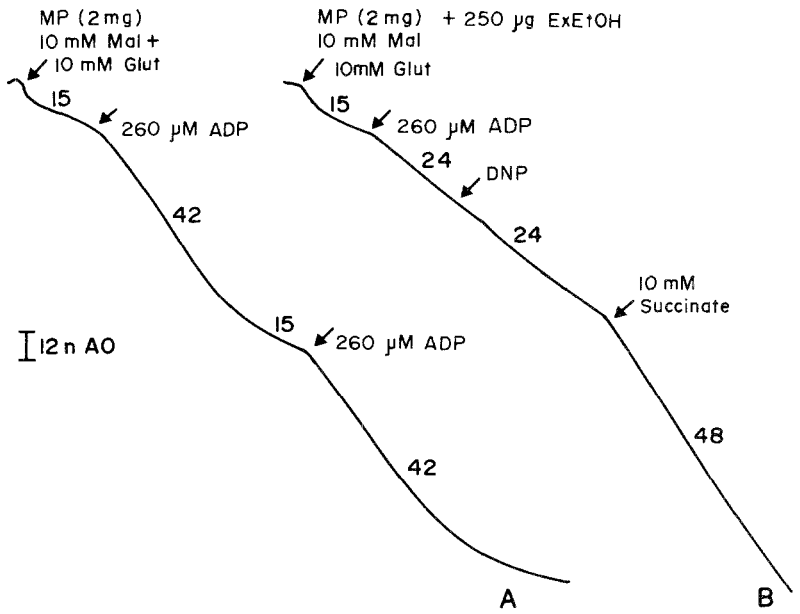

FIG. 5. Oxygen electrode traces: (A) Respiratory control (RC = 2.8) of malate–glutamate oxidation by watermelon mitochondria. (B) Effect of 250 μg of ethanolic extract of pollen added initially on state III of malate–glutamate oxidation. Numbers represent final concentrations in the reaction medium (final volume 3 ml). Numbers on traces refer to nanoatoms of oxygen consumed per minute per milligram of mitochondrial protein.

respiration (state III) with a respiratory control of 2.8 when malate–glutamate was the substrate. Figure 5B demonstrates that the initial addition of 250 μg of the ethanolic extract to mitochondria respiring with malate–glutamate results in a decrease of the state III respiratory rate which was not relieved by DNP. The ethanolic extract acted like an electron transport inhibitor, preventing stimulation of oxygen consumption by ADP and phosphorylation of ADP to ATP. The rate of respiration was the same before and after the addition of DNP. Also, when 10 mM of succinate was added, oxygen consumption was stimulated. This substrate is in the electron pathway at the level of the coenzyme Q (ubiquinone). Ethanol did not produce any effect on the respiratory rate of the mitochondria (data not shown).

Figure 6A and B illustrates the effects of the ethanolic extract on the respiratory rate of watermelon mitochondria with malate and glutamate as substrates. When the extract was added, during state III, the respiratory rate decreased.

Six hundred micrograms of the ethanolic extract added during state III of glutamate–malate oxidation also caused inhibition (Figure 7A). The rate of ox-

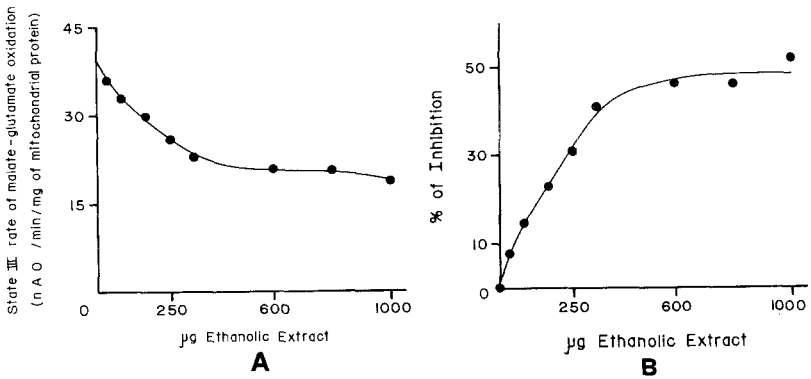

FIG. 6. (A) State III rate of malate-glutamate oxidation by watermelon mitochondria treated with ethanolic extract of corn pollen. (B) Percent of inhibition refers to control of state III rate of malate-glutamate oxidation with the different concentrations of ethanolic extract.

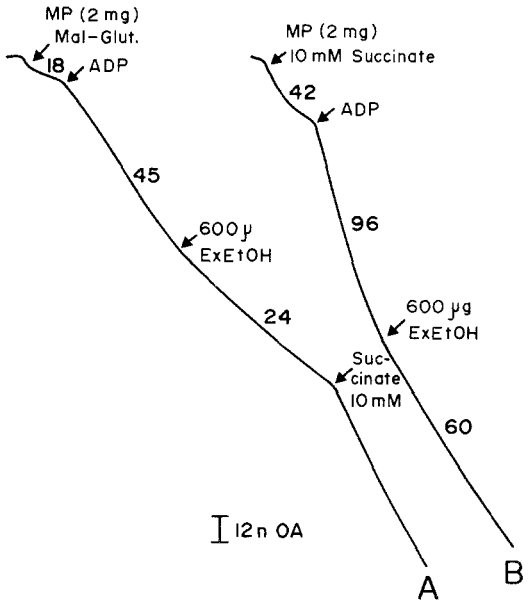

FIG. 7. Oxygen consumption traces illustrating the effect of ethanolic extract of pollen on state III rate of malate-glutamate (trace A) and succinate oxidation (trace B). Numbers given are final concentrations in reaction medium (final volume 3 ml). Numbers on traces are nanoatoms of oxygen consumed per minute per milligram of mitochondrial protein.

ygen consumption decreased from 45 nanoatoms O/min/mg to 24 nanoatoms O/min/mg. Figure 7B shows the rate of succinate oxidation. When 600 μg of the ethanolic extract were added during state III the respiratory rate decreased from 96 to 60 nanoatoms O/min/mg.

Figure 8A and B illustrates the effect of the ethanolic extract on state III succinate oxidation. The respiratory rate decreased with increasing concentration of the extract.

The inhibitory effect on succinate oxidation is smaller than that on malate–glutamate oxidation; however, at the higher concentrations of ethanolic extract, the inhibition was almost the same (Figures 6B and 8B).

In order to locate the probable site of inhibition of the ethanolic extract on the electron pathway, an experiment with menadione or vitamin K_3 (a quinone) was carried out. The oxygen electrode trace shown in Figure 9A and B illustrates that the addition of menadione to mitochondria respiring with malate–glutamate and 600 μg of the ethanolic extract did not neutralize the inhibition. So, we assume that the site of inhibition is not located at the level of coenzyme Q. However, ascorbate–TMPD reversed the inhibitory effect of the ethanolic extract (Figure 9C and D). This substrate releases electrons into the electron pathway at the level of cytochrome *c* facing the outer surface of the inner membrane. Therefore, the ethanolic extract of corn pollen probably inhibits respiration at a site located between coenzyme Q and cytochrome *c* in the electron pathway.

The ethanolic extract had no effect on the oxidation of NADH in submitochondrial particles, probably because it does not cross the inner membrane (Figure 10).

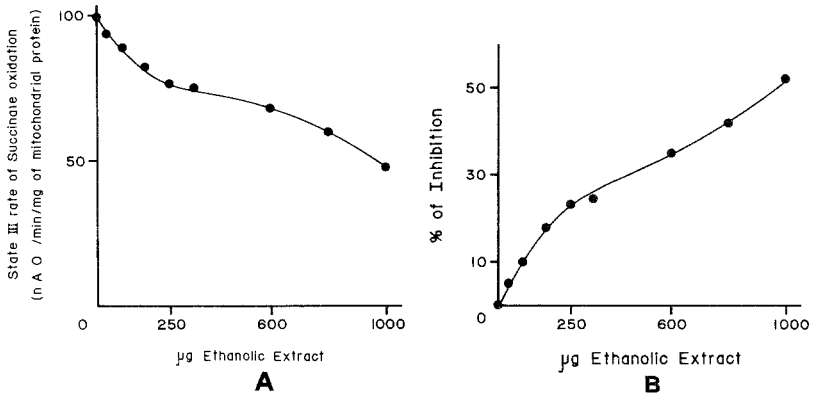

FIG. 8. (A) State III rate of succinate oxidation by watermelon mitochondria treated with ethanolic extract of corn pollen. (B) Percent of inhibition refers to control of state III rate of succinate oxidation with the different concentrations of ethanolic extract.

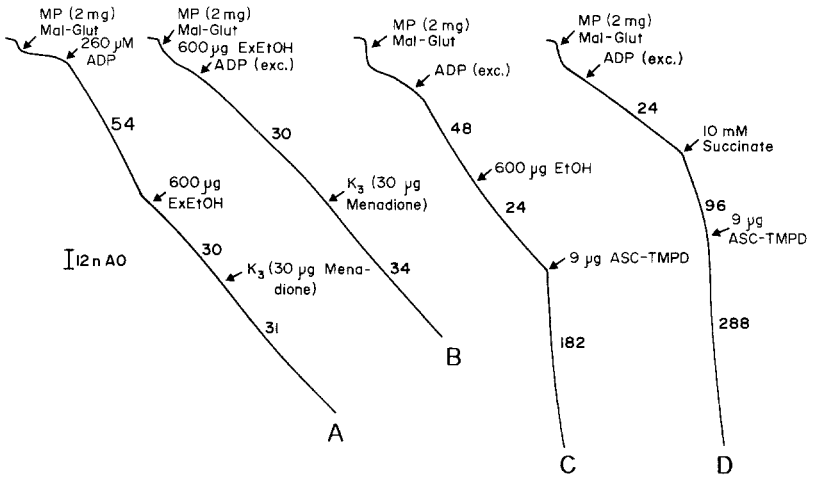

FIG. 9. Effect of ethanolic extract of pollen on state III rate of malate–glutamate, menadione (K_3), and ascorbate–TMPD oxidation by watermelon mitochondria. Numbers given are final concentrations in reaction medium (final volume 3 ml). Numbers on traces refer to nanoatoms of oxygen consumed per minute per milligram of mitochondrial protein.

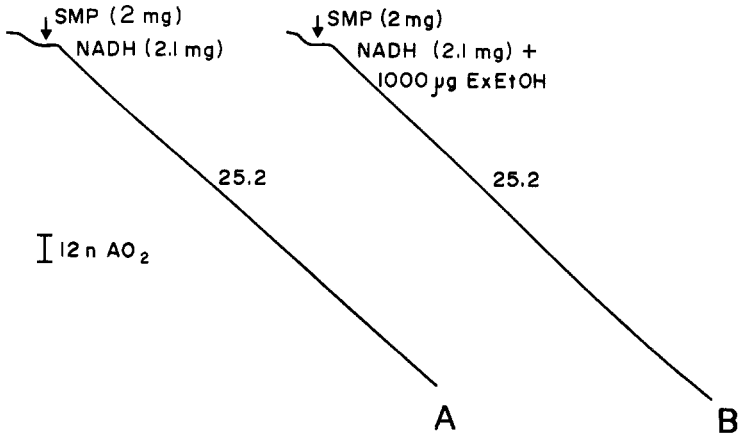

FIG. 10. Oxygen electrode traces illustrating the effect of ethanolic extract on NADH oxidation by watermelon submitochondrial particles. Trace A shows NADH oxidation without extract and trace B with the highest concentrations of ethanolic extract. Numbers given are final concentrations in reaction medium (final volume 3 ml). Numbers on traces refer to nanoatoms of oxygen consumed per minute per milligram of mitochondrial protein.

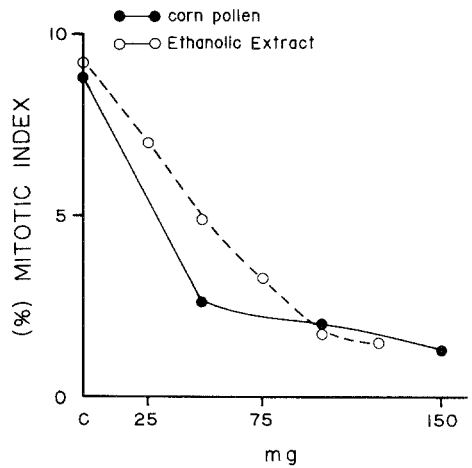

FIG. 11. Mitotic index (%) of meristematic cells of watermelon with corn pollen and with ethanolic extract ($P < 0.01$).

Effects on Cell Division. The mitotic index decreased as the amount of pollen and of ethanolic extract increased (Figure 11). The difference between the control and any of the treatments was significant ($P < 0.01$). But there was no difference among the three corn pollen treatments. Less than 50 mg of ethanolic extract did not produce significant differences ($P < 0.01$). We also observed that the meristematic tissue was destroyed in the treatment with corn pollen and that there were some pycnotic nuclei in the cells treated with the ethanolic extract (Figure 12).

DISCUSSION

The results presented in this study confirm that corn pollen has allelopathic compounds that inhibit plant growth, as Jiménez et al. (1983) reported. The inhibitory effects of the ethanolic extract on the radicle and stem growth of watermelon could be explained by the fact that respiration and energy production were severely inhibited. Inhibition of electron transport was demonstrated in the presence of the ethanolic extract.

Storey (1980) found that plant mitochondria oxidize succinate faster than malate. We confirmed this finding in our study; oxygen consumption at the lower concentrations of ethanolic extract was slower in malate–glutamate than in succinate. Apparently, the ethanolic extract needs a longer period of time to inhibit the specific site in the electron chain, so the inhibitory effect with succinate was not as strong as with malate–glutamate at the lower concentrations.

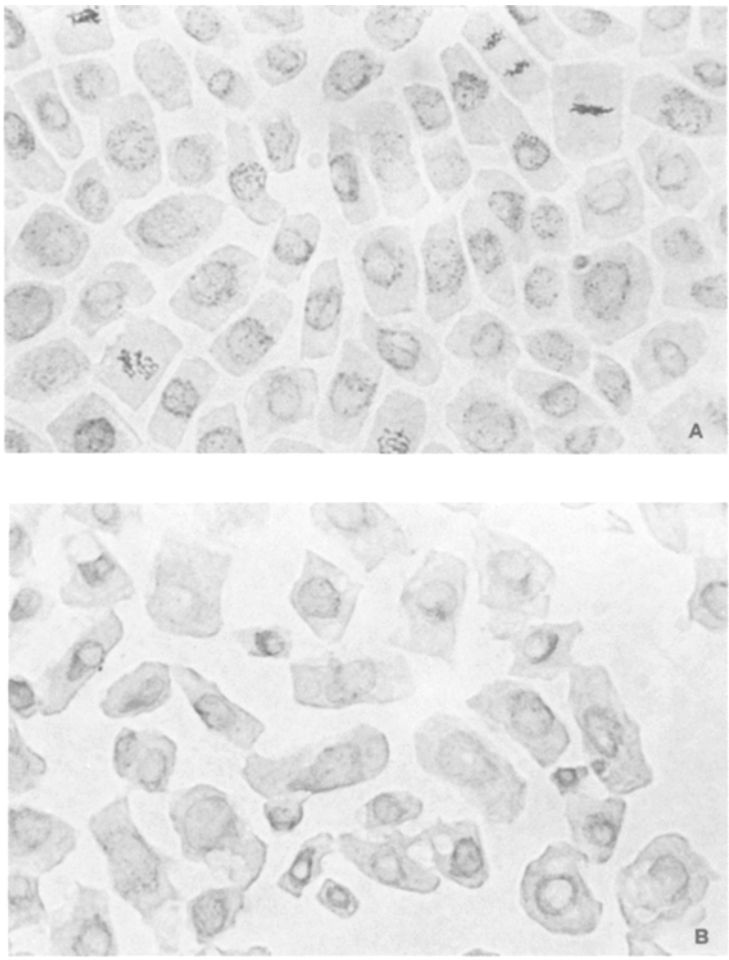

FIG. 12. Appearance of meristematic cells treated with pollen (B, C) and with ethanolic extract (D, E), arrows show the pycnotic nuclei. A is control.

Also, we know that succinate releases electrons at the ubiquinone level and that malate releases electrons at the NADH dehydrogenase level.

The site of action of the ethanolic extract probably is located between the cytochrome *b* and cytochrome *c*. The experiment with synthetic quinone (menadione) showed that the rate of oxygen consumption was not restored as might be expected if the ethanolic extract were acting at the ubiquinone level. However, ascorbate-TMPD reversed the inhibitory effect of the ethanolic extract.

It is well known that ascorbate–TMPD releases electrons at the cytochrome *c* level, which is facing the outer surface of the inner membrane. Douce et al.

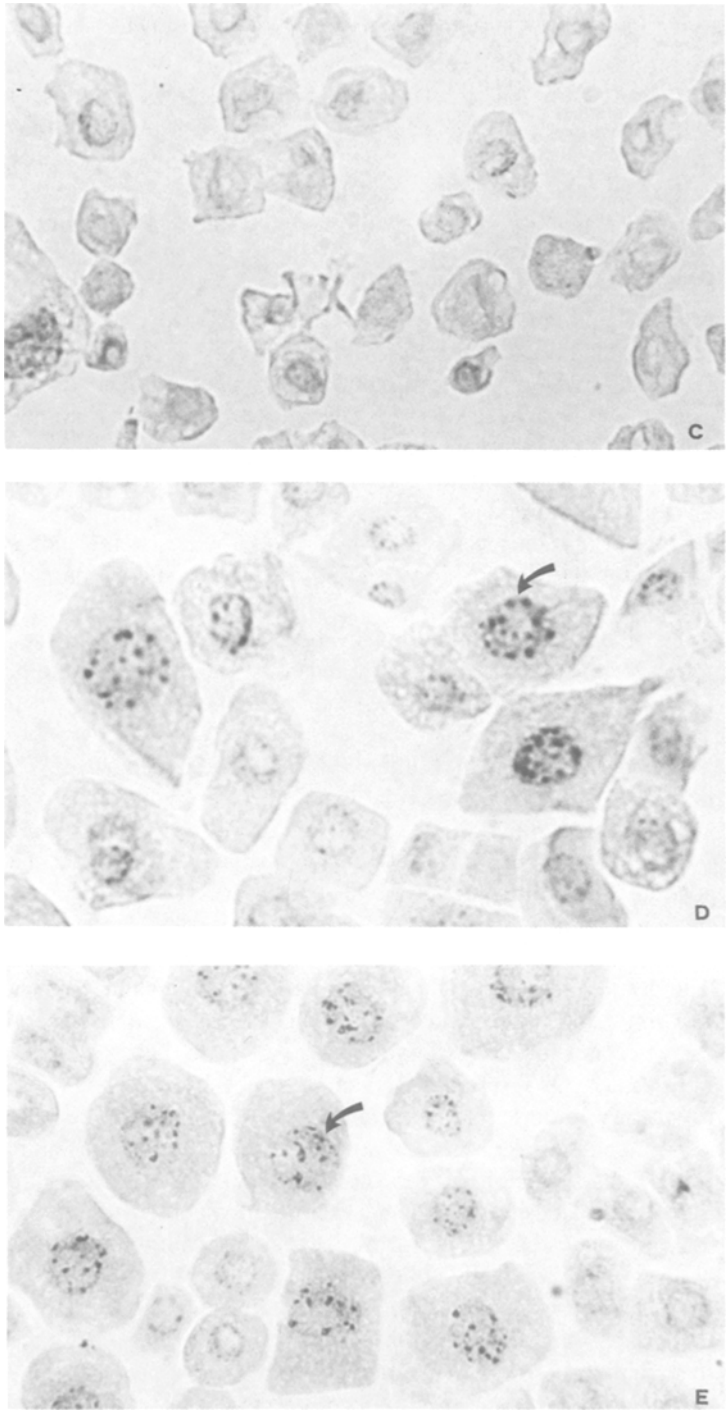

FIG. 12. Continued

(1978) found that β-pinene exerts a strong uncoupling effect at low concentrations, whereas it totally inhibits electron flow at higher concentrations. His work suggests that the inhibition site is probably before cytochrome *c*, at the quinone pool level.

The fact that the ethanolic extract had no effect on the submitochondrial particles suggests that it joins to cytochrome *c*, located inside the submitochondrial particles.

Another process that may be involved in the inhibitory effect of the ethanolic extract is membrane fluidity. Siedow et al. (1978) reported that a quinone analog of dibromothimoquinone decreased the fluidity of the inner mitochondrial membrane and suggested that the inhibition of mitochondrial electron transport might be associated with this effect. They also stated that their results support the concept of Moreland and Huber (1978) in that many lipophilic inhibitors of electron transport may act in a nonspecific fashion by decreasing membrane fluidity. Moreland and Huber (1978) ascribed the effects of some herbicides tested on mung bean mitochondria to a decrease in fluidity and an increase in membrane permeability, and not to a direct interaction with any of the electron-transport compounds.

On the other hand, if inhibition in the respiratory chain exists, oxygen consumption is not stimulated by ADP, and consequently there is no phosphorylation of ADP to ATP. Therefore the production of energy necessary for other processes is decreased.

Muller and his colleagues (Muller, 1965; Muller and Hague, 1967; Muller et al., 1968, 1969) found that the volatile monoterpenes, cineole and camphor, from *Salvia leucophylla* inhibit the growth of *Cucumis sativus* and *Avena fatua*. Oxygen uptake by mitochondria, cell division, and cell elongation in the radicle and hypocotyl were inhibited by these natural products.

Van Sumere et al. (1971) reported that some phenolic compounds, such as aldehydes, benzoic and cinamic acid derivatives, and coumarins reduced the ADP/O ratio and had an uncoupling effect in yeast mitochondria. They concluded that the inhibition of oxidative phosphorylation by these phenolic compounds may account for the regulatory activity of natural growth inhibitors.

Demos et al. (1975) tested the effect of 10 phenolic compounds on hypocotyl growth, respiration and oxidative phosphorylation, and ion transport by mung bean mitochondria (*Phaseolus aureus*). All compounds that inhibited energy metabolism also inhibited hypocotyl growth.

In the present study we also found that cell division is strongly inhibited. Kilham (1966) found that the chemical agents which inhibit cell division can act in two ways: they may affect the synthesis or the structure of DNA–RNA, or they may inhibit energy production necessary for the process of mitosis. Both processes are important for the cell division, and interferences with them generally cause inhibition of the whole process.

Cornman (1946) reported that aqueous solutions of coumarin and para-

scorbic acid block the mitosis in root cell of onion and lily, resulting in an accumulation of metaphases and binucleate cells.

We suggest that interference with respiration and cellular division are not the only physiological mechanisms of inhibition of watermelon seedling growth. There are many other processes that might be affected, including ion transport, membrane transport, and protein synthesis. However, the processes studied are very important for the development and early growth of seedlings. It has been observed (Nawa and Asahi, 1971; Solomos, et al., 1972; Sato and Asahi, 1975), that pea germination is accompanied by a marked increase in respiratory activity of the cotyledons and rapid development of cotyledon mitochondria. This early activity is important because the seedlings are more susceptible to environmental factors, which determine plant establishment and subsequent development. Nevertheless, allelopathic compounds also are active at later stages of growth and, for example, may delay or prevent physiological processes such as flowering or fruiting. Thus, study of the effects of corn pollen allelochemicals on the photophosphorylating chain of chloroplasts would be illuminating.

Our studies of the effects of the allelopathic compounds on respiration and cell division, combined with those of others (Muller et al., 1968, 1969; Koeppe and Miller, 1974; Demos et al., 1975; Van Sumere et al., 1971), allow us to conclude that the effects upon both processes represent an important allelopathic mode of action.

Acknowledgments—We wish to thank Dr. Edmundo Chávez from Instituto de Cardiología, Mexico City, for the laboratory facilities, advice, and revision of this paper; and Dra. Sandra Gómez from Centro de Ciencias de la Atmósfera de la U.N.A.M.

PHEROMONAL COVARIATION AND KINSHIP IN SOCIAL BEE *Lasioglossum zephyrum* (Hymenoptera: Halictidae)

BRIAN H. SMITH[1] and JOHN W. WENZEL

Department of Entomology
University of Kansas
Lawrence, Kansas 66045

(Received September 26, 1986; accepted January 8, 1987)

Abstract—Both males and females of the primitively eusocial bee *Lasioglossum zephyrum* can distinguish among female conspecifics with regard to genealogical relationship. Closely related females covary with respect to Dufour's gland pheromone products which are believed to function in individual or kin recognition. This is the first report of a population-wide parallel between similarity of communicative glandular product and genetic similarity.

Key Words—Pheromone, correlation, kinship, Dufour's gland, social bee, *Lasioglossum zephyrum*, Hymenoptera, Halictidae, lactones.

INTRODUCTION

The importance of recognizing close kin in selecting mates and in social interactions has been shown experimentally in diverse vertebrate and arthropod taxa (Bateson, 1983; Fletcher and Michener, 1987; Getz et al., 1981; Getz and Smith, 1983; Greenberg, 1979; Hamilton, 1964; Smith, 1983) and is expected theoretically (Bateson, 1983; Maynard Smith, 1982). Applicable models assume that there is a set of heritable phenotypic recognition cues, probably chemical, called "discriminators," which the individual compares to its learned or innately programmed memory of the relevant phenotypic cues (Bateson, 1983; Crozier and Dix, 1979; Getz, 1982; Hölldobler and Michener, 1980; Lacy and Sherman, 1983). While generally accepted as likely, prior to this report there

0098-0331/88/0100-0087$06.00/0

was no species in which variation in relevant glandular products was known to correlate with genetic variation.

Overwintered adult females of *Lasioglossum zephyrum* emerge in early spring and mostly build solitary nests into which the first worker brood, most likely full sisters, emerges in early June in Kansas (Batra, 1966). Both males and females discriminate among conspecific females according to genealogical relationship in laboratory studies. Males are preferentially attracted to females unrelated to those the males have previously encountered (Barrows, 1975; Smith, 1983). Females guarding nest entrances admit novel nonnestmate females more often when the entering female is closely related to the guarding female's nestmates (Greenberg, 1979), even when those nestmates are not related to the guarding female herself (Buckle and Greenberg, 1981). Therefore phenotypes used in comparison are learned in the adult stage from nestmates, which in nature are ordinarily relatives. The recognition cues of *L. zephyrum* consist of a pheromone produced by the female (Barrows, 1975; Barrows et al., 1975; Bell, 1974; Kukuk et al., 1977). Living in a nest of unrelated bees does not decrease likelihood of being accepted by a nest of one's kin (Buckle and Greenberg, 1981), and olfactory cues are adequate for males to recognize kin of familiar bees (Smith, 1983). Smith et al. (1985) identified 18 compounds extracted from female bees from three chemical classes: macrocyclic lactones, cuticular hydrocarbons, and isopentenyl esters. The first are products of the sting-associated Dufour's gland, which are used in nest construction and are characteristic for the subfamily Halictinae (Bergström and Tengö, 1979; Cane, 1983; Duffield et al., 1981). Mixtures of the synthetic lactones are attractive to males (Smith et al., 1985). The lactones probably function in sexual communication in *L. zephyrum*, and we believe in communication among female nestmates as well.

METHODS AND MATERIALS

Seven sites of closely aggregated nests of *L. zephyrum* were selected for study during June and July 1983. Aggregations of nests are located along the banks of rivers or streams. The sites sampled were separated by 3 m to 20 km and also were those which provided the background genetic variation for the laboratory breeding program of Greenberg (1979). For each site three to 11 females, mostly workers, were collected from each of several nests between June 30 and July 27 and promptly placed separately in cooled, clean glass vials. Immediately after being brought into the laboratory, the collected females were transferred individually into silanized glass tubes, each just large enough to accommodate an individual female, and kept in the dark for 3–5 hr. The tubes were then cooled to condense the pheromone, after which the females were

removed and the tubes washed with 100 μl of spectral grade hexane. This headspace sample from each female was sealed in a glass ampoule without fractionation or purification and stored at $-10°C$ to $-15°C$ until chemical analysis. The same females used for headspace samples were individually placed in small containers and frozen at $-50°C$ for later allozyme analysis. Detailed analysis of electrophoretic data will be reported elsewhere; only a summary statistic of relatedness calculated by the techniques of Pamilo (1984) is examined here for reference.

Seventy-five headspace samples were analyzed by capillary gas chromatography and later used in the statistical analysis. The samples were analyzed on a Hewlett-Packard 5092 capillary gas chromatograph fitted with a 25-m fused silica SE-30 column. Integration of peak area was performed by an HP 3390 integrator interfaced with the flame ionization detector of the GC. Helium was used as the carrier gas, and all runs were performed splitless for the first 30 sec, followed by a 100:1 split ratio until the end of the run. Temperature was held at 200°C for 5 min, then increased at 5°C/min to 225°C, and held until finished. One microgram of octacosane was coinjected as an internal standard with each sample to allow quantification of the absolute amount of each lactone peak.

All statistical analyses were performed on the untransformed data, using the amount of each lactone released by each bee per minute spent in the glass tube. Stepwise discriminant functions analysis indicated that one site represented by five females was markedly different from the others. If one includes significantly different populations in later analysis, nestmate pairs will, by definition, be more similar than random pairs since the former are always from the same population and the latter include pairs from any of the different populations. We pooled the other six sites and focused analysis on them to examine the type of variation in the largest grouping of individuals who do not differ greatly from each other. The reduced data set of 70 headspace samples was examined by principal components analysis (Dixon, 1981).

RESULTS

Chemical analysis identified octadecanolide, eicosanolide, docosanolide, docosenolide, and tetracosanolide as components of the headspace samples (Figure 1); there was considerable interindividual variation in both amounts and ratios. Minor components were too weakly and inconsistently present, using the headspace extraction technique, to be incorporated into the statistical analysis. Bartlett's sphericity test (Cooley and Lohnes, 1971) applied to Principal Components (PCs) III, IV, and V, indicates a significant deviation from sphericity (chi squared = 89.7, $df = 2$, $P < 0.001$) and justifies inclusion of PC III as an interpretable component.

Octadecanolide and eicosanolide production were highly correlated ($r =$

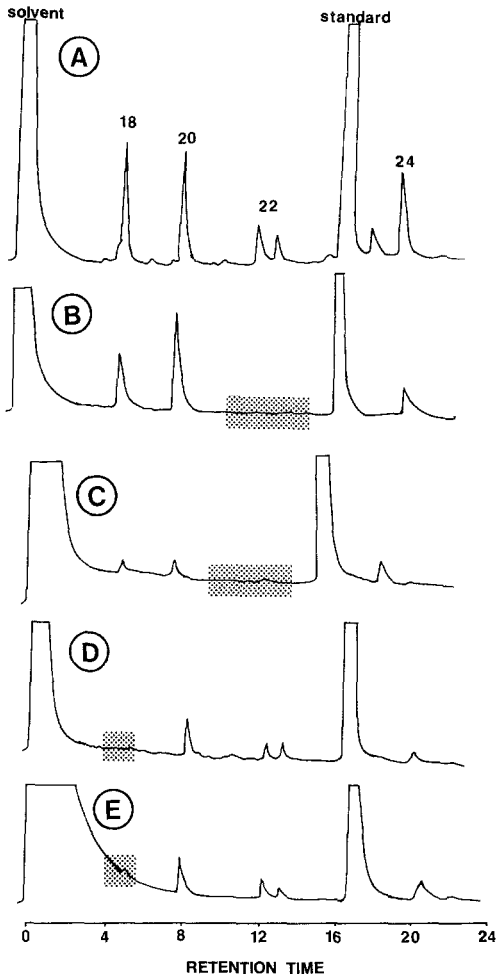

FIG. 1. (A) Capillary gas chromatogram of headspace samples from a female *L. zephyrum*. Peaks from left to right are octadecanolide, eicosanolide, docosanolide, docosenolide, octacosane (internal standard), and tetracosanolide. Numbers above the peaks indicate the numbers of carbons contained in the ring. For further details see Smith et al. (1985). The release rate and standard deviation (parentheses) for each of the lactones in picograms (10^{-12}g) per minute, based on the unreduced data set of 75 females, were as follows, respectively: 0.87 (2.83), 0.92 (9.62), 0.34 (7.37), 0.09 (0.28), 0.54 (0.97). (B and C) Individual chromatograms of a pair of nestmates, lacking 22-carbon lactones (shaded region). (D and E) Chromatograms of a pair of nestmates from a different nest, lacking the 18-carbon lactone (shaded). While the figured pairs of bees demonstrate a striking qualitative difference between family groups, most chromatograms differ largely quantitatively.

0.89, $P < 0.01$), as were both 22-carbon lactones ($r = 0.64$, $P < 0.01$) (Table 1). The first principal component (PC I) can be interpreted as general production rate, which explains 43% of the variance. Accounting for 32% of the variance, PC II appears to be a contrast between bees that produce a great deal of 18- and 20-carbon compounds with little 22-carbon compounds and those bees that produce the opposite mixture. PC III explains 18% of the total variance and appears to contrast 24-carbon lactone production with all others, but maintenance of orthogonality of interpretations is somewhat problematic. Orthogonality (independence of principal components) can be maintained by interpreting PC I as C_{18} and C_{20} production, PC II as C_{22} production, and PC III as C_{24} production. This is similar to the interpretation above, given the preponderance of C_{18} and C_{20} compounds which makes their measure about the same as a "general production" measure. The distinction between the two sets of interpretations is probably of no consequence. This leaves only 8% of the total variance explained by the two remaining PCs.

The 26 pairs of nestmate females are highly correlated with respect to their factor scores on PCs II and III, but not with respect to scores on PC I (Table 1). Neither random pairs of females nor nonnestmate pairs of females from the same aggregation were significantly correlated with respect to scores on any of the first three axes. The mean Pearson product-moment correlation coefficients for 40 sets of 25 randomly paired individuals with the number of significant coefficients in parentheses, were as follows: PC I: $r = -0.001$, (3); PC II: $r = 0.004$, (4); PC III: $r = -0.044$, (4). When 10 different sets of 25 nonnestmates from the same aggregation were paired, the results were as follows: PC

TABLE 1. PRINCIPAL COMPONENT LOADINGS FOR FIVE MACROCYCLIC LACTONES ON FIRST THREE COMPONENTS

	Factor Loadings		
	I	II	III
Octadecanolide	0.809	−0.497	−0.257
Eicosanolide	0.905	−0.345	−0.095
Docosanolide	0.566	0.705	−0.098
Docosenolide	0.310	0.845	−0.221
Tetracosanolide	0.483	0.110	0.866
Variance explained[a]	42.5%	31.5%	18.0%
Nestmate correlation[b]	0.05	0.47*	0.52**

[a] The first three components explain 92% of the total variation.

[b] Pearson product-moment correlation coefficients for the 26 pairs of nestmates included in the PCA. Coefficients for factors II and III are significantly different from zero (*$P < 0.025$; **$P < 0.01$).

I: $r = 0.072$, (0); PC II: $r = 0.14$, (3); PC III: $r = 0.05$, (3). None of the mean coefficients significantly differs from zero, which demonstrates that the correlations among nestmates are not due to either divergence of aggregation means or violations of normality through numerous zero values of production rates for individual lactones.

Allozyme variability allowed calculation of a regression coefficient of the relationship among nestmate females. In all populations of *L. zephyrum* sampled, the nestmates were highly related but were probably not always full sisters ($r = 0.63$–0.95 at $P < 0.05$ with a point estimate for the coefficient of relatedness of $r = 0.79$ v. $r = 0.75$ for full sisters).

DISCUSSION

Earlier laboratory studies demonstrated that both sexes of *L. zephyrum* discriminate among conspecific females by an unknown but presumably chemical mechanism which reveals relatedness between bees. Using passive chemical collection techniques with individual bees from the same wild populations as were examined in the laboratory, we have shown that the relative proportions of the macrocyclic lactones produced in Dufour's gland by the females vary less among nestmates (close relatives) than among random pairs of bees, even within aggregations. Although the observed pattern of chemical variance is expected of any trait for which phenotypic variation is explained largely by genotypic variation, such a relationship has not been previously documented in natural populations for chemical compounds known to play a role in communication.

Divergence of aggregation means does occur, as demonstrated by the distinction of one site in the discriminant functions analysis mentioned in Methods and Materials. This effect alone, however, is not adequate to explain the nestmate correlation, as demonstrated by Monte Carlo-type simulation pairing nonnestmates from the same aggregation, then examining many pairs from within all aggregations.

The similarities found here among nestmates, therefore, do not appear to be due to population structure beyond that of nests. The most likely explanation for similarities among nestmate females is that the composition of the pheromone is largely under genetic control.

The nonsignificant correlation between kin on the primary variance component (PC I) may be due to the effects of age or dominance by which some bees in each nest simply produce more pheromone than others. The correlation between kin on the lesser components (PCs II and III) suggests that regardless of how much pheromone they produce, nestmates are more similar than nonnestmates. The similarity is pronounced as PCs II and III account for half the

total variation. Whether the correlations between the 18- and 20-carbon lactones and between both 22-carbon lactones are due to genetic pleiotropy or another factor is unknown.

A genetic analysis of the same females used in the pheromone study supports the chemical results with regard to nestmate similarity. Allozyme frequencies showing nestmates to be highly correlated but less than full sisters are consistent with Kukuk's (1985) finding that as many as a third of all nests may have a multiply inseminated queen or multiple queens in a New York population. More detailed electrophoretic analysis of relatedness among Kansas bees is considered in another paper (Crozier et al., 1987).

FACTORS INFLUENCING RELEASE OF HOST-MARKING PHEROMONE BY *Rhagoletis pomonella* FLIES

A. L. AVERILL[1] and R. J. PROKOPY

Department of Entomology

(Received May 17, 1985; accepted January 9, 1987)

Abstract—The effect of fly or fruit treatments on quality and/or quantity of host-marking pheromone (HMP) trail substance released by apple maggot flies (*Rhagoletis pomonella*) following oviposition was evaluated. Among flies, considerable variation existed in the amount of HMP substance deposited, but overall, the amount of substance released on successively offered fruit (over a day or a week) did not change appreciably. Fly diet did not influence pheromone activity. Older flies (28 days) or smaller flies released less or less active HMP trail substance than younger flies (14 days) or larger flies. Females deposited a similar amount of trail substance on large (18–19 mm diam.) or HMP-marked fruit as on small (12–13 mm) or unmarked fruit. Starvation reduced the amount of measurable trail substance deposited but resulted in a more active HMP deposition. Discrepancy between trail measurement and behavioral bioassay results for the starvation treatment indicated that trail measurement results may be misleading under conditions that reduce gut contents of the fly.

Key Words—*Rhagoletis pomonella*, Diptera, Tephritidae, apple maggot fly, oviposition deterrent, bioassay, host-marking pheromone.

INTRODUCTION

Studies of insect recruitment and sex pheromones as well as studies of host-marking pheromones (HMP) have identified numerous factors that influence pheromone release. Production of chemical recruitment trails by the ants *Acanthomyops interjectus* May and *Solenopsis geminata* F. (Hantgartner 1969a,b),

[1]Present address: Department of Entomology, New York State Agricultural Experiment Station, Geneva, New York 14456.

as well as by eastern tent caterpillars [*Malacosoma americanum* (F.)] (Fitzgerald and Peterson, 1983) is influenced by individual assessment of food quality. These studies showed that ants produced less continuous recruitment trails and that tent caterpillars produced fewer trails following discovery of poor-quality food compared to high-quality feeding sites. Numerous studies have demonstrated that physiological (e.g., age, mating status) and environmental factors (e.g., temperature, light) influence sex pheromone release by moths (Sanders and Lucuik, 1972; Nordlund and Brady, 1974; Baker and Cardé, 1979; Bjostad et al., 1980), dermestid beetles (Hammack et al., 1976), and olive fruit flies (Mazomenos, 1984). Facultative HMP release has been demonstrated in the pheromone deposition behavior of the tephritid fruit fly, *Anastrepha fraterculus* Wiedemann, according to fruit size (Prokopy et al., 1982a), and Zimmerman (1980, 1982) demonstrated that *Hylemya* females can switch HMP release on and off, depending upon the host species being used and apparently in response to the probability of larval competition.

Immediately following egg-laying in a host fruit, a female apple maggot fly, *Rhagoletis pomonella* (Walsh) (Diptera: Tephritidae), drags her extended ovipositor over the fruit surface and deposits a trail of HMP that deters subsequent females from further oviposition (Prokopy, 1972). Prokopy et al. (1982c) reported that HMP, following apparent production in midgut tissue, is released into the gut contents and accumulates in the hindgut. HMP is released with other gut contents during trail deposition.

We suspected that the behavior of pheromone deposition might represent a fixed action pattern that occurs without alteration (Alcock, 1979). However, whereas dragging the ovipositor following oviposition appears fixed and almost always occurs (Prokopy, 1972), initial lab and field observations revealed considerable variability in time spent dragging and in dragging bout pattern, not only among females, but also among successive dragging bouts by the same female.

To elucidate factors that may influence variability in pheromone release by *R. pomonella* females, we observed pheromone deposition behavior of flies in various behavioral or physiological states and on various fruit treatments. Through measurement of the amount of pheromone trail substance deposited, and through bioassay of female response to deposited pheromone, we evaluated the quantity and quality of pheromone released, usually by individual flies, after a single ovipositional bout. Factors investigated were fly age, fly size, fly diet, starvation, fruit size, and fruit quality.

METHODS AND MATERIALS

Collection and maintenance methods of *Rhagoletis pomonella* are detailed in Prokopy (1981). Unless otherwise stated, all flies were field collected as

larvae from apples and, at time of use, were mature (14–18 days old) and had no previous oviposition experience (naive).

To quantify the amount of trail substance deposited on a fruit, newly marked fruit were dusted with dry magnetic toner, a moisture-sensitive powder used in Olivetti copying machines. Fingerprint and talcum powders were ineffective. The pheromone substance is viscous and is typically a discrete, linear deposition (Figure 1). We measured trail length and area microscopically with an ocular micrometer. The toner technique is most effective for highlighting the HMP trail on very smooth and waxy fruit, such as *Crataegus oxyacantha* Autumn Glory, an introduced, ornamental species of hawthorn that we used in all trail measurement studies. Unfortunately, an insufficient supply of *C. oxyacantha* forced us to use a different species of hawthorn in behavioral bioassays. However, female acceptance of fruit and dragging behavior were equivalent for both hawthorn species.

In the trail measurement studies, a *C. oxyacantha* fruit was attached to a dissecting probe and offered to individually caged flies in a Plexiglas–screen observation cage (15 × 15 × 15 cm). Twenty minutes elapsed between each fruit presentation and, except where indicated, all fruit in a series were offered on the same day.

Time spent during HMP deposition and length and area of trails were quantified for the following categories: (1) *Variability among and within flies:* 14-

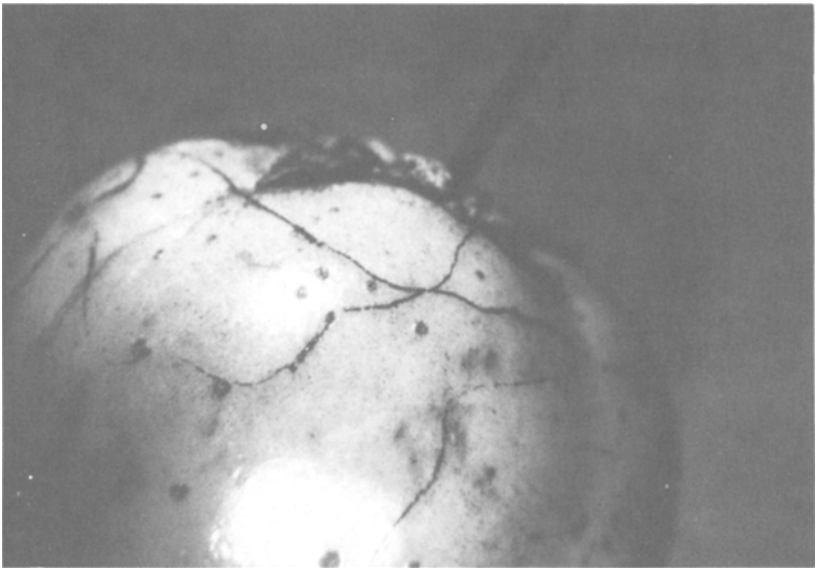

FIG. 1. A HMP trail deposited on a *Crataegus* hawthorn by a *Rhagoletis pomonella* female. The trail has been dusted with Xerox powder.

day-old flies were offered 12 successive 15-mm-diam. fruit. We examined variability among all flies by comparing mean time spent and mean amount of HMP deposited on the 12 fruit. We also considered variability among single bouts by the same fly. (2) *Fly experience over time:* to see if there was a change in deposition over time on the same day, we examined the above data and, for all flies, compared mean time spent and mean HMP released on each fruit (first through twelfth) in the presentation sequence. To see if there was a change in deposition over a week, females (which initially were 14 days old) were offered 12 successive 15-mm-diam. hawthorns on each of seven days. (3) *Fly age:* 14-, 21-, or 28-day-old females were offered 12 successive 14- to 15-mm-diam. hawthorns. (4) *24-hr starvation:* females provided water but no food for 24 hr and females with continuous access to both food and water were offered 12 successive 13-mm-diam. hawthorns. (5) *Fruit size:* females were offered a random series of hawthorns containing six 12- to 13-mm-diam. fruit and six 18 to 19-mm-diam. fruit. (6) *Pheromone-marked and unmarked fruit:* females were offered a random series of 13- to 14-mm-diam. hawthorns containing six clean, unmarked fruit and six pheromone-marked fruit. The pheromone-marked fruit were prepared as follows: pheromone was rinsed with a known volume of distilled water from hawthorns used for oviposition. The amount of pheromone was estimated by counting the number of oviposition punctures in each washed fruit: 1 puncture = 1 dragging bout equivalent (DE). A 20-DE aliquot was applied with a cotton swab onto the assay hawthorns. This amount was known to elicit moderate levels (ca. 47%) of fruit rejection by arriving females (Averill and Prokopy, unpublished data).

For all bioassays of pheromone activity, *Crataegus mollis* (Torr. and Gr.) Scheele (downy hawthorn) were used. Treated and control assay fruit were hung 6–8 cm apart from the ceiling of a Plexiglas–screen (30 × 30 × 30 cm) observation cage. A single mature *R. pomonella* female, which had just begun oviposition in a clean fruit attached to the end of a dissecting probe, was introduced into the assay cage by placing the probe near the cage floor. We allowed the female to fly to an assay fruit overhead and subsequently to visit assay fruit for a maximum of 2 hr. Because females in a physiological state conducive to oviposition accept clean fruit >60% of the time, females were excluded from tests if they rejected several (ca. 6) successive clean fruit. Acceptance (attempting oviposition before leaving) or rejection (leaving without attempting oviposition) was recorded for each visit to a fruit. Immediately following egg deposition, a female was gently transferred to a nonassay fruit, where she commenced and completed ovipositor dragging. In this way, assay fruit were minimally contaminated by pheromone deposited by assay females. For each test, at least 20 females were bioassayed.

The activity of pheromone produced by flies in several treatment categories was bioassayed. (1) *Fly age:* females (10–14, 20–23, or 28–30 days old) were

allowed to oviposit and drag on 15-mm-diam. hawthorns. Because of reduced fly availability, we could not use exactly-aged flies. A fruit marked by a fly from each age category plus two clean fruit were included in each bioassay. (2) *24-hr starvation:* females were starved as in the above starvation tests. During quantitative studies, we noticed that starved females tended to lay a maximum of only five to six eggs (mean $\pm$ SD number of eggs = 3.8 $\pm$ 2.1) when offered 12 successive fruit and tended to deposit more detectable trail substance during their first two dragging bouts than in subsequent bouts. Therefore, to test the effects of starvation on pheromone activity, we ran two bioassay series on 15-mm-diam. fruit. In the first, we collected trails produced during the first or second dragging bouts of starved females and bioassayed them in conjunction with first or second dragging bout trails of unstarved females. Three fruit marked by starved females, three fruit marked by unstarved females, and two clean control fruit were included in a bioassay. In the second series, we collected the third, fourth, or fifth dragging-bout trails of starved and unstarved females. (3) *Fly size:* large and small females selected from a same-age group of flies that originated from hawthorn were allowed to mark 15-mm-diam. *C. mollis* fruit. Four pheromone-marked fruit (two each marked by a small or large fly) plus two clean uninfested fruit were included in a bioassay. Following bioassay, flies were oven dried for 4 hr and weighed. Mean weight ($\pm$ SD) of small flies was 1.49 $\pm$ 0.16 mg and of large flies 3.48 $\pm$ 0.47 mg. (4) *Fly diet:* equal-number cohorts of flies that originated from apple were fed either standard laboratory diet that consisted of a mixture of enzymatic yeast hydrolysate and sugar (Prokopy and Boller, 1970) or aphid honeydew, an important natural food of the apple maggot (Neilson and Wood, 1966; Boush et al., 1969; Dean and Chapman, 1973). Branches of *C. mollis* hawthorn trees containing vigorous colonies of aphids (species unidentified) were collected every few days and held in large buckets in a greenhouse. Honeydew was collected on glass slides under the colonies. Because it was difficult to match the quantity of the two diets, a large excess of both diets was provided from the time of fly emergence until testing. When mature (14–17 days after emergence), individual flies from each group were allowed to oviposit and drag on 16-mm-diam. *C. mollis* fruit. Fruit marked during two dragging bouts were also prepared. Bioassays were run with two clean control fruit plus four marked fruit: two marked during one or two dragging bouts by flies on each diet.

Because several ongoing studies in our lab (e.g., pheromone identification, electrophysiology of pheromone reception) utilized extracts prepared from fruit washings, we ran an additional test wherein pheromone trails were collected (fruit washings) from both of the diet groups and reapplied to fruit as described above. Six, 12, or 23 DE of pheromone produced by flies on either diet were swabbed onto 16-mm-diam. *C. mollis* fruit (treatment). Bioassays were run with six treated fruit (two from each concentration) and two clean control fruit.

RESULTS AND DISCUSSION

Variability in Deposition of Trail Substance Within and Among Flies

Amounts of trail substance produced by 14-day-old flies offered 12 fruit in succession varied substantially, both among flies (Table 1) and among successive dragging bouts by the same fly (Table 2). In the extreme cases, fly 6 dragged for relatively short and consistent periods, but there was less consistency in the amount of substance deposited. Fly 3, on the other hand, exhibited longer (ca. 9×), less consistent dragging times and deposited substantially more (ca. 6×) quantifiable substance.

Variability in Deposition of Trail Substance Over Time

Successive Fruit Marked Over a Day. Mean times spent dragging and pheromone deposition for each of the 12 fruit offered successively to the above females are shown in Table 3. In general, naive flies tended to deposit shorter trails following their initial ovipositional bouts than after succeeding bouts, but this trend was not reflected in time spent dragging or trail area. In subsequent bouts, there was no consistent trend of change in any of the parameters. Thus, no rapid depletion occurs in the amount of quantifiable substance deposited when flies mark a succession of 12 fruit. Because some flies lay up to 30 eggs

in one day, it is possible that pheromone depletion may be noted after such numerous dragging bouts. Under laboratory conditions, however, females lay an average of only about eight eggs per day over their lifetime (Averill and Prokopy, 1987).

Successive Fruit Marked Over a Week. Although mean time spent dragging per fruit was fairly consistent among days when flies marked fruit over seven consecutive days, there was some variability in number of fruit accepted for oviposition and amount of quantifiable trail substance deposited (Table 4). For no known reason, significantly fewer eggs were laid on day 3 than on any other days, significantly more trail material was deposited on day 4, and the least material was deposited on day 6. There were, however, no apparent trends from days 1 to 7 for any of the measures.

Thus, the experience of a fly over a day or week does not appreciably influence the amount of pheromonal trail substance released.

Fly Age

Although 28-day-old females spent equal time dragging, they deposited significantly less trail substance in shorter trails than either 14- or 21-day-old females (Table 5). Because the pheromone, along with other gut contents, is released onto the fruit during deposition of the trail, the difference in amount of trail deposition could be due to differential food intake of young vs. old flies. Webster et al. (1979) demonstrated that food (sucrose) intake is considerably greater in 2-week-old females than in 4-week-old females.

The decrease (ca. 40%) in deposition of trail substance with increase in

fly age (Table 5) parallels results of behavioral bioassays of pheromone activity (Table 6), which show that fruit marked by 10- to 14-day-old females were significantly less acceptable for oviposition than fruit marked by 28- to 30-day-old flies. Fruit marked by 20- to 23-day-old females, which were marked with ca. 30% more trail substance than fruit marked by the 28- to 30-day-old flies (Table 5), were less acceptable for oviposition than fruit marked by the older flies, but this difference was not significant. Further, there was a statistically insignificant increase in acceptability of fruit marked by 20- to 23- vs. 10- to 14-day-old females.

Starvation

Twenty-four-hour starvation severely reduced the mean number of eggs laid as well as the amount of trail substance deposited (Table 7). When offered 12 successive hawthorns, starved females accepted significantly fewer than un-

TABLE 7. NUMBER OF CLEAN FRUIT ACCEPTED FOR OVIPOSITION, TIME SPENT DURING PHEROMONE DEPOSITION, AND LENGTH AND AREA OF HMP TRAIL DEPOSITED BY STARVED (N = 18) AND UNSTARVED (N = 18) *R. pomonella* FLIES OFFERED 12 SUCCESSIVE *C. oxyacantha* FRUIT (VALUES ARE MEANS ± SD)[a]

Treatment	Number of fruit accepted	Time (sec)	Trail length (mm)	Trail area (mm^2)
Starved	3.8 ± 2.1a	18 ± 10a	10.4 ± 9.4a	0.5 ± 0.6a
Unstarved	10.7 ± 2.6b	17 ± 10a	32.6 ± 20.1b	2.5 ± 1.8b

[a]Values in the same column followed by the same letter are not significantly different at the 1% level according to a t test.

starved females. Although the two groups spent approximately equal times dragging following oviposition, starved flies deposited significantly shorter and smaller area trails. Additionally, unlike successive trails produced by unstarved females, the amount of trail substance, y, deposited by starved females following successive ovipositional bouts, x, decreased rapidly ($y = 23.7 - 5.7x$). Following a fly's two initial dragging bouts, the majority of subsequent trails were very fine and barely perceptible. Dissections of females subjected to 24 hr of food deprivation revealed considerable gut content depletion, which may explain the above observation.

Behavioral bioassays of the pheromone produced by starved and unstarved flies showed poor correspondence to trail measurement results. In the first bioassay series, where we collected pheromone deposited following the first two ovipositional bouts, there was no significant difference in percent acceptance of fruit marked with pheromone drags of starved flies (N = 15) vs. unstarved flies (N = 17) (Table 8), even though our earlier measurements of the trails indicated that starved flies deposited only about half as much trail substance as unstarved flies during these dragging bouts. In the second bioassay series, using pheromone deposited following the third, fourth, or fifth ovipositional bouts, the fruit marked by starved females (N = 22) were significantly less acceptable than fruit marked by unstarved females (N = 19) (Table 8). This is a surprising result because quantitatively, starved flies deposited only ca. $\frac{1}{10}$ as much trail substance during these dragging bouts as unstarved flies. It is possible that by reducing gut contents, the effect of starvation may have been to concentrate the pheromone, resulting in a less dilute, more deterrent deposit that was not assessable using our quantification technique. Starvation causes oocyte resorption in many Diptera (Chapman, 1969), and, if such were the case in *R. pomonella*, it would be advantageous for a starving female to produce a highly deterrent pheromone deposition and, thus, maximally protect each of her few remaining eggs.

TABLE 8. PERCENTAGE OF FEMALE *R. pomonella* ACCEPTING FRUIT MARKED WITH HMP PRODUCED BY STARVED OR UNSTARVED FEMALES FOLLOWING FIRST–SECOND OR THIRD–FIFTH OVIPOSITIONAL BOUTS[a]

	Bouts 1–2		Bouts 3–5	
Fruit treatment	Number of female arrivals	Fruit acceptance (%)	Number of female arrivals	Fruit acceptance (%)
Marked by a starved female	52	50a	127	18a
Marked by an unstarved female	64	45a	138	29b
Clean control	28	75b	96	66c

[a]Values in the same column followed by the same letter are not significantly different at the 5% level according to a G test.

This lack of correspondence between quantitative trail measurements and results of the behavioral bioassays demonstrates that for any fly treatment that reduces gut contents, evaluation of *R. pomonella* pheromone release using a trail measuring technique may be misleading. Therefore, trail measurement must be used in conjunction with other techniques or, owing to labor intensity, be eliminated altogether.

Fly Size

Small females deposited pheromone of either decreased quality or quantity as compared to larger conspecifics (Table 9). A significantly greater proportion of female visits resulted in acceptance of fruit marked once by small females as compared to fruit marked once by large females. This occurred in spite of

TABLE 9. PERCENTAGE OF FEMALE *R. pomonella* ACCEPTING *C. mollis* FRUIT MARKED DURING SINGLE DRAGGING BOUT WITH HMP PRODUCED BY LARGE (N = 24) OR SMALL (N = 23) FEMALE[a]

Fruit treatment	Number of female arrivals	Fruit acceptance (%)
Marked by a large female	167	31a
Marked by a small female	123	50b
Clean control	135	65c

[a]Values in the same column followed by the same letter are not significantly different at the 5% level according to a G test.

the fact that small females spent approximately the same time marking fruit (31 sec) and completed the same number of dragging circles (2.4) per fruit as did large females, which spent 33 sec and completed 2.5 circles. (A dragging circle is a distance dragged by a female that approximates the circumference of the fruit and is estimated by eye.) Because reduction in adult size may result from intraspecific larval competition in small hawthorn hosts (Averill and Prokopy, 1987), these results suggest an intriguing effect of overcrowding on subsequent adult fitness: a small female's decreased ability to pheromonally protect oviposition sites may lead to additional infestation by that same female or subsequently arriving females. As a result, her progeny may more likely suffer reduced larval survivorship or stunted development (Averill and Prokopy, 1987).

Quiring and McNeil (1984) have likewise demonstrated that small female alfalfa blotch leafminers, *Agromyza frontella* (Rondani), produce a HMP that is less effective than that produced by large females.

Fly Diet

Females fed either the laboratory diet or honeydew produced equally active pheromone trails (Table 10). Bioassays wherein aqueous extracts of HMP deposited by flies fed honeydew or laboratory diet were applied to fruit revealed no statistical differences between pairs of any of the concentrations tested (Table 10).

Evaluation of the effect of diet on HMP production was necessary because gut contents appear to comprise most of the material released in the HMP deposition (Prokopy et al., 1982c) and because of the debate on possible effects of diet and host substances on pheromone production (e.g., Hardee, 1970; Hendry, 1976; Miller et al., 1976; Byers, 1983; Wiygul and Wright, 1983.)

Fruit Size

When offered a series of small and large hawthorns, flies spent a significantly longer time marking large vs. small fruit. Flies deposited trails that were of greater length and area on large vs. small fruit, but these differences were not statistically significant (Table 11).

In another study, pheromone-depositing females observed in the lab and field dragged their ovipositors for a significantly longer time and distance on large (20 mm diam.) vs. small (12 mm diam.) hawthorns (Averill and Prokopy, 1987). This difference was more pronounced (ca. 40% greater) in the test series reported in Averill and Prokopy (1987) than in the present study. This may be due to sampling error, although a large number of observations was made, or because the size difference between offered fruit was slightly greater in the former test series. Alternatively, the difference might be due to apple origin flies being used in the present test series vs. hawthorn origin flies in Averill and

TABLE 10. PERCENTAGE OF FEMALE *R. pomonella* ACCEPTING *C. mollis* FRUIT (TEST A) MARKED ONCE OR TWICE WITH HMP PRODUCED BY FEMALES FED LABORATORY OR HONEYDEW DIET OR (TEST B) SWABBED WITH AQUEOUS SOLUTION OF 6, 12, OR 23 DRAGGING BOUT EQUIVALENTS (DE) OF PHEROMONE COLLECTED FROM FLIES FED EITHER DIET[a]

Fruit treatment	Number of female arrivals	Fruit acceptance (%)
Test A		
Marked once by a female fed honeydew diet	128	43a
Marked once by a female fed laboratory diet	136	42a
Marked twice by a female fed honeydew diet	137	32b
Marked twice by a female fed laboratory diet	132	26b
Clean control	129	74c
Test B		
Swabbed with pheromone extract from females fed honeydew diet		
6DE	48	40a
12 DE	45	24a
23 DE	67	22a
Swabbed with pheromone extract from females fed laboratory diet		
6 DE	45	31a
12 DE	60	38 a
23 DE	53	25a
Clean control	88	97b

[a]In test A, values followed by the same letter, and in test B, acceptance values of similar DE treatments of either diet followed by the same letter (e.g., 6 DE of extract from females fed honeydew diet vs. 6 DE of extract from females fed lab. diet), are not significantly different at the 5% level according to a G test.

Prokopy (1987). Recent work by Prokopy et al. (1982b) examining comparative behavioral traits suggests that there may be substantial *R. pomonella* host race differences. It is conceivable that selective pressure for "fine-tuned," flexible dragging behavior may be relaxed in populations developing in apple where the larval carrying capacity may exceed 15 or more per fruit (Prokopy, 1972; Cameron and Morrison, 1974) and the amount of pheromone deposited by a single

TABLE 11. TIME SPENT DURING PHEROMONE DEPOSITION, AND LENGTH AND AREA OF HMP TRAIL SUBSTANCE PRODUCED BY *R. pomonella* FLIES ($N = 18$) WHEN DRAGGING ON LARGE (18–19 mm DIAM.) OR SMALL (12–13 mm DIAM.) *C. oxyacantha* FRUIT (VALUES ARE MEANS ± SD)[a]

Fruit size	Time (sec)	Trail length (mm)	Trail area (mm^2)
Small	17 ± 10a	38.9 ± 25.3a	2.5 ± 1.8a
Large	22 ± 12b	45.9 ± 29.8a	2.9 ± 1.9a

[a] Values in the same column followed by the same letter are not significantly different at the 5% level according to a *t* test.

female does not much influence subsequently arriving females (Prokopy, 1972). In contrast, flexible dragging behavior may be adaptively advantageous for populations on hawthorn because: (1) larvae developing in multiple-infested fruit may realize lowered survivorship, (2) the amount of pheromone deposited following a single ovipositional bout is sufficient to deter most females from further egg-laying, and (3) more pheromone is necessary to elicit female deterrence on large (20 mm diam.) fruit vs. small (12 mm diam.) fruit (Averill and Prokopy, 1987).

Pheromone-Marked and Unmarked Fruit

If the amount of pheromone deposited is a flexible trait, flies might deposit less pheromone on fruit that were already pheromone-marked. However, Table 12 shows that females deposited essentially the same amount of trail substance per fruit when offered a series of pheromone-marked or unmarked fruit. Al-

TABLE 12. TIME SPENT DURING PHEROMONE DEPOSITION, AND LENGTH AND AREA OF HMP TRAIL SUBSTANCE PRODUCED BY *R. pomonella* FLIES ($N = 20$) WHEN DRAGGING ON PHEROMONE-MARKED OR CLEAN *C. oxyacantha* FRUIT (VALUES ARE MEANS ± SD)[a]

Fruit treatment	Time (sec)	Trail length (mm)	Trail area (mm^2)
Pheromone-marked	21 ± 14a	30.6 ± 3.6a	1.5 ± 1.4a
Clean	33 ± 21b	23.1 ± 18.3a	1.3 ± 1.4a

[a] Values in the same column followed by the same letter are not significantly different at the 5% level according to a *t* test. Pheromone-marked fruits were prepared by applying an aqueous solution of HMP.

though flies deposited a similar quantity of trail substance on both fruit treatments, they spent significantly less time engaged in trail deposition on pheromone-marked vs. unmarked fruit. Females moved more quickly over the fruit surface during preoviposition behavior and dragging.

SUMMARY

When flies were starved, we found that trail substance measurements were not consistent with behavioral bioassay results of pheromone activity, probably because HMP is released along with other gut contents during trail deposition and gut contents appear to comprise most of the released material. Thus, trail measurement results may be a poor indicator of HMP release and must be evaluated in light of behavioral bioassay results.

Overall, our results suggest that numerous factors may affect the quantity or quality of pheromone released not only by different *R. pomonella* females, but also from one dragging bout to the next by the same female. Of the several factors examined, changes in fly quality (i.e., fly age and size) and starvation produced the greatest differences in pheromone deposition, while changes in fly experience, fly diet, or fruit characteristics (size or presence of pheromone mark) produced less pronounced or no differences.

EFFECT OF VERBENONE ON RESPONSE OF *Dendroctonus brevicomis*[1] TO *exo*-BREVICOMIN, FRONTALIN, AND MYRCENE

PAUL E. TILDEN and WILLIAM D. BEDARD

Pacific Southwest Forest and Range Experiment Station
Forest Service, U.S. Department of Agriculture
Berkeley, California 94701

(Received June 24, 1986; accepted January 13, 1987)

Abstract—*exo*-Brevicomin (E), frontalin (F), and myrcene (M) were released at two rates 10-fold apart with verbenone at four rates 10-fold apart, and without verbenone, in plots with one trap on a vertical cylinder at the pheromone source and one trap on each of four cylinders 5 m away. Catch of the western pine beetle *Dendroctonus brevicomis* decreased with increasing levels of verbenone at both release rates of EFM, but not all differences in catch were statistically significant. Significantly more beetles were caught at the high rate of EFM than at the low rate, combining all rates of verbenone. The percent of total beetles caught at the center trap tended to decrease with increasing rates of verbenone, but the only statistically significant differences were at the low rate of EFM.

Key Words—*Dendroctonus brevicomis*, Coleoptera, Scolytidae, bark beetle, western pine beetle, pheromone, attractant, inhibitor, *exo*-brevicomin, frontalin, myrcene, verbenone.

INTRODUCTION

The colonization of ponderosa pine, *Pinus ponderosa* Dougl. ex Laws., by the western pine beetle, *Dendroctonus brevicomis* LeConte, is mediated by volatile compounds released by the beetles when they bore into the tree (Wood, 1972; Wood and Bedard, 1977). The mixture of *exo*-brevicomin (E) (Silverstein et al., 1968), frontalin (F) (Kinzer et al., 1969), and myrcene (M) (Bedard et al., 1969) was attractive to flying *D. brevicomis* (Bedard et al., 1980a; Wood et

[1] Coleoptera: Scolytidae.

0098-0331/88/0100-0113$06.00/0

al., 1976). The numbers of *D. brevicomis* trapped at and near a source of EFM varied with the relative and absolute release rates of the attractant (Tilden et al., 1983; Tilden and Bedard, 1985). Verbenone (Renwick, 1967) reduced the numbers of *D. brevicomis* trapped at a source of EFM and the natural attractant, and the reduction in catch was greater at a high release rate of verbenone than at a low release rate (Bedard et al., 1980a,b). All four compounds have been isolated from the air around trees under attack by *D. brevicomis* (Browne et al., 1979). Verbenone may be involved in termination of mass attack (Renwick and Vité, 1970) or in regulation of attack density (Byers and Wood, 1980; Byers et al., 1984). Although the roles of verbenone in host colonization are not clear, it may have value as a tree protectant, because it interrupted the response of *D. brevicomis* to bolts cut from a tree under mass attack and appeared to reduce visitation and boring in trees baited with EFM (Bedard et al., 1980b). Verbenone applied to a living tree may prevent initial attacks or attenuate the attack rate so that tree resistance could overcome initial attacks and prevent mass attack and subsequent death of the tree.

Verbenone and other pheromones act as antiattractants for other bark beetles and show promise as agents to prevent attacks or reduce infestations in host trees. A 1 : 1 mixture of verbenone plus *exo-* and *endo*-brevicomin reduced landing of *D. frontalis* Zimm. on previously unattacked trees (Richerson and Payne, 1979), and reduced the density of emerging beetles (Watterson et al., 1982), although trees were successfully attacked. Verbenone reduced the number of *D. adjunctus* Blandford trapped at attractive bolts cut from ponderosa pines attacked by the beetle (Livingston et al., 1983). Verbenone inhibited the response of *Ips paraconfusus* Lanier to natural and synthetic sources of attractant (Byers and Wood, 1980, 1981). MCH (3-methyl-2-cyclohexen-1-one), an antiattractant for *D. pseudotsugae* Hopkins (Rudinsky et al., 1972), reduced attack and brood density in windthrown trees when applied by helicopter in a controlled-release formulation (Furniss et al., 1981; McGregor et al., 1984).

This study is to provide information about the response of *D. brevicomis* to different release rates of EFM and verbenone, a prerequisite to specifying a level of verbenone to protect a tree from successful attack by *D. brevicomis*.

METHODS AND MATERIALS

The study was done July 14, to October 1, 1982. Five plots at least 1.6 km apart were installed on the Bass Lake Ranger District, Sierra National Forest, Madera County, California in 1-hectare or larger openings in stands of ponderosa pine. Five 25.4-cm-diam. × 3-m-long Sonotube cardboard cylinders (Tilden et al., 1983; Tilden and Bedard, 1985) were erected vertically in each plot, with one cylinder at the center of a circle with 5 m radius and the other

four cylinders 90 degrees apart on the circumference of the circle. A cylindrical hardware cloth (0.95-cm mesh) sticky trap 38 cm diam × 30.5 cm high coated with melted Stickem Special was hung around each cardboard cylinder to monitor beetle visitation, with the center of the trap 1.5 m above ground. We used cardboard cylinders to provide the silhouette of a tree and to preclude production of natural pheromones by beetles boring in trees, which would confound our treatments.

E and F, both racemic, and myrcene (purity at least 98%) were evaporated from glass tubes and vials (Tilden et al., 1983; Tilden and Bedard, 1985) at two release rates 10-fold apart and at a ratio that approximated the relative release of the three compounds in nature (Browne et al., 1979; Tilden and Bedard (1985) (Table 1). Verbenone [60:40 of (+) and (−) enantiomers, purity at least 98%] was evaporated at four release rates 10-fold apart from three kinds

TABLE 1. DEVICES USED TO RELEASE *exo*-BREVICOMIN (E), FRONTALIN (F), MYRCENE (M), AND VERBENONE (V), AND RELEASE RATES OF THE COMPOUNDS, SIERRA NATIONAL FOREST, CALIFORNIA, JULY 14, TO OCTOBER 1, 1982

Compound	Release rate (mg/24 hr)[a]	Device
E (1X)	0.7 (0.30)	5 pipets, 0.80 mm ID × 50 mm, flame-sealed one end[b]
F (1X)	0.13 (0.08)	1 pipet, 0.40 mm ID × 32 mm, flame-sealed one end[b]
M (1X)	56.78 (3.16)	3 glass vials, 9 mm ID × 45 mm[c]
E (10X)	8.40 (1.50)	6 tubes, 3.5 mm ID × 52 mm, flame-sealed one end[d]
F (10X)	1.58 (0.25)	1 tube, 2.2 mm ID × 62 mm, flame-sealed one end[d]
M (10X)	700.30 (36.87)	37 vials, 9 mm ID × 45 mm[d]
V (1X)	0.54 (0.19)	one 1.5-ml polyethylene microcentrifuge tube, 10 mm ID × 38 mm, with 4.76-mm-diam. hole in cap[e]

[f] Inside aluminum tea ball.

of devices (Table 1). The devices were put inside containers of various sizes to facilitate handling and to mitigate effects of sun and wind (Table 1) and were hung about 1.3 m above ground at the bottom of the trap on the center cardboard cylinder. The bottoms of the containers were ventilated to permit release of the compounds. Verbenone was put in a container separate from E, F, and M.

Treatments were put out five days per week in the early afternoon (July and August) or late morning (September and October) and picked up the following morning between 0700 and 0830 hr. *D. brevicomis* were picked from traps and placed in labeled vials of kerosene for later counting and sex determination.

The experimental design consisted of two Latin squares (one for each level of EFM) with the factors day group, plot, and verbenone each having five levels (Winer, 1962, pp. 549–554). Fifty days were randomly assigned to 10 day groups so that each group had five days. One of the two levels of EFM and all five of the verbenone treatments (including a control of no verbenone) were presented each day. There were 25 days per level of EFM. Days and day groups were assumed to be random effects, and plots, verbenone, and EFM were assumed to be fixed effects. Data were transformed by $\log_e$ (counts + 1) to equalize variances and examined by analysis of variance. Means of the transformed data were compared by Tukey's honestly significant difference procedure at alpha = 0.05. Means and 95% confidence intervals for the transformed data were back-transformed to median estimates with their associated confidence intervals.

Before the start of the test, release rates of verbenone were measured gravimetrically. Devices were exposed inside a weather shelter near Oakhurst, California (elevation 790 m), where temperatures were assumed to be similar to those in the plots. Weight losses of each device were measured after several 24-hr periods. Release rates of EFM were assumed to be the same as measured the previous year (Tilden and Bedard, 1985).

RESULTS

The numbers of *D. brevicomis* caught at the center and outlying traps appeared to be inversely linearly related, in the log scale, to the log of the verbenone release rate (Figure 1). Analysis of variance of the transformed daily counts of *D. brevicomis* showed a statistically significant effect for verbenone (Table 2). Significantly fewer beetles were caught at the center trap at 10× and greater levels of verbenone for 10× EFM and at 1× and greater levels of verbenone for 1× EFM than were caught when EFM were released alone (Table 3). Significantly fewer beetles were caught at the outlying traps at 100× and

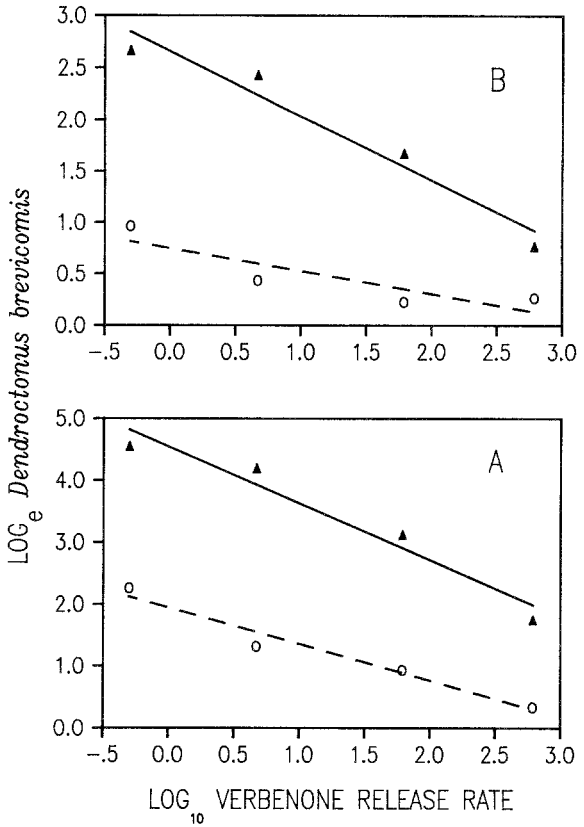

FIG. 1. Mean number [$\log_e$ (counts + 1)] of *Dendroctonus brevicomis* caught per day at one center trap (A) and four outlying traps (B) when *exo*-brevicomin, frontalin, and myrcene were released at two levels and verbenone was released at four levels at center trap. Dark triangles are catch at 10× EFM and open circles are catch at 1× EFM. SE of mean catch at center trap = 0.115 and at outlying traps = 0.114.

1000× levels of verbenone for 10× EFM and at 10× and greater levels of verbenone for 1× EFM than when EFM were released alone. The lowest levels of EFM and verbenone at which significant differences from EFM alone were detected were relatively the same at both release rates of EFM—1× EFM : 1× verbenone and 10× EFM : 10× verbenone (both 1 : 1) at the center trap, and 1× EFM : 10× verbenone and 10× EFM : 100× verbenone (both 1 : 10) at the outlying traps. Reductions in catch at both the center and outlying traps increased with increasing levels of verbenone (Table 3).

TABLE 2. ANALYSIS OF VARIANCE[a] OF *Dendroctonus brevicomis* CAUGHT PER DAY AT AND 5 m AWAY FROM SOURCE OF *exo*-BREVICOMIN (E), FRONTALIN (F), AND MYRCENE (M) RELEASED AT TWO LEVELS ALONE AND WITH VERBENONE RELEASED AT FOUR LEVELS, SIERRA NATIONAL FOREST, JULY 14 TO OCTOBER 1, 1982

[b] P-value of the F ratio. ** denotes $P < 0.01$.
[c] Denominator of F ratio was day groups (EFM) mean square.
[d] Denominator of F ratio was days (day groups) mean square. Denominator of remaining F ratios was error mean square.

The analysis of variance also showed a significant effect for EFM (Table 2). Combining all levels of verbenone, median daily catches of *D. brevicomis* were:

	Center trap	4 outlying traps
10× EFM	40.7	7.1
1× EFM	4.4	0.9

The significant verbenone × EFM interaction at the center and outlying traps indicates that the differences in catch of *D. brevicomis* between the two levels of EFM were not the same at each level of verbenone (Figure 1).

The analysis of variance of percent *D. brevicomis* caught at the center trap showed significant effects due to verbenone and a verbenone × EFM interaction ($P < 0.01$). Within both levels of EFM, percent catch at the center trap tended

to decrease with increasing levels of verbenone, but the only statistically significant differences occurred at 1× EFM (Table 3).

DISCUSSION

The role verbenone plays in host colonization is uncertain (Browne et al., 1979; Byers and Wood, 1980; Wood, 1982), but we believe that, if released at high enough levels, it could interrupt the natural process of colonization initiated by the production of secondary attractant. We believe this is a reasonable expectation for verbenone because the results from this study and previous ones using natural as well as synthetic attractants (Bedard et al., 1980a,b) indicate

that verbenone can reduce the numbers of *D. brevicomis* trapped at a source of attractant, and that increased levels of verbenone are associated with decreased trap catch (Table 3) (Bedard et al., 1980b).

Relatively high levels of EFM were released in this study to ensure adequate numbers of trapped beetles for comparison of treatments. The 1× level of EFM is usually more than adequate to cause baited trees to be successfully attacked (Bedard et al., 1980b). If verbenone were to successfully protect a tree from attack, it would probably have to either prevent the initial random landing of pioneer beetles, prevent boring and sustained feeding, or interrupt the low level of attractant produced by a few initial attacks. Based on the estimates of Browne et al. (1979), the amounts of E, F, and M released in a 24-hr period by two pairs of beetles would be 85, 58, and 69 times less, respectively, than what we released at the 1× level.

We cannot assume that trap catch is an adequate measure of attack rate on a tree, because trapping prevents too many possible events in host colonization. We believe, however, that the dosage response shown in our results suggests that the higher the release rate of verbenone from a tree, the more likely the tree would be protected from beetle attack.

The plot design in this and previous studies (Tilden and Bedard, 1985; Tilden et al., 1983) provide more information about flight response of bark beetles at and near a pheromone source than would be available from a study using a trap only at the source. Increased levels of verbenone in this study were associated with decreased catch on silhouettes 5 m away from the source of verbenone. Verbenone may have an area effect similar to that demonstrated for MCH (Furniss et al., 1981; McGregor et al., 1984), in which the chemical did not have to be applied directly to the tree to result in reduced attack density and brood production. We infer from the results of our studies that the response of beetles at and near the source varies with the chemical composition of the source and with the absolute and relative release rates of the components.

Acknowledgments—We thank Jana L. Morrow for helping to collect the data; Kimberly C. Smith for the statistical design; James A. Baldwin for statistical advice; and George E. Ferrell, Henry A. Moeck, and David L. Wood for helpful reviews of the manuscript.

BEHAVIORAL RESPONSES OF CRAYFISH (*Orconectes virilis* AND *Orconectes rusticus*) TO CHEMICAL FEEDING STIMULANTS

ANN JANE TIERNEY and JELLE ATEMA

Boston University Marine Program
Marine Biological Laboratory
Woods Hole, Massachusetts 02543

(Received May 16, 1986; accepted January 14, 1987)

Abstract—We conducted two experiments to assess how chemical stimuli affect feeding behavior, grooming, and walking in the crayfishes *Orconectes virilis* and *Orconectes rusticus*. In the first experiment, *O. virilis* was tested with 29 amino acids; in the second experiment, *O. rusticus* was tested with 12 amino acids, 13 additional single compounds, and two six-compound mixtures. In *O. virilis*, the following amino acids, in order of potency, elicited feeding movements: L-isoleucine, glycine, hydroxy-L-proline, L-glutamate, L-valine, and B-alanine. Grooming increased in response to L-phenylalanine, L-tryptophan, L-tyrosine, L-leucine, L-methionine, and D-aspartate. In *O. rusticus*, both mixtures and the following single compounds, in order of potency, elicited feeding movements: cellobiose, sucrose, glycine, maltose, glycogen, nicotinic acid methyl ester, putrescine, and L-glutamate. Grooming increased in response to putrescine only, and walking increased in response to glycogen only. The responsiveness of these crayfishes to a wide variety of chemicals may reflect the omnivorous foraging habits of these crustaceans.

Key Words—Crayfish, *Orconectes virilis*, *Orconectes rusticus*, Crustacea, chemoreception, feeding behavior.

INTRODUCTION

Many behavioral studies have demonstrated that amino acids and related compounds are potent feeding stimulants for marine Crustacea, including lobsters (McLeese, 1970; Mackie, 1973; Carter and Steele, 1982; Zimmer-Faust et al., 1984), crabs (Kay, 1971; Hartman and Hartman, 1977; Field, 1977), and shrimp (Hindley, 1975; Carr, 1978; Johnson and Atema, 1986). Amino acids presum-

0098-0331/88/0100-0123$06.00/0

ably provide these flesh-eating species with information about food availability. In contrast, studies of semiterrestrial crabs, which naturally feed on algae and other plant material, demonstrate that feeding is best stimulated by carbohydrates (Robertson et al., 1981; Trott and Robertson, 1984). Chemical feeding stimulants of crayfish are as yet unknown. A purpose of this study was to provide initial information on the chemical response spectrum of two crayfishes and to compare this information to results from similar studies of other crustacea. *Orconectes virilis* and *O. rusticus*, which are common in lakes and streams throughout the midwestern and northeastern United States, are omnivores and consume a great variety of plant and animal material (Lorman and Magnuson, 1978). The flexible feeding habits of crayfish suggest that they might respond to a very broad spectrum of chemicals.

In most cases, feeding is best elicited by specific mixtures of compounds present in prey organisms (Shelton and Mackie, 1971; McLeese, 1970; Mackie, 1973; Carr et al., 1984; Carr and Derby, 1986). However, feeding can also be stimulated by single compounds such as isoleucine (Kay, 1971), ammonium chloride (Borroni et al., 1986), betaine (Carr, 1978), and taurine (Johnson and Atema, 1986). Such single compounds may function as signals for food detection. Johnson and Atema (1986) note that taurine, for example, has excellent signaling properties: it is abundant in prey organisms, but occurs in low concentrations in background seawater. They suggest that crustaceans have consequently evolved chemoreceptors to detect this compound. This idea is supported by the finding that lobsters have large receptor populations narrowly tuned for taurine (Fuzessery et al., 1978; Johnson and Atema, 1983; Johnson et al., 1984).

The dactyl chemoreceptors of crayfish are more broadly tuned than are those of lobsters. One type of receptor responds generally to amino acids (Hatt, 1984); another receptor type responds generally to pyridine compounds (Hatt and Schmiedel-Jakob, 1984). Both receptor types are differentially sensitive to different compounds. Thus, the amino acid receptor is highly sensitive to compounds such as serine, alanine, and histidine and much less sensitive to other amino acids (e.g., glutamate, lysine, tyrosine). Chemicals which very effectively excite receptors may be particularly significant behaviorally, possibly playing a signal role in food detection as suggested for taurine. A second purpose of the present study was to test this hypothesis by assessing the responses of crayfish to single amino acids and comparing this information to the electrophysiologic results of Hatt (1984).

METHODS AND MATERIALS

We collected adult *O. virilis* (27–42 mm carapace length) from Lake Winnipesaukee, Belknap County, New Hampshire. Adult *O. rusticus* (33–40 mm

carapace length) were acquired from a commercial supplier (Connecticut Valley Biological Supply Co., Southampton, Massachusetts). Animals were held individually in plastic basins containing aged tap water (pH 6.9; temperature 20 $\pm$ 2°C). They were fed Purina trout chow three times a week.

During testing, crayfish were isolated in Plexiglas chambers 15 $\times$ 15 $\times$ 7 cm high, filled with 1 liter of aged tap water. A portion of a 1-cc plastic syringe (4.5 cm in length) mounted to the removable top of each chamber formed a delivery tube through which chemicals were injected into the center of the chambers. Prior to testing, animals were placed in the chambers and allowed to acclimate for 72 hr. They were fasted for at least 48 hr before being tested. We conducted experiments between 0800 and 1800 hr under red light (three 40-W incandescent bulbs suspended 40 cm over a row of chambers). When illuminated by red light, the crayfish, which normally were nocturnally active, became more active during the day. The lower light level provided by red bulbs, compared to white bulbs, also reduced visual responsiveness to the observer. Eighteen *O. virilis* (nine males, nine females) and 14 *O. rusticus* (11 males, three females) were tested.

For *O. virilis*, test stimuli were 29 single amino acids; for *O. rusticus*, test stimuli were 25 single compounds and two equimolar mixtures of six compounds (Table 1). The single chemicals were chosen because they have previously been tested as feeding stimulants in other crustaceans and as chemostimulants in electrophysiologic studies of crayfish. The mixtures were tested to determine if combinations of several chemicals would exhibit synergism or antagonism. Each single compound was weighed to prepare a 10^{-2} M solution (for glycogen, a 4 mg/liter solution). To form the amino acid mixture, 50 ml of each 10^{-2} M solution of six amino acids (serine, histidine, glycine, proline, glutamate, lysine) were combined. Likewise, 50 ml of each of two amino acids (serine, glycine) and four additional compounds (glucose, cellobiose, nicotinamide, trimethylamine) were combined to form the general mixture. For both mixtures, the molarity of each single compound was 0.167×10^{-2}; the total mixture molarity was 10^{-2}. Chemicals were dissolved in aged tap water, and the pH of all solutions was adjusted to 6.5 using H_2SO_4 or NaOH. Solutions were placed in 20-ml vials and frozen until the day of use.

In each test, 4 ml of a stimulus solution or control (aged tap water) was injected (over approximately a 10-sec time period) from a 5-ml syringe into the chamber via the delivery tube. Dye experiments indicated that injected solutions diffused to all sides of the chamber within 10 sec and thus contacted the animals within 10 sec, regardless of their positions in the chambers. Since the test chambers contained 1 liter of water, stimulus solutions could be maximally diluted 250 times. Thus, actual concentrations to which animals were exposed were less than the injected concentrations indicated in the results. The test solutions and controls were presented to the crayfish in random order and were blind to the observer. In both experiments, each animal was tested once with each stim-

ulus. Animals were observed for 8 min following stimulus injection, and then the chambers were rinsed and refilled with clean aged tap water. Each crayfish was tested once or twice a day, with at least 3 hr between two tests conducted on the same day.

During the 8 min following stimulus injection, we used stopwatches to record the following four behaviors: total time walking, total time feeding, total time grooming, and the number of times walking legs were touched to the mouth. Time walking was the time animals spent moving across the chamber or climbing the sides. We considered feeding movements to occur when animals

probed or tapped the ground with their first two pairs of walking legs, while opening and closing the dactyls of these appendages. Touching legs to mouth occurred most frequently while animals were performing feeding movements and was considered a feeding response. However, it also occurred during grooming when an animal plucked debris from itself and conveyed it to its mouth. We chose walking, feeding movements and legs touched to mouth as our bioassay because these behaviors were displayed by animals initially presented with a food odor (filtrate from 100 ml of water in which 1 g of trout chow had been soaked for 1 hr). Previous tests also demonstrated that high concentrations of amino acids elicit grooming in *O. virilis* (Tierney and Atema, 1986).

The Friedman two-way analysis of variance by ranks (Siegel, 1956) was used to compare responses to test chemicals and the control for each of the four behaviors recorded. Excepting total time walking in *O. virilis*, significant ($P \leq 0.01$) overall differences occurred in all tests. The Wilcoxon matched-pairs signed-ranks test (Siegel, 1956) was used to compare responses of each test chemical to the control for each of the behaviors shown by the Friedman test to be significantly different overall.

RESULTS

Responses of O. virilis *to chemical stimuli.* Of the 29 amino acids tested six, isoleucine, glycine, hydroxyproline, glutamate, valine, and β-alanine, significantly increased the time spent performing feeding movements, relative to the control (Figure 1A). Two amino acids, tryptophan and tyrosine, significantly reduced the time spent performing feeding movements. Feeding responses to chemicals were also assessed by recording the number of times walking legs were touched to the mouth. Two amino acids, isoleucine and glycine, elicited this behavior significantly ($P \leq 0.05$) more than did the control.

The amount of time spent grooming significantly increased, relative to control tests, in response to six amino acids: phenylalanine, tryptophan, tyrosine, leucine, methionine, and D-aspartate ($P \leq 0.01$, for phenylalanine, tryptophan, tyrosine, and leucine; $P \leq 0.05$ for methionine and D-aspartate).

Responses of O. rusticus *to chemical stimuli.* Eight single compounds and both mixtures significantly increased the time spent performing feeding movements, relative to the control (Figure 1B). The most stimulatory single compounds were the disaccharide sugars cellobiose and sucrose. Maltose and the polysaccharide glycogen were also significantly stimulatory. However, the monosaccharides glucose, mannose, and fructose were not. Cellobiose, sucrose, and maltose were the only chemicals to elicit a feeding response from every animal (Figure 2). The amino acids glycine and glutamate, the amine

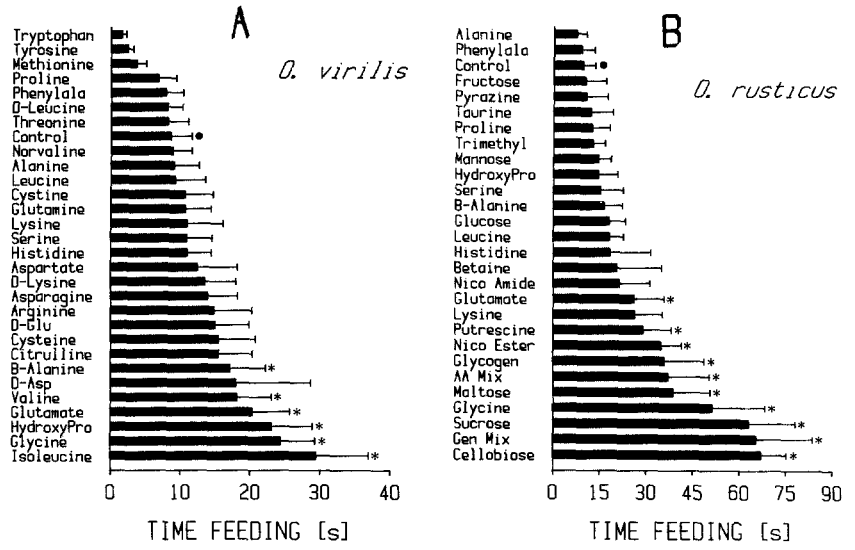

FIG. 1. Feeding responses of *O. virilis* and *O. rusticus* to test stimuli at 10^{-2} M concentration (for glycogen, 4 mg/liter). (A) Bars indicate mean time (seconds) that 18 *O. virilis* spent feeding. (B) Bars indicate mean time (seconds) that 14 *O. rusticus* spent feeding. Horizontal lines indicate SEM. *Time spent feeding is significantly greater in response to test chemicals than in response to control (●), $P \leq 0.05$. Abbreviations: Phenylala, phenylalanine; D-Glu, D-glutamate; D-Asp, D-aspartate; HydroxyPro, hydroxyproline; Pyrazine, pyrazinecarboxamide; Trimethyl, trimethylamine; Nico Amide, nicotinamide; Nico Ester, nicotinic acid methyl ester; B-Alanine, β-alanine; AA Mix, amino acid mixture; Gen Mix, general mixture.

putrescine, and the pyridine compound nicotinic acid methyl ester also significantly stimulated feeding movements. Legs were touched to the mouth significantly more times, relative to the control, in response to the two mixtures and five single compounds (cellobiose, sucrose, glycine, putrescine, and nicotinic acid methyl ester; $P \leq 0.05$).

The amount of time spent walking increased, relative to control tests, in response to only one compound, glycogen ($P \leq 0.05$). Time spent grooming increased in response to putrescine only ($P \leq 0.01$).

In both crayfishes there was marked interanimal variability in general responsiveness to chemical stimuli (illustrated for feeding behavior in *O. rusticus* in Figure 2). In contrast, repeated presentation of the same chemical to crayfish indicated that intraanimal variability was relatively low (Tierney and Atema, personal observation). In our apparatus crayfish were generally consistent in their responsiveness to stimulatory chemicals, with some individuals always highly responsive and others always relatively unresponsive.

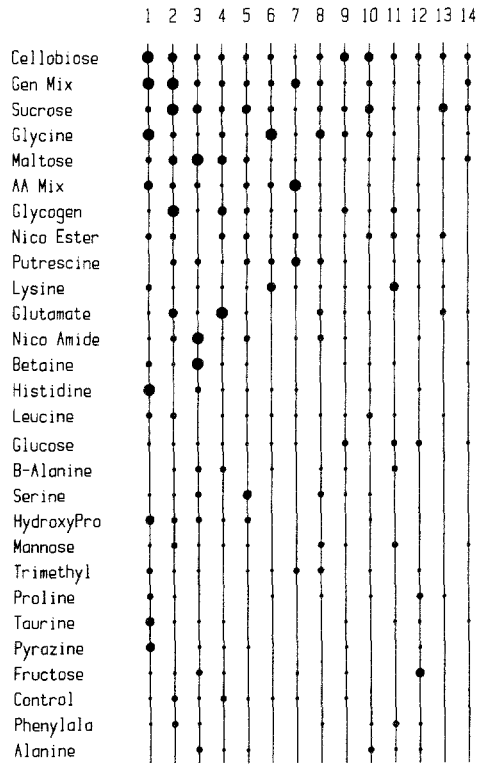

FIG. 2. Interanimal variability: time individual *O. rusticus* spent performing feeding movements in response to chemical stimuli. A continuous line indicates no response, the smallest dots indicate 1–25 sec were spent performing feeding movements, second largest dots indicate 26–75 sec feeding, third largest dots indicate 76–125 sec feeding, and largest dots indicate 126 sec or more feeding. Chemicals are listed in order of potency. Animals are arranged in order of most to least responsive. Abbreviations as in Figure 1.

DISCUSSION

The results demonstrate that even under highly artificial conditions *O. virilis* and *O. rusticus* are stimulated to perform feeding movements by certain single compounds. Cellobiose and sucrose were the most stimulatory compounds tested (Figures 1B and 2), suggesting that carbohydrates are an important feeding stimulus for *O. rusticus*. Additional experiments with *O. virilis* (Tierney and Atema, in preparation) confirm the stimulatory effectiveness of carbohydrates, especially sucrose. Using 20 *O. virilis* and the procedures described above, we found that sucrose was four times more effective at eliciting feeding than were glycine or glutamate. Feeding responses to carbohydrates

have been observed in other crustacean species including porcelain crabs (*Petrolisthes cinctipes*; Hartman and Hartman, 1977), fiddler crabs (*Uca pugilator*; Robertson et al., 1981), and ghost crabs (*Ocypode quadrata*; Trott and Robertson, 1984). Bradycardia following exposure to carbohydrates occurred in crayfish (*Procambarus simulans*; Ashby and Larimer, 1965) and kelp crabs (*Pugettia producta*; Zimmer et al., 1979), indicating the presence of carbohydrate receptors in the branchial chambers of these animals. Like *O. rusticus*, most species were more responsive to disaccharides than to monosaccharides.

Chemosensitivity to specific carbohydrates appears to correlate well with the diets of the animals. Macroalgae, eaten by kelp crabs (Zimmer et al., 1979) and benthic diatoms, a food source for fiddler crabs (Robertson et al., 1981) and ghost crabs (Trott and Robertson, 1984), contain disaccharides as energy storage products. Ghost crabs, which feed on fruit, also responded to fructose and mannose, the major storage products of fresh and decaying fruit. Crayfish are omnivores and consume a wide variety of plant (periphyton and many macrophyte species) and animal (insect larvae, carrion, other crayfish) material (Lorman and Magnuson, 1978; Capelli, 1980). Grazing of macrophytes by *O. rusticus* has been sufficiently extensive to decimate dense stands of water vegetation in Wisconsin lakes (Lorman, 1980). Cellobiose, produced by the partial hydrolysis of cellulose, and sucrose occur abundantly in plants (Davies, 1974) and may provide cues which elicit feeding in natural populations of crayfish.

The amino acids glycine and glutamate elicited feeding movements in both *O. virilis* and *O. rusticus*; isoleucine, hydroxyproline, valine, and β-alanine also elicited feeding movements in *O. virilis*. Excepting D-aspartate, which was more stimulatory than L-aspartate, D isomers of amino acids (D-glutamate, D-lysine, D-leucine) elicited less feeding than did corresponding L isomers. Putrescine, an amine formed from the decarboxylation of ornithine, is found in decaying flesh. In *O. rusticus* it significantly affected feeding behavior and grooming. The increase in time spent grooming when exposed to putrescine suggests that, at test concentrations, this chemical was a general irritant, as well as a feeding stimulant, to the animals. Mixed responses have also been observed in lobsters exposed to ammonia; at low concentrations ammonia is a feeding stimulant, at high concentrations it inhibits feeding (Borroni et al., 1986). Feeding was not associated with the six amino acids that caused increased grooming in *O. virilis*.

In marine crustaceans, amino acids which best elicit feeding include taurine, glycine, β-alanine, glutamate, isoleucine, tyrosine, proline, and methionine (McLeese, 1970; Kay, 1971; Hartman and Hartman, 1977; Hamner and Hamner, 1977; Allison and Dorsett, 1977; Ache, 1982; Johnson and Atema, 1986). These chemicals are abundant in the tissues of marine organisms and probably guide predators and scavengers to food. Amino acids may likewise signal food availability to crayfish. During parts of the year crayfish prey heavily on insect larvae and other crayfish (Capelli, 1980). High concentrations of

free glycine and glutamate occur in the hemolymph of insects (Jeuniaux, 1970), and glycine and glutamate are the most abundant amino acids in the cuticle of crayfish and other crustaceans (Welinder, 1974).

Two amino acids, hydroxyproline and β-alanine, were tested in both species, but elicited feeding in *O. virilis* only. If these compounds are naturally associated with food selection, this difference suggests that the diets of the two species, or the populations sampled, may differ significantly. Compatible with this suggestion is the hypothesis that differences in the natural background concentrations of amino acids may influence responsiveness to food-related chemicals (Johnson and Atema, 1986). The quality and quantity of free amino acids in freshwater is highly variable, and depends on the trophic condition of lakes and the type of vegetation and soil near rivers (Thurman, 1986). This variability may provide a selective pressure that results in differently tuned receptor systems in different species or populations of crayfish.

Bauer et al. (1981) and Hatt (1984) concluded from electrophysiologic studies that the dactyl chemoreceptors of the European crayfish *Austropotamobius torrentium* are sensitive to many amino acids, the most potent being serine, alanine, histidine, β-alanine, ornithine, and proline. Excepting β-alanine, these compounds were not associated with feeding behavior in *O. virilis* or *O. rusticus*. Conversely, the dactyl receptors of *A. torrentium* were relatively insensitive to some compounds (e.g., glutamate, isoleucine) that did stimulate feeding in *O. virilis* and *O. rusticus*. The pyridine compounds pyrazinecarboxamide, nicotinamide, and nicotinic acid methyl ester were also highly stimulatory for *A. torrentium* receptors (Hatt and Schmiedel-Jakob, 1984), but only one of these compounds, nicotinic acid methyl ester, elicited feeding in *O. rusticus*.

Amino acid-sensitive receptors occur on crayfish antennules (Hodgson, 1958), and animals in our behavioral studies may have used these receptors to perceive chemicals that ineffectively stimulate dactyl receptors. Alternatively, differences between physiologic and behavioral responses might result from the testing of single compounds instead of mixtures. Many studies have shown that behavioral responses of crustaceans to mixtures are different from responses to the single components of mixtures (Shelton and Mackie, 1971; Carr, 1978; Robertson et al., 1981; Borroni et al., 1986; Zimmer-Faust et al., 1984). In tests with *O. rusticus*, we found no evidence for synergistic or suppressive interactions among the chemicals in two simple mixtures. This is preliminary evidence that compounds such as serine and histidine, which did not induce feeding when presented singly, also do not inhibit or enhance other compounds in our mixtures. Clearly, however, additional studies, particularly with mixtures that mimic natural foods, are needed to confirm this observation.

Finally, it is possible that the dactyl receptors of *O. virilis* and *O. rusticus* are sensitive to different compounds than are those of *A. torrentium*. The North American species and the European species inhabit different environments, and

chemoreceptors of each species may be tuned in a manner to allow optimal adaptation to local conditions. A more complete understanding of how ecological factors affect the tuning of crustacean chemoreceptors could be gained from studying the ecology, behavior, and chemoreceptor physiology of closely related species adapted to different environments. Crayfish provide ideal subjects for such a comparative study as a great many species are available—approximately 270 in North America—and these animals inhabit virtually every type of freshwater ecosystem.

AMINO ACID CHEMORECEPTION: Effects of pH on Receptors and Stimuli

ANN JANE TIERNEY and JELLE ATEMA

Boston University Marine Program
Marine Biological Laboratory
Woods Hole, Massachusetts 02543

(Received September 8, 1986; accepted January 15, 1987)

Abstract—A current model of amino acid chemoreception has generated the idea that pH affects the efficiency of stimulus–receptor binding by altering the charge distribution on stimulus molecules. The model suggests that amino acids are maximally stimulatory near their isoelectric points. We point out that, within a broad range of pH values, changes in stimulant amino acids cannot account for altered chemoresponsiveness. We suggest instead that pH-induced changes in chemoreception are a result of changes in charge distribution on the protein receptor.

Key Words—Amino acids, chemoreception, pH, proteins, isoelectric points.

INTRODUCTION

Behavioral and electrophysiologic studies have demonstrated that amino acids are effective chemical stimuli for receptors of a great many species. Single amino acids have been used as model compounds to elucidate structure–activity relationships and thus to infer properties of membrane receptor sites (Hara, 1976a, 1982; Bauer et al., 1981; Caprio, 1982; Hatt, 1984; Valentincic, 1985). Based on studies of rainbow trout olfactory responses, Hara (1976a, 1982) has proposed a hypothetical amino acid receptor site. Hara's model, which is outlined below, has implications for pH effects on chemoreception: amino acids are considered to be maximally stimulating near their isoelectric points. Concern about the acidification of freshwater ecosystems due to acid precipitation has generated a growing interest in how low pH affects chemoreception in aquatic animals (Lemly and Smith, 1985; Jones et al., 1985; Tierney and Atema, 1986; Royce-Malmgren and Watson, 1987). Because Hara's model relates pH to stim-

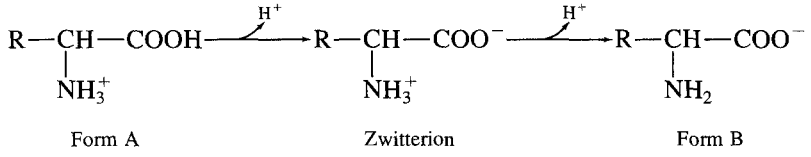
0098-0331/88/0100-0135$06.00/0

ulus–receptor binding, this model has been cited as a possible explanation for why behavioral responses to chemical stimuli are impaired at low pH levels. Here we point out that neither electrophysiologic data on pH effects on amino acid reception in trout nor observations of impaired behavioral chemoresponsiveness are readily understood in terms of Hara's explanation, i.e., that chemoreception is altered by alteration of the charge distribution on stimulus molecules. We suggest instead that pH-induced changes in chemoreception are a result of changes in charge distribution on the protein receptor.

HARA'S MODEL

Hara (1976a) recorded olfactory responses of trout to amino acids and analogs and determined that, for stimulation to be effective, the following features are essential: (1) ionized α-amino and α-carboxyl groups; (2) a free α-hydrogen; (3) a fourth α-moiety of appropriate size and polar nature; and (4) the L, rather than the D isomer, of the amino acid. From these findings, Hara suggested that an amino acid receptor might consist of two charged subsites, one negative and one positive, which interact with the ionized α-amino and α-carboxyl groups. The two subsites are thought to occur in a particular order around a center which interacts with the α-hydrogen, allowing L isomers to bind more easily than D forms. An additional region of the receptor recognizes and binds with the variable fourth α-moiety and gives the receptor its specificity for particular amino acids. Models basically similar to Hara's have been proposed for chemoreception in humans (Shallenberger et al., 1969), crayfish (Hatt, 1984) and sea stars (Valentincic, 1985).

The presence of ionized α-amino and α-carboxyl groups in stimulus molecules and appropriately charged groups in receptor sites is pH dependent. In neutral aqueous solutions, amino acids exist primarily as dipolar ions (or zwitterions). Addition of an acid to a solution of dipolar molecules will cause the carboxyl group to pick up H^+, forming the undissociated carboxyl group; addition of a base will cause the ammonium group to release an H^+:



Amino acids are positively charged (form A) in acidic solution and negatively charged (form B) in alkaline solutions and migrate accordingly in an electric field. For each amino acid there exists an intermediate pH, called the isoelectric point (pI), where there is no net charge on molecules (most are zwitterions and

the very small balance contains equal numbers of forms A and B) and no net movement in an electric field. For monoamine–monocarboxylic amino acids, the isoelectric point is the arithmetic mean of the dissociation constants of the α-carboxyl (pK_1) and the α-amino (pK_2) groups.

According to Hara, amino acids are most effective as chemostimulants when they are at their isoelectric points where zwitterion forms are maximal. To test this idea, Hara (1976b) studied olfactory responses of trout to amino acids at various pH levels. Responses were indeed pH dependent. When presented at their isoelectric points, some amino acids (e.g., serine and methionine) elicited responses 100% greater than responses elicited at pH levels one pH unit removed from the isoelectric point. Hara notes that pH can influence the ionization of (1) receptors, (2) stimulus molecules, and (3) binding between receptors and stimuli. However, in accounting for altered chemoresponsiveness, he emphasizes the role played by ionization changes of stimulus molecules:

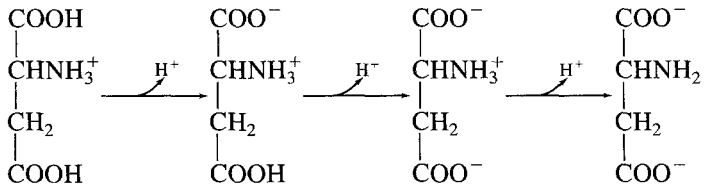
> Most of highly stimulatory amino acids employed had their peak activity somewhere between pH 5.0 and 6.0. The isoelectric points for these amino acids also lie within the same range. This indicates that these amino acids display maximal activity near their isoelectric points at which dipolar ions are at maximum and bearing no net charge. This supports the idea that the binding would take place between ionized amino and carboxyl groups of amino acids and two ionized, one positively and one negatively, subsites of the receptors [Hara, 1976b, p. 38].

EFFECTS OF pH ON AMINO ACIDS AND PROTEINS

As presented by Hara, the concept of an isoelectric "point" where dipolar ions are maximum is misleading. For monoamine–monocarboxylic amino acids there exists, not an isoelectric point, but a broad zone of pH values, delimited by pK_1 and pK_2, where molecules exist almost entirely in the dipolar form. For glycine, for example, the concentration of cationic and anionic molecules is less than one percent of that of zwitterions at all pH values between 4.3 and 7.7 (Edsall, 1943a).

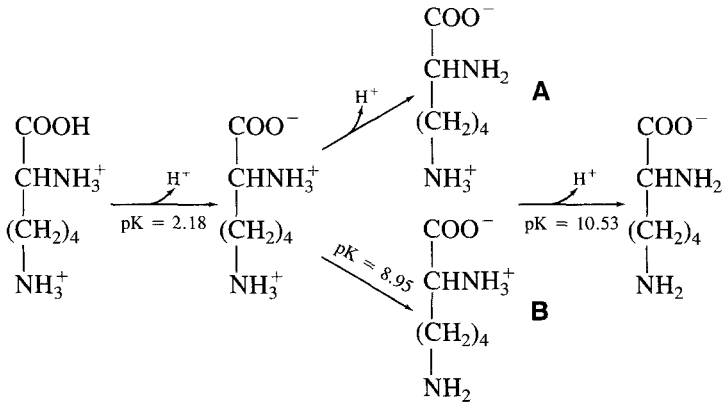
Dicarboxylic amino acids (aspartate, glutamate), diamine amino acids (lysine, arginine, histidine), tyrosine, and cysteine have an additional ionizable group and an additional dissociation constant (pK_R). Consequently, in these amino acids, the presence of ionized α-carboxyl and α-amino groups is not directly correlated with the presence of the zwitterion form of the molecule. This may have implications for the analysis of data in terms of Hara's model. For example, in the aspartate molecule, protons tend to dissociate most readily

from the α-carboxyl group (pK_1 = 1.88 at 25°C; Edsall, 1943a), next from the distal carboxyl group (pK_R = 3.65) and least readily from the α-amino group (pK_2 = 9.60):



The isoelectric point of aspartate is $\frac{1}{2}(pK_1 + pK_2)$ or 2.94, and the compound exists primarily as a zwitterion between pH levels 2.5 and 3.5. However, the great majority of aspartate molecules have the α-carboxyl and α-amino groups ionized in the manner required for Hara's model between pH levels 2.5 and 9.5.

For lysine, a diamino amino acid, protons dissociate in the following manner:



zwitterion

The zwitterion occurs in two forms. The ratio of the highly polar A form to the B form is approximately 1,800,000 to 320,000 (Edsall, 1943a). Thus most zwitterionic lysine molecules do not possess a charged α-amino group. Assuming a charged distal amino group could be accommodated, lysine (and arginine) would, according to Hara's model, be effective chemical stimuli roughly between pH levels 3 and 8, and not at their isoelectric points (9.74 for lysine; 10.76 for arginine).

The above points indicate that Hara's (1976b) data offer no direct support for his idea that the amino acid receptor has two charged subsites that must

interact with ionized amino and carboxyl groups of stimulant amino acids. This idea, in turn, cannot explain the striking differences in responses to amino acids at their isoelectric points and responses one or two pH units removed from the isoelectric points. Alterations in stimulus molecules also cannot account for the pH effects on behavioral responses to chemicals observed in fish (Jones et al., 1985; Lemly and Smith, 1985; Royce-Malmgren and Watson, 1987) and crayfish (Tierney and Atema, 1986). Royce-Malmgren and Watson (1987) found that at pH 7.6 salmon were attracted to glycine and repelled by alanine; at pH 5.1, the salmon were unresponsive to glycine and attracted to alanine. In fathead minnows, reliable responses to chemicals from a food stimulus at pH 7 were reduced at pH 6.5 and eliminated at pH 6.0 (Lemly and Smith, 1985). Likewise, arctic char were attracted to chemicals from food at pH 7.8 and showed reduced attraction at pH levels 5.0 and 4.75 (Jones et al., 1985). Crayfish also showed reduced responses to an amino acid mixture at low pH levels (pH 4.5 and 3.5), relative to responses at pH 5.8 (Tierney and Atema, 1986).

Following Hara (1976b), all of the above reports cite pH-induced changes in stimulus molecules as a possible explanation for altered chemoresponsiveness. Jones et al. (1985, p. 409), for example, suggest that responses of char to chemicals are reduced at low pH because "the structure and charge of stimulatory molecules such as amino acids vary with pH, thereby making each substance, depending on its specific pH curve, more stimulatory at some pHs than at others." However, excepting crayfish tested at pH 3.5, all of the behavioral changes described above occurred at pH levels where alterations in stimulatory amino acids would be negligible. In most of the above studies, reduced responses to chemicals are not readily attributed to malaise induced by lowered pH. The effects of low pH on chemoreception in fish and crayfish appear to be quite specific and, like certain of Hara's (1976b) data, remain to be explained.

The explanation probably involves, not changes in stimulus molecules, but an alternative possibility suggested by Hara (1976b): changes in the state of ionization of the protein receptor. The behavior of protein chemoreceptors may be comparable to that of enzymes. Enzyme proteins typically display an optimum pH where catalytic activity is maximum (Laidler, 1958; Dixon and Webb, 1979). For some enzymes activity drops sharply (within one to two pH units) on either side of the optimum. In all proteins, the α-amino and α-carboxyl groups are tied up in peptide bonds and do not participate in acid and base binding. (Exceptions are the N-terminal and C-terminal groups and cystine, which may possess an α-amino and an α-carboxyl not involved in peptide linkage.) The effects of pH changes on proteins are consequently determined primarily by amino acids with side-chain groups that can ionize (i.e., aspartate, glutamate, histidine, lysine, arginine, tyrosine, cysteine). Although most enzymes contain many such amino acids and many states of ionization, alterations in amino acids at or near the active site are most likely to produce an effect in

binding events. If only one ionic state is catalytically active (as the limited pH range of activity of some enzymes suggests), a significant effect could be caused by the two groups which ionize (or deionize) first as the pH is shifted away from the optimum; additional ionization events would affect only the inactive enzyme (Dixon and Webb, 1979).

Ionizing groups, which in free amino acids dissociate at low or high pH levels, may have pK values that are altered by the proximity of other charged groups in a complex protein molecule (Lehninger, 1975; Dixon and Webb, 1979). Consequently, these groups may in some cases dissociate at pH levels that are closer to neutral in receptor proteins than in free amino acids. Proteins also contain groups (e.g., the imidazolium of histidine and the α-amino of cystine) with pK values in the intermediate (5.5–8.5) pH range (Edsall, 1943b). Thus, it is possible for ionizing groups at a protein receptor site to change charge in response to small pH changes at physiologically appropriate pH levels. Such changes may affect the binding activity of enzymes—and possibly also of chemoreceptors.

If the state of ionization of receptors can indeed affect the efficiency of amino acid–receptor binding, then we can expect different receptors to be affected differently by pH changes. The effects of pH change on chemoreception will depend on which ionizable groups are present at the active site of the receptor, and on the pK values of these groups. Clearly these factors vary among protein receptors. For example, in crayfish (Bauer et al., 1981) and eels (Yoshii et al., 1979), responses to neutral amino acids are not influenced by pH changes between 5 and 9, suggesting that the relevant binding sites on the protein involve groups that do not change charge between these values. Where chemoreception is highly pH dependent, for example in trout (Hara, 1976b) and skates (Novoselov et al., 1980), receptor sites presumably contain groups which change charge at pH levels where marked changes in the efficacy of stimulus–receptor binding are recorded electrophysiologically.

(Received November 11, 1986; accepted January 15, 1987)

Abstract—Olfactory signals may facilitate species recognition between the sympatric voles, *Microtus montanus* and *M. pennsylvanicus*. In an effort to isolate and identify compounds that might contribute to such a chemical communication system, the preputial glands of those voles have been examined. Morphological examinations show both vole species possess preputial glands; however, the glands of *M. montanus* are much larger than those of *M. pennsylvanicus*. Gas chromatographic analysis revealed that the preputial glands of *M. montanus* contain a series of species-typical lipids that are not found in *M. pennsylvanicus*. Using gas chromatography–mass spectrometry and nuclear magnetic resonance spectrometry, the species-typical lipids were identified as esters of branched, saturated, and unsaturated C_5 and C_4 alcohols and straight-chain C_{16}, and "iso" branched C_{17} fatty acids. This is the first description of such esters from mammalian tissues. The results are discussed relative to the possibility that the species-typical esters act as species recognition cues for the sympatric voles.

Key Words—Preputial gland, lipids, esters, *Microtus montanus*, *Microtus pennsylvanicus*, species recognition, pheromone.

INTRODUCTION

The preputial glands are paired accessory sex glands found in all murid and many cricetid rodents. The glands are holocrine and primarily produce lipids;

[3]Current address: W. Alton Jones Cell Science Center, Inc., 10 Old Barn Road, Lake Placid, New York 12946.

0098-0331/88/0100-0143$06.00/0

some of those lipids possess attractive properties and presumably act as pheromones (Bronson and Caroom, 1971; Brown and Williams, 1972; Gawienowski et al., 1975; Brinck and Hoffmeyer, 1984). The weight and lipid composition of the preputial glands are controlled by androgenic hormones (Sansone and Hamilton, 1967; Spener et al., 1969; Ebling, 1977; Mukherjea, 1977), and the presence of attractive compounds in the glands is also sensitive to the action of gonadal hormones (Gawienowski et al., 1975; Thody and Dijkstra, 1978; Lucas et al., 1982; Brink and Hoffmeyer, 1984). It has been suggested that the glandular products are released in connection with urinary marking (Bronson, 1976; Christiansen et al., 1978), and recent evidence supports that suggestion (Brinck and Hoffmeyer, 1984).

The voles *Microtus montanus* and *M. pennsylvanicus* are sympatric in southwestern Montana (Hodgson, 1972; Douglass, 1976) and are morphologically similar. However, the voles have marked karyotypic differences (Hsu and Bernischke, 1973) and do not hybridize (Gray et al., 1977). For these sympatric voles, the devices that facilitate the discriminations made between hetero- and homospecific mates are critically important. Olfactory signals can direct discriminations between hetero- and homospecifics in voles (Godfrey, 1958), deermice (Moore, 1965), and other rodents (Nevo et al., 1976). The importance of pheromonal communication in the voles *M. montanus* and *M. pennsylvanicus* has been demonstrated by several responses to chemical cues that affect reproductive physiology (Berger and Negus, 1982; Baddaloo and Clulow, 1980; Stehn and Jannett, 1981; Mallory and Clulow, 1977), and it is likely that these voles also use pheromones for species recognition cues.

In this communication we describe investigations of preputial glands as a source of species recognition pheromones. The preputial glands and the preputial gland lipids of adult male *M. montanus* and *M. pennsylvanicus* have been characterized. The compounds judged to be the most probable components of a pheromonal species recognition system have been identified. The chemical characteristics of the compounds identified are discussed with regard to a possible function as species recognition pheromones.

METHODS AND MATERIALS

Animals, Trapping, and Housing. Wild *M. montanus* and *M. pennsylvanicus* were live trapped from two sympatric populations during the summer breeding season from Gallatin and Madison Counties, Montana. The rodents were transported to the laboratory where they were housed one animal per cage under natural lighting conditions and supplied with Nutrena Feeds rabbit chow and water ad libitum. Sawdust shavings and cotton balls were provided for bedding material. A three-day laboratory acclimation period allowed the voles

time to groom themselves and remove any trap-related debris prior to collection of surface lipids. Wild voles classed as "adult" animals met the following criteria: (1) visible tubular development in the caudal epididymis (Boonstra and Youson, 1982; Christiansen et al., 1978); (2) scrotal testes; and (3) body weight greater than 25 g. Laboratory-raised *M. montanus* were used for determination of preputial gland weight in that species. These animals were housed as previously described (Rowsemitt and Berger, 1983) and were a gift from Dr. Carol Rowsemitt (University of Utah, Salt Lake City, Utah).

Lipid Collection, Extraction, and Storage. Voles were sacrificed by an overdose of ether vapor or by cervical dislocation. Preputial glands were excised and frozen in 3 ml water at −20°C until extracted. For lipid extraction the preputial glands were thawed, homogenized, and extracted by the method of Bligh and Dyer (1959). All lipids collected from the extractions were concentrated under a stream of nitrogen and stored in chloroform–methanol (2:1, v/v) at − 20°C, in a nitrogen atomosphere.

Chromatography and Spectra. Preparative thin-layer chromatography (TLC) on 250-μm silica layers (Si250 TLC plates; J.T. Baker Chemical Co., Phillipsburg, New Jersey) provided separation of the major lipids using a hexane–diethylether (95:10, v/v) solvent system. The TLC plates were sprayed with a rhodamine 6G solution (1 mg/ml in H_2O–ETOH; 1:1, v/v), and neutral lipid bands were visualized under UV light. Discrete areas were scraped from the plate, and the lipids were eluted from the adsorbent with hexane.

Gas chromatography (GC) of crude total lipid samples and the lipid fractions collected from TLC plates employed a Varian 3700 gas chromatograph (Varian Associates, Sugar Land, Texas) equipped with a flame ionization detector. Chromatographic separations for routine analysis were accomplished with two columns: (1) a 2-mm-ID × 2-m glass column packed with 3% SE-30 on Supelcoport 100/200; and (2) a 30-m, DB-1 (0.250-μm film; 0.25-mm-ID) capillary column (J and W Scientific, Inc., Rancho Cordova, California). A 30-m, DB-225 (0.250-μm film; 0.25-mm-ID) capillary column (J and W Scientific) was used to investigate the double-bond configuration of certain compounds. Details of GC parameters are given in the figure legends. Separation of neutral esters by preparative gas chromatography was accomplished using a thermal conductivity detector and a 1.25-m × 6-mm-ID, stainless-steel column packed with 5% SE-52 on Chromosorb 100/200 (isothermal, 260°C).

Gas chromatography–mass spectrometry (GC-MS) utilized a VG Instruments 7070E mass spectrometer (VG Instruments, Stamford, Connecticut), operating at 70 eV, which was coupled to a Varian 3700 gas chromatograph equipped with a 30-m DB-5 (0.250-μm film, 0.25-mm-ID) capillary column (J and W Scientific). The column was routinely programmed from 170 to 250°C at 2°C/min to provide resolution of the natural esters prior to introduction into

the ion source. Alcohols investigated by GC-MS were chromatographed (DB-5 column) at 25°C, isothermal for 5 min, then programmed at 5°C/min. A Supelcowax 10 (30-m, 0.25-μm film, 0.25-mm-ID) capillary column (Supelco, Bellefonte, Pennsylvania) was used for certain free alcohol analyses.

Nuclear magnetic resonance (NMR) spectra were obtained in a Fourier transform mode on a Bruker WM-250 MHz NMR spectrometer (Bruker, Billerica, Massachusetts) in $CDCl_3$. Chemical shifts were measured relative to tetramethylsilane.

Ester Synthesis. Hexadecanoic acid (Sigma, St. Louis, Missouri), (*Z*)-9-hexadecenoic acid (Sigma), and 15-methylhexadecanoic acid (Accurate Chemical Co., Westbury, New York) were converted to acid chlorides by reaction with thionyl chloride (50°C, 1 hr) (Aldrich, Milwaukee, Wisconsin). Synthetic esters were prepared by reacting acid chlorides with alcohols (50°C, 45 min) from the following list: 2-methyl-1-propanol, 3-methyl-1-butanol, 2-methyl-1-butanol (J.T. Baker Chemical Company), and 3-methyl-2-buten-1-ol (Aldrich). 2-Methyl-(*E*)-2-buten-1-ol was synthesized by reducing 2-methyl-(*E*)-2-butenoic acid (Aldrich) with lithium aluminum hydride and esterified as described above. The reaction mixtures were diluted with water, and the synthetic esters were extracted into hexane and purified over a column of Bio-Sil A (Bio-Rad Laboratories, Richmond, California).

Fatty acid methyl esters of the vole lipids were produced by transesterifying natural esters with Meth-Prep II (Applied Science, Inc., Deerfield, Illinois). The methyl ester of (*E*)-9-hexadecenoic acid was purchased from Sigma. Other methyl ester standards were purchased from Sulpelco and Applied Science.

Other Analytical Techniques. For location of double bonds, unsaturated lipids were subjected to ozonolysis (Beroza and Bierl, 1967). Gas chromatography was used to compare the ozonolysis products with aldehyde standards. The chromatography was achieved on a 2-m × 2-mm-ID glass column packed with 3% Silar 5 CP. The column temperature was held at 60°C for 5 min and then programmed to 250°C at 10°C/min and held at 250°C for 21 min.

Free alcohols from the natural esters were analyzed after microsaponification of approximately 20 μg of the natural ester with 10 μl of 5% KOH in methanol. The reaction mixture was heated at 45°C for 30 min, and the free alcohols were extracted into 10 μl of methylene chloride.

Microhydrogenation, over palladium catalyst, of approximately 20 μg of the natural esters was performed as described by Parliment (1973).

Histological Preparations. Tissues were fixed in 4% neutral buffered formalin, dehydrated through graded alcohols (70%, 95%, 100% ethanol), cleared with xylene, and embedded in paraffin. Tissue sections (5 μm) were cut and stained with a routine hematoxylin and eosin procedure.

RESULTS

Preliminary Characterization. Gross morphologic differences between the preputial glands of *M. montanus* and *M. pennsylvanicus* are readily apparent. The glands of the *M. montanus* closely resemble the superficial morphology of lab mouse preputial glands and possess a distinct vesicular appearance with a distal arrangement of bulbar enlargements filled with a clear, amber colored, viscous oil. In contrast, the *M. pennsylvanicus* preputial glands are minute and contain a thick, waxy secretion (*M. montanus* preputial gland weight = 68.8 mg $\pm$ 27.4, $N = 11$; *M. pennsylvanicus* preputial gland weight = 9.8 mg $\pm$ 1.9, $N = 10$; $P < 0.002$ Mann-Whitney U test). Due to the small size and unusual appearance of the preputial glands in *M. pennsylvanicus*, the actual presence of preputial glands in that species was questionable. Subsequent examination of hematoxylin–eosine-stained *M. montanus* preputial glands and the questioned tissues in *M. pennsylvanicus* revealed that the cellular structures of the tissues from both species were identical. The cytologic similarities indicated that the *M. pennsylvanicus* possess preputial glands.

Different lipid profiles for the two species (Figure 1) were revealed by gas chromatography of 10 μg of mature male preputial gland total lipids (3%, SE-30; detection limit = 10 ng). The chromatograms presented are each from the lipids of one individual but are characteristic of chromatograms from the 23 wild, mature male *M. montanus* and the 14 wild, mature male *M. pennsylvanicus* examined. The presence of the species-characteristic peaks at a retention time of about 5 min in *M. montanus* and their absence in *M. pennsylvanicus* was consistent in all individuals examined. The *M. montanus*-specific lipids (Figure 1) were not found in brain, liver, kidney, muscle, or adipose tissues taken from mature male *M. montanus*. Additionally, those same compounds were not present in the preputial gland lipids of mature male laboratory rats (Holtzman albino, $N = 6$) and mice (CD1, $N = 5$).

Defining the general compound class to which the *M. montanus* specific lipids belong was accomplished by TLC. Total preputial gland lipids were fractioned by preparative TLC and specific lipids from discrete TLC adsorbent bands were collected and analyzed by GC. The gas chromatograms showed that the TLC band corresponding to the *M. montanus* typical lipids ($R_f = 0.60$) migrated just below a wax ester standard (hexadecyl stearate, $R_f = 0.68$) but above an alkyl acetate standard (hexadecyl acetate, $R_f = 0.40$). The GC peaks (Figure 1) at 13 min and 15 min ($R_f = 0.68$) cochromatographed with hexadecyl stearate. The gas chromatographic behavior (3% SE-30) of the *M. montanus* typical lipids was compared to that of known standards, and the resulting chromatograms showed those compounds had retention times similar to C_{22} and C_{23} hydrocarbon standards. The *M. montanus* lipids that had retention times of

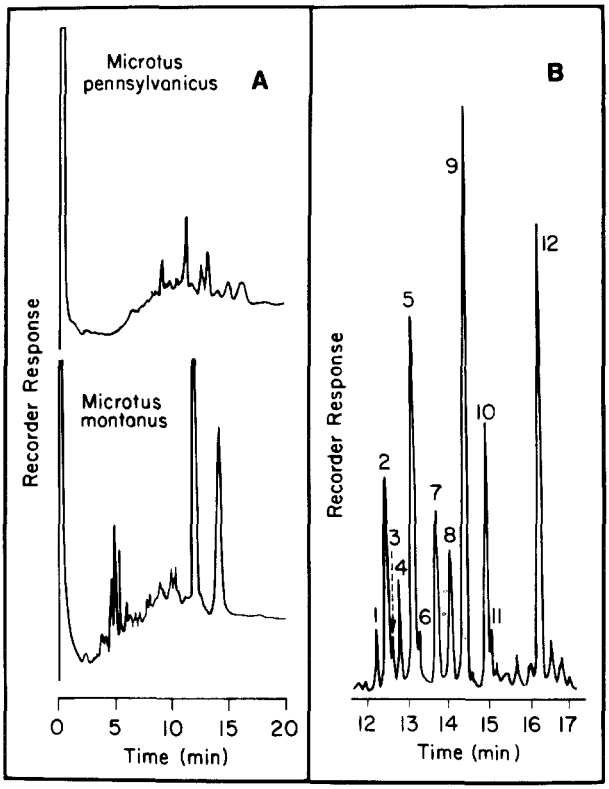

FIG. 1. Gas chromatograms of total preputial gland lipids from *Microtus montanus* and *M. pennsylvanicus* (panel A) and a capillary gas chromatogram of the species-typical lipids from *M. montanus* (panel B). The chromatograms in panel A illustrate the resolution of total preputial gland lipids (10 μg) on a 2-m × 2-mm-ID glass column packed with 3% SE-30; column temperature was programmed from 180° to 295°C at 15°C/min. Panel B shows capillary column resolution of the compounds from *M. montanus* which elute from the packed column (panel A) at a retention time of about 5 min. The chromatography was achieved on a 30-m × 0.25-mm DB-1 column (0.250-μm film) that was temperature programmed from 170° to 250°C at 2°C/min.

approximately 13 and 15 min (Figure 1) eluted from the SE-30 column between C_{32} and C_{34} hydrocarbon standards.

Capillary GC resolved the species-typical lipids as shown in Figure 1. The structures corresponding to the numbered peaks were investigated. The molecular weights of the lipids, determined by mass spectrometry, are listed in Table 1. High-resolution mass spectra indicated each compound contained two oxygen atoms (Table 1), consistent with the ester function. Fragment peaks in the

12	338	$C_{22}H_{42}2_2$	1

mass spectra suggested the lipids to be esters derived from 16- and 17-carbon acids and 4- and 5-carbon alcohols; either moiety could be saturated or monounsaturated. Each spectrum contained fragment peaks $(M - RCOOH)^+$ (e.g., $m/z = 68$ or 70 in Figure 2), which are characteristic of esters containing long-chain fatty acids. In addition, peaks corresponding to $(RCOOH)^+$ and $(RCOOH + H)^+$ were also seen ($m/z = 256$ and 257 in Figure 2). Finally, acylium ions, resulting from alpha cleavage at the carbonyl, were present in the spectra ($m/z = 239$ in Figure 2).

The species-typical lipids were separated into three fractions by preparative GC. The chromatography resolved peaks 1–6 from peaks 7–11 and isolated peak 12. Hydrolysis of each GC fraction permitted GC and GC-MS analysis of the resulting alcohols. The acyl moieties were analyzed as fatty acid methyl esters.

Alcohol Moieties. The species-typical lipids contain two pairs of isometric C_5 alcohols and one C_4 alcohol (Table 2). The saturated C_5 alcohols eluted from GC before *n*-pentanol and were, therefore, believed to be branched. Mass spectra of the saturated alcohols were diagnostic for 3-methyl- and 2-methyl-1-butanols (Table 2). Mass spectra and GC retentions of the natural alcohols and respective authentic standards were identical. The configuration at the asymmetric center of 2-methyl-1-butanol was not determined.

Mass spectra showed that the remaining C_5 alcohols had molecular weights of 86 (one degree of unsaturation), but analysis by NMR was required to determine their structures. The NMR spectrum of peak 12 (Figure 1), which had

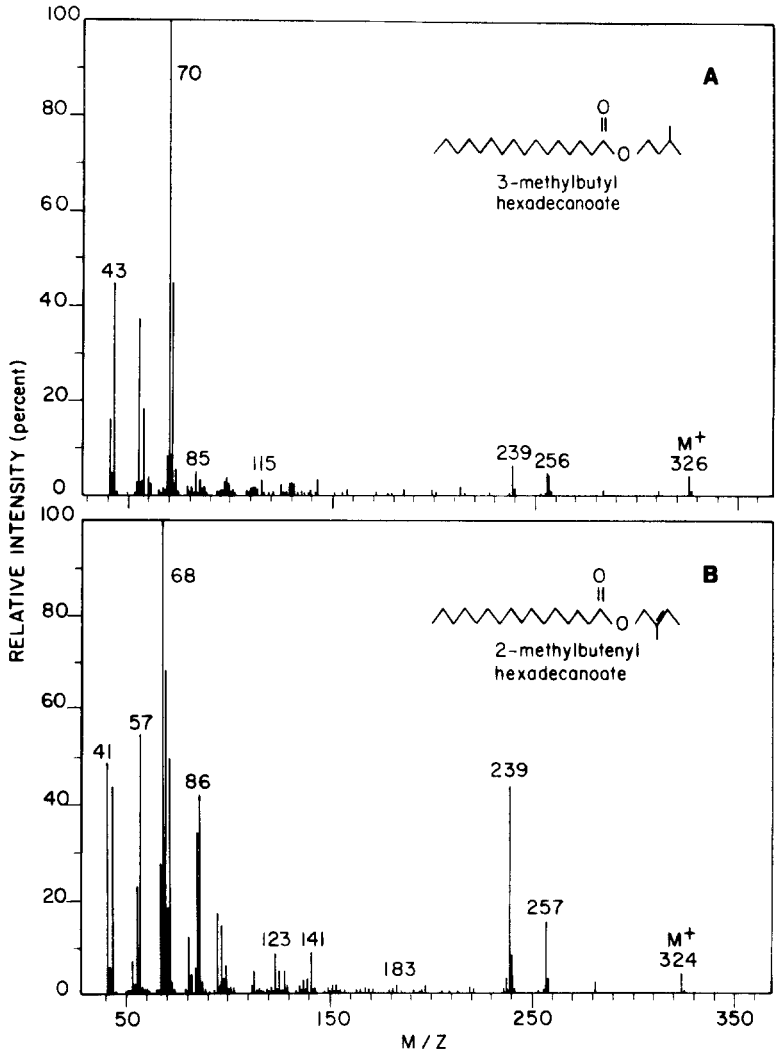

FIG. 2. Mass spectra of peak 5 (panel A) and peak 9 (panel B) of the species-typical esters from the preputial glands of adult male *Microtus montanus*. The spectra are nominal mass enhanced; structure assignments are based on GC, GC-MS, and NMR analyses.

been isolated by preparative GC, indicated the alcohol moieties were 2-methyl- and 3-methyl-2-buten-1-ol. For the ester of 2-methyl-2-buten-1-ol, the definitive NMR resonances were: δ4.44 (2H, s, $-C\underline{H}_2O-$); δ5.54 (1H, q, J = 7 Hz, $CH_3-C\underline{H}=$), and for the ester of 3-methyl-2-buten-1-ol: δ4.49 (2H, d, J

[a] The species-typical esters were resolved by preparative GC as indicated. A + indicates presence in a particular GC fraction; ++ indicates the major alcohols or acids in a given GC fraction.

[b] A + under GC, MS, NMR, and O_3 (ozonolysis) indicates the natural product showed behavior identical to known standards when analyzed by the given techniques.

[c] *m/z* (relative intensity).

[d] 2-Methyl-1-proponal was not recovered from the ester hydrolysis products but was indicated by mass spectral data for peak 1 and was confirmed by GC and GC-MS analyses of peak 1 and known standards.

[e] The mass spectra of 2-methyl-2-buten-1-ol and 3-methyl-2-buten-1-ol were almost identical. NMR analysis provided definitive structure assignments of those alcohols.

[f] The fatty acids were analyzed as fatty acid methyl esters.

= 7 Hz, $-C\underline{H}_2O-$); δ5.32 (1H, t, J = 7, $=C\underline{H}-CH_2O-$). Hexadecanoic esters of synthetic 2-methyl-(*E*)-2-buten-1-ol and 3-methyl-2-buten-1-ol produced NMR resonances identical to those listed above. Peak integrations of the resonances from the natural esters indicated the ester of 2-methyl-2-buten-1-ol to be the predominant isomer (ratio of isomers = 4:1).

The configuration of the double bond in 2-methyl-2-buten-1-ol has not been unequivocally established. However, in the NMR spectra of trisubstituted olefins, the olefinic hydrogens of *E* and *Z* isomers frequently exhibit different chemical shifts (Silverstein et al., 1981). The resonances of the alcohol moiety from the natural ester were identical to those of the hexadecanoic ester of synthetic 2-methyl-(*E*)-2-buten-1-ol, which strongly supports the *E* configuration in the natural ester.

These unsaturated alcohols were not separated by capillary GC, despite concerted efforts, nor were their esters. The natural alcohols did show identical GC retentions with the synthetic standards, and their mass spectra were in agreement also. The mass spectra of the two unsaturated alcohols were nearly identical.

Finally, the mass spectrum of GC peak 1 suggested the presence of a C_4 alcohol (M^+-56 and M^+-57). Based on comparison of GC retention and mass spectra of the natural and synthetic esters, that alcohol was determined to be 2-methyl-1-propanol. The C_4 alcohol was not recovered after hydrolysis of the natural esters.

Acyl Moieties. The species-typical esters contain three major fatty acids (Table 2). Hexadecenoic acid was characterized by GC and GC-MS and was identical to an authentic standard. (*Z*)-9-Hexadecenoic acid is the most abundant unsaturated fatty acid. The structure is supported by GC and GC-MS data. The position of the double bond was determined by analysis of ozonolysis products, and the double-bond configuration, by comparing GC retention (DB-225) of the methyl ester with standard methyl (*Z*)- and (*E*)-9-hexadecenoates. Finally, 15-methylhexadecenoic acid was identified by NMR, GC, and GC-MS. The iso configuration was obvious from the NMR spectrum of peak 12 (δ0.84, 6H, d, J = 7 Hz). This signal collapsed to a singlet upon irradiation at δ1.62. The NMR data eliminated other methyl group positions from consideration. The GC retention and mass spectrum of the natural acid methyl ester were identical to those of the authentic standard.

Ester Structures. The assigned structures of the species-typical esters are listed in Table 3. These were based on the acids and alcohols identified from the hydrolysis of preparative GC fractions. In every case, the natural and synthetic esters had identical GC retentions and mass spectra.

It was learned from the synthetic ester standards that only those with 2-methyl-2-buten-1-ol produced an appreciable mass spectral fragment at m/z = 86 (Figure 2). This fragment had an intensity of less than 0.5% in esters of

	3-methylbutenyl 15-methylhexadecanoate	+	+	+	+	

[a] A + under GC, MS, NMR, and H_2 (catalytic hydrogenation) indicates chromatography, spectra, and hydrogenation products are identical to known standards.

[b] *m/z* (relative intensity).

[c] 3-Methylbutenyl (*Z*)-9-hexadecenoate may also be present.

[d] 3-Methylbutenyl hexadecanoate may also be present.

[e] 2-Methylbutenyl 15-methylhexadecanoate accounts for ~70% of the area under peak 12. Available evidence indicates a *trans* double bond.

3-methyl-2-buten-1-ol. Thus, the predominant isomer of peaks 7 and 9 could be determined from the mass spectra even though the isomers were not separated by GC.

Hydrogenation of the species-typical lipids also supported the assigned structures. Gas chromatograms of the hydrogenation products showed an increase in the quantity of the expected saturated esters and a concomitant loss of the unsaturated compounds. The hydrogenated esters were analyzed by GC-MS, and the spectra of the resulting saturated products were consistent with the assigned structures.

The analytical techniques used could not provide definitive structure assignments for peaks 4 and 8. However, some information was obtained. The peak 4 and peak 8 esters possess an unsaturated C_{16} fatty acid. From GC retention comparisons, the fatty acid is not (*Z*)- or (*E*)-9-hexadecenoic acid. It is probable that the fatty acid of the peak 4 and 8 esters is a double-bond positional isomer of (*Z*)-9-hexadecenoic acid. Hydrogenation of peaks 4 and 8 produces 3-methylbutyl and/or 2-methylbutyl hexadecenoate by GC retention. From the mass spectra and the proportions of the various alcohol moieties in the other esters, peak 4 is believed to contain an ester of 3-methyl-1-butanol and peak 8, an ester of 2-methyl-2-buten-1-ol. The mass spectrum of peak 8 contains the $m/z = 86$ peak which is diagnostic for this alcohol (Table 3).

DISCUSSION

The preputial glands of adult male *M. montanus* are much larger than the glands of adult male *M. pennsylvanicus*. Treatment of *M. montanus* with testosterone propionate increases the weight of the preputial glands (Jannett, 1978). More recently, Rowsemitt et al., 1988 have confirmed the androgen sensitivity of the preputial glands in *M. montanus* and have shown that levels of the species-typical esters described in this report are also androgen-dependent. Similar findings of androgens affecting the size and content of the preputial glands have been reported by other investigators (Sansone and Hamilton, 1967; Spener et al., 1969; Ebling, 1977). It is not known if preputial gland growth in *M. pennsylvanicus* responds to androgens in the same manner as do the preputial glands of *M. montanus*.

The preputial glands of mature male *M. montanus* contain novel esters. Those esters are composed of 2-methyl- and 3-methyl-1-butanols; 2-methyl- and 3-methyl-2-buten-1-ols; and C_{16} and C_{17} fatty acids. This report is the first to describe fatty acid esters containing saturated and unsaturated C_5 alcohols in mammalian tissues. Using GC retention comparison techniques, the presence of methyl branched fatty acids from laboratory mouse preputial glands (Sansone and Hamilton, 1967; Snyder and Blank, 1969) has been suggested. The struc-

ture of the 15-methylhexadecanoic acid reported here has been characterized by GC, GC-MS, and NMR.

Diversity and complexity of scent gland compounds is common in mammalian chemical communication systems (Stoddart et al., 1975; Stoddart, 1974; Epple et al., 1979; see Beauchamp et al., 1976, for a review). If the species-typical esters of *M. montanus* preputial glands are pheromones, they certainly fit that pattern of complex odor formulations. The occurrence of at least 12 compounds that differ by the position or presence of only one carbon is an indication of the complexity of the *M. montanus* species-typical lipids. Finding two compounds under peak 12 demonstrates the similarity of certain compounds. It is apparent that given a few predominant alcohols and fatty acids, the vole preputial glands produce esters in a manner that gives considerable end-product diversity.

The uniqueness and physical properties of the *M. montanus* preputial gland esters suggest they may serve as volatile chemical signals. The molecular weights of the species-typical esters from *M. montanus* range from 322 to 340; all compounds have total carbon numbers of either 21 or 22. Esters of butyric acid ranging from 21 to 28 total carbons (molecular weight range = 310–410) have been described as chemical signals that convey species and subspecies information (Epple et al., 1979). Another study has demonstrated rodent olfactory responses to esters containing 22 carbon atoms (Stacewicz-Sapuntzakis and Gawienowski, 1977). With respect to general compound class, total carbon numbers, and molecular weights, the novel esters from the *M. montanus* preputial glands are similar to previously described odorous compounds that demonstrate attractive properties.

It has been theorized (Wilson and Bossert, 1963) that through evolution, the chemical properties of a pheromone are manipulated to maximize effectiveness for a given function. A hypothetical pheromone should be composed of the most efficient formulation of "persistent" vs. "diffusion" qualities: the relative proportion of those qualities will depend on the pheromone function. It follows that chemosignals mediating short-lived phenomena, for instance alarm signals, should possess a readily diffusible, highly volatile, nature. On the other hand, in order to maximize the communicative efficiency of the sender, home-range marking signals should be more persistent. This persistence allows an animal to advertise a signal over a long distance for a long period of time and requires only minimal redeposition to ensure constant signal emission.

The persistence design feature of pheromones is not without limitations; volatility is correlated with molecular weight in a given homologous series. As molecular weight (and persistence) increases, eventually vapor-phase existence of a molecule becomes almost impossible. The upper practical volatility limit then is an important design factor for pheromones. Wilson and Bossert (1963) suggested that, due to physiochemical characteristics restricting volatility of

large compounds, the upper-limit molecular weights of volatile pheromones would fall in the range of 300–400. The compounds that facilitate species and subspecies recognition in tamarins (Epple et al., 1979) span a molecular weight range of 310–410. The *M. montanus* species-typical preputial gland esters have molecular weights ranging from 322 to 340. The tamarin species recognition cues as well as the identified *M. montanus* preputial gland esters possess molecular weights in the range of what might be predicted for species-recognition pheromones.

This investigation represents the initial work aimed at identifying a rodent species recognition pheromone. Novel, species-typical esters from the preputial glands of adult male *M. montanus* have been identified, and those esters possess molecular characteristics similar to the esters that can function as species-recognition cues (Epple et al., 1979). Although we do not know the function of the species-typical esters, there are no data which argue against those novel esters serving as species-recognition pheromones. We are currently using the compounds isolated for this investigation in bioassays designed to assess the attractive properties of the species-typical esters.

Acknowledgments—This research was supported in part by a grant from Sigma Xi, The Scientific Research Society (C.J.W.) and by a Research-Creativity grant from Montana State University (R.E.M.). We thank J. Sears, who took the mass spectra, and T. Schram, who furnished the NMR spectra. Dr. C. Rowsemitt provided animals used for a portion of the study, and her generosity is gratefully acknowledged. Statistical analyses were accomplished using the MSU-STAT computer program developed by Dr. R.E. Lund at Montana State University (copyright 1983).

(Received September 30, 1986; accepted January 15, 1987)

Abstract—Electroantennograms (EAGs) were recorded from unmated, laboratory-reared, male and female *Ceratitis capitata* (medfly) in response to a range of C_1 and C_2 to C_{12} carbon chain-length aliphatic alcohols, aldehydes, acetates, and acids, and lactones, some of which are known volatiles from leaves and fruits. A large degree of EAG response uniformity between the sexes was observed, with only eight of the 70 compounds tested eliciting significantly larger amplitude EAG responses from female than male antennae. In general, for the five functional-group series tested, aldehydes and alcohols elicited greater responses than acetates, lactones, and acids. The unsaturated alcohols, aldehydes, acetates, and acids elicited equal or larger amplitude EAG responses than their comparable saturated compounds. For four of the functional-group series tested, the EAG response amplitude was significantly greater for a particular carbon chain length, with responsiveness to primary alcohols and aldehydes peaking at C_6, acids peaking at C_{5-6}, and acetates peaking at both C_5 and C_8. The EAG responses to both the 2- and 3-position monoenic alcohols peaked at C_6 and C_8, while the secondary alcohols peaked at C_7. The greatest EAG responses of all compounds tested were elicited by monoenic C_6 alcohols and aldehydes that are constituents of the "general green-leaf odor" that emanates from most plants. The potential adaptive benefit of selective sensitivity to green-leaf volatiles is discussed in regard to foraging behavior of medflies.

INTRODUCTION

The Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann) (medfly), is a polyphagous pest worldwide, attacking over 250 varieties of fruits, nuts, and vegetables (Hagen et al., 1981). It is widely assumed that medflies and other tephritid fruit flies use olfactory cues, in addition to visual cues (Cytrynowicz et al., 1984; Nakagawa et al., 1978; Prokopy and Roitberg, 1984; Prokopy and Economopoulos, 1976), to seek and assess habitat, food, and ovipositional resources (Prokopy and Roitberg, 1984). Such a phenomenon has been observed in studies of the behavior of the apple maggot, *Rhagoletis pomonella* (Walsh), in response to fruit model traps emanating apple volatiles (Prokopy et al., 1973; Reissig et al., 1982). However, there is little behavioral evidence (Bateman, 1972; Féron, 1962; Keiser et al., 1975) to substantiate this assumption of olfactory orientation to plant volatiles by *C. capitata*.

The olfactory fragrance of a plant and, in particular, a ripening fruit, is a complex blend of usually over a hundred(s) detectable volatile compounds, possessing various functional groups and ranging in structure from simple, short, straight carbon chains to complex multiring sesquiterpenes (e.g., Buttery, 1981; Van Straten and Maarse, 1983) (Table 1). Although the host-plant range of medflies is extremely broad and diverse, most of the host-plant and fruit odors will share some constituents from various classes of volatiles, e.g., aliphatic alcohols, aldehydes, acetates and acids, and monoterpenes, sesquiterpenes, and lactones (Buttery, 1981; Van Straten and Maarse, 1983; Visser et al., 1979) (Table 1).

Little is known about the neurophysiological reception of plant volatiles by Diptera in general, let alone *C. capitata* and other tephritid species. To date, only four electrophysiological studies have been reported on tephritid fruit flies. Recently, Van Der Pers et al. (1984) utilized the electroantennogram (EAG) technique to study the responsiveness and sensitivity of male and female *Dacus oleae* (Gmelin) (olive fruit fly) to six components of its putative pheromones and five chemical analogs, some of which are commonly occurring plant volatiles. An EAG study on tephritids that tested "generally occurring fruit volatiles" was briefly reported by Guerin et al. (1983a). They recorded EAGs from female antennae of three species, *D. oleae, Rhagoletis cerasi* (L.) (cherry fruit fly), and *C. capitata*. Although 30 volatiles were tested (series of aliphatic C_5 to C_{12} terminal position alcohols, aldehydes, and esters), only heptanal, octanal, nonanal, and (*E*)-2-nonenal were reported to elicit the highest amplitude

EAGs. In addition, Fein et al. (1982) recorded the EAGs of *R. pomenella* to a group of seven esters they identified from apple odor.

The purpose of this initial study was to investigate, by means of EAGs, peripheral olfactory selectivity of adult *C. capitata* to commonly occurring classes of host-plant and fruit volatiles, including the ubiquitous "general green-leaf volatiles" (Visser et al., 1979). The volatiles tested ranged from C_1 or C_2 to C_{12} saturated and unsaturated aliphatic alcohols, aldehydes, acids, acetates, and a series of lactones (Table 1). This research was further intended to provide a basis for studies of single-cell responses by surveying and assessing the degree that the antennal olfactory system of medflies is receptive to classes and/or particular plant/fruit volatiles.

METHODS AND MATERIALS

Insects. Pupae of *C. capitata* were obtained from a laboratory colony, periodically infused with feral flies, maintained at the USDA, Tropical Fruit and Vegetable Research Laboratory, Honolulu, Hawaii. Upon their arrival, pupae were segregated by sex and placed in separate cages. After eclosion, adult flies were provided sucrose cubes, hydrolyzed protein, and water until they were tested two to five days after emergence.

Olfactory Stimuli. Table 1 lists the compounds tested, their supply sources, and purities. The compounds were dissolved in spectrometric grade hexane (that was additionally distilled and treated with an antioxidant) at a rate of one part test compound and nine parts hexane solvent, forming 10% volume per volume solutions. From these solutions, test cartridges were produced for each compound by pipetting 1-μl aliquots onto separate 1 × 2-cm pieces of fluted, glass-fiber filter paper, which were then inserted into individual Pasteur pipets. Before or during each experiment, new cartridges were loaded with compound, individually sealed in zip-lock plastic bags, placed in a freezer (−4°C), and then transferred to a fume hood just prior to testing.

Electrophysiological Recording Technique. Electroantennogram (EAG) techniques used here are a modification of previous techniques utilizing glass capillary Ag–AgCl electrodes filled with insect saline (Schneider, 1957a; Light, 1983). Intact flies were immobilized by a yoke in a Plexiglas block. The recording electrode was inserted into the distal region of the terminal antennal segment or funiculus, while the indifferent electrode was positioned into the hemocoel of the cranial cavity. The signal was amplified 100× by a Grass P-16 microelectrode amplifier (Quincy, Massachusetts) and viewed on either an analog (Tektronix 5113, Beaverton, Oregon) or digital (Nicolet 4094, Madison, Wisconsin) storage oscilloscope. EAG deflections were measured directly from the stored screen image or from either photographs (Tektronix C5-A camera, Polaroid-type 667 film) or digital graphs from an *x–y* plotter (Hewlett Packard 7475A, Sunnyvale, California).

Odor Delivery. The odor delivery system and stimulation technique were essentially the same as that described by Light (1983). A constant flow (1.0 liter/min) of charcoal-filtered and humidified compressed air was passed-over the antenna through a disposable nozzle (automatic pipet tip, Centaur Chemical, Stamford, Connecticut) positioned ca. 1 cm from the antenna. When activated by a timing circuit, a three-way solenoid valve diverted the purified air through the stimulus cartridge where evaporating volatiles were picked up and carried into the nozzle and then onto the antenna. Stimulation duration was 1.0 sec. Because of the variation in volatility of test compounds, only relative comparisons can be made between the odorous stimuli.

Experimental Procedure. For each stimulus, EAGs were recorded from at least five flies of each sex. "Control" stimulations (using filter papers either untreated or impregnated with 1 μl of the hexane solvent) and "standard" stimulations (using fresh cartridges impregnated with 1 μl of 1% hexan-1-ol) were interspersed at approximately every fifth to tenth stimulation.

EAGs to test compounds were evaluated by measuring the maximum amplitude of negative deflection ($-$mV) elicited by a given stimulus and then subtracting the amplitude of the response to the preceding control. The millivolt responses to all compounds were converted to percentage values of the response to the accompanying 1% hexan-1-ol standard, as used in other EAG studies on insect olfaction (Dickens, 1984; Dickens and Boldt, 1985; Light, unpublished). This conversion or normalization of each response to a percentage of standard response allowed for comparison of responses within an individual and among individuals (Payne, 1975). Furthermore, this procedure minimizes and the observed variability in (1) absolute responsiveness among preparations, (2) order of presentation of compounds, and (3) the time-dependent variability in antennal responsiveness (Light, 1983; Dickens, 1984). Mean responses were compared using a t test and the nonparametric Mann-Whitney test (Snedecor and Cochran, 1967). Each stimulation was followed by an interval of ca. 90 sec of clean air. This interval was adequate for recovery of the EAG amplitude, as demonstrated by the measured percent recoveries of both sexes to shorter, 60-sec intervals between two separate 10% stimulations of hexan-1-ol (100.6% $\pm$ 1.8% for males and 99.3% $\pm$ 2.1% for females).

RESULTS

Selectivity

In general, the following EAG results suggest significant differences in the size of acceptor populations for the various odorants and/or odorant classes examined. Although slight differences between males and females in the magnitude of their EAG responses to each test odorant was found, in only a few cases were the differences significant.

The mean responses of *C. capitata* antennae to the hexan-1-ol standard (1 μl of 1% v/v hexane) were not significantly different between males and females, with mean EAGs of -1.09 mV (SE = 0.08 mV) and -1.14 mV (SE = 0.11 mV) for 15 males and 13 females, respectively.

Aliphatic Alcohols. For the series of saturated primary alcohols tested, responses of both male and female medflies peaked at hexan-1-ol and declined as carbon chain lengths either increased and decreased from six (Figure 1). Only for undecan-1-ol were EAG magnitudes found to be significantly different between the sexes, with female antennae more responsive than male antennae ($P < 0.05$).

In general, for both of the limited series of *E* geometric configurations of the 2- and 3-unsaturated primary alcohols tested, antennal responsiveness of both sexes increased as chain length increased from three to eight carbons (Figure 2). The only exception found was of female antennae being slightly, but not significantly, more responsive to (*E*)-2-hexen-1-ol than to (*E*)-2-octen-1-ol. (*E*)-2-Buten-1-ol elicited significantly greater ($P < 0.05$) EAGs from females than males.

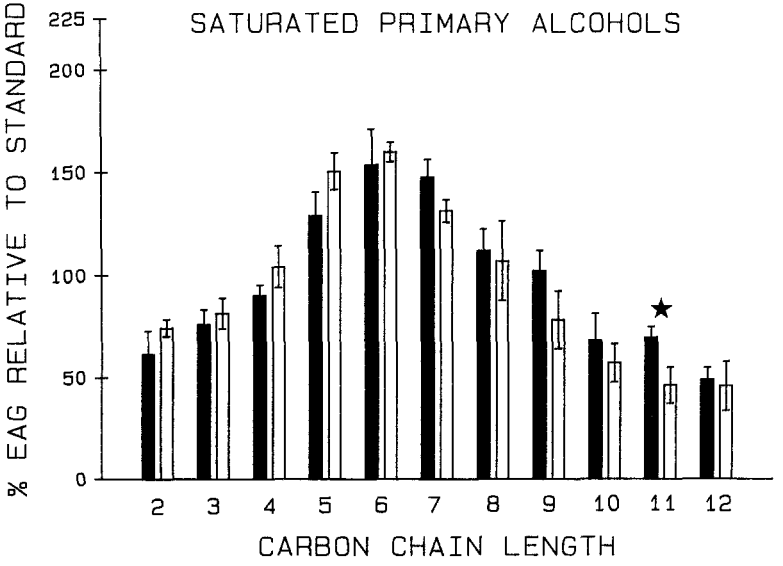

FIG. 1. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of saturated primary alcohols of various carbon chain lengths. Vertical lines represent standard errors, $N = 5$, a 100% response is approx. -1.1 mV, and stars represent significant differences in responsiveness between the sexes.

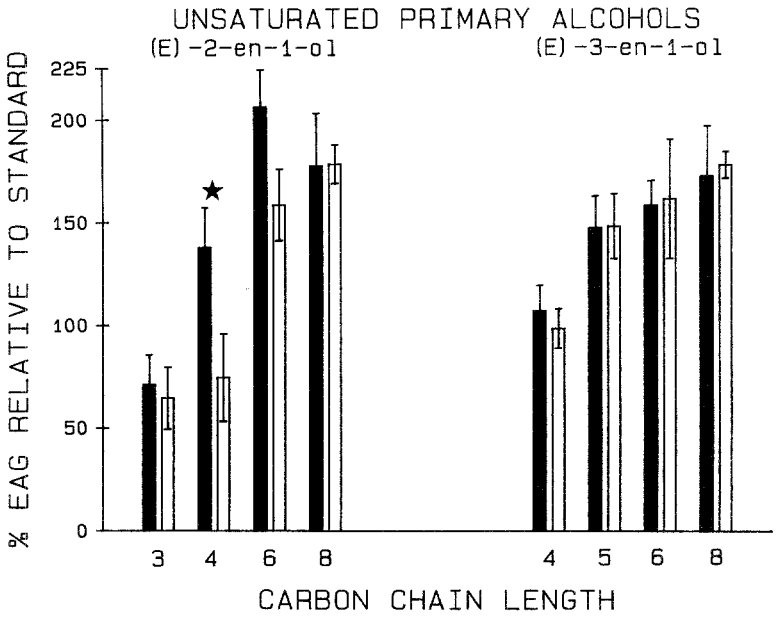

FIG. 2. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of unsaturated (*E*)-2- and (*E*)-3- primary alcohols of various carbon chain lengths. See Figure 1 legend for further information.

In two tests where *E* and *Z* geometric isomers of both hex-2-en-1-ol and hex-3-en-1-ol were compared, no significant differences were found between either of the hexenol isomers (Figure 3). Furthermore, there were no significant differences for either sex between the commonly tested 2- and 3-position unsaturated alcohols (i.e., the butenols and octenols, Figure 2) except for the hexenols (Figure 3). For males and females, both the (*Z*)- and (*E*)-hex-2-en-1-ol isomers elicited significantly ($P < 0.05$) greater EAGs than their hex-3-en-1-ol isomeric counterparts.

For the limited series of racemic saturated secondary alcohols tested, both male and female antennae were significantly less stimulated as chain length increased from seven to 11 carbons (Figure 4). EAGs of females to the secondary alcohols were slightly greater than males and were significantly greater ($P < 0.05$) for (±)-heptan-2-ol. The responses to the only 3-position and unsaturated secondary alcohol tested, (±)-1-octen-3-ol, were intermediate to the responses elicited by (±)-heptan-2-ol and (±)-nonan-2-ol. As with (±)-hepan-2-ol, female antennae were more responsive than male antennae to (±)-1-octen-3-ol.

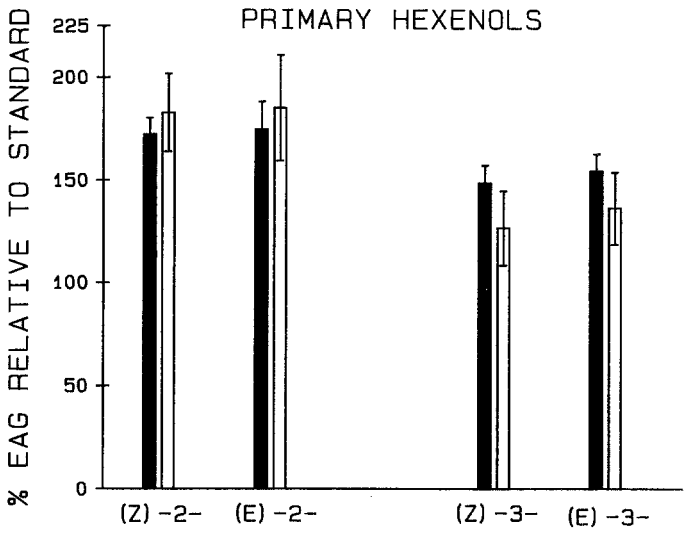

FIG. 3. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of primary hexenols. See Figure 1 legend for further information.

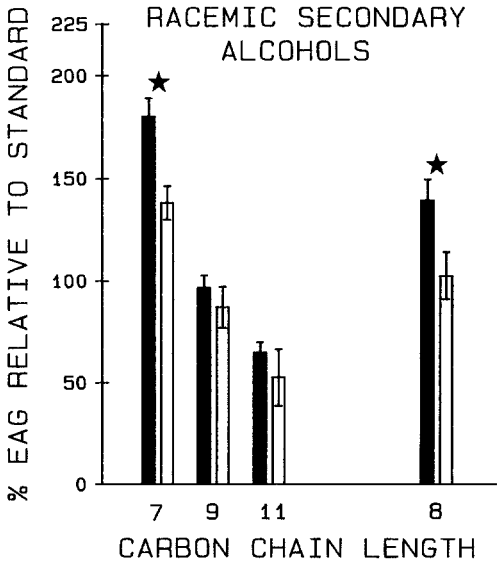

FIG. 4. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of racemic secondary alcohols of various carbon chain lengths, either saturated [(±)-heptan-2-ol, (±)-nonan-2-ol, and (±)-undecan-2-ol] or unsaturated [(±)-1-octen-3-ol]. See Figure 1 legend for further information.

Aliphatic Aldehydes. Both male and female antennae were significantly more responsive to the six- to 10-carbon chain saturated aldehydes than to either the lower or higher chain-length aldehydes (with the exception of dodecanal for females) (Figure 5). There was generally a stepwise progressive decrease in antennal responsiveness to aldehydes as chain length increased from hexanal to undecanal, but there was a significant upturn in responsiveness from undecanal to dodecanal. Among the saturated aldehydes tested, only hexanal elicited significantly different responses ($P < 0.05$) between the sexes, with female antennae more responsive than male antennae. Both of the unsaturated aldehydes tested, (*E*)-2-butenal and (*E*)-2-hexanal, elicited significantly greater ($P < 0.01$) EAGs than their saturated aldehyde counterparts (Figure 5).

Aliphatic Acids. The response magnitude rose significantly for both pentanoic and hexanoic acids over the lower, relatively level responses to both increasing and decreasing chain lengths of the other saturated acids (Figure 6). The inclusion of a double bond slightly, but not significantly, increased EAG responsiveness to both 2-propenoic and (*E*)-2-hexenoic acids over their respective saturated acids (Table 2 and Figure 6).

Aliphatic Acetates. The series of saturated acetates elicited EAGs that

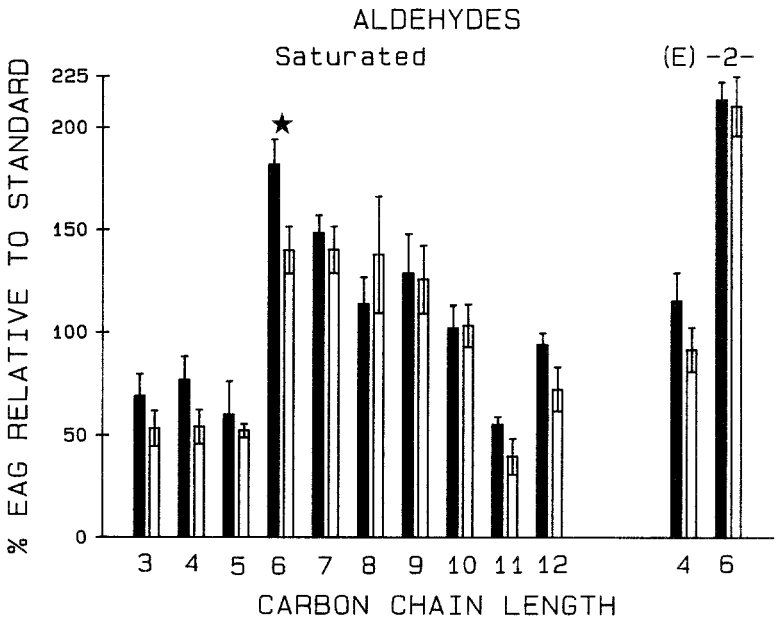

FIG. 5. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of saturated and (*E*)-2-unsaturated aldehydes of various carbon chain lengths. See Figure 1 for further information.

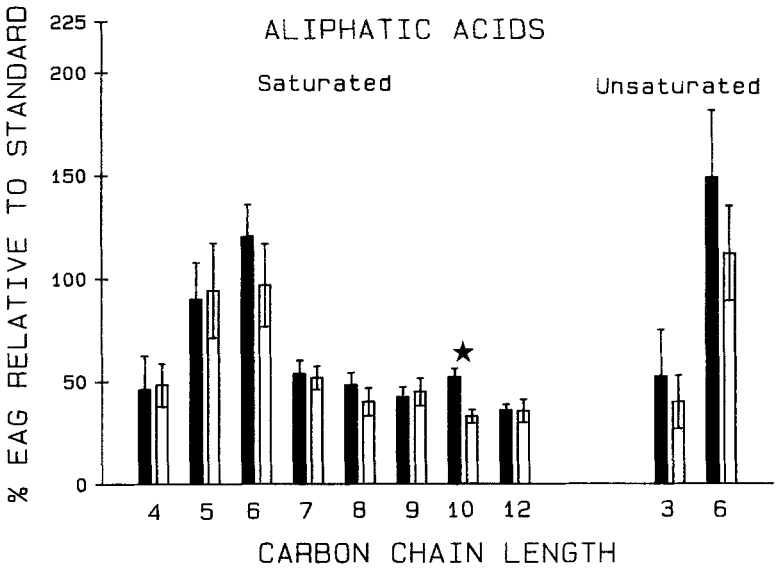

FIG. 6. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of aliphatic acids of various carbon chain lengths and 2-propenoic and (*E*)-2-hexenoic acids. See Figure 1 for further information.

TABLE 2. OCCURRENCE AND MILLIVOLT MAGNITUDE OF NEGATIVE/POSITIVE POLARITY EAGS OBSERVED IN *Ceratitis capitata*

Compound	Sex	Number of positive/negative polarity responses out of five replications[a]			Magnitude of polarity phases[b]	
		ER	−/+	+	Negative ($X \pm$ SE)	Positive ($X \pm$ SE)
Acetic acid	M	0	5	0	−0.46 ± 0.09	+0.93 ± 0.14
	F	1	2	0	−0.19 ± 0.09	+1.48 ± 0.30
Propanoic acid	M	0	3	2	−0.29 ± 0.14	+1.31 ± 0.28
	F	0	2	2	−0.12 ± 0.16	+1.74 ± 0.25
Butanoic acid	M	1	4	0	−0.61 ± 0.08	+1.46 ± 0.25
	F	0	4	0	−0.39 ± 0.28	+1.31 ± 0.27
2-Propenoic acid	M	0	4	0	−0.63 ± 0.28	+1.58 ± 0.17
	F	0	4	0	−0.50 + 0.17	+1.55 ± 0.23
Pentanoic acid	M	2	0	0

Hexanoic acid	M	2	0	0		
	F	0	0	0		

[a] ER, early recovery; −/+, negative/positive polarity response patterns; +, positive polarity response patterns; see text for definitions.
[b] Mean millivolt responses for −/+ and + data, exclusive of ER data.

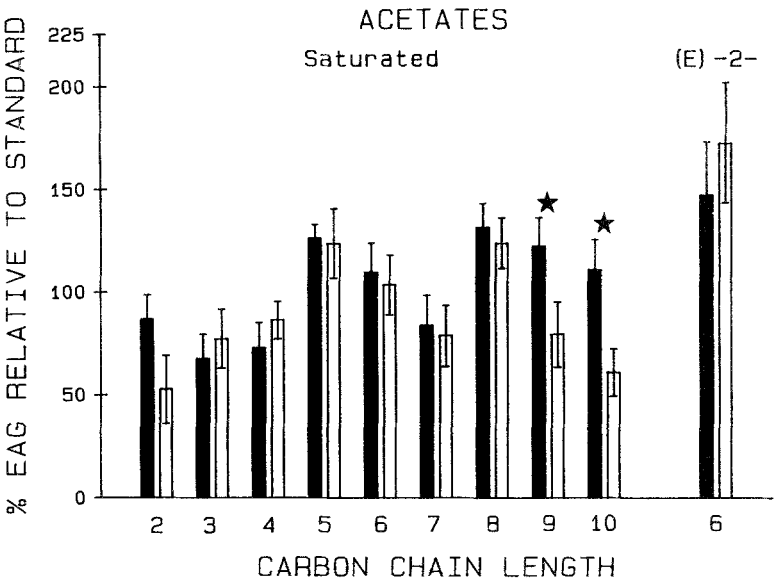

FIG. 7. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of saturated acetates of various carbon chain lengths and the unsaturated (*E*)-2-hexyl acetate. See Figure 1 for further information.

peaked at both C_5 and C_8 (Figure 7). Female antennae were significantly more responsive ($P < 0.05$) than male antennae to both nonyl- and decyl-acetates.

Lactones. The EAGs to a series of lactones did not significantly vary as either (1) side-chain length of the gamma-lactones increased from zero (gamma-butyrolactone) to seven carbons (gamma-undecalactone) except for the greater female responsiveness to gamma-nonalactone (i.e., five-carbon side-chain) or (2) as the lactone ring increased from four (gamma) to five (delta) carbons (Figure 8). Except for gamma-nonalactone, for each lactone tested, male EAGs were slightly, but not significantly, greater than female EAGs.

EAG Response Polarity

The EAGs recorded to the majority of the volatiles tested had purely negative voltage polarities and time-course shapes. Upon odor stimulation, the majority of the recordings typically consisted of a rapid negative voltage deflection that was more or less maintained throughout the odor stimulation duration followed, upon termination of the odor stimulation, by a slower, more gradual (positive polarity) approach or recovery to (but not exceeding) the prestimulation background potential (Figure 9A). However, to specific short chain-length acids alone, a range in degree of biphasic, "negative, then positive polarity" EAGS during odor stimulation was observed (Figure 9B–D). These biphasic

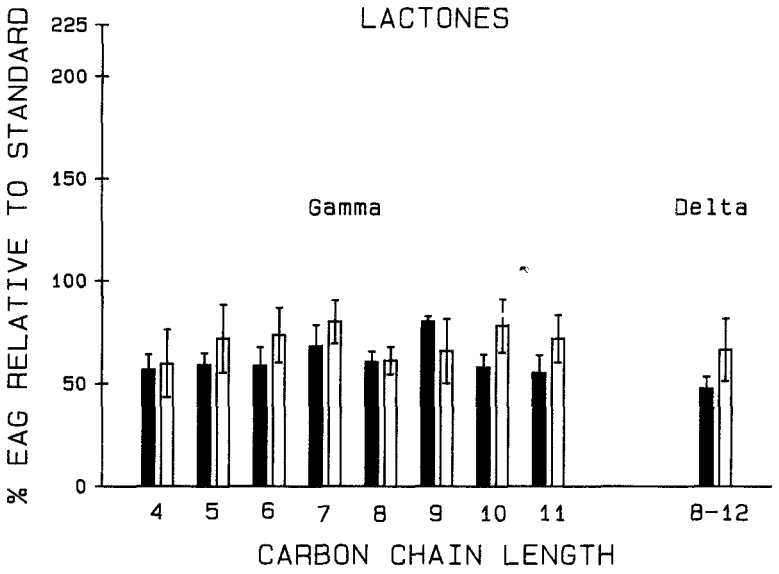

FIG. 8. Mean EAG responses of female (filled bars) and male (blank bars) *C. capitata* to 1-μl doses of 10% solutions (v/v) of gamma-lactones of various carbon chain lengths and a mixture of C_8–C_{12} delta-lactones. See Figure 1 for further information.

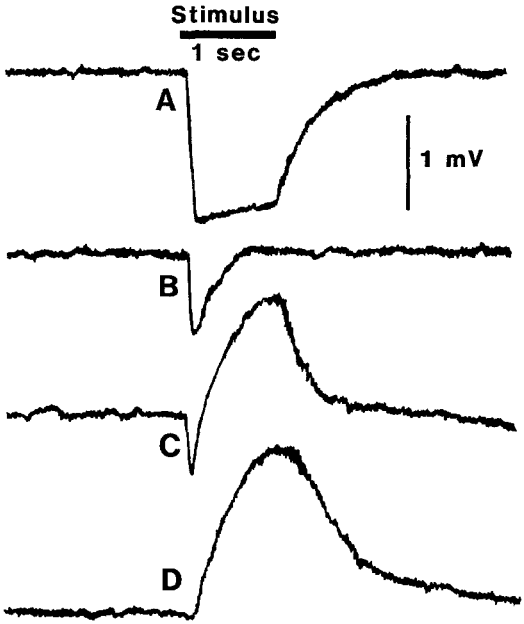

FIG. 9. Reproduction of the four types of EAG polarity and time-course shapes recorded from a single male medfly: (A) typical "negative-polarity" EAG, in this case to hexan-1-ol, (B) "early recovery" EAG to pentanoic acid; (C) biphasic "negative-positive" EAG to butanoic acid; and (D) "positive polarity" EAG to propanoic acid.

EAGs ranged from: (1) "early recovery"; (2) "negative positive" polarity; to (3) an apparently "positive polarity." The "early recovery" was typified by an initial, negative, stimulus-onset response that became spikelike in shape, its recovery to baseline starting immediately during the odor stimulation period and not after its cessation (e.g., 40% of the male's responses to pentanoic and hexanoic acids, Table 2). The "negative/positive" EAG was characterized by the initial negative deflection being reversed by a two to seven times greater positive deflection that greatly overshot the prestimulus baseline during the remainder of the stimulus duration, then, after stimulus termination, the response potential returned to the baseline level [e.g., stimulations by acetic, propanoic, 2-propenoic, and butanoic acids; Table 2]. In the apparently "positive polarity," the response potential never dipped, but rose slowly during stimulation and then dropped to baseline potential after stimulation cessation (e.g., responses of certain individuals to propanoic acid, Table 2).

DISCUSSION

The EAG response is thought to be the expression of generator potentials of many simultaneously stimulated receptor cells with potentially different acceptor specificities (Boeckh et al., 1965; Kaissling, 1971; Schneider, 1969). Further, the negative amplitude of the EAG deflection as been interpreted to be a measure of the relative number of acceptors responding to an odor stimulus (Payne, 1975; Dickens and Payne, 1977). Thus, the EAG results presented here, in general, suggest significant differences in size of acceptor populations for the various odorants and/or odorant classes examined.

Polarity of EAG Responses

Positive polarity and biphasic EAG potentials have been observed before (e.g., Schneider, 1957a, b). Positive polarity EAG responses were elicited by a puff of air during deep ether narcosis in male *Bombyx mori* (L.), while cycloheptanone elicited biphasic "early recovery" waveforms, and air puffs during the beginning phase of ether or chloroform narcosis evoked biphasic negative/positive potentials (Schneider 1957a, b). At the receptor level, Schneider (1969) and others (Boeckh et al., 1965; Kaissling, 1971) have correlated extracellularly recorded, negative-polarity generator potentials (termed depolarizations) with "excitation" (i.e., increased action potential frequency) in receptor neurons, and positive-polarity receptor potentials (termed hyperpolarizations) with "inhibition" (i.e., decreased action potential frequency) in receptor neurons. Boeckh (1962, 1967) and Kaissling (1971) observed positive extracellular DC potentials that they termed "inhibitory potentials" when sensilla basiconica of both the blowfly, *Calliphora erythrocephala*, and the carrion beetles, *Thanatophilus rugosus* and *Necrophorus humator*, were stimulated with propanoic,

butanoic, or pentanoic acids. We found that these same short-chain acids also elicited positive and biphasic EAGs in medfly antennae. However, whether the polarity of EAGs is an accurate representation of receptor potential depolarizations, hyperpolarizations, or the subtractive interaction of the two polarizations must be questioned because of the extreme attenuation inherent in EAG recordings. Further, Kafka (personal communication) and others have suggested that biphasic and positive-polarity EAGs might be recording artifacts attributable to electrode potentials.

Effects on EAG Responsiveness

Sexuality. Although slight differences between males and females in the magnitude of their EAGs to each test odorant were found, in only a few cases were the differences significant. Among the 70 compounds tested, only eight compounds, undecan-1-ol, (*E*)-2-buten-1-ol, (±)-heptan-2-ol, (±)-1-octen-3-ol, hexanal, nonyl acetate, decyl acetate, and decanoic acid, elicited significantly larger EAGs in female antennae than in male antennae. On the other hand, the general similarity in antennal responses between the sexes suggests a common ecological need for host-plant and/or habitat recognition by both sexes. Once alighting on the plant, the sexes might utilize the resource in a similar manner: for example, attaining food (plant sap, nectar, honeydew, protein, etc.); or in a dissimilar manner: for instance, for males as a lekking and courtship site or for females as an ovipositional site.

No sexual dimorphism in EAGs to plant volatiles has been reported for other tephritid fruit flies, e.g., the apple maggot (Fein et al., 1982) and the olive fruit fly (Van Der Pers et al., 1984), or for many other insect species, e.g., *Leptinotarsa decemlineata* (Visser, 1979), *Yponomeuta* species and *Adoxophyes orana* (Van Der Pers, 1981), *Rhynchaenus quercus* (Kozlowski and Visser, 1981), and *Oulema melanopus* and *Pseudaletia unipuncta* (Wellso et al., 1984).

Carbon Chain Length. For four of the five functional-group series tested, both definitive EAG amplitude maxima and antennal responsiveness profiles were affected by variation in carbon-chain length. Overall, it appears that medfly antennae were selectively more responsive to six-carbon and, to a lesser extent, five-, seven-, and eight-carbon, chain lengths for these functional-groups, which are ubiquitous in fruit and leaf volatiles.

The present EAG study is the first to have systematically assessed carbon-chain series on each of these fundamental functional-group classes, while for the most part limited series of only aldehydes and primary alcohols have been tested on other species. Similar to the medfly, the Colorado potato beetle (Visser, 1979) and the oak flea weevil (Kozlowski and Visser, 1981) were found to have peak EAG responses to both C_6 aldehydes and alcohols. Antennal respon-

siveness of the cotton boll weevil, *Anthonomus grandis* (Dickens, 1984), and the cereal aphid, *Sitobion avenae* (Yan and Visser, 1982), peaked at C_6 for the primary alcohol series. However, for aldehydes, the majority of the EAG plant-volatile studies have found that responsiveness peaks at heptanal, with a ranking for most species of C_7, C_8, C_9, and then C_6 [for Diptera: *C. capitata*, *D. oleae*, and *R. cerasi* (Guerin et al., 1983a); *P. rosae* (Guerin and Städler, 1982; Guerin et al., 1983b); and *Delia antiqua* (Guerin and Städler, 1982); for Lepidoptera: *Yponomeuta* spp. (Van Der Pers, 1981) and for Coleoptera: *A. grandis* (Dickens, 1984); and *Trirhabda bacharides* (Dickens and Boldt, 1985)].

Unsaturation. For the limited number of monoenic alcohols, aldehydes, acids, and acetates tested, the unsaturated monoenes elicited equal or larger EAGs than their comparable saturated compounds. Significantly greater responses for both medfly sexes were observed for both (*E*)-2- and (*E*)-3-octen-1-ol over octan-1-ol, (*E*)-2-hexenal and (*E*)-2-butenal over their saturated analogs, and (*E*)-2-hexenyl acetate over hexyl acetate. In addition, female antennae responded significantly greater to (*E*)-2-buten-1-ol than butan-1-ol. In all but one study on EAG response selectivity, the EAG responses to monoenic alcohols, aldehydes, and acetates exceeded those to saturated analogs (see Visser, 1983, 1986). The exception is a study of *D. antigua*, where hexan-1-ol elicited a greater response than the unsaturated isomeric analogs tested (Guerin and Städler, 1982).

Functional Groups. Under our experimental conditions, the greatest antennal responses generally were elicited by aldehyde and alcohol moieties, followed by acetate, lactone, and acid functional groups, as has been found in most species (see above references and Visser 1983, 1986). Furthermore, the monoenic aldehyde, (*E*)-2-hexenal, elicited greater EAGs in medflies than the 2- and 3-position (*E*)- and (*Z*)-hexen-1-ols and other monoenic alcohols, which in turn exceeded the saturated aldehydes and alcohols. The saturated secondary alcohols elicited responses slightly greater than or equal to the saturated primary alcohols.

Thus, carbon-chain length, unsaturation, and type and position of functional groups all have significant effects on the magnitude of the EAG response (i.e., the relative numbers of acceptors responding throughout the antennal olfactory organ) of medflies to odor molecules. The specificities and affinities of the presumed acceptor classes that are present on the medfly antennae are still unknown. However, our preliminary single-cell recordings from various trichoid and basiconic antennal hairs and pegs indicate that receptors are present that are narrowly and specifically tuned to chain length, functional group(s), and chirality of the odor molecules (Dickens et al., unpublished). Of the ca. 30 recordings to date, we have not discovered any receptors with broad responsiveness to various chain lengths of a functional group. However, receptors have been found that are selectively "tuned" to virtually a "single" chain

length for a particular functional group, while responding differentially over a broader range of chain lengths to another functional group. These observations will be explored through further selectivity, sensitivity, and differential adaptability experiments on single receptors.

Green-Leaf Volatiles. The top 16 compounds eliciting the greatest antennal responses of male and female medflies can be ranked as follows: (*E*)-2-hexenal ≥ (*E*)-2-hexen-1-ol ≥ (*Z*)-2-hexen-1-ol ≥ (*E*)-2-octen-1-ol ≥ (*E*)-3-octen-1-ol ≥ (*E*)-2-hexenyl acetate ≥ hexanal > heptan-2-ol ≥ (*E*)-3-hexen-1-ol ≈ (*Z*)-3-hexen-1-ol ≈ hexan-1-ol ≈ heptanal ≈ heptan-1-ol ≈ (*E*)-3-penten-1-ol ≈ (*E*)-2-hexenoic acid ≈ octanal. This ranking is dominated (five of the top 11 compounds) by what have been termed "green odors" or "general green-leaf volatiles" because of the ubiquitous production of these compounds by either intact or, more often, damaged plant leaf parenchyma (see Visser et al., 1979; Buttery, 1981). Produced through the oxidative fragmentation of the plant fatty acids, linoleic and linolenic acids, the following green-leaf volatiles are commonly identified in various ratios, depending on the plant species: hexanal, hexan-1-ol, (*Z*)-3-hexenal, (*Z*)-3-hexen-1-ol, (*E*)-2-hexenal, and (*E*)-2-hexen-1-ol.

Along with plant species-specific blends of important discriminatory "key compounds" (often terpenes and their analogs), the green-leaf volatiles dominate the selective EAG responsiveness of insect antennae over aldehydes and alcohols with shorter or longer carbon chain lengths [e.g., carrot fly (Guerin and Visser, 1980); onion and cabbage root flies (Guerin and Städler, 1982); the syrphid fly, *Metasyrphus venablesi* (Hood Henderson and Wellington, 1982); Colorado potato beetle (Visser, 1979); oak flea weevil (Kozlowski and Visser, 1981); cotton boll weevil (Dickens, 1984); the chrysomelid, *T. bacharides* (Dickens and Boldt, 1985); and *Yponomeuta* spp. and *A. orana* (Van Der Pers 1981)]. Thus, as with most species studied electrophysiologically (Visser, 1983, 1986), medflies have antennae "selectively tuned" for reception of green-leaf volatiles. This suggests that medfly antennae have greater populations of acceptors for these six-carbon volatiles. The general receptivity for leaf volatiles by phytophagous insects appears to be comparable, apparently, regardless of the ecological host range of the herbivorous insect, ranging from the near monophagy by *T. bacharides* (a biological control candidate for the weed, *Baccharis halimifolia* L.), to polyphagy by medflies.

Most detailed EAG studies to date have utilized oligophagous insects. In the few studies where kairomonal attractants have been identified or suggested, these are "key compounds" that are relatively unique to the host species or host genus. Such compounds often elicit large EAG responses that significantly exceed the responses to green-leaf volatiles. A well-studied example is the carrot fly where (*E*)-asarone and (*E*)-methylisoeugenol elicit large EAG responses and are attractive in the field (Guerin et al., 1983b). Further, Guerin et al.

(1983b) found that the attraction of *P. rosae* to (*E*)-asarone was synergized by (*E*)-2-hexenal. But in only a few cases have general green leaf volatiles been attractive along (see Visser, 1986; Visser and Ave, 1978). Whether single consitituents of the general green-leaf odor or other fruit odors attract medflies is uncertain. In field tests in Sardinia, Guerin et al. (1983a) found that heptanal attracted predominantly female medflies to sticky traps. However, in field tests in Hawaii, we found no attraction to a total of 21 individual saturated and unsaturated primary alcohols, aldehydes, and acetates (Cunningham et al., unpublished). Thus, questions remain about the effectiveness of the individual components of the green-leaf odor as well as the entire and properly proportioned blend emitted by the plant.

Because of the widespread occurrence of general green-leaf volatiles throughout plants, it is unlikely that their qualitative presence alone could serve to discriminate between host and nonhost plants. On the other hand, the relatively high selectivity and responsiveness of *C. capitata* antennae, and other insect antennae, to the general green-leaf volatiles suggests a large sensory investment in the reception of these compounds that may be adaptive. The reception of green-leaf volatiles may be fundamental to such short- and/or long-range appetitive behaviors that occur on foliage, such as foraging for water, food, and shelter, and the establishment and subsequent attractiveness of lek sites. Because these foraging and lekking behaviors of medflies are readily observed on both host and nonhost plants (Christenson and Foote, 1960; Prokopy and Roitberg, 1984; Prokopy et al., 1986), it is possible that the more universal plant olfactory cues, i.e., the general green-leaf volatiles, might influence these discriminative searching behaviors. The perception of the complex or specific host-plant odors may result in the initiation and maintenance of various searching or foraging behaviors that are mechanistically based on visual optomotor anemotactic and/or phototelotactic orientation (Light, 1986). Such has been hypothesized for the cherry fruit fly (Levinson and Haisch, 1984), the apple maggot (Prokopy, 1986), and the medfly (Féron, 1962; Nakagawa et al., 1978).

A number of additional experiments must be undertaken before determining the applicability of the EAG technique to screen a series of plant volatiles for their potential semiochemical activity with medflies. These additional experiments are presently under investigation (Jang et al., unpublished) and include laboratory and field bioassays, along with comparative EAG studies utilizing known potent male lures (i.e., trimedlure and α-copaene), putative male pheromones (Baker et al., 1985), and the range of volatiles present in specific host fruits.

Acknowledgments—The authors gratefully acknowledge the technical assistance of Janice Nagata, USDA-ARS, Hilo, Hawaii, in helping with the EAG recordings. The authors are appreciative of the helpful comments and suggestions of Drs. B.C. Campbell, R. Flath, R. Cunningham, and the journal's reviewers.

Abstract—In bioassays for allelopathy, where responses to treatments are determined in conjunction with responses to independent controls, statistical comparisons among treatments require an index which measures each treatment response (T) in relation to its control response (C). The most commonly used index, the treatment-control ratio (T/C), exhibits two analytical problems. First, means of T/C values are distorted upward when any of the individual values is greater than one, i.e., when stimulation occurs. Second, the distribution of T/C values may not be normal and homoscedastic. We provide two alternative indices of response whose means do not exhibit the upward distortion of T/C means. Then, the two indices are compared to T/C values in an empirical test for normality and homoscedasticity on a large bioassay data set. Results indicate that for this data set, one of the alternatives, RI, is clearly superior. RI is defined as $1 - (C/T)$ if $T \geq C$ and as $(T/C) - 1$ if $T < C$.

Key Words—Bioassay, response index, allelopathy, normality, homoscedasticity, parametric analysis.

INTRODUCTION

One problem apparent in the allelopathic literature is how to analyze inhibition and stimulation responses across a series of bioassays, each of which has its own control. In experiments with only one control, statistical analysis is relatively standard because absolute responses from treatments are compared to those from the control. However, with multiple experiments where different

0098-0331/88/0100-0181$06.00/0

treatments are conducted with independent controls, comparisons are often made with the ratio of each treatment response to its control response (e.g., Newman, 1978; AlSaadawi and AlRubeaa, 1985; AlSaadawi et al., 1985; Gilmore, 1985; Stevens and Tang, 1985; Carter and Grace, 1986).

The treatment/control ratios (T/C) present two analytical problems. First, averaging ratios across several experiments may produce an upward distortion in the mean if any of the T/C values is greater than one. For example, suppose bioassays of a source plant leachate were conducted in two different months with separate controls. Such an experiment would have two purposes: to determine monthly variation in effects and to determine the effect over all months. If T/C is 0.5 the first month and 2.0 the second month, then the arithmetic mean of the ratios is 1.25, which would suggest stimulation overall. But clearly, the treatment response is double the control in the first month and the control response is double the treatment response in the second month, so the net effect over both months logically is neither inhibition or stimulation. Therefore, the arithmetic mean of T/C values produces an upward distortion in the mean effect of the two treatments.

The second analytical problem with ratios is that they commonly are not distributed normally, so parametric statistical tests may be inappropriate. The arcsine of the square root of ratios often is recommended to normalize them (Sokal and Rohlf, 1969). However, this transformation is useful only when the ratios are true proportions, i.e., when they range from zero to one, because the arcsine of a variable is defined positively only when the variable ranges from zero to one. With bioassays, T/C values may be greater than one if stimulation occurs, so the transformation is impossible.

Here, we suggest alternative response indices which do not exhibit an upward distortion in their arithmetic means and which may be useful when researchers wish to apply parametric statistics to determine differences in mean effects of treatments.

METHODS AND MATERIALS

Choosing an Index of Response. If we define T/C as the ratio of a single treatment response to its control response, the mean of the ratios of N treatments is given by

$$\overline{T/C} = [\sum (T/C)]/N \tag{1.0}$$

Then, the problem is to define an index, whose mean does not exhibit the upward distortion associated with $\overline{T/C}$.

Logarithms of T/C values can be averaged arithmetically across N independently derived ratios as follows, where LI refers to the "log index":

$$\overline{LI} = \left(\sum LI\right)/N = [\sum \log (T/C)]/N \tag{2.0}$$

LI has the advantage of avoiding the upward distortion associated with averaging the untransformed ratios, but it has the disadvantage that logarithmically transformed ratios are difficult to interpret on visual inspection. Use of logarithms to the base 2 at least permits recognition of halvings of effects (i.e., an *LI* of 0 indicates a mean treatment response equal to the control response, and an *LI* of -1 indicates a mean treatment response one half of the control, etc.). Theoretically, *LI* can range from $-\infty$ to $+\infty$. Positive values of *LI* indicate stimulation by treatments and negative values indicate inhibition.

One way to avoid the difficulty of inspection of logarithmically transformed ratios is to take the inverse (antilogarithm) of $\overline{LI}$ after it has been computed. However, presentation of the inverse of $\overline{LI}$ has the complication that standard errors about it are asymmetrical. The inverse of $\overline{LI}$ is the same as the geometric mean (*GM*) of the *T*/*C* values:

$$\text{antilog}\left\{\left[\sum \log\,(T/C)\right]/N\right\} = \left(\prod\,(T/C)\right)^{1/N} = GM \tag{2.1}$$

A second index that does not exhibit the upward distortion associated with averaging *T*/*C* values is *RI*, the "response index," determined as follows:

$$\text{If } T > C, \text{ then } RI = 1 - (C/T) \tag{3.0}$$

$$\text{If } T < C \text{ then } RI = (T/C) - 1 \tag{3.1}$$

Then, *RI* values may be averaged arithmetically as follows:

$$\overline{LI} = \left[\sum\,(RI)\right]/N \tag{3.2}$$

RI ranges from -1 to $+1$, with positive values indicating stimulation by the treatments and negative values indicating inhibition by them, relative to the controls. *RI* is easy to interpret on visual inspection because it is simply the proportional reduction of the treatment relative to the control when stimulation occurs (a negative *RI*) or of the control relative to the treatment when inhibition occurs (a positive *RI*).

To illustrate the use of *LI* and *RI* in comparison to *T*/*C*, we have selected a large set of bioassays conducted to test for allelopathic effects. Ten source leachates were prepared from fresh leaf and litter samples, collected monthly from plants in Florida's sand pine scrub community. Four target seeds—three native grasses and commercial lettuce—were placed in the leachates and in controls of distilled water to determine germination rates and radicle growth. Each month's bioassays had an independent control. [Details of the bioassays and raw data are given by Richardson (1985)].

The three variables, *T*/*C*, *LI* and *RI*, were calculated for each combination of source leachate, control, month, and target species. Means and standard deviations were then determined for each target species for both germination and radicle length of seedlings. For comparisons with $\overline{T/C}$, $\overline{LI}$ was reconverted to a ratio through its inverse function (antilog $\overline{LI}$) and $\overline{RI}$ was reconverted through

its inverse function ($1 + \overline{RI}$ if $\overline{RI} \leq 1.0$ and $1/(1 - \overline{RI})$ if $\overline{RI} > 1.0$); note that these inverse functions were applied to the means ($\overline{LI}$ and $\overline{RI}$), not to the individual values (*LI* and *RI*). The results (Table 1) showed that $\overline{T/C}$ behaved similarly to the inverse of $\overline{LI}$ (Pearson's $r = 0.979$, $P = 0.0001$) and to the inverse of $\overline{RI}$ ($r = 0.981$, $P = 0.0001$), and the two inverses behaved even more similarly to each other ($r = 0.997$, $P = 0.0001$). However, for each species' germination or radicle length, the inverse of $\overline{LI}$ and the inverse of $\overline{RI}$ were less than or equal to $\overline{T/C}$ (Table 1)—a result illustrating the upward distortion of the arithmetic mean of *T*/*C* values.

The difference between $\overline{T/C}$ and the inverse of $\overline{LI}$ was highly correlated with the standard deviation about $\overline{T/C}$ ($r = 0.972$, $P = 0.0001$), because the geometric mean is less than the arithmetic mean by a function of the standard deviation around the arithmetic mean (Beckenbach and Bellman, 1961). In contrast, the inverse of $\overline{RI}$ differs from $\overline{T/C}$ only to the degree that some of the *T*/*C* values are greater than one. For example, the difference between $\overline{T/C}$ and the inverse of $\overline{RI}$ is correlated strongly with $\overline{T/C}$ plus one standard deviation ($r = 0.983$, $P = 0.0001$). In fact, if all *T*/*C* values are less than one, then the inverse of $\overline{RI}$ equals $\overline{T/C}$.

Normality and Homoscedasticity of Indices of Response. Given the three indices of response, *T*/*C*, *LI*, and *RI*, application of parametric statistics to determine differences in mean responses of various treatment groups requires that the distributions of the indices be normal with equal (homoscedastic) variances.

TABLE 1. $\overline{T/C}$, $\overline{LI}$, AND $\overline{RI}$ VALUES FROM DETERMINED BIOASSAYS FOR GERMINATION AND RADICLE LENGTH OF THREE GRASSES (*Andropogon gyrans*, *Leptochloa dubia*, AND *Schizachyrium scoparium*) AND LETTUCE (*Lactuca sativa*)[a]

Species	*N*	$\overline{T/C}$	Inverse of $\overline{LI}$	Inverse of $\overline{RI}$
Germination				
Andropogon gyrans	77	0.91	0.86	0.88
Leptochloa dubia	80	0.79	0.76	0.79
Schizachyrium scoparium	90	0.82	0.75	0.81
Lactuca sativa	150	0.90	0.85	0.90
Radicle length				
Andropogon gyrans	77	1.10	0.93	0.95
Leptochloa dubia	80	0.96	0.95	0.95
Schizachyrium scoparium	90	1.00	0.95	0.97
Lactuca sativa	150	1.51	1.41	1.36

[a] The *N* bioassays result from 10 different species leachates applied monthly to the test seeds.

A review of the sample distributions of *T/C*, *LI*, and *RI* from the bioassays described above (Richardson, 1985) provides empirical data on normality and homoscedasticity.

The distributions of *T/C*, *LI*, and *RI* for germination and for radicle length of each target species were tested for differences from normality with the Kolomogorov *D* statistic. For a given sample size, a larger *D* value indicates a greater deviation from normality. For eight such tests, distributions different from normal were statistically significant ($P \leq 0.05$) in four tests for *T/C*, in six test for *LI*, and in three tests for *RI* (Table 2). If we chose the best index as the lowest *D* value from each of the eight cases and we arbitrarily scored indices as ties when *D* values are within 0.01 of each other, then both *T/C* and *RI* were best in seven of eight cases, whereas *LI* was best in only two of eight cases. Thus, although no index provided normal distributions in all cases, both *RI* and *T/C* performed much better than *LI*.

To compare homoscedasticity of variances, the standard deviations (sd_1) about $\overline{T/C}$, $\overline{LI}$, and $\overline{RI}$ for germination and radicle length of each of the four target species were determined (Table 3). Next, the four standard deviations were averaged to yield a mean ($\overline{sd}_1$) and standard deviation (sd_2) of the standard deviations. Then, the coefficient of variation was calculated from the mean and standard deviation ($CV = 100^* (sd_2/\overline{sd}_1)$. For germination and for radicle length, the *CV* of the standard deviations of $\overline{RI}$ was lower than the *CV* for $\overline{LI}$ or for $\overline{T/C}$, so $\overline{RI}$ provides the most homoscedastic index of the three (Table 3).

TABLE 2. OBSERVED *D* VALUES FROM KOLOMOGOROV TEST FOR DIFFERENCES FROM NORMALITY OF DISTRIBUTIONS OF THREE INDICES OF RESPONSE: *T/C*, *LI*, AND *RI*[a]

Species	*N*	*T/C*	*LI*	*RI*
Germination				
Andropogon gyrans	77	0.09	0.08	0.08
Leptochloa dubia	80	0.09	0.11**	0.09
Schizachyrium scoparium	90	0.11**	0.19**	0.10*
Lactuca sativa	150	0.29**	0.40**	0.30**
Radicle length				
Andropogon gyrans	77	0.16**	0.07	0.06
Leptochloa dubia	80	0.08	0.11*	0.08
Schizachyrium scoparium	90	0.09	0.13**	0.08
Lactuca sativa	150	0.08*	0.11**	0.15**

[a] Smaller *D* values indicate less difference from normality for comparisons of a given sample size. Probabilities of significant difference from normality of the observed *D* (or larger) are indicated by * for $P \leq 0.05$ and by ** for $P \leq 0.01$.

TABLE 3. STANDARD DEVIATIONS ABOUT $\overline{T/C}$, $\overline{LI}$, AND $\overline{RI}$ FOR FOUR TARGET SPECIES' GERMINATION AND RADICLE LENGTH, MEAN AND STANDARD DEVIATION ($\overline{sd}_1 \pm sd_2$) OF STANDARD DEVIATIONS, AND COEFFICIENT OF VARIATION OF MEAN AND STANDARD DEVIATION

Species	*N*	*T/C*	*LI*	*RI*
Germination

CV (%)		61	47	39

DISCUSSION

Calculating a mean effect over many treatments with independent controls is valid only if the treatments, which are different at the treatment level, represent true replicates at a higher level. Bioassays for allelopathy often involve treatments with independent controls under many circumstances: (1) to determine seasonal variation, (2) to provide pH or osmotically adjusted controls, (3) to determine effects of temperature on activity, and (4) to determine field location effects on treatments in blocked or split-plot designs. In most of the above cases, determination of overall effects may be as important as investigation of differences among treatments, and experiments are designed so treatments represent true replicates for determination of overall effects. Generally, as specific treatment effects become known, more complicated designs with independent controls are necessary in order to assess treatment effects under more realistic conditions. Thus, as investigations become more sophisticated, the alternative indices, *RI* and *LI*, may become more appropriate than simple *T/C* ratios.

In addition to avoiding the upward distortion of mean effects associated with the arithmetic mean of *T/C* values, it is necessary to use an index that tends to exhibit normality and homoscedasticity. For the data set used here, *RI*

and *T/C* were superior to LI in regard to normality. RI was superior to both *T/C* and *LI* in regard to homoscedasticity.

With other data sets, we have found that *RI* is usually, but not always, superior to *LI* and *T/C*. We do not expect universal acceptance of *RI* as some innately superior index of response, but we recommend testing indices for normality and homoscedasticity before applying parametric statistical tests for treatment differences.

The statistical considerations recommended here are not a substitute for proper experimental design and biological interpretation. In some cases, treatment differences are so extreme that statistical considerations may be preempted. For example, an unmentioned, minor problem with averaging *LI* values is that *LI* is undefined when $T/C = 0$. However, when the treatment completely suppresses germination, statistical tests may be unwarranted. Similarly, we have found that *RI* usually proves superior to *LI* and to *T/C* in not deviating from normality only when treatment effects are moderate. With extremely large inhibitory or stimulatory effects, *RI* often deviates more from normality than *LI* and *T/C* (i.e., see lettuce radicle length in Table 2), but where effects are larger, statistical considerations are less necessary for biological interpretation.

Abstract—In the first trap design, a rotating windvane was connected to a 30 × 30 × 30-cm "square box" sticky trap enclosing a synthetic pheromone source (*exo*-brevicomin, frontalin, and myrcene) at the windvane's rotation axis. A second design used the windvane attached to two tubular (19-cm-diam. × 30-cm) sticky traps each suspended 120 cm from the same pheromone source and opposingly aligned "downwind" and "upwind" of the windvane. Significantly more beetles of each sex of *Dendroctonus brevicomis* LeC. (Coleoptera: Scolytidae) were caught on the downwind side compared to the upwind side of the square-box design. Even larger differences in catch, four times more males and 3.4 times more females, were found on the downwind tubular trap compared to the upwind one. The windvane trap design provides rigorous evidence that insects, especially bark beetles, orient upwind to pheromone sources (from at least 1.2 m downwind until reaching the source).

Key Words—*Dendroctonous brevicomis*, Coleoptera, Scolytidae, pheromone, anemotaxis, upwind orientation, *exo*-brevicomin, frontalin, myrcene.

INTRODUCTION

Upwind flight orientation by insects to pheromone has become a well-known fact or paradigm. This knowledge is based largely on correlative evidence be-

[1] *Dendroctonus brevicomis* LeC. (Coleoptera: Scolytidae).

tween wind direction and observations of flying insects or trap catches in the field. There are many studies on Lepidoptera and other insects orienting to pheromone sources in wind tunnels (Kellogg et al., 1962; Farkas and Shorey, 1974; Kennedy, 1977, 1983; Kennedy et al., 1980, 1981; Cardé, 1984). In some larger insects it is possible to correlate wind direction measurements using windvanes and simple observations of wing fanning (Elkinton et al., 1984). With many smaller insects, such as bark beetles, it is difficult to document their upwind flight orientation response to pheromone. Consequently, "very little (olfactory) research has investigated orientation by flying beetles, nor has it addressed the intricacies of orientation behaviour" (Borden, et al., 1985).

One reason this is so is that bark beetles have been difficult to fly in wind tunnels. Flight exercise is required in at least some bark beetles before they will take off flying upwind in pheromone-bearing wind (*Scolytus multistriatus:* Choudhury and Kennedy, 1980) or before they will ignore light and respond instead to attractant odors (*Trypodendron lineatum:* Graham, 1959). Even with flight exercise, preliminary studies (Byers, Schlyter, and Löfqvist, unpublished) on *Ips typographus* in a wind tunnel have been largely unsuccessful. The beetles fly towards lights and seem to have difficulty orienting upwind without leaving the plume and striking the side of the tunnel. The possibility that bark beetles are "less accurate" than moths when orienting to a pheromone source may be explained by differences in their requirements: male moths need to find females while bark beetles must find only an aggregation spread widely over a tree. Thus, it is possible that orientation mechanisms in flying bark beetles may be different from those in better-understood insects.

Due to the inherent difficulties of wind-tunnel experiments and flight observations on small beetles, close-range orientation studies have been done in the laboratory on walking bark beetles. The open arena bioassay has indicated they walk upwind and chemotactically orient to pheromone sources (Wood and Bushing, 1963; Birch and Wood, 1975; Byers and Wood, 1981) or to host odors (Byers et al., 1985). The beetles could also do so under natural conditions, although we have little or no evidence of this.

In the field, there are several studies on bark beetles that indicate, with various degrees of credibility, that beetles fly upwind to pheromone sources, presumably when stimulated by pheromone molecules within a plume. However, these studies were not truely rigorous, in that they relied on descriptive observation or they utilized correlations between wind direction and trap catches. For instance, McMullen and Atkins (1962) and Rudinsky (1963) observed that Douglas-fir beetles flew "upwind" and directly to a pheromone source although some "flew by and circled back before landing." Gara (1963) stated *Ips paraconfusus* take off in all directions, but usually with the wind. Upon encountering pheromone-laden air, they oriented against the wind and flew back toward the source of attraction.

Later studies have attempted to quantify the orientation behavior by catch-

ing beetles in traps placed at or near a pheromone source (Chapman, 1962; Gara, 1963; Coster and Gara, 1968; Seybert and Gara, 1970; Gray et al., 1972; Tilden et al., 1979; Byers, 1983; Helland et al., 1984; Schlyter et al., 1987). The conclusions of these studies, however, were all dependent on correlations of trap catch with wind direction measured nearby (usually at one place) and time-averaged. Thus, sometimes the wind direction may not have been aligned with the "prevailing wind direction," and it was not known precisely what the relative frequencies of beetle attraction/wind direction were over certain periods during the test. Therefore, the objective of this study was to obtain direct evidence of upwind orientation to a pheromone source which was both quantitative and not dependent on correlative wind data. A pair of rotating traps on a windvane which aligns with the wind provides a novel design for testing anemotactic orientation to odor sources in insects. The hypothesis is that the "downwind" trapping surfaces will intercept and catch significantly more beetles than the control traps placed "upwind."

METHODS AND MATERIALS

A windvane was constructed that held either a box-type sticky trap or two tubular sticky traps suspended on opposing arms. A 5-mm metal shaft served as the axle which rotated inside two ball bearings fixed near the top of a 1.5-m metal pole that was driven vertically into the ground. A polycarbonate vane was attached to a support about 16 cm from the axle and counterbalanced by metal weights (Figure 1). The dimensions of the vane were approximately 2 mm thick $\times$ 15 cm top $\times$ 38 cm bottom $\times$ 39 cm and 45 cm sides. In the first trap design, a square box was constructed from four, 30 $\times$ 30-cm, 6.3-mm wire-mesh screens coated with Stikem Special,® Seabright Enterprises, Emeryville, California. The box rested on 4-mm fiber board and was aligned so that the downwind side was perpendicular to the vane (Figure 1).

In the second trap design, 19-cm-diam. $\times$ 30-cm-high tubular sticky traps were constructed from the same materials and suspended equidistant from the axle (120 cm) on the ends of a 2 $\times$ 2-cm wooden beam (Figure 2). The two opposing traps were aligned with the vane so that one trap would be consistently downwind while the other was upwind of the pheromone source. The pheromone components of *D. brevicomis*, *exo*-brevicomin and frontalin (both >96%), and the host component, myrcene (>98%), all from Chem. Samples Co., Cleveland, Ohio, were released individually from glass tubes (two for each component) inside a dispenser (Byers and Wood, 1980; Tilden and Bedard, 1985). The release rates varied significantly with temperature but were estimated to be about 3 mg/day of each component.

Beetles were collected from the sides of the box trap once or twice daily (seven replicates) during its placement in the Sierra National Forest near Bass

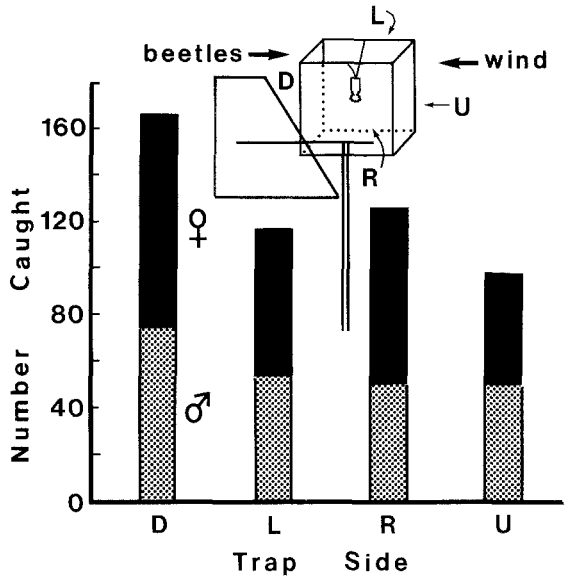

FIG. 1. Upwind orientation of *D. brevicomis* to a pheromone source within a "box" sticky trap (30 cm on a side) placed upon a windvane at 1.4 m height. The pheromone components, *exo*-brevicomin, frontalin and myrcene, were each released at 3 mg/day from within the box trap. Letters designate trap sides orientation: D = downwind, R = right and L = left of downwind, and U = upwind.

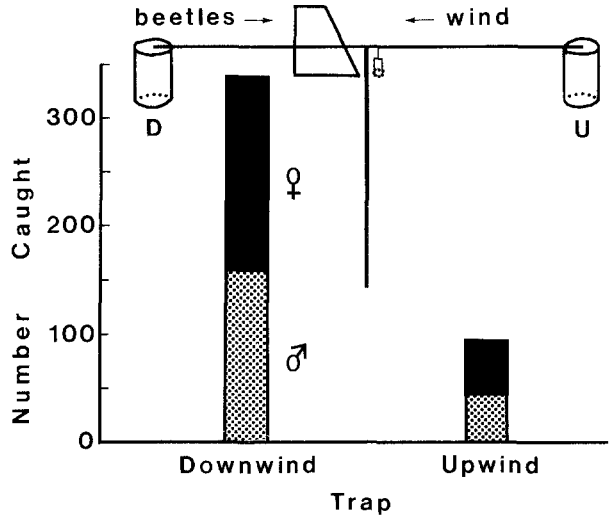

FIG. 2. Upwind orientation of *D. brevicomis* to a pheromone source placed at the rotation axis of a windvane (1.4 m height). Opposing tubular sticky traps (30 cm × 19 cm diam.) were aligned with the wind direction and each was 1.2 m from the rotation axis. The pheromone components, *exo*-brevicomin, frontalin, and myrcene, were each released at 3 mg/day in the forest.

Lake, Madera County, California, at 1000 m elevation (August 19–23, 1985). The opposing traps of the second design were similarly picked of beetles (six replicates) during testing in the same area (August 24–27, 1985). Wind speeds were measured with a fan anemometer for several 1-min periods during general alignment with the windvane in order to obtain an estimate of environmental conditions. Effects of position on the distributions of catch between the downwind side and the other three sides of the box trap and also between the opposing traps were determined with the Wilcoxon matched-pair test. Binomial confidence limits for sex ratios were calculated (Byers and Wood, 1980) and compared for significant differences with chi square.

RESULTS

The catches of *D. brevicomis* on the downwind, left and right of downwind, and upwind sides of the box sticky trap situated on the windvane are shown in Figure 1. As might be expected, if the beetles were flying upwind just prior to landing, the downwind side caught more beetles (32.3%) than either the left (22.8%) or right sides (25.7%) or the upwind side (19.3%), and the upwind side caught the fewest beetles. The downwind side caught significantly more males and females than did the upwind side (1.5 and 1.9 times more, respectively, ($P < 0.05$), and the sex ratios caught on the various sides were not significantly different (Table 1). It is apparent, however, that each of the four sides caught a significant proportion of the total catch.

TABLE 1. NUMBER OF *D. brevicomis* CAUGHT AND RATIOS (WITH 95% BINOMIAL CONFIDENCE LIMITS) ON WINDVANE TRAP WITH BOX TRAP OR OPPOSING TRAPS (SEE FIGURES 1 AND 2)

	Number caught		Sex ratio
	Male	Female	M/F[a] 95% BCL
Box trap			
Downwind side	74	92	0.80(0.59–1.09)
Left side[b]	53	64[c]	0.83(0.58–1.19)
Right side[b]	56[c]	76	0.74(0.52–1.04)
Upwind side	50[c]	49[c]	1.02(0.69–1.51)
Opposing traps			
Downwind trap	156	182	0.86(0.69–1.06)
Upwind trap	39[c]	53[c]	0.74(0.49–1.11)

[a] Sex ratios were not significantly different ($P > 0.05$, χ^2).
[b] When one is facing upwind.
[c] Wilcoxon matched-pair test showed trap surfaces had significantly different distributions of catch for a particular sex compared to the corresponding downwind side or downwind trap ($P < 0.05$).

In order to further test the anemotactic orientation hypothesis, two opposing traps were placed 120 cm from the pheromone source such that one trap was always aligned downwind while the other was upwind (Figure 2). Here it can be seen that the trap catches were even more different since four times more males and 3.4 times more females were caught on the downwind trap compared to the upwind trap (Figure 2). The differences in catch were statistically significant for both males and females ($P < 0.05$), while the sex ratios caught on each trap were not significantly different (Table 1). The wind was observed to change direction rather frequently (about once every minute) by as much as 180°. This was apparently more variable than observed earlier (Byers, 1983). Wind speeds varied between 0.5 and 1.5 m/sec with brief periods of calm (wind changing). All tests were conducted during favorable flight weather (warm and sunny, midday temperature 25–32°C).

DISCUSSION

The catches of *D. brevicomis* on the respective sides of the box sticky trap on the windvane indicate that both sexes orient upwind to pheromone sources, at least in the final landing stage. The fact that significant proportions apparently were caught on sides other than the downwind side can be explained in several ways. One possibility is that the wind direction changed more abruptly than could be followed by the windvane so that anemotactic beetles were caught by inappropriate sides. It is almost certain that the zigzag flight path of bark beetles as they traverse a narrowing plume (as in other insects, Kellogg et al., 1962; Traynier, 1968) would cause significant catches on the sides. The observation of earlier scientists also indicate that beetles that fly out of the odorous air attempt to turn and even circle back to the source, resulting in catches on the upwind side. After the experiments were concluded, I became aware of another example where a similar windvane trap (as in Figure 1) indicated that onion flies oriented upwind to host-plant odors, at least within 20 cm of the source (Dindonis and Miller, 1980). A box trap of much larger dimensions would have probably given much larger differences in catch among the sides.

Tests of anemotaxis on a larger dimension were attempted by separating the trapping surfaces about 120 cm from the source in both the downwind and upwind directions. The higher catches on the downwind trap indicated that beetles were responding anemotactically at least 1.2 m from the pheromone source. The fact that some beetles were caught on the upwind trap can be explained by: (1) the windvane may have sometimes lagged behind the change in wind direction and (2) not all anemotactic beetles were caught by the downwind trap and, when they were not trapped at the source, they dispersed at random on even continued more or less upwind until they were caught by the upwind trap. It

would have been interesting to have compared these results with a test where a box trap was also placed over the source in order to reduce the possibility of the second explanation above. Of course, many trap configurations are possible in combination with the windvane concept.

Lindelöw and Weslien (1986) sum up our knowledge of *I. typographus* flight behavior during the dispersal flight: "when released, beetles always flew downwind for at least 10–15 m, after which time they were impossible to observe." However, it is sometimes possible to observe beetles a few meters before landing at a pheromone source during the late afternoon as sunlight is transmitted through their wings. Others have used white sheets to offer a contrast (Chapman, 1962; Seybert and Gara, 1970). These observations are not quantitative and are only correlated with wind direction, which is often imperfectly known.

Several quantitative studies have provided evidence for upwind orientation to attractive sources in bark beetles but one or more drawbacks are apparent: (1) the tests used marked beetles, often selected, that were subsequently released (unnaturally), (2) the tests were performed in unnatural settings (cages, grassland), (3) the tests used fixed-position traps that may not have been optimally aligned with the prevailing wind direction, (4) the wind direction was averaged and could only be correlated on a gross scale since instantaneous catch and wind direction were not determined, and (5) the wind measurements were usually only at one location and somewhat distant from the traps, and in some cases measurements were from weather stations several kilometers away.

Chapman (1962) found that more *Trypodendron lineatum* were caught on the downwind sides of sticky traps placed over attractive logs (drawbacks 3–5 above). Gara (1963) performed an interesting experiment in which a line of nine traps, placed parallel to the wind direction, released pheromones from each in increasing and then decreasing amounts. Marked *Ips paraconfusus* were then released at either the upwind or downwind areas of the line. The suggestion was that since the percent recoveries on the traps were virtually identical, this must mean that beetles released upwind flew with the wind until turning upwind in response to pheromone, while beetles released downwind flew immediately upwind in response to pheromone. Ignoring anemotactic theories and personal observation of flying beetles, however, one could argue that there is a more simple explanation of Gara's results. This is that beetles do not utilize wind direction when orienting to pheromone as their release either upwind or downwind made no difference on their distribution of recapture along the trap line. However, the windvane trap results presented here allow us to believe more strongly in Gara's explanation.

Coster and Gara (1968) released marked *D. frontalis* in a grassland area from four cardinal directions that were 30.5 m from a pheromone source. The beetles released from the downwind direction were recaptured in the highest

proportion, but the numbers were probably too low for reliable statistics (drawbacks 1–5). Seybert and Gara (1970) found that caged *I. pini*, artificially induced to fly, flew proportionately more to the upwind wall (75%) when the cage was placed 6 m downwind of a pheromone source (no statistics, drawbacks 2–4). In a similar experiment with caged *D. ponderosae*, Gray et al. (1972) showed a statistically significant preference for upwind flight to attractants (drawbacks 2–4). Tilden et al. (1979) used sticky traps in four cardinal directions at 1.5- and 4.5-m distances from a pheromone source to monitor the attraction of *D. brevicomis*. They found that the downwind trap consistently caught more beetles than the upwind trap (drawbacks 3–5). Byers (1983) used three trap rows, each 21 m long of 15 sticky traps, placed perpendicular to the prevailing wind and each succeeding row was 4.6 m further downwind from a pheromone source in order to observe the upwind orientation of *I. paraconfusus*. Both sexes were caught in a narrowing and concentrating pattern as they approached the source, but the male catch at the source was significantly reduced compared to female catch (also compared to the sex ratios on the rows of traps), indicating that male orientation to pheromone is less focused than that of females (drawbacks 3–5).

Helland et al. (1984) released marked *I. typographus* in grassland from four cardinal directions either 12 or 20 m from a central pheromone source. Beetle catch was monitored in 64 traps, each capable of catching beetles from four cardinal directions with respect to the source, stationed in eight 24-m-long "spokes" radiating from the source. The pattern of catch was consistent with an upwind orientation to pheromone, for beetles released downwind, and there was evidence that beetles "swarmed" around the source and did not always move straight into the trap (drawbacks 1–5). In many respects their results are reminiscent of those obtained by Gara (1963) above. Schlyter et al. (1987) placed barrier traps in four cardinal directions each 3 m from a central pheromone source and found that *I. typographus* was again caught in a pattern consistent with upwind anemotaxis (although the wind measurements were taken several kilometers away from the experiment, drawbacks 3–5).

The present study provides a method for continuously integrating wind direction and flight intensity in a natural setting with naturally responding beetles. Thus, the method of coupling a windvane with beetle traps circumvents the five experimental drawbacks encountered in the past. However, much more remains to be understood about close-range flight orientation (observed here) and as well longer-range orientation that often was probed in the experiments discussed above.

Acknowledgments—I am grateful to the USFS and W.D. Bedard, P.E. Tilden, and M.I. Haverty for providing the facilities for research in the field. I am especially grateful to P.E. Tilden for helpful assistance and information. I thank D.L. Wood, Department of Entomological Sciences, University of California, Berkeley, and J. Löfqvist, Department of Animal Ecology, University of Lund, Sweden, for providing me with research facilities and funding.

NOVEL DIFFUSION–DILUTION METHOD FOR RELEASE OF SEMIOCHEMICALS: Testing Pheromone Component Ratios on Western Pine Beetle

JOHN A. BYERS

Department of Animal Ecology, University of Lund
S-223 62 Lund, Sweden
Department of Entomological Sciences, University of California
Berkeley, California 94720

(Received September 22, 1986; accepted January 20, 1987)

Abstract—Each of the pheromone components of the Western pine beetle, *Dendroctonus brevicomis* LeC. (Coleoptera: Scolytidae), *exo*-brevicomin (E) and frontalin (F), were released in the forest at various ratios 0.01 : 1, 0.1 : 1, or 1 : 1 to a constant dose of the opposite component (E or F) plus the host monoterpene myrcene (M), which were each released at 1.5 mg/day. The components were released by a new method that combines the principles of chemical diffusion through a tube with mole percentage dilution of the chemical. Both sexes of *D. brevicomis* were attracted similarly at comparable ratios (and release rates) of E or F and showed similar logarithmic relationships (r^2 = 0.92–0.99). The bark beetle predator, *Temnochila chlorodia* (Mannerheim) (Coleoptera: Trogositidae) was apparently less sensitive to E than *D. brevicomis*, being relatively less attracted to amounts of E equivalent to that released by 70 females, while none were attracted to that from seven females (while this rate still attracted significant numbers of conspecifics). The apparent insensitivity of bark beetles to extreme ratios between pheromone components in contrast to moths is discussed. The advantages of the diffusion–dilution method of releasing semiochemicals compared to previous methods of absorbents, wicks, capillary tubes, and semipermeable plastic membranes are also discussed.

Key Words—*Dendroctonus brevicomis*, Coleoptera, Scolytidae, *Temnochila chlorodia*, Trogositidae, pheromone, frontalin, *exo*-brevicomin, myrcene, controlled release.

INTRODUCTION

Knowledge of qualitative and quantitative release of synthetic semiochemicals from dispensers is of major importance to the understanding of the chemical ecology of an organism. During isolation of relevant semiochemicals, one must usually dispense volatile compounds in order to evoke certain behaviors which can then be compared to the natural ecology. Thus, scientists are interested in simulating and experimenting with these natural processes by varying the release rates of semiochemicals and quantifying the behavioral reactions. Generally, with a laboratory or field bioassay, the experimenter wants to know (1) the purity of the semiochemical and whether it remains pure during the test and (2) the semiochemical's rate of release and whether it remains constant. One usually wants to release a very pure semiochemical whose purity remains constant and to know that the exact release rate remains constant during the test. Ideally, one should be able to adjust the release rates to any specified amount conveniently and within a range of several orders of magnitude. To date I know of no release methods which allow experimenters this degree of power—but such a method is presented here.

Several methods have been used in varying degrees with advantages and disadvantages for the experimenter. Some of these methods include: (1) release from wicks in bottles containing pure semiochemicals or solvent mixtures, (2) release from rubber septa that have absorbed semiochemical, (3) release from semipermeable plastic bags or vials containing semiochemical, and (4) release from open-ended tubes of glass or other inert material containing semiochemical. These methods, discussed in more detail later, all have one or more disadvantages, such as uneven release rates over time, possible reactive effects on the semiochemicals, or they are inconvenient to specify or vary the release rate (which is often practically limited to a narrow range). In this paper, a new method for releasing semiochemicals, which combines the principles of volatile gas diffusion through a tube (Fick's first law) with Raoult's law of vapor pressures for mixtures of volatile liquids, is presented.

In bark beetles (as in most other previous insect studies), the release of synthetic pheromone components has usually been done at only one level. The level was not necessarily similar to the natural release rate, and often the experimenter had only a rough estimate of the degree of correspondence (Roelofs, 1979). In fact, a compound cannot be properly termed a semiochemical until the synthetic release and behavioral response is determined at levels that correspond to the natural biologic condition. This is a major problem in chemical ecology and, until quite recently, has generally been ignored because of practical difficulties. Natural release rates of pheromone from bark beetles, which must feed in order to produce it, have been especially difficult to measure because of the low amounts relative to host volatiles (Schlyter et al., 1987a).

Browne et al. (1979) and Schlyter et al. (1987a) are among the few who have determined the average release rate of pheromone from bark beetles feeding in a host tree. The former estimated that a female Western pine beetle (*Dendroctonus brevicomis* LeC. (released her pheromone component, (+)-*exo*-brevicomin (E), at 4.1 μg/day, while the male released his component, (−)-frontalin (F), at 0.86 μg/day. Together these two components with the host monoterpene myrcene (M), released by boring activity at 410 μg/day/entrance hole (Browne et al., 1979), are equally attractive to both sexes (Wood et al., 1976). Tilden and Bedard (1985) have used these component ratios to test three release rates over two orders of magnitude (1×, 10×, and 100×) compared to similar levels of a 1 : 1 : 1 (E : F : M) ratio. Their release rates of the active enantiomers of the 1 : 1 : 1 mixture at the 1× level began at amounts equivalent to that released by 52 females and 220 males according to calculations based on the results of Browne et al. (1979), assuming beetles release pure enantiomers (Stewart et al., 1977). The highest level (100×) was equivalent to 5200 females and 25,000 males. Tilden and Bedard (1985) also tested a 5 : 1 : 400 (E : F : M) ratio at 1×, 10×, and 100× (i.e., 87 females and 76 males at 1×), but since the ratios of more than one component were varied simultaneously and the levels of all components were different from the 1 : 1 : 1 ratio and level, they could not easily determine the effects of various component ratios. Very few studies, in fact, have investigated the behavioral effects of pheromone component ratios in Scolytidae (Schlyter et al., 1987b).

Therefore, the purpose of this study was to test the effects of changing the ratio of either E or F relative to a standard 1 : 1 : 1 (E : F : M) bait on the attractive response of both sexes of *D. brevicomis*. Since Tilden and Bedard (1985) had investigated the effects of release rates equivalent to large beetle aggregations, it was decided to decrease the amounts released of either component from about 3.5 × (183 females and 872 males) down to .035 × of their lowest rate or about two females or nine males. In order to obtain these low release rates, a new semiochemical release method, termed "diffusion–dilution," was developed and applied.

METHODS AND MATERIALS

Diffusion–Dilution Method of Semiochemical Release. Fick's differential equations describing diffusion can serve to determine the instantaneous rate of release of a semiochemical from a capillary tube:

$$\text{release rate} = -\pi * r^2 * D * (C_2 - C_1)/x \qquad (1)$$

Where: r = radius of the tube, D = diffusion coefficient, C_2 = liquid concentration, C_1 = 0 (assuming convection carries vapor away), and x = distance between tube opening and meniscus level of liquid (Villars and Be-

nedek, 1974) (* = BASIC symbol for multiply). More complicated equations (Brooks, 1980) are needed to describe the release over time as the level of liquid decreases in the tube. In practice, however, it is usually more accurate to measure the release rate over the expected experimental period because one does not know precisely the diffusion coefficient (D) and other contributing factors (e.g., meniscus curvature, surface tension, and temperature effects). Tilden and Bedard (1985) and others (Browne, 1978; Byers and Wood, 1980; Byers, 1982; Tilden et al., 1983) have used 52-mm-long × 3.5-mm-ID glass tubes sealed at the bottom to dispense *exo*-brevicomin (E) and myrcene (M) by filling the tubes to a level about 40 mm below the opening. Similarly, they have used 62-mm-long × 2.2-mm-ID tubes to dispense frontalin (F) by filling to a level about 50 mm below the opening. At these distances, diffusion is rather constant over time (pseudo zero order; Brooks, 1980), and so the measured release rate of each has been considered constant at about 1.5 mg/day (Tilden and Bedard, 1985).

The concentration (C_2) is actually the vapor pressure of the semiochemical, and this can be varied according to Raoult's law, which states that the vapor pressure (release rate) of a volatile substance (semiochemical) is proportional to its mole fraction in a solvent. The following equation can then be derived for purposes of diluting semiochemicals with solvent in order to obtain a specific semiochemical release rate:

$$mls = fws * (gsem/fwsem - fsem * \text{gsem/fwsem})/\text{fsem/gs} \qquad (2)$$

Where: *mls* = milliliters of solvent; *fws* = formula weight (= molecular weight) of solvent; *gs* = grams solvent per milliliter (density); *gsem* = grams of semiochemical; *fwsem* = formula weight of semiochemical; and *fsem* = mole fraction of semiochemical ($0 < fsem \leq 1$). For example, a stock solution of E in ethanol that would yield a release rate 10% that of a neat solution and that is to be made using 0.5 g of E would require 0.52 ml of E (0.5 g * ml/0.96 g) and 1.6 ml ethanol ([46 g/mole * (0.5 g/156 g/mole − 0.1 * 0.5 g/156 g/mole)/0.1] * ml/0.828 g). Stock solutions of E in ethanol that should release about 1%, 0.1%, 0.01%, and so forth, that of a neat solution can then be made simply from the 10% solution by serial 1:10 (1 + 9) dilutions.

Testing Pheromone Component Release Rates on Beetles. Field tests of *D. brevicomis* pheromone component ratios were conducted in the Sierra National Forest near Bass Lake, California, at 900 m elevation, August 20–30, 1985. Various release ratios of E to F + M or F to E + M were composed, based on the formula above, using ethanol as the diluting solvent and the appropriate glass tubes (each component alone) of Tilden and Bedard (1985) described above (Table 1, Figure 1A). Tubes with fresh solution were replaced each morning in order to minimize release rate errors due to differential loss of the ethanol and the consequent effect on concentration of the semiochemical. Two groups (about 100 m apart) of eight sticky traps each (6-mm mesh metal-screen cylinder, 19

TABLE 1. CATCHES OF MALE AND FEMALE *Dendroctonus brevicomis* (AND SEX RATIOS) AND *Temnochila chlorodia* ON STICKY TRAPS RELEASING VARIOUS RATIOS OF ETHANOL (A), FRONTALIN (F), *exo*-BREVICOMIN (E), AND MYRCENE (M)

Component release rates[a]	*D. brevicomis*			*T. chlorodia*	
	Male	Female	M/F sex ratio (95% BCL)[b]	Male	Female
A[c]	0	0		0	0
F + M + A[c]	6	10	0.60 (0.23–1.59)	0	0
E + M + A[c]	8	3	2.67 (0.77–9.26)	4	2
0.01 F (in A[d]) + E + M	53**[e]	57*	0.93 (0.64–1.35)	5	4
0.01 E (in A[c]) + F + M	60**	68**	0.88 (0.62–1.25)	0	0
0.1 F (in A[d]) + E + M	98	107**	0.92 (0.70–1.20)	4	7
0.1 E (in A[c]) + F + M	124**	158**	0.78 (0.62–0.99)	2	1
E + F + M + A[c]	155	170	0.91 (0.73–1.13)	5	4

[a] E, F and M were each released at approximately 1.5 mg/day or fraction thereof.
[b] Sex ratios were not significantly different ($P > 0.05$, χ^2) 95% BCL = 95% binomial confidence limits.
[c] A (ethanol) was released from E-tubes at about 66 mg/day.
[d] A (ethanol) was released from F-tubes at 21 mg/day.
[e] Wilcoxon matched-pair tests indicated catch was significantly different from the catch on the corresponding 10% serial rate (or control for the 0.01 rate) within the same sex at $P < 0.05$ (*) or $P < 0.01$ (**).

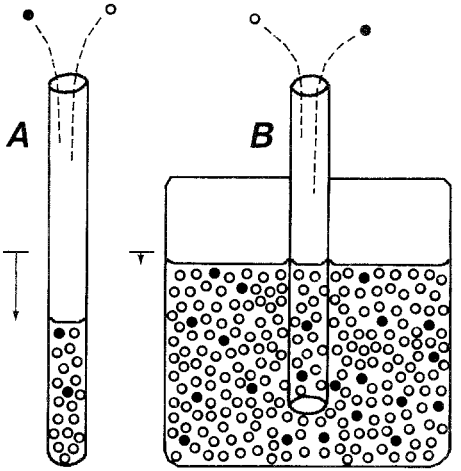

FIG. 1. Cross-sections of two possible dispensers for semiochemical release that demonstrate Raoult's law of solute–solvent volatization. The mole percentages of semiochemical (●) and solvent (○), e.g., 10% and 90% as shown, determine the corresponding release rates of each compared to respective neat solutions as controlled by the diffusion rate through the tube. Dispenser B is preferable to dispenser A because the larger reservoir remains practically constant, both in concentration and level, as does the release rate, during prolonged periods of release.

cm diam. × 30.5 cm high, coated with Stikem Special placed at 1.2 m height; Bedard and Browne, 1969) contained the respective baits (Table 1) in sun/wind protective dispensers (Byers and Wood, 1980). The traps were randomized each day (six, 1-day replicates/trap) within a group and were spaced 25 m apart on a line. *D. brevicomis* and *Temnochila chlorodia* (Mannerheim) were collected each day and their sex was determined.

Wilcoxon matched-pair tests were used to compare the male and female catches on the 1:1:1 (E:F:M) ratio to their corresponding catches on the 0.1 E or 0.1 F ratios, and these ratios were compared to corresponding 0.01 dilutions, while the 0.01 dilutions were compared to each of the components alone. Binomial confidence limits for sex ratios were calculated (Byers and Wood, 1980) and compared for significant differences with chi square. The relationships of E or F release (mg/day) with trap catch (E:F:M = 100%) were determined using several regression equations [power, exponential, logarithmic, linear, $Y = a + bX^2$, and $Y = a + b/X$].

RESULTS

The alcohol-diluted E and F tube dispensers seemed to yield the predicted release rates based on the logarithmic relationship with the catch of *D. brevi-*

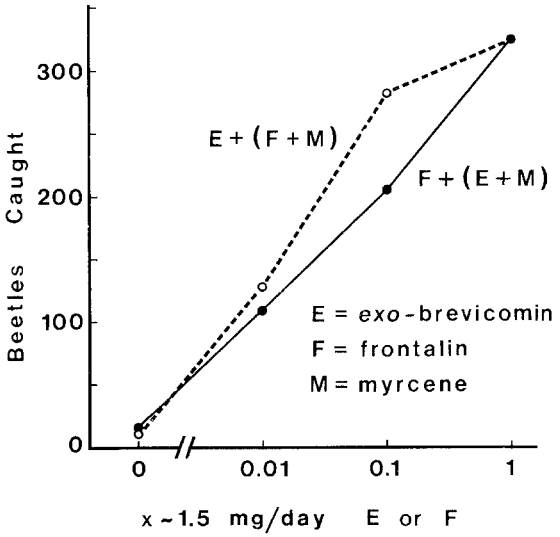

FIG. 2. Attraction of *D. brevicomis* to pheromone component ratios released from sticky traps. Various rates of E (*exo*-brevicomin) plus constant rates of F (frontalin) and M (myrcene), each at 1.5 mg/day, or various rates of F plus constant rates of E and M (each point represents mean of 12 one-day replicates) were released in the Sierra National Forest, August 20–30, 1985.

comis (Figure 2). The increases in catch of each sex to increases in either component were in most cases statistically significant for each 10-fold increase in release (Table 1). However, the catch on the 1:1:1 ratio at 1.5 mg each/day was not significantly different from that on the 0.1 E or 0.1 F releases. The sex ratios of catch on all pheromone component ratios and rates were comparable and not significantly different based on chi-square analysis (Table 1). However, on the E or F components alone there is an indication of sexual preferences, but the numbers are too low for reliable statistics. It is interesting to note that the total catches for each of the component ratios at a particular release rate were similar, as were the catches of each sex (Figure 2, Table 1). Ethanol (A in Table 1) was perhaps not the most appropriate choice for solvent as some "less aggressive" bark beetles use it to locate hosts (Moeck, 1970; Klimetzek et al., 1986). However, ethanol did not appear to be attractive to *D. brevicomis* when presented alone, although the possibility remains that it might have enhanced the attraction to the pheromone components.

Logarithmic relationships (linear increase in attraction with 10-fold increases in pheromone release) are usually expected for dosage–response curves. Several curvilinear regressions of *D. brevicomis* component release (X), but not including $X = 0$ since this value is infinitely smaller than 0.01, against percent catch (Y), E:F:M catch = 100%, confirmed that logarithmic curves had the highest coefficients of determination. The logarithmic relationship of male response to F (+ E + M) from 0.01 to 1 had an $r^2 = 0.99$, $Y(\%) = 92.9 + 14.3 \ln X$, and female response to F (+ E + M) over the same range had an $r^2 = 0.99$, $Y(\%) = 92.9 + 14.4 \ln X$. The male response to E (+ F + M) from 0.01 to 1 had a $r^2 = 0.96$, $Y(\%) = 98.2 + 13.3 \ln X$, and female response an $r^2 = 0.84$, $Y(\%) = 102.4 + 13.0 \ln X$.

T. chlorodia was caught in a pattern consistent with an attraction to E only, as noted previously (Bedard et al., 1980). However, both sexes seem equally responsive to release rates of E, and they seem less sensitive than *D. brevicomis* because proportionately less were caught on the traps with the 0.1 and 0.01 E releases (Table 1).

DISCUSSION

Diffusion–Dilution Release of Semiochemicals. Let us first consider diffusion from the glass tube with a neat solution of semiochemical in which the release rate is inversely proportional to the depth of the meniscus level in the tube (equation 1). If we assume an average release rate of F of 1.5 mg/day over 10 days, according to Tilden and Bedard (1985), when the meniscus changed from 53 below the top (as it was similar to this, see Methods and Materials) to a level 4 mm lower after 10 days (about 14.5 mg loss), then the beginning instantaneous rate on the first day should have been 1.56 mg/day and the ending rate 1.45 mg/day (equation 1). Another viewpoint is that the change in meniscus

level is inversely proportional to the square root of time (Brooks, 1980; Kydonieus, 1980). Thus, if we begin with a release of 12.4 mg/day at $t = 1$, solved by successive approximation by computer, with a nearly full tube of F, then after 63 days of elution we would expect a rate of 1.56 mg/day and, 10 days later, about 1.45 mg/day (as above). The assumed total release $[\Sigma_{t=1}^{732} 12.4/(t/10)^{-1/2}]$ would equal 206.5 mg, which corresponds to a meniscus level change in the F tube of 57.1 mm, close to our 57-mm ending level assumed above.

These calculations indicate that for all practical purposes the release rate is constant (pseudo zero order) for a particular test period. This is true as long as the meniscus is relatively far from the tube opening and the level does not change much, such as when low amounts are released from a not-too-volatile substance (pheromone). The advantage of tube dispensers is that the release rate can be immediately adjusted to the pseudo constant rate by placing a small amount at a level several centimeters from the opening. The weight and volume changes can also be easily determined by weighing and by measuring meniscus level changes.

Larger release rate discrepencies should be expected when using the above diffusion method with diluted semiochemical (diffusion–dilution), although they should be much less than an order of magnitude used here. The solvent used was ethanol, which is not too volatile for a solvent (bp 78.5°C, vapor pressure 61–122 mm at 26–36°C) but much more so than M (2.06–3.42 mm at 26–36°C, which, based on the neat release rate, is similar to E). However, the higher volatility of ethanol meant that proportionately more was released than E or F over time, which would cause the mole percentage of these compounds to increase during the day. Thus, at most we would expect an increase of E or F release of 43% during the 10-h flight period (0900 to 1900 hr) based on the measured loss of ethanol in the tube (30% of total). Since some E or F also was released, the actual increase was less than 43%.

A compensatory phenomenon was simultaneously occurring since the meniscus level also fell about 30%; this would cause the reverse effect and diminish the rate of release (at most 9%). These partially compensating effects occurred throughout the day, so the error in release rate became larger with time. However, variation in temperature probably had effects at least as, or more, severe (up to 100% as seen from the vapor pressures over the daily temperature range, above). Absolute errors on the order of 10% could be possible if calibration had been at sea level but testing was at higher altitudes (L.E. Browne, personal communication). In any case, these errors during the course of the day were on the order of less than 50–100%, insignificant compared to the 1000% differences between each serial 1 : 10 dilution.

The tube-type release device is adequate for most experiments, but if tests for longer periods and constant rates are desired, a similar device with a larger reservoir is preferred (Figure 1B). Both dispensers shown in Figure 1 would

have the same release rate initially since their openings and diffusion distances are identical. However, as noted above, after a time both the concentration of semiochemical and diffusion distance change in the tube, while a similar release from the larger reservoir has little effect (Figure 1). Many other solvents could be used. Theoretically, it is desirable to have a solvent that has chemical properties and polarity similar to the released semiochemical. Work is now underway to determine the release rates of various semiochemicals in different solvents by means of porapak Q volatile collections and quantitative gas–liquid chromatography.

Comparison with Other Controlled Release Methods. The first dispensers that released synthetic bark beetle pheromones used filter paper (Wood et al., 1967) or metal tubes containing gas–liquid chromatographic packing to hold the compounds until they evaporated (Wood et al., 1968). Since then, experimental elution devices have included four major types. The first type uses various absorbent materials, such as rubber septa, and is widely used with moth pheromones. Depending on the absorbent, this type generally has release curves that decrease exponentially or geometrically, thus being rather constant after several days of elution. I believe this method is less desirable because the rates change dramatically soon after application, and it is difficult to specify and vary the release without much laborious measurement. A second method has used wicks dipped in semiochemical (Tilden et al., 1979; Bedard et al., 1980), but the inexact surface area and physical properties of wicks make it difficult to either specify or vary the release accurately. A third method uses semipermeable plastic bags or vials to enclose semiochemical (Vité et al., 1986; Klimetzek et al., 1986; Schlyter et al., 1987b). This results in a constant release rate that is proportional to the thickness of the plastic and its surface area (Kydonieus, 1980). However, it is easy to see that release rates over several orders of magnitude are impractical due to the limitation of dispenser sizes. Furthermore, much testing is needed for each particular vial or bag to determine the release rate, so rates cannot be specified over a broad range. In all these methods, the absorbent, wick, or semipermeable plastic could have degrading effects on a particular semiochemical which would not be expected if inert materials are used.

The "test-tube" type dispenser used here has many advantages over the other three methods in that glass will not affect the semiochemical, and the rate can be specified depending on the area of the opening and the level of the liquid. The criticism of Kydonieus (1980) that capillary reservoir systems have parabolic curves of release (large amounts initially) can be easily overcome by using tubes with liquid levels that are several centimeters from the top opening. The major problem has been that a large array of tube sizes is needed (which cannot be varied freely) to encompass several orders of magnitude in release, the same problem as with the plastic bags. However, by mole percentage dilution, one

can specify any desired rate that is less than a known rate of a neat semiochemical. A mixture of semiochemicals probably could be released from one dispenser solution if their mole percentages were relatively small (< 10% of neat). These small mole percentages would tend to minimize any unpredicted effects on both vapor pressures and possible physical interactions between semiochemical molecules.

Attraction to Pheromone Component Ratios. Both male and female *D. brevicomis* had similar attraction levels over the concentration range of either E or F (with constant release rates of M and the opposite component). In fact, one may find it somewhat surprising that all the logarithmic relationships were very similar (see Results, Figure 2) because males seem to prefer E alone while females prefer F alone (Bedard et al., 1969; Vité and Pitman, 1969; Pitman and Vité, 1971; Hughes and Pitman, 1970; Byers, 1987) (Table 1). On the other hand, Byers and Wood (1981) found that both sexes were equally responsive (logarithmic relationship) at each step in a concentration range of E : F : M covering five orders of magnitude in the laboratory. Similarly, regression analysis of the results of Tilden and Bedard (1985) shows that *D. brevicomis* males and females have logarithmic attraction levels to increasing E : F : M release rates (r^2 = 0.82–0.99) at a center trap and traps 5 m away. Furthermore, the separation of E and F components either horizontally or vertically from 0 to 3 m (perpendicular to the mean wind) decreased the catch on each component but more or less equally for both sexes (Byers, 1987). Thus, except for the components alone, the sexes seem to respond equally to all comparable ratios and concentrations of E : F. This suggests that each component is equally important and has a similar function in the synergism and in the orientation to sources.

In contrast, Schlyter et al. (1987b) varied the ratios and rates of release of (−)-*cis*-verbenol (cV) and 2-methyl-3-buten-2-ol (MB), keeping one or the other constant, and found differences in the response of *I. typographus* to each component. They suggested that MB was more important for close-range orientation, while cV was more important further downwind from the source. Their theory was based largely on differences between catches on traps placed at the source and those placed a few meters away. However, regression analysis of their results indicates both MB and cV have logarithmic relationships (r^2 = 0.88–0.98) of concentration ratio and catch on both "close and long-range traps." Further work on component release ratios with traps at varying distances from the source is needed for both bark beetle species before we can form definitive theories on the function of the synergistic components during the upwind orientation to pheromone.

The release of various extreme component ratios is rather unnatural. A 1 : 100 ratio of F : E (0.01 F) at 1.5 mg E/day would simulate nine males with 183 females, which probably never occurs in nature. Despite these extreme sex ratios of simulated feeding beetles, the responses of *D. brevicomis* to the above

ratio (0.01 F) or to 872 males with two females (0.01 E) were still significant, catching about 34% and 39%, respectively, as many beetles as that on E:F (872 males and 183 females).

In contrast, some moths can be exceptionally sensitive to component ratio variations of as little as 10% or less when the synergists are *E* and *Z* isomers of long-chain monounsaturated acetates (Roelofs and Cardé, 1977; Cardé and Baker, 1984). As shown here and by Schlyter et al., (1987b), one reason bark beetles may be less sensitive to component ratios than moths could be because they must respond to ratios from various groups of beetles and not to a "preferred" individual with a consistent ratio. Initially the beetle aggregation would be composed of small numbers so the variation in semiochemical ratios would be expected to be rather large until later when a statistical mass-average would result. However, male moths would be better adapted if they were able to respond to the individual variation in ratios of many potential female mates—this variation is theoretically larger than the variation between small populations, all other things being equal. Another possible reason is that bark beetles often synthesize pheromone components from monoterpene precursors in the tree, where we expect a large variation (Sturgeon 1979), whereas moths synthesize their components de novo (Bjostad and Roelofs, 1981). This could explain the insensitivity of *I. typographus* for cV:MB ratios since cV is made from α-pinene in Norway spruce (Klimetzek and Francke, 1980). In *D. brevicomis*, biosynthesis of F does not seem to be affected by the host, while E is only produced by the female during feeding (Byers, 1983a), although we do not know if a host precursor is involved. Finally, both *I. typographus* and *D. brevicomis* are faced with a changing ratio between pheromone components during the colonization of a tree, introducing even more potential variation (Birgersson et al., 1984; Byers et al., 1984).

Pheromone Qualification. The term "pheromone" was defined by Nordlund (1981) in his semiochemical glossary as "a substance that is secreted by an organism to the outside that causes a specific reaction in a receiving organism of the same species." Using this definition without the implicit quantitative qualification, it is possible to believe erroneously that one has identified a "pheromone" when in fact the substance is irrelevant. This is because many secreted substances, if presented in unnaturally high concentrations, could cause a specific reaction (death or repellency and possibly inhibition, interruption, or disruption of other behaviors). Furthermore, many substances are believed to be active only in small amounts relative to other pheromones, e.g., verbenone in *D. frontalis* (Rudinsky 1973), 2,3-MCH in *D. pseudotsugae* (Rudinsky and Ryker, 1980), or ipsdienol in *I. typographus* (Schlyter et al., 1987c). Some bark beetle pheromones are attractive at lower release rates but become progressively less attractive to the male sex only, e.g., *I. paraconfusus* (Byers, 1983b) and *I. typographus* (Schlyter et al., 1987b,c). Many moth species are

known to be disrupted by higher, and unnatural, concentrations of their pheromone (cf. Cardé, 1984). Therefore, in order to properly define an isolated substance as a certain type of semiochemical, one should have a knowledge of the natural secretion rate compared to the effects of release of synthetic substances on the receiving organism in relation to its ecology. It is hoped that the diffusion–dilution method presented here will aid chemical ecologists in answering the second question concerning release rates of synthetic compounds.

Acknowledgments—This work was supported in part by grants from USA, NSF (INT-8503520), and Sweden, STU (84-3937), NFR, FRN, and SJFR. I am appreciative of the USFS and W.D. Bedard, P.E. Tilden, and M.I. Haverty for providing the facilities for research in the field. I am very grateful to P.E. Tilden for helpful assistance and information concerning my field studies. I would like to thank D.L. Wood, Department of Entomological Sciences, University of California, Berkeley, for providing me with a research base in collaboration with J. Löfqvist and the Department of Animal Ecology, University of Lund, Sweden. I also appreciate the helpful discussions with my colleagues, O. Anderbrant and F. Schlyter, here in Lund.

CHEMICAL CORRELATES OF RHESUS MONKEY FOOD CHOICE:
The Influence of Hydrolyzable Tannins

(Received September 8, 1986; accepted January 22, 1987)

Abstract—Feeding behavior was quantified of free-ranging adult rhesus monkeys in the Himalayan foothills of northern Pakistan. Twenty-eight food and 63 nonfood plant samples were collected and analyzed for tannins, alkaloids, fiber, lignin, protein, amino acids, total nonstructural carbohydrates, and free glucose. Most major foods of the rhesus were low in tannins and high in nutrients. The rhesus ate mainly parts of herbaceous plants, although woody plants were more abundant, possibly because herbs were lower in condensed tannins than woody plants. Feeding was negatively correlated with the astringency of tannins, ellagitannins, and total phenolics among all samples. Among leaves of both herbs and woody plants, feeding was negatively correlated with measures of hydrolyzable tannins. Total protein, total nonstructural carbohydrates, and water were not related to food choice and may not have been limiting at the site.

Key Words—*Macaca mulatta*, rhesus monkeys, food choice, tannins, nutrients.

INTRODUCTION

Generalist herbivores such as rhesus monkeys must make complex decisions in order to select a nutritionally balanced, nontoxic diet from among available plant parts and species that vary greatly in chemical composition (Boyd, 1971;

Glander, 1981; Milton, 1979). Mathematical foraging models predict that food choice should be related to the rate of nutrient acquisition (e.g., energy, protein, etc.) and to the costs of foraging and food acquisition (Belovsky, 1984; Emlen, 1966; MacArthur and Pianka, 1966; Pyke et al., 1977). Herbivore food choice may also be influenced by the presence of plant defense compounds such as alkaloids, tannins, nonprotein amino acids, and cyanogenic glycosides (Harborne, 1982; Swain, 1977; Rosenthal and Janzen, 1979).

In this study we investigated the relationship of plant chemistry to the feeding behavior of free-ranging rhesus monkeys (*Macaca mulatta*) in the Himalayan foothills of northern Pakistan. The selection by the rhesus of different plant species and parts was quantified, and food and nonfood plant samples were collected. These samples were analyzed for nutrient content (total protein, free amino acids, glucose, and total nonstructural carbohydrates) and plant defensive substances (tannins, alkaloids, fiber, and lignin) that might influence food selection. The main goal of this project was to determine which of these factors were important in influencing the diet of the animals under study. The results of the study were tested against the prediction that the rhesus should select for limiting nutrients and avoid overingestion of toxins or digestibility-reducing compounds.

The primates most extensively studied in regard to the chemistry of their foods are the Old World monkey subfamily Colobinae. Colobines have a ruminant-like modified forestomach in which microbial fermentation occurs, and are thus capable of greater digestion of plant fiber and probably detoxification of plant defense chemicals than animals with hindgut (monogastric) fermentation (Freeland and Janzen, 1974; Parra, 1978). Colobines generally choose as their main foods items low in fiber and tannins (McKey et al., 1981; Oates et al. 1977, 1980), but because their diets usually include more leaves and unripe fruits than monogastric primates such as rhesus monkeys, colobines probably ingest higher levels of tannins and plant cell wall components (fiber) than other primates.

Of the monogastric primates, the best studied in terms of food chemistry is the New World mantled howler monkey (*Alouatta palliata*) which consumes mainly tree leaves and fruits (Milton, 1979; Glander, 1981). In Costa Rica, howlers select mainly leaves low in condensed tannins and high in protein and balanced amino acids (Glander, 1981). Among the Old World primates, a comparison of high ($N = 5$) and low preference ($N = 8$) food plants of western gorillas (Pongidae) showed that preferred plants were lower in lignin than less preferred plants (Calvert, 1985). Within the Old World subfamily Cercopithecinae (the subfamily that includes rhesus monkeys), food selection by vervet monkeys (*Cercopithecus aethiops*) from two species of acacia is negatively correlated with condensed tannin contents (Wrangham and Waterman, 1981). The rhesus troop studied in Pakistan differs from the above-mentioned primate species in the temperate rather than tropical nature of its habitat. The diet of these

rhesus differs from those of most primates in the greater consumption of herbaceous leaves and stems and may be most similar to that of baboon species (Richard, 1985). Unlike most previous studies of primate food chemistry, in the present work we chemically analyzed many common plant items that were never eaten as well as items that were eaten.

Tannins have been related to decreased food consumption, growth, and survival in studies with captive rodents (Glick and Joslyn, 1970a; Lindroth and Batzli, 1984; Tamir and Alumot, 1970). In field studies tannins have been negatively related to food choice of ruminants (Provenza and Malechek, 1984) and primates (see above). The antifeedant effect of tannins in vertebrates may be due to a "puckery" or astringent mouth feel caused by the binding of tannins to salivary proteins (Bate-Smith, 1972a). Inhibition of growth in mammals by tannins has been linked to decreased protein digestibility in vivo in rats (Tamir and Alumot, 1970) and voles (Lindroth and Batzli, 1984; Lindroth et al., 1986), increased excretion of endogenous nitrogen (Glick and Joslyn, 1970b), as well as direct toxic effects (Lindroth and Batzli, 1984). In contrast, inhibition of protein digestibility by tannins has not been demonstrated in insects in vivo, and it has been suggested that many insects have digestive adaptations (e.g., high gut pH, presence of surfactants, binding of tannins to peritrophic membrane) which allow them to minimize the effects of tannins (Bernays et al., 1980, 1981; Martin and Martin, 1984; Martin et al., 1985).

Tannins fall into two main structural classes of polyphenolics: condensed tannins (proanthocyanidins), which are composed of two or more flavanol units bound together by carbon–carbon linkages, and hydrolyzable tannins, which are esters of sugars and gallic acid (gallotannins) or hexahydroxydiphenic acid or related phenolics (ellagitannins). The distribution of hydrolyzable tannins is restricted to some families of dicots, whereas condensed tannins occur in most plant families (Swain, 1979). Condensed tannins inhibit feeding in several primate species including *Colobus guereza* (Oates et al., 1977), *C. satanas* (McKey et al., 1981), *Presbytis johnii* (Oates et al., 1980), and *Cercopithecus aethiops* (Wrangham and Waterman, 1981). Hydrolyzable tannins have been identified in some plants in these studies but have not been specifically quantified. Their impact on primate feeding behavior is therefore little explored. In the present study we separately quantified condensed tannins, gallotannins, ellagitannins, total phenolics, and total astringency of plant samples to determine which of these aspects of tannin content were most related to food choice by rhesus monkeys.

METHODS AND MATERIALS

Study Site and Field Methods. All results of the feeding study and descriptions of the field site are presented in detail elsewhere (Goldstein, 1984). The study site was a forest area of approximately 7 km^2 (encompassing most of the

home range of the focal animal troop) in the Murree Hills of northwestern Pakistan near the village of Dunga Gali (73°22'E, 34°3'N) at an elevation of 2000–2750 m. Climate at the site was temperate, with a monsoon season from July through August and 5–8 m of snow each winter. The boundaries of the site were for the most part naturally occurring delimiters such as ridges and streams. The site was divided into six elevation zones (150 m each) starting at 2000 m and up to 2750 m. Transects (100 m) were laid out along contour lines placed midway through each of the six elevation zones. The transects were marked off across the entire width of the site in each elevation zone. The abundance of tree and shrub species was measured by counting all woody plants (dbh > 5 cm) within areas 5 m to each side of the first 20 m of each 100 m transect. A total of 279 transects was sampled. The dominant tree species at the site were *Abies pindrow* and *Pinus wallichiana* with *Taxus baccata*, *Cedrus deodara*, and *Picea smithiana* also occurring commonly. The major hardwood trees found in the area included *Quercus dilatata*, *Prunus cornuta*, *Populus ciliata*, and *Juglans regia*. In disturbed sites, which made up 30% of the study area, grasses, *Trifolium* (clover), and *Viburnum* shrubs were common. The area has been protected by the government against uncontrolled use, but portions of the forest have been periodically disturbed by human habitation and agriculture.

During the period from September 1978 through August 1979, the feeding behavior of nine adults (two males and seven females) in one rhesus troop was quantified using instantaneous focal animal sampling (Altmann, 1974). Data on feeding and other activities were recorded at the beginning of each minute during 10- or 20-min observation periods. Theese periods were spread evenly throughout the day from dawn to dusk. A total of 3646 of the minute feeding records were collected. The results of the feeding study are expressed as the percent of the total number of feeding records that each item was recorded as eaten. These values represent an estimate of the proportion of the total time allotted to feeding that was spent on each item. The troop was difficult or impossible to locate during some months in the winter and monsoon, and so these seasons are underrepresented in the feeding data set. Feeding accounted for 45% of all activity records of the rhesus. Consumption of insects and mushrooms was negligible (0.06% combined). Fully 84% of the feeding records were of vegetative plant parts while only 12% were of fruits, flowers, and seeds.

Ninety-one plant samples were collected for chemical analysis. These included samples of 28 different items that were seen to be eaten by the rhesus. In collecting these items, we chose samples that were as similar as possible to those eaten by the study animals (i.e., same tree, same patch of herbs, same stage of maturity, etc.). Sixty-three very common items that were never seen to be eaten and thus could be inferred to be low in preference were also sampled. Most of the food and nonfood samples consisted of 10 or more individual items (leaves, fruits, etc.) which were later combined for analysis. Thirty-seven

of the plant samples (mostly fruits and flowers) were weighed and stored fresh in ethanol in an attempt to better preserve phenolic contents (Swain, 1979) and to prevent molding of water-rich samples that would have required a very long drying period. All other samples were weighed, air dried, reweighed, and stored dry. No samples were collected at the site of several important foods (grasses and needles of *Abies* and *Pinus*) because we could not precisely identify the items being eaten in these cases (e.g., young vs. mature needles, leaf tips vs. leaf bases, species of grasses, etc.). Samples of needles from *Pinus wallichiana* and *Abies concolor* (no samples of *Abies pindrow* were available) were collected from the Arnold Arboretum, Boston, Massachusetts, on Nov. 2, 1986, in order to provide approximate chemical values for conifer needles.

Chemical Methods. The dried samples were ground to pass a 60-mesh sieve and extracted in replicate three times with hot 50% aqueous methanol. The ethanol-preserved samples were cut up with scissors or crushed with a glass rod, heated to boiling, filtered, and the residue extracted two times with 50% methanol. For all samples, the three extracts were combined, filtered, brought up to a known volume, and stored at 4°C. All phenolic and tannin analyses were performed on these extracts.

Total extractable phenolic contents were measured using the Folin-Denis method with tannic acid as a standard (Singleton and Rossi, 1965). Condensed tannins and ellagitannins were quantified using standard methods, and percent dry weight values were calculated from E 1%, 1 cm values (Bate-Smith, 1972b, 1975). Gallotannins were quantified by reaction of the plant extracts with 5% potassium iodate at 0°C for 50 min and measurement of the pink color produced at 550 nm using tannic acid (supplied from Fisher Scientific) as a standard (modified from Bate-Smith, 1977). For samples that showed increased absorbance with the condensed, gallo-, or ellagitannin assays, an absorption spectrum was prepared to determine if the sample had a spectral peak appropriate for that assay (540–560, 550 and 600, respectively). Samples that did not have such a peak were considered negative for that analysis. The protein-precipitating capacity (astringency) of extractable tannins was assayed using dilute blood protein and expressed as dry weight tannic acid equivalents as described in Bate-Smith (1973a) except that instead of fresh human finger blood, diluted defibrinated rabbit blood (Gibco) was used (Marks, 1985). Because condensed tannins are not always totally extractable (Bate-Smith, 1973b, 1975), the unextracted powder and/or the residue (after extraction) of each sample were also analyzed for astringency and condensed tannins. Total astringency (TAE; tannic acid equivalents) and CT (total condensed tannin) values represent the sum of values for extracts plus residues for ethanol-preserved samples, or the higher of the values for unextracted powders or extracts plus residues in the case of dried samples (Marks, 1985).

The gallotannin and ellagitannin methods have not been tested with such

a diverse set of plant materials before, but they have been used to quantify tannins in maples (Bate-Smith, 1977, 1978), geraniums (Bate-Smith, 1981), and *Prunus* (Schroeder, 1986). The gallotannin (iodate) method reacts somewhat with hexahydroxydiphenic acid-type residues of ellagitannins as well as galloyl residues, whereas the ellagitannin method is specific for ellagitannins (Bate-Smith, 1977). These two methods were significantly correlated with each other and with measures of astringency and total phenolics for the 91 plant samples in this study (Marks, 1985). Significant concentrations (>1%) of gallo- and ellagitannins were found almost exclusively in plant families (e.g., Fagaceae, Geraniaceae, Hippocastanaceae, Polygonaceae, Rosaceae, Saxifragaceae, etc., see Appendix 1) known to contain these compounds (Bate-Smith, 1972c, 1984), thus confirming the specificity of these assays.

Total nonstructural carbohydrates of the aqueous methanol extracts were quantified using the phenol–sulfuric method (Strickland and Parsons, 1972). Free glucose in these extracts was measured with the glucose oxidase–peroxidase method (Raabo and Terkildsen, 1960). Fiber (crude normal fiber) was prepared by a modification of the method of Morrison (1972). The powder or residue of each sample was extracted sequentially with aqueous methanol, ether, dichloromethane, and hot 3% sulfuric acid. The residue (fiber) was dried and weighed. Lignin in this fiber fraction was determined by the acetyl bromide method of Morrison (1972).

All samples were spot tested for the presence of alkaloids by recording the amount of precipitation with Dragendorff's reagent on a 0–3 visual scale after appropriate solvent extraction (Marks et al., 1985). Free amino acids were measured in aqueous methanol extracts using the ninhydrin method (Spies, 1957). Total protein was quantified by hydrolyzing plant material with 3% sulfuric acid at 100°C for 24 hr and using ninhydrin to measure the amino acids released (Marks et al., 1985).

Statistical Analyses. Because plant parts may differ greatly in chemical composition and because herbs may differ from woody plants in their defensive chemistry, the plant samples were divided into subsets by part (leaves, flowers, fruits, stems, etc.) and by habit (herbaceous vs. woody). Herb leaves and herb whole plants were not found to be significantly different in two-tailed t tests and thus were combined into one subset (referred to hereafter as herb leaves). Woody plants and herbs were compared by part (leaves, flowers, and stems) using two-tailed t tests). Other part types were insufficient in sample size for statistical analysis. Spearman correlations between feeding and the chemical variables were calculated for leaves of herbs and woody plants separately and for the whole data set ($N = 91$). Spearman rather than Pearson correlations were used because the feeding data were not normally distributed (most plants had 0 feeding observations). All statistics were done using SAS on an IBM mainframe computer.

RESULTS

Major Foods of Rhesus Monkeys. The plants eaten most often by the rhesus on a yearly basis are listed in Table 1 along with data on chemical composition and percent of total feeding records. By far the most important food sources were *Trifolium* sp. (30% of total feeding observations), unidentified herbs and grasses, and *Abies pindrow*. Other items were important foods during certain seasons. For example, roots of *Oenothera rosea* were staple items during winter, and *Viburnum* fruits and flowers were readily consumed when available in the spring.

Two species of clover occurred at the study site, *Trifolium repens* and *Trifolium praetense*, the former being much more common. Because these species were indistinguishable in the field except during flowering stages, the two species were treated as a single item in the feeding study and sample analyses. Tannin contents in clover were negligible as measured by hemanalysis and chemical methods, and protein content was 16.5%, similar to the mean for all 91 samples (16.2%). Some populations of *Trifolium repens* are known to be cyanogenic (Conn, 1979). All six *Trifolium* samples gave negative results when tested using picric acid paper (Marks, 1985); however, tests for cyanogenesis with dried sample are inconclusive because of possible destruction of cyanogenic glycosides upon drying (Conn, 1979).

Major foods were generally low in astringency (the mean TAE value for the most eaten 10 items sampled of those analyzed was 2.7 as compared to 4.6 for all 91 samples; data from Tables 1 and 2) and high in protein (*Populus ciliata* and *Prunus cornuta* leaves and *Oenothera rosea* roots) or total nonstructural carbohydrates (*Viburnun foetens* flowers and fruits). The conifer needles collected at the Arnold Arboretum were high in tannins and low in protein; the pine and fir needles eaten by the rhesus were probably similar (see Feeding and Plant Abundance, below). Analysis of *Trifolium*, *Juglans* leaves, *Prunus* leaves, and *Oenothera* roots for individual amino acid contents showed that sufficient amounts of most essential amino acids are available to the rhesus in these foods (Marks, 1985).

Relationships Between Feeding and Chemistry. The results of the chemical analysis for all 91 different plant samples are presented in Appendix 1 alphabetically by plant family. Two or more replicate samples were collected and analyzed for *Trifolium* sp. whole plants, *Rumex nepalensis* leaves and seeds, and *Viburnum foetens* flowers. Only the averages of the replicate values are included in Appendix 1 because the results were very similar between replicates (Marks, 1985). Mean chemical contents of herbaceous and woody plant parts are compared in Table 2. Among leaves and flowers, condensed tannins were lower in herbs than in woody plants. Flowers and stems of herbs were lower in fiber than those of woody plants.

Correlations between feeding and chemical contents among leaves of woody plants and herbs and for all samples combined are shown in Table 3. Other subsets were too small (Table 2) or contained too few eaten items for correlational analyses. Total astringency, phenolics, and ellagitannins were significantly negatively correlated with feeding for all 91 samples. Feeding was negatively correlated with gallotannins among leaves of woody plants and with both gallo- and ellagitannins among leaves of herbs. All other chemical variables showed no significant relationships with feeding.

Feeding and Plant Abundance. Selection by the rhesus among tree and shrub species from which parts were eaten can be explained partially on the basis of plant abundance alone. A plot of abundance vs. percent of total feeding records (Figure 1) suggests a linear relationship between the two variables with the exception of one point (*Pinus wallichiana*). The Pearson correlation coefficient between feeding and abundance for the eight trees is insignificant (r = 0.274), but when the outlying point (*Pinus*) is excluded, the correlation coefficient is highly significant (r = 0.942, $P < 0.01$). The samples of *Pinus wallichianum* collected at the Arnold Arboretum contain 5.3% condensed tannins and 11% protein (Table 1). Pine species also contain monoterpenes (e.g., α-pinene) which deter feeding by mammals (Farentinos et al., 1981). Thus pine may be chosen less than other items due to high secondary compound and low

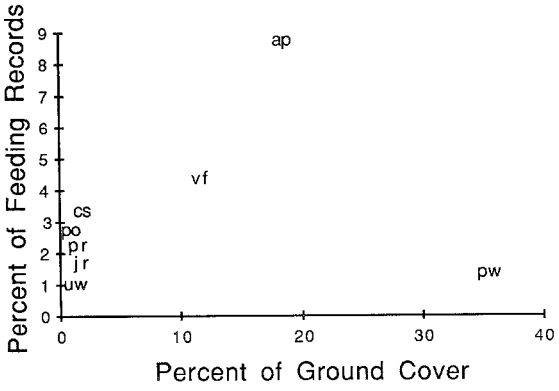

FIG. 1. Percent of plant species abundance vs. percent of feeding records. Tree and shrub abundance expressed as percent ground cover vs. percent of rhesus monkey feeding records. All data are from Goldstein (1984). ap = *Abies pindrow*, cs = *Cedrela serrata*, jr = *Juglans regia*, po = *Populus ciliata*, pr = *Prunus cornuta*, pw = *Pinus wallichiana*, uw = *Ulmus wallichiana*, vf = *Viburnum foetens*.

nutrient contents. Fir needles (Table 1) contain similar levels of tannins and nutrients to pine. The large numbers of feeding records for both pine and fir were most likely due to the extremely great abundance of these trees. Possible chemical factors involved in the greater use of fir needles over those of pine cannot be examined because of lack of samples of these items from the study site.

DISCUSSION

For all 91 samples and among vegetative parts of herbs and woody plants, feeding was significantly negatively correlated with hydrolyzable tannins (gallo- or ellagitannins) but not with condensed tannins. Previous studies have shown that primate feeding behavior is negatively related to condensed tannin content (Glander, 1981; McKey et al., 1981; Oates et al., 1977; Wrangham and Waterman, 1981), but this is the first demonstration of inhibition of primate feeding by hydrolyzable tannins. Using thin-layer chromatography, Gartlan et al. (1980) detected hydrolyzable tannins in 27 and 31% of the samples from Kibale and Doula-Edea, respectively. By our methods (potassium iodate for gallotannins and nitrous acid for ellagitannins), the samples from Pakistan appear to contain more hydrolyzable tannins than those examined by Gartlan et al. (1980), hydrolyzable tannins occurring at levels of 0.2% and above (potassium iodate method) in 50% of the samples (data from Appendix 1). Other northern temperate forests contain many of the same genera as those occurring at the Pakistan site and are therefore likely to have similar levels of hydrolyzable tannins to those reported here. Further research is required to test the hypothesis that hydrolyzable tannins may be more important as feeding deterrents in temperate forests than in tropical forests.

More than 50% of all feeding records were of herbaceous plants located in disturbance zones, even though these zones made up less than 30% of the study site area (Goldstein, 1984). Herb leaves and flowers were lower in condensed tannins than those of woody plants (Table 2). Selection for parts of herbaceous plants over those of woody plants, even though woody plants are more abundant, shows an apparent preference for herbs, which in part may be due to lower condensed tannin contents in herbs than woody plants (Table 2) (Bate-Smith, 1972a). Pine and fir needles (not included in the means in Table 2) were likely to be high in condensed tannins (Table 1), whereas grasses and other herbaceous plants that were not sampled were probably low in condensed tannins (Bate-Smith, 1972a; Capinera et al., 1983; Rice and Pancholy, 1973). The lack of negative correlation between condensed tannins and feeding (Table 3) may be due to incomplete sampling of food items and to the confounding

TABLE 1. PERCENT OF FEEDING RECORDS AND CHEMICAL COMPOSITION OF FAVORED FOOD PLANTS

Plant item	% of feeding records	Percent dry weight				
		Tannins[a]	Fiber	Protein	Free amino acids	TNC[b]
Herbs

[a]All means are percent dry weight except water contents.
[b]TAE = total astringency, CT = total condensed tannins, ET = ellagitannins, GT = gallotannins, TP = total phenolics, AA = amino acids, TNC = total nonstructural carbohydrates, SD = standard deviation.
[c]a,b,c = Means with different letters are significantly different ($P < 0.05$) in Tukey multiple comparison tests.

factor of plant abundance. Neither gymnosperms nor monocots contain hydrolyzable tannins (Swain, 1979). Therefore the negative correlations between feeding and hydrolyzable tannin contents would not have been diminished had samples of grasses and conifer needles been included in the chemical and statistical analyses.

The lack of selection for protein and the relatively high average protein contents of both the eaten (17.5%) and uneaten plant samples (15.9%) as compared to the amount of protein used to maintain captive rhesus (16.4%; Greenberg, 1970) indicates that the rhesus may not be protein limited, except possibly in winter when all foods are minimally available (Marks, 1985). In contrast, Glander (1981) found that mean protein content in tree leaves in Costa Rica was only 11% and that leaves eaten by howler monkeys were significantly higher in protein than uneaten leaves. Thus animals may only select for protein when it is limiting in their environment. Water content also showed no relationship to rhesus monkey food choice and was probably not limiting due to abundant precipitation throughout most of the year.

Our results show that food selection by rhesus monkeys in Pakistan is influenced by the presence of hydrolyzable tannins in leaves of both herbs and woody plants. Feeding was negatively correlated with hydrolyzable tannins, total phenolics, and astringency among all samples, but in no cases were condensed tannins related to food choice. These results indicate the importance of measurement of hydrolyzable tannins, astringency, and total phenolics in addition to condensed tannins in future studies of the effects of tannins on food choice by animals feeding on dicotyledonous plants. Although nutrients may have influenced the selection of individual items (e.g., in important foods, see Table 1), nutrients showed no overall relationship to feeding by rhesus monkeys and may not have been limiting in the environment. This premise was not fully tested, however, because several important food items were not collected and because the abundance of food items was not sufficiently quantified (only the abundance of common trees was measured, and the abundance of individual plant parts was not quantified). We suggest that in future studies of this type, collection of samples of all major food items and more complete measures of food abundance will facilitate a more accurate characterization of the important factors in herbivore food choice.

(Received September 24, 1986; accepted January 22, 1987)

Abstract—Reactions of lesser peachtree borer [*Synanthedon pictipes* (G&R)] to volatiles of peach wood, either natural or chemically fractionated, were observed. Mated females were stimulated by and responsive to such materials and deposited significantly more eggs on substrates, including unnatural hosts, that had been treated with aqueous mixtures of bark-canker materials. Stimulation to oviposit occurred even when the female was blinded, indicating the presence of chemical cues. Natural canker–bark extracts immediately stimulated ovipostion and for a few hours significantly increased the number of eggs laid. However, average fecundity was not increased. Antennectomy did not significantly decrease response to volatiles by gravid females, and alternate sites of such chemoreception were not located. Complex mixtures derived by solvent extraction, steam distillation, and volatiles trapping from bark, canker, and gum all had activity. Observations of insect behavior in outdoor cages and also in the laboratory indicated that visual, chemosensory, and mechanosensory receptors are involved in host finding and oviposition.

Key Words—Attractants, extracted volatile compounds, *Synanthedon pictipes*, Lepidoptera, Sesiidae, chemosensory, insect behavior, oviposition, mechanosensory, host-insect interactions, olfactory receptors, oviposition behavior, apple, peach, pear, plant odors, *Prunus* spp.

INTRODUCTION

In recent years, research on elucidation of insect–host interactions has included ovipositional responses of gravid females to their hosts. This relationship is crucial in most insect–plant interactions, but unfortunately it is sometimes difficult to establish and is the least understood relationship involved in such interactions (Stadler, 1983). It is generally accepted that chemical cues may invoke both long- and short-range orientation by the ovipositing female to the host. The distinction between feeding and ovipositional stimulation is often obscure, as exemplified by the dipteran pests (*Liriomyea* spp.). Fortunately, in studying nonfeeding lepidopterous females this problem is not encountered. However, with such females, moisture may become extremely important in their host-seeking (Saxena and Goyal, 1978). Another issue that needs clarification is the distinction between ovipositional stimulation and ovipositional attraction. Although these functions are not necessarily mutually exclusive (Brown et al., 1970), a chemical attractant may not stimulate oviposition, and, conversely, a stimulant may not attract.

The lesser peachtree borer, *Synanthedon pictipes* (G&R) (LPTB), is an important pest of peaches and cherries in most production areas. The host range of LPTB consists of the genus *Prunus*; it may therefore be considered a restricted feeder, thus requiring fairly specific host-finding mechanisms. Females tend to oviposit on roughened bark of healthy trees near wounds where fresh gum is present (Bobb, 1959). Neonate larvae utilize light, chemotaxes, and thigmotaxes as cues in an active search for entry into the bark (Wiener and Norris, 1982). The reproductive behavior of adult Sesiidae females has been reported by Girault (1907), King (1917), Bobb (1959), and Cleveland et al. (1968), but the chemical relationships between the mated female and her host plants have not been defined. Observations have generally concluded that females are markedly attracted to the gummy deposits on peach wood that originate from cankers formed by cold damage, *Cytospora* sp. fungi, or mechanical injuries. A chemical isolated from peach bark, larval frass, and gum mixtures was reported by Gentry and Wells (1982) to be attractive to gravid females of peachtree borer, *S. exitiosa* (Say). Since *S. exitiosa* and *S. pictipes* are congeneric species, some commonality in such behavior might be expected.

Our research was conducted to quantify the attractancy of gravid LPTB females to components of peach bark and to determine if such components stimulate oviposition or increase fecundity. This paper presents the results of our attempts to isolate and identify such components and to record the ovipositional behavior of LPTB in the laboratory and field at Vincennes, Indiana, Peoria, Illinois, and Delaware, Ohio.

METHODS AND MATERIALS

LPTB was reared using the methods of Cleveland et al. (1968). Newly mated females were maintained in screen cages on damp sand at 10°C until used in experiments, either the same or the next day. Various parameters of response were determined in preliminary experiments. For experiments utilizing natural canker and gum, the cankerous areas on either Cresthaven or Redskin peach trees were removed by cutting both sides and ends of the canker and scraping bark, canker, gum and debris from the entire area. Gum was isolated by carefully selecting debris-free material. Healthy bark used as check material was peeled from 10- to 15-cm-diam. limbs from the same trees. All test materials were maintained in sealed plastic bags at 4 ± 1°C until used. Materials for scanning electron microscopy were mounted on aluminum stubs with conductive cement and sputter-coated (model Hummer V, Technics, Springfield, Virginia) with 500 Å of gold. SEM observations were performed with a Hitachi model S-500 (Mountainview, California) at 20 KV accelerating voltage.

Chemical Cues Experiment. Small branches (2.5 × 25 cm), cut from pear trees (a LPTB nonhost) and from peach trees (a host) were presented to LPTB adult females in 50 × 50 × 50-cm screen cages in an air-conditioned greenhouse. In test 1, branch ends were impaled by nails to a 35 × 35-cm board and exposed to 10 gravid females. Pear branches were coated with aqueous canker–gum mixtures and tested in comparison to nontreated (clean) pear branches and water wicks. In test 2, peach wood was similarily treated and exposed to LPTB. The board was rotated periodically to ensure equal environmental exposure of each treatment. The test was replicated six times and data were submitted to analysis of variance.

Visual Cues Experiments. In test 1, to determine the role that sight may play in host response, latex paint was applied to both compound eyes of 10 mated females. No adverse effects of the paint treatment upon the insects was noted. These treated insects were placed into a 30 × 30 × 30-cm screen cage which contained one peach branch (10 × 2 cm), treated with an aqueous canker–gum–bark mixture from Redskin peach trees, and one pear branch the same size. A duplicate cage was used with 10 control (nonpainted) females. Behavior and egg deposition were observed in both cages for 6 hr.

In Test 2, females, either normal or blinded with latex paint, were caged with apple, pear, and peach branches (10 × 2 cm). The canker–gum–bark mixture was layered onto a moist cotton pad placed beneath the branches but inaccessible to the insects. The cages consisted of 3.78-liter ice-cream cartons (20 × 18 cm) with the middle of the carton removed and replaced with screenwire. A screen bottom separated the cotton pad 5 cm from the rest of the cage.

Treated cages as well as controls without the canker material consisted of three replications of three insects. After log transformation, 24-hr egg counts were submitted to analysis of variance and Duncan's (1955) multiple-range test.

Ovipositional Stimulation Experiments. Two other types of tests were conducted to determine if peachwood canker or gum might actively stimulate oviposition or increase fecundity. In the first experiment, air from the exhaust of an air compressor was passed through flasks containing aqueous suspensions of either canker material, gum, healthy bark, or distilled water. The volatile-laden air immediately flowed into four 13.5 × 10.5 × 3.5-cm plastic sweater boxes containing exhaust ports in the opposite ends. The boxes were layered with 2-cm-thick cotton batting saturated with distilled water. Twelve females, eclosed and mated the same day, were introduced into each box, and the eggs that were deposited on either the cotton or the box were counted after 24 hr in one series of tests and 48 hr in a second series of tests.

Another experiment was conducted in individual plastic 100-ml cups (6.5 × 6 cm) with copper screen covers. Aqueous canker material (0.5 ml) was applied to the center of a 1-cm layer of moist cotton either on top of the cotton so that the insects could contact it or inverted so that the material was not accessible either tactilely or visually to the insects although they were exposed to volatiles. Each treatment was replicated 25 times; moist cotton pads were used as controls. Surgically altered LPTB females were used as subtreatments consisting of five replicate Latin-square arrangements as follows: (1) normal mated female, (2) mated female with one antenna removed at base of pedicel, (3) mated female with both antennae removed, (4) mated female with both antennae three-fourths removed, and (5) mated female with tip of hypopharnyx removed. Cups were maintained in an air-conditioned greenhouse at 85 ± 5°C and 75 ± 10% relative humidity. Eggs were counted at 24-hr intervals for 72 hr. The entire test was replicated on each of five dates, and the mean number of eggs per test was submitted to analysis of variance after log transformation using the individual tests as replicates. A similar test was conducted and 80% confidence levels were computed for egg production at 5-, 24-, and 48-hr intervals to determine if the canker extracts might cause more immediate effects.

Behavior in Outdoor Cages. A 1.8 × 1.8 × 2.4-m screen cage was constructed for outdoor observations of LPTB behavior. Peach branches of various sizes and shapes, with and without foliage, were suspended at a height of 1.5-m in the four quadrants of the cage into which 10 mated females were released. Observations were made only on sunny, warm days since LPTB females were found to be unresponsive under other conditions. Females were observed for ovipositional movements and egg deposition.

A large 6 × 2.5 × 2.5-m cage was constructed over two peach trees (var. Cresthaven) in a peach orchard located at Southwestern Indiana Purdue Agri-

cultural Center, north of Vincennes. One tree was spot treated with 2-chloroethylphosphonic acid (Union Carbide Corp.) to promote gum formation. After two weeks, copious gum production around the treated portions of the trunk and limbs and a general weakening of the tree was apparent with some shedding of foliage. Varying numbers of gravid LPTB females were released from the middle of the cage, and the females were observed for periods varying from 1 to 6 hr. Behavior and egg deposition were observed.

A replicated experiment was conducted in which a 2-cm-thick peach branch was divided into four 8-cm sections and placed in the four quadrants of the small cage containing 12 females which were replaced on three consecutive days. Treatments consisted of (1) a smooth branch section, (2) an identical section with canker–gum mixture applied, (3) a section with one small (0.5 cm) new canker, and (4) a section with one large (1.5 × 0.5 cm) older canker. After log transformation, total egg numbers were submitted to analysis of variance and Duncan's (1955) multiple-range test.

Olfactometer Experiments with Natural Canker Materials. To quantify LPTB ovipositional behavior, we devised an olfactometer from a 50 × 5.5-cm glass tube. One end was closed with a cork containing a length of 0.5-cm latex tubing leading to a vacuum pump which was exhausted outside. The other end of the glass tube was corked with a rubber stopper modified to hold a screen cage (8.5 × 4 cm) in which the test insect was confined inside the tube during testing. Air from outside the laboratory was drawn through a charcoal filter into a glass sample chamber and finally into the olfactometer. The sample chamber contained a filter paper strip (2 × 0.5 cm) on which a drop (generally 0.01–0.02 ml) of test material was placed. Air flow was adjusted to 0.1–0.3 m/sec and the temperature was maintained at 18 ± 2°C. A fluorescent desk lamp was positioned directly over the insect holding cage of the olfactometer. A single insect was placed in the cage which was then attached to the front rubber stopper and inserted into the chamber. The insect was allowed to acclimate to the air flow for 30 sec prior to inserting the treated filter paper strip into the air flow. Reactions were observed and recorded for at least 1 min. Strong ovipositional thrusts with the ovipositor were considered positive responses. Five insects were used for each observation. Insects were maintained overnight on damp sand at 10°C and were used only one or two times during one days' observations.

In one experiment, females, surgically altered in a manner similar to those in the ovipositional stimulation experiment, were exposed to natural volatiles from canker material in the olfactometer in an attempt to determine the location of chemoreceptors. Response was tabulated according to abdominal movement, and subsequent egg deposition in plastic cups layered in cotton (Cleveland et al., 1968) was recorded for each insect.

Olfactometer Experiments with Materials Isolated from Canker and Bark.

To collect volatiles from bark, peachwood bark (var. Redskin and Bisco) was collected in the spring of 1982 and frozen dry at −18°C. These materials (ca. 1.0 kg from each variety) were ground in a Wiley mill; the ground bark was placed in a 40 × 60-cm plastic bag that had been outfitted for collection of volatiles. Nitrogen, at a flow rate of 1 liter/min, was used to sweep volatiles onto 1 × 8-cm Tenax columns. Collections proceeded for 4.5 days, but were interrupted each night, when the bark was refrozen. A new trap with fresh Tenax was used each day. The traps were eluted with 10 ml of acetone to remove condensed moisture and then with 50 ml of diethyl ether. Washings were combined, and the solvent was concentrated by distillation through a 1 × 30-cm Vigreux column. Residual acetone was codistilled with pentane, leaving the sample in 10 ml of pentane (fraction 1). Portions (200 g) of the ground Redskin and Bisco peach bark after volatile collection were stirred for 2 hr each with three 500- to 600-ml portions of distilled water at room temperature. After a brief settling period, the water was decanted through glass wool to remove most suspended materials. The fine particles remaining were allowed to settle out overnight under refrigeration. The decanted aqueous extract was subjected to a continuous extraction with diethyl ether for 18 hr, and the ether extract was concentrated by distillation through a 1 × 30-cm Vigreux column. Residual ether was codistilled with pentane to provide 10 ml of fraction 2. A portion of the ether-extracted material was insoluble in pentane, so it was dissolved in 10 ml of acetone (fraction 3).

For fractionation of gum and canker, samples (ca. 3–4 kg total) were collected from Redskin peach trees on July 29, 1982, at Vincennes, placed together in a carboy and immediately covered with dichloromethane. The carboy and contents were transported to Peoria and stored at 4°C. After a month, the contents of the carboy were mixed thoroughly, and a 5-ml sample of the dischloromethane solution was removed and served as fraction 4. Gum and cankers (21 g) were cut into 2- to 5-mm sections and then Soxhlet extracted for 3 hr with acetone. The residue was air-dried, ground finely in a mortar, and reextracted with acetone for 7 hr. The combined extracts were concentrated to ca. 20 ml on a rotary evaporator at 40°C, and the concentrate was divided into two equal portions (one portion = fraction 5). The remaining portion was subjected to azeotropic distillation with absolute ethanol on a rotary evaporator at 40°C to remove water, then the ethanol was removed with dichloromethane, and the sample (fraction 6) was redissolved in 10 ml of acetone.

A second portion of gum and canker material (20 g) was chopped and then stirred with 500 ml of distilled water at room temperature for 4 hr. The water extract was decanted and subjected to a 3-hr simultaneous steam distillation–extraction using a Likens-Nickerson apparatus with dichloromethane as the extracting solvent at ambient pressure (Likens and Nickerson, 1964). Dichloromethane was codistilled with pentane, thus giving fraction 7 for assay.

Finally, a third portion of gum and canker material (20 g) was chopped and then stirred with 200 ml of distilled water at room temperature for 4 hr. The total slurry was extracted in a separatory funnel with diethyl ether–ethyl acetate (1 : 1) to give fraction 8 after distillation of the solvent. Samples were sealed in ampules until assayed against gravid LPTB females.

Cytospora *Experiment.* Cankerous lesions on peach trees, which are known to be attractive to ovipositing LPTB, are usually associated with fungal pathogens. Swift (1986) reported that cankers associated with *Cytospora* were infested with LPTB earlier and to a greater extent than uninfected wounds. He suggested that the *Cytospora* may have caused a physical alteration of the wounds making them more suitable for egg deposition and larval invasion. The most important organism causing such cankers, *Cytospora cincta* Sacc., was cultured on potato–dextrose–agar, and aqueous washes of the cultures were exposed to LPTB females in the olfactometer to determine whether it played a role in host specificity of LPTB.

RESULTS AND DISCUSSION

Chemical Cue Experiment. Observations of LPTB behavior in cages showed that more eggs were deposited on branches that were coated with extracts of gummy, cankerous peachwood bark. Pearwood, a nonhost of LPTB, became attractive when peach canker material was applied to it. In a 6-hr observation of branches impaled on nails exposed to LPTB females (test 1), significant differences ($P = 0.01$) were observed. Pearwood alone received 11% (SE = 1.6) of total eggs, while identical pearwood with canker material on it received 82% (SE = 10.7), and a water wick control had 7% (SE = 1.2) of total eggs. When peach wood was exposed in a similar test (test 2), wood with canker material received 82% (SE = 16.1), while wood without such material had only 14% (SE = 5.9) of total eggs, and a water wick check had 4% (SE = 1.3). In these experiments, some eggs were always deposited on unnatural hosts such as the pear wood or moist cotton. This may have been due to a concentration of volatile molecules from the treated ar.. causing stimulation of females resting on these sites. However, some indiscriminate egg-laying may be expected from laboratory-reared LPTB, since they normally oviposit on moist cotton without the presence of host stimuli.

Visual Cue Experiments. In test 1, blinded females immediately responded and began ovipositional movements in the presence of peach and pear wood. They moved about the cage and, upon encountering the branches, would oviposit. After 6 hr, an average of 13.9 eggs per blind female had been laid, with 70% on peach and 30% on pear. Normal females had laid 21.0 eggs per female with 98% on peach and only 2% on pear.

Results of test 2, in which normal and blind females were exposed to three different types of wood with and without stimulation by canker extracts, are shown in Table 1. When no canker was present, normal females oviposited almost exclusively on peach wood. However, in the presence of strongly attractive canker material, peach was not preferred over apple but was preferred over pear. In this experiment, the numbers of eggs deposited by normal females were greater where additional canker material was not present, although the difference was not significant. It is not known whether the greater egg deposition was due to a few particularly fecund individuals or to the presence of inhibitory volatiles in high concentrations of canker material. Blind females in canker-saturated environments indiscriminately desposited eggs on all three substrates, but apple apparently corresponded more closely to peach than pear in stimulating tactile response from LPTB. It was observed that blind females were strongly responsive to the canker material. When blind females were stimulated, then placed upon an apple branch, they immediately began probing with their ovipositor. Unstimulated blind females ordinarily remained docile. Since eggs are desposited on such nonhosts by blind insects, it would seem logical that the sensory hairs present on the ovipositor (Figure 1) were mechanoreceptors rather than chemoreceptors. Since no transmission electron microscopic examinations were made, it is unknown how either the long (± 100 μm) or the short (1.0–1.5 μm) structures are innervated. In these observations, there was never any evidence of chemoreception by the ovipositor. However, in the presence of a strong enough stimulus, even a normal female will oviposit on apple or pear. Normal females lay a much higher percentage of eggs on the wood than on cotton (75:25), than blind females do (16:84). This is an indication that sight does have some significance, as well as that blind females may ovi-

posit indiscriminately in the presence of stimuli. Another indication of the importance of sight is the observation that while normal females are stimulated and will follow a canker source in still air, blind females, although stimulated, will not follow such a source.

Ovipositional Stimulation Experiments. Preliminary observations showed that females placed in closed Petri dishes were inactive and did not oviposit in the presence of peach canker material. However, after removal of the tops and replacement with screen covers, abdominal responses began immediately. It is unknown whether the observed lack of response in closed dishes was due to habituation, to a repellent in the chemical, or to other causes. After exposure to air, females in the treated dish laid 166 eggs compared with only 72 in the untreated dish (18 hr). This led to the hypothesis that fecundity of LPTB increased in the presence of canker material. This hypothesis, however, was rejected after examination of the data from the experiments in which ovipositing LPTB females were exposed to volatiles from canker, gum, and bark of peach. In the first experiment, in which air was bubbled through aqueous substrates into a plastic oviposition chamber, mean numbers of eggs per female were lowest in the control chamber, both after 24- and 48-hr observations. However, no significant differences existed among the treatment means.

Plastic cups with screen tops were used to provide a free exchange of air in the second test. A complicating factor in using bioassays such as these with LPTB is the propensity of the colonized female to oviposit on cotton or other substrates where sufficient moisture is present. For this reason, the canker was placed on the under side of the cotton in one set of tests to detect quantitative differences caused by volatile fractions. Results of this test also indicated that no significant differences in egg production occurred either in the presence or absence of canker material or its volatiles. This was true whether the female had been surgically altered or was normal.

Another experiment, again in plastic cups, in which counts of eggs from five females were made at shorter intervals (Figure 2), indicated that a significant effect was produced by the canker material but also that it was short-lived. The canker apparently stimulated early egg production, but total fecundity was not statistically increased. This observation is in line with other observations in the laboratory and field and indicates that the canker material not only attracts mated female LPTB, but also stimulates oviposition to some degree. However, the fact that unstimulated insects will oviposit in the presence of moisture complicates interpretation of these data.

Behavior in Outdoor Cages. The behavior of gravid LPTB females was observed inside a small cage in the presence of various peachwood substrates. Several interesting observations were made which may aid in understanding ovipositional behavior in the field: (1) There was no attraction to peach foliage even on hot, sunny days. (2) Most oviposition occurred on rough areas of the

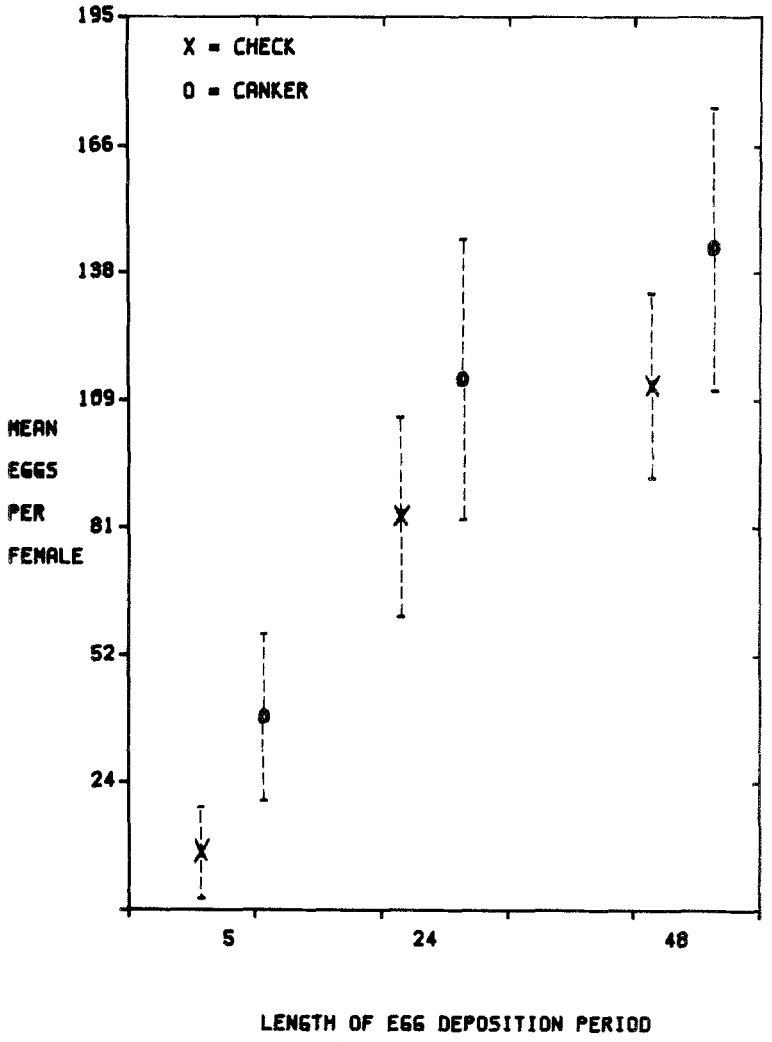

FIG. 2. Egg production of mated LPTB in the presence of host volatiles over time after mating.

bark. (3) Branches less than ca. 1 cm, even with canker extract on them, were not attractive for oviposition. (4) Branches with natural cankers were extremely attractive. (5) Although excised canker material would attract females to a substrate, oviposition upon that substrate seemed to depend on the texture. Thus, in the field, chemosensory and mechanosensory receptors as well as vision, function in the act of oviposition.

Observations in the large field cage were made on warm, sunny days because females would rarely fly on overcast days, and on windy days, they became lost in the grass. Females exhibited a high degree of attraction to sunny areas of the cage, preferring to rest on the side of the cage or tops of the trees in direct sunlight. When released in the center of the cage between the treated and untreated tree, they would usually orient toward the treated tree with the copious gum deposits, although the attraction to light seemed to be greater than attraction to either tree. When greater numbers of females (>50) were released, some could readily be located in the treated tree and, more rarely, in the untreated tree. The untreated tree had more foliage, which may have provided more hiding places, but ovipositing females were found much more often on the treated tree. Once the females alighted on the tree, they were immediately stimulated and walked around on the branches (usually the larger branches and trunk) with their abdomens dragging until they located a site that was sufficiently rough to oviposit. The rougher bark and canker areas invariably received more eggs than smoother areas. Much exploring of the cracks and crevices was made with the ovipositor prior to oviposition. The setae present on this organ (Figure 1) must function to locate the most strategic position for eggs after chemoreceptors have led the female to the proper site. These observations indicate that olfaction, as with many other insect species, is important for close-range identification of a suitable host by LPTB.

Results of the replicated experiment using a segment branch are presented in Table 2. The branch section containing a large, older canker received significantly more eggs ($P = 0.05$) than one with canker material applied, and also had significantly more eggs ($P = 0.01$) deposited on it than sections with no added material or with only a small canker.

Olfactometer Experiments with Natural Canker Materials. LPBT females exhibit a definite typical response pattern when stimulated by volatiles from natural canker material. This includes antennal movement, followed by a downward arching of the posterior abdomen with associated ovipositional thrusts of

the ovipositor. This behavior does not occur when either virgin females or males are exposed to such volatiles. Results of the test to attempt to determine the location of chemosensory structures on the LPTB are shown in Table 3. Unfortunately, we were unable to determine sensory sites since olfactory-mediated excitement was obtained no matter which type of surgery was applied. Even complete antennectomy failed to suppress ovipositional movements in the presence of stimulatory materials. Since the antennectomy retained the scape of the antennae, we thought that enough sensory receptors may have been present there to invoke response. However, coating these structures with fingernail polish did not cause further suppression of response. Using another lepidopterous insect, *Plodia interpunctella* HBN., Deseo (1976) found that, following 50% antennectomy, olfactory stimuli which ordinarily increased fecundity lost their effect, and fecundity became the same as if there were no stimulation. This indicated that the chemoreceptors involved in oviposition were located on the distal half of the antennae. Similarly, Yamamoto and Fraenkel (1960) found that oviposition in the tobacco hornworm appeared to be initiated by olfactory stimuli which were completely suppressed by amputation of the antennae.

It is evident from our research that the sensory receptors mediating oviposition only function after mating. However, experiments involving ablation of various parts of the LPTB body reported here, as well as other observations, including tarsal amputation and ablation of tarsal sensilla with acids, failed to determine the sites of such receptors. Stadler (1976) stated that negative results in ablation experiments may not only be the effect of the removed sensory input, but could also be a kind of irritation or reduction in general activity. In our observations, ablation obviously had a detrimental effect upon the insect, but, contrary to expectations, positive rather than negative results were obtained. Whether this may be a result of elimination of inhibitory influences has yet to be determined. In any event, the location of chemoreceptors functioning in ovi-

positional response of LPTB is still unknown, and although the majority of the receptors may reside on the antennae, those present on other parts of the body apparently function in the absence of antennal receptors.

Olfactometer Experiments with Materials Isolated from Canker and Bark. Assays of mixtures obtained by solvent extraction, steam distillation, and volatiles trapping from peach wood and canker–gum materials indicated the extreme difficulty of isolation of the component(s) responsible for ovipositional response. Of the three fractions obtained by steam distillation of peach bark, there was little difference in response to Redskin or Bisco fractions (Table 4). Fractions 1 and 3 both elicited a good ovipositional response, while fraction 2 elicited only a 10% response to Redskin and 20% to Bisco; this was the only variation between the two. Apparently, most of the activity was concentrated in the pentane-insoluble fractions. The Soxhlet-extracted fractions from canker and gum were all active, except fraction 4 which elicited no response. The dichloromethane-extracted fractions showed the least activity, although enough active volatiles were present for stimulation.

Other fractionation procedures utilizing various solvents, collection columns, and distillation procedures were attempted, but all failed to isolate the activity into a recognizable fraction. One problem is that the active molecules apparently excite the LPTB at extremely low concentrations. Behavioral responses such as those employed in these experiments are apparently not suitable for quantitatively distinguishing between fractions when all or most of the fractions contain volatiles that elicit response. For this reason, some of these same materials were assayed with the electroantennogram (EAG) method. Results of these studies (Anderson et al., 1987) indicate that this technique may be more discriminating and probably should be used for primary screening prior to un-

dertaking behavioral assays. Habituation by such active volatiles, as well as repellent or inhibitory effects due to hypernormal concentrations within the bioassay arena, are possibilities, among others, that need exploring.

Cytospora *Experiment.* When extracts of *Cytospora cincta* cultures were presented to gravid LPTB females in the olfactometer, no response was evident. Although LPTB larvae aid in invasion by this organism by producing new openings in host tissue previously sealed off by callus tissue (Hildebrand, 1947), *Cytospora* apparently has no chemical function in attraction of females to host plants or to stimulation of oviposition.

In finding and consuming host plants, insects may draw upon olfaction, vision, mechanoreception, gustation, and perhaps additional signals. The lesser peachtree borer, according to our observations, uses at least the first three signals in varying degrees. The LPTB has a survival advantage in that it may oviposit in the same host tree whence it encloses. However, earlier authors (Girault, 1907; King, 1917) reported that mated females flew from tree to tree, and subsequently observations have confirmed this, but reports of distances flown are sketchy. To some degree, either sight or olfaction or both must be involved in host-finding. Wind-tunnel observations (Reed, unpublished data) show that mated female LPTB will orient upwind and fly 3 m to a source of canker material, indicating that olfaction may be important at some distance. Observations in the greenhouse (Reed, unpublished data) indicate that the female in flight can follow a hand-held source of canker volatiles, attempt to land on it, and oviposit. These observations plus results of the studies reported here indicate that LPBT females rely upon olfaction in host feeding. More research is needed on the aspect of discrimination between olfaction and sight and on determination of distances involved in such relationships. Electrophysiologic procedures may be helpful in elucidation of these relationships. However, it must be recognized that chemoreception of plant chemicals is far more complex than the perception of pheromones (Stadler, 1980).

Acknowledgments—The authors thank Steve Ries, Department of Plant Pathology, University of Illinois, for furnishing the culture of *Cytospora cincta*. We also thank Naomi Tromley, Paula Moriarty, Diana Marchino, and Bruce Zilkowski for their excellent technical assistance throughout all phases of the research. Appreciation is extended to Drs. Erich Stadler, Dale Norris, John Neal, Jr., and Frank Slansky, Jr. for their critical reviews of the manuscript.

VARIABILITY OF CHEMOSENSORY STIMULI WITHIN HONEYBEE (*Apis mellifera*) COLONIES: Differential Conditioning Assay for Discrimination Cues

WAYNE M. GETZ,[1] DOROTHEA BRÜCKNER,[2] and KATHERINE B. SMITH[1]

(Received October 27, 1986; accepted January 26, 1987)

Abstract—Differential training of honeybee workers using the proboscis extension reflex is applied to the problem of evaluating compounds that may potentially provide cues for kin recognition in the honeybee *Apis mellifera*. These cues were obtained by contaminating glass rods and steel needles with different materials found in the hive. In particular it is shown that workers discriminate between: cuticular waxes from different adult workers; eggs from the same and different hives; similar aged larvae within the same hive; and needles contaminated with the Nasonov gland secretions of different adult workers. It appears that some of these differences are due to phenotypic variation among individuals that cannot be directly attributed to environmental factors.

Key Words—Chemosensory cues, olfaction, kin recognition, honeybees, *Apis mellifera*, Hymenoptera, Apidae, differential conditioning, proboscis extension reflex, learning.

INTRODUCTION

Chemicals play a role in mediating kinship interactions in several social insect species (for reviews, see: Breed and Bennett, 1987; Gadagkar, 1985; Gamboa et al., 1986a). Honeybees, for example, are polyandrous and can discriminate within the hive between those individuals that are their full sisters and those that are their maternal half sisters (Frumhoff and Schneider, 1987). The recognition cues appear to have a genetic component (Breed et al., 1985; Getz and

0098-0331/88/0100-0253$06.00/0

Smith, 1983, 1986). It has also been shown that there is sufficient genetic variability in the volatile odors emanating from adult workers so that, using the proboscis extension reflex, workers can be differentially trained to discriminate between groups of adult workers from different patrilines within the same hive (Getz et al., 1986). Preferential rearing results, obtained by Noonan (1985) and Page and Erickson (1984), suggest that nurse bees can assess the relatedness of larvae to themselves. There is even evidence that workers are able to assess the relatedness of eggs or, at least, very young larvae to themselves (Visscher, 1986).

In several other species of social insects, kin and nestmate recognition, mediated by olfactory cues, is also a well-established phenomenon. Questions relating to the origin of these cues—specifically, the relative contributions of environmental sources, gestalt sources (chemicals transferred between individuals), and individual genetic variation—have been addressed in carpenter ants (Carlin and Hölldobler, 1986, 1987; Carlin et al., 1987), fire ants (Obin, 1986), paper wasps (Gamboa et al., 1986a, b), and sweat bees (Buckle and Greenberg, 1981; Smith and Wenzel, 1987). Although we have previously demonstrated that volatile odors contain information that potentially could be used by workers to assess their kinship to other workers (Getz et al., 1986), cues sensed through contact chemoreception appear to be more likely as candidates for recognition of kin (for a discussion of this see Obin, 1986). Inside a crowded hive, volatiles are constantly mingling, and the origin of a particular odor may be masked. On the other hand, it is possible that a worker can readily determine the relative fraction of certain chemicals present in the epicuticle of another individual by placing its antennae on that individual. Evidence suggests that genetic variation in the composition of cuticular waxes of worker honeybees exists (Carlson and Bolten, 1984). In other species of social insects, especially several species of ants (Clement et al., 1987; Morel and Vander Meer, 1987; Obin, 1986), the existence of variation in the cuticular wax components of individuals is well established.

It has been reported that workers use "the colony odour, which adheres to their body" to recognize individuals that belong to the same honeybee colony (Renner, 1960). It has also been demonstrated, using differential conditioning of the proboscis extension reflex, that the olfactory system of worker honeybees is sensitive enough to discriminate between mixtures containing different proportions of the following compounds occurring in the epicuticle of workers: the two fatty acids, un- and dodecanoic acids; and mixtures containing different proportions of the two *n*-alkanes, tri- and pentacosane (Getz and Smith, 1987). Many other chemicals may be implicated in recognition including secretions from the Nasonov and mandibular glands (Breed, 1981; Crewe, 1982; Free and Winder, 1983). Thus the picture is complex, and the role of recognition cues could be context-dependent.

A first step towards understanding the problem of kin recognition within

honeybee colonies is to identify sources of variation in the chemosensory labels of individuals. In the experiments described here, we show how the proboscis extension reflex in honeybees can be used to identify and assay the discrimination of such chemosensory cues. Exactly how an individual can use these cues to assess its relatedness to other individuals, however, is a question that involves some understanding of the honeybee olfactory system and, more generally, how olfactory signals are stored and processed by individuals (for further discussion on this point, see Getz and Chapman, 1986).

METHODS AND MATERIALS

In all experiments the proboscis extension reflex in honeybees was used to differentially condition workers to discriminate between two glass rods or two stainless-steel needles contaminated with various worker secretions and hive products. A total of three hives was used. Each hive was obtained by instrumentally inseminating a dark queen with semen from one dark and one light drone to yield two visually distinguishable worker patrilines: a light patriline and a dark patriline (for more details see Getz et al., 1986). The differential conditioning methodology is modified from Bitterman et al. (1983) and reported in detail in Getz et al. (1986). For the sake of completeness, we summarize the methodology below.

In the late afternoon on the day preceding an experiment, 40–50 workers (primarily foragers) were removed from the hive and harnessed in small brass tubes with their mouthparts, antennae, and legs free to move. They were then fed a 1.5 M sucrose solution until satiated and left overnight in the dark, at room temperature (around 18°C). The following morning, one half to one hour prior to training, each bee was fed several droplets of sucrose solution.

As elucidated in the experiments discussed below, pairs of 50-mm-long, 1-mm-OD, hollow glass rods or pairs of thin steel dissecting needles were used in the differential training experiments. These rods and needles were prepared within an hour of the start of each replicate of an experiment. Depending on the experiment, glass rods were contaminated by rubbing them on various parts of workers of different ages and life stages or areas of comb. Also, the tips of some glass rods were dipped in albumen which then acted as a "glue" to extract eggs from cells. The needles were used in experiments involving Nasonov gland secretions. Each needle was contaminated by rotating its tip in the area of the opening to the Nasonov gland located between the 6th and 7th abdominal tergites of an adult worker. This area was exposed by stretching the abdomen with forceps (for more details see Pickett et al., 1980). With the exception of experiment 7 described below, care was taken that the needles did not touch any part of the bee other than Nasonov gland area.

Individual bees were differentially conditioned to respond (by extending their proboscides; see Bitterman et al., 1983) to one of two contaminated rods

or needles. Stimulation was achieved by touching a rod to both antennae. The positive conditioned stimulus (CS+) was rewarded with 1.5 M sucrose solution as a positive unconditioned stimulus (US+). The latter was given as a droplet to the bee to drink immediately after a 3-sec application of the CS+ (if the proboscis had not been extended, extension was elicited by touching the antenna with the same solution). The negative conditioned stimulus (CS−) was unrewarded and, if the proboscis was extended upon stimulation, a drop of 1.0 M solution of sodium chloride was placed on the proboscis as a negative unconditioned stimulus (US−) (for more details see Getz et al., 1986).

In each experiment, approximately 30 bees were differentially conditioned to two different rods by presenting one or other of these rods in a sequence of 16 trials. This conditioning was carried out by placing each test bee in turn on a platform below an air exhaust system approximately every 10 min and stimulating it with the CS+ (using the appropriate rod or needle) and the associated US+ or the CS− and, when necessary, the associated US−. The stimuli were presented in the following order (the indicated division into two eight-trial groups is only for the purposes of data analysis):

16 trial sequence

$$= \begin{cases} \text{Trial (training):} & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ \text{CS:} & + & - & - & + & - & + & + & - \\ \\ \text{Trial (evaluation):} & 9 & 10 & 11 & 12 & 13 & 14 & 15 & 16 \\ \text{CS:} & + & - & - & + & - & + & + & - \end{cases}$$

Data were obtained by scoring the number of errors that an individual bee made during trials 9–16 (evaluation sequence). Thus, responses (extension of the proboscis) to any of trials 10, 11, 13, or 16, or nonresponses to any of trials 9, 12, 14, or 15 were scored as errors. Each individual could thus make 0–8 errors and an error histogram and average error $\bar{e}$ could be calculated for each group. The distribution of errors in these histograms can be compared using an $n \times 2$ chi-squared contingency table analysis, where the value of n depends on whether the tail categories of the histograms need to be combined to meet minimum expected frequency criteria (for more details see Getz et al., 1986).

The following experiments were conducted using pairs of glass rods. The number of times each experiment was repeated is noted in parentheses.

Experiment 1. (A) Each rod was rubbed on the cuticle of the dorsal surface of the thorax of a different forager from the same hive (not repeated). (B) As a no-discrimination control for the above experiment, each rod was rubbed on the cuticle of the dorsal surface of the thorax of the same forager (two replicates). (C) As a discrimination control for the above experiment, one rod was uncontaminated and the other rod was rubbed on the cuticle of the dorsal surface of the thorax of a forager (not repeated).

Experiment 2. (A) Each rod was rubbed on the cuticle of the dorsal surface of the thorax of a different newly eclosed worker (both workers were removed from cells just prior to eclosion—see Getz and Smith, 1986 for details) (two replicates). (B) As a control for the above experiment, each rod was rubbed around the inner surface of a different cell (two replicates).

Experiment 3. (A) Each rod was pushed into the center of a different cell containing a curled 5-day-old larva (avoiding any type of injury to the larva) (two replicates). (B) As a control for the above experiment, each rod was dipped into a different cell containing a globule of food provisioned by the workers (two replicates).

Experiment 4. (A) Each rod was tipped with wetted albumen (as a glue) and was used to remove an egg from a cell, where both eggs came from the same hive (four replicates). Note that, as far as was possible, eggs were selected from contiguous cells to increase the probability that they were of similar age. (B) As a control for the above experiment, the same procedure was repeated except the eggs were from different hives (three replicates).

Experiment 5. To obtain a baseline error level for the above discrimination experiments, one rod was contaminated with paraffin wax and the other with beeswax (not repeated).

The workers and material used to contaminate rods in the above experiments all came from the same hive, except for one of the rods in each replicate of experiment 4B which required the use of a second hive. A third hive set up from the same genetic stock as the first two provided bees for the following Nasonov gland secretion experiments which used pairs of steel needles rather than glass rods.

Experiment 6. (A) Each needle was rotated in the exposed Nasonov gland area of a different individual forager, where both individuals were from the same hive (two replicates). (B) As a discrimination control for the above experiment, one needle was contaminated with Nasonov gland secretion while the other was not (cf. experiment 1C) (not repeated).

Experiment 7. As in 6A, each needle was first rotated in the exposed Nasonov gland area of a different individual, but then was also rubbed on the upper thorax of that same worker. Both individuals were from the same hive (cf. experiment 1A) (not repeated).

Note that the designations FS and HS are used in the Results section below to indicate whether a particular replicate of one of the experiments 1A, 2A or 6A involved full or half sisters, respectively.

RESULTS

The sample size and average error over the eight-trial evaluation sequence (see Methods and Materials) are given in Table 1 for each replicate of each experiment. The largest values for the average error $\bar{e}$ were obtained for the no-

TABLE 1. SUMMARY OF RESULTS[a]

Expt. No.	Brief description	Rep. No.	CS+	CS−	Test group size (N)	Average number of errors ($\bar{e}$)
1A	Different foragers	i	Thorax (FS[b])	Thorax	25	3.2
		ii	Thorax (HS[b])	Thorax	32	3.4
B	Same forager	i		Thorax	29	4.6
		ii		Thorax	29	4.4
C	Control	i	Clean rod	Thorax	16	2.1
		ii	Thorax	Clean rod	17	1.5
2A	Different eclosing workers	i	Thorax (HS)	Thorax	35	3.5
		ii	Thorax (FS)	Thorax	31	3.9
B	Different cells	i	Cell 1	Cell 2	35	4.2
		ii	Cell 1	Cell 2	39	4.1
3A	Different larvae	i	Larva 1	Larva 2	35	1.9
		ii	Larva 1	Larva 2	32	2.8

B	Different larval food	i	Cell 1	Cell 2	35	3.9
		ii	Cell 1	Cell 2	38	3.9
4A	Eggs from same hive	i	Egg 1	Egg 2	22	3.1
		ii	Egg 1	Egg 2	21	3.0
		iii	Egg 1	Egg 2	24	4.0
		iv	Egg 1	Egg 2	21	3.9
B	Eggs from different hives	i	Egg 1	Egg 2	26	3.8
		ii	Egg 1	Egg 2	23	3.6
		iii	Egg 1	Egg 2	19	3.4
5	Control[c]	i	Paraffin	Beeswax	12	1.7
		ii	Beeswax	Paraffin	13	0.4
6A	Different workers	i	Nasonov (HS)	Nasonov	29	4.2
		ii	Nasonov (HS)	Nasonov	30	3.7
B	Control		Nasonov	Clean needle	26	0.5
7	Combination		Nasonov plus thorax (HS)	Nasonov plus thorax	30	3.5

[a]The significance of these results is discussed in the text.
[b]FS and HS denote whether the two individuals are full sisters or maternal half sisters, respectively.
[c]Both replicates are actually the same run of an experiment in which the test bees have been split in two groups, each receiving the mirror image treatment with regard to the CS+ and CS− stimuli.

discrimination control experiment (1B), where the error combined across both replicates is $\bar{e} = 4.5$ ($n = 58$). The lowest values for $\bar{e}$ were obtained for the discrimination control experiments (1C, 5, 6B), especially for the runs beeswax vs. paraffin ($\bar{e} = 0.4$) and Nasonov vs. clean needle ($\bar{e} = 0.5$). Note from experiments 1C and 5 that there appears to be an asymmetry in the results based on which of the stimuli are used as the CS+ and CS−. In experiment 1C, discrimination is stronger (that is, $\bar{e}$ is smaller) when the contaminated rather than the blank rod is used as the CS+ ($P < 0.01$, 2×2 chi-squared analysis). In experiment 5, discrimination is stronger when the more natural beeswax stimulus is used as the CS+ ($P < 0.05$, 2×2 chi-squared analysis). Thus, in conjunction with our experience in using odor stimuli (unpublished results), it appears that workers are more easily trained to discriminate between two chemosensory stimuli if they are positively conditioned to the stimulus that is either stronger or contextually the more natural of the two than vice versa.

In experiments 1A and 1B, the results from replicates within experiments are very similar, but across experiments the differences between any two replicates are significant, at least at the $P < 0.01$ level (2×4 chi-squared analysis). Furthermore, the results obtained from either replicate of experiment 1A are significantly different from either replicate of experiment 1C, at least at the $P < 0.05$ level (2×3 chi-squared analysis). Thus it follows that workers can perceive differences between rods rubbed on the backs of different foragers but discrimination is not as strong as exhibited by the discrimination control.

Since the replicates in experiment 1B are so similar ($P > 0.95$, 4×2 chi-squared analysis), they can be combined and used as a no-discrimination control for experiment 2A, as well as for the other experiments discussed below. In this case, both replicates exhibit that discrimination has taken place (for example, replicate ii of experiment 2A is significantly different from the no-discrimination control at the level $P < 0.01$, 3×2 chi-squared analysis), albeit not as strongly as obtained in the different foragers experiment 1A. Only the results from replicates i of experiment 1A and ii of experiment 2A are significantly different (in this case $P < 0.01$, 3×2 chi-squared analysis). The results from experiment 2B can be used to assess whether differences in the cuticular waxes of eclosing workers could be due to contaminants picked up from the inside surfaces of cells. Only replicate ii of this experiment differed significantly from the combined no-learning control ($P < 0.05$, 4×2 chi-squared analysis), while only replicate i of experiment 2A differed significantly from both replicates of experiment 2B (in both cases $P < 0.01$, 4×2 chi-squared analysis).

Among all experiments, the level of discrimination between pairs of natural cues was strongest in the different larvae experiment ($P < 0.001$, 4×2 chi-squared analysis for both replicates of experiment 3A when compared with the no-learning control). The results of experiments 3B can be used to assess whether food contaminants influence the larval discrimination results. Although

both replicates of experiment 3B indicate that some level of discrimination is evident with respect to the no-learning control experiment 1B ($P < 0.05$ for replicate i and $P < 0.01$ for replicate ii, 4×2 chi-squared analysis), the level of discrimination is much weaker than in the larval experiment 3A (for any two replicates between experiments 3A and 3B, we have $P < 0.001$, 4×2 chi-squared analysis).

The results across replicates of the discrimination between eggs experiments 4A and 4B are quite variable. Furthermore, there is no evidence for increased discrimination in the case of eggs obtained from different hives compared with the case of eggs obtained from the same hive. In replicates iii and iv of experiment 4A, discrimination is weak but evident when compared with no-learning control experiment 1B ($P < 0.05$ for both replicates, 3×2 chi-squared analysis). However, replicates i and ii of experiment 4A exhibit stronger levels of discrimination than do replicates iii and iv (for example, the results of replicates i and iv are significantly different at $P < 0.05$ while the results of replicates ii and iii are significantly different at $P < 0.001$, 2×2 chi-squared analysis).

From experiments 6A and 6B it is evident that, although honeybee workers experience no difficulties learning to discriminate the Nasonov gland secretion, they do experience some difficulties discriminating between secretions from half sisters in the same hive. A stronger level of discrimination is exhibited in replicate ii when compared with replicate i ($P < 0.05$, 3×2 chi-squared analysis) but, interestingly, little improvement in the level of discrimination is obtained through the addition of cues from the thorax in experiment 7. Note that it is difficult to compare the results from experiments 6A and 7 with 1A since the bees are from different hives, which may affect the level of cue variability among individuals (even though the hives are from the same genetic stock).

DISCUSSION

The results indicate that workers can discriminate between glass rods rubbed over the epicuticle of different foragers irrespective of whether the individuals are full or half sisters. They appear to be able to do the same if the individuals are newly eclosed half sister workers, but possibly to a lesser extent if the newly eclosed workers are full sisters. The difference between cues in the cuticle of eclosing individuals cannot be attributed to contaminants picked up in the cells. One could speculate that newly eclosed full sisters are more similar than half sisters in terms of recognition cues, but they become more distinct through environmental odors acquired as adults. However, the results presented here are too cursory to come to any firm conclusions. A definitive study of this and some of the other questions discussed below would involve testing several

hives, preferably set up with specific genealogies. It would also involve more replicates per hive and perhaps the presentation of stimuli obtained from groups containing different numbers of individuals, as was done in our volatile odor recognition cue study (Getz et al., 1986).

The Nasonov gland secretion also exhibits some variability between individuals, and this variability may be enhanced through additional cuticular wax discrimination. As mentioned in the previous section, the results of experiments 7 and 1A cannot be compared since different hives were used in these experiments. Thus one cannot come to any conclusions relating to additive or synergistic effects of cues. Again, a definitive study involves an extensive amount of experimentation and is required before any concrete conclusions can be reached.

The relatively strong differences in cues produced by different larvae raises some interesting questions. First, these differences cannot be attributed to contamination from the food provisioned for those larvae. The cues, however, may have nothing to do with individual or kin recognition, but may reflect the cues (pheromones) that larvae use to communicate their physiologic state (for example, need for food) to the nurse bees (see Jaycox, 1970; Free and Winder, 1983).

Prior to the experiment, we had anticipated that if workers could discriminate between eggs, then the level of discrimination would be stronger if the eggs come from different hives rather than the same hive. This would be the case, as discussed by Visscher (1986) in interpreting the results of his experiments, if queen pheromone or cues from an environmental source played an important role in labeling eggs. Although discrimination is evident in all replicates of within- and between-hive experiments, the strongest level came from the within-hive replicates. Thus it would appear that some other factors, such as the age of the egg (developmental stage), provide the strongest cues for discrimination. That is not to say that other cues do not exist or, if cues do exist, that they cannot be perceived by the nurse bees.

This raises the general question of what we are able to infer about an individual's ability to discriminate cues by observing its behavior. In the context of discrimination training, failure to observe discrimination does not imply that the test individuals are not detecting differences between two stimuli. This includes the proboscis extension reflex; individuals that are particularly hungry, regardless of any other considerations, may extend their proboscides in the hope of being fed, or some individuals may be able to detect differences but are poor learners. Also, it may be easier to train bees using the proboscis extension reflex if the cues occur naturally in a nectar-gathering context, for example certain floral odors. Finally, if one conducted experiments, such as 7, to assess the combined effects of two sets of cues, then the occurrence of thresholds, saturation effects, hierarchical ordering of information (see Carlin and Hölldobler, 1986), to mention just a few, would obscure what the insect is actually sensing.

CONCLUSION

From the results presented here, it is clear that the proboscis extension reflex can be used to assess the potential of different secretions as a source of labels for kin recognition. The situation is not always straightforward since time-dependent differences in the physiology of individuals, especially in preadult stages, may influence the results. Once a promising systems, such as cuticular waxes in adults, has been identified, then more extensive studies, including the heritability aspects of the labeling system, need to be undertaken.

(Received October 31, 1986; accepted January 27, 1987)

Abstract—Evaluations conducted by placing *Heliothis virescens* (F.) sex pheromone (virelure) dispensers at different distances in the predominant downwind and upwind directions from *Heliothis zea* (Boddie) pheromone traps indicated that reductions in *H. zea* male captures were greatest relative to distance when the *H. zea* traps were located downwind from the virelure dispensers than when the traps were located upwind. When operating traps for both species at the same site, the influence of virelure dispensers on captures in *H. zea* pheromone traps would be minimized by placing the *H. zea* traps upwind of the *H. virescens* traps and, if wind direction is variable, the traps should be spaced at least 75 m apart.

Key Words—Tobacco budworm, cotton bollworm, *Heliothis virescens*, *Heliothis zea*, Lepidoptera, Noctuidae, sex pheromone, virelure, trapping, pheromone interaction.

INTRODUCTION

The identification of the sex pheromone components for the cotton bollworm (BW), *Heliothis zea* (Boddie) (Klun et al., 1980a) and the tobacco budworm (TBW), *Heliothis virescens* (F.) (Klun et al., 1980b) in conjunction with the development of a sex pheromone trap (Hartstack et al., 1979, 1980) for these two important pest species has created greater opportunities for the development of trapping systems for surveillance and prediction as well as for studying the movement of the adults. Since these two pests are frequently found in the same fields, the ideal trapping system would be one in which the same trap could be used for both species; however, considerable research has shown that the pheromones are not compatible for use in the same trap.

Haile et al. (1973) reported that the baiting of electric grid traps with virgin TBW and BW females simultaneously reduced the number of males captured by 24.2% and 77.5%, respectively, when compared with traps baited with one or the other species. At lower densities, the reductions in captures of TBW were not evident, while the reductions in captures of BW were consistently high. As such, there was a stronger and more consistent inhibitory effect of TBW females on BW male captures than vice versa. Roach (1975) reported that baiting pheromone traps with both BW and TBW virgin females resulted in a reduction in the capture of both species as compared to traps baited with only one species. Roach (1975) suggested that some form of behavioral or chemical antagonism existed between the moths or their pheromones when the species were combined. Carpenter et al. (1984) reported that trap captures of BW males were significantly reduced when BW and TBW pheromone or virgin female baits were used together in the same trap but that the presence of BW pheromone in the same trap did not significantly reduce male entrapment of TBW. These studies indicate that when attempting to trap both *Heliothis* species in the same pheromone trap, BW captures were reduced, but TBW captures were not reduced.

Research conducted indicates the cause for this effect. Klun et al. (1980a,b) reported that all four components identified from heptane washes of ovipositors of BW also were found in TBW, but that three additional components were identified in TBW. Klun et al. (1980b) reported that one of these components, (*Z*)-9-tetradecenal (Z9-TDAL), appeared to be a deterrent to BW attraction and that field data indicated that Z9-TDAL had a role in the maintenance of pheromonal specificity in the two species. Shaver et al. (1982) found that very small amounts (0.2–0.37%) of Z9-TDAL reduced captures of BW when mixed with the four components of the BW pheromone in dental rolls. Significant reductions were also observed when Z9-TDAL was formulated in rubber septa with the BW pheromone mixture even at quantities as low as 25 μg/septum when the original pheromone load was 2.5 mg. Shaver et al. (1982) also reported that

(Z)-11-hexadecen-1-ol, another of the components identified from heptane washes of TBW ovipositors but not found in BW, reduced captures of BW, but the amounts needed were larger (1.85–7.50%).

These studies show that one or two components found in TBW and not in BW which contribute to species specificity are responsible for the incompatibility of the two pheromones in the same trap and that the major effect expected would be on BW.

Ample evidence has been cited for the reduction of BW captures in traps baited with both species. However, because of the large effects on BW captures of very small quantities of at least one of the TBW pheromone components, a concern when operating traps baited with sex pheromone of only one species, but when both species are being trapped in the same area, is the distance between traps of the two species needed to minimize the interaction between the two. Since pheromone is windborne, another concern was the influence of wind direction. The results of a study conducted during the 1983 and 1984 growing seasons on the influence of wind direction and distance on the interaction between BW traps and TBW sex pheromone dispensers are reported here.

METHODS AND MATERIALS

The studies were conducted in a corn field located in Burleson County, Texas. A 75–50 wire cone trap (Hartstack et al., 1979) was used with its base maintained at tassel level. Laminated plastic dispensers manufactured by the Hercon Division (Health-Chem Corporation, South Plainfield, New Jersey, which contained all four components in the ratios initially identified (Klun et al., 1980a) at a dose of 1.25 mg of total sex pheromone in a 3.2-cm^2 (2.54 × 1.27 cm) dispenser, were used to bait the BW traps during both years of the study. Two different TBW sex pheromone (virelure) dispensers were used during the two years. In 1983, laminated plastic dispensers, also manufactured by Hercon, containing the two major virelure components at a 16 : 1 ratio at a dose of 20 mg in a 1.6 cm^2 (1.27 × 1.27 cm) dispenser were used. In 1984, black PVC plastic dispensers containing the two major virelure components at a ratio of 14 : 1 at a dose of ca. 6 mg of total pheromone (Hendricks, 1983; Hendricks et al., 1987) were used. The dispensers for both species were replaced every two weeks.

Because alignment of the BW pheromone traps and the virelure dispensers was difficult relative to wind direction, the prevailing wind direction for the time of the growing season when the studies were conducted was determined by compass reading, and this orientation was 168° (SSE) magnetic compass reading for the upwind direction.

To evaluate the downwind effects of virelure dispensers on their captures,

the BW traps were installed 5 m from the edge of the corn field and virelure dispensers were placed initially at 5, 15, and 30 m upwind of them. (Figure 1). Some studies were conducted up to 60 m in 1983. The virelure dispensers were attached to the top of steel reinforcement bars that were 2 m high. The bars were placed in 1.5 m pieces of electrical conduit driven into the ground. The evaluations consisted of four treatments: three different intervals between BW traps and the virelure dispensers and one treatment without virelure dispensers which served as the check. A line of 16 traps with 100 m between traps was used in 1983. The experimental design was a Latin-square in time with the treatments being rotated each night so that each treatment was at each location in each replicate during a four-day period. The rotation involved moving the virelure dispensers to the appropriate distance each night while the traps were kept at the same location. Edge traps baited with BW pheromone dispensers were installed at both ends of the trap line to minimize the edge effects. The same experimental design was used in 1984, except for the 200 m between traps to minimize the possibility of interaction between treatments in adjacent traps and there were no edge traps in the trap line because of insufficient space in the field. The distances studied in 1984 were 5, 50, and 75 m and the check with no virelure dispensers.

The interaction when the BW traps were located upwind of the virelure dispensers was evaluated only in 1983. The BW traps were installed 35 m from the edge of the field, and the distances between the trap and the virelure dispensers were 5, 15, and 30 m. There was a check treatment with no virelure

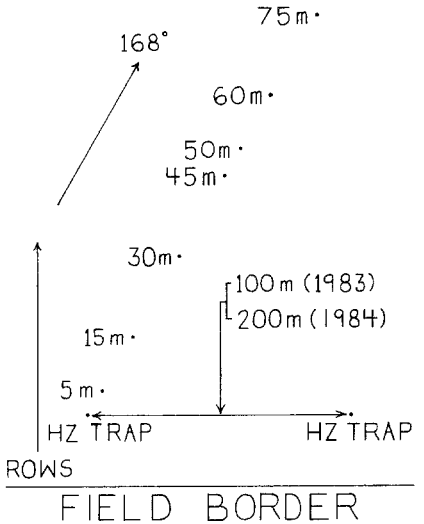

FIG. 1. Downwind array of traps, 1983–1984.

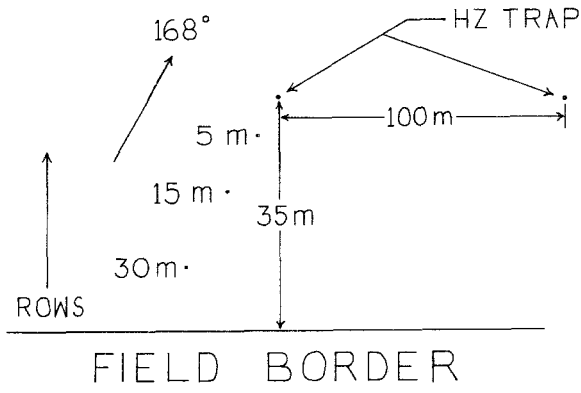

FIG. 2. Upwind array of traps, 1983.

dispensers (Figure 2). The experimental design was the same as for the downwind evaluations. The line of 16 traps spaced 100 m apart was a continuation of the trap line used for the evaluation of downwind effects, and it also had edge traps.

To evaluate the effect of variability in wind direction and speed on the results of the experiments, hourly wind direction and speed readings were obtained from the FAA Flight Service Station at Easterwood Airport, College Station, Texas, located ca. 13.4 km from the field where experiments were conducted. The readings for the period between 10 PM and 1 AM (CST) were used. The wind direction was categorized as being $\pm 90°$, $\pm 45°$, or $\pm 22.5°$ deviation from the 168° wind direction used in the experiments. Wind direction categories were assigned only when there were at least two hourly readings with wind speeds >0 m/sec. Specific categories of wind direction were assigned when at least two readings fell within the smallest wind direction interval. When wind velocity was >0 m/sec only once on any one night, the wind velocity was considered 0 and no wind direction was assigned for that night. Wind direction was not specified when it was not in any of the three categories.

The data were analyzed in four-day intervals necessary to complete the rotations. Analysis of variance was used and the means were compared using Duncan's multiple-range test with $\alpha = 0.05$ through use of the General Linear Models Procedure (SAS Institute, 1982).

RESULTS AND DISCUSSION

Table 1 shows the mean captures of BW males per trap per night during each four-day interval when the BW traps were located 5, 15, and 30 m downwind from the virelure dispensers as compared to captures in check traps with

[b] Data for 7/28 were used in the analysis because there was an error in the rotation of treatments.

no virelure dispensers. Captures were extremely high the first few days of the test and tended to be more stable thereafter. In the first interval for the period July 7–10, 1983, only the 5-m treatment was significantly different from the others. In the next two intervals for the period July 11–18, significant differences in captures were observed between the check, the 30- and 15-m treatments, and the 5-m treatments. When the data for all three intervals were analyzed together, there were significant differences between the check, the 30- and 15-m treatments, and the 5-m treatment. A very large reduction was observed with the 5-m distance. Categorization of wind velocity and direction during the test period (Table 2) indicated that wind direction was within $\pm 22.5°$ of the SSE prevailing wind direction three nights, within $\pm 45°$ on three nights, within $\pm 90°$ on three nights, and from an unspecified direction on three nights.

Since the categorization of wind speed and direction could not be specified for at least the first two nights when BW captures were very high, data from the first two days were dropped and data from two days at the end of the evaluation period were used. For the two nights that were added, the wind direction was within $\pm 22.5°$ of the SSE prevailing wind. Analysis of these data indicated that the differences between treatments were more consistent throughout the evaluation period, and it showed a reduction between the 30-m and the 15-m treatments. Overall, the 5-m treatment caught only about half the number of males captured in the check.

Two intervals in which the 5-m treatment was replaced with a 45-m distance and that were conducted between July 21 and 29, 1983, indicated a significant difference in the captures between the check and the 45- and 30-m treatments. The 15-m treatment was significantly different from the others. During this test period, wind conditions were very good for the evaluation since wind direction was within $\pm 22.5°$ of the SSE prevailing wind direction seven of the eight nights.

Although captures had declined considerably by the time of the last interval (July 30–August 2), in which the 15-m treatment was substituted with a 60-m treatment, the only significant difference observed was between the check and the 30-m treatment, but there was still a trend for a reduction due to the presence of the virelure dispensers. During this period, wind conditions were suitable during two nights and there were two nights when there was no wind.

In 1984, the studies were designed to identify the limits of the interaction when the traps were located downwind from virelure dispensers. The results in each of the three intervals from June 23 to July 4 were consistent with no significant differences observed between the check, 75-m, and 50-m treatments, although all these were significantly different from the 5-m treatment. Analysis of data from all three intervals combined indicated that there was still a tendency for reductions in the mean number of males captured at the 75-m and 50-m distances; however, the reductions were relatively small compared to the 5-m

[c] If there was only one hourly reading with wind speeds >0 m/sec during any one night, the wind speed was considered to be 0 and no wind direction category was assigned.

When the BW traps were located at various distances upwind from virelure dispensers, the effects were less than when the BW traps were located downwind (Table 4). In the first two intervals for the period July 7–14, 1983, no significant differences were observed among the check, 30-m, and 15-m treatments. In the two intervals between July 19 and 26, the only significant difference was between the 5-m treatment and the other treatments. There was a trend for the effect of the virelure dispensers to decrease as the distance increased. The overall results for all five intervals indicated that the only significant difference was between the 5-m distance and the other treatments and showed decreasing effect with increased distance, with both the check and the 30-m treatments being very similar. For the 20-day period of the evaluation, there were three nights when the wind direction exceeded the 90° deviation, three nights with no wind, and nine, two, and three nights, when the wind was within ±22.5°, ±45°, and ±90° of the SSE wind direction, respectively (Table 2).

Reduction of BW captures when the virelure dispensers were located upwind was expected since the wind conveys the the virelure pheromone com-

[a] Means in same column for the same test period followed by the same letter are not significantly different [$\alpha = 0.05$, Duncan's multiple-range test].

ponents downwind and into the area where the BW would be responding to its pheromone, thus disrupting or repelling the males. The virelure components may not have to overlap the pheromone plume from the BW sex pheromone trap to have an effect on reducing captures since the presence of the virelure components may be sufficient to disrupt the BW male searching behavior prior to locating the sex pheromone plume from the trap. When the BW traps were located upwind of the virelure dispensers, the influence of the pheromone components from the dispensers was reduced because the exposure of the BW males to virelure in the trap area would be minimized. In this case, the trap area includes the BW sex pheromone plume as well as the area that searching BW males would have to cross to find the plume from the pheromone trap.

Although these data do not provide an absolute measure of the interaction between BW traps and virelure dispensers relative to wind direction and distance, it does provide some guidelines from which to make initial recommendations relative to the minimum spacing between BW and TBW traps. Since the greatest effects were observed when BW traps were located downwind from virelure dispensers, and the least effect was when they were located upwind, the interaction between the two, at least relative to captures in BW traps, should be minimized by installing the BW traps in a direction upwind from *H. virescens* traps. If wind direction is expected to be variable, the traps should be spaced at least 75 m apart.

RESPONSE OF MOUNTAIN PINE BEETLE, *Dendroctonus ponderosae* HOPKINS, AND PINE ENGRAVER, *Ips pini* (SAY), TO IPSDIENOL IN SOUTHWESTERN BRITISH COLUMBIA[1]

(Received November 15, 1986; accepted January 28, 1987)

Abstract—In bioassays conducted with walking beetles in the laboratory (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol were attractive alone, but reduced the attraction of both sexes of the mountain pine beetle, *Dendroctonus ponderosae* Hopkins, to extracts of female frass. Field trapping studies indicated that attraction of *D. ponderosae* to a stimulus composed of myrcene + *trans*-verbenol + *exo*-brevicomin was significantly reduced with the addition of (±)- and sometimes (*S*)-(+)-ipsdienol. Thus, (*S*)-(+)-ipsdienol produced by males of this species may act as an antiaggregation pheromone. (*S*)-(+)-Ipsdienol is thought to function as a repellent allomone against the pine engraver, *Ips pini* (Say), in regions where *I. pini* utilizes (*R*)-(−)-ipsdienol as an aggregation pheromone. However, in southwestern British Columbia *I. pini* was attracted to the (±)-ipsdienol used in field bioassays of *D. ponderosae*, a finding consistent with the production of both enantiomers by *I. pini* in this region. When presented with the ternary semiochemical bait for *D. ponderosae*, (±)-ipsdienol was not attractive to *I. pini*. Thus, the activity of (*S*)-(+)-ipsdienol as a repellent allomone against *I. pini* seems to be replaced in southwestern British Columbia by the inhibitory effects of myrcene, *trans*-verbenol, *exo*-brevicomin, or some combination thereof.

Key Words—*Dendroctonus ponderosae, Ips pini*, Coleoptera, Scolytidae, pheromone, bark beetle, ipsdienol.

INTRODUCTION

The mountain pine beetle, *Dendroctonus ponderosae* Hopkins, is a destructive forest pest which attacks several species of pine in western North America. These bark beetles mass attack host trees in response to aggregation pheromones and host tree kairomones which are released as the beetles bore into the tree. The female-produced terpene alcohol *trans*-verbenol, in combination with host tree monoterpenes, is partially responsible for the aggregation of *D. ponderosae* (Pitman et al., 1968), while low concentrations of *exo*-brevicomin, produced by males, are also involved (Rudinsky et al., 1974; McKnight, 1979; Conn et al., 1983; Borden et al., 1983).

Once a certain attack density is reached, the attack switches to adjacent trees (McCambridge, 1967; Geiszler and Gara, 1978; Geiszler et al., 1980), preventing the increased competition within hosts and reduced brood survival which occur at overly high attack densities (Reid, 1963). This switching was hypothesized to be due to a decrease in resin flow (Renwick and Vité, 1970), and a decrease in aggregation pheromone production (Pitman and Vité, 1969; Borden et al., 1987), but more likely results from the production of antiaggregation pheromones (Rudinsky et al., 1974; Borden et al., 1987). Several compounds that are produced by *D. ponderosae* have been found to inhibit attraction in laboratory and field tests, and this has led to speculation that they may act as antiaggregation pheromones. These compounds include frontalin (Ryker and Libbey, 1982), *exo*- and *endo*-brevicomin (Ryker and Rudinsky, 1982), verbenone (Ryker and Yandell, 1983), and pinocarvone (Libbey et al., 1985).

Hunt et al. (1986) have shown that male *D. ponderosae* exposed to myrcene vapors produce large quantities of ipsdienol, a compound which Byers (1982) reported as a possible antiaggregation pheromone for the western pine beetle, *Dendroctonus brevicomis* LeConte. Ipsdienol is also the aggregation pheromone of the pine engraver, *Ips pini* (Say) (Birch et al., 1980; Lanier et al., 1980). Moreover, there is pronounced geographic variation in the response of *I. pini* to the enantiomers of ipsdienol (Birch et al., 1980; Lanier et al., 1980). The production of ipsdienol by both *D. ponderosae* and *I. pini* and the sympatric distribution of these species in southwestern British Columbia suggests that this compound may be used in interspecific communication. We report the responses of walking *D. ponderosae* in the laboratory, as well as flying *D. ponderosa* and *I. pini* in the field, to (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol alone and in combination with *trans*-verbenol, *exo*-brevicomin, and the host tree monoterpene myrcene.

METHODS AND MATERIALS

Laboratory Bioassays. Bioassays were performed in a draftfree, darkened room using an open arena olfactometer similar to that described by Borden et

al. (1968). Groups of 10 beetles were released from overturned, 60 × 20-mm disposable Petri dishes, on a 24-cm-diam. filter paper. The release point was 8 cm lateral to and 12 cm downwind of the outlet of an airstream with a flow rate of 1400 ml/min. During the summer of 1984, four or five groups of 10 beetles were used for each treatment, while in 1985 the number was expanded to 100 beetles in groups of 10. A 6-V, 25-W microscope light was placed at the opposite end of the filter paper to draw the photopositive beetles across the airstream. Twenty microliters of a pentane dilution of each test stimulus was deposited on a rolled filter paper (4.25 cm diam.) inside a glass tube (1 cm ID). The glass tube was placed at the outlet of the airstream, which then flowed across the center of the arena perpendicular to the path of the walking beetles. Each group of beetles was allowed 2 min to respond to the test material. A positive response was scored when a beetle walked to within 1 cm of the stimulus source.

The experimental stimuli used in the bioassays were (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol (sources and purities listed in Table 1), each tested at concentrations ranging between 4 and 400,000 ng/20 μl pentane. These same dilutions of (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol were also tested in combination with pentane extracts of frass produced by female *D. ponderosae* boring in lodgepole pine bolts for 24 hr. Control stimuli were pentane and the pentane extract of frass produced by females. The frass extract was tested at a concentration of 0.02 g equivalents when used as a standard or combined with ipsdienol dilutions. The frass standard was used whenever bioassays were being performed to verify that the test beetles were responsive. Tests were not run on days with low barometric pressure as beetles responded poorly on these days. Beetles were kept in disposable Petri dishes at 2–4°C between bioassays but were rewarmed to room temperature 10 min prior to use. Each time a new stimulus was tested, the filter paper arena was changed and the bioassay room was aired out.

Percent positive response data were transformed using the arcsine transformation (Sokal and Rohlf, 1981), and then analyzed by ANOVA and the Newman-Keuls test using SPSS^x (SPSS, 1983).

(*S*)-(+)-Ipsdienol (95% optical purity) and (*R*)-(−)-ipsdienol (98% optical purity) were obtained by kinetic resolution of racemic ipsdienol (Sharpless et al., 1983) utilizing the Sharpless asymmetric epoxidation (Katsuki and Sharpless, 1980) to the extent of 80%. The enantiomeric excesses of the isolated products were determined by capillary gas chromatography of the acetyl-(*S*)-lactyl derivatives as reported by Slessor et al. (1985).

Field Trapping Experiments. All field trapping experiments were done in 1984 and 1985 in lodgepole pine forests near Shinish Cr. Road, approximately 30 km northeast of Princeton, British Columbia. All compounds tested in the field are listed in Table 1, along with the sources, purities, release devices, and release rates.

TABLE 1. SOURCE, PURITY, RELEASE DEVICES, AND RELEASE RATES (AT 22°C IN LABORATORY) FOR MONOTERPENES AND TERPENE ALCOHOLS TESTED FOR ATTRACTANCY TO *D. ponderosae* IN THE FIELD

Compound	Source	Purity[a] (%)	Release device	Approximate release rate (mg/24 hr)
β-Myrcene (M)	Sigma Chem. Co. St. Louis, Missouri	98	Traps: 25 ml polyethylene snap cap vial (closed)	150.00
		85	Trees: two 1.8-ml polyethylene centrifuge tubes (closed)	20.00

[b] (*S*)-(+)- and (*R*)-(−)-ipsdienol resolved from (±) by E. Czyewska, Department of Chemistry, Simon Fraser University.

Trapping experiments were done in a randomized block design using eight-funnel, multiple funnel traps (Lindgren, 1983) placed in lines 25 m apart with 25 m between each trap. Baits were suspended from a wire attached to the third funnel from the bottom of the trap such that the bait was positioned about 1 cm below that funnel. Jars at the bottoms of the traps contained an aqueous solution of approximately 2.5 ml/liter of Liqui-nox detergent (Alconox Inc., New York, New York) to decrease surface tension and kill trapped insects, and 40 mg/liter of sodium azide to inhibit microbial growth; beetles were collected from these jars and preserved in 90% ethanol prior to being counted and their sex determined.

In 1984, eight replicates were performed of the following bait treatments: (1) myrcene + *trans*-verbenol + *exo*-brevicomin + high release rate (±)-ipsdienol; (2) myrcene + *trans*-verbenol + *exo*-brevicomin + low release rate (±)-ipsdienol; (3) myrcene + *trans*-verbenol + *exo*-brevicomin; (4) high release rate (±)-ipsdienol; (5) low release rate (±)-ipsdienol; and (6) unbaited control.

In 1985, 12 replicates were performed of the following bait treatments: (1) myrcene + *trans*-verbenol + *exo*-brevicomin + (±)-ipsdienol; (2) myrcene + *trans*-verbenol + *exo*-brevicomin + (*S*)-(+)-ipsdienol; (3) myrcene + *trans*-verbenol + *exo*-brevicomin + (*R*)-(−)-ipsdienol; (4) myrcene + *trans*-verbenol + *exo*-brevicomin; (5) (±)-ipsdienol; (6) (*S*)-(+)-ipsdienol; (7) (*R*)-(−)-ipsdienol; and (8) unbaited control.

One experiment of two days duration was conducted in 1984 and, in 1985, three experiments each of three days duration were conducted with baits re-randomized after each experiment.

Tests for homogeneity of variances were performed on the numbers of beetles caught using Cochran's *C* test as well as the Bartlett-Box *F* test using SPSS^x (1983). The data were heteroscedastic; therefore, they were analyzed using the Kruskal-Wallis test (Sokal and Rohlf, 1981) followed by a nonparametric multiple comparisons test (Conover, 1980, p. 231). The data on sex ratios were homoscedastic, so they were analyzed by ANOVA and the Newman-Keuls test using SPSS^x (1983).

Baited-Tree Experiments. Two baited-tree experiments were laid out in a randomized block design at the same location as the trapping experiment. The baits were contained in waterproofed, cardboard receptacles (Phero Tech Inc., Vancouver, British Columbia) stapled onto mature lodgepole pine trees of diameter at breast height (dbh) 22–34 cm, which were a minimum of 15 m apart. In 1984, 10 replicates were performed of the following bait treatments: (1) myrcene + *trans*-verbenol + *exo*-brevicomin + high release rate (±)-ipsdienol; (2) myrcene + *trans*-verbenol + *exo*-brevicomin; (3) high release rate (±)-ipsdienol; and (4) unbaited control.

In 1985, 11 replicates were performed of the following bait treatments: (1)

myrcene + *trans*-verbenol + *exo*-brevicomin + (±)-ipsdienol; (2) myrcene + *trans*-verbenol + *exo*-brevicomin + (*S*)-(+)-ipsdienol; (3) myrcene + *trans*-verbenol + *exo*-brevicomin + (*R*)-(−)-ipsdienol; (4) myrcene + *trans*-verbenol + *exo*-brevicomin; (5) (±)-ipsdienol; (6) (*S*)-(+)-ipsdienol; (7) (*R*)-(−)-ipsdienol; and (8) unbaited control.

Following the flight period, attack densities were assessed on all of the trees in the experiments by counting the entrance holes within two, 20 × 40-cm frames held at eye level on opposite sides of the trees at 90° from the bait station.

The data were homoscedastic (Cochran's *C* and Bartlett-Box *F* tests), so mean attack densities were analyzed by ANOVA and the Newman-Keuls test using SPSS^x (1983).

RESULTS

Table 2 shows the responses of both sexes of *D. ponderosae* in laboratory bioassays to dilutions of (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol. In most of these experiments (±)-, (*S*)-(+)-, or (*R*)-(−)-ipsdienol at one or more concentrations elicited a significantly higher percentage of positive responses than pentane controls, particularly at higher concentrations of ipsdienol. Ipsdienol at the two highest concentrations (400,000 ng/20 μl pentane and 40,000 ng/20 μl pentane) often elicited positive responses that were not significantly different from responses to female frass extracts.

Table 3 shows the responses of both sexes of *D. ponderosae* in laboratory bioassays to female frass extracts combined with either (*S*)-(+)-, (*R*)-(−)-, or (±)-ipsdienol at various concentrations. In most of these experiments the ipsdienol inhibited responses to the attractive frass extract, although the effect was significant only at low concentrations of ipsdienol.

Field trapping studies in 1984 (Figure 1A) indicated that traps baited with (±)-ipsdienol at high or low release rates were not significantly more attractive to *D. ponderosae* than unbaited control traps. When the attractive bait composed of myrcene + *trans*-verbenol + *exo*-brevicomin was combined with (±)-ipsdienol at high or low release rates, trap catch was significantly lower than for myrcene + *trans*-verbenol + *exo*-brevicomin alone, indicating that (±)-ipsdienol inhibits response of *D. ponderosae* to these attractive semiochemicals.

Field trapping studies in 1985 (Figure 1B–D) generally supported the results obtained in 1984. In all three experiments, traps baited with (±)-, (*S*)-(+)-, or (*R*)-(−)-ipsdienol were not significantly more attractive to *D. ponderosae* than the unbaited control traps. In two of three experiments, (±)-ipsdienol significantly inhibited response to myrcene + *trans*-verbenol + *exo*-brevicomin. (*S*)-(+)-Ipsdienol significantly inhibited the attractiveness of myr-

cene + *trans*-verbenol + *exo*-brevicomin in one of three experiments. (*R*)-(−)-Ipsdienol did not induce a significant inhibition in any of the experiments.

Because of the large numbers of beetles caught in traps in the 1985 experiments, sex was only determined for the beetles caught in the July 26–29 ex-

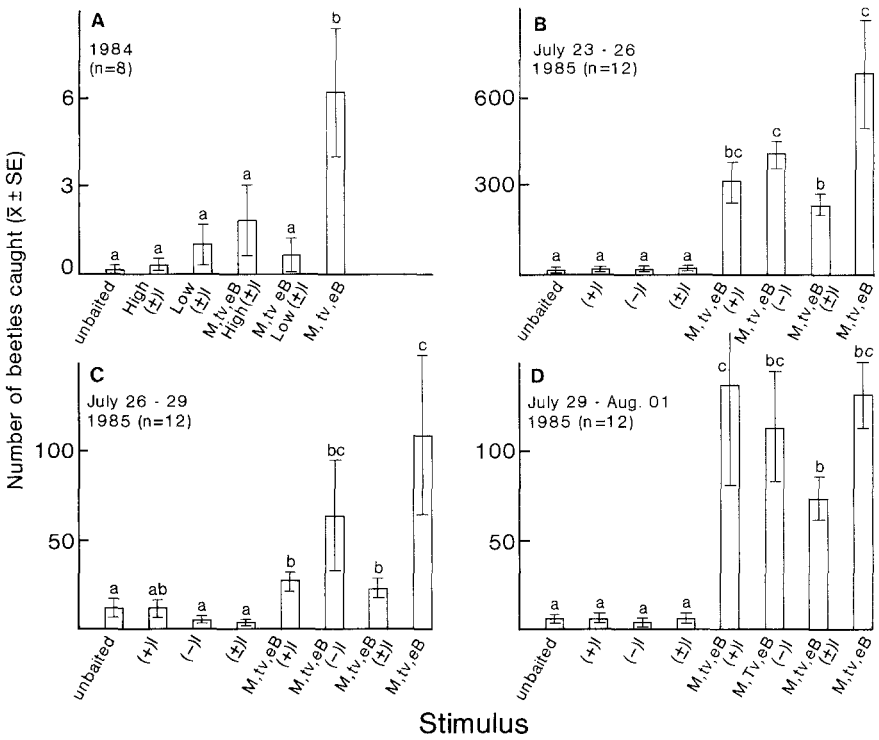

FIG. 1A–D. Number of *D. ponderosae* caught (±SE) in multiple-funnel traps baited with beetle-produced volatiles and host monoterpenes. Experiments conducted in 1984 and 1985 at Shinish Cr. Road, 30 km northeast of Princeton, British Columbia. In each experiment values with the same letter are not significantly different ($P > 0.05$), nonparametric multiple comparisons test (Conover, 1980, p. 231).

periment. The ratios of males to females caught were not significantly different (Newman-Keuls test, $P > 0.05$) for all baits containing myrcene + *trans*-verbenol + *exo*-brevicomin. However, these ratios (range 59–70% male) were all significantly higher (Newman-Keuls test, $P < 0.05$) than those for baits that contained only ipsdienol, or for unbaited traps (range 22–34% male). This result may indicate that traps baited with the standard semiochemical bait composed of myrcene + *trans*-verbenol + *exo*-brevicomin were more attractive to males than females.

In 1984 and 1985 the mean attack densities on trees baited with myrcene + *trans*-verbenol + *exo*-brevicomin were higher than on trees that were also baited with (±)-, (*S*)-(+), or (*R*)-(−)-ipsdienol (Table 4), although the effect was never statistically significant. Neither (±)-, (*S*)-(+)-, nor (*R*)-(−)-ipsdienol alone induced attack at levels above control trees by any scolytid species.

[a]Values for treatments in each experiment followed by the same letter are not significantly different ($P > 0.05$), Newman-Keuls test.

Although the field trapping studies were designed to test the responses of *D. ponderosae*, the traps also caught numerous pine engravers, *I. pini* (Figure 2A–D). The 1984 data indicated that *I. pini* were strongly attracted to (±)-ipsdienol, with the high release rate being significantly more attractive than the low release rate (Figure 2A). Traps baited with myrcene + *trans*-verbenol + *exo*-brevicomin were not significantly more attractive than the unbaited control traps. When this three-component mountain pine beetle bait was added to (±)-ipsdienol, the attractiveness of (±)-ipsdienol to *I. pini* was significantly reduced. Thus, either myrcene, *trans*-verbenol, *exo*-brevicomin, or some combination of these compounds inhibits the response of *I. pini* to its aggregation pheromone.

The 1985 data for *I. pini* supported the 1984 data, although in the July 29–August 1 experiment, there were no significant differences in response (Figure 2B–D). In addition, neither (*S*)-(+)- nor (*R*)-(−)-ipsdienol were more attractive than an unbaited control, indicating that the two enantiomers were synergistic in attracting *I. pini* in this region. In both 1984 and 1985 the sex ratios of trapped *I. pini* did not appear to be affected by the stimulus present in the traps, although too few beetles were captured to perform statistical analyses on sex ratios.

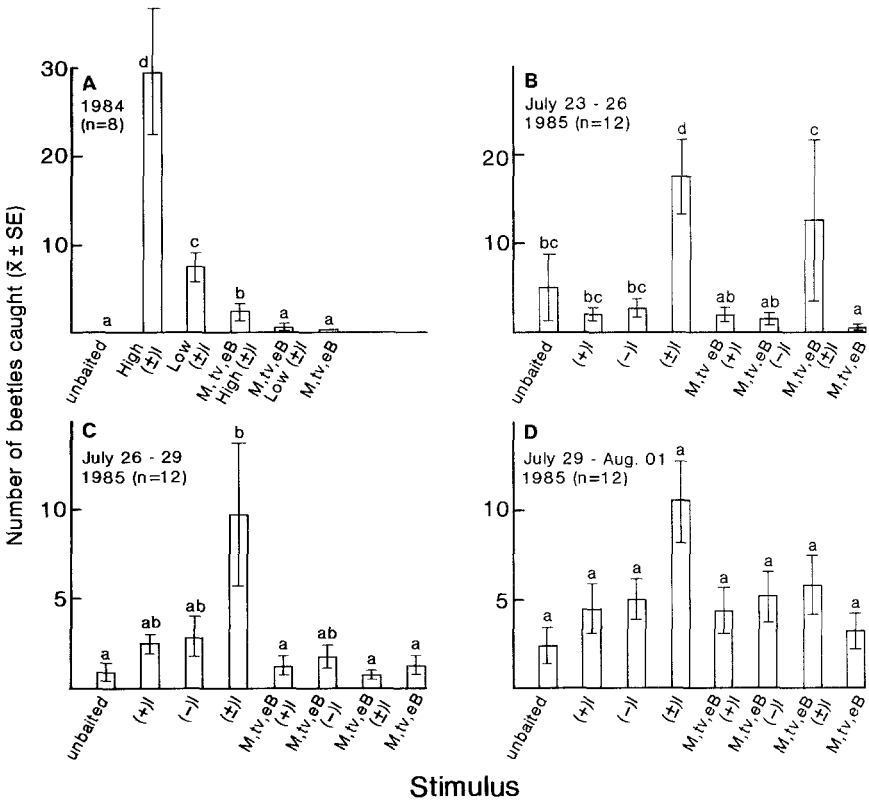

FIG. 2A–D. Number of *I. pini* caught (±SE) in multiple-funnel traps baited with beetle-produced volatiles and host monoterpenes. Experiments conducted in 1984 and 1985 at Shinish Cr. Road, 30 km northeast of Princeton, British Columbia. In each experiment values with the same letter are not significantly different ($P > 0.05$), nonparametric multiple comparisons test (Conover, 1980, p. 231).

DISCUSSION

Bioassays show that (*S*)-(+)-ipsdienol may weakly inhibit the attraction of both sexes of *D. ponderosae* to the attractive semiochemicals present in extracts of female frass in the laboratory (Table 3), as well as inhibiting attraction to a blend of myrcene + *trans*-verbenol + *exo*-brevicomin in the field (Figure 1A–D, Table 4). Thus, the 97% (*S*)-(+)-ipsdienol produced in large quantities by male *D. ponderosae* (Hunt et al., 1986) may function as an antiaggregation pheromone. In this way male beetles could contribute to the regulation of attack density, spacing, and termination of the attack on host trees. This could help

to prevent overly high attack densities that result in increased competition within hosts and reduced brood survival (Reid, 1963). When the (*S*)-(+)-ipsdienol concentration reached a high level, incoming beetles would avoid that host and attack other trees. The role of (*S*)-(+)-ipsdienol as an epideictic or spacing pheromone would facilitate a more efficient partitioning of the phloem tissue resource. A similar epideictic role is hypothesized for *trans*-verbenol, (+)-ipsdienol, and verbenone in *D. brevicomis* on ponderosa pine (Byers, 1983; Byers et al., 1984).

The reduction in trap catch due to ipsdienol (Figure 1A–D) is similar in magnitude to the reductions caused by other compounds that have been reported as antiaggregation pheromones of *D. ponderosae* (Ryker and Libbey, 1982; Ryker and Rudinsky, 1982; Ryker and Yandell, 1983; Libbey et al., 1985). Further study is required to determine how any or all of these compounds interact to modify the behavior of *D. ponderosae* in natural systems, as well as whether these compounds have any potential as pest-management tools.

Although male *D. ponderosae* produce large quantities of (*S*)-(+)-ipsdienol (Hunt et al., 1986), (±)-ipsdienol has a much stronger inhibitory effect than (*S*)-(+)-ipsdienol on the attraction of *D. ponderosae* to its aggregation pheromones (Figure 1A–D, Tables 3 and 4). This strongly inhibitory activity of (±)-ipsdienol suggests that the beetles in this geographic region may be exposed to an approximately racemic mixture of ipsdienol in nature. Although *I. pini* from California, Idaho, and southeastern British Columbia produce predominantly (*R*)-(−)-ipsdienol (Birch et al., 1980; Plummer et al., 1976; Slessor et al., 1985), *I. pini* from Manning Park, about 65 km from our study site, produce an average of 34% (*R*)-(−)-ipsdienol with tremendous variation between individuals (Miller et al., unpublished). Possibly the strong inhibitory effect of (±)-ipsdienol on *D. ponderosae* in our experiments represents an adaptation to avoid competition from a sympatric population of *I. pini* that produces both enantiomers of ipsdienol in substantial amounts. This avoidance response would be particularly advantageous to *D. ponderosae*, as *I. pini* develop more rapidly and may outcompete *D. ponderosae* within host trees (authors' unpublished observations).

It would be interesting to test the inhibitory effects of (*S*)-(+)-, (*R*)-(−)-, and (±)-ipsdienol on *D. ponderosae* in California, Idaho, and southeastern British Columbia where *I. pini* produce predominantly (*R*)-(−)-ipsdienol (Birch et al., 1980; Plummer et al., 1976; Slessor et al., 1985). It is possible that selection pressure due to competition with *I. pini* in these areas would favor *D. ponderosae* which were more strongly inhibited by (*R*)-(−) than by (±)-ipsdienol.

It is not known why the inhibitory effect of ipsdienol on the attraction of *D. ponderosae* to extracts of female frass in the laboratory was most pronounced at low concentrations (Table 3). The decreased inhibition at higher

concentrations may be due to the slight attractive effect of ipsdienol at higher concentrations (Table 2).

The attractiveness of ipsdienol in the laboratory at the highest concentration tested (400,000 ng/20 μl pentane and 40,000 ng/20 μl pentane) (Table 2) is somewhat surprising because of the inhibitory effects of low concentrations of (*S*)-(+)-, (*R*)-(−)- and (±)-ipsdienol on the response of *D. ponderosae* to female frass extracts (Table 3). However, the concentrations that are significantly more attractive than the pentane controls are probably higher than any ipsdienol concentrations likely to occur in nature. Although it is possible that ipsdienol could be a multifunctional pheromone in *D. ponderosae* and that it has different effects depending on the concentration, it is more likely that the attraction was an artifact of using artificially high concentrations or that a minor contaminant in the ipsdienol was causing the attraction.

Although Pitman et al. (1966) cautioned that variation in olfactory behavior between laboratory and field bioassays greatly limits the usefulness of laboratory bioassays, their reservations have proven to be without foundation for many species. However, with *D. ponderosae*, bioassay results are often very different depending on whether the study is conducted in the field or with walking beetles in a laboratory olfactometer. While myrcenol was attractive to *D. ponderosae* of both sexes in laboratory bioassays (Conn, 1981), it slightly inhibited the response to other attractants in the field (Conn et al., 1983). Similarly, 3-caren-10-ol was attractive in the laboratory (Conn, 1981), but this compound did not effect total trap catch in the field (Conn et al., 1983). Our laboratory and field results for ipsdienol are also contradictory. The divergence of laboratory and field results may be a result of differences in the responses to natural frass in the laboratory and the three-component semiochemical bait in the field. Alternatively, these differences may be due to concentration effects or to the test compounds having different effects on flying and walking insects. Until proven reliable, bioassays conducted with walking *D. ponderosae* in the laboratory should not be used as anything more than a preliminary test of compounds that should subsequently be field tested.

The response of *I. pini* to multiple funnel traps baited with (±)-ipsdienol, as well as the lack of a response to (*S*)-(+)- or (*R*)-(−)-ipsdienol (Figures 2A–D), indicates that *I. pini* in this region require both enantiomers to induce a response. This result is in agreement with the findings of Miller et al. (in press) that *I. pini* from nearby Manning Park produce an approximately 34:66 ratio of (*R*)-(−)- to (*S*)-(+)-ipsdienol on the average. This ratio of ipsdienol enantiomers suggests that *I. pini* from southwestern British Columbia are genetically close to New York populations, which also produce both enantiomers in a similar ratio, and for which both enantiomers act synergistically to produce a response (Lanier et al., 1980). These two populations are clearly distinct from populations from California (Birch et al., 1980), Idaho (Plummer et al., 1976), and the Kootenay region of southeastern British Columbia (Slessor et al., 1985).

The inhibitory effect of the ternary mountain pine beetle bait on the response of *I. pini* to (±)-ipsdienol indicates that either myrcene, *trans*-verbenol, *exo*-brevicomin, or some combination of these compounds inhibits the response of *I. pini* to its aggregation pheromone. Birch et al. (1980) have shown that *I. pini* from California are attracted to (*R*)-(−)-ipsdienol, the naturally predominating enantiomer, while (*S*)-(+)-ipsdienol interrrupted the response of *I. pini* to an attractive source in field tests. Notably (*S*)-(+)-ipsdienol is produced by *I. paraconfusus* (Silverstein et al., 1966) and *D. brevicomis* (Byers, 1982), both of which are sympatric competitors of *I. pini* in California. Thus, in regions where *I. pini* is repelled by (*S*)-(+)-ipsdienol, it could act as a repellent allomone to keep *I. pini* out of trees attacked by *I. paraconfusus* (Birch et al., 1980), *D. brevicomis* (Byers, 1982), or *D. ponderosae* (Hunt et al., 1986). It should be noted that Byers (1982) suggested that ipsdienol may be involved in regulating the colony density of *D. brevicomis* without testing the effect of (*S*)-(+)-ipsdienol, the enantiomer produced by this species. Our data on the inhibitory effects of (*S*)-(+)- and (±)-ipsdienol for *D. ponderosae* suggests that Byers may not have been justified in assuming that the inhibitory activity that he found in (±)-ipsdienol would necessarily be present with (*S*)-(+)-ipsdienol, the enantiomer produced by *D. brevicomis*.

If *trans*-verbenol or *exo*-brevicomin, which are both produced by *D. ponderosae*, are involved in inhibiting the attraction of *I. pini* to (±)-ipsdienol, then they may be functioning as repellent allomones to reduce interspecific competition for the same hosts. In this way the activity of (*S*)-(+)-ipsdienol as a repellent allomone against *I. pini* may be replaced in southwestern British Columbia by the inhibitory activity of one of these compounds. Alternatively, *I. pini* may simply be avoiding high concentrations of myrcene due to their preference for dead and dying trees which probably have more tolerable levels of monoterpenes.

Acknowledgments—We thank Dr. H.D. Pierce, Jr., for assistance with the chemical analysis; Dr. E.K. Czyzewska for the resolution of (*S*)-(+)- and (*R*)-(−)-ipsdienol from (±)-ipsdienol; and Dr. B.S. Lindgren of Phero Tech, Vancouver, British Columbia, for the loan of the funnel traps. We also acknowledge L.J. Chong, W.D. Brown, and T.E. Guthrey for assistance with the field work; and thank Dr. H.S. Whitney for reviewing the manuscript.

(Received September 15, 1986; accepted February 2, 1987)

Abstract—This paper is the second in a series on cardenolide fingerprinting of monarch butterflies and their host-plant milkweeds in the eastern United States. Spectrophotometric determinations of the gross cardenolide content of *Asclepias asperula* plants in north central Texas indicated wide variation ranging from 341 to 1616 μg/0.1 g dry weight. The mean plant cardenolide concentration (886 μg/0.1 g) is the highest for any milkweed species on which monarch cardenolide profiles have been produced. Forty-one butterflies reared individually on these plants contained a skewed distribution of cardenolide concentrations ranging from 231 to 515 μg/0.1 g dry weight with a mean of 363 μg/0.1 g. The uptake of cardenolide by the butterflies was independent of plant concentration, suggesting that saturation occurs in cardenolide sequestration by monarchs when feeding on cardenolide-rich host-plants. Female monarchs contained significantly greater mean cardenolide concentrations (339 μg/0.1 g) than did males (320 μg/0.1 g). The mean dry weight of the male butterflies (0.211 g) was significantly greater than the female mean (0.191) so that the mean total cardenolide contents of males (675 μg) and females (754 μg) were not significantly different. Butterfly size was not significantly correlated to butterfly cardenolide concentration when differences due to sex and individual host-plant concentration were removed. Thin-layer chromatograms of 24 individual plant–butterfly pairs developed in two sol-

[1] Lepidoptera: Danaidae.
[2] Apocynales: Asclepiadaceae.

0098-0331/88/0100-0295$06.00/0

vent systems resolved 22 individual spots in the plants and 15 in the butterflies. *A. asperula* plants appear to contain several relatively nonpolar cardenolides of the calotropagenin series which are metabolized to more polar derivatives in the butterflies. Quantitative evaluation of the R_f values, spot intensities, and probabilities of occurrence in the chloroform–methanol–formamide TLC system produced a cardenolide fingerprint clearly distinct from those previously established for monarchs reared on other *Asclepias* species. Our data support the use of fingerprints to make ecological predictions concerning larval host-plant utilization. *A. asperula* subsp. *capricornu* and *A. viridis* Walt. are the predominant early spring milkweeds throughout most of the south central United States. Cardenolide-rich monarchs reared on these two species may be instrumental in establishing and reinforcing visual avoidance of adults by naive predators throughout their spring and summer breeding cycle in eastern North America.

Key Words—*Asclepias asperula*, milkweed, Asclepiadaceae, *Danaus plexippus*, monarch butterfly, Lepidoptera, Danaidae, Oncopeltus, Hemiptera, Lygaeidae, cardenolide, cardiac glycoside, digitoxin, chemical ecology, chemotaxonomy, chemical defense, ecological chemistry, thin-layer chromatography, plant–insect interactions, coevolution.

INTRODUCTION

In this paper we present the second analysis in a series of investigations of monarch remigration and recolonization along the western margins of their distribution in the eastern United States. Our purposes are to establish the timing and extent of host-plant utilization by monarchs as they remigrate from Mexican overwintering sites into temperate North America, to establish the quantitative variation in cardenolide contents of butterflies as they relate to their host plants, and to develop thin-layer chromatography cardenolide fingerprints of adult monarchs for milkweed species commonly utilized during recolonization.

In our first paper (Lynch and Martin, 1987), we reported on the cardenolide characteristics of monarchs reared as larvae on *Asclepias viridis* Walt. in northwestern Louisiana. We now report on cardenolides in monarch butterflies collected as larvae or chrysalids in populations of *A. asperula* (Dcne.) Woods. in north central Texas. For those monarchs remigrating through Texas and Louisiana, *Asclepias viridis* and *A. asperula* represent the first common and widespread milkweeds they encounter. In Florida, *A. viridis* is more localized and *A. humistrata* is more heavily utilized for oviposition by monarchs (Brower, 1961, 1962; Cohen and Brower, 1982). Clearly, these three species are the principal milkweeds that migrant monarchs encounter as they reach the temperate United States and serve as larval host-plants for many, if not most of the first spring generation of monarch larvae.

METHODS AND MATERIALS

Geographic and Ecological Distribution of Asclepias asperula. *Asclepias asperula* Dcne., a common milkweed of the subgenus Asclepiodora, has a widespread distribution in the southwestern United States in two distinct subspecies (Woodson, 1954). *A. asperula* subsp. *asperula* (Dcne.) Woods. ranges from eastern California across Arizona and New Mexico into the westernmost counties of Texas, northward throughout Colorado and Utah into southern Idaho, and southward through northern Mexico to the states of Durango and Tamaulipas. *A. asperula* subsp. *capricornu* (Woods.)Woods. occurs in a wide vertical band from south central Texas through central Oklahoma and into north central Kansas. Both subspecies are largely absent throughout most of western Texas, western Oklahoma, and western Kansas, and remain both geographically and morphologically distinct.

Recaptures of autumnal migrating monarchs (Urquhart and Urquhart, 1978) and numerous personal observations in Texas, the Great Plains, and the southwestern United States (Lynch, unpublished field catalog) all suggest *A. a. asperula* occurs to the west of the eastern monarch's migration routes and does not play a significant role as a monarch host-plant. Therefore, no pairwise samples were collected from the typical subspecies for our analysis. In contrast, *A. a. capricornu* often occurs abundantly within the region of monarch remigration and appears to serve as a major host plant for first and second-generation monarchs in temperate North America. Figure 1 illustrates the known distribution of *A. asperula* subsp. *capricornu*. Along the eastern boundary of its distribution, this milkweed is often abundant in open fields and pastures and often occurs in close sympatry with *A. viridis*, a morphologically similar milkweed of the same subgenus. Although they largely remain distinct, individuals with intermediate vegetative and floral morphology may occur, suggesting occasional hybridization between the two species (Lynch, personal observation). Other milkweed species do occur in this region but are only occasional and produce less biomass.

Location, Methods, and Dates of Sample Collections. During May 1983, immature monarchs (*Danaus plexippus* L.) were collected from milkweeds in open pastures and roadsides in northcentral Texas. Collections of individually matched plant–butterfly pairs generally followed the procedures established in Brower et al. (1982, 1984a,b) and Lynch and Martin (1987). Fifth-instar larvae were collected along with a sample of leaves from their individual host-plant. A portion of this material was placed with the larva into an 8-oz. clear plastic food container (Sweetheart Plastics No. 40, Wilmington, Massachusetts), and the remaining leaves were placed in one-pint freezer bags and frozen for later chemical analysis. In addition to searching for and collecting wild fifth-instar

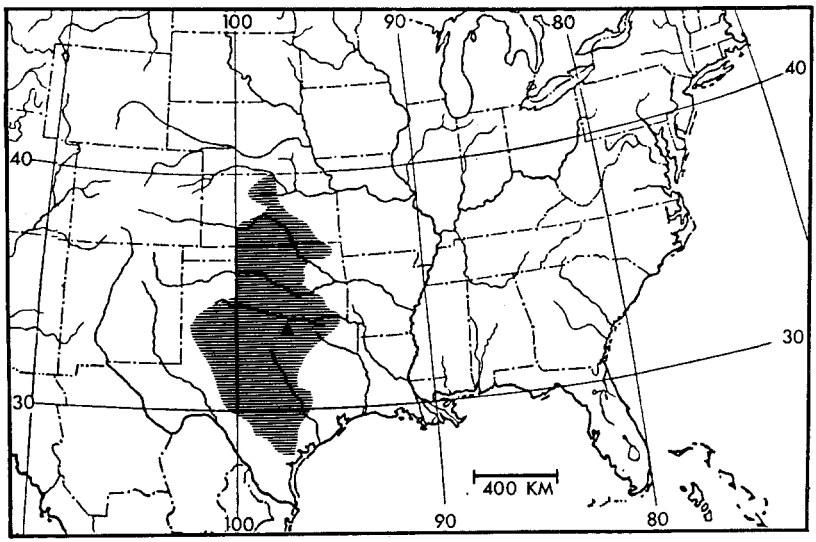

FIG. 1. The known geographic distribution of the milkweed *Asclepias asperula* subsp. *capricornu* (Woods.) in the United States (after Woodson, 1954). The triangle locates the northcentral Texas population analyzed in this study. See text for discussion of relative abundance.

larvae, small larvae were bagged with nylon net bags on individual host-plants and later collected as chrysalids or as late fifth-instar larvae.

The rearing of the butterflies and the treatment of plant material following collection was identical for both bagged and unbagged material. Any chrysalids collected from bags were removed along with their silken pads which were then taped to the lid of the container. Within three days each fifth-instar larva had spun a silken pad on the lid of the container and hung upside down to shed its last larval skin. After pupation, the remaining leaves in the container were discarded, and a Whatman No. 1 filter paper was placed on the bottom to reduce humidity and to soak up fluids evacuated during emergence. The containers were stored at room temperature until emergence. Upon darkening of the chrysalids (usually occurring the evening before emergence), small cylinders of metal window screen were sandwiched between the lid and bottom of the container creating an open air cage in which the emerging adults could hang to expand and dry their wings. Approximately 12 hr after emergence, each butterfly was placed in a glassine envelope and frozen for later measurement and chemical analysis. Each plant–butterfly pair was provided with a collection number (S.P. Lynch, unpublished field catalog). A single-digit alphabetical suffix was used to identify more than one butterfly collected from the same host plant.

In all, 41 pairwise butterflies (22 females and 19 males) were analyzed from 31 individual plants. Wild collections included Nos. 6665, 6666, 6668, and 6669B collected May 7, near Denton; No. 6670A collected May 7, near Decatur; Nos. 6701A and 6701B collected May 8, near Mineral Wells, and No. 6702 collected May 8, near Granbury. Thirty-five *A. asperula* plants were each bagged with two first- or second-instar larvae in an open pasture in Denton on May 7. Eighteen chrysalids and 15 fifth instars were collected from the bags on May 21. These were Nos. 6983B, 6984A, 6984B, 6985–6987, 6988A, 6988B, 6989, 6990A 6990B, 6991, 6992A, 6992B, 6993–6998, 6999A, 6999B, 7000, 7001, 7002A, 7002B, 7003, 7004, 7005A, 7005B, 7006A, 7006B, and 7007B.

Determination of Total Cardenolide Content. The individual plant and butterfly samples were prepared and extracted with 95% ethanol as described by Brower et al. (1972). Spectrophotometric determinations were performed at 626 nm with a Gilford 280 single-beam UV–visible spectrophotometer at 20.0°C following the 2,2′,4,4′-tetranitrodiphenyl (TNDP) method of Brower et al. (1972, 1975), Brower and Moffitt (1974), and Lynch and Martin (1987), except for slightly different cuvette dilutions. Freshly prepared TNDP solutions were used and stored in a refrigerator for no longer than 10 days. In the absence of the molar absorptivities of the TNDP complex of the *A. asperula* cardenolides, estimates were obtained using a digitoxin standard and reported in micrograms (equivalent to digitoxin) per 0.1 g dry weight (Roeske et al., 1976; Brower et al., 1982).

Thin-Layer Chromatography (TLC). Pigments and other interfering substances were removed in a lead acetate precipitation procedure (Nelson et al., 1981; Brower et al., 1982) which utilized 6 ml of the *A. asperula* or butterfly extract. After cleanup, the evaporated residue was dissolved in a calculated amount of chloroform in order to deliver 75 or 100 μg/20 μl of solution.

Twenty microliters of the plant and butterfly samples were spotted with Drummond Wiretrol 5-μl pipet onto a heat-activated 20 × 20-cm TLC plate (0.25 mm, EM Science 5765, Silica Gel 60 F-254 or EM Science 11845, Silica Gel 60 with a preconcentrating zone) providing six plant–butterfly pairs and three digitoxin and digitoxigenin (Sigma Chemical Co., St. Louis, Missouri) standards per plate. Development was in preequilibrated filter paper-lined glass chambers in either chloroform–methanol-formamide (CMF) (90 : 6 : 1 by volume) four times or in ethyl acetate–methanol (EM) (97 : 3 by volume) two times (Brower et al., 1982). The plates were visualized by spraying with 20 ml of 0.4% TNDP in toluene followed by 20 ml of 10% potassium hydroxide in 50% aqueous methanol. The plates were photographed within 1 min. using Kodachrome 25 film and a Pentax Spotmatic 35 mm camera equipped with a Pentax ringstrobe.

Four plates were run in each of the two solvent systems. Each plate contained six plant–butterfly pairs of mixed sexes, two pairs each selected from the

low, middle, and high ranges of plant cardenolide concentration based on spectroassay results. Similar concentration ranges were intentionally placed in different positions on each plate to reduce or eliminate error due to plate position. Pooled plant and butterfly extracts were prepared and spotted on the plates. Three of the four TLC plates developed in the EM solvent system contained a preconcentrating zone of kieselguhr and were not spotted with any pooled butterfly sample. Two additional plates containing pooled *A. asperula* and *A. viridis* extracts, respective pooled butterfly extracts, and the cardenolides, desglucosyrioside, labriformin, and labriformidin were developed, one in CMF and one in EM.

All plates contained the two digitoxin and digitoxigenin standards spotted as a mixture in the outermost positions and the center. The distance of the concentrated centers of each sample spot from the origin was measured to the nearest 0.5 mm and later converted to an $R_{digitoxin}$ (R_d) value by drawing a line from the outer digitoxin spots to the central spot and dividing the spot migration distance by the calculated digitoxin migration distance. Comparisons of TLC patterns were also based on the mean and standard deviations of each spot's intensity value (SI) as well as each spot's probability of occurrence (PO). Spot intensity was determined using a subjective but consistent visual 1–5 scale with 1 being the lightest and 5 the darkest.

Statistical Analyses. Statistical analyses were made on an IBM 3330 computer housed at Louisiana State University in Baton Rouge utilizing SAS statistical software, release 82.2 (SAS, 1982). Statistical procedures generally followed those in Lynch and Martin (1987). We analyzed dry weights, wing and body measurements, cardenolide concentrations, and total cardenolide content of the butterflies, as well as the cardenolide concentrations of the plants. Using PROC UNIVARIATE and FREQ PLOT NORMAL tests to examine frequency distributions and to test for normality, all data except cardenolide concentrations in the butterflies were determined to be within normal ranges.

A two-step regression was carried out on the spectrophotometric data, the first to consider the overall relation of cardenolides in the butterflies (Y, the dependent variable) to their corresponding host-plant cardenolides (X, the independent variable), the calculated r^2, the slope, and the intercept; and the second to analyze the dependence of the butterfly cardenolide concentration, butterfly dry weight, and the total cardenolide per butterfly on the cardenolide concentration of the plants (total and by sex). Unless otherwise indicated in the text, type IV sums of squares statistics were used if empty cells were present in the matrix or there was one or more significant interactions in the model, whereas type II sums of squares were used if there was none.

Two-way analyses of variance (ANOVA) were also carried out on the TLC data to determine the influence of sex and plate number and their interaction on both R_d values and on SI values. Although we realize that our TLC spot com-

parison methodology largely predetermines the correspondence of the respective plant and butterfly spots for each plant–butterfly pair, the SAS linear regression program allows for the simultaneous testing of the dependence of the R_d values or the SI values for all butterfly spots on the corresponding values of their respective plant spots as affected by plate variation or sex in the entire sample.

RESULTS

Measurements of Gross Cardenolide Content. We found *A. asperula* host plants to be rich in cardenolides. Each of the 31 plants used in this study contained high amounts of cardenolides, with concentrations ranging from 341 to 1616 μg/0.1 g dry weight. The mean concentration for all plants measured was 886 μg/0.1 g dry weight with a standard deviation of 254.5 μg (Table 1). The pattern of variation is shown in Figure 2. The curves over the histograms for both plants and butterflies display the limits of the expected normal distributions calculated by the z statistic (Steel and Torrie, 1960). The concentration distribution for the plants, although negatively kurtotic (moment of kurtosis = −0.33), was approximately normal (moment of skewness = 0.07; mean and median, respectively, 886 and 903 μg; $W = 0.973$, $P < 0.54$).

Butterflies reared on *A. asperula* were also found to be cardenolide-rich with a mean of 363 μg cardenolide/0.1 g dry weight. The range of cardenolide concentrations in the butterflies, 231–515 μg/0.1 g dry weight, was narrower than the range in the plant samples (Table 1). The concentration distribution in the butterflies was not normally distributed (moment of skewness = 0.34; mean and median, 362.9 and 346.1 μg, respectively; $W = 0.936$, $P < 0.037$). The $\log_{10}$ transformed data, however, did not depart significantly from normality (moment of skewness = 0.04; mean and median, respectively 2.55 and 2.54; $W = 0.947$; $P < 0.085$). Further statistical analyses involving butterfly concentrations are therefore based on the $\log_{10}$ transformed data.

TABLE 1. CARDENOLIDE CONCENTRATIONS OF MONARCH BUTTERFLIES, *Danaus plexippus* L., AND THEIR HOST-PLANT MILKWEED, *A. asperula* subsp. *capricornu* (Woods.) Woods.[a]

		Plant material			Butterfly material		
	N	Mean	SD	Range	Mean	SD	Range
Males	19	847.16	228.37	341–1274	320.97	54.69	231–431
Females	22	919.68	275.96	341–1616	399.12	75.85	285–515
Total	41	886.07	254.54	341–1616	362.90	76.95	231–515

[a] Data are μg (equivalent to digitoxin) per 0.1 g dry wt. of butterfly or plant material.

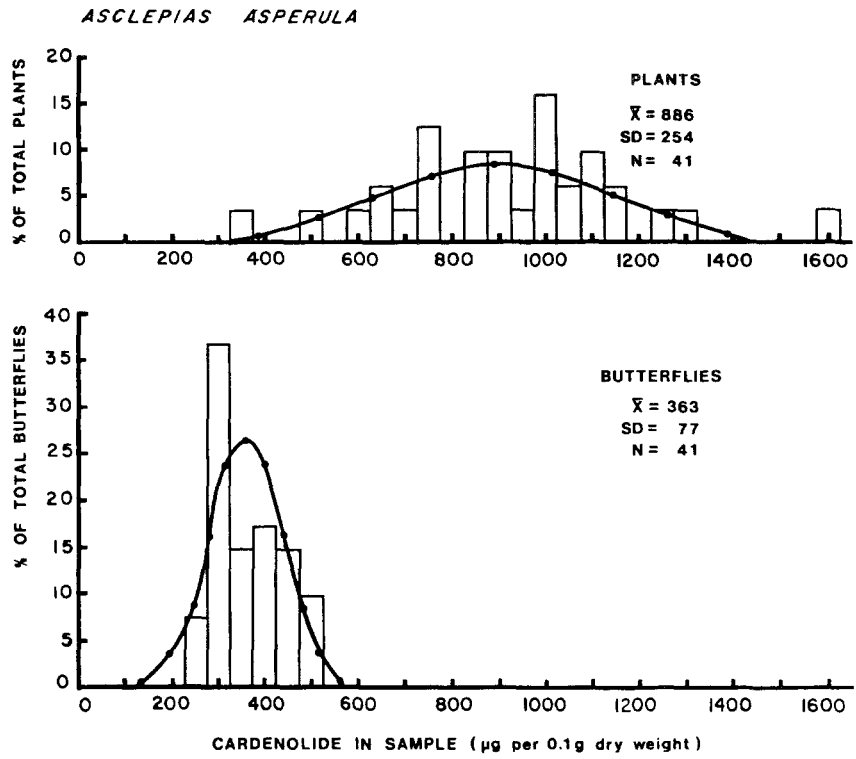

FIG. 2. Frequency distributions of the gross cardenolide content of 41 *Asclepias asperula* plants and 41 monarch butterflies reared thereon. Concentrations are expressed as µg per 0.1 g dry weight, equivalent to digitoxin. The width of each bar is 50 µg. The curves above the histograms are the normal distrubutions calculated by the z statistic (Steel and Torrie, 1960).

Table 1 shows differences in the mean cardenolide concentrations of plants fed on by the male vs. the female butterflies. An analysis of variance indicated that the difference in the plants according to the sex of the butterfly is not significant ($F = 0.82$, $P < 0.37$). However, differences in the means for log cardenolide concentrations in male and female butterflies were significant ($F = 13.61$, $P < 0.0007$; $r^2 = 0.26$). The grand variances of the cardenolide concentrations of the plants upon which male and female butterflies were reared were not significantly different (for the s^2 male/s^2 female, $F = 1.46$ with 18 and 21 *df*, $P < 0.42$) nor were the grand variances of the log cardenolide concentrations between the male and female butterflies ($F = 1.36$ with 18 and 21 *df*, $P < 0.51$).

The mean cardenolide concentration in the plants was 523 μg (2.4 times) greater than that of their respective butterflies, and the overall range of variation in the plants (SD = 254.5) was also greater than that in the butterflies (SD = 77.0). Therefore, the regression of butterfly concentrations on their respective plant concentrations is not a significant fit to either a linear or log plot (Figure 3, Table 2A). For graphic simplicity, we have plotted the "best fit" linear model $Y = 0.003X + 360$ in Figure 3. The calculated regression model, $\log_{10} Y = 0.00001X + 2.539$ (Table 2A) was not a significantly better fit. In the latter regression, which utilizes the log transformed butterfly concentrations, $r = 0.036$ ($P < 0.82$), the intercept was significantly different from 0 ($P < 0.0001$), and the slope was not ($P < 0.82$).

In a second set of regressions comparing plant and butterfly cardenolide concentrations by the sex of the butterfly (Table 2B), we found that the overall model was highly significant ($P < 0.0012$) and that plant concentration, sex, and their interaction were all significant using type IV SS statistics. By running separate regressions on each sex, we found that there was no significant correlation between butterfly concentration and plant concentration (females $P < 0.166$; males $P < 0.099$).

Table 3 lists the dry weights and total cardenolide contents of the butterflies. The dry weights were normally distributed (mean and median = 0.201 and 0.205 g, respectively; $W = 0.967$, $P < 0.401$) with the average male butterfly being slightly heavier (0.211 g) than the female (0.191 g). The total cardenolide contents were also normally distributed (mean and median = 717 and 692 μg, respectively; $W = 0.974$, $P < 0.573$). The variances for the two sexes did not differ significantly for either dry weight ($F = 1.67$; $df = 18, 21$; $P > 0.26$) or total cardenolide ($F = 1.07$; $df = 18, 21$; $P > 0.88$). Analyses of the variances indicated that the mean dry weights of the two sexes were significantly different ($F = 4.46$, $P < 0.0412$) but that the mean total cardenolide content in the female butterflies (754 μg) was not significantly greater ($F = 3.63$, $P < 0.0642$) than in the males (675 μg).

A regression analysis was run to determine the relationship of the butterfly dry weights (Y) to the cardenolide concentrations of the plants (X). The overall model indicated no significant correlation ($r^2 = 0.005$; $F = 0.185$, $P < 0.67$) as did models with either sex. The dry weights of the butterflies were similarly compared to the log cardenolide concentrations of the butterflies. The main regression model indicated a significant negative correlation between butterfly dry weight and cardenolide concentration ($\log_{10} Y = -1547.1X + 5952.4$; $r^2 = 0.203$; $P < 0.0031$). However, the second regression model, which also included sex and the plant concentration as covariates, indicated no overall significant correlation ($R^2 = 0.273$; $F = 1.77$, $P < 0.1268$) and that, when using type II SS statistics, none of the variables or their interactions were significant predictors of butterfly dry weight (all P values > 0.22).

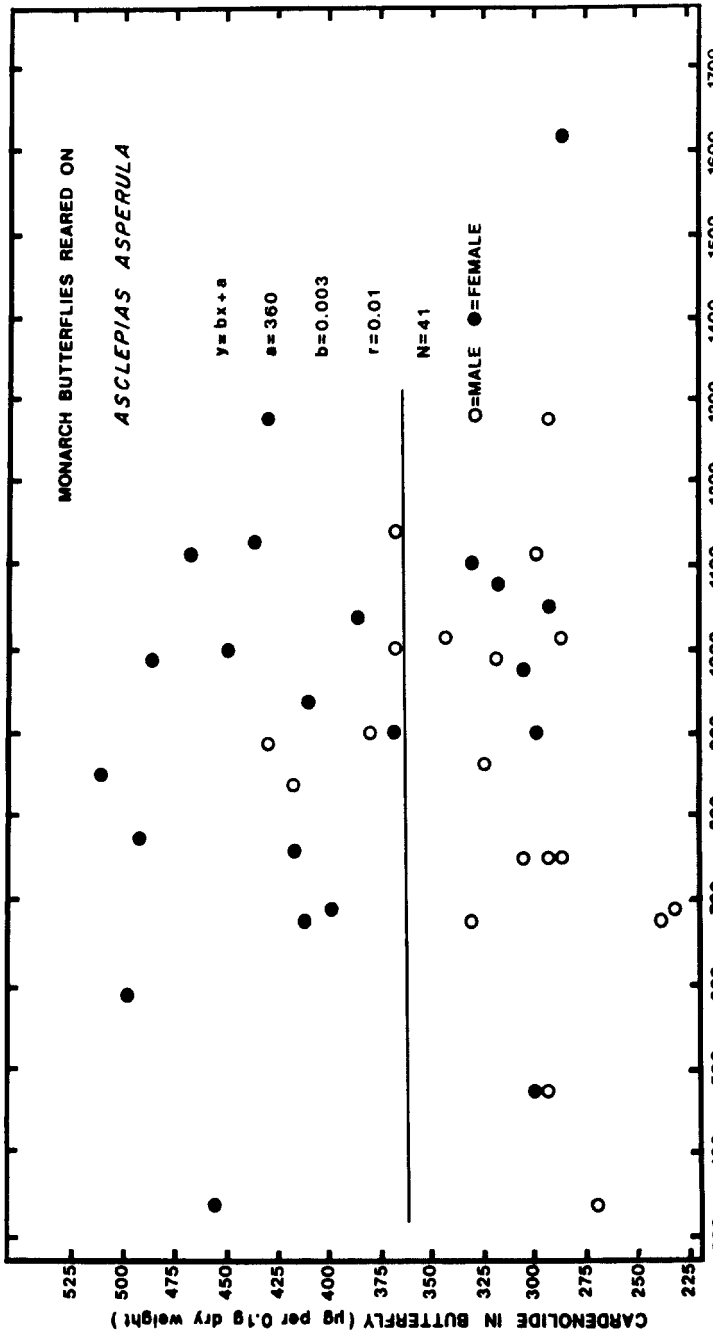

FIG. 3. Cardenolide concentrations of monarch butterflies (*Y* axis) as a function of the cardenolide concentrations of their larval food plant, *Asclepias asperula* (*X* axis). Each of the 41 data points represents one plant–butterfly pair. Open circles are males and solid circles are females. The line is derived from the regression equation $Y = bX + a$.

TABLE 2. LINEAR REGRESSION ANALYSES OF CARDENOLIDE CONCENTRATIONS (LOG_{10} μg/0.1 g DRY WT) IN BUTTERFLIES (Y = DEPENDENT VARIABLE) VS. CARDENOLIDE CONCENTRATIONS (μg/0.1 g DRY WT) IN THEIR RESPECTIVE PLANTS, ACCORDING TO FUNCTION LOG_{10} $Y = bX + a$.

The same linear regression model used to compare butterfly cardenolide concentrations and dry weights was also run to relate total cardenolide in the butterflies to the plant concentrations. We found no significant dependence of butterfly total cardenolide on the plant concentration ($r^2 = 0.006$; $F = 0.241$, $P < 0.626$) and that both sexes similarly showed no dependence. Based on the equation $Y = 0.0419X + 680.18$, the overall model predicts that butterflies which fed on plants containing 341 μg/0.1 g cardenolide (the lowest plant concentration in our study) would contain approximately 694.5 μg, those which fed on 886-μg plants (the mean plant concentration) would contain 717.3 μg, and those which fed on 1616-μg plants (the highest plant concentration in our study) would contain 747.9 μg. The second regression for total cardenolide indicated that neither the log plant concentration nor the sex of the butterflies nor their interaction were significant predictors when using type II SS statistics.

TLC Cardenolide Profiles of Plants and Butterflies. Although TLC plates were run in two separate solvent systems, only those plates run in the chloroform–methanol–formamide (CMF) system were analyzed quantitatively. As found by Brower et al. (1982, 1984a,b) with three California milkweeds and by Lynch and Martin (1987) with *A. viridis* in Louisiana, the ethyl acetate–methanol (EM) system resolved fewer cardenolides in *A. asperula* than did the CMF system and the individual spots were larger and less well defined. While the EM system may eventually provide information on the identity of individual cardenolide compounds by confirmation with known standards and may prove useful in their isolation and purification, the CMF system has proven more valuable in the quantitative analyses of individual cardenolides and in the establishment of TLC "fingerprint" profiles. For these reasons the remaining discussion will be concerned entirely with the CMF profiles.

Figure 4 is a photograph of portions of two plates run in the CMF system. Represented are six butterfly–plant pairs including four female butterflies (Nos. 7005, 6994, 7001, and 6666) and two male butterflies (Nos. 6983B and 6669B). The number sequence of the individual spots is in the channel between the first plant–butterfly pair shown on plate 15 and between the first plant–butterfly pair shown on plate 14. Additional spot numbers have been added where spots are particularly clear, and the standards are identified along the right and left margins. Headings for each pair include the research number (top), identity as either plant (P) or butterfly (B), and the approximate amount of cardenolide spotted, in micrograms (lowest figures).

Table 4 summarizes the means and standard deviations for both $R_{digitoxin}$ (R_d) and spot intensity (SI) values for all the spots in the 24 plant and butterfly samples analyzed by TLC. Also included in Table 4 are the probability of occurrence of each spot (PO) based on the proportion of plants or butterflies in which each spot occurred and the subsample size or number of times each spot was detected. The mean migration distance for the 12 digitoxin references (three

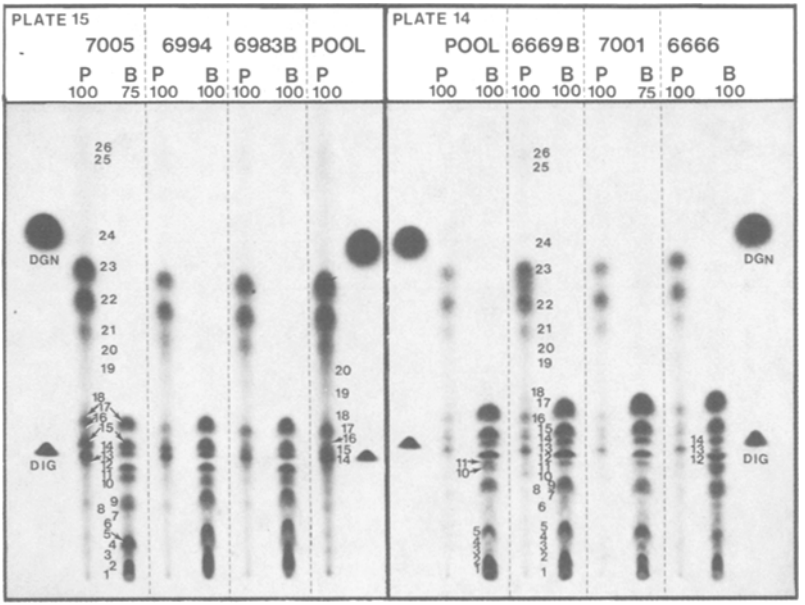

FIG. 4. Photographic reproduction of the thin-layer chromatographic profiles of the cardenolides present in monarch butterflies and their host plant, *Asclepias asperula*. Represented are six plant–butterfly pairs run in the chloroform–methanol–formamide system including two males (No. 6983B and 6669B) and four females (Nos. 7005, 6994, 7001, and 6666). Twenty-six individual spots were resolved including 22 in the plants (all except spots 2, 4, 7, and 9) and 15 in the butterflies (all except spots 8, 16, and 18–26). Also included are two standards, digitoxin (DIG) and digitoxigenin (DGN), which were run on each plate. Several spots with low color intensity are visualized poorly through photographic reproduction (but see the generalized drawing in Figure 5).

on each plate) was 32.1 mm with a range of 29.0–38.0 mm and a SD of 5.7 mm. The 12 corresponding digitoxigenin references had a mean migration distance of 87.8 mm with a range of 82.0–90.5 mm and a SD of 3.6. The mean R_d value for digitoxigenin in the 12 reference channels was 2.75 with a range of 2.5–2.9 and a SD of 0.15.

Relatively weak spots were occasionally absent or difficult to discern in individual plants or butterflies, yet the standard deviations of the R_d values are low, indicating the resolution of the cardenolides is good. Figure 5 represents the mean cardenolide profile for the 24 plants and butterflies utilized in the TLC analysis. The relative positions and darkness of the spots are calculated from the mean R_d and SI values presented in Table 4. The shapes and sizes of the spots are drawn from a representative TLC plate and then generalized in the

[a]Data are based on chromatograms of 24 butterflies and the corresponding plants on which they were reared (chloroform–methanol–formamide system).

figure. The mean R_d values for the 12 digitoxin and digitoxigenin standards are also indicated as dotted lines across the profile. In all, twenty-six spots were resolved in the CMF system. Twenty-two spots were discerned in the plants and 15 in the butterflies. Spots 2, 4, 7, and 9 were not present in any of the plants, while spots 8, 16, and 18–26 were absent in the butterflies.

In the plants there were six spots (Nos. 1, 6, 14, and 24–26) which were

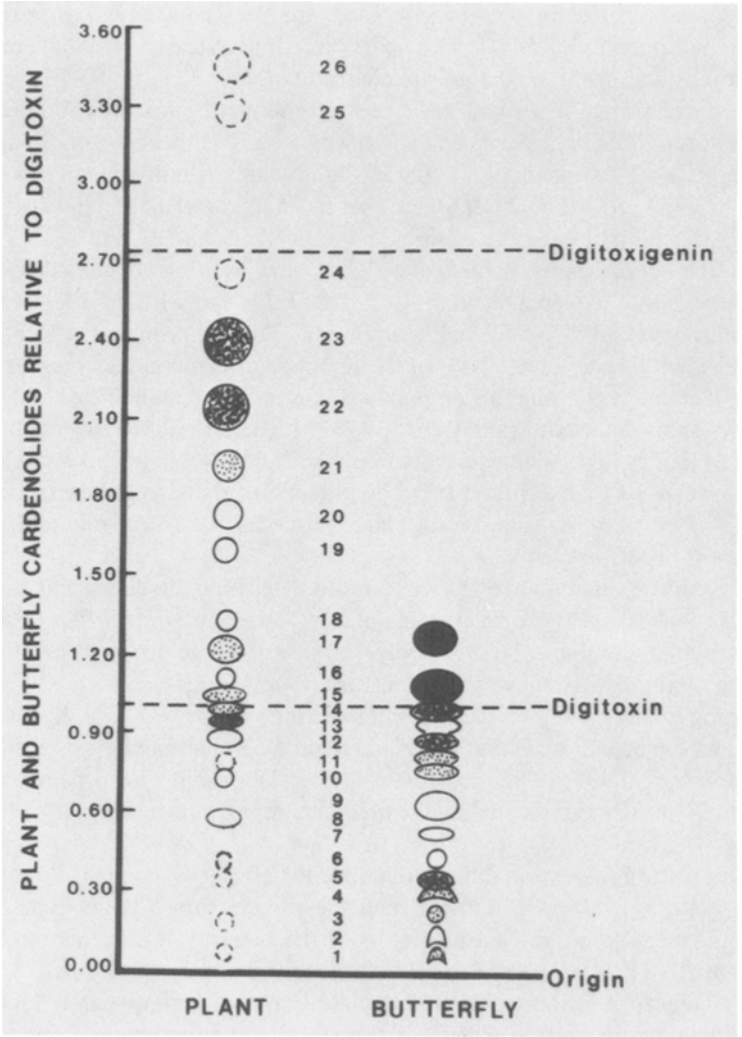

FIG. 5. The mean cardenolide profiles for 24 monarch butterflies and their individual *Asclepias asperula* host plants based on the chloroform–methanol–formamide TLC system. Shown are the mean R_d and spot intensity values for 22 plant and 15 butterfly cardenolide spots. Spot intensities are represented as follows: $1.00 < 1.25$, dotted circle; $1.25 < 2.00$ closed circle; $2.00 < 3.00$, light stipple; $3.00 < 4.00$, dark stipple; 4.00–5.00 black circle. The mean R_d value for digitoxigenin was 2.75.

detected in less than 50% of the samples ($PO < 0.50$), although we found these spots consistently present in pooled samples spotted with an estimated 100 μg of cardenolide. This left 16 spots present in at least 50% of the individual profiles and useful as diagnostic characters (Nos. 3, 5, 8, 10–13, and 15–23). Twelve spots (55%) had an $R_d > 1.0$ (above digitoxin) while 10 spots (45%) had an $R_d < 1.0$. Spots 25 and 26 were consistently above digitoxigenin, although spot 22 occasionally migrated slightly above digitoxigenin's position. Spots 8, 13, 15, 17, and 21–23 were present in all 24 plant channels and generally had the highest spot intensities.

In the butterflies, no spots had a $PO < 0.50$, leaving all spots detected as diagnostic. Only two spots had an $R_d > 1.0$ (13%, spots 15 and 17), while the remaining spots (87%) were below digitoxin. The butterflies only stored cardenolides within the lowest 36% of the R_d range of cardenolides present in the plants. The mean R_d value for all plant spots was 1.29 compared to 0.64 for all butterfly spots detected. Spots 1, 2, 5, 9, 11, 12, 14, 15, and 17 were observed in all 24 butterflies. Where in common, the butterfly spots had significantly greater mean SIs than did their corresponding plant spots with the exception of spot 13. The mean SI value for all plant spots was 1.96 compared to 3.15 for all butterfly spots.

Several regression analyses were run to determine the dependence of butterfly R_ds and SIs on the corresponding plant R_ds. Because of low POs of several of the spots in common R_f range, only 160 of a possible 408 spot pairs (24 × 17 plant–butterfly pairs) were present and used in this analysis. Our initial regression model examined the dependency of the butterfly R_ds on the plant R_ds alone. As expected, we found a high degree of correlation ($F = 16639$, $P < 0.0001$; $r^2 = 0.991$). This near one-to-one relationship of the paired plant–butterfly R_d values is indicated by the predicted regression equation $Y = 1.018X + 0.005$.

Our second regression model contained the effects of the plant R_ds, the sex of the butterfly, the plate number, and their interactions. Using type IV SS statistics, the only significant predictors of the butterfly R_ds in this model are the plant R_ds ($F = 15{,}695$, $P < 0.0001$) and plate number ($F = 3.73$, $P < 0.013$). Duncan's option indicated that plate 1 contained significantly higher R_d values than the other three plates while plates 2 and 3 and plates 3 and 4 were not significantly different. The experimental variable created by differential migration rates on the plates for separate TLC runs is difficult to control, but fortunately, although statistically significant, its magnitude is not great. We strongly suggest that both sexes be run on each plate as we have done so that possible differences attributable to sex and plates can be separated.

Similar regression analyses were run for the spot intensities. Again, our initial regression model examined the dependency of the butterfly SIs on the plant SIs alone. This regression indicated a weak but significant correlation (F

$= 11.27$, $P < 0.0010$; $r^2 = 0.0667$) and produced the equation for the line $Y = 0.373X + 2.725$. To remain consistent with our treatment of the R_d values, our second regression contained the effects of the plant SIs, sex, plate, and their interactions. The overall model was not significant ($F = 1.37$, $P < 0.1674$). Again with type IV SS statistics, only the plant SIs contributed significantly to the model ($F = 9.47$, $P < 0.0025$), and the R^2 (0.125) was only slightly greater than the r^2 (0.0667) of the plant SIs alone. Duncan's option indicated that none of the plates or their combinations were significantly different in spot intensity.

DISCUSSION

General Field Observations During Sample Collections. Each spring millions of monarch butterflies return to temperate North America through Texas and Louisiana from their overwintering sites in Michoacan, Mexico. Whether monarchs reaching the Atlantic Coastal Plain pass up the Florida peninsula or remigrate into Texas and Louisiana and then travel across the Gulf Coast has not yet been elucidated (Brower, personal communication). The overwintering colonies begin to break up in early to mid-March and by late March the first remigrants can be seen across the southern United States (Lynch and Martin, Brower and Malcolm, personal observations). In Texas and Louisiana, *A. asperula* subsp. *capricornu* and *A. viridis* represent the first abundant and widespread milkweeds they encounter.

We have found numerous early instars on *A. asperula* subsp. *capricornu* in central and eastern Texas by early April. First-, second-, and early third-instar larvae usually feed on floral parts, remaining hidden in the more compact preanthesis inflorescences. Later instar larvae usually feed on the leaves. While only a small percentage of larvae reach the fourth- and fifth-instar stages (Lynch and Martin, personal observations), the abundance of *A. asperula* in central to eastern Texas suggests a great number of larvae survive to pupate and emerge as adults. By early May the remigrants, faded and battered by the journey, largely disappear, and freshly emerged first generation adults can be seen in increasing numbers. In Texas, adult monarchs are seldom seen after late May, and immature stages are generally absent even though many plants remain green and healthy through most of June. We have observed freshly emerged monarchs in central Oklahoma in late May searching and mating in fields of *A. viridis* and *A. asperula* and in central Kansas during June laying eggs on *A. speciosa* and *A. syriaca*.

For the majority of our pairwise samples, we circumvented the problem of low survivorship by removing crab spiders from the plants and bagging two first- or second-instar larvae on randomly selected plants. This virtually eliminated spider predation and tachinid parasitism, a common problem in rearing

wild-found larvae. Bagging provided the further advantage of knowing without question that larvae ate only on the individual plants from which they were collected. In contrast to western U.S. monarchs, which nearly always form their chrysalids upon their host plant (Brower et al., 1982, 1984a, b), no chrysalids were found on unbagged plants. Even bagged monarchs tended to spin their pads on the nylon net bags rather than on the leaves of the plant.

Quantitative Variation of Plant and Butterfly Cardenolides. A. asperula subsp. *capricornu* plants contain a higher mean cardenolide concentration than other *Asclepias* species examined to date, with the possible exception of three closely related, leafless desert species of the series roseae (*A. albicans*, *A. subaphylla*, and *A. masonii*) that have not been reported as host-plants for monarchs (Brower et al., 1982, 1984a, b; Roeske et al., 1976; Seiber et al., 1983, 1984; Lynch and Martin, 1987; Lynch, personal observations). While wide variation occurred in the cardenolide concentrations of the *A. asperula* plants, a much narrower range of variation was found in the respective butterflies. The mean cardonolide concentration in the butterflies was also much lower than in the plants. In *A. eriocarpa*, another cardenolide-rich milkweed, Brower et al. (1982) also found the butterflies had a lower mean concentration and a narrower concentration range than their host plants. The opposite was observed in *A. viridis*, where both the mean and range of cardenolide concentration in the butterflies was greater than in the plants (Lynch and Martin, 1987). Similar patterns were found in *A. californica* and *A. speciosa* butterfly–plant pairs (Brower et al., 1984a, b). Both species have a lower mean cardenolide concentration than *A. viridis*.

These data indicate there is a limit to the amount of cardenolide the butterflies can absorb and that saturation occurs. Seiber et al. (1980) suggested that monarchs sequester cardenolides more efficiently when present in low concentrations, with uptake generally conforming to an inverse logarithmic relationship with increasing concentrations. Butterflies reared on host-plants rich in cardenolides would sequester these compounds at or near maximum (or optimum) concentrations and butterflies reared on low cardenolide host-plants would significantly reflect host-plant concentrations up to maximum (or optimum) levels. Therefore, the regression equation $Y = a(\log_{10} X) + b$ should fit the overall relationship between monarch and host-plant concentrations. Work with *A. californica* (Brower et al., 1984a), *A. speciosa* (Brower et al., 1984b), and *A. viridis* (Lynch and Martin, 1987) confirm this relationship.

We were unable statistically to confirm any relationship between cardenolide concentrations in the butterflies and their respective host-plants in this study. All *A. asperula* plants examined contained high levels of cardenolide, and our samples represented only the saturation portion of the curve. The calculated slopes were so small that concentrations and total cardenolide in the butterflies approximated the intercept. Although we chose to log transform the

butterfly concentration data, so that we could assume normality in our statistical analyses (e.g., Table 2), and plotted the linear regression of butterfly concentrations on their respective plant concentrations in Figure 3, we recognize that neither may reflect the overall cardenolide concentration relationships between monarchs and their various host-plants.

Duffey et al. (1978) and Scudder et al. (1986) suggest that cardenolides in *Oncopeltus*, a common milkweed bug, are sequestered in a specialized inner epithelium (the dorsolateral space) through a nonsaturable, passive diffusion process in proportion to the cardenolide content in the food source and the hemolymph. While the mechanisms for cardenolide uptake in monarchs are unknown, patterns observed in all monarch–milkweed pairwise analyses to date could fit a physical uptake model. Larvae feeding on *A. asperula* and other cardenolide-rich host plants would ingest a total amount of cardenolides approaching or exceeding their physical limits of absorption and/or storage. A relatively narrow range of cardenolide concentrations would therefore be expected in the adults, largely restricted to the physical variation among individual butterflies and not significantly correlated to host-plant concentrations. On milkweeds containing low to moderate amounts of cardenolides, the total cardenolides ingested by individual larvae would be less than that imposed by their physical limitations. Variations in host plant concentrations would compound the physical variation among the butterflies so that a wide range of variation would be expected. Diffusion rates into available larval tissues would decelerate as tissue concentration increased, producing the logarithmic relationship seen in *A. speciosa* (Brower, et al., 1984b), *A. californica* (Brower et al., 1984a), and *A. viridis* (Lynch and Martin, 1987). That saturation does not occur in *Oncopeltus* may simply reflect the presence and function of its specialized dorsolateral space.

The higher mean concentration of cardenolide we observed in female butterflies compared to male butterflies reared on *A. asperula* is consistent with data on butterflies reared on several other *Asclepias* species (Brower and Glazier, 1975; Brower et al., 1975, 1982, 1984b; Lynch and Martin, 1987) and in wild summer-breeding populations in the eastern United States (Brower et al. 1972, Brower and Moffitt, 1974). These data may simply reflect differences in the reproductive morphology between males and females. Brower (1984) cites work with Thomashow in which eggs produced by butterflies reared on *A. curassavica* were found to contain higher levels of cardenolide (0.6% by dry weight) than adults (0.4%). A female may lay as 100 (Erickson, 1973) to 400 eggs (Urquhart, 1960), and as much as 97–388 μg of cardenolide could be present in the female reproductive tract. Dixon et al. (1978) found that monarch females that had laid all their eggs were less emetic to pigeons than freshly eclosed females.

Brower et al. (1972) generated considerable controversy when they first

suggested that monarchs incur a physiologic cost in sequestering cardenolides. More recent work by Brower et al. (1982, 1984a, b) and Lynch and Martin (1987) do not directly support this hypothesis. Vaughan and Jungreis (1977) indicated the presence of cardenolide-resistant Na, K-ATPases in the monarch which may reduce or eliminate physiologic costs of cardenolide sequestration in monarchs. Moore and Scudder (1985) report similar ouabain-resistant Na, K-ATPases in *Oncopeltus*, which similarly does not appear to incur physiologic cost from the sequestration of cardenolides.

If size reduction is used as a potential indicator of metabolic cost in monarchs, higher levels of sequestration in females in comparison to the significantly larger males confuse the issue. Female monarchs also tend to feed on host-plants with higher cardenolide concentrations (Brower et al., 1982, 1984a,b; Lynch and Martin, 1987). Although not statistically significant, *A. asperula*-reared female butterflies fed on host-plants with a mean cardenolide concentration of 920 μg/0.1 g while males fed on host plants with a mean of 847 μg/0.1 g. We ran several regressions on *A. asperula* butterflies and their host plants to examine the relationship between size and cardenolide content. There was a significant negative correlation between all 41 butterfly dry weights and cardenolide concentration ($F = 9.925$, $P < 0.0031$). Female dry weights alone were also negatively correlated with their cardenolide concentrations ($F = 8.26$, $P < 0.0094$), while males were not ($F = 0.505$, $P < 0.487$). In a multiple regression model including butterfly concentration, host-plant concentration, and the sex of the butterflies, none of the variables or their interactions were significantly correlated to butterfly dry weight using type II SS statistics.

Qualitative Analyses of Plant and Butterfly Cardenolides. Comparisons of the standards, desglucosyrioside, labriformin, and labriformidin, with pools of plants and butterflies spotted on the same plate and developed in the EM system clearly indicated the absence of these three compounds in the butterflies and only their possible occurrence in the plants. The match of the particularly high R_f values of spots 26 and 25 in the CMF system suggests they may be the epoxy cardenolides labriformin and labriformidin, respectively. Both compounds are characterized by having unusually high oxygen–carbon ratios and are highly nonpolar. Plant spot 16 in the CMF system could be desglucosyrioside, a 3′-OH derivative of labriformin and labriformidin. However, it has been established (Seiber et al., 1980; Nelson et al., 1981; Brower et al., 1982, 1984b) that monarchs metabolize labriformidin to labriformin and labriformidin to desglucosyrioside when obtained from their hosts-plants. Thus the absence of these compounds in monarchs obtained from *A. asperula* plants strongly suggests the absence of desglucosyrioside, labriformin, and labriformidin in these plants. Carolyn Nelson (personal communication) has suggested that acetate derivatives of various cardenolides also have high R_f values and could be mistaken for labriformin and/or labriformidin. As no additional standards were present

on our plates, we chose not to speculate further on the identity of the cardenolides in *A. asperula.* No specific cardenolides have been isolated and identified from the *Asclepias* subgenus Asclepiodora, and both *A. viridis* and *A. asperula* may well contain previously unidentified cardenolides.

Although unique, the general TLC patterns of *A. asperula* plant and butterfly cardenolides are similar to those found in *A. viridis* and also conform to those observed by Brower et al. (1982, 1984a, b) in *A. eriocarpa*, *A. speciosa*, and *A. californica.* Larval metabolites are more polar than their parent cardenolides, providing a pattern of cardenolides with lower R_f values in the CMF system. Relatively few milkweed cardenolide structures have been established, and most spots found in established TLC fingerprint profiles remain unknown. In addition, different compounds may have similar polarities and fail to separate in a particular system (e.g., calactin and calotropin in the CMF system and desglucosyrioside and labriformin in the EM system). Nevertheless, the general storage pattern appears consistent for those milkweed species examined so far and similarities in certain cardenolides or even entire series do not preclude the possibility of distinguishing among cardenolide patterns for butterflies reared on different milkweeds.

Cardenolide Profiles and Monarch Migration. Although we have observed large instar larvae in April on *A. amplexicaulis*, *A. longifolia*, and *A. viridiflora*, these milkweed species are less common and produce considerably less biomass than either *A. asperula* subsp. *capricornu* or *A. viridis*. Brower (1961, 1962) and Cohen and Brower (1982) report that the common sandhill milkweed, *A. humistrata* Walt., is heavily utilized by monarch remigrants in western and central Florida. If remigrating monarchs do in fact oviposit predominantly on these three southern milkweeds as they reenter the temperate United States, the majority of late spring and early summer breeding monarchs seen in the central and northeastern United States and Canada would possess their characteristic TLC profiles. All three milkweeds are relatively rich in cardenolides and produce adult monarchs that contain high levels of these compounds. These toxic first generation monarchs could be instrumental in educating naive predators as they continue northward, establishing visual rejection by would-be predators of later generation monarchs regardless of taste or toxicity due to cardenolide content (Lynch and Martin, 1987; Brower and Malcolm, in preparation).

Seiber et al. (1986) have shown that 85% of all monarchs sampled from the overwintering sites in Mexico contain similar patterns of epoxy cardenolide glycosides, which suggests that *A. syriaca* and *A. speciosa* are the predominant late summer food plants of monarchs in eastern North America. Both species produce monarchs relatively poor in cardenolides (Brower et al., 1984b; Seiber et al., 1986), and the predominant glycosides in each are the polar syrioside and aspecioside which appear to have a significantly lower emetic potency than cardenolides of intermediate polarity often sequestered by monarchs in Califor-

nia (Brower et al., 1982, 1984b). Therefore, the continued presence of highly toxic, first spring generation adults during the summer breeding cycle in eastern North America would be particularly critical in reinforcing visual avoidance of monarchs by potential predators.

More extensive avian and rodent predation occurs at the Mexican overwintering site than occurs in overwintering sites along the California coast (Calvert et al., 1979; Fink and Brower, 1981; Fink et al., 1983; Brower et al., 1984b; Brower and Calvert, 1985). Brower and Moffitt (1974) showed that 49% of the overwintering adults in California contained sufficient cardenolides to individually produce emesis in blue jays. The cardenolide-rich *A. eriocarpa* and *A. erosa* both are utilized heavily by late summer breeding monarchs in California (Brower et al., 1982; Lynch, personal observations). Brower and Fink (1981) calculated that only 10% of the butterflies sampled at the Michoacan overwintering site were individually emetic. In contrast, Brower and Moffitt (1974) showed that nearly 55% of their September sample population of Massachusetts monarch adults were emetic. Brower et al. (1972) earlier found that approximately 40% of fall migrating monarchs in Ontario and Massachusetts contained emetic concentrations of cardenolide but that migrating monarchs in Maryland and Florida contained significantly less cardenolide.

Brower (personal communication) suggests these geographic differences in emetic potencies of late summer monarchs in eastern North America may reflect cardenolide loss in metabolism and excretion as the butterflies migrate southward. Alternately, we suggest that large numbers of adults reared as larvae on *A. viridis*, *A. asperula*, and *A. humistrata* are still present in the mid and late summer northern populations but that progressively fewer of these early generation butterflies survive as monarchs emigrate southward in the fall. This hypothesis can be verified by matching cardenolide fingerprint profiles of wild-caught northern butterflies against established cardenolide fingerprints of butterflies reared on the predominant southern milkweeds.

Acknowledgments—We are grateful to Rita Horton, Laura Clark, and Mary Lowery for their assistance in the field and in the laboratory. Dr. Lincoln P. Brower has been particularly helpful in overcoming technical problems in the laboratory and in manuscript preparation, and Dr. James N. Seiber generously provided us with cardenolide standards. This research has been supported by the American Heart Association, Louisiana, Inc., and by LSU Shreveport Faculty Research Grants.

RESPONSE OF GENERALIST AND SPECIALIST INSECTS TO QUALITATIVE ALLELOCHEMICAL VARIATION

M. DEANE BOWERS and GILLIAN M. PUTTICK[1]

Museum of Comparative Zoology
Harvard University
Cambridge, Massachusetts 02138

(Received July 3, 1986; accepted February 3, 1987)

Abstract—We examined the effects of a set of four biosynthetically related iridoid glycosides, aucubin, catalpol, loganin, and asperuloside, on larvae of a generalist, *Lymantria dispar* (Lymantriidae), the gypsy moth, and an adapted specialist, the buckeye, *Junonia coenia* (Nymphalidae). In general, *L. dispar* grew and survived significantly less well on artificial diets containing iridoid glycoside, compared to a control diet without iridoid glycosides. In choice tests, previous exposure to a diet containing iridoid glycosides caused larvae subsequently to prefer iridoid glycoside-containing diets even though they were detrimental to growth and survival. In contrast, *J. coenia* larvae grew and survived better on diets with aucubin and catalpol, the two iridoid glycosides found in the host plant *Plantago lanceolata* (Plantaginaceae), than on diets with no iridoid glycoside or with loganin and asperuloside. The results of choice tests of diets with and without iridoid glycosides and between diets with different iridoid glycosides reflected these differences as well. These results are discussed in terms of (1) differences between generalists and specialists in their response to qualitative variation in plant allelochemical content, (2) the induction of feeding preferences, and (3) the evolution of qualitative allelochemical variation as a plant defense.

Key Words—Iridoid glycoside, *Junonia coenia*, *Lymantria dispar*, Lepidoptera, Nymphalidae, Lymantriidae, induction, insect–plant interaction, generalist herbivore, specialist herbivore.

INTRODUCTION

Plant families are often characterized by the presence of a particular group of allelochemicals. For example, the Cruciferae contain glucosinolates (Hegnauer,

[1] Current address: Chemistry Department, Northeastern University, Boston, Massachusetts 02115.

0098-0331/88/0100-0319$06.00/0

1973; Rodman and Chew, 1980), the Asclepiadaceae contain cardenolides (Hegnauer, 1973; Gibbs, 1974), and the Scrophulariaceae contain iridoid glycosides (Jirawongse, 1964; Kooiman, 1970; Jensen et al., 1975). Plant species within such families usually contain some, but not all, of the taxon-specific array of biosynthetically related compounds, and closely related species may have different subsets of the array. However, there may be variation among populations of a single species, among individuals within a population, and among different parts of an individual plant (Dolinger et al., 1973; McKey, 1979; Brower et al., 1982; Roby and Stermitz, 1984a; Louda and Rodman, 1983a,b) in what particular compounds are present and in what amounts they occur. This pattern may also change through the season (Brower et al., 1982; Mooney and Chu, 1974) and the conditions under which the plant is growing (Lincoln and Mooney, 1984; Rhoades, 1979; Cooper-Driver et al., 1977; McKey et al., 1978). Thus the spectrum of chemical compounds to which an insect herbivore is exposed may vary with the individual plant or plant population, the part of the plant eaten, and the phenology of the plant and insect, as well as among species or genera.

Many insect species specialize on a particular set of plant species characterized by a distinctive group of allelochemicals (Ehrlich and Raven, 1964), such as pierid butterflies on the glucosinolate-containing crucifers (Rodman and Chew, 1980) and checkerspot butterflies in the genus *Euphydryas* on plants containing iridoid glycosides (Bowers, 1983). In contrast, generalist insect species are predicted to be repelled or poisoned by such qualitative chemical defenses, and indeed, often are (Feeny, 1976).

Qualitative allelochemical variation may be an important component of plant defense. Different individual compounds of the same chemical class may have very different effects on insect herbivores and occur within a single plant; thus the chemical composition of an individual plant may be important in whether or not it is a suitable hostplant (Chambliss and Jones, 1966; Metcalf et al., 1980; Miller and Feeny, 1983; Bentley et al., 1984a,b; Berenbaum, et al., 1986). In addition, the combination of two or more related compounds or types of compounds may have positive or negative synergistic effects on insects feeding on those plants (Nielsen et al., 1977; Berenbaum, 1985). Therefore, qualitative or quantitative variation in the chemical make-up of host plants may be critical determinants of fitness for individual insects.

The experiments presented in this paper examine the responses of specialist and generalist insect herbivores to an array of biosynthetically related plant allelochemicals, the iridoid glycosides. The iridoid glycosides are a group of monoterpene-derived compounds found in over 50 families of plants (Bobbitt and Segebarth, 1969; Jensen et al., 1975, Hegnauer and Kooiman, 1978; El-Naggar and Beal, 1980; Dahlgren et al., 1981; Gershenzon and Mabry, 1983). Larvae of butterflies in the genus *Euphydryas* use iridoid glycosides as feeding stimulants and attractants (Bowers, 1983), as do larvae of the buckeye, *Junonia*

coenia Hbn. (Nymphalidae), another specialist on iridoid glycoside-containing plants (Bowers, 1984). In addition, butterflies in the genus *Euphydryas* sequester iridoid glycosides to use in their own defense against predators (Bowers, 1980, 1981; Bowers and Puttick, 1986; Stermitz et al., 1986a). Two iridoid glycosides, ipolamiide, found in plants of the genus *Stachytarpheta* (Verbenaceae), and specioside, from *Catalpa speciosa* (Bignoniaceae), are deterrent to generalist insects (El-Naggar and Doskotch, 1980; Bernays and DeLuca, 1980).

To compare the response of a generalist and a specialist insect to a natural array of different iridoid glycosides, we chose the generalist species, *Lymantria dispar* (L.) (Lymantriidae), the gypsy moth, and the specialist, *J. coenia*. *J. coenia* feeds on a variety of plants that contain iridoid glycosides (Bowers, 1984). The experiments were designed: first, to compare the response of generalist and specialist insects to the iridoid glycosides; second, to determine how qualitative variation in allelochemical content affects these insects; and third, to compare the effectiveness of iridoid glycosides in inducing feeding preferences in a generalist and a specialist insect.

METHODS AND MATERIALS

Organisms and Culture Conditions. Cultures of the test species were maintained in environmental chambers under conditions of 14 : 10 hr light–dark photoperiod, and temperatures of 25°C day, 20°C night.

Lymantria dispar is a generalist feeder and has been recorded feeding on over 450 species of plants (Leonard, 1974). Egg masses were obtained from the Gypsy Moth Rearing Facility at Otis Air Force Base, Massachusetts, where they are raised on an artificial diet (J. Baker, personal communication). Our culture was maintained on an artificial diet with no additives (see below).

Junonia coenia is a specialist on iridoid glycoside-containing plants and has been recorded in the wild on host-plant species from four families: Acanthaceae, Plantaginaceae, Scrophulariaceae, and Verbenaceae (Bowers, 1984). Larvae use iridoid glycosides as feeding stimulants (Bowers, 1984), and adult females use these compounds as oviposition cues (Pereyra and Bowers, unpublished). *Plantago lanceolata* L. (Plantaginaceae) is a commonly utilized host plant (Bowers, 1984), even though it is an introduced species. The *J. coenia* culture was started from eggs obtained from females collected in Columbia, South Carolina, and maintained on leaves of *P. lanceolata* collected from plants grown in an experimental garden in Cambridge, Massachusetts.

Iridoid Glycosides and Artificial Diets. The four iridoid glycosides used in this study, aucubin, catalpol, loganin, and asperuloside (Figure 1), are biosynthetically related (Inouye, 1971) and occur in a variety of angiosperm families (Table 1). Aucubin is a precursor of catalpol, and these two are perhaps the most ubiquitous of all iridoid glycosides, occurring together in many plant spe-

TABLE 1. PLANT FAMILIES CONTAINING THE FOUR IRIDOID GLYCOSIDES USED IN THIS STUDY[a]

Plant Family	Iridoid glycosides
Apocynaceae	aucubin, loganin
Bignoniaceae	catalpol
Buddleiaceae	aucubin, catalpol
Callitrichaceae	aucubin, catalpol
Caprifoliaceae	loganin
Cornaceae	aucubin, loganin
Daphniphyllaceae	asperuloside
Ericaceae	asperuloside
Eucommiaceae	aucubin, asperuloside
Globulariaceae	aucubin, catalpol, asperuloside
Hammamelidaceae	asperuloside
Hippuridaceae	aucubin, catalpol
Lentibulariaceae	aucubin, catalpol
Loganiaceae	aucubin, loganin
Orobanchaceae	aucubin
Plantaginaceae	aucubin, catalpol
Rubiaceae	asperuloside
Scrophulariaceae	aucubin, catalpol
Verbenaceae	aucubin

[a] Sources for these data were Bobbitt and Segebarth (1969) and El-Naggar and Beal (1980).

cies (El-Naggar and Beal, 1980; Kaplan and Gottlieb, 1982), although they may also occur independently of each other (El-Naggar and Beal, 1980). Loganin is quite prevalent in the Loganiaceae and Caprifoliaceae, and it may occasionally be found in the same plant species as aucubin (El-Naggar and Beal, 1980). Asperuloside has been particularly well-documented as characteristic of the Rubiaceae (e.g., Kaplan and Gottlieb, 1982, and references therein). It only rarely occurs with the other three iridoid glycosides used in this study (Bobbitt and Segebarth, 1969) (Table 1). Aucubin and catalpol are characteristic of many *J. coenia* host plants (Bowers, 1984), while loganin and asperuloside are not.

Both for rearing of larvae and choice experiments, artificial diets were made according to the basic recipe of Lincoln et al. (1982). A control diet (AD) contained no additional components. The experimental diets contained 0.05 g iridoid glycoside per 28.4 g dry weight diet, thus presenting larvae with a diet with 0.18% dry weight iridoid glycoside, well within the range of iridoid glycoside content normally found in plants (Bobbitt et al., 1961; Roby and Stermitz, 1984b). Four iridoid glycosides were used for these experimental diets: asperuloside (AD + asp), aucubin (AD + auc), catalpol (AD + cat), and loganin (AD + log). All four iridoid samples were pure by high-performance liquid chromatography (HPLC) analysis. A sixth diet contained 0.09% each aucubin and catalpol (AD + a&c), thus the total amount of iridoid glycoside in this diet was equivalent to the total amount in the other diets. A seventh diet contained dried, finely ground leaves of *P. lanceolata*, comprising 3.5% dry weight of the diet (AD + P.l.).

Growth Rate and Survival. Larvae were reared in Petri dishes with damp paper towel taped to the lid to maintain humidity. To compare growth and survival of *J. coenia* and *L. dispar* in response to an array of iridoid glycosides, larvae were reared on six different diets: AD, AD + auc, AD + cat, AD + log, AD + asp, and AD + P.l. In addition, *J. coenia* larvae were also reared on AD + a&c. Newly hatched, unfed larvae of each species were put onto each of the artificial diets in groups of 10. For each species there were five replicates in each treatment, with one exception: there were only four replicates of *L. dispar* larvae on AD + asp. Larvae were weighed as a group at hatching and weighed and counted every five days thereafter for 15 days. One-way analyses of variance were performed on the $\log_{10}$-transformed weights, and arcsin-transformed percentage survival, and followed by Student-Newman-Keuls (SNK) range tests to test for differences among the means.

Choice Tests. To determine whether larvae could distinguish between diets with and without iridoid glycosides and between diets with different iridoid glycosides, and to determine the effect of previous rearing experience (induction), choice tests were conducted in Petri dishes with individual larvae in the last instar. Prior to testing, larvae had been reared from hatching on one of the seven test diets described above. Larvae were starved for approximately 12 hr

and then an individual larva was put into a Petri dish and offered cubes (approximately 8 × 6 × 6 mm) of two artificial diets placed about 1.5 cm apart in the middle of the dish. They were allowed to feed ad libitum for 48 hr. The sample sizes ranged from six to 10 larvae for each test, depending on the number of larvae available. The dry weight of each diet eaten was calculated using standard gravimetric methods (Waldbauer, 1969; Bowers, 1983, 1984). In a few cases, if larvae did not eat any diet, the amount eaten was a negative number (see Bowers, 1983, 1984), which was assumed to be 0 for analysis. The amounts eaten of the two diets were compared by two-way ANOVA with diet and larva as the main effects.

RESULTS

Growth and Survival. The incorporation of iridoid glycosides into the artificial diets clearly had a detrimental effect on the growth of *L. dispar* larvae; they weighed 1.5–3 times less after 15 days on the artificial diets with iridoid glycosides than on the diet without iridoid glycosides (Table 2). Diets could be grouped according to their effect on larval weights: (1) larvae reared on AD were the heaviest; (2) those reared on the diets with aucubin, catalpol, and *P. lanceolata* leaves were intermediate; and (3) those on the diets with loganin and asperuloside grew the least (Table 2). Although the specific ranks of the diets within these groups changed over the course of the experiment (Table 2), the weights of larvae fed on the diet with *P. lanceolata* leaves, which contain aucubin and catalpol [in amounts ranging from 0.05 to 1.0% dry weight (Fajer, unpublished data)], were always very similar to those of larvae on the diets with aucubin and catalpol. Survival of larvae was not significantly different on the different diets ($F = 2.40$, $df = 4, 19$, $0.05 < P < 0.10$) (Table 2).

Aucubin and catalpol were necessary for successful larval feeding and growth of *J. coenia* (Table 3). Again, the diets fell into three groups: (1) larvae grew best on the diets with aucubin and catalpol (AD + auc, AD + cat, AD + P.l., and AD + a&c), (2) larvae grew about half as well on AD, and (3) larvae weighed one quarter to one fifth less on the diets with loganin and asperuloside as on those with aucubin and catalpol (Table 3). Interestingly, the diets containing loganin and asperuloside supported the poorest growth in both *L. dispar* and *J. coenia*. The similarity of larval weights on AD + a&c with those on the other three diets containing aucubin and catalpol was not surprising. On day 5, *J. coenia* larvae were heaviest on the diet with catalpol and were still heaviest at the end of the experiment on day 15. Although there was a marginally significant effect of diet on survival ($P = 0.05$), and SNK analysis did not detect differences among the diets, larval survival loosely corresponded to larval weights (Table 3).

TABLE 2. MEAN WET WEIGHT (±SE) PER LARVA IN MILLIGRAMS AND MEAN PERCENTAGE (±SE) SURVIAL OF *Lymantria dispar* LARVAE REARED ON ARTIFICIAL DIETS WITH AND WITHOUT IRIDOID GLYCOSIDES[a]

[a]Weights were compared by one-way ANOVA followed by the Student-Newman-Keuls range test. The *P* value indicates the results of the ANOVA, and the same letters indicate mean weights that were not significantly different across diets at $P < 0.05$ by the Student-Neuman-Keuls range test (Sokal and Rohlf, 1969). Although there was a significant difference among the percent of larvae surviving on the various diets, SNK did not distinguish among the means.

Choice Tests. Larvae of *L. dispar* that had been reared on artificial diet with no additives and were then given a choice of diets with and without iridoid glycosides showed no preference for AD over AD + cat or AD + log (Figure 2). Surprisingly, they significantly preferred the diet AD + asp over AD even though this diet reduced growth (Figure 2). When *L. dispar* larvae were reared on diets that contained iridoid glycosides, a preference for iridoid glycosides was induced (Jermy et al., 1968), and they significantly preferred those diets (Figure 2), even though iridoid glycosides depressed growth when added to the diet (Figure 2). The choice tests between two different iridoid glycoside-containing diets showed that a preference was induced by the presence of loganin, and larvae preferred it over the diet with catalpol, but no preference was induced by aucubin when larvae were given a choice with aucubin and catalpol.

Larvae of *J. coenia* will not feed and survive well enough to use in choice tests if reared on an artificial diet without either iridoid glycosides or plant material that contains iridoid glycosides. Larvae that had been reared on artificial diet with 3.5% *P. lanceolata* leaves significantly preferred diets with leaf material or iridoid glycosides over the diet with no additives (Figure 3). They did not distinguish between the diet with *P. lanceolata* leaf material, which contains aucubin and catalpol, and diets with pure aucubin and catalpol (Figure 3). Results with *J. coenia* from California were the same (Bowers, 1984). Larvae that had fed on iridoid glycoside-containing diets significantly preferred those diets to diets without iridoid glycosides (Figure 3), even though some of these diets contained iridoids that depressed growth (Figure 3). One exception was in larvae offered a choice of the diet with catalpol and the control diet. Although the mean amounts eaten are very different for the two diets, the differences were not statistically significant due to one caterpillar which ate equal amounts of the two diets, while others all preferred AD + cat.

Interestingly, *J. coenia* larvae that had been reared on AD + a&c preferred this diet over AD + P.l. Larvae given the same choice but which had been reared on AD + P.l., ate similar amounts of the two diets (Figure 3). However, a comparison of the proportion of AD + P.l. eaten by larvae that had been reared on each of these two diets showed no significant difference (one-way ANOVA after arcsin transformation, $F = 3.71$, $df = 1, 16$, $0.05 < P < 0.10$). *J. coenia* larvae also preferred AD + log over AD + cat when they had been reared on AD + log. If reared on AD + cat and given this same choice, the mean amounts eaten are again quite different, but this is not statistically significant because two of nine larvae preferred AD + cat over AD + log, while the rest preferred AD + log (Figure 3). A comparison of the proportion of AD + log eaten by these two groups of larvae showed that larvae ate a significantly higher proportion of AD + log when they were reared on that diet (one-way ANOVA after arcsin transformation, $F = 5.59$, $df = 1, 16$, $P < 0.05$). This comparison suggests that larvae may have an innate preference for the iridoid

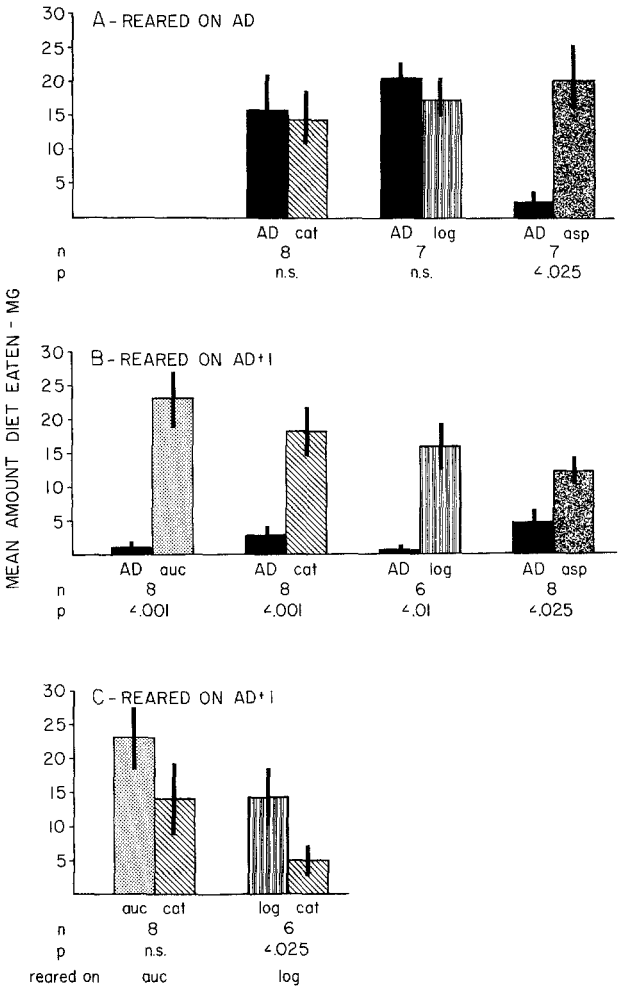

FIG. 2. Choice test results for *Lymantria dispar*. (A) Larvae reared on artificial diet with no additives and then given a choice of diets with and without iridoid glycosides. Choice tests were not run for AD + auc because of low numbers of larvae. (B) Larvae reared on an artificial diet with an iridoid glycoside and then given a choice of that diet and a control diet with no iridoid glycosides. (C) Larvae reared on a diet with an iridoid glycoside and then given a choice between that diet and another diet with a different iridoid glycoside. The vertical bars on each column indicate one standard error. *P* values are for the diet effect in a two-way ANOVA with larva as the other main effect. AD = artificial diet with no iridoid glycosides (control); auc = artificial diet with 0.18% aucubin; cat = artificial diet with 0.18% catalpol; log = artificial diet with 0.18% loganin; asp = artificial diet with 0.18% asperuloside.

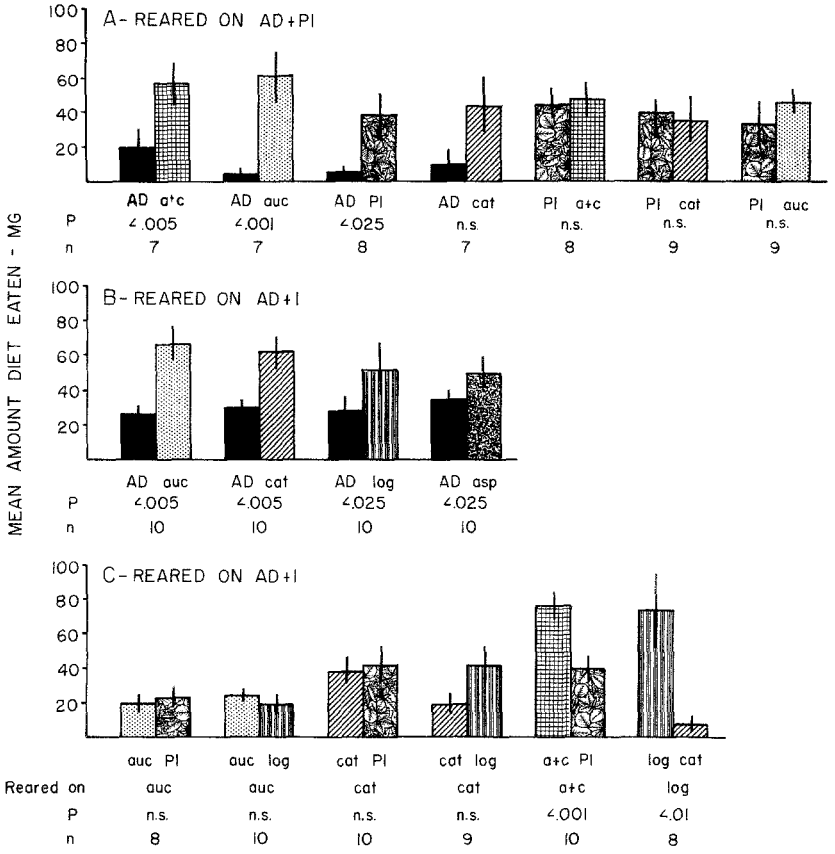

FIG. 3. Choice test results for *Junonia coenia*. (A) Larvae reared on an artificial diet with 3.5% dry weight ground leaves of *Plantago lanceolata* and then given a choice of diets with and without iridoid glycosides. (B) Larvae reared on an artificial diet containing 0.18% of an iridoid glycoside and then given a choice of that diet and a control diet containing no iridoid glycosides. (C) Larvae reared on an artificial diet containing 0.18% of an iridoid glycoside and given a choice of that diet and another diet with either another iridoid glycoside, 3.5% dry weight ground leaves of *P. lanceolata*, or 0.09% aucubin + 0.09 catalpol. The vertical bars on each column indicate one standard error. *P* values are for the diet effect in a two-way ANOVA with larva as the other main effect. AD = artificial diet with no iridoid glycosides (control); auc = artificial diet with 0.18% aucubin; cat = artificial diet with 0.18% catalpol; log = artificial diet with 0.18% loganin; asp = artificial diet with 0.18% asperuloside; P.l. = artificial diet with 3.5% dry weight *P. lanceolata* leaves; a&c = artificial diet with 0.09% aucubin + 0.09% catalpol.

glycoside loganin and that being reared on that diet strengthens that preference. This behavior was not expected since AD + log reduces growth (Table 3).

DISCUSSION

The generalist, *L. dispar* and the adapted specialist, *J. coenia*, responded differently to the presence of iridoid glycosides in their food. In general, *L. dispar* grew and survived less well on diets with iridoids, while *J. coenia* performed best on diets with the two iridoid glycosides typical of its primary host plant *P. lanceolata*. We did not distinguish between deterrent or toxic effects (Blau et al., 1978; Miller and Feeny, 1983; Brower, 1984) of the various iridoid glycosides in these experiments as the basis for differential growth on diets with and without these compounds (Puttick and Bowers, 1988). For both insect species, catalpol and aucubin supported better growth of larvae than loganin and asperuloside (Tables 2 and 3).

The results with *J. coenia* suggest that loganin and asperuloside may be toxic rather than deterrent to these larvae: larvae prefer diets containing these two iridoid glycosides in choice tests (Figure 3), but grow very poorly on those diets. A toxic effect might be expected since loganin and asperuloside are not found in the host plants of *J. coenia*, which are in the Plantaginaceae, Scrophulariaceae, Verbenaceae, and Acanthaceae (Table 1). An alternative explanation may be that loganin and asperuloside are more toxic or deterrent to first-instar larvae than to later instar larvae. Early instar toxicity may be due to a lack of detoxifying enzymes in the gut of early instars (Gould, 1984; Cohen, 1983). Growth might be slowed in the early instars, leading to differences in the total growth of larvae on loganin and asperuloside compared to the diets with other iridoid glycosides. Thus *J. coenia* appears to be physiologically adapted to the specific iridoid glycosides, catalpol and aucubin, which are typical of its host plants, and not to iridoid glycosides as a group. However, in choice tests, *J. coenia* larvae chose diets with iridoid glycosides that decrease growth rate (loganin and asperuloside) over a diet without these compounds. From a chemical perspective, this behavior suggests that for specialists such as *J. coenia*, the basic iridoid skeleton may be important in eliciting attraction, but that physiological tolerance to particular iridoids depends on the specific chemical structure.

L. dispar generally grew poorly on diets with iridoid glycosides, but showed an induced preference for these compounds in the diets. De Boer and Hanson (1984) found an induction of feeding preference for non-hostplant species in *Manduca sexta* (Sphingidae), but these plants were not toxic to the larvae. Induction of preference for artificial diets has been shown previously (Stadler and Hanson, 1978) but not for diets which were deleterious to larvae, as we found. One explanation for this apparently maladaptive behavior is provided by

work on other lepidopterous larvae which showed that hostplant switching may cause reduction in growth rate and less efficient conversion of food (Schoonhoven and Meerman, 1978; Scriber, 1979, 1982; Barbosa et al., 1986). In other words, since hostplant switching may be metabolically costly, induction of feeding preference could still be adaptive overall.

These results have important implications in considering patterns of herbivory in plant populations. Most plants do not contain a single defensive compound, but contain a suite of biosynthetically related compounds (for iridoid glycosides, see Stermitz et al., 1986a). Individual plants or populations may vary in which particular compounds are present and in what amounts (e.g., Dolinger et al. 1973; Berenbaum et al., 1986). The work of Stermitz et al. (1986b) on *Castilleja sulphurea* (Scrophulariaceae) provides a case in point. They found that some populations of *C. sulphurea* have as many as eight iridoid glycosides. The relative amounts of these different iridoid glycosides vary substantially from one population to another. One population was found to contain almost solely (95%) catalpol; in contrast, other populations sampled contained catalpol in amounts ranging from 21% to 46% of the total iridoid glycoside content.

Individual compounds may have particular effects on the insect herbivores, such as we have shown with iridoid glycosides and *J. coenia* and *L. dispar*. These compounds may also interact to produce synergistic effects. Mutations leading to variations in enzyme kinetics or blockage of certain biosynthetic steps may cause variation in the relative amounts of chemical constituents in different individual plants, or to the accumulation of some compounds and not others. Because different but biosynthetically related compounds may have very different effects on both generalists and specialists, such alteration in chemical composition may protect individual plants with such mutations. For example, in *P. lanceolata*, a mutation may cause a modification of the biosynthetic pathway leading to the accumulation of a precursor of aucubin and catalpol which is not normally found in *P. lanceolata*. Individuals (or populations) with this altered iridoid glycoside composition may be protected from herbivory by specialists, such as *J. coenia*, which our results suggest is not physiologically adapted to iridoid glycosides as a group but only to the specific iridoid glycosides characteristic of its host plants. Such qualitative and quantitative variation in allelochemical profile of plants must be an important determinant of patterns of herbivory in plant populations.

Acknowledgments—We thank May Berenbaum, Frances Chew, Fred Gould, Nancy Stamp, and Frank Stermitz for comments on the manuscript; and Frank Stermitz for unpublished data. Tim Becktold, Jennifer Cornell, Zoia Larrin, and Matt Philpott provided excellent and entertaining laboratory assistance. Fred Nijhout generously provided *J. coenia* larvae. Dave Lincoln allowed us to use his HPLC and provided *J. coenia* adults. We particularly appreciate iridoid glycosides provided by W. Berkowitz, J. Bobbitt, and A. Stephenson. This work was supported by the Milton Fund of Harvard University and NSF grant BSR-8307353 to D. Bowers.

(Received July 3, 1986; accepted February 3, 1987)

Abstract—The behavioral and physiological effects of plant allelochemicals have been difficult to demonstrate; it is not often clear whether the compounds are deterrent, toxic, or both. In this study, we compared the qualitative and quantitative effects of several iridoid glycosides on a generalist lepidopteran herbivore, *Spodoptera eridania* (Noctuidae). Larval growth and survivorship and larval preference or avoidance were measured on artificial diets containing different iridoid glycosides at different concentrations. We also tested the toxicity/deterrence of these compounds. We found that iridoid glycosides retarded larval growth significantly at relatively low concentrations and that they were usually avoided in preference tests. The toxicity/deterrence test did not always reflect the results of these other tests. The merits of using a variety of methods for determining deterrence and/or toxicity of plant allelochemicals are discussed.

Key Words—Iridoid glycosides, *Spodoptera eridania*, Lepidoptera, Noctuidae, allelochemical variation, toxicity/deterrence, plant–insect interaction.

INTRODUCTION

Plant allelochemicals such as alkaloids, coumarins, terpenoids, and others may function as deterrents and/or toxins to generalist and nonadapted specialist insect species (e.g., Burnett et al., 1974; Berenbaum, 1978; Blau et al., 1978;

[1] Present address: Chemistry Department, Northeastern University, Boston, Massachusetts 02115.

0098-0331/88/0100-0335$06.00/0

Miller and Feeny, 1983), while adapted specialists may be unaffected by the same allelochemicals and may use them as feeding or oviposition cues (e.g., Chambliss and Jones, 1966; Schoonhoven, 1972; Bowers, 1983, 1984). Iridoid glycosides (Figure 1) are typical of over 50 plant families including the Scrophulariaceae, Bignoniaceae, Verbenaceae, Acanthaceae, Plantaginaceae, Caprifoliaceae, and Oleaceae (Jirawongse, 1964; Kooiman, 1972; Jensen et al., 1975). Several species of Lepidoptera, including those in the genus *Euphydryas* (Nymphalidae) (Bowers, 1983), *Ceratomia catalpae* (Sphingidae) (Nayar and Fraenkel, 1963), and *Junonia coenia* (Nymphalidae) (Bowers, 1984), specialize on plants that contain iridoid glycosides, and the larvae use these compounds as feeding attractants and stimulants. On the other hand, iridoid glycosides appear to deter generalist insects. For example, ipolamiide was a feeding deterrent for three generalist insect species: *Spodoptera littoralis* (Lepidoptera: Noctuidae) and *Schistocerca gregaria* and *Locusta migratoria* (Orthoptera: Acrididae) (Bernays and DeLuca, 1981); specioside from *Catalpa speciosa* (Bignoniaceae) was deterrent to generalist insects (Chang and Nakanishi, 1983). In addition,

growth rates of gypsy moth larvae *Lymantria dispar* (Lymantriidae) were depressed on artificial diets containing iridoid glycosides (Bowers and Puttick, 1988).

The effects of plant allelochemicals on insect behavior and/or physiology have been difficult to demonstrate (Schoonhoven, 1972; Feeny, 1975; Rhoades, 1979). It is often not clear whether the compounds deter feeding, whether they have a toxic effect once they have already been ingested (Waldbauer, 1962), or both. Blau et al. (1978) developed an assay for toxicity which "permitted a clearer distinction between feeding inhibition and toxicity". Using this method, Blau et al. (1978) found that allylglucosinolate, found in many cruciferous plants, was acutely toxic to larvae of *Papilio polyxenes* (Papilionidae), which do not normally feed on crucifers, while larvae of *Pieris rapae* (Pieridae), which are crucifer specialists, were not affected. Larval growth of the generalist, *Spodoptera eridania* (Cram.) (Noctuidae), was inhibited by high but not by low concentrations of the compound. Usher and Feeny (1983) also used this method and found that atypical secondary compounds occurring in the family Cruciferae, such as alkaloids, cucurbitacins, and cardenolides, were not toxic to *P. rapae*. Similarly, Miller and Feeney (1983) found that benzylisoquinoline alkaloids were toxic to, and/or feeding inhibitors of, three generalist Lepidoptera species: *Hyphantria cunea* (Arctiidae), *L. dispar*, and *S. eridania*.

In this study, we compared the qualitative and quantitative effects of several iridoid glycosides on a generalist lepidopteran herbivore, the southern army worm, *S. eridania*. First, in a series of experiments to compare the qualitative effects of different iridoid glycosides, we compared the growth rates and survivorship of larvae on artificial diets containing each of the four iridoid glycosides aucubin, catalpol, loganin, and asperuloside, with those on a control diet. Then, by means of choice tests, we determined larval preference for or avoidance of diets containing these four compounds. Finally, we tested whether these four compounds were toxic to *S. eridania* larvae using the method of Blau et al. (1978). Second, we determined the quantitative effects of another iridoid glycoside, catalposide, by comparing growth rates and survivorship of larvae reared on artificial diets containing different amounts of this compound. We also measured larval preference for or avoidance of diets containing different amounts of catalposide and determined whether catalposide was toxic or deterrent to larvae and in what amounts.

METHODS AND MATERIALS

Southern Armyworm S. eridania. *Spodoptera eridania* is widely distributed across the southern United States. Larvae feed on a wide variety of herbaceous plants including agricultural crops (Metcalf et al., 1962; Soo Hoo and Fraenkel,

1966; Tietz, 1972). They are easy to maintain in the laboratory and have been used in several studies on the effect of different allelochemicals on generalist insect herbivores (e.g., Blau et al., 1978, Scriber and Feeny, 1979, Miller and Feeny, 1983). *Spodoptera eridania* larvae used in our experiments were reared from eggs from laboratory strains obtained from M. Evans at the University of Wisconsin and from D. Lincoln at the University of South Carolina. Larvae were reared in Petri dishes and maintained in the laboratory under controlled conditions (25°C 16 hr light–20°C 8 hr dark) on artificial diet (Bowers, 1983).

Qualitative Effects of Iridoid Glycosides. To study the effects of different iridoid glycosides on larval growth and survival, larvae were fed artificial diets containing purified catalpol (AD + cat), aucubin (AD + auc), loganin (AD + log), or asperuloside (AD + asp) at levels of 0.18% dry weight of the diets or on a control diet with no iridoid glycosides. This amount is well within the range of iridoid glycoside levels normally found in plants (Bobbitt et al., 1961; Roby and Stermitz, 1984). Growth rates of larvae were measured by rearing five groups of 10 larvae on each of these experimental diets and on the control diet. Hatching was synchronized by refrigeration. Newly hatched larvae from several egg masses were mixed, weighed in groups of 10, placed on diet, and reared for 15 days, by which time larvae were usually in the fifth instar. Larvae were counted and weighed as a group every five days. Larval weights were log-transformed and compared by one-way analysis of variance (ANOVA) followed by the Student-Newman-Keuls (SNK) range test (Sokal and Rohlf, 1969). The number of larvae surviving was compared by one-way ANOVA followed by the SNK range test.

After the growth experiment, the surviving larvae were reared on the same diets for one to two days until they reached the last instar, when surviving larvae were put into choice tests. Larvae were starved for 18 hr and then individually given a choice between the diet they had been reared on and one of the other diets. They were allowed to feed ad libitum for 48 hr, and then the dry weight of each diet eaten was calculated using standard gravimetric methods (Waldbauer, 1968).

The method of Blau et al. (1978) was used to test whether iridoid glycosides were toxic and/or deterrent to *S. eridania*, using newly molted final instar larvae. Determination of the calibration line and the feeding assays were carried out concurrently using freshly made artificial diets. To calculate the calibration line, the control diet (AD) was fed to 40 individual larvae in separate Petri dishes for 24 hr in amounts ranging from none to *ad libitum*. Relative growth rate (RGR) and relative consumption rate (RCR) were calculated for each larva as follows: RGR = biomass gained/mean larval weight (mg/mg/day), and RCR = food ingested/mean larval weight (mg/mg/day).

Mean larval weight was calculated as the average of the weight at the

beginning and the end of the experiment. Feeding assays to determine the deterrent and/or toxic effects of iridoid glycosides were run for 24 hr. Twenty individual larvae in Petri dishes were fed on each of the four artificial diets containing iridoid glycosides, or on a control diet with no additives. Larvae and remaining food were frozen at the end of the experiment, then dried at 50°C for 96 hours. Final dry weights of food remaining and of larvae were determined directly. Starting weights of larvae and diets were converted from fresh to dry weights using conversion factors obtained from additional larvae and diet set aside at the beginning of these arrays.

Quantitative Effects of Iridoid Glycosides. An analogous set of experiments to those described above (growth and survival, diet choice, and deterrence and/or toxicity) were carried out to determine whether iridoid glycosides had a dose-dependent effect on *S. eridania*. Larvae were reared on artificial diets containing the iridoid glycoside catalposide (Figure 1), comprising 0, 0.36, 0.72, 1.8, 3.6, and 7.2% dry weight of the diet, for 15 days. Growth and survivorship were determined as described above. Surviving larvae from this experiment were then reared to the final instar when they were given a choice test. The diets used for the choice tests were: a control with no iridoid glycoside (AD), AD + 1.8% catalposide and AD + 7.2% catalposide.

The toxic and/or deterrent effects of increasing doses of catalposide were determined by the method of Blau et al. (1978), using two strains of *S. eridania*. The first strain was the same as that used for the experiments described above. A calibration line using 40 larvae fed varying amounts of the control diet was obtained (see above), and concurrently, 20 larvae were tested on diets containing 0.18, 0.36, 0.72, 1.8, 3.6, or 7.2% catalposide. This experiment was repeated using a second strain obtained from D. Lincoln at the University of South Carolina, and adding an additional experimental diet containing 5.4% catalposide.

RESULTS

Qualitative Effects of Iridoid Glycosides. After 15 days, the weights of *S. eridania* larvae on artificial diets with different iridoid glycosides were significantly different (Table 1). Larvae grew as well on the diet containing asperuloside as on the control diet, while growth rate was reduced almost by half on diets containing aucubin and loganin, and larvae grew least on the diet containing catalpol (Table 1). Survivorship of larvae was significantly lower on diets containing catalpol, aucubin, and loganin than on the control diet or AD + asp, on which larval survivorship was similar (Table 1).

To compare the effects of iridoid glycosides on young and old larvae, we

[a]Results within each choice test were compared by means of paired *t* tests. All diets contained 0.18% of the iridoid glycosides. AD = artificial diet, auc = aucubin, cat = catalpol, log = loganin, asp = asperuloside.

RGR in the older larvae. There was a significant interaction between diet and age, indicating that the effects of the diets on growth changed with the age of the larvae (Table 2). Mortality was two to ten times higher in the younger larvae, but there was no significant interaction between diet and age in their effect on mortality (Table 2).

Results from the choice tests showed that larvae that were reared on AD without iridoid glycosides preferred this control diet to diets with iridoid glycosides added (Table 3). However, if larvae were reared on diets containing any one of the four iridoid glycosides and then given a choice of that diet and the control, they showed no preference for the control diet but ate equal amounts of the control diet and the diet with iridoid glycosides (Table 3), with the exception of larvae reared on AD + log which preferred the control diet. If larvae were reared on a diet with iridoid glycosides and then given a choice of two diets each with a different iridoid glycoside, they showed no preference with one exception: larvae reared on AD + asp and given a choice of AD + cat and AD + log preferred AD + cat. Larvae reared on all diets except AD + auc were offered the choice of AD + cat and AD + log. Larvae reared on the control diet (AD) and on AD + asp preferred AD + log, while those reared on AD + cat and AD + log showed no preference (Table 3).

Neither catalpol nor loganin appear to have had a toxic or a deterrent effect as measured by the method of Blau et al. (1978), since the data points for these diets fell just above the calibration line but inside the 95% confidence limits (Figure 2). However, aucubin and asperuloside did have a toxic effect, since data points for these two diets fell below the calibration line and outside of the 95% confidence limits.

Quantitative Effects of Iridoid Glycosides. Weight of larvae after 15 days was significantly lower in those fed diets containing 0.36, 0.72, and 7.2% catalposide than in larvae reared on AD only (Table 4); larval weights on diets with 1.8% and 3.6% catalposide were lower than those on AD but not significantly so. RGR was higher for younger larvae in both control and experimental treatments (Table 5), as we found for larvae on the other four iridoid glycosides (Table 2). Mortality was also significantly higher for the younger larvae (Table 5). There was a significant interaction between age and diet for both RGR and mortality, indicating that the response of larvae to increasing doses of catalposide changed with age.

Larvae showed significant differences in diet preferences (Table 6). Larvae reared on AD without iridoid glycosides showed a preference for AD when the choice was AD or AD + 7.2% catalposide, but larvae reared on AD + 1.8% catalposide showed no preference for AD over this diet. However, if larvae were reared on AD + 1.8% catalposide, they preferred it to AD + 7.2% catalposide. Larvae reared on AD + 7.2% catalposide preferred the other diets

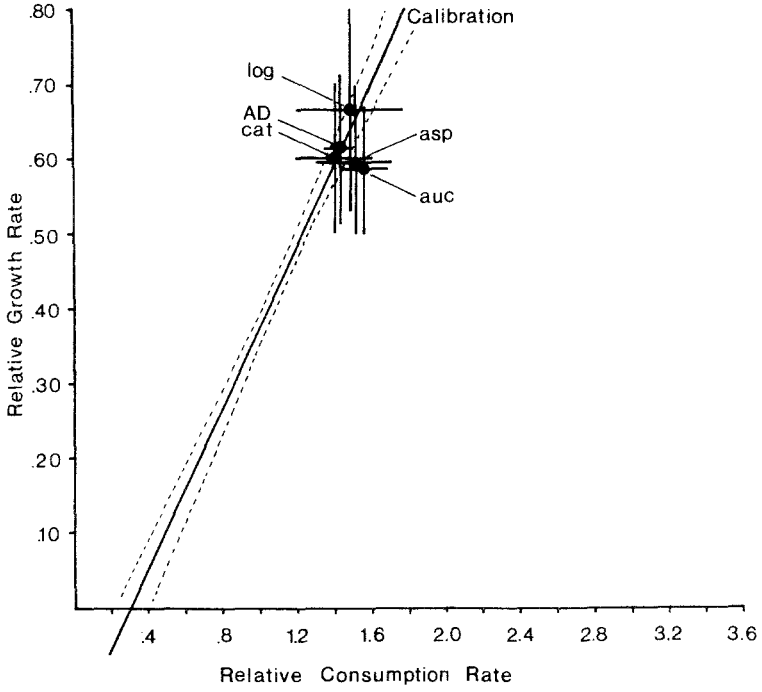

FIG. 2. Relative growth rates (RGR) (mg/mg/day) and relative consumption rates (RCR) (mg/mg/day) of *Spodoptera eridania* larvae fed artificial diets containing 0.18% of the iridoid glycosides catalpol (cat), aucubin (auc), loganin (log), and asperuloside (asp) for 24 hr during the final instar. Each data point represents the mean and range of values for 20 larvae. (Calibration line: $y = -0.19x + 0.55$, $N = 34$, $r = 0.96$).

to this diet. In short, larvae avoided the diet with the highest concentration of catalposide, even when they had been reared on it.

The results from the toxicity/deterrence test were in general agreement with the results from the growth experiment. Catalposide appeared to have a toxic effect on both strains of larvae at all the concentrations tested (Figure 3A and B), since all the data points fell below the calibration one and outside the 95% confidence limits of the calibration line. However, there were some differences in the response of the two strains to catalposide. Larvae of the first strain responded to the highest concentration (7.2%) by an extremely high consumption rate (Figure 3A), whereas consumption rates of larvae of the second strain were in the same range at all catalposide concentrations (Figure 3B). Larvae of the second strain were more efficient at converting food into body mass, achieving higher RGRs for the same range of RCRs than the first strain did (Figure 3A and B).

TABLE 6. MEAN AMOUNTS (MG ± SD) OF ARTIFICIAL DIETS EATEN BY LAST-INSTAR LARVAE OF *S. eridania* IN CHOICE TESTS[a]

Diet prior to test	Choice		Mean amount eaten		N	P
	Diet 1	Diet 2	Diet 1	Diet 2		
AD	AD	AD + 7.2% C'side	19.6 ± 9.9	5.7 ± 9.4	10	<0.005
	AD	AD + 1.8% C'side	9.1 ± 7.2	8.9 ± 6.8	9	NS
AD + 1.8% C'side	AD + 1.8% C'side	AD	11.7 ± 9.7	8.6 ± 5.7	10	NS
	AD + 1.8% C'side	AD + 7.2% C'side	23.4 ± 36.4	2.1 ± 3.5	10	<0.05
AD + 7.2% C'side	AD + 7.2% C'side	AD	0.9 ± 1.0	10.1 ± 9.2	10	<0.025
	AD + 7.2% C'side	AD + 1.8% C'side	3.2 ± 4.7	8.9 ± 6.4	10	<0.05

[a] Results within each choice test were compared by means of paired t tests. AD = artificial diet, C'side = catalposide.

DISCUSSION

In this study, we used three methods to examine the response of the generalist herbivore, *Spodoptera eridania*, to iridoid glycosides: (1) We determined how the growth and survival of *S. eridania* were affected by qualitative and quantitative variation in the iridoid glycoside content of their diet. (2) We tested larval preference for or avoidance of diets containing different iridoid glycosides. (3) We tested whether the compounds were toxic or deterrent to the larvae. The results suggested that all three methods should be used in order to assess how a particular group of plant allelochemicals may or may not affect a particular insect species.

Qualitative Effects of Iridoid Glycosides. The growth of armyworm larvae was significantly depressed by three of the four iridoid glycosides tested (catalpol, aucubin, and loganin). Larvae grew slowest on catalpol, but growth was also depressed by aucubin and loganin. However, larvae grew almost as well on the diet containing asperuloside as on the control diet, and even for young larvae, mortality when fed on the diet with asperuloside was quite low (Table 2). These results suggested that at least three of the iridoids tested are either deterrent or toxic to armyworm larvae. However, the method of Blau et al. (1978) showed aucubin and asperuloside were toxic to armyworm larvae, while

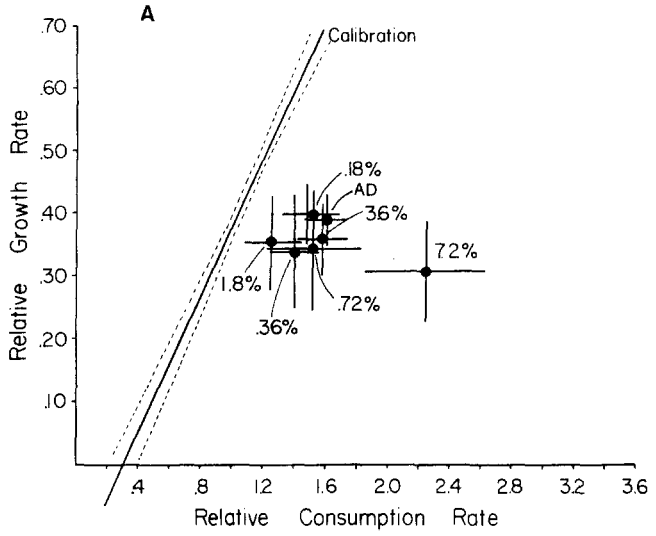

FIG. 3. (A) Relative growth rate (RGR) (mg/mg/day) and relative consumption rates (RCR) (mg/mg/day) of *Spodoptera eridania* larvae of the first strain (from Wisconsin) fed artificial diets containing different amounts of the iridoid glycoside catalposide. Each data point represents the mean and range of values for 20 larvae. (Calibration line: $y = -0.19x + 0.55$, $N = 34$, $r = 0.96$) (B) Relative growth rates (RGR) (mg/mg/day) and relative consumption rates (RCR) (mg/mg/day) of *Spodoptera eridania* larvae of the second strain (from South Carolina) fed artificial diets containing different amounts of the iridoid glycoside catalposide. Each data point represents the mean and range of values for 20 larvae. Means and ranges of diets with 0.36, 0.72, and 7.2%; and 3.6, and 5.4% catalposide, respectively, had values that were not different by more than 0.01 mg/mg/day; consequently, these values are shown as two single points to avoid confusion. (Calibration line: $y = 0.01x + 0.44$, $N = 40$, $r = 0.96$).

loganin and catalpol were not. This is in contradiction to the results from the longer-term growth experiment (Table 1). Short-term tests such as the toxicity/deterrence test of Blau et al. (1978) are often revealing and are very convenient, and it is important to be able to distinguish between deterrence and toxicity. However, longer-term tests such as the measurement of growth rates may yield results that reflect more accurately the effects of allelochemicals, even though long-term growth rates do not directly test whether the compounds are deterrent or toxic to larvae.

Larval age at which such tests measuring growth, consumption, and preference or avoidance are conducted may be important in the interpretation of the results, since developmental differences have been shown to exist among insects both in food preference and larval performance (Slansky and Scriber, 1985). A

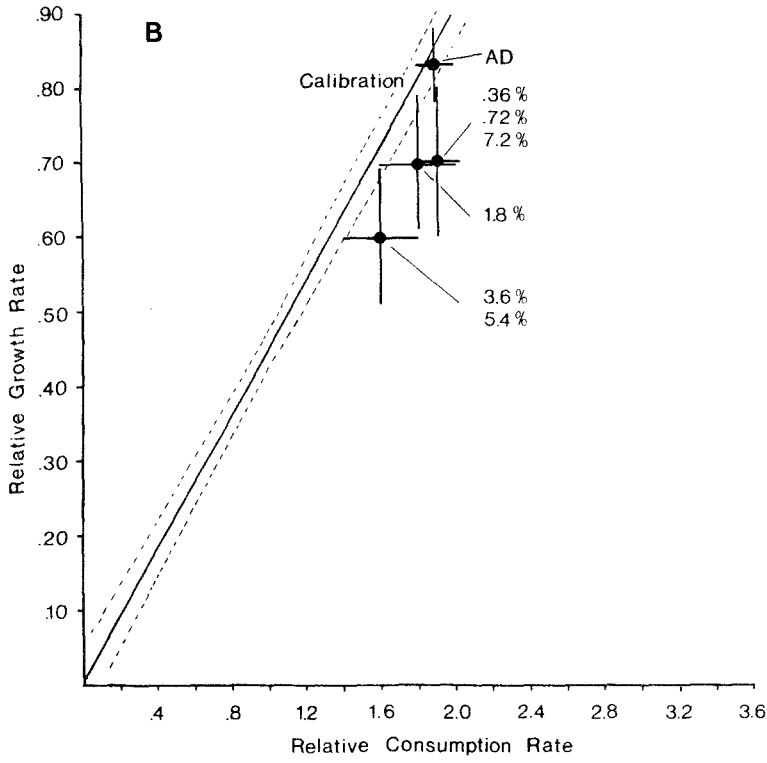

FIG. 3. Continued.

24- or 48-hr test on older larvae may not be a good indicator of the overall effects of a particular compound or group of compounds.

In general, one might expect that the RGR of younger larvae would be higher than that of older larvae (Slansky and Scriber, 1985), as we found. Although we expected the effect of different iridoids on RGR to be more apparent in earlier rather than in later instars, we found that the growth rates of smaller larvae on the different diets were not depressed relative to the control diet (Table 2). The very small differences among RGRs at 0–5 days may, in part, be due to the technical difficulties involved in quantifying small amounts of growth in very small larvae. Our experiments showed that mortality of young *S. eridania* on diets with iridoid glycosides was much higher than that of older larvae which had been feeding on these diets for 10–15 days, and also that the effects of different iridoids on mortality of young larvae were significant. In other words, the younger larvae were more susceptible to the effects of iridoid glycosides. One possible reason for this may be the lack of detoxification enzymes in the early stages. In particular, the mixed-function oxidase (MFO) system has been

implicated in protecting herbivorous insects from plant allelochemicals (Krieger et al., 1971; Brattsten et al., 1977; Ahmad, 1982). There have been no successful demonstrations of MFO activity in first- and second-instar larvae of any lepidopteran, implying that younger larvae may lack the enzymatic machinery necessary to detoxify certain compounds (Gould, 1984).

The results of the choice tests indicated that all four iridoid glycosides were deterrent to *S. eridania* larvae if they had not previously fed on diets with iridoid glycosides. However, the results of the toxicity/deterrence tests did not indicate that these compounds were deterrent. Interpreting the results of these two different tests is complicated by the fact that the presence of a choice situation appears to be critical: if larvae are not given a choice they will eat diets with iridoid glycosides, but they will avoid these compounds if given an alternative. The choice tests suggest that plants containing iridoid glycosides would be avoided by these larvae if alternative hosts were present. On the other hand, if larvae were first reared on diets containing iridoids, subsequent choice tests indicated no preference for diets either with or without iridoids, except in the case of loganin where larvae preferred the control diet (Table 3). Although a preference for iridoid glycosides was not induced (Jermy et al., 1968; De Boer and Hanson, 1984) by feeding on diets containing these compounds, neither did larvae avoid iridoid glycosides (with the exception of loganin). In a similar experiment using the same array of diets fed to another generalist lepidopteran, *L. dispar*, larvae initially made no distinction between diets with and without iridoid glycosides when previously reared on the control diet. However, *L. dispar* larvae significantly preferred diets with iridoid glycosides when they had previously been reared on these diets, even though iridoids decreased their growth and increased their mortality (Bowers and Puttick, 1988). The effects of iridoid glycosides may thus be quite different for different generalist species.

Quantitative Effects of Iridoid Glycosides. In general, the growth rate of larvae was depressed by the presence of the iridoid glycoside catalposide in the diet, and larvae avoided diets with the highest concentration of catalposide in the choice tests. There was not, however, a clear dosage-dependent response in the growth of larvae to increasing amounts of catalposide (Table 4). Low levels decreased growth, intermediate levels showed gradually increasing growth with increasing dosage, and the highest dosage (7.2%) dramatically reduced growth. The toxicity/deterrence test on the same strain used for the above growth and choice tests showed a greatly increased consumption rate at the highest dosage, while results at the lower dosages were closely clustered (Figure 3A). The higher consumption rate of larvae on the highest dosage may have occurred in an effort to maintain growth rate by increasing throughput or favoring rate over efficiency (Slansky and Feeny, 1977).

We are unable to explain why the results for larvae from this first strain fed on the control diet did not fall on the calibration line that was produced

using larvae fed on this same control diet. However, this necessitated our repeating the experiment with another group of larvae, which we obtained from another source. The two strains of armyworm performed quite differently in the toxicity/deterrence test. The second strain maintained a growth efficiency for a given consumption rate that was almost double that of the first strain of larvae, and the very high consumption rate observed for larvae of the first strain on 7.2% catalposide was not observed in the second strain. One implication of this for plant chemical defense is that plants may be subjected to a variable array of responses on the part of herbivores. Such variability may induce plants to change levels of defensive compounds in different parts of their range, depending on the particular herbivores present.

In summary, the results of these experiments suggest several important points regarding the experimental study of the effects of plant allelochemicals on insect herbivores. First, different species of generalists (and specialists), as well as different populations or strains of the same species, may be quite different in their response to a particular group of chemical compounds; such differences may confound our attempts to generalize about how plant allelochemicals might affect different groups of insects. Second, relatively small changes in chemical structure may have large effects on insect feeding responses. Aucubin and catalpol, for example, are very closely related biosynthetically (Inouye, 1971) and have very similar structures, yet these two compounds had very different effects on *S. eridania*. Finally, assessment of the effects of plant allelochemicals on herbivorous insects should involve not only tests of toxicity or deterrence, growth and mortality, or food choice alone, but a combination of these. Such a multifaceted approach should provide a more integrated view of how insects respond to plant allelochemicals.

Acknowledgments—We would like to thank Z. Larrin, M. Camarena, W. Diamond, and S. Grunow for their assistance in the laboratory; J. Glyphis and two anonymous reviewers for their comments on the manuscript. Mark Scriber and Mark Evans generously provided us with the first strain of *S. eridania*, and Dave Lincoln the second strain. We particularly appreciate receiving iridoid glycosides from W. Berkowitz, J. Bobbitt, and A. Stephenson. This work was supported by NSF grant BSR-8307353 to D. Bowers.

OXYGENATED MONOTERPENES PRODUCED BY YEASTS, ISOLATED FROM *Ips typographus* (COLEOPTERA: SCOLYTIDAE) AND GROWN IN PHLOEM MEDIUM[1]

(Received October 27, 1986; accepted February 3, 1987)

Abstract—When yeasts associated with *Ips typographus* beetles were grown in an aqueous phloem medium for two days, the main oxygenated monoterpenes produced were α-terpineol and borneol. Terpinene-4-ol, myrtenol, and *trans*-pinocarveol were also found but in lesser amounts. Of the six strains used in this study, *Hansenula capsulata* and *Candida nitratophila* produced the largest amounts of oxygenated monoterpenes. Addition of α-pinene to the phloem medium generally reduced the amounts of oxygenated monoterpenes, probably because this substance is toxic to all tested yeast species. Our *Candida diddensii* strain seemed to be particularly sensitive to α-pinene. None of the yeast strains produced *cis*-verbenol, *trans*-verbenol, or verbenone from the medium or from added α-pinene.

Key Words—Microbial transformations, microorganisms, yeasts, bark beetle, Coleoptera, Scolytidae, *Ips typographus*, oxygenated monoterpenes, α-terpineol, borneol.

INTRODUCTION

Yeasts are commonly associated with bark beetles (Shifrine and Phaff, 1956; Callaham and Shifrine, 1960; Whitney, 1971), but it is uncertain what role they play in the attack sequence of tree-killing bark beetles (Bridges et al., 1984). It

[1]This study was made within the project "Odour Signals for Control of Pest Insects."

0098-0331/88/0100-0353$06.00/0

is generally supposed that beetles inoculate a tree with different fungi in order to overcome the tree's resistance to attack (Whitney, 1982). One line of defense that the trees have against a bark beetle–fungus attack is a resin containing toxic terpenoids; the beetles have adapted to this by detoxifying oxygenation of some of the compounds (Hughes, 1973). In view of the general occurrence of mixed function oxidases (White et al., 1980), it is reasonable to believe that fungi and bacteria possess a similar detoxification system. A *Bacillus cereus* strain isolated from the North American bark beetle *Ips paraconfusus*, could convert α-pinene to *trans*-verbenol, *cis*-verbenol, and probably myrtenol (Brand et al., 1975). The verbenols are among those substances known as attractants for many bark beetle species, but in view of other findings (Byers and Wood, 1981; Conn et al., 1984), it is still uncertain how microorganisms are involved in the production of pheromones.

In our work with the spruce bark beetles, *Ips typographus* (L.), and its associated yeasts, we found that some of the yeasts could convert the beetles' aggregative pheromone component *cis*-verbenol to verbenone (Leufvén et al., 1984), a substance suspected to have antiaggregative properties (Bakke, 1981). The oxygenated monoterpenes found by Birgersson et al. (1984) in guts of *I. typographus* beetles attacking a Norway spruce (*Picea abies*, Karst.), were both qualitatively and proportionally different from those found in the gallery walls surrounding the beetles (Leufvén and Birgersson, 1987). There is a striking similarity between the shape of the curves depicting the varying amounts of certain oxygenated monoterpenes found in phloem surrounding *I. typographus* beetles from different attack phases (Leufvén and Birgersson, 1987) and the curve showing the total number of colony-forming units (produced on Sabouraud medium) originating from beetles in different attack phases (Leufvén and Nehls, 1986).

In the present study, we have investigated the ability of *I. typographus* associated yeasts to produce, from a water extract of spruce phloem, some of the oxygenated monoterpenes found in phloem from the walls of bark beetle galleries. To see which oxygenated monoterpenes, if any, the isolated yeast strains could produce from the pheromone precursor α-pinene under our *in vitro* conditions, we added this substance to some of the incubations.

METHODS AND MATERIALS

The yeast strains used in this study were *Candida diddensii* (CCUG 11142), *Candida nitratophila* (CCUG 11139), *Cryptococcus albidus* var. *diffluens* (CCUG 11141), *Cryptococcus laurentii* var. *magnus* (CCUG 11125, now reclassified as *Cryptococcus heveanensis*), *Hansenula capsulata* (CCUG 11140),

Hansenula holstii (CCUG 11128) and *Pichia pinus* (CCUG 13846). All of these strains were isolated from natural Swedish populations of *Ips typographus* bark beetles. The strains, which are deposited with the Culture Collection University of Göteborg (CCUG), have also been used in previous studies (Leufvén et al., 1984; Leufvén and Nehls, 1986).

All incubations were made in aqeuous phloem and bark medium prepared in the following way. Phloem and bark of Norway spruce were cut in centimeter-size pieces and extracted for 4 hr in tap water at room temperature; approximately 250 g phloem and bark were used per liter of water. After removal of the solid material by filtration through coarse paper, the medium was frozen in 0.5-liter bottles and stored until used. After thawing and autoclaving, the phloem medium had a pH just below 6.

Cotton-wool-stoppered, 250-ml Erlenmeyer flasks with 50 ml of phloem medium were used for all incubations. After being heavily inoculated with yeasts from Sabouraud's solid medium, the culture flasks were kept at room temperature and continually agitated for two days. At the end of the incubation period, two 4-ml aliquots were transfered to screw-capped centrifugation tubes. To facilitate extraction, yeast cells were removed by centrifugation; in a preliminary experiment, only very small amounts of extractable oxygenated monoterpenes were found in the yeast pellet. Each of the two supernatants were extracted three times with a total of 2.5 ml of a mixture of 10% diethyl ether in pentane. The extracts of the two supernatants were combined, and 2.5 μg of heptyl acetate in hexane were added as a standard.

In some experiments, racemic α-pinene (EGA-Chemie) dissolved in ethanol was added during the incubation. At the time of inoculation, 5 mg of α-pinene was added, followed by another 10 mg after one day of incubation. The total volume of added ethanol was 300 μl. Prior to its use, the α-pinene was passed through a short, heat-activated, silica column in order to remove oxygenated monoterpenes. Camphene and β-pinene, 0.56% and 1.22%, respectively, were present as impurities in the α-pinene used. Phloem medium without inoculated yeasts was used as a control in all incubation experiments.

The ether–pentane extracts were concentrated by evaporation and analyzed on a Finnigan 4021 GC-MS system equipped with a 25-m fused silica column, ID 0.15 mm, coated at the Department of Chemical Ecology with a 0.30-μm-thick film of Superox FA (RSL). The initial temperature in the gas chromatograph was 50°C for 4 min, followed by an increase of 8°C/min up to 200°C and then kept isothermal. Compounds were quantified by measuring the area of prominent and/or typical mass spectral fragments and comparing the calculated total peak area with that of added heptyl acetate (cf. Leufvén and Birgersson, 1987). The mass fragments used for each compound are shown in Figures 1 to 3.

RESULTS

The major oxygenated monoterpenes found in the phloem medium after the two-day incubation period were α-terpineol, borneol, terpinene-4-ol, *trans*-pinocarveol, myrtenol, and an unidentified alcohol. The amounts of these major components, per 50 ml of medium, are presented in Figures 1 and 2. The bars represent the means from three different incubations, except the controls in which five (no α-pinene added) or six (α-pinene added) incubations were carried out.

Under the in vitro conditions used in this study, our *Candida nitratophila* and *Hansenula capsulata* strains produced the largest amounts of oxygenated monoterpenes. *Candida diddensii*, *Hansenula holstii*, and *Pichia pinus* also produced relatively large amounts of certain of these monoterpenes, whereas *Cryptococcus albidus* var. *diffluens* and *Cryptococcus laurentii* var. *magnus* usually only produced minor amounts.

The main product after incubation in the phloem medium was α-terpineol (Figure 1), especially when the *C. nitratophila* strain was used. However, if α-pinene was not added, the amounts produced by this strain, per 50 ml medium, varied greatly: i.e., from 60 to 250 μg. Large amounts of α-terpineol were also produced by *H. capsulata* but quantities varied largely for this strain as well.

The compound found in the second largest amounts was borneol (Figure 1), the largest amounts of which were produced by *H. capsulata* followed by *C. nitratophila* and *C. diddensii*. The amounts of borneol produced by the different yeast strains was partly paralleled, but on a smaller scale, by the amounts of *trans*-pinocarveol produced (Figure 2). Terpinene-4-ol (Figure 2) was found as a major oxygenated monoterpene, especially after incubations with *H. capsulata*, but was also present in relatively large amounts in control incubations without yeasts. Myrtenol and an unidentified monoterpene alcohol (having 79 and 93, respectively, as characteristic mass spectral fragments) were produced in incubations with *H. capsulata*, in amounts of 5–10 μg/50 ml of medium. The unidentified terpene was also produced in incubations with *C. nitratophila* (Figure 2).

None of the yeast strains used could produce *cis*-verbenol, *trans*-verbenol, and verbenone, substances which participate in regulation of bark beetle behavior, from compounds present in the phloem medium or from the added α-pinene. Verbenone was detected in amounts of up to 2 μg/50 ml medium, but there were no differences between incubations with and without yeasts (Figure 3).

Small amounts of a nonterpenoid compound, 2-phenyl-ethanol, were produced by some of the yeast strains, particularly *H. holstii*, *H. capsulata*, and *C. nitratophila* (Figure 3).

In addition to the above-mentioned compounds, minor amounts of several

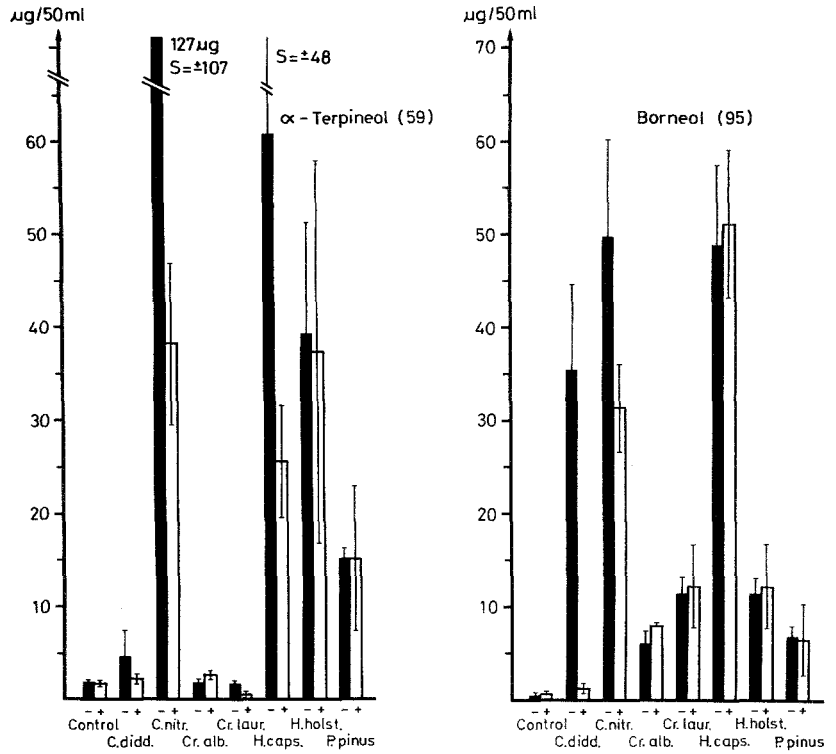

FIG. 1. Amounts of α-terpineol and borneol extracted from 50 ml of phloem medium inoculated with different strains of yeasts and incubated for two days with (solid bars) or without (open bars) added α-pinene. Thin vertical bars represent standard deviation. The mass fragment used for quantification is shown in parentheses after the compound name.

other substances were detected in the extracts from some of the inoculated incubations. Myrtenal and perilla alcohol were among those compounds, as was an unidentified substance with a mass spectrum closely resembling borneol (large *m/z* 95 fragment) but with a retention time similar to that of myrtenol. The two unidentified compounds reported from *I. typographus* gallery phloem, called monoterpene alcohol A and B (*m/z* 71 and 93) by Leufvén and Birgersson (1987), were also detected in the phloem medium after incubation with several of the yeast strains, i.e., *C. nitratophila*, *H. capsulata*, *H. holstii*, and *P. pinus*.

In general, the amounts of oxygenated monoterpenes produced in incubations to which racemic α-pinene was added (open bars in the figures) were lower than those produced in incubations without α-pinene. The most obvious examples are the production of borneol (Figure 1), *trans*-pinocarveol, myrtenol,

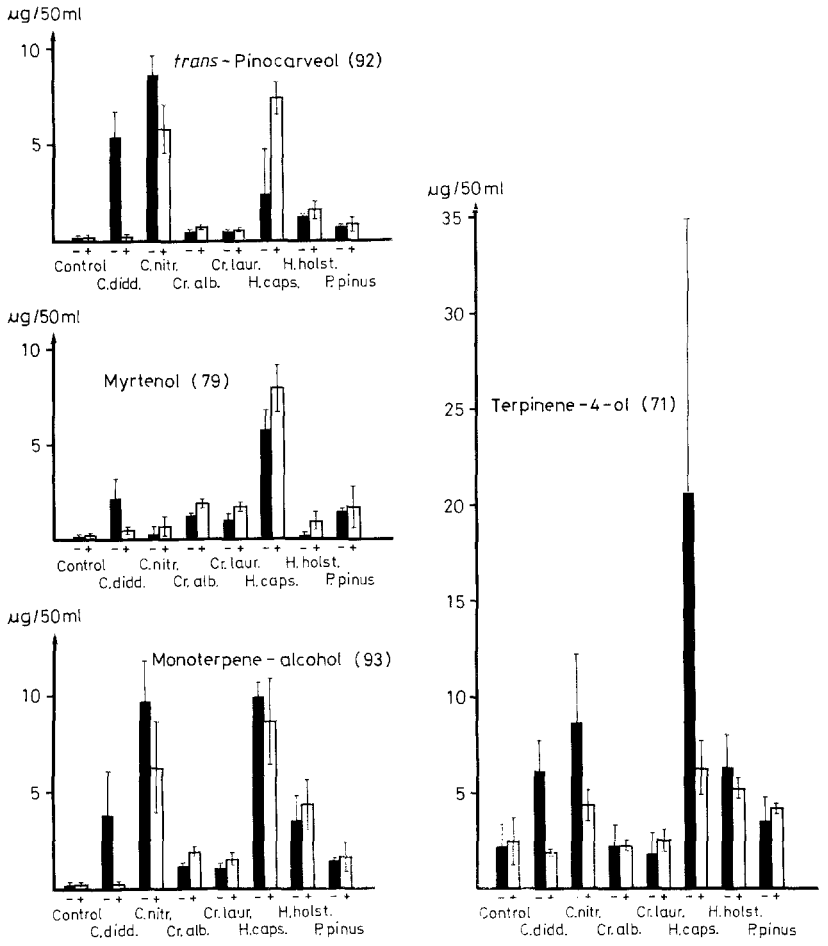

FIG. 2. Amounts of terpinene-4-ol, *trans*-pinocarveol, myrtenol, and an unidentified monoterpene alcohol extracted from 50 ml of phloem medium inoculated with different strains of yeasts and incubated for two days with (solid bars) or without (open bars) added α-pinene. and the unidentified monoterpene alcohol, quantified on mass spectral fragment *m/z* 93 (Figure 2), by *C. diddensii*. Contrary to this general trend, larger amounts of *trans*-pinocarveol and myrtenol were found after incubation of *H. capsulata* in phloem medium in which α-pinene was added than were found after incubation of this yeast strain in medium to which α-pinene had not been added.

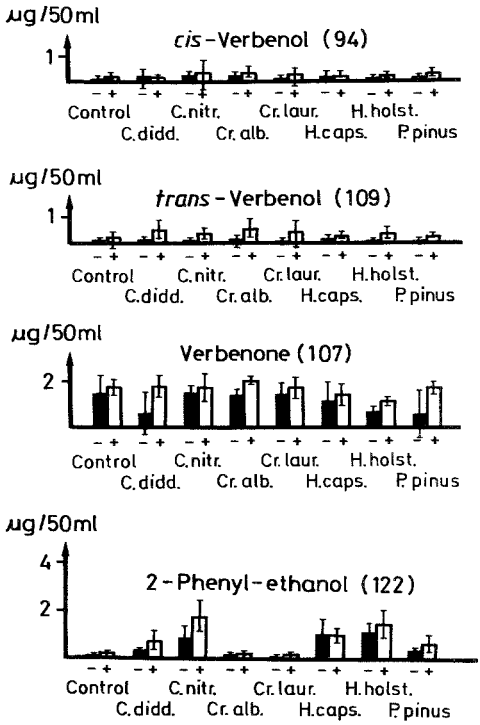

FIG. 3. Amounts of *cis*-verbenol, *trans*-verbenol, verbenone, and 2-phenylethanol extracted from 50 ml of phloem medium inoculated with different strains of yeasts and incubated for two days with (solid bars) or without (open bars) added α-pinene. Thin vertical bars represent standard deviation. The mass fragment used for quantification is shown in parentheses after the compound name.

DISCUSSION

The main oxygenated monoterpenes found in phloem medium after incubation with yeasts isolated from the spruce bark beetle were α-terpineol and borneol. These two compounds were also found as the major oxygenated monoterpenes in phloem surrounding spruce bark beetle galleries in an attacked Norway spruce (Leufvén and Birgersson, 1987). Terpinene-4-ol, *trans*-pinocarveol, myrtenol, *trans*-verbenol, and verbenone were also found in relatively large amounts in the phloem walls and, with the exception of *trans*-verbenol and verbenone, these compounds were also produced by some of the yeasts used in the present study. The failure of our strains to produce the verbenols and verbenone could, of course, be explained by incorrect in vitro conditions,

but we assume that the isolated yeast strains do not produce the verbenols, at least not from compounds present in, or added to, the incubation medium. The small amounts of verbenols and verbenone actually detected were probably autoxidation products from terpene hydrocarbons. This is well in accordance with the similarity in the amounts of verbenone found in all yeast incubations and controls (Figure 3). The inability of our beetle-associated yeast strains to produce verbenols and/or their previously reported ability to convert verbenol to verbenone (Leufvén et al., 1984) agrees with the findings of Conn et al. (1984), who demonstrated that axenic beetles exposed to α-pinene vapors had more verbenols in their guts than septic beetles treated in the same way. On the other hand, a bacterial strain isolated from bark beetles has been used to produce both *cis*- and *trans*-verbenol from α-pinene (Brand et al., 1975).

The origin of the oxygenated monoterpenes found in the phloem medium after incubation is still unclear. In this study, preparation of the medium by water extraction and subsequent sterilization by autoclaving probably excluded all monoterpene hydrocarbons from the incubation medium. Preliminary chromatographic investigations of the medium did not indicate the presence of any monoterpene hydrocarbons. Larger terpenoids that may have been present in the medium could have been precursors of the oxygenated monoterpenes, but this possibility has not been investigated.

Addition of α-pinene to the incubation medium usually failed to increase the amounts of oxygenated monoterpenes present after incubation. The production of *trans*-pinocarveol, and possibly myrtenol, by *H. capsulata* are exceptions. However, in most cases, the addition of α-pinene probably had a more or less toxic effect, especially in some of the incubations with *C. diddensii*. The decrease in production is not surprising, since it is known that monoterpene hydrocarbons are somewhat toxic, even to fungi associated with bark beetles (Raffa et al., 1985; DeGroot, 1972). In our experiments with the addition of α-pinene to *H. capsulata* incubations, the production of *trans*-pinocarveol, and possibly myrtenol, from α-pinene increased, while the production of α-terpineol and terpinene-4-ol from unknown sources decreased. This change in priority of production makes it very tempting to suggest that in order to detoxify α-pinene, *H. capsulata* converts it to *trans*-pinocarveol and possibly myrtenol. In view of the fact that *H. holstii* and *C. diddensii* were the yeasts isolated in the largest numbers from *I. typographus* beetles (Leufvén and Nehls, 1986), it is surprising that *C. diddensii* seems to be the yeast strain less suited to cope with the toxic properties of α-pinene. The major producers of oxygenated monoterpenes, *H. capsulata* and *C. nitratophila* were both bark beetle associates isolated in lesser numbers by Leufvén and Nehls (1986). The reason for this discrepancy concerning production ability and numbers isolated is not clear, but one has to bear in mind that conditions in the natural environment of the yeasts and during *in vitro* incubations are inevitably different and that the yeast

strains isolated by Leufvén and Nehls (1986) came from crushed beetles, not from gallery wall phloem.

The nonterpenoid compound 2-phenylethanol was not detected in gallery wall phloem (Leufvén and Birgersson, 1987), but it was found in bark beetle guts (Birgersson et al., 1984) and was found to be produced by yeasts, especially *H. holstii*, growing in synthetic Sabouraud medium (Leufvén et al., 1984), and in a phloem medium from pine (Brand et al., 1977). It is not yet evident whether or not this compound plays a part in the "attack dynamics" of the bark beetle–microorganism complex, although this has been suggested (Renwick et al., 1976).

Despite the fact that *in vitro* incubations have been used, this study shows that some of the compounds found in phloem from gallery walls of *I. typographus* beetles attacking Norway spruce can be produced by yeasts associated with the bark beetle. The actual precursors of the oxygenated monoterpenes are, however, not revealed by this study.

Acknowledgments—The staff at the Department of Clinical Bacteriology, Göteborg University, helped us with preparation of culture media and maintaining the cultures. A.-B. Wassgren prepared the GC columns and P. Ödman corrected the language. Several colleagues at our department and at other departments made valuable comments on the manuscript. This study was made as part of the project "Odour Signals for Control of Pest Insects" funded by Swedish Research Councils (NFR, FRN, SJFR, STU) and by Swedish forest industries.

(Received September 22, 1986; accepted February 9, 1987)

Abstract—This study investigated the influence of the major anal-gland compounds from the stoat (*Mustela erminea*) and fecal and urine compounds from the red fox (*Vulpes vulpes*) in generating an avoidance response by montane voles (*Microtus montanus*), as well as suppressing feeding by montane and meadow (*M. pennsylvanicus*) voles on apple trees in orchards. In trap bioassays, a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane significantly reduced vole captures. Other mixtures of stoat compounds reduced the number of new voles captured but not total individuals. 2,5-Dihydro-2,4,5-trimethylthiazoline, a component of fox feces, significantly reduced vole captures in one of two bioassays. Deer mice (*Peromyscus maniculatus*) did not show a negative response to any predator odor. In overwinter field bioassays, mixtures of 2-propylthietane and 3-propyl-1,2-dithiolane clearly reduced vole feeding on apple trees in four test blocks. 2,5-Dihydro-2,4,5-trimethylthiazoline and a synthetic fox urine mixture also significantly reduced vole attack in respective orchard blocks. Similarly, the intensity of vole feeding, in terms of amount of bark and vascular tissues removed from trees, was reduced by 60% to 97% in predator odor treatments compared with the control. Our study reports the first long-term (four to five months) use of synthetic semiochemicals as area repellents for crop protection from vole feeding damage.

Key Words—Anal-gland compounds, 2-propylthietane, 3-propyl-1,2-dithiolane, stoat, vole, red fox urine, feces, 2,5-dihydro-2,4,5-trimethylthiazoline, crop protection, feeding suppression, orchard, interspecific communication, kairomones, predator odors, *Microtus* spp., *Vulpes vulpes*, mustelids.

INTRODUCTION

The use of chemical signals may have several applications in wildlife management and crop protection. In particular, preparations of predator odors have significantly reduced feeding by herbivore species such as snowshoe hares (*Lepus americanus*) (Sullivan et al., 1985a; Sullivan, 1986) and black-tailed deer (*Odocoileus hemionus columbianus*) (Müller-Schwarze 1972, 1983; Melchiors and Leslie, 1984; Sullivan et al., 1985b). The synthetically produced active components of certain predator odors have successfully reduced feeding damage to forest seedlings by snowshoe hares (Sullivan and Crump, 1984, 1986a) and generated an avoidance response by northern pocket gophers (*Thomomys talpoides*) in an agricultural environment (Sullivan and Crump, 1986b). Similarly, several stress-inducing odorants from fox (*Vulpes vulpes*) feces have been reported for the rat (Vernet-Maury et al., 1984).

Several species of voles (genus *Microtus*) inflict feeding damage to agricultural and forest crops in various parts of the world. These herbivorous rodents feed on the bark, vascular tissues, and sometimes roots of trees in fruit orchards and coniferous and deciduous forest plantations as well as vegetable, grain, and forage crops in cultivated fields (see reviews by Hansson and Nilsson, 1975; Green, 1978; Byers, 1984, 1985; Hansson, 1985). The use of toxicants has been the major method to control voles. However, the advent of predator odors as area repellents may provide effective protection for forest and agricultural crops from vole depredations.

Avoidance responses of voles (*M. agrestis*) to predator odors, particularly those of the weasel (*Mustela nivalis*) and stoat (*M. erminea*), were reported in several studies (Stoddart, 1976, 1980; Gorman, 1984). These responses are innate and presumably adaptive since the chances of an individual vole suffering predation would be reduced (Gorman, 1984). Stoats (also called ermine or short-tailed weasels) and related mustelids prey on voles throughout their ranges in north temperate and boreal latitudes. In addition, the red fox is another principal predator of voles and related rodents.

The chemical composition of anal gland secretions has been reported for the stoat (Crump 1978, 1980; Schildknecht and Birkner, 1983; Crump and Moors, 1985). The major sulfur-containing compounds identified in these studies were 2-propylthietane, 2-pentylthietane, and 3-propyl-1,2-dithiolane. Similarly, the most active volatile component of fox feces was identified as 2,5-dihydro-2,4,5-trimethylthiazoline (Vernet-Maury, 1980; Vernet-Maury et

al., 1984), and in fox urine was 3-methyl-3-butenyl methyl sulfide (Wilson et al., 1978; Whitten et al., 1980; Sullivan and Crump, 1986a).

This paper reports on the influence of the major anal-gland compounds from the stoat and the fecal and urine compounds from the fox in generating an avoidance response by montane voles (*M. montanus*), as well as suppressing feeding by montane and meadow (*M. pennsylvanicus*) voles on apple trees in orchards.

METHODS AND MATERIALS

Predator Odor Compounds. Anal-gland compounds from the stoat, 2-propylthietane, 2-pentylthietane, and 3-propyl-1,2-dithiolane, were prepared according to Crump (1978, 1980, 1982). Two other constituents, indole and *o*-aminoacetophenone, were available commercially. In an attempt to simulate the anal-gland secretion of the stoat, one group of compounds (2-propylthietane, 3-propyl-1,2-dithiolane, and indole) was mixed with squalene (on a 1:1 basis) in a 16:1:4 ratio (mixture *X*). A second group of compounds (2-propylthietane, 3-propyl-1,2-dithiolane, indole, and *o*-aminoacetophenone) was mixed in a 7:1:0.1:0.6 ratio (mixture *Y*). These two ratios approximate those found in stoats in the wild. A third group of compounds (2-propylthietane, 2-pentylthietane, and 3-propyl-1,2-dithiolane) was mixed in a 4.5:1:1 ratio (mixture *Z*). In addition, 2-propylthietane and 3-propyl-1,2-dithiolane were mixed in a 1:1 ratio.

The principal active component from fox feces, 2,5-dihydro-2,4,5-trimethylthiazoline, was prepared by bubbling ammonia (gas) into a stirred mixture of 3-mercaptobutan-2-one (Hromatka and Haberl, 1954) (7.8 g), acetaldehyde (11 g), and anhydrous sodium sulfate (8 g) in ether (50 ml) for 20 min at room temperature and then for a further 10 min with heating under reflux (Dubs and Pesaro, 1974). The mixture was cooled, filtered, and concentrated. Distillation of the residue gave *cis*- and *trans*-2,5-dihydro-2,4,5-trimethylthiazoline, 5 g (57%), bp 69-72°/18 mm. Mass spectrum: 129 (52 114 (30) 88 (100) 69 (65) 55 (53) 42 (85). PMR ($CDCl_3$) 1.5 (m, 6, C_2 and C_5 methyls), 2.1 (2s, 3, C_4 methyls), 4.3 (1, m, H_5), 5.5 (1, m, H_2). The NMR spectrum was identical with that of authentic material (Mussinan et al., 1977).

The principal volatile component from red fox urine, 3-methyl-3-butenyl methyl sulfide, was prepared according to Wilson et al. (1978). 2-Phenylethyl methyl sulfide was prepared by alkylation of the corresponding thiol (von Braun et al., 1929), which was obtained from 2-phenylethanol via the Bunte salt method of El-Hewehi and Taeger (1958). An undiluted synthetic mixture of these latter compounds and the commercially available 4-heptanone, 6-methyl-5-hepten-2-one, benzaldehyde, acetophenone, 2-methylquinoline, and gerany-

lacetone was prepared according to the composition of compounds reported by Wilson et al. (1978) and Whitten et al. (1980). This mixture was composed of pure compounds only with no odor fixative. Purity of synthesized compounds ranged from 95% to 98%.

All compounds and mixtures were dispensed in 140-μl capillary tubes (75 mm in length). The capillary tubes protected the compounds from adverse weather conditions and, for optimum evaluation purposes, maintained the respective odor around the entrance to live-traps in the trap bioassays and around the base of apple trees in the tree bioassays. In the trap bioassays, three or four tubes were anchored in the ground near the entrance to a trap. In the tree bioassays, one capillary tube was attached to young (1-year-old) trees and two tubes were attached to large older (15–30 years) trees by plastic twist ties. Approximately 30 mg of each compound (neat) or test mixture was placed in a given capillary tube using a 1-ml microsyringe with 20-gauge needle. In all bioassays, empty capillary tubes were available as controls to complete the design of a given experiment.

Trap Bioassays. Bioassays were conducted at the Agriculture Canada Research Station, Summerland, British Columbia, Canada, during fall periods from September 1983 to October 1985. The study area was located in old field grassland habitat composed mainly of crested wheatgrass (*Agropyron cristatum*) with several herbaceous annuals in minor abundance. The climate is semiarid and so the study area was irrigated at three-week intervals during summer months to maintain a suitable habitat for voles. Deer mice (*Peromyscus maniculatus*) also occupied this habitat in numbers substantial enough to warrant recording in the bioassays. Yellow pine chipmunks (*Eutamias amoenus*) and Great Basin pocket mice (*Perognathus parvus*) also were present but in minor abundance and were rarely captured during bioassays.

Montane voles were live-trapped on checkerboard grids with Longworth live-traps. Separate control and treatment grids were used in each of three experiments. In experiment A, each grid had 15 (3 $\times$ 5) trap stations, and in experiments B and C, each grid had 18 (3 $\times$ 6) stations, located at 15.2-m intervals. Two live-traps were set at each station near recently used vole runways. Traps were baited with whole oats, and coarse brown cotton was supplied as bedding. In all experiments, traps were set on the afternoon of day 1, checked on the mornings of days 2 and 3, and then removed from the grids. Trapping periods were conducted at three- or four-week intervals in experiment A on September 26–28, October 22–24, and November 7–9, 1983; in experiment B on September 3–5, 25–27, and October 22–24, 1984; in experiment C on September 8–10, 28–30, and October 19–21, 1985.

Traps were cleaned thoroughly before trapping commenced, and there were no periods of prebaiting (i.e., traps locked open and set in field) during these experiments. For control periods prior to experiments, locked traps were set in

the field to prebait with subsequent trapping to monitor vole populations on respective control and treatment grids. All voles captured were ear-tagged with serially numbered tags, sex and breeding condition noted, weighed on Pesola spring balances, and point of capture recorded.

The following compounds were tested: a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane in experiment A; mixture Y of stoat anal-gland compounds, and 2,5-dihydro-2,4,5-trimethylthiazoline in experiment B; mixture Z of stoat anal-gland compounds, and 2,5-dihydro-2,4,5-trimethylthiazoline in experiment C.

Tree Bioassays. Each of two blocks (each 560 m^2 in area and separated by 100 m) was planted with 48 (6 × 8) 1-year-old crabapple (*Malus* spp.) trees on November 11–12, 1983 in the grassland study area at Summerland Research Station. One block served as a control and the other was treated with a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane. Comparable densities (110 per hectare) of voles were present in each block. Vole feeding damage to trees (proportion girdled) was checked on December 1, 1983, February 2, and finally on March 2, 1984, when the experiment was terminated. Voles were no longer feeding on the apple trees as preferred alternative vegetation had begun to appear.

In a second experiment, a 1-hectare block of Spartan apple orchard (30-year-old trees with interplanted rows of 15-year-old trees at an overall spacing of 5.6 × 4.6 m) at the Coldstream Ranch, 12 km east of Vernon, British Columbia, was assigned treatments as follows: 100 (10 × 10) trees with one tube of 2-propylthietane and one tube of 3-propyl-1,2-dithiolane attached to opposite sides of the base of each tree; 50 (5 × 10) trees with the mixture X of stoat anal-gland compounds; 100 (10 × 10) trees with 2,5-dihydro-2,4,5-trimethylthiazoline on every second tree; 50 (5 × 10) trees with the synthetic fox urine mixture on every second tree; 40 (4 × 10) trees with 3-methyl-3-butenyl methyl sulfide on every second tree; and 50 (5 × 10) trees as controls. This block had an average density of 80–90 voles per hectare. Treatments were dispensed on November 11, 1983, and feeding damage (proportion of trees attacked) by montane and meadow voles was checked on February 4 and March 20, 1984. The experiment was then terminated. The area of bark and vascular tissues removed by vole attack may be considered as a measure of feeding intensity. The height and width of each damage wound were recorded to give an approximate measurement of the amount of bark and vascular tissues removed from a given tree.

In the third experiment, each of three blocks (each 560 m^2 in area and separated by 50 m) was planted with 48 (6 × 8) 2-year-old crabapple trees on October 25, 1985, in old field grassland habitat adjacent to the Coldstream Ranch orchard at Vernon, British Columbia. One block served as a control, the second block had a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane,

and the third block had 2,5-dihydro-2,4,5-trimethylthiazoline. This block had an average density of 60–70 voles per hectare. Feeding damage to trees (proportion attacked) was checked on March 31, 1986, at which time the experiment was terminated.

Statistical Analysis. Comparisons of the number of individuals and total captures of montane voles and deer mice, and number of trees surviving (Summerland) and attacked (Vernon), on control and treatment areas during each experiment were analyzed by chi-square with significance levels of $P < 0.05$ and $P < 0.01$.

RESULTS

Trap Bioassays. The 1:1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane significantly reduced the number of voles captured in traps in experiment A (Table 1). This reduction was evident in both number of individuals caught and total captures. In terms of individuals on the treatment grid, 77.4% (31 to 7) fewer voles were captured in the trapping period with the anal-gland mixture compared with the preceding control period. In addition, vole numbers rebounded dramatically to 33 animals during the subsequent control period. In experiment B, the number of voles captured was reduced by the presence of the stoat anal-gland compounds, but these differences were not statistically significant (Table 1). However, the presence of 2,5-dihydro-2,4,5-trimethylthiazoline at trap entrances did result in significant avoidance of traps by voles during the first night and for total captures. There was little difference between control and treatment grids in vole response to traps for 2,5-dihydro-2,4,5-trimethylthiazoline and mixture Z in experiment C.

There were no significant differences between the proportions of male and female voles captured on control and treatment grids in these three experiments (Table 2). Similarly, the proportion of breeding male and female voles differed little between control and treatment areas. Significantly more males were in reproductive condition on the treatment than control grid in the control period of experiment B. However, this difference was not related to any of the predator odor treatments. The number of voles captured for the very first time (i.e., previously untagged) was significantly reduced on the treatment grid with mixtures of stoat anal-gland compounds in experiments B and C. There was no difference in proportion of new voles between control and treatment for the 1:1 ratio of 2-propylthietane and 3-propyl-1,2-dithiolane.

Table 3 lists the number of deer mice captured during the trapping periods within each experiment. Deer mice did not avoid any of the predator odors when comparing control and treatment captures. In addition, there were no differences between the proportions of male and female deer mice captured, those in breeding condition, or those newly caught on control and treatment grids.

Tree Bioassays. Results of the bioassay with young apple trees at Summerland during the 1983–1984 winter are illustrated in Figure 1A. The 1:1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane clearly reduced vole feeding on trees to a significant degree in the treatment block. Snow cover from December 15 to January 20 may have reduced the effectiveness of the odor as voles, via snow tunnels, were able to feed above the protective zone of the stoat odor. However, as of March 1984, only 16.7% of control trees had not been girdled by voles compared with 80.4% of treatment trees.

The results of experiments conducted at Vernon during the 1983–1984 winter are illustrated in Figures 1B–D. The stoat anal gland mixture X was the most effective in suppressing vole feeding. The compounds 2-propylthietane

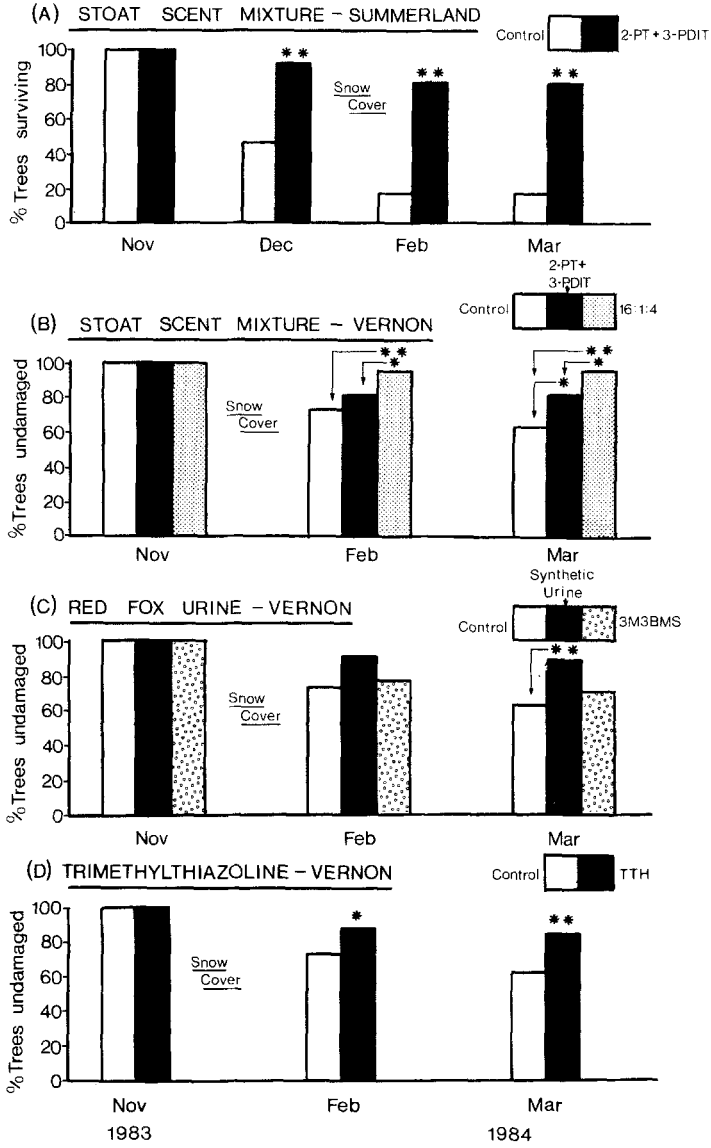

FIG. 1. (A) Percentage of 1-year-old apple trees that survived feeding damage by voles in control (n = 48) and treatment (n = 46) blocks at Summerland Research Station. Treatment consisted of stoat anal gland compounds (stoat scent mixture): 2-propylthietane (2-PT) and 3-propyl-1,2-dithiolane (3-PDIT) (1 : 1 ratio). Percentage of apple trees damaged by voles in control and treatment blocks at Coldstream Ranch, Vernon. Treatments consisted of (B) stoat scent: 2-PT and 3-PDIT (1 : 1 ratio) and the stoat anal gland mixture X (16 : 1 : 4); (C) synthetic red fox urine and 3-methyl-3-butenyl methyl sulfide (3M3BMS); and (D) 2,5-dihydro-2,4,5-trimethylthiazoline. Trials were started on November 11–12, 1983 and terminated in March 1984. $*P < 0.05$, $**P < 0.01$; significant difference by chi-square.

and 3-propyl-1,2-dithiolane, attached separately to opposite sides of each tree in that block, also had significantly less damage than control trees (Figure 1B). 3-Methyl-3-butenyl methyl sulfide, the highly volatile and characteristic skunky odor of fox urine, did not suppress damage. However, only 13 of the 36 capillary tubes still had active compound at the end of the trial. The synthetic fox urine mixture did suppress feeding damage (11.6% compared with the control level of 37.5%), possibly because the volatility of 3-methyl-3-butenyl methyl sulfide was retarded by the mixture of seven other compounds (Figure 1C). 2,5-Dihydro-2,4,5-trimethylthiazoline also significantly reduced the number of trees damaged by voles compared with the control (Figure 1D).

The amounts of bark and vascular tissues removed in vole feeding attacks at Vernon during the 1983–1984 winter for various treatments and the control are listed in Table 4. Voles clearly fed more (3.8–5.0 times) intensively on control trees than on those with the mixtures of stoat anal-gland compounds. This pattern was also evident in the blocks (2,5-dihydro-2,4,5-trimethylthiazoline and the fox urine mixture) that had a treatment tube attached to every second tree. The most dramatic difference in feeding was recorded in the block with 2,5-dihydro-2,4,5-trimethylthiazoline where, on treated trees, removal of bark and vascular tissues was 3.1% of that on control trees. The 3-methyl-3-butenyl methyl sulfide treatment did not follow this pattern with comparable amounts of bark and vascular tissues removed from trees with the odor (10.5 cm^2) and those without (16.1 cm^2).

The bioassay with young apple trees at Vernon during the 1985–1986 winter resulted in 81.3% of control trees undamaged by voles compared with 97.9% for the trees with a 1:1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane. The 2,5-dihydro-2,4,5-trimethylthiazoline treatment

TABLE 4. AVERAGE AMOUNTS OF BARK AND VASCULAR TISSUES REMOVED IN VOLE FEEDING ATTACKS IN VERNON APPLE ORCHARD DURING 1983–1984 WINTER (Sample size in parentheses)

	Amount of bark and vascular tissues (cm^2) removed per tree	
	Average	95% confidence limits
Control	16.1(48)	6.9–25.3
2-Propylthietane + 3-propyl-1,2-dithiolane	4.2(96)	1.3–7.1
Stoat anal-gland mixture X (16:1:4)	3.2(47)	−3.1–9.5
2,5-Dihydro-2,4,5-trimethylthiazoline	0.5(47)	−0.1–1.1
Fox urine mixture	6.5(21)	−2.3–15.3
3-Methyl-3-butenyl methyl sulfide	10.5(17)	−0.1–21.1

(81.3%) did not differ from the control in terms of undamaged trees. In general, vole attack of these 2-year-old trees was considerably less than that recorded in the similar experiment at Summerland during the 1983–1984 winter.

DISCUSSION

This study has clearly demonstrated that voles will avoid traps treated with certain anal-gland compounds of the stoat as well as the principal component of fox feces, 2,5-dihydro-2,4,5-trimethylthiazoline. Our technique using trap bioassays was similar to that used by Stoddart (1976, 1980) and Gorman (1984), who also reported that voles avoided traps scented with weasel and stoat anal-gland secretions, respectively. Both of these latter studies reported that a certain proportion of the vole population did enter live-traps treated with weasel or stoat odor as was also found in our study. Clearly, there is a certain level of behavioral heterogeneity within these natural populations as outlined by Stoddart (1983) in his discussion regarding the use of live-traps as a tool for olfactory bioassays. This heterogeneity may also partly explain the lack of avoidance by marked voles recorded for the mixtures of anal-gland components in experiments B and C and for the 2,5-dihydro-2,4,5-trimethylthiazoline in experiment C. Further evidence for this heterogeneity was provided by the significantly fewer new voles captured in the stoat anal-gland treatment than control traps in experiments B and C (see Table 2). This trend suggests that significant results may have been obtained if these experiments had been conducted in areas where the vole population was not dominated by marked individuals who had some previous experience with live-traps. It should also be noted that, on average, there were 35–50% fewer voles in 1985 (experiment C) than 1983 (experiment A), which reflects the multiannual cycle of *M. montanus* (Sullivan and Sullivan, in preparation), another potential source of heterogeneity in trap responses.

Neither mixture of stoat anal-gland compounds (Y nor Z, see Table 1) generated a significant avoidance of traps by voles compared with the 1 : 1 ratio of 2-propylthietane and 3-propyl-1,2-dithiolane in experiment A. These results suggest that a lower concentration of 2-propylthietane or addition of a substantial medium such as squalene or petroleum jelly to retard the volatility of this compound may generate a consistent avoidance response by voles. Similarly, the responses of voles to traps treated with 2,5-dihydro-2,4,5-trimethylthiazoline was inconsistent, which could be related to variable release rates of the compound in the two trials.

In terms of crop protection, consistent overwinter avoidance of apple trees with various predator odors has been demonstrated. The 1 : 1 ratio of 2-propylthietane and 3-propyl-1,2-dithiolane in three test blocks and the mixture X in one test block effectively suppressed feeding on trees by voles compared with a control. The synthetic fox urine mixture and 2,5-dihydro-

2,4,5-trimethylthiazoline also significantly reduced feeding by voles but the latter compound did not differ from the control in a second overwinter experiment. Other than variable release rates as discussed for the trap bioassays, we do not have an explanation for this variability in vole response to 2,5-dihydro-2,4,5-trimethylthiazoline. Of all compounds tested in the Vernon orchard block during the 1983–1984 winter, 2,5-dihydro-2,4,5-trimethylthiazoline reduced the average amount of bark and vascular tissues removed to 0.5 cm^2 per tree, the lowest value of all predator odors tested (Table 4).

The lack of response of deer mice to the stoat anal-gland compounds and 2,5-dihydro- 2,4,5-trimethylthiazoline was clearly a paradox. Similar results were obtained for the Eurasian counterpart, *Apodemus sylvaticus*, of the North American deer mouse for both weasel (Stoddart, 1976, 1980) and stoat (Gorman, 1984) scent. We do not have a logical explanation for the lack of response of deer mice to predator odors. However, a speculative argument might lie in the opportunistic and inquisitive nature of this rodent species which lives in many different habitats. Thus, the species is much more dispersed over the landscape than *Microtus* spp., for example, which have well-defined habitat preferences. Because of this widespread distribution, deer mice may persist as a species despite an apparent ambivalent attitude towards predator odors and the presumed greater likelihood of being preyed upon.

The use of semiochemicals as area repellents for crop protection and wildlife management has been advocated by Shumake (1977) and Müller-Schwarze (1983). In terms of pheromones, avoidance and reduced activity responses to intraspecific odors have been reported in fossorial yellow voles (*Lagurus luteus*) (Fan, 1983), bank voles (*Clethrionomys glareolus*) (Brinck and Hoffmeyer, 1984), and other rodents such as muskrats (*Ondatra zibethicus*) (Van Den Berk and Müller-Schwarze, 1984) and beaver (*Castor canadensis*) (Müller-Schwarze and Heckman, 1980; Müller-Schwarze et al., 1983). However, there have been no long-term (e.g., overwinter) field tests of synthetic pheromones as area repellents. To date, only synthetic predator odors or kairomones have been field tested and found to significantly suppress feeding by snowshoe hares (Sullivan and Crump, 1984, 1986a) and generate an avoidance response in pocket gophers (Sullivan and Crump, 1986b). The present study has assessed the overwinter (four to five months) efficacy of several synthetic predator odors designed as area repellents for crop protection from vole attack. When encapsulated in controlled-release devices, these compounds have considerable potential for providing long-term protection for forest and agricultural crops that experience vole feeding damage. Additional work is required to determine the optimum concentrations, mixtures, and release systems for these compounds when formulated for long-term field use.

(Received September 22, 1986; accepted February 9, 1987)

Abstract—This study investigated the influence of the major anal-gland compounds from the stoat (*Mustela erminea*) and ferret (*M. putorius*) in generating an avoidance response by northern pocket gophers (*Thomomys talpoides*) in tree fruit orchards in the Okanagan Valley of British Columbia, Canada. A secondary objective assessed the impact of additional predator odors on gopher avoidance behavior in laboratory bioassays. In field bioassays, a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane, as well as 3,3-dimethyl-1,2-dithiolane, placed in gopher burrows did not reduce the number of gophers colonizing treatment versus control grids in orchard blocks. However, these predator gophers did dramatically alter the distribution of gophers. Significantly more gophers were captured at perimeter than nonperimeter trap stations on treatment versus control grids in two of three orchards. In all orchards, significantly more gophers were captured at perimeter stations after the predator odors had been placed in burrows than prior to the start of the experiment. Gophers clearly avoided 2,5-dihydro-2,4,5-trimethylthiazoline, a component of fox (*Vulpes vulpes*) feces, but did not avoid 2,2-dimethylthietane from the mink (*M. vison*) or 3-methyl-3-butenyl methyl sulfide from fox urine in laboratory bioassays. Poor avoidance was also recorded for 3,3-dimethyl-1,2-dithiolane, although this may be due to the state of polymerization of this compound. An improved formulation is required to dispense these semiochemicals in controlled-release devices within orchards and other forest–agricultural areas.

INTRODUCTION

Interspecific chemical communication between predator and prey may be manipulated to manage mammalian herbivore pests for forest and agricultural crop protection. Sullivan et al. (1988) have outlined several studies using preparations and synthetic components of predator odors to generate avoidance responses and suppress feeding in various species of herbivores. In particular, Sullivan and Crump (1986a) reported on the avoidance response of northern pocket gophers (*Thomomys talpoides*) to mustelid anal-gland compounds.

Pocket gophers are a persistent problem in the fruit-growing regions of British Columbia, Canada (Anderson and Kluge, 1986; Sullivan et al., 1987) and Washington and Oregon in the United States. The fossorial vole, *Microtus pinetorum*, occurs in orchards of the eastern United States and Canada (Byers, 1984, 1985). These fossorial rodents feed on the bark, vascular tissues, and roots of orchard trees. Pocket gophers also inflict similar feeding damage to coniferous seedlings in reforestation areas of western forests (Barnes, 1973; Barnes et al., 1982; Crouch, 1982). Feeding damage by these rodents may result in reduced growth and yield or direct mortality from girdling.

The influence of the major anal-gland compounds from the stoat (*Mustela erminea*) and ferret (*M. putorius*) in generating an avoidance response by pocket gophers was conducted in laboratory bioassays and field bioassays in natural (grassland) habitats (Sullivan and Crump, 1986a). The effective compounds tested were 2-propylthietane, 3-propyl-1,2-dithiolane, a mixture of stoat compounds, and 3,3-dimethyl-1,2-dithiolane. Additional sulfur-containing compounds which may be relevant predator odors for pocket gophers include 2,2-dimethylthietane from anal-gland secretion of the mink (*M. vison*) (Schildknecht et al., 1976, 1981; Brinck et al., 1978; Anderson and Bernstein, 1980; Sokolov et al., 1980), 2,5-dihydro-2,4,5-trimethylthiazoline from fox (*Vulpes vulpes*) feces (Vernet-Maury et al., 1984), and 3-methyl-3-butenyl methyl sulfide from fox urine (Wilson et al. 1978; Sullivan and Crump, 1986b).

This paper reports on (1) the influence of these additional compounds plus 3,3-dimethyl-1,2-dithiolane in generating an avoidance response by pocket gophers in laboratory bioassays, and (2) an assessment of the effectiveness of the mustelid compounds reported by Sullivan and Crump (1986a) in acting as area repellents to pocket gophers in tree fruit orchards.

METHODS AND MATERIALS

Predator Odor Compounds. Anal-gland compounds from the genus *Mustela* (2-propylthietane, 3-propyl-1,2-dithiolane, 2,2-dimethylthietane, and 3,3-dimethyl-1,2-dithiolane) (also in fox feces, see Vernet-Maury et al., 1984) were prepared according to Crump (1978, 1980a,b, 1982). 2-Propylthietane and 3-propyl-1,2-dithiolane were mixed in a 1 : 1 ratio. 2,5-Dihydro-2,4,5-trimethylthiazoline and 3-methyl-3-butenyl methyl sulfide were prepared according to the procedures outlined in Sullivan et al. (1988).

All compounds were dispensed in 140-μl capillary tubes (75 mm in length). The capillary tubes provided a point source of odor and prevented contamination of the arena or pocket gophers, themselves, in the laboratory bioassays. This encapsulation also protected the compounds from adverse environmental conditions in the field bioassays. Approximately 30 mg of each compound or mixture was placed in a given capillary tube using a 1-ml microsyringe with a 20-gauge needle. An empty capillary tube represented the control to complete the design of a given bioassay.

Laboratory Bioassays. The avoidance behavior of pocket gophers to the various predator odors was assessed by tallying the number of "captures" in the control and treatment rooms of a bioassay arena (see Sullivan and Crump, 1986a, for details of arena and bioassay procedure). In general, the arena, with a Longworth live-trap extending into an opening in each of the control and treatment rooms, simulated a burrow system for a gopher to enter. One capillary tube with a given compound was attached with adhesive tape to the floor of the tunnel of the live-trap in the treatment room. An empty tube was attached in a similar manner to the trap in the control room.

The number of gophers captured in each room was tallied to assess the impact of each compound on avoidance behavior. The control and treatment rooms were alternated for each trial, with individual gophers being tested only once in a given trial. Only one trial was conducted per given day with a new compound tested on each consecutive day. Five groups of gophers were tested. Each group was tested initially with both arena rooms acting as controls to determine if there was a preference by individual gophers to enter and be "captured" in one room or the other. Depending on availability of compounds, 2,5-dihydro-2,4,5-trimethylthiazoline was tested on all five groups, 2,2-dimethylthietane and 3,3-dimethyl-1,2-dithiolane were each tested on two groups, and 3-methyl-3-butenyl methyl sulfide was tested on one group. Sample sizes of each group varied depending on number surviving throughout the series of trials and exclusion from results of those individuals responding to neither control nor treatment conditions. All gophers were collected from intensive study areas

at Summerland and Vernon, British Columbia, Canada. Male and female gophers were pooled for all trials.

Field Bioassays. Pocket gopher populations were monitored on control and treatment grids in a Bartlett and d'Anjou pear (*Pyrus domestica*) orchard at the Agriculture Canada Research Station and a private Spartan apple orchard (*Malus domestica*), both in Summerland, British Columbia, Canada, and in a MacIntosh apple orchard at the Coldstream Ranch, 12 km east of Vernon, British Columbia. Age and spacing of trees in each orchard was: Summerland pear—15 years at 4.6 × 6 m; Summerland apple—27 years at 6 m × 6 m; Vernon apple—30 years at 4.7 × 6.2 m interspersed with 4.7 × 9.2 m. All orchard populations were monitored at three-week intervals from July to October 1985 and subsequently in April (Vernon), July (pears), and April to July 1986 at three-week intervals (Summerland apple). Gopher populations could not be monitored over the winter because of frozen ground.

Gophers were live-trapped on 0.41-hectare (pears), 0.42-hectare (Summerland apple), and 1-hectare (Vernon apple) checkerboard grids with Longworth live-traps. The pear and Summerland apple orchard grids were irregularly shaped with 24 and 27 trap stations, respectively; the Vernon grids had 49 (7 × 7) stations. All stations were located at 15.2-m intervals. Live-traps were set within recently used tunnels or burrows indicated by fresh excavations of soil. Thus, traps did not usually have permanent stations but were moved in response to gopher activity. Traps were baited with whole oats, peanut butter, and carrot; coarse brown cotton was supplied as bedding. Traps were set on day 1, checked on the morning and afternoon of day 2 and morning of day 3, and then locked open between trapping periods. Each of the Summerland pear and apple control and treatment grids had 15–20 traps set in a given trapping period. An average of 20–25 traps was set on each of the Vernon grids during a trapping period. All gophers captured were ear-tagged with serially numbered tags, breeding condition noted, weighed on Pesola spring balances, and point of capture recorded.

To further assess the field efficacy of the mustelid anal-gland compounds that gophers avoided to a significant degree in the laboratory tests of Sullivan and Crump (1986a), capillary tubes containing the mixture of 2-propylthietane and 3-propyl-1,2-dithiolane and tubes containing 3,3-dimethyl-1,2-dithiolane were attached to the inside of 500-ml (73 × 110 mm) cans (open at both ends) by plastic twist-ties and placed in gopher burrows. Prior to these field experiments in August 1985, all resident gophers were permanently removed during two consecutive trapping periods from the control and treatment grids in each orchard block. This removal allowed the odor of the anal-gland compounds to fumigate the burrow system of the treatment grid without disturbance from the digging activities of resident gophers.

The mixture of two compounds (two tubes per can with one tube directed each way and with two cans per each of the squares on a matrix grid) was placed in the burrows of the treatment grids of the Vernon and Summerland apple orchards on August 24–25 and August 29–30, 1985, respectively. 3,3-Dimethyl-1,2-dithiolane was dispensed in an identical manner on the treatment grid of the Summerland pear orchard on August 24, 1985. Cans with empty tubes were placed in burrows at the same density and systematic distribution on each control grid in a given orchard. These experiments commenced immediately after completion of the second removal trapping period in each orchard. The experiments tested whether or not new gophers would colonize or avoid the treatment area that smelled of a mustelid predator. In general, gophers that colonize a new area usually inhabit the already existing burrow systems.

Statistical Analysis. Comparisons of the number of gophers captured in control and treatment rooms in the pen bioassays as well as number of gophers and location of captures on control and treatment grids in the field bioassays were analyzed by chi-square with significance levels of $P < 0.05$ and $P < 0.01$.

RESULTS

Laboratory Bioassays. The responses of gophers to the various predator odor compounds are illustrated in Figure 1. There was no difference between males and females in these trials. Gophers avoided the 2,5-dihydro-2,4,5-trimethylthiazoline from fox feces with significant differences between control and treatment in two trials and near significance ($P = 0.058$) in a third. They did not avoid the 3,3-dimethyl-1,2-dithiolane from the ferret, 2,2-dimethylthietane from the mink, or 3-methyl-3-butenyl methyl sulfide from fox urine. Similarly, the control trials showed no difference in gopher preference for either arena room.

Field Bioassays. The responses of gophers to mustelid anal-gland compounds in the field are illustrated in Figure 2. Comparable numbers of gophers colonized both control and treatment grids in all orchard blocks following the two removal periods and placement of the repellent compounds in the ground. At the Vernon apple orchard, 2.5 times as many new gophers appeared on the control compared with the treatment grid during the first trapping period (September). However, this difference was not evident in subsequent trapping periods in October. There was no difference between any of the control and treatment grids in number of gophers in July 1986, 11 months after the experiment began.

At first, these results were quite discouraging, particularly in light of

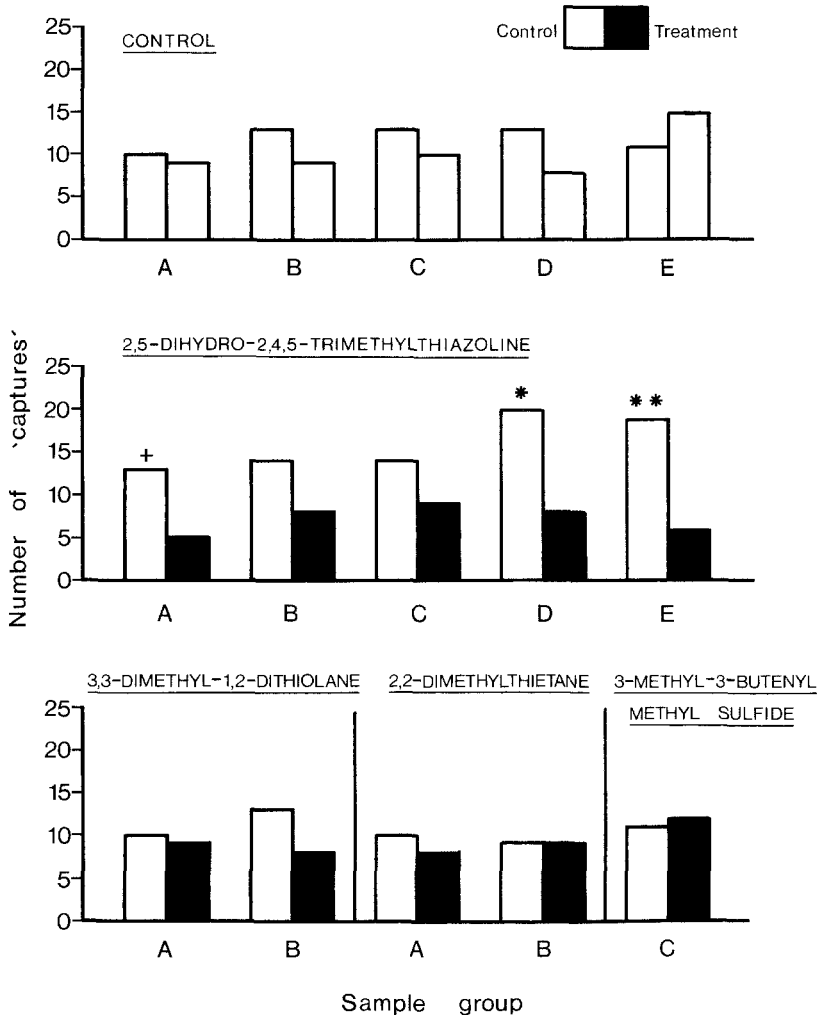

FIG. 1. Avoidance behavior responses ("capture" in live-traps) of pocket gophers to predator odors in the laboratory bioassay arena. $*P < 0.05$; $**P < 0.01$; significant difference by chi-square. $^{+}P = 0.058$.

the significant laboratory and field bioassay results reported by Sullivan and Crump (1986a). Although the anal-gland compounds did not alter the number of gophers on treatment compared with control grids, these predator odors did dramatically alter the distribution of gophers (Figure 3). In both Summerland orchards, significantly more gophers were captured at perimeter than nonperimeter trap stations on the treatment versus control grids. In addition, this sig-

All gophers were removed from grids in two consecutive trapping periods in August 1985 prior to placement of mustelid anal-gland compounds in burrow systems of treatment grids.

nificant pattern was also evident when comparing location of gopher captures before and after the placement of repellent in the ground on treatment grids at the Summerland pear and Vernon apple orchards. In this regard, the results from the Summerland apple orchard approached significance ($P = 0.08$). There

were no significant differences between the control and treatment grids at Vernon with respect to perimeter and nonperimeter captures of gophers.

DISCUSSION

The results of laboratory bioassays in this study indicate that 2,5-dihydro-2,4,5-trimethylthiazoline will produce an avoidance response by pocket gophers. This compound should clearly be tested in the field as a potential gopher repellent, particularly in light of the significant results obtained with voles (*Microtus* spp.) reported by Sullivan et al. (1988). The other component of fox feces (and ferret anal-gland secretion), 3,3-dimethyl-1,2-dithiolane, was not effective in laboratory bioassays. This compound was somewhat effective in earlier bioassays with results from three trials (control vs. treatment): 14–9; 14–9; 8–1 (Sullivan and Crump, 1986a). In addition, 3,3-dimethyl-1,2-dithiolane, in association with 3-propyl-1,2-dithiolane (both polymerized) produced a significant overwinter reduction in number of gophers (Sullivan and Crump, 1986a). This former compound also significantly altered the distribution of gophers in a pear orchard in this study. Again, additional work is warranted to determine the optimum efficacy of 3,3-dimethyl-1,2-dithiolane in repelling gophers from crop protection areas. Since dithiolanes readily polymerize when exposed to ambient conditions, their effectiveness and durability may be a function of this change. A similar polymerization occurred with 3-propyl-1,2-dithiolane in another field study, and this may have contributed to its longevity (Sullivan and Crump, 1984).

The major compound of the mink, 2,2-dimethylthietane, and one from red fox urine, 3-methyl-3-butenyl methyl sulfide, did not affect the avoidance behavior of gophers in the laboratory. These results are somewhat surprising even though the mink is not a major predator of pocket gophers. As outlined by Sullivan and Crump (1986a), weasels and snakes are the most important predators, in terms of body size, of gophers because they are capable of entering subterranean burrows. The red fox will excavate burrow systems to prey on gophers, and this may help explain the significant avoidance response generated by 2,5-dihydro-2,4,5-trimethylthiazoline. The lack of response to the fox urine component, 3-methyl-3-butenyl methyl sulfide, is in accord with the results of Vernet-Maury et al. (1984) in their experiments with stress-inducing odorants in the rat. Interestingly, this fox urine component is effective in suppressing feeding in the snowshoe hare (*Lepus americanus*) as shown by Sullivan and Crump (1986b).

Although the number of gophers captured on treatment grids in our orchards did not differ from the controls, the distribution of gophers within the treatment grid area was significantly affected. The majority of gophers did not

enter beyond the perimeter of our treatment grids. This result, along with those of Sullivan and Crump (1986a), provides strong conclusive evidence that gophers will avoid predator odor (at least certain mustelid anal-gland compounds) that has been placed in their burrow systems in a field situation. Our technique of dispensing odors clearly needs improvement. The majority of cans used in the trials could not be relocated after the 1985–1986 overwinter period. Thus, there was no measure of how many cans were still functional. A technique is required to dispense the compounds in controlled-release devices at a multitude of sources within burrows in a given orchard or other forest–agricultural area. Once the resident gophers are removed, as many burrows systems as possible should be "fumigated" with one or more predator odors. Formulation of such devices is clearly a critical next step to effective use of these semiochemicals for crop protection from pocket gophers.

The rapid colonization of removal areas by gophers was an indication of the intense social pressure which forces the annual surplus of juvenile as well as adult gophers into any available "open habitat" (Sullivan and Crump, 1986a; Sullivan and Sullivan, in preparation). Thus, to keep gophers completely out of an orchard block, a buffer strip of at least 25 m should be added to the area treated with predator odors. Gophers may then colonize and reside on the outside of an orchard without causing any feeding damage within the orchard itself. An additional technique could utilize a mechanical burrow builder (Anderson and Kluge, 1986) to make artificial burrows within the buffer strip around an orchard. These burrows could then be fumigated with predator odors as a line of defense against colonist gophers. Similar strategies could be adapted to other forest and agricultural situations.

(Received November 3, 1986; accepted February 9, 1987)

Abstract—Three chemicals isolated from ovipositor rinses of virgin female *Eoreuma loftini* Dyar (Mexican rice borer) moths were identified as (Z)-13-octadecenyl acetate (I), (Z)-11-hexadecenyl acetate (II), and (Z)-13-octadecenal (III) in the approximate ratio 8:1:1.3, respectively. Preliminary tests indicate that in laboratory bioassays, these chemicals in the above ratio induce the same activity response as heptane extracts of rice borer ovipositors. Only one combination of two chemicals (I and III, 6.2:1 ratio) elicited a similar response. Individual chemicals elicited no response. In field tests, the average number of male rice borer moths caught per night over a five-night period was the same in traps baited with 200–600-μg quantities of the 8:1:1.3 ratio of chemicals dispensed from strips of filter paper as with traps baited with virgin females. The two-component mixture (I and III, 6.2:1 ratio) was not active in the field.

INTRODUCTION

Mexican rice borers (MRB), *Eoreuma loftini* Dyar (Lepidoptera: Pyralidae) (previously *Chilo loftini* Dyar and *Acigona loftini* Dyar) were first found in sugarcane fields in the lower Rio Grande Valley in Texas in the summer of 1980 (Fors, 1981; Fors and Abarca, 1983; Johnson and Van Leerdam, 1981). Its previously recorded range was Arizona, California, and Mexico. MRB caused yield losses in sugarcane in the 1980–1981 season (Fors, 1981) and were found in several alternate hosts (Johnson and Van Leerdam, 1981). Since the MRB could potentially become the primary pest of sugarcane in the lower Rio Grande Valley of Texas, research was initiated to develop technology to manage MRB populations to reduce sugarcane damage. Female sex pheromones have been identified for species related to MRB, including *Chilo zacconius* (Zagatti et al., 1983), *Chilo suppressalis* (Nesbitt et al., 1975), *Chilo partellus* (Nesbitt et al., 1979), and *Chilo sascariphagus* (Nesbitt et al., 1980). The presence of a female sex pheromone in MRB was demonstrated by Brown et al. (1988). The research reported herein was designed to identify sex pheromone components of this rice borer and to verify their activity in preliminary laboratory and field evaluations.

METHODS AND MATERIALS

Insects. Insects used in this study were obtained from a colony maintained by USDA, Animal and Plant Health Inspection Service (APHIS) at rearing facilities in San Benito, Texas, and Moore Air Base, Mission, Texas. Larvae were reared on a modified soy flour–corn grits diet at 29 ± 1°C. The insects were sexed as pupae, and males and females were kept separate to ensure availability of virgin adults. All adults were kept at 26 ± 1°C on a 14:10-hr light–dark photoperiod. The photoperiod was adjusted in insects used for laboratory bioassay so that the dark phase coincided with normal working hours.

Preparation of Ovipositor Extracts. Ovipositor extracts were prepared by excising ovipositors from virgin MRB females (24–48 hr old) during the period in which they were actively calling, normally about 5 hr after start of scotophase. Ovipositors were obtained by gently squeezing the abdomen of suitable females to cause extension of the ovipositor, which was excised with fine dissecting scissors. Excess fat tissue was trimmed with dissecting scissors, and the cut surface was touched to paper tissue to remove contaminating hemolymph. Excised ovipositors were then soaked in heptane for 2 hr; normally 50 ovipos-

itors were soaked in ca. 1 ml of heptane, giving 50 female equivalents (FE)/ml. The ovipositors were removed from the heptane, and the extracts were tested in the laboratory bioassay to verify activity. The laboratory bioassay was reported by Brown et al. (1988) and consisted of suspending test materials in glass jars containing five male MRB and observing the males for 1 min to determine individual responses. A numerical rating was assigned for each male depending on the type and intensity of response as follows: 1 = no response; 2 = intermittent crawling; 3 = continuous crawling; 4 = crawling with intermittent flying or fluttering of wings; 5 = continuous flying or fluttering of wings (including attempted mating with test material). Each material was tested with four different groups of males giving a total of 20 observations per test material.

Fractionation of Ovipositor Extract. The crude ovipositor extract was fractionated on an 80–120 mesh silica gel column (2.2 × 22.0 cm) by eluting with 100-ml portions each of hexane; 1, 2, 5, 10, and 25% ether in hexane; and then with ether and methylene chloride. Fractions (50 ml) collected were monitored by the laboratory bioassay and were analyzed by capillary gas chromotography (GC) on the 50-m OV-1701 column.

GC and GC-MS Analyses. Gas chromatography was performed on a Varian 3700 gas chromatograph equipped with either: (1) 50 m × 0.32 mm ID vitreous silica OV-1701 column (SGE, Austin, Texas), (2) 50 m × 0.25 mm ID vitreous silica Silar 10C (Alltech Associates, Deerfield, Illinois), or (3) 25 m × 0.32 mm ID vitreous silica BP-1 column (SGE, Austin, Texas) using a Grob splitless injection system and a flame ionization detector. N_2 pressure was 22 psig. Retention times and temperature programs are shown in Table 1. Mass spectral studies were performed on a Finnigan 1020 OWA mass spectrometer equipped

[a] OV-1701, 50 m × 0.32 mm vitreous silica (SGE, Austin, Texas), 60°C for 1.0 min followed by 15°C/min heating to 225°C, N_2 flow 1.8 cc/min.

[b] BP-1, 25 m × 0.32 mm vitreous silica (SGE, Austin, Texas), 60°C for 1.0 min followed by 7°C/min heating to 200°C, N_2 flow 2.0 cc/min.

[c] Silar 10C, 50 m × 0.25 mm vitreous silica (Alltech Associates, Deerfield, Illinois), 60°C for 1.0 min followed by 10°cc/min heating to 180°C, N_2 flow 1.7 cc/min.

with a 1.83 m × 2 mm ID glass column packed with OV-101 on Chromosorb 750, 100–125 mesh, pressure 20 psig, temperature programmed from 80 to 230°C at 20°/min. Compounds present were tentatively identified by comparison of their spectra with those of the EPA-NIH Mass Spectral Data Base (Heller and Milne, 1978). Standard compounds were purchased or prepared by published methods and were subjected to GC and mass spectral analyses for comparison of retention times and mass spectra.

Individual components of 100 FE of MRB ovipositor heptane rinse were separated by preparative GC on a modified Tracor 550 chromatograph using a 2 m × 4 mm ID 1.5% SP-2250/1.95% SP-2401 on 100/120 Supelcoport column at 160°C and collected in 1.7-mm glass capillary tubes using a Brownlee-Silverstein thermal gradient collector (Brownlee and Silverstein, 1968). The double-bond positions were established by microozonalysis. These components, along with commercial or synthesized standards, were then ozonized in methylene chloride (Beroza and Bierl, 1967), treated with triphenyl phosphine, and analyzed by capillary GC on a 50-m OV-1701 column at 50°C.

The concentration of each of the three identified chemicals in ovipositors of virgin MRB females was determined by GC analysis of heptane extracts from 10 groups of 50 ovipositors. Analyses were performed on the 50-m OV-1701 capillary column at a temperature program of 60°C for 1.0 min followed by 15°C/min heating to 225°C with a N_2 flow of 1.8 cc/min. Quantitation was made by comparing with standards of the identified compounds.

Laboratory and Field Tests. Activity of combinations of (Z)-13-octadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-13-octadecenal was tested in the laboratory by the method described by Brown et al. (1988). (Z)-11-Hexadecenyl acetate was prepared for these tests by acetylating (Z)-11-hexadecen-l-ol with acetic anhydride and pyridine. (Z)-13-Octadecenal was obtained commercially, and (Z)-13-octadecenyl acetate was prepared by first reducing (Z)-13-octadecenal to (Z)-13-octadecen-l-ol using excess sodium borohydride in methanol at 0°C and then acetylating with acetic anhydride and pyridine. Purity of the three compounds was determined by capillary GC on a 50-m OV-1701 column and isomeric purity was determined on a 50-m Silar 10C column. A stock solution in hexane was prepared containing pheromone components in the ratio of 8:1:1.3 of (Z)-13-octadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-13-octadecenal, respectively. Dilutions were made to determine the limits of sensitivity in laboratory tests. Also 100 ng of the pheromone blend, single compounds, and all possible combinations of two compounds in the same ratios as they occur in the blend identified from ovipositor extracts were compared with freshly prepared ovipositor extracts for activity in the laboratory bioassay.

All blends and extracts were dispensed from ca. 2-cm^2 strips of filter paper in the laboratory bioassay. The effectiveness of the 8:1:1.3 ratio of the three

chemicals in capturing male MRB in field trapping studies was determined by comparison of catches of male rice borers in traps baited with three virgin females and in traps baited with different amounts of the pheromone blend. The pheromone blend (200, 400, or 600 μg) was dispensed onto ca. 2-cm^2 strips of filter paper, and traps were baited late each afternoon to ensure that the chemicals would be emitted during the period of sexual activity of the male MRB moths. Pherocon IC (Zoecon Corporation, Palo Alto, California 94304) traps were used in all field studies, and the traps were placed 50 m apart and 5 m inside a sugarcane field. Tests were run three times with four replicates per run. Traps were randomized nightly. Pheromone blend of the same ratio was impregnated in black PVC plastic dispensers (Hendricks, 1983) at a rate of 5 mg pheromone per lure and was compared with similar PVC lures containing 5 mg total concentration of all possible combinations of two compounds in the ratios identified from ovipositor extracts. Male MRB catch in traps baited with the synthetic chemicals was compared with catches in traps baited with three virgin females. The data were analyzed using ANOVA and comparison of the means was made with Duncan's new multiple-range test.

RESULTS AND DISCUSSION

Fractionation and GC-MS Analyses. Three components were present in all ovipositor extracts examined. GC-MS analyses revealed that several samples also contained varying amounts of straight-chain C_{21}, C_{23}, and C_{25} hydrocarbons and an unidentified phthalate. However, these hydrocarbons and the phthalate were not present in some of the active extracts, nor were they present in active fractions obtained from silica gel columns. Activity in laboratory bioassays was obtained with fractions eluted with 5% and 10% ether in hexane from silica gel columns. Each of the active fractions contained the three components detected in all ovipositor extracts. These three components were tentatively identified by comparison with a mass spectral library as octadecenal, hexadecenyl acetate, and octadecenyl acetate. Related species are known to use 16-, and 18-carbon alcohols, aldehydes, and acetates with a double bond in the 11 or 13 position, respectively, as pheromonal components.

Previously reported sex pheromone components for related *Chilo* species include: (1) (*Z*)-11-hexadecenal and (*Z*)-13-octadecenal from *C. suppressalis* (Nesbitt et al., 1975); (2) (*Z*)-11-hexadecenal and (*Z*)-11-hecadecen-1-ol from *C. pastellus* (Nesbitt et al., 1979); (3) (*Z*)-13-octadecenyl acetate and (*Z*)-13-octadecen-1-ol from *C. sacchariphagus* (Nesbitt et al., 1980); and (4) hexadecan-1-ol and (*Z*)-11-hexadecen-1-ol from *C. zacconius* (Zagatti et al., 1983). Several of these compounds were prepared for comparison, and it was found that (*Z*)-13-octadecenal, (*Z*)-11-hexadecenyl acetate, and (*Z*)-13-octadecenyl acetate had the same retention times on the 50-m OV-1701, BP-1, and Silar

10C capillary columns as the three compounds isolated from ovipositor extracts and also produced identical mass spectra. Retention times and relative amounts of these components in ovipositor extracts are shown in Table 1.

The concentration of the compounds identified as (Z)-13-octadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-13-octadecenal was determined to be 56.3 ng per ovipositor in a ratio of 8 : 1 : 1.3, respectively, from ovipositors of 24 to 48-hr-old virgin MRB females. Both the *E* and *Z* isomers of 11-hexadecenyl acetate and 13-octadecenyl acetate were available for comparative purposes, and the *E* and *Z* isomers had retention times of 18.13 min and 18.45 min for the 11-hexadecenyl acetate isomers and 21.78 and 22.40 min for the 13-octadecenyl acetate isomers, respectively, on the Silar 10C capillary columns. Samples of the three standards and of individual compounds isolated from the ovipositor extracts were epoxidized using *m*-chloroperbenzoic acid in methylene chloride at 0°C. Retention times on capillary columns were identical and peaks were sharp and symmetrical, indicating isomers are as stated.

Ozonolysis of each isolated compound and its commercial or synthesized standard yielded an aldehyde with the same retention time (11.68 min) as *n*-valeraldehyde by capillary GC analysis on OV-1701 at 50°C, indicating that the double bond in each compound is between carbon 5 and carbon 6 from the hydrocarbon end. For comparison, (Z)-7-, (Z)-9-, and (Z)-11-hexadecenyl acetate were subjected to GC analysis under the conditions given in Table 1. Retention times were 23.86, 24.01, and 24.37 min for the (Z)-7, (Z)-9, and (Z)-11 isomers, respectively, on the OV-1701 column; and 18.03, 18.17, and 18.45 min, respectively, on the Silar 10C column. Silar 10C is equivalent to SP2340, which has been used to provide good resolution of positional isomers of monounsaturated alcohol, aldehyde, and acetate pheromonal blends found in lepidopteran insects (Heath and Tumlinson, 1984).

Preliminary Laboratory and Field Tests. In laboratory bioassays, response of male rice borer moths to a blend of 8 : 1 : 1.3 (Z)-13-octadecenyl acetate, (Z)-11-hexadecenyl acetate, and (Z)-13-octadecenal, respectively, was similar in intensity to response of the males to heptane extracts of ovipositors obtained from virgin females (Table 2), with relative responses of 3.5 for the synthetic chemicals and 4.1 for the ovipositor extracts. The deletion of (Z)-11-hexadecenyl acetate from the mixture of synthetic chemicals caused a significant decrease in the response of males, although laboratory response to the mixture of (Z)-13-octadecenyl acetate and (Z)-13-octadecenal was significantly greater than response to the solvent blank. However, none of the chemicals induced a response in males in the laboratory when tested either alone or in pairs lacking in either (Z)-13-octadecenyl acetate or (Z)-13-octadecenal.

Trap catch data for virgin females and pheromone blend [8 : 1 : 1.3 ratio of (Z)-13-octadecenyl acetate, (Z)-11-hexadecenyl acetate and (Z)-13-octadecenal, respectively] showed no significant difference in average number of male

TABLE 2. LABORATORY ACTIVITY AND TRAP CATCHES ON MALE RICE BORER MOTHS EXPOSED TO (Z)-11-HEXADECENYL ACETATE (Z11–C_{16}Ac), (Z)-13-OCTADECENAL (Z13–C_{18}Al) AND (Z)-13-OCTADECENYL ACETATE (Z13–C_{18}Ac) IN VARIOUS BLENDS

Component blend	Laboratory response rating[a]	Trap Catch (males/trap/night)[b]

I + II + III (8.0:1.0:1.3)	3.5 a	3.8 b
Females[e]	4.1 a	6.1 a
blank	1.4 c	0 d

[a] 100 ng of blend or chemical was dispensed onto 2-cm^2 filter paper strips.
[b] Pheromone blends were formulated in black polyvinyl chloride.
[c] Numbers followed by the same letter are not significantly different, $P = 0.05$, Duncan's new multiple-range test.
[d] Individual compounds were not tested for trap catch in field tests.
[e] In laboratory tests, 1.0 FE of heptane ovipositor extract was used as a control; in field tests, control traps were baited with three virgin females/trap.

MRB moths caught per trap night in the traps baited with females or with 200, 400, or 600 μg of pheromone. In a test to evaluate the various combinations of two chemicals formulated in PVC as lures, virgin females did catch significantly more moths than the three-component mixture (8:1:1.3 ratio) formulated in a PVC slow-release lure (Table 2). Of the combinations of two chemicals, an 8:1 mixture of (Z)-13-octadecenyl acetate plus (Z)-11-hexadecenyl acetate and a 6.2:1 mixture of (Z)-13-octadecdenyl acetate plus (Z)-13-octadecenal caught some moths, although considerably less than either the females or the three-component blend.

Results from our tests indicate that all three components of the MRB sex pheromone identified in this study are necessary for a complete response by MRB males. Although there was a definite response in laboratory studies to a two-component blend consisting of (Z)-13-octadecenyl acetate and (Z)-13-octadecenal, the response was limited to wing fluttering and movement toward the source, with no attempt to land on paper strips containing the chemicals. However, males responding to the three-component blend frequently landed on the treated paper and exhibited precopulatory mating behavior, including curvature of the abdomen (Brown et al., 1988). Likewise, when the three-component blend was dispensed on small strips of filter paper attached to dowel

rods placed in sugarcane fields, rice borer males were observed through night vision equipment to land on the strip and exhibit precopulatory mating behavior. Some of the moths responding in such a manner were captured to confirm that they were male MRB.

When the various binary blends of pheromone components were placed in sugarcane fields in the same manner, a few male rice borers were detected hovering and orienting toward binary mixtures of (Z)-13-octadecenyl acetate combined with either (Z)-11-hexadecenyl acetate or (Z)-13-octadecenal, but none were observed landing on baits of these binary mixtures. No response was detected toward filters treated with a binary mixture of (Z)-11-hexadecenyl acetate and (Z)-13-octadecenal. This is in agreement with the trap catch data in which trap catches were greatest in traps baited with the three-component mixture, followed by binary mixtures containing (Z)-13-octadecenyl acetate, and none caught in traps baited with (Z)-11-hexadecenyl acetate plus (Z)-13-octadecenal. The fact that all the MRB caught in traps baited with the synthetic chemical blend were males and that males contacting the chemical blends in sugarcane fields exhibited typical precopulatory mating behavior supports the conclusion that these chemicals are components of the pheromone system in Mexican rice borers.

Acknowledgments—We thank Dr. S.B. Vinson, Texas A&M University, College Station, Texas, for use of equipment used during the GC-mass spectral studies; and Dr. R.E. Doolittle, USDA, ARS, Gainesville, Florida, for providing *Z* and *E* isomers of C_{16} and C_{18} acetates.

EVIDENCE FOR OCCURRENCE OF MOUNTING SEX PHEROMONE ON BODY SURFACE OF FEMALE *Dermacentor variabilis* (SAY) AND *Dermacentor andersoni* (STILES) (ACARI: IXODIDAE)[1]

J. GORDON C. HAMILTON and DANIEL E. SONENSHINE

Department of Biological Sciences, Old Dominion University
Norfolk, Virginia 23508

(Received December 9, 1986; accepted February 9, 1987)

Abstract—Male *Dermacentor variabilis* and *D. andersoni* respond to an unknown chemical or chemicals present on the body surfaces of partially engorged conspecific female ticks. Following contact, the males mount the females and apply their mouthparts and legs against the female dorsal body surface. Then, the males turn with these appendages still in close contact and crawl to the female's venter, whereupon they locate the gonopore, probe the vulva, and copulate. Similar responses are elicited by heterospecific as well as conspecific females. However, the response is lost when the female cuticle is cleaned (delipidized) with organic solvents. It can be restored by applying hexane extracts prepared from female cuticle to the previously cleaned females. Males do not use surface texture as the primary stimulus for mate recognition. Male ticks also respond to hexane extracts applied to spherical inanimate objects, ("dummy" female), suggesting that a chemical or chemicals soluble in organic solvents has been transferred to these objects. These findings suggest the existence of a previously undescribed pheromone, the mounting sex pheromone (MSP). This contact sex pheromone enables males excited and attracted by 2,6-dichlorophenol to identify the female as a potential mating partner. The MSP is the second in the series of three sex pheromones guiding the hierarchy of behavioral responses which constitute tick courtship behavior.

Key Words—*Dermacentor variabilis*, *Dermacentor* andersoni, acarina, acari, Ixodidae, mounting sex pheromone, ticks, American dog tick, Rocky Mountain wood tick.

INTRODUCTION

In ticks, as in insects, mating is regulated by pheromones, primarily sex pheromones. The best known sex pheromones are the volatile phenolic compounds, e.g., 2,6-dichlorophenol (2,6-DCP). These compounds, which have been reported in 14 species of ixodid ticks, are secreted by sexually mature females to attract mate seeking males (Sonenshine, 1985). However, recognition of the volatile pheromone does not guarantee mating. In some species, the male will copulate only if it recognizes a species-specific pheromone in the vulva (Sonenshine et al., 1982). In others, mounting of heterospecific females may be aborted before the male reaches the gonopore (Khalil et al., 1983). Males attracted to 2,6-DCP placed on inanimate objects fail to recognize these objects as potential mates and leave quickly even if they make physical contact with them (Sonenshine, unpublished). These observations suggest that some stimulus provided by the body surface of the sexually mature female tick may be required to induce mounting and further exploration of these mating partners by the males. This stimulus may act as a contact sex pheromone. Alternatively, the characteristic shape and texture of the cuticular ridges may provide the recognition signal.

Cuticular contact sex pheromones occur in several insects, e.g., tsetse flies (Carlson et al., 1978). In arachnids, e.g., Tetranychidae (Cone, 1979) and spiders (Watson, 1986), they act as arrestants, with the male "guarding" the immature female until she molts to the adult stage. However, no contact sex pheromone of cuticular origin has been described in ticks.

We report the results of studies to establish the role of cuticular compounds and physical features of female ticks in mediating the mating behavior of male ticks.

METHODS AND MATERIALS

The American dog tick, *Dermacentor variabilis*, was colonized from wild-caught ticks collected near Richmond, Virginia. The Rocky Mountain wood tick, *Dermacentor andersoni*, was colonized from a population obtained from the U.S. Public Health Service, Rocky Mountain Laboratory, Hamilton, Montana. Ticks were reared and stored for experimentation as described previously by Sonenshine et al. (1977).

Newly emerged male and female adult ticks of both species were allowed to feed on laboratory rabbits (*Oryctalagus cuniculus*), immunologically naive to ticks, and were removed from the host six to seven days postattachment. They were used either in bioassays or to prepare cuticular extract.

Preparation of Cuticular Extracts. Cuticular extract (extract) was prepared from 100 engorging female ticks of each species, which were removed from the host rabbit after feeding for six to seven days. The ticks were frozen to facilitate removal of the cuticle (−20°C). Once frozen, the females were cut in two along the anterior–posterior midline and the body contents removed. The tick cuticle was placed in precleaned screw-top vials containing Shen's solution (Oliver, 1972). The cuticle was shaken briefly in the Shen's solution, and the solution then discarded. This cleaning process was repeated three to five times until all the visible blood and other contaminants had been removed from the cuticle. The cuticle was then dried on tissue paper and transferred to precleaned vials containing GC spectrophotometric grade hexane (2× distilled, Burdick and Jackson Labs., Inc., Muskegon, Michigan). The cuticle and solvent were vigorously shaken together, allowed to settle (5 min), the solvent decanted into another precleaned vial, and the extraction process repeated (three times). The combined solvent extract was reduced to 0.3 ml (N_2) in a precleaned microvial and stored at −20°C until required for bioassay. This extraction process is similar to one described by Gilby (1980). Male cuticular extract was prepared from fed (seven days) adults. These were frozen to −20°C. Once frozen, they were washed in hexane (100 ml) three times and the combined solvent extract reduced to 0.2 ml (N_2).

Bioassays. Three types of bioassay were carried out: on conspecifics, on heterospecifics, and on inanimate objects that could be coated with extract. All male ticks were prescreened to ensure that only those that were responding to females were used in the bioassays. Females were also prescreened to ensure that they were capable of exciting a mating response by the male before being cleaned. The females were cleaned as described below and assayed to ensure that they would no longer attract males before the extract was applied. Bioassays were performed in the laboratory at approximately 25°C on filter paper in a 9-cm-diam. Petri dish. The response of the male when presented to the immobilized female was scored by a system based on the mating behavior sequence described by Sonenshine (1985). The female was immobilized by attaching its anterior end to adhesive tape. The mating behavior sequence used in these experiments was as follows: (1) orientation of the male towards the female or "dummy" female (2,6-DCP source); (2) awareness of the female (touching with appendages); (3) mounting of the female; (4) turning on the dorsal surface of the female; (5) movement of the male to the ventral surface; and (6) locating and probing the gonopore.

Each stage was given one point when the male had achieved that stage. The number of points gained by each male was recorded. The number of times that the males successfully located and probed the gonopore were also recorded. The first two stages were not included in the final analysis as they are a measure

of the attractiveness of the 2,6-DCP, which has already been established for *D. andersoni* and *D. variabilis* (Sonenshine et al., 1977). Thus a completely successful male would gain four points in locating and probing the gonopore. The number of points gained by the males in their response to females or extracts was totaled and compared to the control using a one-tailed *t* test for comparing percentages (Sokal and Rohlf, 1969).

Chemical Removal of Female Cuticle Compounds. D. variabilis and *D. andersoni* females were cleaned in hexane after preliminary trials had demonstrated that it was as effective in removing the cuticular lipids as a combination of hexane, chloroform, and acetone. Females were cleaned by immersing them in the solvent and "scrubbing" them with a fine, stiff-bristle brush. The detached, partially fed female ticks were cleaned in this way for 10 min, which invariably resulted in the death of the female tick (hereafter termed "cleaned" female). Following surface cleaning, the females were tested for their ability to excite male mating response. This was done by adding 6 ng of 2,6-DCP (Aldrich Chemical Company, Inc., Milwaukee, Wisconsin) with a microcapillary pipet to the foveal gland area of the dorsal surface. Male responses were scored as previously described. Controls for these experiments were unmodified females tested with the same males challenged previously with the surface-cleaned females.

Extract-Coated Females. Cleaned females of both species were coated with either conspecific or heterospecific extract and then were bioassayed with conspecific and heterospecific males. Only those females that had been solvent cleaned and that had failed to excite the male mating response beyond stage three were treated and used in these bioassays.

In the conspecific bioassays, test females were coated with 6 μl of female extract containing ca. 1.5–2.0 female equivalents. Following coating, the females were maintained at host skin temperature (30°C) in sealed vials in an incubator to allow complete solvent evaporation. Control females were treated in exactly the same way, but only hexane was added. 2,6-DCP was added to both test and control females before being tested with the males. To perform the assay, a male was placed alongside the female (<2 cm), and its responses were observed and recorded. The same males were used in the test as in the controls, e.g., male 1 was used with both test female 1 and control female 1 and then discarded.

In the heterospecific assays, the cleaning and scoring schedule was the same as used for the conspecifics (see above). Cleaned *D. variabilis* females were coated with *D. andersoni* female extract and were tested with *D. variabilis* and *D. andersoni* males. Cleaned *D. andersoni* females were coated with *D. variabilis* female extract and tested with *D. variabilis* and *D. andersoni* males. Controls were cleaned females with hexane only. Cleaned females were coated with conspecific male extract (approximately 1.5–2.0 male equivalents). Sol-

vent was allowed to evaporate. Extract-coated females were then tested with conspecific males as described above.

Physical Disruption of Female Cuticle. The surface of the female was abraded with fine sandpaper to completely remove the cuticular ridges which the male may be using as orientation cues to locate the gonopore. No solvents were applied and no chemicals were removed. 2,6-DCP was added, and the male response observed as described above.

Inanimate Objects ("Dummy" Female Ticks). Males prescreened with conspecific females were used for this test. Smooth, inert spherical plastic beads (18 mm diam.) were prepared by roughening the surface with sandpaper and attaching them with fine copper wire to a cardboard support. A sample of extract (16 μl containing ca. 4–5 FE) was added incrementally to the entire surface and the hexane solvent allowed to volatilize while the treated specimen was held in an incubator (30°C). Each species extract was tested with both *D. variabilis* and *D. andersoni* males. Controls were plastic beads with hexane only added. The time spent by the male in contact with extract-coated dummy ticks was recorded. The same male was used for both the test and control parts of the experiment. The data were analyzed using a paired one-tailed t test, SAS Statistical Package (SAS Institute Inc., Cary, North Carolina).

RESULTS

The results of these experiments are summarized in three tables: Table 1, Conspecific Assays; Table 2, Heterospecific Assays; and Table 3, Inanimate Objects Assays.

The first column of the tables, "Extract Added," specifies which extract (*D. andersoni* female or *D. variabilis* female), if any, was added to either the cleaned female or inanimate objects. The second column, "Species of Female Treated," shows the species of female, if any, to which the extract was added (this column is not included in Table 3 as extract was added to inanimate objects only). This column also gives other relevant information on any other modification, i.e., if the female tick in column one was cleaned (clean) or not cleaned (n/clean) or if it was abraded (abraded) or not abraded (n/abraded). The third column, "Species of Male Used," shows which males were used in the bioassays.

Conspecific Assays. The male mating response was significantly reduced ($P < 0.01$) when solvent cleaned *D. andersoni* and *D. variabilis* females were tested with the males of both species (Table 1, experiments 1 and 2). When conspecific cuticular extract was applied to the prescreened, cleaned females, the male response was shown to be significantly greater than when it was absent ($P < 0.01$) (Table 1, experiments 3 and 4). In the case of *D. variabilis*, the

mating response was 100% restored, with *D. andersoni*, it was 86.3% restored. When the surface of the *D. andersoni* and *D. variabilis* females was abraded with find sandpaper, the male mating response was again greatly reduced ($P < 0.01$) (Table 1, experiments 5 and 6). Males did not respond to extracts made from the body surfaces of other conspecific males at the same concentration that was found to be effective for female extracts.

Heterospecific Assays. D. variabilis males showed a significant response to *D. andersoni* female extract when placed on cleaned *D. variabilis* females ($P < 0.01$) (Table 2, experiment 1). *D. andersoni* males also showed a significant response to *D. andersoni* female extract when placed on cleaned *D. variabilis* females ($P < 0.01$) (Table 2, experiment 2). *D. variabilis* males showed a significant response to *D. variabilis* female extract placed on *D. andersoni* females ($P < 0.01$) (Table 2, experiment 3). *D. andersoni* males also showed a significant response to *D. variabilis* female extract placed on *D. andersoni* females ($P < 0.05$) (Table 2, experiment 4). *D. variabilis* males showed a significantly higher response to conspecific female extract (100%) than to het-

erospecific female extract (83.8%) ($P < 0.05$). *D. andersoni* males showed a significantly higher response to conspecific female extract (86.3%) than to heterospecific female extract (61.3%) ($P < 0.05$). *D. variabilis* males were more responsive to conspecific female extract (100%) than *D. andersoni* males (86.3%) ($P < 0.05$). *D. andersoni* males and *D. variabilis* males were equally responsive to heterospecific extract (no significant difference between percentage scores).

Inanimate Objects (Dummy Ticks). *D. andersoni* males responding to conspecific extract-coated dummy female ticks showed a significantly higher percentage score than those males presented with controls ($P < 0.05$). *D. andersoni* female extract induced *D. andersoni* males to attempt the complete mating sequence (stage 6) in four cases (Table 3, experiment 1). However, the *D. andersoni* male response to dummy ticks coated with *D. variabilis* female extract was not significant (Table 3, experiment 2). *D. variabilis* males responding to conspecific extract-coated dummy female ticks showed a highly significantly increased percentage score compared to those males responding to controls ($P < 0.01$) (Table 3, experiment 3). *D. variabilis* males also showed a significantly increased response to *D. andersoni* female extract when compared with the controls ($P < 0.05$) (Table 3, experiment 4). Male *D. variabilis* ticks reached stage 6 seven times when responding to *D. variabilis* female extract and three times when responding to *D. andersoni* extract.

An analysis of the total time spent by each male tick in contact with the dummy tick revealed that *D. andersoni* males spent a highly significantly in-

creased amount of time on *D. andersoni* female extract-coated ticks ($P = 0.0031$). The amount of time spent by *D. andersoni* males in contact with *D. variabilis* females extract-coated dummy ticks was not significantly different from the time spent by the *D. andersoni* male on the control dummy tick. The amount of time spent by male *D. variabilis* ticks in contact with female *D. variabilis* extract-coated dummy ticks was highly significant ($P = 0.0001$). Male *D. variabilis* also spent a highly significant amount of time in contact with *D. andersoni* female extract-coated dummy ticks ($P = 0.0047$). The same statistical analysis demonstrated that there was no significant difference in the amount of time spent on each of the control dummy ticks.

DISCUSSION

The results of the bioassays clearly indicate the presence of a cuticular sex pheromone, the mounting sex pheromone (MSP), produced by *D. andersoni* and *D. variabilis* females. Following their attraction by 2,6-DCP, males encountering this pheromone mount the females and apply their legs and mouthparts against the female body surface so that the male body is in direct contact with the female. Then, while still in close contact, they move to the female's venter and probe until they locate the gonopore. Thus, this sex pheromone mediates the mounting phase of ixodid tick courtship behavior, as described by Sonenshine (1985). This cuticular sex pheromone is essential for recognition of the female as a potential mating partner. Males are unable to recognize females

lacking this cuticular pheromone as potential mates, and these males terminate their courtship activities. However, the males' mating response can be restored by depositing the extract onto the bodies of surface-delipidized females or even transferred onto inanimate objects (dummy ticks), evidence which supports the hypothesis that this represents pheromone-mediated behavior.

Our evidence indicates that male *D. andersoni* and *D. variabilis* have a similar response to both heterospecific and conspecific females. There was no significant difference between the mounting responses of the males of either species to heterospecific vs. conspecific extracts when the extracts were applied to cleaned female ticks. However, male *D. andersoni* did not respond to female *D. variabilis* extract applied to dummy ticks, even though they exhibited strong, positive responses to the same extract applied to cleaned females.

Cuticular lipids are known to serve as sex pheromones in several species of insects where they act as contact aphrodisiacs. In the housefly, three compounds occur in the cuticular lipid fraction of sexually mature females which attract sexually active males. The most active component is an unbranched C_{23} alkene, (*Z*)-9-tricosene; the C_{28}–C_{30} methylalkanes, (*Z*)-9,10-epoxytricosane and (*Z*)-14-tricosen-10-one, enhance its activity (Blomquist et al., 1984). In the tsetse fly, *Glossina morsitans*, three paraffins which occur on the surface of the females, 15,19-dimethylheptatriacontane, 17,21-dimethylheptatriacontane, and 15,19,23-trimethylheptatriacontane, induce mating attempts by male flies upon contact with the females (Carlson et al., 1978). In both the housefly and tsetse fly examples, the compounds that act as cuticular sex pheromones are nonvolatile, requiring physical contact by the male before they can be detected. Following recognition of the pheromone in these insects, the males respond with mating attempts usually resulting in copulation.

Aside from the fact that male ticks also appear to require recognition of some lipid or lipids on the cuticle in order to mate, there is little similarity with the insect examples described above. In the case of ticks, the males have already been excited to begin mate seeking behavior by 2,6-DCP. The cuticular lipids act as a "mounting sex pheromone," enabling the male to recognize the female as a suitable mating partner and aid its search for the gonopore. Thus, the tick mounting sex pheromone is part of a multicomponent pheromone system that directs a sequence of behavioral events, i.e., mate seeking, mounting, location of the gonopore, and copulation. In contrast, the different hydrocarbons that comprise the dipteran pheromones all excite a single behavioral response, i.e., release of copulatory activity. The cuticular mounting sex pheromone is the third sex pheromone described in *D. variabilis* and *D. andersoni*, distinctly different from the general attractant sex pheromone and the highly species-specific genital sex pheromone. The mounting sex pheromone mediates a specific series of events in a complex hierarchy of stimulus and response events that constitutes courtship in these species.

(Received October 24, 1986; accepted February 10, 1987)

Abstract—The soldier beetle *Chauliognathus lugubris* is shown to contain triglycerides and glyceride ethers of 8-dihydromatricaria acid, and waxes of the C_{12} homolog of this acid, as well as the previously reported free acid. The triglycerides contain one, two, or three dihydromatricariate moieties, with any remaining positions esterified with normal fatty acids. The glyceride ethers were monostearyl ethers of glycerol esterified with dihydromatricaria acid and oleic or linoleic acid. The waxes, which also include a dihydromatricaria chromophore in the alcohol moiety, occur only in the females and are present in paired accessory glands in the abdomen. The ethers are restricted to females and appear to be associated with developing eggs. The triglycerides are much more abundant in females than males. Triglycerides, glyceride ethers, and waxes represent about 95% of the dihydromatricariate moiety (average, ca. 590 μg) in females with free acid the remainder; in males free acid is present to over 50% (ca. 22 μg) and the remainder is triglyceride (ca. 15 μg). Larvae contain mainly tridihydromatricariate-substituted triglyceride and a smaller quantity of the free acid.

Key Words—Dihydromatricaria acid, triglyceride, (Z)-dec-8-ene-4,6-diynoic acid, glyceride ethers, waxes, antifeedant, *Chauliognathus lugubris*, Coleoptera, Cantharidae, accessory glands, defense.

INTRODUCTION

The presence of (Z)-8-dihydromatricaria acid [(Z)-dec-8-ene-4,6-diynoic acid] in soldier beetles was first reported by Meinwald et al. (1968) for *Chauliog-*

0098-0331/88/0200-0411$06.00/0

nathus lecontei. These authors showed that the acid was produced as a milky secretion in a series of defensive glands in the prothorax and the first eight abdominal segments. The same acid, along with precoccinelline and related alkaloids, was also found in the Australian species *C. lugubris* (F.) [=*C. pulchellus* (Macleay)] (Moore and Brown, 1978). Subsequently Eisner et al. (1981) reported dihydromatricaria acid in glands and hemolymph of *C. pennsylvanicus* and demonstrated its feeding deterrency to jumping spiders (*Phidippus* spp.). In the present paper we report the additional presence in *C. lugubris* of triglycerides and glyceride ethers of dihydromatricaria acid, and waxes of the C_{12} homolog of this acid with C_{12} and C_{14} alcohols also including the dihydromatricaria chromophore. The waxes and ethers occur in females only.

Nomenclature. The term "dihydromatricaria chromophore" is used to describe the chromophore associated with the conjugated ene-diyne system present in dihydromatricaria acid (Figure 1), which gives rise to the UV spectrum described by Eisner et al. (1981) [233 nm, (log ξ = 3.03), 240 (3.45), 254 (3.78) 267 (3.99) and 282 (3.90)]. The term "total dihydromatricariate" is used for all material bearing the above chromophore regardless of the chemical nature or chain length. It is normally expressed quantitatively as the corresponding amount of free dihydromatricaria acid.

METHODS AND MATERIALS

Gas Chromatography. Gas chromatography (GC) was conducted on a Varian 2100 instrument with a Varian CDS 111 data processor, and with flame ionization detectors and a nitrogen flow of 25 ml/min. The following glass columns were used: column 1, 2 m × 2 mm ID of 3% (w/w) OV-101 on Chromosorb W; column 2, 2 m × 3 mm ID of 5% (w/w) OV-101 on Gas-Chrom Q; column 3, 4 m × 3 mm ID of 5% (w/w) Carbowax 20 M on Gas-Chrom Z; column 4, 2 m × 3 mm ID of Porapak P; and column 5, 2 m × 3 mm ID of 1.5% (w/w) OV-17 on Gas-Chrom Q.

Samples for mass spectra or other purposes were collected from the gas chromatograph in capillary tubes cooled, when necessary, by carbon dioxide snow. Kovats' indices (I) were measured isothermally using saturated alkanes as standards. Percentage compositions, when quoted, are uncorrected for the response factors of the individual components.

Thin-Layer Chromatography. Thin-layer chromatography (TLC) was performed using two main systems: system 1, 200-mm glass plates coated with silica gel HR with zinc sulfide fluor and developed with dichloromethane; and system 2, 200-mm glass plates coated with aluminum oxide G with zinc sulfide fluor developed with hexane–ether 2:1. Visualization was by ultraviolet (UV) irradiation (254 nm) or iodine staining. When required, the components were

recovered from the plates by excision of the spot or band, extraction of the material with dichloromethane–methanol 9 : 1, filtration of the extract, and concentration to the desired volume in a stream of nitrogen.

High-Performance Liquid Chromatography. High-performance liquid chromatography (HPLC) was performed on a Waters Associates instrument with two M6000 pumps, a model 720 system controller, and a model 450 variable wavelength UV detector. The column was a Regis Workhorse octadecylsilyl 300 × 4.6 mm ID reversed phase. Gradient programmed elution (system A) was used with two solvents: water (A) and methanol–2-propanol 7 : 3 (B). The stages used were: initially 25% A, 75% B; at 8 min, 10% A, 90%B; at 23 min, 100% B, at 30 min, 100% B; at 31 min, 25% A, 75% B. All gradients were linear, the flow rate was 2 ml/min, and the wavelength was set to 267 nm. Alternatively, an isocratic system (system B), with methanol–dichloromethane 85 : 15, a flow rate of 2 ml/min, and simultaneous UV and refractive index (RI) detection, was used. Samples for mass spectroscopy and other purposes were obtained by collection and evaporation of the eluant.

The quantities quoted in Tables 1 and 2 (except for the free acid) are the HPLC peak height at 267 nm for a 50-μl injection at sensitivity ×1.0. The solvent gradient was such that, within experimental error and except for the free acid, the peak widths at half height were constant. For the free acid, the width was only one third that of the other components and its quantity was calculated accordingly.

Mass Spectrometry. Mass spectra were determined on a VG Micromass 70-70 mass spectrometer interfaced to a Hewlett Packard 5790A gas chromatograph and a VG 11-250 data system. Volatile samples were introduced via GC with a 25-m bonded-phase 5% phenyl-, methyl-silicone capillary column (SGE, BP5, 0.5 μm film thickness). Components of low volatility, after separation by TLC or HPLC, were analyzed by flash volatilization from an extended gold support (Brown et al., 1985), or a polyimide probe tip, with rapid data acquisition. This method markedly increased the relative abundance of molecular parent ions compared with conventional probe techniques, simplified the fragmentation patterns, and facilitated the analysis of unresolved mixtures. Electron ionization (EI) mass spectra were determined with an ionization energy of 70 eV and trap current of 100 μA. Chemical ionization (positive ion, PCI, and negative ion, NCI) mass spectra were obtained at 50 eV ionization energy and 200 μA emission current. Methane, isobutane, and ammonia were used as reagent gases at estimated source pressures of 100, 80, and 60 Pa, respectively. Source temperatures were 180–210°C.

Ultraviolet Spectroscopy. Ultraviolet spectroscopy was performed on a Pye Unicam SP 8000 recording spectrophotometer. Dichloromethane and methanol were the solvents in 1-mm or 10-mm quartz cells.

Insects. Batches of *C. lugubris* beetles were obtained from beneath flow-

ering *Eucalyptus* spp. trees according to season in the Canberra area. Larvae were obtained from soil and litter samples also collected in the Canberra area.

Treatment of C. lugubris. The secretion from the gland was obtained as described previously (Moore and Brown, 1978).

Total extraction, *C. lugubris* beetles, or parts thereof, were crushed in dichloromethane and left in this solvent at 5°C for 24 hr. The dichloromethane extract was separated by filtration, the residue reextracted with dichloromethane and filtered again, and the filtrates combined. The dichloromethane solution was diluted to 25 ml for UV spectroscopy or concentrated for TLC analysis. Estimates of total dihydromatricariate were made by measurements of the UV absorbance of the untreated dichloromethane extracts using the extinction coefficient given by Eisner et al. (1981). The relative abundances of the different components were determined by a TLC separation followed by UV absorbance measurements. Samples for HPLC were purified by chromatography on a silica Sep-Pak eluting with dichloromethane–methanol 9:1. The solution was then evaporated, the residue taken up in methanol–2-propanol 7:3 (500 μl), and the resulting solution filtered through a nylon membrane (pore size 0.45 μm).

Transesterification. Methanolysis reactions were carried out by heating in 1% sulfuric acid in methanol (50 μl) in a Reacti-vial at 100°C for 15 min. The product was used directly for GC or TLC analysis. Acetic acid transesterifications were carried out similarly using 1% sulfuric acid in acetic acid at 90°C for 2 hr.

Hydrolysis of Glyceride Ethers. A sample of the glyceride ether was treated with methanolic sodium hydroxide (1%, 50 μl) at 70°C for 30 min in a sealed Reacti-vial. The resulting solution was extracted with hexane and the hexane extract treated with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) (25 μl) at 70°C for 30 min. The hexane solution was analyzed directly by GC.

Hydrogenation. Hydrogenations were carried out in septum-sealed Reacti-vials (with a vent) with a trace of Adams platinic oxide catalyst and methanol (20–30 μl) as solvent. The hydrogen was introduced by means of a syringe and bubbled through the mixture to provde agitation.

Ozonolysis. Microzonolyses were conducted in carbon disulfide solution in a Reacti-vial cooled by carbon dioxide snow. Ozonized oxygen was bubbled through using a 10-ml syringe, which previously had been charged from the ozonizer, till a starch iodide paper turned blue. The ozonide was then decomposed with a trace of triphenylphosphine and the resulting solution analyzed directly by GC (column 3 at 70°C and column 4 at 120°C).

Reference Compounds. (*Z*)-8-Dihydromatricaria acid and its methyl ester used as reference compounds were from samples previously characterized (Moore and Brown, 1978) from *C. lugubris* glands. Tripalmitin was obtained from Calbiochem (La Jolla, California) and batyl alcohol from Sigma Chemical Company (St. Louis, Missouri).

RESULTS

Chromatographic Separations. Previous work on various species of *Chauliognathus* involved either analysis of secretion obtained directly from the defensive glands or chemical extractions, specifically aimed at isolating only free acids. However, TLC analysis (on silica with dichloromethane–methanol 9:1) of a dichloromethane extract of whole *C. lugubris* beetles showed, in addition to the free acid, a great deal of UV-absorbing material of high R_f. Subsequently TLC (system 1) showed the free dihydromatricaria acid at the origin, a major UV absorbing spot (fraction A) at R_f 0.70, and a partially resolved series of components from R_f 0.60 to 0.30. Exposure to iodine vapor gave rise to strong staining at R_f 0.55 probably due to the normal fats (tripalmitin had R_f of 0.55). Methyl dihydromatricariate had R_f of 0.64 but was not present in the extract. The UV spectrum of fraction A (in methanol) and that of the partially resolved band showed the characteristic dihydromatricaria chromophore (cf. Eisner et al., 1981). Absorbance measurements showed that the free acid represented about 5% of total dihydromatricariate, fraction A about 45%, and the other band about 50%.

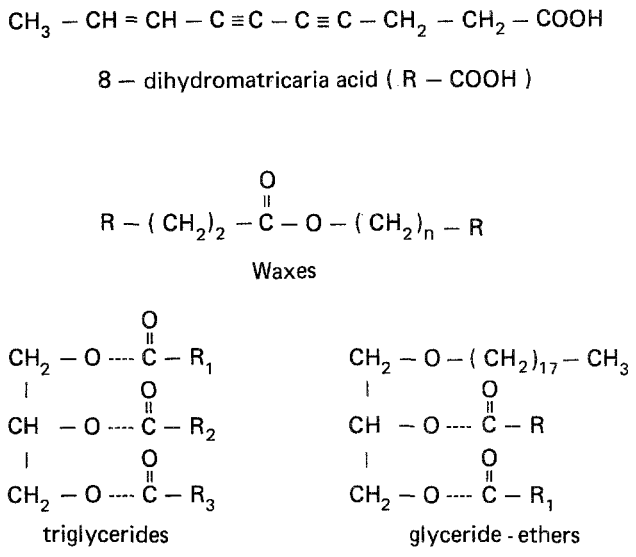

FIG. 1. Formulas for *C. lugubris* components. A dotted line indicates that the position of the substituent may be undetermined. Waxes: A1, $n = 3$; *A2*, $n = 5$. Glyceride ethers: B1, R_1 = linoleyl, B2, R_1 = oleyl. Triglycerides: C, $R_1 = R$, $R_2 = R_3$ = palmityl, stearyl, oleyl or linoleyl; D1, $R_1 = R_2 = R$, R_3 = linoleyl; D2, $R_1 = R_2 = R$, R_3 = palmityl or oleyl; D3, $R_1 = R_2 = R$, R_3 = stearyl; E, $R_1 = R_2 = R_3 = R$.

TLC with system 2 gave better resolution and produced four clearly resolved spots. These had R_f values of 0.74 (ca. 60% of the total absorbance), 0.6 (7%), 0.43 (15%), and 0.23 (15%), and there was a little free acid at the origin. All of these fractions showed the dihydromatricaria chromophore. The strong iodine-staining area coincided with the spot at R_f 0.74. Subsequent TLC of the components from these spots on system 1 showed that the R_f 0.74 spot comprised fraction A and another fraction (B) with R_f 0.53; the 0.6 material had R_f 0.47 (fraction C); the 0.43 material had R_f 0.43 (fraction D); and the 0.23 material had R_f 0.35 (fraction E).

Reversed-phase HPLC of the *C. lugubris* mixture achieved greater resolution of the components and the observed peaks have been correlated with HPLC analyses of the separate TLC fractions A–E (Table 1). Normal-phase HPLC added little to the information derived from silica TLC and was not continued.

Identification of Fraction A. GC analysis of TLC fraction A (column 1, 250°C) showed four major peaks with retention times 7.95 min (15%, I = 2903), 9.01 min (5%, I = 2951), 13.50 min (51%, I = 3106), and 15.26 min (28%, I = 3155). These indices suggested that the components were two pairs of homologs with a chain-length difference of two carbon atoms. Separate GC analyses of HPLC peaks A1 and A2 showed that the first two GC components

TABLE 1. HPLC OF *C. lugubris* DICHLOROMETHANE EXTRACT

[a] The peak height (cm) represents the total dihydromatricariate content of the component.
[b] From mass spectroscopic measurements.

were derived from A1 and the second pair from A2. The mass spectra of the material from peaks A1 and A2 (PCI, methane) showed the presence of components with molecular weights of 348 (MH^+ m/z 349) and 376 (MH^+ m/z 377), respectively.

Fraction A1 was methanolyzed and the product analyzed by TLC (system 1). Two UV-absorbing spots were resolved at R_f 0.59 [cf. methyl (Z)-8-dihydromatricariate at 0.60] and at R_f 0.23. Both of these components showed the characteristic dihydromatricaria UV spectrum. GC analysis (column 2, 150°C) of the R_f 0.59 band from methanolysis of A1 showed two peaks; the major one had R_t of 7.16 min (90%, I = 1698) and the minor had R_t 8.68 min (10%, I = 1747). After catalytic reduction, these two peaks collapsed to one, which was identified by GC R_ts (columns 2 and 3) as being due to methyl dodecanoate. GC-MS (EI) of the unreduced methyl ester fraction showed that both components had molecular weights of 204 and similar fragmentation patterns. The mass spectra were strongly reminiscent of that of methyl (Z)-8-dihydromatricariate and thus these components are almost certainly the Z and E isomers of the C_{12} homologue of methyl 8-dihydromatricariate. Ozonolysis of the major methyl ester component gave only acetaldehyde as a detectable product. The major component would be thus methyl (Z)-dodec-10-ene-6,8-diynoate and the minor component probably the E isomer. The stereochemistry was assigned by analogy with the C_{10} homologs, where Meinwald et al. (1968) have shown the Z isomer to predominate.

Material from the R_f 0.23 fraction from methanolysis of A1 was analyzed by GC on column 1 at 150°C and two components were detected; these had retention times of 5.87 min (76%, I = 1647), and 7.15 min (24%, I = 1698). After catalytic reduction only one component was detected and this was identified by GC R_ts (columns 2 and 3, 150°C) as dodecanol. GC-MS of the unreduced material showed molecular weight of 176 for the first eluting material. These components were therefore, presumably, the Z and E isomers of a C_{12} alcohol containing the dihydromatricaria chromophore. Ozonolysis led to the detection of only acetaldehyde showing the components of this methanolysis fraction to be (Z)- and (E)-dodec-10-ene-6,8-diynol. There was a greater proportion of the E isomer than is the case with the methyl esters. A1 therefore consisted of waxes derived from the above acids and alcohols.

The main component of fraction A1 was (Z)-dodec-10-ene-6,8-diynyl (Z)-dodec-10-ene-6,8-diynoate. E isomers (particularly in the alcohol moiety) were represented in less abundant waxes of A1. Similarly A2 was shown to contain waxes of the homologous (Z)- and (E)-tetradec-12-ene-8,10-diynol and (Z)- and (E)-dodec-10-ene-6,8-diynoic acid. The minor wax fractions, A3 and A4, appeared to be mixtures and were not studied further.

Identification of Fraction B. Fraction B was obtained by successive TLC on systems 1 and 2. However, the strong iodine staining, concurrent with the

UV absorption, indicated that the dihydromatricariate-containing components were cochromatographing with the ordinary fats. HPLC (system B) of fraction B showed two UV-absorbing peaks with retention times of 5.66 min (B1) and 6.52 min (B2). In addition to these components, the RI detector showed several other components, presumably fats, at longer retention times.

The mass spectrum of B2 (PCI, NH_3) showed an $(M + NH_4)^+$ ion at *m/z* 770, consistent with a molecular weight of 752, and major fragments at *m/z* 591 (M-161, loss of dihydromatricariate), and *m/z* 471 (M-281, loss of oleate). The negative ion spectrum (NCI, isobutane) showed a small ion at *m/z* 751 $[(M - H)^-]$ and major ions at *m/z* 281 (oleate) and *m/z* 161 (dihydromatricariate). These spectra were consistent with a monostearyl ether of glycerol esterified with dihydromatricaria acid and oleic acid.

The mass spectrum (PCI, NH_3) of B1 was rather similar and showed an ion at *m/z* 768, indicating a molecular weight of 750, and major ions at *m/z* 589 (M-161, loss of dihydromatricariate) and *m/z* 471 (M-279, loss of linoleate). Thus B1 was very similar to B2 except that the oleate moiety had been replaced by linoleate. This slightly more polar component would be expected to elute before B2 on reversed-phase HPLC.

Methanolysis of B2 followed by GC analysis (column 3 at 200°C) showed that the major methyl esters produced were in fact methyl oleate and methyl dihydromatricariate. The small quantities of other esters produced probably arose because the sample was not completely clear of the normal fats. There was some evidence of the latter in the form of small peaks at higher mass in the mass spectrum and in the fact that the ratio of dihydromatricariate to fatty ester was lower than expected. Methanolysis of B1 was not very helpful because of even greater interference from these fats. However, the abundance of methyl linoleate was much higher than in any of the other methanolysis reactions.

Transesterification of B2 with acetic acid–sulfuric acid followed by GC (column 1, 180°C programmed at 4°C/min) gave two major components with R_t 7.48 min and 18.64 min, respectively. The mass spectrum of the short R_t material (PCI, NH_3) showed a probable molecular weight of 368, consistent with replacement of one of the ester groups by acetate and elimination of the other. The mass spectrum of the long R_t material (PCI, NH_3) showed a probable molecular weight of 428 and was consistent with replacement of both the original ester moieties in the molecule by acetate.

Hydrolysis followed by silylation of B1 and B2 gave a product with an R_t (columns 1 and 5) identical with that of the trimethylsilyl ether of batyl alcohol (racemic 3-octadecyloxy-1,2-propanediol). This supported the presence of a stearyl ether moiety, probably in a primary position, in B1 and B2.

Identification of Fraction C. The mass spectrum of TLC fraction C (PCI, NH_3) showed prominent $(M + NH_4)^+$ ions at *m/z* 782 (mol wt 764) and 756 (mol wt 738) consistent with triglycerides with one dihydromatricariate and two

oleate moieties; and one dihydromatricariate, one oleate, and one palmitate, respectively. There were additional less intense ions representing glycerides with other possible combinations of fatty acids.

Methanolysis of fraction C followed by GC analysis (column 3 at 200°C) led to the detection of the following methyl esters: methyl palmitate (17%), methyl (*Z*)-8-dihydromatricariate (16%), methyl (*E*)-8-dihydromatricariate (5%), methyl stearate (7%), methyl oleate (51%), and methyl linoleate (3%). The ratio of dihydromatricariate to the normal fatty esters (allowing for chain length) was consistent with a 1 : 2 ratio of dihydromatricariate to fatty esters.

HPLC showed that fraction C was composed of a number of different components most of which were minor. Because of the small amounts of the components, individual mass spectra were not recorded. This greater nonhomogeneity was consistent with random distribution of fatty acid moieties in two positions of glycerol.

Identification of Fraction D. The mass spectrum (PCI, NH_3) of D2, the major HPLC peak of fraction D, indicated that at least two compounds were present. The major one had a molecular weight of 644 [$(M + NH_4)^+$ *m/z* 662] and fragments at *m/z* 483, 363, and 103; the minor component had a molecular weight of 618 [$(M + NH_4)^+$ *m/z* 636] and had fragments at *m/z* 457, 363, and 103. These mass spectra indicated that the major component was a triglyceride with two dihydromatricariate moieties and one oleate group (ions of *m/z* 483 represented M-dihydromatricariate and *m/z* 363 M-oleate). The minor component would be similar but with a palmitate group instead of the oleate.

The minor components of the fraction D (D1 and D3) showed molecular weights of 642 and 646, respectively, and were therefore considered to be triglycerides with linoleate and stearate in addition to the two dihydromatricariate groups.

Methanolysis of fraction D followed by GC analysis (columns 2 and 3) led to the detection of methyl (*Z*)-8-dihydromatricariate (45%), the *E* isomer (4%), methyl palmitate (10%), methyl oleate (34%), methyl stearate (5%), and methyl linoleate (1.5%). These data supported the mass spectral findings since the peak area ratio of the normal fatty esters to dihydromatricariate (ca. 1 : 1), after allowing for differences in molar responses to the detector because of chain length, was close to that expected for a triglyceride with two dihydromatricariate moieties and one fatty ester moiety.

Identification of Fraction E. The mass spectrum (PCI, NH_3) of fraction E showed a molecular weight of 524 [$(M + NH_4)^+$ *m/z* 542] and also major fragment ions at *m/z* 363 (M-161, loss of dihydromatricariate) and *m/z* 103. All these data indicated that fraction E was a triglyceride with dihydromatricariate in all three positions. This was confirmed by methanolysis of fraction E followed by GC analysis (column 2 at 150°C programmed at 4°C/min to 250°C and column 3 at 150°C) when only methyl (*Z*)-dihydromatricariate and about

10% of the *E* isomer were detected. Fraction E was therefore largely tri-(*Z*)-8-dihydromatricarin.

Biological Distribution of Components. To appreciate better the role of the various dihydromatricaria-containing components, an attempt was made to locate precisely their occurrence in the beetles. Earlier work had shown that the defensive glands contained little but the free acid. Males (3, average weight 40 mg) and females (3, average weight 60 mg) were assayed individually by UV spectroscopy. Males contained an average of 37 μg of total dihydromatricariate but females averaged much higher at 590 μg. TLC separation (system 1) followed by UV estimation of the resulting fractions showed that the males contained 22 μg of free acid and the remaining material was in the band representing fraction B–E. Females, however, contained only 24 μg of free acid; ca. 44% (260 μg) of the total dihydromatricariate was fraction A (waxes) and the remainder (306 μg) was in the band due to fractions B–E.

The above findings were subsequently supported and expanded by HPLC analyses of individual males and females. These results are summarized in Table 2. Males again were shown to contain much less dihydromatricariate material than females, and most of theirs was free acid; the remainder was triglyceride. Males did not appear to contain any waxes or ethers, and the small quantities of these components detected in some specimens could well have been acquired adventitiously through contact with females. It was again noticeable that the free acid content of both sexes was similar, but females had very much more

TABLE 2. HPLC ANALYSIS OF INDIVIDUAL BEETLES

			Fraction

[a]The values quoted are the peak heights (cm) at 267 nm and $\times 1.0$ sensitivity for a 50-μl injection from 500 μl of solution.

of the bound dihydromatricariate. There was considerable variation in the proportions of the various components between individuals. This may have reflected the level of maturity as well as individual variation.

Since individual males were very low in dihydromatricariate, an extract of 40 males was analyzed by TLC (system 1). The bands corresponding to the free acid and triglyceride–glyceride ether were removed (no waxes were present) and, after extraction, the UV spectra of the resulting solutions were recorded. These showed that free acid represented ca. 55% of the total dihydromatricariate. Subsequently HPLC analysis of the triglyceride–glyceride ether band extract showed that it contained mainly triglycerides with a single dihydromatricariate moiety (C, 64%) with smaller quantities of disubstituted (D, 8.5%) and trisubstituted (E, 27%) triglycerides. No glyceride ethers were detected. These data were consistent with those for individual males (Table 2) and confirmed the absence of waxes and glyceride ethers in males.

The following parts of beetles were then assayed separately for dihydromatricariate: (1) Elytra, from males or females contained very little dihydromatricariate material. (2) The area from around the defensive gland of several combined males and females contained mainly free acid but with small quantities of the other components. (3) Eggs, removed by dissection, contained triglycerides (mainly with two or three dihydromatricariate moieties) and ethers (37%). No waxes or free acid were detected. (4) Viscera from males contained mainly triglycerides with a smaller quantity of the free acid.

Since the wax was present only in the females and was absent from the eggs, it seemed likely that it would occur in abdominal accessory glands and be used for coating the eggs immediately prior to oviposition. This was confirmed upon dissection when large paired colleteral glands were discovered. These glands, which were replete with a white wax like substance, filled much of the sixth and seventh abdominal segments and opened, via individual ducts, into the vagina. GC analysis of their contents revealed only the components of the wax fraction A, of the total extracts.

The very high level of glyceride ethers in eggs suggested that, in the extracts studied, these components were largely derived from eggs and hence would be absent from males. Also it might be expected that nongravid females would be low in ethers. To confirm this supposition, an extract of a number of females of low gravidity was examined. This sample showed a high level of wax (60%) but only about 6% of glyceride ethers (16%) after allowance for waxes and free acid; most of the remainder was triglyceride. This value for ethers was lower than for the bulk sample (21%), despite the fact that the latter contained males as well as females. These data indicated that the glyceride ethers were associated with eggs or possibly the ovarian system as a whole. Thus the level of glyceride ethers in individual females reflects the state of ovarian development.

Several batches of larvae of *Chauliognathus* spp., after extraction with dichloromethane, showed the characteristic dihydromatricariate UV spectrum. TLC and HPLC of this solution showed that the major UV-absorbing material was fraction E (trisubstituted triglyceride); there was a small quantity of free acid present, but none of the other components was detected.

Preliminary investigation of a female of *Chauliognathus nobilitatus* (Erichson) by HPLC showed a very similar distribution of dihydromatricaria-containing compounds. However, in this species, there was very little, if any, free acid, and the wax fraction (A) showed greater diversity in chain length.

DISCUSSION

The detection, in *C. lugubris*, of glycerides and waxes based on the dihydromatricariate moiety contributes to our knowledge of the defensive chemistry of these beetles. The results also demonstrate a significant difference between the sexes, which was not apparent in the case of the defensive glands. In males the free acid accounts for much of the total dihydromatricariate content, but in the females it constitutes only a very small proportion of the total.

The dihydromatricariate-containing triglycerides are probably associated with the fat body and would provide a further dose of antifeedant material to increase the discomfort of any predator naive enough to consume one of these beetles; they may also act as a reserve of the acetylenic moiety from which depleted defensive glands are replenished. The greater abundance of dihydromatricariate-substituted material in females than in males presumably reflects the larger bulk of fat body and the presence of accessory glands and developing eggs in the former sex.

An interesting discovery reported in this paper concerns the wax-containing accessory glands present only in females. The waxes have the dihydromatricaria chromophore incorporated into both their alcoholic and acidic components; they are present in very substantial quantities (ca. 300 μg/female or about 0.5% of body weight). The location of the glands and the nature of their secretion suggest that they dispense an egg protectant. The waxes contained in these glands would be deposited on the eggs as they are laid providing, possibly, both a bacteriostatic and antifeedant protective coating. It is noteworthy that the chain length of the acidic component of the wax is increased to C_{12} and that the alcoholic moiety to mainly C_{14} but with a smaller proportion of C_{12} material. This increase in chain length presumably enhances the properties of the wax in its role as a protective surface lipid.

We have no knowledge of the specific role of the glyceride ethers in eggs but they are presumably part of the protective mechanism. As far as we are aware, this is the first report of glyceride ethers from insects, although they

have been reported previously from marine sources, especially shark liver oil, and from mammals and microorganisms (see Downing, 1976).

(Received October 30, 1986; accepted February 12, 1987)

Abstract—The response of *Microplitis croceipes* (Cresson) to odors from a plant–host complex was investigated using a four-choice olfactometer. Female, but not male, parasitoids responded in a dose-dependent fashion to volatiles from the plant–host complex and oviposition experience enhanced this response. Female age had no apparent effect on the response. Both artificially damaged leaves and frass elicited positive responses but of lower magnitude than those elicited by the plant–host complex. Volatiles collected from the plant–host complex placed on filter paper also elicited positive responses by female parasitoids.

Key Words—Hymenoptera, Braconidae, *Microplitis croceipes*, *Heliothis zea*, parasitoid, host selection, volatile attractant, olfactometer.

INTRODUCTION

Host location, as defined by Lewis et al. (1976), is often mediated by chemical cues (Vinson, 1976). These chemical cues are defined as long- and short-range, depending on whether they act over a distance that precludes gustation (i.e., are olfactory) or act only by gustation (Vinson, 1976; Weseloh, 1981). Only a few long-range chemical cues used by parasitoids during their host-location

[1] Mention of a commercial or proprietary product does not constitute an endorsement by the USDA.

0098-0331/88/0200-0425$06.00/0

process have been identified. A few examples are the plant odors allyl isothiocyanate by *Diaeretiella rapae* (Hymenoptera: Ichneumonidae) (Read et al., 1970), α-pinene by *Heydenia unica* (Hymenoptera: Pteromalidae) (Camors and Payne, 1972), and several sesquiterpenes by *Campoletis sonorensis* (Hymenoptera: Ichneumonidae) (Elzen et al., 1984).

Although 13-methylhentriacontane has been isolated from *Heliothis zea* (Boddie) (Lepidoptera: Noctuidae) and shown to elicit the short-range behaviors of antennation and ovipositor probing in the parasitoid *Microplitis croceipes* (Cresson) (Jones et al., 1971), no long-range chemical cues have been identified for female *M. croceipes*. There is evidence that *M. croceipes* does use olfactory cues during its host-location process; Drost et al. (1986) reported on the response of *M. croceipes* in a wind tunnel to olfactory cues. This paper reports olfactometric studies of the response of *M. croceipes* to olfactory cues and factors that might affect its host-location behavior.

METHODS AND MATERIALS

Insects. Microplitis croceipes, reared on *H. zea*, were obtained as pupae from the Insect Biology and Population Management Research Laboratory (Tifton, Georgia). The pupae were held for emergence in an environmental chamber maintained at 26°C, a relative humidity of ca. 70%, and a photocycle of 15:9 hr light–dark. Male and female parasitoids were caged together to allow mating and were provided with water and honey.

Heliothis zea eggs were obtain from the Insect Attractants, Behavior, and Basic Biology Research Laboratory (Gainesville, Florida). After hatching, larvae were fed pink-eye, purple-hull cowpea [*Vigna unguiculata* (L.)] seedlings.

Olfactometer. The response of *M. croceipes* to volatile chemicals was examined in a four-choice olfactometer (Pettersson, 1970) with dimensions as described by Vet et al. (1981) (Figure 1). Differences are as follows: internal chamber height was 16 mm; inlet port inside diameter was 9.5 mm; and insect trap, odor chamber, and humidifying vials were of a slightly different design (Figure 1). In addition, illumination was provided by a 20-W circular fluorescent lamp 20 cm above the olfactometer. The complete olfactometer system was housed in a room maintained at 27–28°C.

A vacuum pump, placed outside the room, drew air through the olfactometer at a rate of 1200 ml/min (300 ml/min through each of the four quadrants). Odor fields were visualized using ventilation smoke tubes (Mine Safety Appliances Co., Pittsburgh, Pennsylvania). The pressure inside the olfactometer was never more than 4 cm of water (ca. 2.9 mm Hg) below atmospheric pressure when measured with an open-end, water-filled manometer connected to the olfactometer at the center extractor tube.

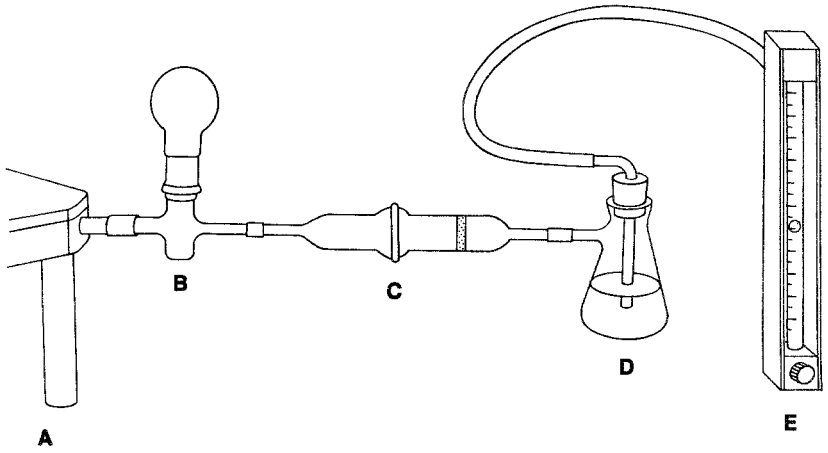

FIG. 1. Schematic diagram of air inlet system for each arm of four-choice olfactometer: (A) olfactometer; (B) parasitoid trap vial; (C) odor chamber; (D) humidifying vial; and (E) flowmeter.

General Experimental Procedure. All experiments were conducted 3–6 hr after parasitoids had experienced "lights-on." Parasitoids were tested singly by introducing them through the disconnected extractor tube. The relative time spent in each quadrant and the time of final choice were recorded with an Epson HX-20 portable computer with optional expansion unit. A final choice was defined as the entrance of a parasitoid into an insect trap vial. Time of final choice was defined as time between introduction into the olfactometer and entrance into an insect trap vial. Parasitoids were given a maximum of 10 min to make a final choice. The percent time per quadrant was calculated based on total time spent in each of the four quadrants before a final choice was made. Each insect was tested only once and, after ca. 10–20 insects were tested, the olfactometer, trap vials, and odor chamber vials were dismantled, rinsed with absolute ethanol, and washed in hot detergent.

System Bias. The response of inexperienced female *M. croceipes M. croceipes* in the olfactometer when no odor source was present was examined to determine if females exhibited preferences toward any quadrant(s). Twenty-eight 3-day-old female *M. croceipes* were tested to humidified air only (controls) in all four quadrants.

Effect of Oviposition Experience and Odor Concentration. Three-day-old females were used to study the effects of oviposition experience and odor concentration on female response. Inexperienced females had no oviposition experience or any previous exposure to larvae, frass, or foliage. Experienced females had searched larval-damaged foliage with frass present and had oviposited once

in an *H. zea* larva just prior to being tested. The odor source consisted of a third-instar *H. zea* larva feeding on a 4-day-old (ca. 6-cm-tall) cowpea seedling with the accompanying foliage damage and frass. This odor source was placed in the odor chamber (Figure 1C) and was termed one plant–host complex equivalent (PHCE). Four concentrations of PHCE odor were tested (1.00, 0.75, 0.50, and 0.25 PHCE). PHCEs of less than one were produced by splitting the odor flow and adding back humidified air to regain the original 300 ml/min flow rate. The odor was introduced into only one quadrant, the other three quadrants contained humidified air only (controls). Each replicate consisted of an inexperienced and an experienced female (random order) being tested to each of the four odor concentrations (in order of increasing concentration) in each of the four quadrants (in random order) (32 females per replication). Seven such replications were made.

Male Response. The response of male *M. croceipes* to one PHCE was examined using 3-day-old males with no previous exposure to larvae, frass, or foliage. Seven males were tested to the odor source at each of the four quadrants (in random order) for a total of 28 males.

Effect of Female Age. The effects of age on female response were studied using 0.75 PHCE as the odor source. Four age classes were used: 1, 3–4, 6–7, and 10–12 days after adult emergence. Each replicate consisted of an inexperienced female in each of the four age classes (in random order) being tested at each of the four quadrants (in random order) (16 females per replication). Seven such replications were made. Inexperienced females were used in this and the following experiments because we were interested in the innate response of females.

Source of Attraction. To determine the origin of attractive volatile chemicals, three possible sources were compared to the PHC for activity. These were damaged leaves, *H. zea* larvae, and frass. Damaged leaf odor was produced by using a wire to make four 2-cm-long scratches on a 4-day-old cowpea seedling just prior to testing. Larval odor was from a third-instar *H. zea* larva which had fed on cowpeas for two days preceding testing. The larva was placed in the odor source chamber without foliage or frass. Frass odor was obtained from ca. 10 fresh (less than 1-hr-old) pellets of frass from third-instar *H. zea* larvae feeding on cowpea seedlings. Each replicate consisted of an inexperienced female being tested to each of the four treatments (in random order) in each of the four quadrants (16 females per replicate). Seven such replicates were made.

Collection and Assay of Attractive Volatiles. Volatiles were collected from the plant–host complex to determine if such attractants could retain their bioactivity. Volatiles were collected from third-instar *H. zea* larvae actively feeding on cowpea seedlings. This odor source was contained in a glass chamber (5.0 cm ID × 20.0 cm long), consisting of two halves connected by a 50/50 ground-glass joint. The male half held a coarse-glass frit to provide laminar flow through

the chamber. Both halves had a 24/40 ground-glass joint, opposite the 50/50 joint, to connect the chamber to the rest of the volatile collection system. Humidified and prefiltered (activated charcoal) air was blown at a rate of 300 ml/min over 3–5 PHCE for 2–4 hr. Plant–host-complex volatiles were collected on activated charcoal (ca. 1.5 mm thick and 4 mm diam.) and subsequently extracted with three 20-μl volumes of methylene chloride and two 20-μl volumes of pentane. The methylene chloride–pentane extract was then tested at the following concentrations: 0.1, 0.5, 1.0, 5.0, and 10.0 plant–host complex hour equivalents (PHCHE). Fifty microliters of each extract was placed on filter paper (4.25 cm diam.), which was then placed in the odor chamber after the solvent had dried. One replicate consisted of an inexperienced female being tested to each of the five concentrations, in order of increasing concentration, in each of the four quadrants (random order), 20 females per replication. Eight such replicates were made.

Statistical Analyses. Friedman rank sums (FRS) (Conover, 1980), based on percent times per quadrant, were used to test for quadrant preferences when all four odor fields contained humid air only (controls).

In all other experiments, each treatment was tested against three controls, and preference for the treatment odor field over control odor fields was tested using FRS. To compare percent times per odor field between treatments, Duncan's new multiple-range test (DNMRT) (Steel and Torrie, 1960) was used after analysis of variance (ANOVA) of percents transformed by angular transformation. Percent making final choices were compared with DNMRT after ANOVA of percent making final choices after angular transformation. For all dose–response data, the concentration sum of squares were divided into polynomial components and the reported equations represent the polynomials in X using significant components. Times of final choice were compared by DNMRT after ANOVA. Significance levels were 0.05 in all tests.

RESULTS

General Behavioral Observations. After being released into the olfactometer, the parasitoids were observed to walk on the bottom, top, and sides of the olfactometer, occasionally stopping to groom their antennae, legs, wings, or abdomens. Parasitoids also made occasional flight attempts, defecated, and stood motionless.

When female parasitoids crossed from a control field into a sample field, they frequently began more intensive antennation and also walked more slowly, although these behaviors were not quantified. Females also were observed to follow the border between sample and control fields and to make klinotactic turns after leaving a sample field.

Bias. Female parasitoids spent an averge of 29, 28, 16, and 27% of their time in quadrants 1, 2, 3, and 4, respectively. There was no significant preference for any quadrant ($P > 0.25$), and no female made a final choice to humid air only.

Experience and Concentration. The effects of oviposition experience and odor concentration on female response are shown in Table 1. Both inexperienced and experienced females spent significantly more time in the test odor field than control odor fields at all odor concentrations. Experienced females spent a greater percent of their time in the odor field than inexperienced females at all concentrations tested ($P << 0.005$). Although mean percent time spent in the odor field increased with odor concentration for both types of females, the ANOVA indicated a significant linear effect of PHC odor concentration (x) on percent time in the test odor field (y) only for experienced females ($y = 30.4x + 57.0$; $N = 112$; $r = 0.37$; $P < 0.01$).

There were significant effects of both experience and concentration on percent making final choice. Experienced females were more likely to make final choices than inexperienced females and there were significant linear effects of odor concentration (x) on percent making final choice (y) for both inexperienced females ($y = 68.6x + 26.8$; $N = 28$; $r = 0.69$; $P < 0.01$) and for experienced females ($y = 50.0x + 55.4$; $N = 28$; $r = 0.62$; $P < 0.01$).

TABLE 1. RESPONSE OF INEXPERIENCED AND EXPERIENCED FEMALE *M. croceipes* TO FOUR CONCENTRATIONS OF PLANT–HOST COMPLEX ODOR[a]

Type of female / Odor conc. (PHCE)	Mean % time in odor field[b]	Mean % making final choices	Mean time of final choice (sec)
Inexperienced			
0.25	54.8	46.4	233.8
0.50	60.2	57.1	195.2
0.75	64.8	78.6	146.5
1.00	67.4	96.4	155.9
Experienced			
0.25	64.8	64.3	258.0
0.50	75.4	82.1	211.2
0.75	81.7	100.0	117.0
1.00	84.8	100.0	133.6

[a] Twenty-eight females were tested at each experience–concentration combination.
[b] Both types of females spent significantly ($P < 0.005$) more time in the treatment odor fields than control odor fields at all concentrations tested using Friedman rank sums.

The ANOVA of times of final choice revealed a significant effect only for odor concentration, and no significant effect of experience on time of final choice ($P > 0.25$). ANOVA revealed a significant decrease in time of final choice (y) with increased odor concentration (x) for both inexperienced females ($y = -93.1x + 238.0$; $N = 78$, $r = 0.25$; $P < 0.05$) and experienced females ($y = -181.3x + 291.8$; $N = 97$; $r = 0.36$; $P < 0.01$).

Males. Male parasitoids did not spend significantly more time in the plant–host complex odor field than control odor fields ($P > 0.25$), nor did they make any final choices to this odor source.

Age. All age classes tested spent significantly more time ($P < 0.005$) in the treatment odor fields than in control odor fields; however, there were no differences in percent time in odor field between any age classes ($P > 0.1$). The number of females ($N = 28$) making final choices were 20, 20, 18, and 17 for the 1, 3- to 4-, 6- to 7-, and 10- to 12-day-old parasitoids, respectively, and were not significantly different ($P > 0.25$). There also was no significant effect of age on time of final choice ($P > 0.25$).

Individual Components. The responses of inexperienced female parasitoids to individual components of the plant–host complex are shown in Table 2. Female parasitoids spent significantly more time in the odor fields that contained damaged-leaf odor and frass odor than in control odor fields. However, females spent significantly more time in odor fields containing plant–host complex odor than in odor fields that contained damaged-leaf or frass odor. Female parasitoids did not spend more time in the odor field containing *H. zea* larval

TABLE 2. RESPONSE OF INEXPERIENCED FEMALE *M. croceipes* TO INDIVIDUAL COMPONENTS OF PLANT–HOST COMPLEX[a]

Odor source	Mean % time odor field[b]	Mean % making final choice[c]	Mean time of final choice (sec)[d]
Plant–host complex	68.7**,c	82.1a	143.5
Artificially damaged leaves	50.7**,b	32.1b	160.4
Frass	46.9**,b	32.1b	161.5
H. zea larvae	34.5NS,a	3.6c	287.5

[a] Twenty-eight females were tested to each odor source.

[b] **Denotes females spent significantly ($P < 0.005$) more time in treatment odor fields than in control odor fields, NS denotes no significant difference ($P = 0.05$) from control (P calculated using Friedman rank sums). Percents with letters in common do not differ significantly ($P = 0.05$) using Duncan's new multiple-range test (DNMRT).

[c] Column means with letters in common do not differ significantly ($P = 0.05$) using DNMRT.

[d] There were no significant differences among the components in time of final choice (F test P value > 0.25).

odor than in control odor fields. Female parasitoids also made significantly more final choices to damaged leaves and frass than to *H. zea* larva, but fewer than to the plant–host complex. The ANOVA on the times of final choice did not reveal any significant effect of odor source ($P > 0.25$).

Collected Volatiles. The responses of inexperienced females to the collected plant–host complex volatiles are shown in Table 3. Female parasitoids neither spent significantly more time in the odor fields that contained the two lowest concentrations (0.1 and 0.5 PHCHE) than in control odor fields, nor did they make any final choices to these concentrations. Female parasitoids did, however, spend more time in the odor fields that contained 1.0, 5.0, and 10.0 PHCHE than in control odor fields. ANOVA revealed significant linear and quadratic components of collected volatile concentration (x) on percent time in the odor field (y) ($y = 21.7 + 16.6x - 1.2x^2$; $N = 160$; $r = 0.51$; $P < 0.01$). ANOVA also revealed significant linear and quadratic components of collected volatile concentration (x) on percent making final choice (y) ($y = -3.2 + 14.5x - 0.9x^2$; $N = 80$; $r = 0.73$; $P < 0.01$). The ANOVA on the times of final choice did not reveal any significant effect of concentration ($P > 0.1$).

DISCUSSION

The results demonstrate that female, but not male, *M. croceipes* respond in a dose-dependent fashion to volatiles from the *H. zea* larva–cowpea plant–host complex. Although females without any experience responded (i.e.,

TABLE 3. RESPONSE OF INEXPERIENCED FEMALE *M. croceipes* TO FIVE CONCENTRATIONS OF COLLECTED PLANT–HOST COMPLEX VOLATILES PLACED ON FILTER PAPER[a]

[b] * and ** denote significantly ($P < 0.05$ and $P < 0.005$, respectively) more time spent in treatment odor fields than control odor fields, NS denotes no significant ($P = 0.05$) difference from controls (P calculated using Friedman rank sums).

[c] There were no significant differences between any concentrations in time of final choice (F test P value > 0.1).

innately), there was a clear effect of oviposition experience on female response. It is not clear whether this is a case of associative learning (olfactory cues with oviposition) or a case of a change in state of motivation, although learning appears to be an important part of host selection by parasitoids (Arthur, 1981). The effect of the "oviposition experience" may not be the oviposition per se but rather the exposure to damaged leaves, frass, and/or salivary secretions, etc. In fact, Drost et al. (1986) demonstrated that the wind-tunnel response of female *M. croceipes* exposed only to frass was no different than that of females exposed to the plant–host complex including oviposition. This type of experience might be used to increase the efficiency of parasitoids released into the field (Gross et al., 1975).

Age of inexperienced female parasitoids had no apparent effect on their response in the olfactometer. Drost et al. (1986) reported similar results for experienced females in wind-tunnel studies.

The results of the individual component experiments suggest that no single component elicits a response equal to the PHC, but that some combination, acting either additively or synergistically, is required. Preliminary findings suggest that the sum of all components may not give the complete activity either and that some interaction such as larval feeding or salivary secretions on the leaf tissues might be required. These effects will be investigated in future studies.

Although female parasitoids spent approximately an equal amount of time in the odor field that contained either the plant–host complex odor or the collected volatiles, fewer final choices were made to the collected volatiles than to the plant–host complex. This is probably due to the extreme volatility of the collected volatiles, which were never active for more than 10 min, and possibly to differences in the ratios of chemicals released by the plant–host complex and the collected volatiles.

In conclusion, our data clearly indicate that *M. croceipes* females respond to olfactory cues from the plant–host complex. The fact that females are attracted to leaves artificially damaged and to frass suggests that *M. croceipes* may use volatile chemicals from these sources as synomones and kairomones (as defined by Nordlund and Lewis, 1976), respectively, during its host-location process. In addition, we feel that this olfactometer can be used to identify volatile attractants for *M. croceipes* and that these chemicals might be used to improve the effectiveness of *M. croceipes* in the field.

IRIDOID GLYCOSIDE SEQUESTRATION BY TWO APOSEMATIC *Penstemon*-FEEDING GEOMETRID LARVAE[1]

FRANK R. STERMITZ,[2] DALE R. GARDNER,[2] and NOEL McFARLAND[3]

(Received November 21, 1986; accepted February 12, 1987)

Abstract—The iridoid glycoside catalpol was found to be sequestered by larvae of *Meris alticola* feeding on *Penstemon virgatus* and by larvae of *Neoterpes graefiaria* which utilize *P. barbatus*. The strikingly similar larval patterns of these two ennomine geometrids were previously considered to be disruptive, but predator-based Müllerian mimicry is equally likely to be involved. The cryptic adult moths generally contain only small amounts of catalpol, having left most of the bitter iridoid in the pupal case and in the meconium excreted after eclosion. One *Neoterpes* female did contain considerable catalpol in the abdomen, presumably in the eggs.

Key Words—*Meris alticola*, *Neoterpes graefiaria*, Lepidoptera, Geometridae, *Penstemon virgatus*, *Penstemon barbatus*, Scrophulariaceae, iridoid glycosides, catalpol, Müllerian mimicry, sequestration.

INTRODUCTION

The remarkable similarity between last-instar larval color patterns of *Meris alticola* and *Neoterpes graefiaria* in Arizona has been described and pictured (Poole, 1970). Genesis of the black-and-white striped and yellow–orange spot-

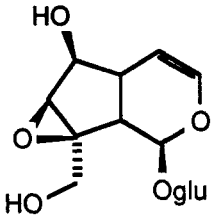
0098-0331/88/0200-0435$06.00/0

ted patterns was discussed, assessed as being disruptive, and attributed to adaptation based on an unusual grazing behavior. Müllerian mimicry based on distastefulness was not ruled out, but was considered unlikely since the *Penstemon* host plants were not known to contain poisonous secondary metabolites. It has recently been established, however (Bowers and Puttick, 1986; Stermitz, et al., 1986), that aposematic *Euphydryas* (checkerspot butterfly) species sequester bitter iridoid glycosides, such as catalpol, from larval host plants.



catalpol

It was suggested (Stermitz et al., 1986) that all aposematic insects monophagous on iridoid-containing plants would sequester these bitter substances. Since *Penstemon* species are now well-known to contain iridoid glycosides, an investigation of *Meris–Neoterpes–Penstemon* chemistry was undertaken.

METHODS AND MATERIALS

Collections and Treatment of Organisms. Six late instar larvae of *Meris alticola* Hulst and rosette stage *Penstemon virgatus* A. Gray were collected May 31, 1986, on the Fort Valley Experimental Station grounds, 7.5 miles northwest of Flagstaff, Arizona. This was the same location previously described (Poole, 1970). One larva was found on the host plant and the others were found basking longitudinally on grass stalks. No other larvae were encountered in several hours of searching. Larvae were fed in the laboratory on *P. virgatus* until cocoon spinning began. After completion of pupation, the silk cocoons were removed from the pupae and the pupae transferred to vials containing filter paper on the bottom and sides. Eclosion occurred approximately two weeks later. Adult moths were removed from the vials two days after eclosion and dried prior to analysis. The filter papers were extracted with methanol and the solution evaporated to dryness to obtain the meconium extract.

One last-instar larva of *Meris alticola* was found consuming *Besseya plantaginea* (James) Rydb. in Greta Valley west of Guffey, Colorado, on June 11,

1985, and was transferred to the laboratory on a leaf where cocoon formation and pupation took place. Several days after eclosion, the pupal case and cocoon silk were separated and the adult was pinned. Identification of the adult was by D. Ferguson, Smithsonian Institution, and it was then returned for analysis.

Several rosettes of fresh Arizona *P. virgatus* were held in the refrigerator for larval feeding in Colorado and were analyzed when all larvae had pupated. Collections of *P. virgatus* were also made in Park County, Colorado near Jefferson where it is host to the checkerspot butterfly *Poladryas arachne*.

One female adult *Neoterpes graefiaria* (Hulst) was taken at a UV light on August 4, 1986, 0.5 mi. west of Highway 92, on Lot 4, Ash Canyon Road, in the Southeast Huachuca Mountains, Cochise County, Arizona (elevation 5100 ft). It oviposited in a small jar, and the larvae (McFarland rearing No. R8612), which hatched out 11 days later, were reared on leaves of *P. barbatus* (Cav.) Roth. Feeding continued on refrigerator-held leaves in Colorado until September 8, when several larvae began to form cocoons. Frass and small bits of leaves or dirt were incorporated into the cocoons. Pinching of the last-instar larvae with tweezers elicited reflex bleeding from the intersegmental membrane area. The clear liquid was collected with a micropipet and washed from the pipet with methanol into vials where the methanol was evaporated. Two last-instar larvae were crushed into methanol and the methanol filtrate used for analysis. Two adults eclosed 21 days after pupation. These were immediately removed to vials containing filter paper on the bottom. Meconium material was obtained as above, and the adults were killed and allowed to dry at room temperature before analysis. The webbing material was highly contaminated with frass and host-plant parts and was not analyzed. The webbing was removed from the pupal case before analysis. Leaves of *P. barbatus* that remained after larval feeding were used for iridoid analysis.

Iridoid Glycoside Analyses. Qualitative iridoid analyses were by thin-layer chromatography (TLC) and quantitative analyses were by gas chromatography (GC) of the trimethylsilyl derivatives, as previously described in detail (Stermitz et al., 1986). A detailed investigation of the host plants for the present study was not necessary. In the case of *P. barbatus*, recent reports (Chaudhuri et al., 1981; Junior, 1982) characterized the iridoid content. Comparative TLC, GC, and [^{1}H]NMR spectroscopy on the crude iridoid fraction from our collection showed catalpol and globularin (10-cinnamoylcatalpol) to be the major components as expected from the literature data. No literature data was available on *P. virgatus*, but an analysis (L'Empereur and Stermitz, unpublished results) of Colorado collections, which are host to *Poladryas arachne*, showed that catalpol and globularin are also the major iridoids of this *Penstemon*. The same iridoids were shown by comparative TLC and GC to also be the major iridoids of Arizona *P. virgatus*.

RESULTS

The numbers of larvae available, as well as losses and other difficulties in rearing, did not allow us to get the most complete set of analytical data desirable for all insect stages, but the analyses we did obtain clearly show sequestration of relatively large amounts of catalpol by the larvae. Specific data for four *M. alticola* are given in Table 1 and for four *N. graefiaria* in Table 2.

In the case of the *Meris*, we did not directly analyze larvae, but assumed that the total catalpol content of pupal case, cocoon silk, meconium, and mature adult combined would reflect the catalpol present in the original larva, presuming no pupal metabolism of the iridoid. One reason for this approach was that our first (rather incomplete) analysis was on the insect raised on *Besseya plantaginea* (fourth entry of Table 1). This had shown a remarkable catalpol content (19% of the dry weight) in the cocoon silk. An alternative explanation was that the adult had released meconium on the silk after eclosion. The Arizona *Meris* larvae were all raised through to adulthood, so that meconium and cocoon silk could be checked separately. The data for males 1 and 2 suggests that this interpretation may be correct, since high meconium and low silk catalpol content was found. This is somewhat clouded by the fact that all the Arizona *Meris* produced relatively poor cocoons as compared to the cocoon of the Colorado specimen. The low dry weights for the Arizona silk are shown in Table 1. The reason for this is not known, but these and similar geometrids sometimes do form poor cocoons if the proper substrate or arrangement of substrate is not available for the construction of these rather elaborate structures.

The *Meris* larvae and adults are close in size to those of *Euphydryas anicia*, which we have studied more extensively (Stermitz et al., 1986; Gardner and Stermitz, in preparation). The total iridoid load is comparable as well, with

TABLE 1. *Meris alticola* ANALYSES

Male 4	unknown[b] (1.7)				(21 μg/μl[d])

[a] Dry weight.
[b] Larval weight was not recorded. Visually, the larvae are similar in size or slightly smaller than *Meris alticola* larvae (see Table 1).
[c] Four microliters analyzed from one emission.
[d] Eight microliters analyzed from one emission.

entries 1–4 of Table 1 showing 1.0%, 3.8%, 3.1%, and 3.8% total catalpol calculated as percent dry weight of the adult butterfly. In the *Meris* case, the catalpol has generally been eliminated after the larval stage, while *Euphydryas* keep appreciable amounts of catalpol in the adult. In the case of the one female *Meris* available, little catalpol was found in the meconium, cocoon silk, and pupal case. The adult abdomen was therefore separated from the remainder of the insect prior to analysis. The abdomen section, presumably with eggs, was indeed high in catalpol content.

A direct analysis was done on two *Neoterpes* larvae (Table 2). These were kept without food for about 48 h so that much of the gut could be emptied. The resulting catalpol content, about 2 mg per larva, was comparable to that found in the *Meris*. The pupal case and meconium yielded large quantities of catalpol (Table 2), with relatively little in one adult and somewhat more in the second.

Hemolymph obtained from reflex bleeding of the disturbed *Neoterpes* larvae was analyzed for catalpol content. A single emitted drop (4 μl) was obtained from one larva, while the second emitted more material (8 μl). The total catalpol content of these emissions were 0.11 and 0.17 mg, respectively, from which the entries of Table 2 were calculated. The genesis of the material is not known, although it appears to arise from the intersegmental membrane area.

DISCUSSION

The finding of high catalpol content in immature stages, pupal cases, cocoon silk, and meconium of *Meris* and *Neoterpes*, as well as in the liquid emitted by *Neoterpes* reflex bleeding, suggests that Müllerian mimicry could be

a basis for the strikingly similar larval patterns. Since it has been shown (Bowers, 1981) that *Euphydryas phaeton* butterflies are unpalatable to bluejays if their larvae feed on catalpol-containing plants (including *Penstemon antirrhinoides*), bird predation might be responsible for development of this mimicry. Other predators that depend on visual cues could also be involved. Bitter iridoid glycoside sequestration has been suggested to account for other Lepidopteran mimicry as well. Thus, it was suggested (Bowers, 1981) that adults of western U.S. *Euphydryas* butterflies may be members of a Müllerian mimicry ring. Batesian mimicry could account for the adult resemblances between palatable *Chlosyne harrisii* and unpalatable *E. phaeton* and, particularly, for their "virtually indistinguishable" larvae as suggested by Bowers (1983).

We have not observed any direct predator pressures on *Meris* and *Neoterpes*. It was suggested (Poole, 1970) that the *Meris–Neoterpes* resemblance was not likely to be a predation-based mimicry because of the relatively low population densities of these organisms, since a critical density (Holling, 1965) was probably not present. It has, however, been pointed out (Endler, 1986) that, in the absence of direct observation of predator pressures, one can use mimicry as a basis for suggesting that such pressures had indeed occurred. In fact, it has been stated (Endler, 1986) that "mimicry can be one of the strongest lines of evidence for natural selection in the wild." The development of the *Meris–Neoterpes* resemblance may have been based on predation pressures when populations of the organisms were much higher. Final proof that we are observing mimicry must await experimental demonstration of *Meris* and *Neoterpes* larval distastefulness as well as predator avoidance of one organism after encountering the other.

Finally, the present work also extends the variety of defensive strategies employed by insects utilizing iridoid glycoside-containing plants (Bowers and Puttick, 1986). We can add deposition of these bitter substances in cocoon silk and in an emission from reflex bleeding when larvae are disturbed. It seems likely that we are only beginning to appreciate the breadth and depth of iridoid glycoside utilization by insects.

Acknowledgments—We thank D.C. Ferguson, Smithsonian Institution, for identification of *Meris alticola*.

(Received May 22, 1986; accepted February 13, 1987)

Abstract—Experiments were conducted to evaluate the effectiveness of some weed extracts against field dodder *Cuscuta campestris* Yunck. on alfalfa (*Medicago stiva* L.) and to identify and quantify the phytotoxic agents of these extracts. All concentrations of aqueous extract of every weed showed significant effectiveness on dodder when compared to the untreated plant under lath house and field conditions. Control percentages of the (0.5 g) of Bermuda grass (*Cynodon dactylon*) and wall goosefoot (*Chenopodium murale*) ranged between 83 and 96, and the same concentration caused injury to alfalfa foliage up to 43% when applied in the field. Phytotoxic agents were identified as phenolic compounds such as chlorogenic, isochlorogenic, *p*-coumaric acids, and scopoletin. Their quantities varied with species; Bermuda grass had the highest content (32.2 μg/g dry weight) followed by Johnson grass (*Sorghum halepense*), well goosefoot, and tumble pigweed (*Amaranthus albus*). These results might aid in screening for effective alternate approaches for controlling dodder on alfalfa planted for seeds.

Key Words—Extracts, phytotoxicity, *Medicago sativa*, dodder, *Cuscuta campestris, Amaranthus albus, Chenopodium murale, Cynodon dactylon, Sorghum halepense.*

INTRODUCTION

Dodder, *Cuscuta campestris*, is considered one of the most important parasitic weeds that infest a broad spectrum of plants in the world. It is especially detrimental to alfalfa (*Medicago sativa* L.) (Dawson, 1970, 1978). Lee and Timmons (1956) reported that field dodder causes great losses to alfalfa planted for

0098-0331/88/0200-0443$06.00/0

seed production through direct seed reduction, increased harvest and seed-cleaning costs, and lower quality and sale value of seeds.

Many approaches have been studied, such as mechanical, cultural, or chemical, to control dodder on alfalfa (Ashton, 1976). Of these, herbicides are the most promising but their use depends on whether alfalfa is cultivated to produce seeds or animal feed. One of the recent alternatives to herbicides is allelopathy as an aid for weed control. Several researchers have begun to evaluate crop plants and weeds for their allelopathic potential for weed control or as sources of naturally occurring herbicides (Massantini et al., 1977; Putnam and Duke, 1974; Al-Saadawi, 1985). Fay and Duke (1977) found that some of the *Avena* spp. accessions contained scopoletin (6-methoxy-7-hydroxycoumarin) an allelopathic agent that reduced annual weed growth and caused chlorosis, stunting, and twisting when planted in close association. Leather (1983) reported that the aqueous extracts of sunflower (*Helianthus annuus*) cultivars inhibited germination and suppressed 75% of wild mustard (*Brassica Kaber*) growth. Rhizobitoxin, another allelopathic agent, produced by *Rhizobium japonicum*, was found to have the same phytotoxic effects as the herbicide amitrol (IH-1-2,4-triazol-3-amine) on some weed species (Owens, 1973).

Relatively few studies have dealt with the effect of weed plant extract on growth of other weeds. Our tests, therefore, were developed to evaluate the phytotoxic potential of some weed extracts on field dodder (C. campestris) infesting alfalfa. Another goal was to isolate and/or identify the phytotoxic compounds present in those weed extracts.

METHODS AND MATERIALS

Plant Materials and Extraction. Four weeds were collected during July and August of 1984 from the Agricultural and Water Resources Center Research Station in Fudhailyia, 25 km northeast of Baghdad. The weeds were tumble pigweed (*Amaranthus albus* L.), wall goosefoot (Chenopodium murale L.), Bermuda grass (Cynodon dactylon L. Pers.) and Johnson grass (*Sorghum halepense* L.). Procedures used for extraction were basically those of Wang and Francis (1978). All parts of each weed were cut into 2 to 3-cm pieces and left to dry at room temperature for three days, then macerated in a blender with 80% methyl alcohol in a ratio of 1:2.5 w/v. The mixture was allowed to stand overnight under refrigeration. After filtration, extracts were evaporated to dryness under pressure. The residues were dissolved in water to the desired concentrations: 0, 0.05 0.25, and 0.5 g dry weight material per milliliter of water.

Lath-House Experiment. Alfalfa seeds var. Local were planted in clay loam soil in 10-cm-diam. plastic pots in August 1984 under lath-house conditions. Dodder seeds were treated with concentrated sulfuric acid for 20 min to enhance

germination, and 50 seeds were planted in each pot with alfalfa. Alfalfa was thinned to one plant per pot when the plants reached 5 cm in height. The experiment was set in a split-plot design with three replications. The main plots represented weed extracts, while the subplots represented extract concentrations. Thirty days after planting, dodder stems and tendrils started to cover the alfalfa plants. At this stage, extracts were sprayed on the dodder and alfalfa using a 1-liter pot-sprayer and at 20°C and 70% relative humidity. A single application of each concentration of each extract was applied to cover both alfalfa and dodder foliage. Two weeks later, treatments were evaluated. Dodder control was visually estimated on a scale of 0 (for no effect) to 10 (for 100% effectiveness). The same scale was used to evaluate treatment injury to alfalfa foliage. After two additional weeks, dodder and alfalfa dry weights were taken for each treatment. All statistical analyses and tests were conducted according to the methods designated by Steele and Torrie (1980).

Field Experiment. A uniform alfalfa field was chosen to conduct the field experiment at the Agricultural and Water Resources Center Station, Fudhailyia. The experimental setting was a split-plot design with three replications. Plots of 50 × 50 cm were prepared in which the alfalfa stand was cut to 5 cm height in the spring of 1985. Small plots were chosen to achieve uniformity in the alfalfa stand and to minimize the amount of extract needed for experimentation. Field dodder infestation was initiated by placing infected alfalfa seedlings in each plot to allow contact with healing foliage. The dodder branched, then almost covered, all the alfalfa, and at this stage treatments were applied. Evaluation of the treatments was made according to the same scale used in the lathhouse experiment. The dry weights of both alfalfa and dodder were taken at random and for each plot.

Identification of Phytotoxins. Since many phytotoxic substances in plants are phenolic in nature (Chou and Young, 1975), an attempt was made to isolate toxic phenolic compounds from various parts of the weeds. Each aqueous weed extract was concentrated by vacuum to 10 ml and further extracted with petroleum ether three times to remove chlorophyll and fatty compounds. The extract was then chromatographed on Whatman No. 1 paper in one dimension with BAW (*n*-butanol–acetic acid–water) 63:10:27. The chromatograms were examined with short (2537 Å) and long (3360 Å) UV light. The distinctive bands were cut from the chromatograms and eluted with 50% aqueous methanol. Eluates of bands were reduced to dryness, taken up in 5 ml absolute methanol, and chromatographed on Whatman No. 1 paper in two different solvent systems: 6% AA (6% aqueous acetic acid) and BAW (63:10:27), respectively. The spots were detected under long- and shortwave UV light with and without ammonium gas (NH_3) and the chromatograms sprayed with diazotized *p*-nitroaniline (Bray et al., 1950) and diazotized sulfanilic acid reagents (Smith, 1960). Phytotoxic phenolics appeared as absorbing or fluorescing spots under

UV light with distinguishable colors after being sprayed with reagents. Quantitative estimation of total phenolic compounds was done by using Folin deines pigment according to Pearson (1970).

RESULTS

Lath-House Experiment. Treatments of tumble pigweed, wall goosefoot, and Bermuda grass extracts killed almost all the exposed stems and tendrils of field dodder one week after application. Control of dodder, measured as a percentage of the control treatment, dodder, and alfalfa foliage dry weights, and foliage injuries were summarized in Table 1.

Results showed highly significant differences between treated and untreated dodder. Control of dodder was increased with higher extract concentrations except for that of wall goosefoot at 0.25 g/ml water, which was less effective than the 0.05 concentration. For all weed extracts, no significant differences

were found between their mode of control at 0.25- and 0.5-g concentration levels, as these gave an average control of 80–90%. The highest control was obtained with the 0.5- and 0.25- concentrations of Bermuda grass.

Treated dodder dry weights were significantly lower than untreated. Although no significant differences were found between the concentrations of the same weed extract, higher reduction in dodder weights with higher concentrations was noticeable. An exception was that of 0.25 g/ml water of wall goosefoot, as mentioned before. This was consistent with the percentages of dodder control obtained. An average of 80–90% reduction in dodder foliage dry weight was obtained from extract treatments when compared to the untreated control. This indicates the high phytotoxic characteristics of these extracts.

Alfalfa foliage injury was rated on the whole appearance of plants compared to those not treated. The highest percent of injury (13.3%) was caused by the application of 0.5 g/ml of goosefoot although statistically the precent injury was not different from that of lower concentrations. Most injured plant foliage did recover.

All treatments caused an increase in alfalfa dry weights except with 0.05 g of Bermuda grass, which reduced it to 0.17 g/plant compared to 0.267 g/plant for those not treated. However, all other treatments raised alfalfa weights in inverse proportion to their inhibitory effectiveness on dodder. In all treatments and for all concentrations, wall goosefoot extracts stimulated alfalfa growth the most, resulting in 0.53 g/plant compared to 0.43 g/plant for Johnson grass and tumble pigweed and to 0.46 g/plant for Bermuda grass.

Field Experiment. Dodder control (percentage) and its dry weight and alfalfa foliage injury and its dry weight results were recorded (Table 2). Comparing weed extracts, and for all concentrations used, wall goosefoot gave the highest percentage of dodder control (73%) followed by Bermuda grass and tumble pigweed (64 and 55%, respectively). Highly significant differences were found between treated and untreated plots. The differences between weed extract concentrations were also significant, and that was obvious for wall goosefoot: 0.05, 0.25, and 0.5 g/ml water which resulted in 50, 73.3, and 96.6% dodder control, respectively.

Reduction in dodder dry weights was inversely proportional to concentration and higher percentages of control. Significant differences were also found between dodder dry weights of the treated and untreated plots. Higher concentrations of all plant extracts (0.25 and 0.5 g) caused a higher percentage of injury to alfalfa. However, no significant differences were found between Johnson grass and tumble pigweed concentrations in alfalfa foliage injury. Bermuda grass and wall goosefoot extracts at 0.5 g caused the highest percentage injury to alfalfa foliage (43.3%). In general, higher extract concentrations caused noticeable injuries to alfalfa foliage in the field as compared to pot-planted

alfalfa. However, this injury did not affect foliage dry weights. Even though higher extract concentrations resulted in higher injury to foliage, weights increased with higher concentrations and consequently higher dodder control.

Identification of Phytotoxins. Phytotoxins identified were phenolic compounds found in weed extracts (Tables 3 and 4). Chlorogenic and isochlorogenic acids were found in all extracts. Tumble pigweed extract contained *p*-coumaric acid and scopoletin, while wall goosefoot extract contained scopoletin and chlorogenic and isochlorogenic acids. All phenolic acids, except *p*-hydroxybenzoic acid and scopoletin, were found in Bermuda grass extract. Chlorogenic, isochlorogenic, *p*-coumaric, and *p*-hydroxybenzoic acids were identified in Johnson grass extract. Unknown compounds were also found but not identified. Their R_fs and colors under UV light suggest a flavonoid nature (Table 4).

Quantitative analyses showed that Bermuda grass, Johnson grass, wall goosefoot, and tumble pigweed contained up to 32.2, 21.4, 21.1, and 9.3 μg/g dry weight of phenolic compounds, respectively (Table 4). The high percent

of dodder control and alfalfa injury caused by 0.5 g of Bermuda grass might be explained by the higher (32.2 μg/g) concentration of phenolic compounds.

DISCUSSION

Results of both pot and field experiments suggested that toxicity of weed extracts on field dodder had increased when higher concentrations were used, when 0.25 g of wall goosefoot was used. However, considerable injury to alfalfa foliage occurred, especially when 0.25 and 0.5 g of both wall goosefoot and Bermuda grass were applied under field conditions. The difference in alfalfa injuries between pot and field results might be explained by the higher temperature in the field (32 $\pm$ 2°C) compared to 20 $\pm$ 2°C under lath-house conditions. Considering alfalfa injury for both experiments; 0.25 g of tumble pigweed and 0.05 and 0.5 g of Johnson grass were the best treatments. However, Bermuda grass at 0.25 g gave the highest dodder control but in the field resulted in 35% injury to alfalfa.

Many reports have shown the inhibitory activity of phenolic compounds. Rasmussen and Rice (1971) identified ferulic and *p*-coumaric acids from *Sporobolus pyramidatus* and found allelopathic effects on associated species, resulting in either reduced growth or eliminating them from the stand. Langdale and

Ciddens (1967) reported that small quantities of the same acid were effective in inhibiting IAA activity in *Avena* spp. coleoptiles. More detailed study was conducted by Zenk and Muller (1963) and showed that these aicds increase IAA decarboxylation in *Amaranthus retroflexus* seedlings. Chlorogenic acid was found to inhibit many enzymes such as photophosphorylase (Sondheimer, 1964). Lodhi (1975) tested the biological activity of ferulic, caffeic, and *p*-coumaric acids isolated from hackberry (*Celtis laevigata*) leaves and found that they reduced germination and growth of associated herbaceous species. Al-Algawi (1980) found that Bermuda grass eliminated growth of associated species and the same plant leaf and rhizome inhibited seed germination and seedling growth of cotton and some weeds (Abdul-Rhaman, 1983). All of these studies, as well as others, support the assumption that extract phytotoxicity of the weeds in this study might be due to the phenolic compounds.

Results of this study showed strong evidence that plant parts of these weed species contain phenolic compounds that have phytotoxic activity against dodder. With respect to the possible practical use of these extracts as an approach for dodder control, these rates might be too high to be of commercial and practical importance. This is supported by Shettel and Balke (1983), who concluded that relatively higher concentrations were required to reduce plant growth. However, other detailed studies should be concentrated on screening for naturally occurring chemicals in a wide spectrum of wild plants. It would also be useful to determine which of these phenolic compounds have phytotoxic activity and the mechanisms of such phytotoxicity.

EXTRACTION OF TANNIN FROM FRESH AND PRESERVED LEAVES

ANN E. HAGERMAN

Department of Chemistry
Miami University
Oxford, Ohio 45056

(Received January 7, 1987; accepted February 23, 1987)

Abstract—The extractability of tannin from fresh, lyophilized, and dried leaves collected at various times in the growing season was determined using the radial diffusion assay for protein-precipitating phenolics. The amount of tannin extracted depended on the method of leaf preservation and on the maturity of the leaf. Early in the season, more tannin was extracted from lyophilized leaves than from fresh leaves, but late in the season more tannin was extracted from fresh leaves. At all times, more tannin was extracted with aqueous acetone than with aqueous or acidic methanol.

Key Words—Leaf preservation, tannin extraction, phenolic analysis, protein precipitation.

INTRODUCTION

Although tannin is frequently cited as an example of a plant defensive chemical (Swain, 1979), experimental documentation of a defensive role for tannin is limited. Clear demonstration of a defensive function for tannin depends on accurate quantitation of tannin. When adequate analytic methods are available, it will become possible to determine whether there is any correlation between tannin content and patterns of herbivory.

The accuracy with which a chemical component in a biological matrix, such as tannin in a plant leaf, can be determined depends on several factors. The tissue of interest must be collected and preserved so that the component is not altered or destroyed. The component must be extracted from the tissue in high yield. The method of assaying the component must be free of interferences from other materials present in the extract. However, there is no consensus on

0098-0331/88/0200-0453$06.00/0

the best method for preserving leaves or the most efficient solvents for extracting tannins (Swain, 1979). Definitive studies of the role of tannin have been hampered by the limited knowledge of appropriate methods for sample collection and tannin extraction.

Although extraction and analysis of fresh tissues would probably minimize changes to the tannin, most studies of the ecological role of tannin are conducted under conditions where immediate analysis is impossible. Instead, tissues are collected and preserved for later extraction and analysis. Lyophilization is thought to be the gentlest method of preservation, and lyophilized leaves may be equivalent to fresh leaves (Martin and Martin, 1983). However, diminished extractability of tannin after lyophilization has been noted in some cases (Price et al., 1979). Drying the tissue at ambient or at elevated temperature is more convenient than lyophilization, although little tannin can be extracted from samples dried at elevated temperatures (Bate-Smith, 1975; Price et al., 1979). Lower temperature drying is preferable (Swain, 1979), but even drying at room temperature may alter the chemical nature of tannin (Butler, 1982).

Three solvents are commonly used to extract tannin from plant samples: boiling aqueous methanol, aqueous acetone, or acidic methanol. Boiling aqueous methanol is thought to be the most effective solvent for condensed tannin (Bate-Smith, 1975), but the recovery of tannin is estimated to be as low as 30% for some tissues (Bate-Smith, 1973a; Swain, 1979). Since aromatic ester (depside) bonds are hydrolyzed by aqueous alcohols, they are thought to be unsuitable for extraction of hydrolyzable tannin (Haslam et al., 1961; Swain, 1979).

Aqueous acetone is routinely used to extract hydrolyzable tannin (Jones et al., 1976; Foo and Porter, 1980), but no quantitative estimates of recovery are available. Some authors believe condensed tannin is extracted quite efficiently with aqueous acetone (Feeny and Bostock, 1968; Fletcher et al., 1977; Lane and Schuster, 1981), but others have found that condensed tannin is recovered in low yields when aqueous acetone is employed (Stafford and Cheng, 1980; Martin and Martin, 1984).

Acidic methanol is the best solvent for extracting the condensed tannin from some varieties of sorghum (Price et al., 1978). It is hypothesized that the tannin in those varieties is chemically unique, perhaps covalently attached by an acid-labile bond to some component of the grain. Although aqueous methanol (pH 5–6) causes methanolysis of depside bonds in hydrolyzable tannins, at more acidic pH values (pH < 3) methanolysis does not occur (Haslam et al., 1961). Thus acidic methanol should be appropriate for extraction of hydrolyzable tannin. The applicability of acidic methanol as an extractant of plant tissues other than sorghum has not been demonstrated, but it may be useful in cases of strong interaction between tannin and other components of the tissue. Some plants contain tannin that is completely unextractable with aqueous acetone or alcohol (Bate-Smith, 1973a, 1975).

The purpose of this study was to compare several methods of leaf preser-

vation and to quantitate the extractability of tannin with various solvents. The study was conducted throughout one growing season, and the effect of leaf maturity on tannin extractability was also noted.

METHODS AND MATERIALS

The leaves used in this study were collected from trees on the Miami University campus throughout the growing season of 1986. A single tree of each type was used for all samples, and all samples were collected from low branches on the north side of the trees. Three species of trees were used: burr oak, *Quercus macrocarpa*; sugar maple, *Acer saccharum*; shagbark hickory, *Carya ovata*. Specimens have been deposited in the Miami University herbarium.

The leaves were removed from the trees and immediately put on ice. Major veins were removed with a razor blade and discarded. The leaves were cut into small pieces (~ 2 cm^2), frozen in liquid nitrogen, and ground with a mortar and pestle. The powder was either extracted immediately, or lyophilized, or oven dried at 40°C or at 90°C.

Extractions were performed either in test tubes or in miniature columns. If test tubes were used, the sample was weighed into the tube, mixed with the solvent, and centrifuged after the extraction was completed. The supernatant was removed and the final volume of extract recovered was recorded. In a faster method for extracting samples, 1-ml micropipet tips were used as columns. The end of the plastic pipet tip was sealed by touching it with a hot glass rod. A polyethylene frit cut to the proper size with a cork borer was inserted ~ 0.75 mm from the tip to support the plant tissue. The tissue was placed in the tip, on the frit, weighed, and the solvent was added. After the extraction was completed, the sealed end was cut off, the column placed in a large test tube, and centrifuged. The extract was collected in the test tube. This method provided excellent recovery of the extract for small samples (100 mg) of fresh or dried tissue.

For all the solvents, the tissue was initially extracted for 30 min at room temperature. If the solvent was to be heated, the sample was placed in an 85°C water bath for an additional 10 min of extraction.

The extracts were assayed with the radial diffusion assay (Hagerman, 1987). Wells were made in the bovine serum albumin-containing plates with a 4-mm punch, and three 8-μl aliquots of extract were applied to each well. After 94 hr, the diameter of the ring that developed was measured. The diameter squared is proportional to amount of tannin added to the well (Hagerman, 1987). The data were expressed as centimeters squared per gram dry tissue. These values could be converted to milligrams tannic acid per gram tissue or to milligrams condensed tannin per gram tissue using a standard curve (Hagerman, 1987), but those values would not be more meaningful than the unconverted raw data for the leaves that contained both types of tannin.

Tannic acid or quebracho tannin (Asquith and Butler, 1985) was added to fresh spinach or young barley leaves, and the tannin recovered from the leaves determined with the Prussian blue assay (Price and Butler, 1977). The leaves (0.34 g) were cut into small pieces, and placed in a mortar with sand, 3.0 ml of the solvent, and a 100-μl aliquot of a 100 mg/ml tannin solution. The leaves were ground with a pestle, centrifuged, and the supernatant assayed for total phenolics. Control samples without added tannin were used to determine the phenolics from the barley or spinach, and those values were subtracted from the values obtained for the spiked leaves. The Prussian blue assay was run on aliquots of tannin, and the recovery from the leaves was then calculated as percent of tannin added to the leaves.

RESULTS

Leaves of oak and maple contain both condensed and hydrolyzable tannin (Feeny and Bostock, 1968; Bate-Smith, 1977; Schultz and Baldwin, 1982); hickory contains only condensed tannin (Wilken and Cosgrove, 1964). The radial diffusion assay (Hagerman, 1987), which was used to determine the extracted tannin, does not discriminate between condensed and hydrolyzable tannin. Condensed tannin gives a lower response than hydrolyzable tannin with this assay. The response to a mixture of tannins is equal to the sum of the responses to the individual components of the mixture (Hagerman, 1987).

The extraction of tannin from lyophilized maple or oak leaves collected in midsummer was most efficient when 70% aqueous acetone was used (Table 1). Aqueous alcohol did not extract as much tannin as did the acetone. Boiling aqueous methanol apparently destroyed some tannin in the maple leaves. Heated aqueous acetone extracted less tannin than did unheated acetone (data not shown).

Similar results were obtained in experiments in which condensed or hydrolyzable tannin was added to fresh leaves just before the leaves were homoge-

[b] Not determined.

nized in various solvents (Table 2). The added tannin was most efficiently recovered with aqueous acetone as the solvent. Less tannin was recovered with the alcohol-containing solvents, although acidic methanol was as effective as aqueous acetone for recovery of hydrolyzable tannin (Table 2). However, when lyophilized tannin-containing tissues were extracted, acidic methanol was much less efficient than aqueous acetone (Table 1).

The extractability of tannin was determined for leaves collected at different times during the growing season. In the early summer, much more tannin was extracted from lyophilized maple leaves by aqueous acetone than was extracted by heated methanol (Table 3). As the summer progressed, the amount of tannin extracted by acetone decreased more rapidly than the amount extracted by alcohol. In the late summer, equal amounts of tannin were extracted from the lyophilized maple leaves by aqueous acetone or by heated aqueous methanol (Table

TABLE 3. EXTRACTION OF TANNIN[a] FROM LYOPHILIZED MAPLE LEAVES COLLECTED ON VARIOUS DATES

[a] Tannin determined by the radial diffusion assay and expressed as cm^2/g dry tissue. Each value (± SD) is the mean of at least three determinations. Values followed by the same letter are the same at the 95% confidence interval (*t* test).

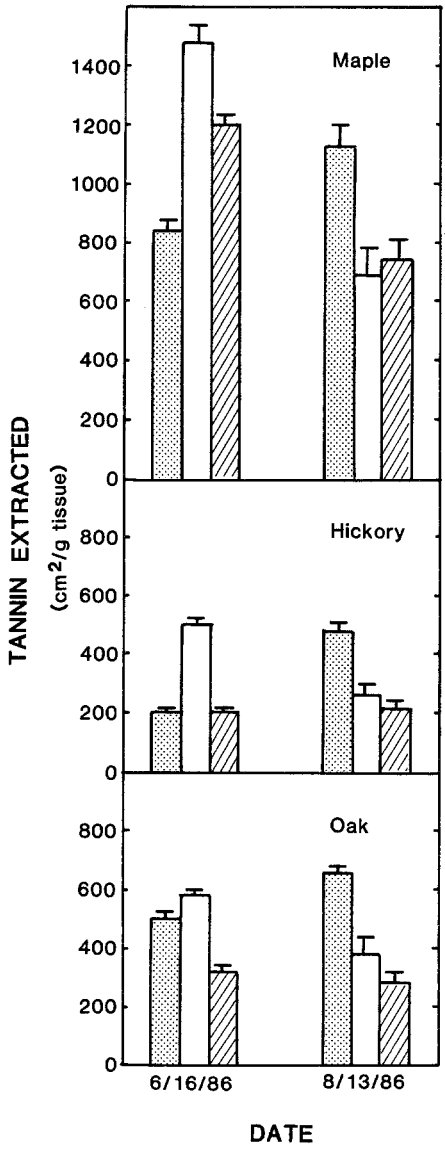

FIG. 1. Tannin extracted from fresh, lyophilized, and dried leaves. Leaves were collected on the indicated date and were either extracted immediately (▨), lyophilized and then extracted (□), or dried at 40°C and then extracted (▨). The tissue was extracted with 70% aqueous acetone and the extracts analyzed with the radial diffusion assay (Hagerman, 1987). Tannin was calculated on the basis of dry weight. Error bars show 1 SD from the mean of at least three trials.

3). Similar results were obtained with lyophilized oak or hickory leaves and with dried leaves from all three species (Figure 1). It has previously been noted that the amount of tannin in plant tissues diminishes throughout the growing season (Bate-Smith, 1973a; Butler, 1982). However, the role solvent plays in determining the apparent magnitude of the seasonal change has not been previously noted.

The extractability of tannin from leaves preserved by several methods was determined at two times during the growing season (Figure 1). Early in the season, more tannin was extracted from lyophilized leaves than from fresh leaves. Late in the season, the amount of tannin extracted from lyophilized leaves diminished, as noted above. However, the amount of tannin extracted from fresh leaves collected late in the season was greater than the amount that could be extracted from fresh leaves collected early in the season. The extraction of tannin from the dried leaves was quite efficient for some samples and less efficient for other samples. Drying at elevated temperatures was particularly harmful; no tannin could be extracted from hickory leaves that were dried at 90°C, and only a small amount of tannin could be extracted from oak or maple leaves dried at 90°C. Similar amounts of tannin were extracted from frozen samples of late-season leaves and from fresh samples of the same leaves.

DISCUSSION

It is not possible to recommend a single optimal protocol for extraction of tannin from all plant samples. Each sample has unique characteristics, including the structure of the tissue and the composition of the tannin, that determine tannin extractability (Bate-Smith, 1973a; Swain, 1979). Although a very limited number of samples were examined in the study described here, some general recommendations can be made based on these results.

Aqueous acetone appears to be the best solvent for extracting tannin from leaf tissue. Aqueous alcohol or acidic alcohol does not extract more tannin than aqueous acetone. Heated aqueous alcohol may extract less tannin than aqueous acetone. Acetone is an effective solvent because it inhibits interaction between tannin and proteins (Hagerman and Robbins, 1987) and thus prevents tannin from binding to leaf proteins during homogenization. However, acetone inhibits many of the common precipitation assays for tannin (Bate-Smith, 1973b; Hagerman and Butler, 1978; Martin and Martin, 1983), so procedures for analysis of acetone extracts must be chosen carefully. Acetone does not interfere with the radial diffusion assay because the acetone evaporates before the tannin–protein interaction takes place (Hagerman, 1987). Acetone does not interfere with most chemical assays for tannin (Price and Butler, 1977; Price et al., 1978).

To minimize artifacts associated with leaf preservation, leaves should be extracted and analyzed immediately after collection. However, if analysis of fresh tissue is impossible, tissue should be lyophilized or dried at low temperature rather than in the sun or in an oven. If tissues must be dried a higher temperature, analysis of at least a few samples of fresh tissue, for comparison with the dried tissue, would provide insight into the changes in tannin extractability associated with drying.

Tannin levels and extractability change dramatically through the growing season. Environmental conditions such as light intensity affect phenolic biosynthesis and accumulation (Balsa et al., 1979; Waterman et al., 1984). Seasonal changes in leaf morphology, moisture content, and chemistry may affect tannin extractability (Swain, 1979). Comparisons of tannin levels in plants must be made cautiously since tannin extractability is dependent on many factors. The seasonal variation in tannin extractability observed in this limited study of three temperate-climate species may not resemble the seasonal changes in other plants. Studies of the ecological significance of tannin should include investigations of seasonal variations for the plant of interest, using the plant preservation and tannin extraction techniques that will be used in the ecological study.

[2]*USDA, ARS, Boll Weevil Research Laboratory Mississippi State, Mississippi*

(Received July 11, 1986; accepted February 24, 1987)

Abstract—Behavioral and electrophysiological studies with live intact larvae and larval rinses of the red imported fire ant, *Solenopsis invicta* Buren, give undeniable evidence of a volatile material associated with the larvae of the ant that is capable of eliciting a response from brood-tending workers. In a Y-tube bioassay, worker ants were attracted equally to an airstream blown over sibling larvae or heterocolonial larvae. Workers were also attracted to a rinse of the larvae in a spot bioassay, aggregated about a piece of surrogate brood in another bioassay, and retrieved surrogate brood treated with the rinse material. A dose–response curve constructed from electroantennograms of workers revealed a receptor response of 1–100 brood equivalents.

Key Words—*Solenopsis invicta*, Hymenoptera, Formicidae, brood recognition, pheromone, fire ant, behavior, olfaction, orientation, bioassays.

INTRODUCTION

The brood of an ant colony can be considered to be not only the growing point of the colony, but also the storage tissue or energy capital (Wilson, 1971). When the colony falls upon hard times, the brood can serve as the prime source of food. It is not surprising then that the early investigators of the behavior of workers toward the brood focused mainly on the trophallaxis of either the stomodeal or proctodeal larval secretions (Stager, 1923; LeMasne, 1953; Torossian, 1961). While these studies did explain some of the feeding behavior, other

0098-0331/88/0200-0463$06.00/0

behaviors toward the brood were left unexplained. Watkins and Cole (1966) presented the first evidence that the brood of the army ant, *Neivamyrmex apacithorax* (Emery), produced a pheromone that induced specific worker tending behavior. Later experiments by Glancey et al. (1970) showed that the brood of the red imported fire ant (RIFA), *Solenopsis invicta* Buren, also produce a pheromone that elicits particular worker behaviors (e.g., tending, grooming, moving, etc.) and is extractable and capable of being bioassayed. Robinson and Cherrett (1974) found that hexane would remove a behaviorally active material from larvae of *Atta cephalotes*, but they were unable to isolate the active fraction.

Investigations by Walsh and Tschinkel (1974) on RIFA led them to question the report of Glancey et al. (1970). Ignoring the food bioassays conducted by Glancey et al. (1970), they insisted that the latter's findings represented a food response. Walsh and Tschinkel (1974) concluded that they had found the brood pheromone, that it was a nonvolatile contact pheromone, that it was intimately tied up with the cuticle, and that the cuticle had to be contacted in order for a response to follow.

Later, Bigley and Vinson (1974) reported that the brood pheromone of RIFA was triolein, a triglyceride. This finding was questioned by VanderMeer (1983), who did not feel confident about assigning a structure based only on thin-layer chromatography.

This present paper presents the results of additional behavioral studies. The first evidence of a noncontact component of the brood pheromone is presented. Using larval rinses, we assayed workers for contact-mediated and non-contact-mediated responses to the brood pheromone. Additionally, EAG responses of brood tenders to larval rinses were measured.

METHODS AND MATERIALS

Source and Maintenance of Test Insects

Worker ants that were observed to be tending brood were collected from the vicinity of various laboratory colony brood piles. These "brood tenders" are the youngest workers and are more responsive to various pheromones (Glancey, unpublished data) than the older foraging workers. The colonies were maintained at 27 $\pm$ 1°C in Williams cells (Bishop et al., 1980) and fed honey–water and the Brooks diet. This diet, developed by T. Brooks, University of Georgia at Athens, consists of ground beef, peanut butter, eggs, sugar, salt, sorbic acid, vitamins, and water. The materials are blended with gelatin, allowed to cool and congeal, and the solidified material is cut into 1-inch squares. These squares are dipped into melted paraffin (Paraplast). When the test protocol called for the use of live larvae, the larvae were collected from colonies other than the

ones used for the collection of the brood tenders. Field larvae were collected by digging up a field colony and separating the brood from the soil.

Chemical Stimuli

Larval Rinses. The larval rinses for the behavioral bioassays were obtained by collecting field colonies and separating the larvae from the soil and workers. This separation was greatly facilitated by moving the larvae back and forth with the use of a camel's hair brush. This motion caused the larvae to cohere together due to the presence of larval hooks. These larvae could then be lifted away from the pupae. Groups of live larvae were weighed, the numbers counted, and an average weight of 0.53 mg/larva calculated. Only worker larvae were collected, mainly third and fourth instar. An estimated 250,000 larvae were collected in this manner. The larvae were rinsed in nanograde pentane for 30 sec, the extract transferred to a freezer, and the larvae discarded. The rinse was held in a freezer until used in a given bioassay.

In order to ensure that the responses obtained were not due to a food reaction, we compared the response to larval rinses with responses to pentane rinses made from American cockroaches (*Periplanata americana*). The cockroaches were obtained from the USDA's IAMARL cockroach-rearing facility located at the Gainesville Laboratory. Cockroaches, if available from the rearing section, are normally fed to our ant colonies as a source of insect protein. Previous work had shown that worker ants are attracted to and masticate a spot on filter paper to which a cockroach rinse has been applied (Glancey, unpublished data). The roaches obtained from the rearing section were weighed and rinsed with nanograde hexane. Initial tests made with the larval rinses showed that it required 500 larvae (226 mg) to elicit a response from the workers. Accordingly, a solution was made up which gave us 500 larval equivalent (LE) per 20 μl of pentane. Similarly 226 mg of roaches were rinsed in pentane and reduced to 20 μl. Both the brood rinse and the cockroach rinse were quantified by capillary GC with an external standard to give comparable amounts of extracted material (Kovats index range 900–4500) in both rinses.

Electrophysiological Experiments. Volatiles were collected from worker larvae by rinsing 1, 10, or 100 larvae in nanograde pentane for 30 sec. Excess pentane was evaporated under a stream of nitrogen until a final volume of 10 μl was reached. The 1-hexanol (>99% purity) used as a standard was obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin).

Bioassays

Attraction to a Spot. A 5.5-cm piece of Whatman No. 1 filter paper was divided into four quadrants by drawing two intersecting lines through the center. A small pencil dot was placed in the middle of each quadrant. A number between

1 and 4 was assigned at random to each one of the dots. Treatments assigned randomly to the dots were 20 μl each of the larval rinse, the cockroach rinse, and the pentane solvent; a fourth treatment consisted of a cohort of live larvae (ca. 300) that were placed on the spot and removed after 15 min. After the larvae were removed, the other dots were treated. The treated filter paper was placed in the bottom half of 5.5-cm plastic Petri dish. Twenty brood tenders obtained from our laboratory colonies were placed in the disk and another dish inverted over the bottom half to keep the ants from escaping. At 1-min intervals, counts were made of the ants within 0.5 cm of the spot.

Olfactometer Bioassay. Live larvae were tested for the production of volatiles in a Y-tube olfactometer. This olfactometer was modeled after a design by VanderMeer et al. (1979) and is described completely by VanderMeer et al. (1988). The olfactometer consists of two 24/40 ground glass joints sealed to one of the arms of a 5-cm Y tube such that 1 cm of each Y-tube arm extended through half the ground glass joints. Three hundred third- and fourth-instar colony or field larvae were placed in one of the choice chambers. The other choice chamber was left blank. Compressed air was split into two streams, each stream being independently controlled by flowmeters. Airflow was regulated at 0.2 l/min into each choice chamber. Fifty brood tenders, selected at random, were chilled for 10 min (6°C) in the refrigerator and then placed in a small bronze wire cage. The open end of the cage was attached to the stem of the Y tube and the airflow turned on.

The initial choice of the first 20 ants that responded by walking into one of the choice chambers was recorded. Ants that were not trapped in the choice chamber and returned to the stem entrance were not counted. The entire olfactometer was rinsed after each test with acetone and dried. Another set of larvae from the same colony was tested with another set of workers from the same colony. However, the choice chamber in which the larvae were placed was reversed. After this test was run, the two scores were combined to give one replicate. This type of procedure eliminated any bias that was inherent in the individual choice chambers. Data were analyzed statistically by use of a chi-square test.

Surrogate Bioassay. This bioassay was developed in our research of the queen recognition pheromone (Lofgren et al., 1983). A section of a rubber needle-seal septum was treated with one of the rinses or pentane. The septum was air dried and then placed in a 9-cm Wilson cell which had all the ports sealed. The septum was placed in a 2-cm^2 area drawn upon the castone bottom of the cell, and 20 worker ants were placed in the cell. The data were quantified by counting the numbers of ants clustering in the 2-cm^2 area at 1-min intervals for 5 min. At the end of the 5-min run, the ants and septum were discarded and a new cell used for the next trial. Three different colonies were tested in this manner for three replications.

Retrieval of Brood Surrogates by Disrupted Colonies. This particular

bioassay was also designed for use in our green pheromone research. When a colony is opened and the brood and workers are scattered about the colony area, the workers immediately begin to collect the brood, lay trails back to the nest, and carry the brood along these trails. We have simulated this in the laboratory by using a laboratory colony in a large box (1.2 m^2) (Glancey et al., 1983). The rearing cell containing the colony is opened and the brood and workers scattered about the box. In the present bioassay, small pieces of colored construction paper (2 mm^2) (Union Camp Corp., Chamblee, Georgia) were soaked overnight in the rinses (larval or cockroach) or solvent. The papers were air dried, the colonies disrupted, and 10 pieces each of the various colored papers deposited in the area of disruption. Differently colored papers were used for each treatment, but no colonies received the same colored paper treated with the same rinse. One hour after the papers were deposited, observations were made of their fate. If the papers were taken inside the cell and placed with the brood, the test was scored as a positive response. Sometimes the ants had difficulty getting the paper through the small entrance hole into the cell. If the ants placed the papers beside the entrance hole because they could not get it into the cell, and if they placed some of the scattered brood next to the papers, then that test was recorded as a positive one. Five replications using five different colonies were made in this manner.

Data for the attraction and surrogate bioassays were evaluated for significance using the general linear model procedure of SAS Institute (1982) and by the Waller-Duncan *K*-ratio *t* test.

Electrophysiology Procedures. Electroantennogram (EAG) techniques utilized in these studies were modified after an earlier study (Schneider, 1957) and are described in detail elsewhere (Dickens and Payne, 1977; Dickens, 1981). In brief, Ag–AgCl capillary electrodes filled with physiological saline (Pantine, 1948; Oakley and Schafer, 1978) were used. The recording electrode was introduced into the distal end of the terminal antennal segment which was prepunctured by a sharpened tungsten needle. The indifferent electrode was inserted into the head capsule. The signal was amplified 10-fold by a Grass P-16 DC microelectrode preamplifier prior to viewing on a Tektronix 5223 digitizing oscilloscope. An *x–y* plotter recorded EAGs on graph paper for subsequent analyses and storage.

Odorous stimuli were delivered on filter paper (8 × 18 mm) inserted into glass cartridges (80 mm long; 5 mm ID) oriented toward the preparation from ca. 1 cm. Stimulus duration was 1 sec with an airflow of 1 m/sec. A range of concentrations was used to develop a dose–response curve. The stimuli were presented in order from the lowest to the highest concentrations. A 3-min interval was allowed between each stimulus. Three replications were run using three different insects. Response to the pentane control was subtracted from response to the other compounds.

Stimulation with 1-hexanol, a component of the green leaf volatile com-

plex (Visser et al., 1979), at 100 μg was used as a standard so that responses from different preparations could be compared (Dickens, 1984; Dickens and Boldt, 1985). In addition, the 1-hexanol is ideal as a standard since most insects, indeed most animals, encounter this odor in their daily environment. Six-carbon alcohols and aldehydes are omnipresent as components of the odor of green leaves (Visser et al., 1979). Thus one could predict the presence of many receptors on the antennae of the worker ants since green plants and associated green odors form a large part of their environment via the mound construction. Mean response of the brood tenders to the standard was -0.38 mV (SE = 0.04; N = 3). Each stimulus was either preceded or followed at 4 min by a stimulation with the standard. Responses to intervening test stimuli were represented as a percent of the mean of the two nearest responses to the standard (Dickens, 1978, 1981). The size of the EAG was considered to be a measure of the relative number of responding acceptors (Payne, 1975; Dickens and Payne, 1977).

RESULTS AND DISCUSSION

The results of the bioassays are given in Tables 1–4. In Y-tube olfactometer trials with intact, live larvae, it was determined that 300 immatures were capable of eliciting a statistically significant response from brood tenders (Table 1). Worker response to sibling larvae was not significantly different from worker response to heterocolonial, field-collected brood. These data strongly suggest that worker response to a brood pheromone attractant does not require contact chemoreception and that this response is not mediated by worker conditioning to colony-specific brood odors, be they heritable or environmental. Similar evidence for the presence of a volatile attractant given off by brood of the RIFA is presented in the work by Lofgren et al. (1983). In olfactometer bioassays in which ants were given the option of orienting to an airstream blown over their own colony queen or to an airstream being blown over larvae from their own colony or from an alien colony, the ants responded equally to the airstream over their own larvae and over alien larvae. The implication here is

TABLE 1. OLFACTOMETER RESPONSE OF BROOD TENDERS TO 300 LIVE, INTACT IMMATURES[a]

Response to	No. attracted ($X \pm$ SD)	No. not attracted ($X \pm$ SD)	χ^2 (1 df)
Own brood	161 (26.83 ± 2.32)	79 (13.17 ± 2.32)	10.44
Alien brood	159 (26.50 ± 2.74)	81 (13.5 ± 2.74)	9.57

that regardless of the source of the brood, or the brood–worker kinship, a volatile is present that causes attraction. Observations in the field have shown that when a colony is disturbed and some of the larvae are buried beneath the soil, the worker ants are quite adept at locating each and every piece of brood. It is quite possible that the workers are locating the buried brood by the presence of the brood pheromone. It might be argued that the workers are using substrate vibrations produced by the larvae to locate them. However, it has not been shown that RIFA larvae are capable of producing sound. Lenoir (1984) has shown that, in research with the ant *Cataglyphis cursor*, colony workers recognize sibling brood immediately. If, however, workers have been adopted into the colony, these adoptees do not initially recognize the larvae as sisters. However, after six days, the adopted workers begin to tend brood indicating the inhibition has disappeared. Lenoir's work not only demonstrates the presence of a brood-tending pheromone, but also presents data that show brood kin recognition.

Further evidence for the perception by brood tenders of odorous stimuli emanating from the larvae was obtained from the electrophysiological studies. A dose–response curve constructed from EAGs to increasing larval equivalents showed receptor response to increase from a threshold of ca. 1–10 larval equivalents to a saturation level of ca. 10–100 larval equivalents (Figure 1). As seen in Figure 1, the maximum response to the brood rinse was 20% of the 1-hexanol

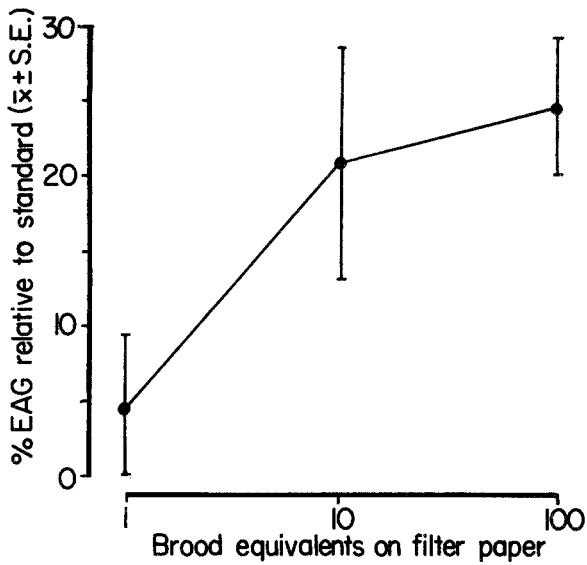

FIG. 1. Dose–response curve constructed from mean EAGs of brood tenders (N = 3) to increasing brood equivalents on filter paper. Vertical bars represent standard errors.

TABLE 2. RESPONSE OF BROOD TENDERS FED TWO DIFFERENT DIETS IN SPOT ATTRACTION BIOASSAY

Treatment	Response, % ($X \pm$ SE)	
	Normal diet	Roach diet
Brood rinse	79 ± 2.3A[a]	57.8 ± 5.7G

standard. One may wonder if this is indeed a significant response and why brood tenders should exhibit greater EAG responses to the leaf volatiles than to the brood pheromone. The green leaf volatiles may be detected by numerous receptors with broad specificity, while the brood pheromone receptors may be few in number but highly specific. A situation similar to the one described above occurs in the boll weevil (Dickens, 1984, and unpublished data). Furthermore, disregarding the peripheral receptor system, higher order neural processing may amplify and modulate plant odors and pheromones quite differently. Thus, in this case, the 20% response does indeed represent a significant value. Little or no response was obtained with the volatiles from triolein.

The results from the brood rinse experiments (Tables 2–4) show that some kind of attractive material is being extracted from the larvae. In the spot attraction test, regardless of the type of diet, the workers responded best to the rinse of the larvae (Table 1). In this test, where workers have a choice of orienting to a particular spot and settling down, the implication is that there is a contact

material present that causes the workers to respond. In the natural setting of a colony, the brood tenders do not wander about, but tend to remain on the brood pile while carrying on their activities. This tendency to settle down is seen also in the response to the spot upon which the larvae had rested. These responses to the larval rinse spot or the larval resting spot agree with the findings of Walsh and Tschinkel (1974) that a pheromone is present that is intimately tied up with the cuticle. However, their conclusion was that the workers needed to contact the brood in order for a response to follow. Our data show that this latter conclusion may not necessarily be true.

Cockroach extracts were not active in tests with disrupted colonies. Ants from both tests responded to small pieces of paper treated with the larval rinse by stacking scattered brood upon the papers, by building trails from the nest to the papers, and by returning the papers to the area of the nest. No papers treated with the cockroach rinse or the solvent control were treated in this manner.

Data from both behavioral bioassays and electrophysiological studies show that volatile compounds are associated with RIFA larvae and that these compounds are capable of eliciting a response by brood tending workers. The failure of Walsh and Tschinkel (1974) to detect a volatile compound might be explained by the use of workers other than brood tenders and the extremely small amounts of the pheromone present on single larvae. We found it necessary to use at least 300 larvae to elicit an olfactometer response. Response by the workers to brood cuticle suggests that the brood recognition pheromone may have at least two components: one, a volatile component that draws the workers near the brood; and two, a contact material that causes retrieval behavior. The two components together evidently have a very shallow active space around each larva.

The question arises as to whether the pheromone is produced by the larvae or whether it is the result of some material being applied to the larvae. We know that when the RIFA queen lays an egg, she draws the ovipositor over the

egg and applies venom to it (VanderMeer, unpublished data). This material may serve not only as an antibiotic, but also as a means to alert the brood tenders to carry the egg to the brood pile. An egg-laying queen has an entourage of workers that mill about her posterior end during the egg-laying period. When an egg is deposited and the sting drawn across it, these workers enter a very highly excited state. The egg is quickly picked up and taken to the brood pile. Another possibility for the origin of the material may be the mere physical transfer of worker hydrocarbons to the brood. These hydrocarbons may facilitate the brood tender's feeding and grooming of the larvae. Such behavior is already known in the case of the myrmecophilous beetle, *Myrmecaphodius excavaticollis* (VanderMeer and Wojcik, 1982). This RIFA symbiont is capable of acquiring the RIFA hydrocarbon pattern and, being so marked, is able to move freely about the colony and obtain food directly from workers. Finally, the attention paid to the brood may simply be a result of the topical application of venom by the brood tenders. Obin and VanderMeer (1985) have shown that worker ants disperse venom through the air by raising the abdomen and vibrating the gaster (termed "gaster flagging"). Although these authors suggest that this behavior is a method of dispersing antibiotics, it may also be that it is the method of marking the brood for tending behavior. Regardless of the source of the material that causes brood tending, it is obvious that some chemical is present and that this material is capable of being extracted and tested.

THE INFLUENCE OF DIETARY β-CARBOLINE ALKALOIDS ON GROWTH RATE, FOOD CONSUMPTION, AND FOOD UTILIZATION OF LARVAE OF *Spodoptera exigua* (HUBNER)

JANICE CLYMER CAVIN and ELOY RODRIGUEZ

Department of Developmental and Cell Biology
University of California at Irvine
Irvine, California 92717

(Received November 10, 1986; accepted February 26, 1987)

Abstract—β-Carboline alkaloids are found worldwide in many plant families. Harman, harmine, and other simple β-carboline alkaloids were tested for activity against a generalist phytophagous insect, the beet armyworm [*Spodoptera exigua* (Hubner)]. Chronic dietary exposure tests (neonate to pupa) reveal potent antifeedant and possible toxic effects. Acute dietary exposure tests on fifth-instar larvae also demonstrate antifeedant activity.

Key Words—β-Carboline alkaloids, harman, harmins, *Spodoptera exigua* (Hubner), beet armyworm, antifeedant, Lepidoptera, Noctuidae.

INTRODUCTION

There are 26 angiosperm plant families and three fungi genera that contain simple β-carbolines (Allen and Holmstedt, 1980). Among these are the Leguminosae, Malpighiaceae, Symplocaceae, Passifloraceae, and Zygophyllaceae. Although isolated in small quantities from plants, these secondary metabolites have significant potency in animal systems. The simple β-carbolines have been shown to inhibit monoamine oxidase and induce tremor (Coates and Cox, 1972), to intercalate into DNA (Duportail and Lami, 1975), to interfere with UV-induced DNA damage repair systems (Chang et al., 1978), to inhibit sodium–potassium ATPase activity (Murumo et al., 1976), to be phototoxic against microorganisms (McKenna and Towers, 1981), to be antitrypanosomal (Cavin

0098-0331/88/0200-0475$06.00/0

et al., 1987), and to cause hypothermia (Leonard and Stonier, 1971). Because of the worldwide distribution in plants, and the wide range of activity of the simple β-carboline alkaloids, their influence on the growth and development of a generalist phytophagous insect was undertaken in this study.

Polyphagous, or generalist, insects utilize a range of generalized detoxification enzymes (Krieger et al., 1971), enzyme induction systems (Brattsten et al., 1977), or simply avoid toxic plants. The activity of various β-carboline alkaloids on the growth, consumption, and food utilization of a generalist insect, the lepidopteran, *Spodoptera exigua* (Hubner), is described in this study. The simple β-carbolines under consideration are lipid soluble at pH 8–9, the pH of the insect gut. Therefore, they pass readily through the gut lining into the hemolymph. Simple β-carboline alkaloids present in an artificial diet were found excreted unchanged in the frass (Cavin, in preparation). Their low molecular weights (182–212) would allow any absorbed compounds to be at least passively transported out by means of the Malpighian tubules. However, although they are apparently not metabolized, some of the simple β-carbolines, when added to a controlled artificial diet, are perceived by the insect larvae because they reduce feeding significantly. Toxic effects were seen with long-term exposures.

METHODS AND MATERIALS

Spodoptera exigua (Hubner) larvae were obtained from a colony kept in the phytochemistry laboratory at the University of California at Irvine. The experimental groups were maintained in an incubator with a 16-hr light–8-hr dark photoperiod at 26.5°C.

The treated diet was prepared by mixing the test chemical, in methanol, with the dry portion of the insect mix (Bioserv mix No. 9219), the solvent evaporated at room temperature in a fume hood overnight, and then freeze-dried. The wet diet was then prepared according to package instructions. The control group diet was treated with methanol.

Acute Toxicity Tests. Spodoptera exigua (Hubner) were raised on insect diet to the pharate fifth stage. Maintenance of a regular dark–light schedule during rearing allowed the selection of large experimental groups which molted during the same hour of the day. Prior to each experiment, over 250 larvae were chosen at the third-instar stage and placed on fresh diet. After reaching the pharate fifth stage, just before their expected molt, a group of pharate fifth-instar larvae with an average weight of 75 mg ± 10 mg were selected for each experiment. A preliminary test on a group of such larvae determined their dry weight–wet weight ratio. The proportion of gut contents to whole body weight in larvae 24 hr after their molt into the fifth instar was also determined in another

preliminary experiment by placing larvae eating artificial diet on diet dyed a different color and collecting their frass until its color changed.

Just before molting, as described above, pharate fifth larvae were placed on artificial diet containing a simple β-carboline (prepared as above). Individual larvae were weighed, placed in plastic cups with over 500 mg prepared diet, and allowed to eat ad libitum for 24 hr. This time period was chosen as representative of a short-term exposure because the greatest amount of food is eaten during the final instar. Larvae in the control group would often enter the prepupal stage within 48 hr, so a shorter time frame was chosen. Initial larval weights and amount of diet were measured. After 24 hr, their individual wet weights, the separate dry weights of leftover food, and the dry weights of their frass were measured. The collective dry weight of each treatment group was obtained to determine the average ratio of larval dry weight to wet weight. The initial proportion of dry to wet weight of the food was determined. These data, plus the assumptions that (1) the gut contents of pharate larvae are empty and (2) the average proportion of the dry weight of gut contents in larvae 24 hr into the fifth instar remains constant, were used to determine growth and consumption indices.

Approximate digestibility (AD), efficiency of conversion of ingested food (ECI), and efficiency of conversion of digested food (ECD) were determined as described by Waldbauer (1968), and the mean relative growth rate (RGR) was based on Radford (1967). Dry weight measurements were used. The initial weight was a predetermined percentage of the wet weight based on the preliminary study described above. The final weight used in determinations was the dry weight of the larva minus the predetermined percentage determined for gut contents. The mean relative consumption rate (RCR) was measured as RGR/ECI. The expected 24-hr growth rate of fifth-instar experimental larvae given their consumption rate was compared with a consumption rate versus growth rate calibration curve determined for the stock colony (Griswold, unpublished).

Chronic Toxicity Studies. A study using a control group and a group fed a 500 μg/g harman-treated diet began with pharate third-instar larvae and continued 144 hr, when most of the control group was well into the fifth instar. Their initial proportion of dry weight to wet weight was determined by a selection of larvae as described above for the pharate fifth-instar tests. RGR, RCR, AD, ECI, and ECD were determined.

Experiments were conducted on larvae raised entirely from birth on treated diets. The larvae were placed on diets with different concentrations of a compound. Harman and harmine were chosen for investigation. Two neonates were reared per cup until the second instar, at which time the smaller of the two was removed. Fresh, treated diet was administered by day six. Larval weights were measured eight days after hatching. Larval weights were compared using an analysis of variance between the groups of each experiment, then a nested anal-

ysis of variance between experimental replications. In addition, the number of days until adult emergence, and the number of abnormalities in pupal and adult formation were noted.

Data shown are mean and standard deviations. Nested ANOVA was used between experimental replicates. ANOVA was conducted to include all concentrations and, when shown to be significantly different, each group was compared with the control by means of Dunnett's (1955) multiple comparison test, except for the pharate third-instar experiment which was analyzed using the Student's t statistic because there were only two groups. Confidence limits for percentages are based on the binomial distribution (Rohlf and Sokal, 1981).

One hundred micrograms per gram equals 0.01% wet weight. Molecular weight harman = 182.22 g/mol, 100 μg = 0.54 mM/kg wet weight diet; molecular weight harmine = 212.25 g/mol, 232 μg = 1.09 mM/kg wet weight diet.

RESULTS

Acute Exposure Studies. Groups with harman-treated diet showed significant reduction of both their relative growth rate and relative consumption rate ($P \leq 0.01$) at 5 mM/kg (0.1% wet weight) (Table 1). Groups with 5 mM/kg (0.1% wet weight) harmine-treated diet also showed reduced growth and consumption rates ($P \leq 0.01$) (Table 1). The growth rate of experimental larvae, given their reduced consumption, correlates with expected values from the growth rate–consumption rate curve. The food utilization indices, AD, ECI, and ECD, revealed no significant differences among treatment groups. Tests with harmol (5 mM/kg), harmalol (10 mM/kg), 6-methoxyharman (2.7 mM/kg), and harmaline (10.9 mM/kg) showed no significant reduction of growth rate, food consumption, or food utilization.

Chronic Exposure Tests. The analysis of the effects of harman-treated diet given to pharate third-instar larvae (Table 2) reveal reduced relative consumption rates and relative growth rates over a six-day period. Although both the RGR and RCR differed significantly from the control group ($P \leq 0.001$), there were no significant differences in the other indices.

Complete larval exposure tests (Table 3) identified larval weight differences. Nested ANOVA determined no significant differences between experimental replicates, but significant differences between chemical treatment groups. An ANOVA–linear regression analysis did not allow a linear correlation to be made, but plotted points suggest that the effective dose for 50% reduction of larval weights in eight days is less than or equal to 0.8 mM/kg wet weight (0.015% wet weight) harman and 3.8 mM/kg wet weight (0.08% wet weight) harmine. The time until adult emergence of harman treatment groups increased

by approximately one day per additional 0.55 mM/kg, a 22% increase for the 1.65 mM/kg treatment group. There was a significant difference (99% confidence level) between groups in the number of nonemergent adults in the harman treatment groups at 1.65 mM/kg (0.03% wet weight) and a significant difference (99% confidence level) in the number that did not pupate in the harmine treatment groups in experiments with dosages above 1 mM/kg (0.02% wet weight).

DISCUSSION

Harman and harmine both slow the growth rate of a generalist phytophagous insect. Harman is more potent than harmine (7-methoxyharman). Harmol, harmalol, 6-methoxyharman, and harmaline had no effect on growth rate in the amounts tested. The reduced growth rate in both long- and short-term experiments of *Spodoptera exigua* (Hubner) given diets treated with harman and harmine is due primarily to the antifeedant effect of those compounds. The results indicate that the experimental larvae reach their expected growth rate for their rate of food consumption. Additionally, food utilization analysis (ECD, ECI, AD) showed no significant difference between control and treatment groups. The six-day test with third- to fifth-instar larvae given harman-treated diet con-

firmed the differences between control and treatment growth and consumption rates. These partial dietary exposure tests do not indicate that there are any toxic effects of harman or harmine on *Spodoptera exigua* (Hubner) larvae.

The eventual maturation after sufficient biomass is reached and lack of a disproportionate number of abnormalities in the neonate treatment groups on less than 1.65 mM/kg (0.03%) harman (Table 3) also suggest that the reduction in growth is a result of a reduced food consumption rate and not a latent toxicity in smaller quantities of harman. However, increases in the number not able to pupate properly and adults with crumpled wings were seen when higher amounts of harman and harmine were consumed. The significant number of abnormalities in the harman treatment groups at 0.03% wet weight harman and in the harmine treatment groups indicates the toxicity of harman and harmine to sensitive pupal development at higher concentrations (>0.5 mM/kg, 0.02% wet weight). When a sufficient amount of harman or harmine is consumed, their potential toxicity becomes more evident. However, the profound antifeedant effect of harman precludes the complete study of this phenomenon at the gross level. Physiological studies of isolated insect metabolic systems would more clearly identify sensitive sites.

The antifeedant activity of harman is significant in that it prolongs the maturation of *Spodoptera exigua* (Hubner) up to 22% at quantities as low as 0.03% wet weight (Table 3). A longer period of development would increase the risk of exposure to other environmental dangers. The effective dose of harman to reduce larval weight at day 8 (when the control groups reached the middle of the fifth instar) by 50% (ED_{50}) is 0.015%. The ED_{50} for harmine is 0.08% wet weight. Even fifth-instar larvae show reduced RCRs and RGRs during short-term exposures at 0.1% wet weight ($P \leq 0.01$) (Table 1).

Harmine has been quantified at 0.546% dry weight in the leaves of *Banisteriopsis caapi* (Spruce) (Malpighiaceae) (Rivier and Lindgren, 1972) and in the seeds of *Peganum harmala* L. (Zygophyllaceae) at 1.05% dry weight (Hegnauer, 1973). Harman has been found in quantities of 0.15% dry weight in the leaves of *Prosopis nigra* (Leguminosae) (Moro et al., 1975) and 0.24% dry weight in *Symplocos racemosa* Roxb. (Symplocaceae) (Hegnauer, 1973). These quantities are much higher than the ED_{50} for *Spodoptera exigua* (Hubner). In addition, multiple β-carboline alkaloids are often present in the same plant. The additive antifeedant and toxic effect of multiple simple β-carbolines is probably significant in a plant's defense against generalist insect herbivory.

The data from this study indicate the potency and significance of alkaloids produced by plants in defense against insect herbivores. Some of the other plant alkaloids shown to have some antifeedant properties include *N*-methylflindersine (Chou et al., 1977), wilforine (Monache et al., 1984), vinblastine (Meisner et al., 1981), and the β-carboline reserpine (Janzen et al., 1977). The small amounts of alkaloids found in plants have long been predicted to be toxic to

insects as well as mammals, but only limited testing has been conducted to verify this. Research has been focused on plant secondary metabolites found in higher quantities in plants. All ecological investigations should compare the potency of secondary metabolites with actual quantities present in plants. Low ED_{50} levels of alkaloids may show them to be more significant in protection from insect herbivory than previously considered. The small amounts of alkaloids found in plants relative to other secondary plant metabolites should not deter researchers from conducting insect toxicity or antifeedant tests.

Acknowledgments—J.C. appreciates financial support from the Regents Dissertation Fellowship and the Chancellor's Patent Fund at UCI. We thank Margot Griswold for use of the growth rate-consumption rate calibration curve of *Spodoptera exigua* (Hubner) in the UCI colony.

(Received December 1, 1986; accepted February 27, 1987)

Abstract—Females of *Myelois cribrella* contain about 20 ng/gland of the primary sex pheromone components (*Z*)-9-tetradecenyl acetate, (9*Z*,12*E*)-9,12-tetradecadienyl acetate, and (*Z*)-11-hexadecenyl acetate in proportions of 4:11:5, respectively. These physiologically active components are accompanied by a number of related compounds such as (*Z*)-9-tetradecen-1-ol, hexadecyl acetate, (9*Z*,12*E*)-9,12-tetradecadien-1-ol, (*Z*)-11-hexadecen-1-ol, octadecyl acetate, octadecan-1-ol, and eicosyl and docosyl acetates. Octadecyl acetate, the most abundant component, represents about 42 ng/female moth; however, no physiological activity could be attributed to it. In field tests, a trap baited with a 1-mg mixture of (*Z*)-9-tetradecenyl acetate, (9*Z*,12*E*)-9,12-tetradecadienyl acetate, and (*Z*)-11-hexadecenyl acetate in a ratio of 1:2:1 caught more male moths than three live female moths.

Key Words—*Myelois cribrella*, sex pheromones, Lepidoptera, Pyralidae, solid-sample injection, (*Z*)-9-tetradecenyl acetate, (9*Z*,12*E*)-9,12-tetradecadienyl acetate, (*Z*)-11-hexadecenyl acetate.

INTRODUCTION

Myelois cribrella Hübner (Lepidoptera: Pyralidae) belongs to the pyralid subfamily Phycitinae and is widely distributed in central and southern Europe

[1] Pheromones, 58. Pheromones, 57: Bestmann et al. (1987).
[3] Present address: Department of Biology, Peking University, Beijing, P.R. China.

0098-0331/88/0200-0485$06.00/0

including Great Britain and Asia. The distribution area includes Syria, Armenia, the Altai Mountains, and Japan (Leraut, 1980; Staudinger and Rebel, 1901). The adults of this nocturnal moth appear from the second half of June until the beginning of August. The larvae feed in late summer on heads of thistles and, in central Europe especially, on *Cirsium vulgare* (Savi) Ten., *Cirsium eriophorum* (L.) Scop., *Carduus nutans* L., and *Onopordum acanthium* L. In autumn, the larvae burrow into the thistle stems, make large galleries in the pith and hibernate in the stems as nearly full-grown larvae. In spring, they cut circular exit holes and pupate in the larval galleries (Beirne, 1954; Hasenfuss, 1960).

Many members of the subfamily Phycitinae are known as pests. The pheromones of a number of them, especially of those considered as stored-product pests, have been identified (Arn et al., 1986). The species *M. cribrella*, nevertheless, is not mentioned as a pest, and no information was available on its female sex pheromone. Here, we describe the characterization of its pheromone and formulation of a specific lure for the field attractancy tests.

METHODS AND MATERIALS

Insect Material. Myelois cribrella specimens were collected as pupae from dead stems of various thistles found on a hill in the vicinity of Erlangen (Bavaria, Germany). The pupae were sexed, placed in plastic boxes containing moist sawdust, and maintained under a reversed 15 : 9 hr light–dark cycle. After emergence, the females were observed carefully during the scotophase under a red lamp to observe the calling behavior and period.

Gas Chromatography. Capillary gas chromatography with flame ionization detection was performed on a Packard-United Technologies 438A instrument equipped with a splitless injector and a Shimadzu Chromatopack C-R3A data system. The "pheromone glands" of 2- to 4-day-old female moths were excised during the period of maximum calling, encapsulated in soda glass capillaries, and injected into the GC according to the solid sampling technique described by Attygalle et al. (1986). Columns and temperature programs were: (1) fused-silica capillary column (FSCC) SP-2340 (25 m × 0.22 mm), 2 min at 60°C, 60–195°C at 4°C/min; and (2) FSCC CP-19 (chemically bonded phase, 12 m × 0.2 mm), 2 min at 60°C, 60–270°C at 10°C/min.

Gas Chromatography—Mass Spectrometry. A Finnigan 9502 gas chromatograph, fitted with a Grob-type split–splitless injector and a solid sampler (Morgan and Wadhams, 1972; Attygalle et al., 1986), linked to a Finnigan 3200E quadrupole mass spectrometer with a Data System 6000 was used: Columns and temperature programs were (3) FSCC SP-2340 (25 m × 0.22 mm), 4 min at 60°C, 60–195°C at 6°C/min, splitless injection via a solid sampler, split-vent kept closed for 1 min.

Electrophysiology. Simultaneous flame ionization and electroantennographic detection (FID and EAD) was performed by splitting the gas chromatographic effluent and directing the major part over a male antenna (Struble and Arn, 1984; Arn et al., 1975). By means of implanted capillary electrodes on the antenna, the retention times of physiologically active compounds present in the effluent were determined.

Electroantennograms and recordings from single sensilla trichodea were made on excised antennae of males according to the method described by Kaissling (1974). Glass tubes containing a strip of filter paper (20 × 7 mm) on to which a known amount of a given test substance had been pipetted as a hexane solution, were used as odor sources. The receptor potentials (DC recording) and the spike pattern (AC recording) evoked by several test compounds were registered (single-cell recording, electrosensillogram, ESG) by "puffing" air over an odor source onto the antenna. Similarly, the EAG amplitudes evoked by a large number of pheromone and pheromone-like chemicals available in our laboratory were measured. Among the test compounds were all those chemicals already known as pyralid sex pheromones (Arn et al., 1986; Tamaki, 1987; Bestmann and Vostrowsky, 1980).

Chemicals. All the chemicals used in this study were from our laboratory collection of pheromones. [For the synthesis of the substances used in this study, see Bestmann and Vostrowsky, (1979).]

Field Tests. The attraction of male moths to different formulations of test substances was investigated in the hills near Ebermannstadt (Bavaria, Germany) in July 1986. The traps used were obtained from Hoechst AG, Frankfurt (Biotrap).

The bait chemicals were dispensed from short pieces of rubber tubing (3 cm × 12 mm OD, 8 mm ID) suspended 3 cm above the sticky bottom (9.5 × 25 cm). Virgin female moths (2 to 3 days old) used to bait traps were caged in a small mesh container and positioned the same way as the chemical baits. The traps were hung randomly, about 1 m above the ground in a line at a right angle to the predominant wind direction.

RESULTS AND DISCUSSION

Analysis of Gland Volatiles. Under our laboratory conditions *M. cribrella* showed maximum calling activity ca. 6–7 hr after the onset of the scotophase. During the calling period, which lasts for about 30 min, the abdomen of the insect curves upwards and the ovipositor is extruded, thus exposing the intersegmental glandular membrane between the segments VIII and IX (Figure 1). This type of calling behavior is typical for most members of Phycitinae (Krasnoff et al., 1983).

Different parts of the abdominal tip of 3-day-old female moths were excised

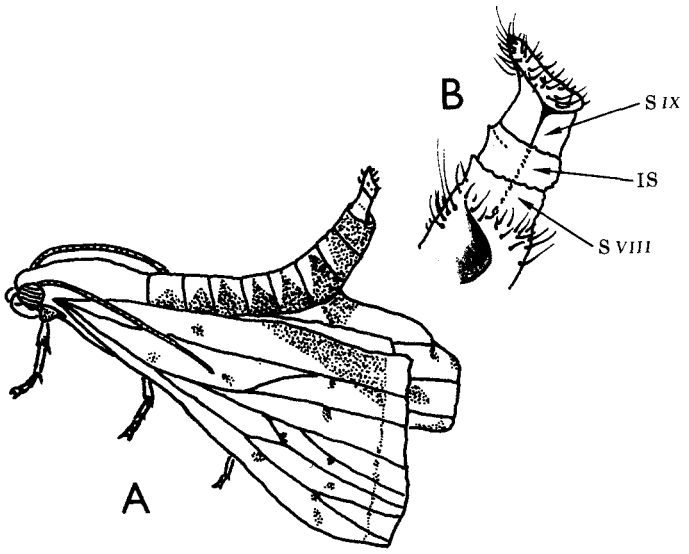

FIG. 1. (A) Female *M. cribrella* showing the characteristic calling behavior. (B) Detailed illustration of the abdominal tip. SVIII, 8th abdominal segment; SIX, 9th segment; IS, intersegmental membrane.

during the calling period and analyzed by GC via a solid-sample injection technique (Attygalle et al., 1986). Pheromone-like substances were found only in the intersegmental membrane between the segments VIII and IX (Figure 2A). For example, the membrane between the segments VII and VIII contained only hydrocarbons as volatile constituents (Figure 2B). A comparison of the two chromatograms, as shown in Figure 2, facilitated the identification of the hydrocarbon peaks in the upper profile.

The identification of the chromatographic peaks was achieved by comparison of retention times with those of authentic samples. The polar stationary phase SP-2340 used in this investigation is able to resolve most of the positional and geometrical isomers of unsaturated compounds found as lepidopteran pheromones (Heath and Tumlinson, 1984). Further confirmation was provided by combined gas chromatography–mass spectrometry. Figure 3 shows a reconstructed gas chromatogram (RGC) and several mass chromatograms obtained by subjecting female glands to GC-MS analysis. The amount of material from five glands was sufficient to obtain complete EI mass spectra of pheromone-related compounds. The mass spectra were compared by the method of Horiike and Hirano (1982) with those from a series of candidate compounds to establish the correct identity.

Acetates usually give a characteristic ion at m/z 61 due to protonated acetic

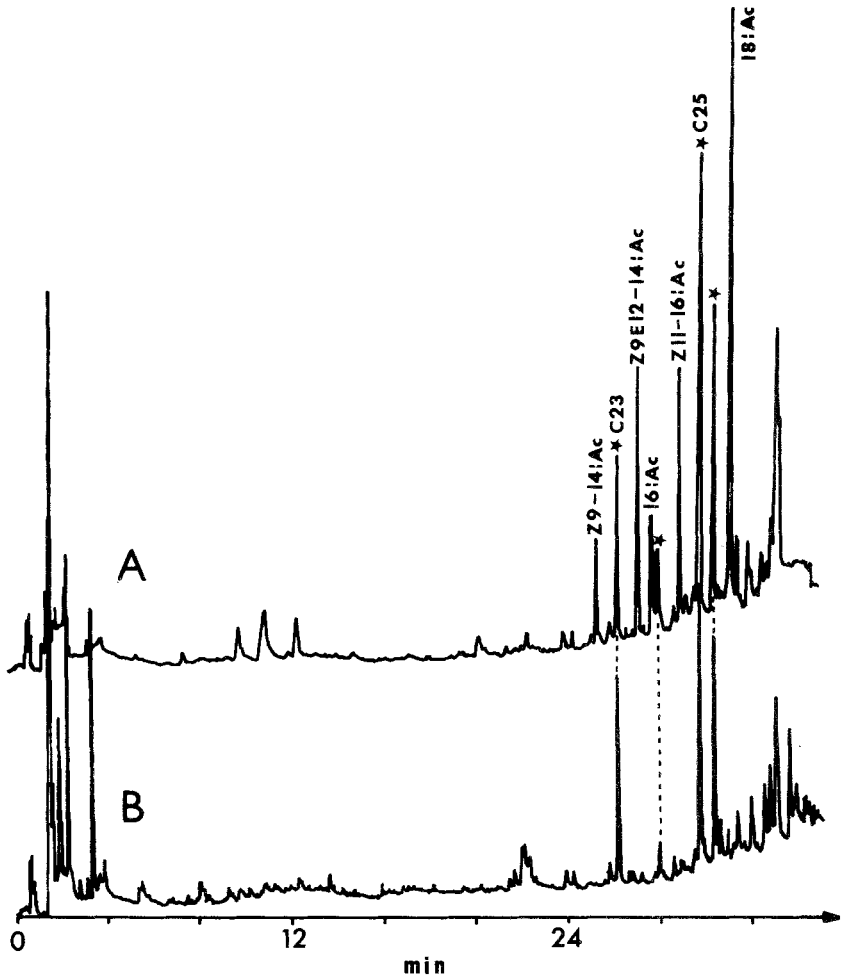

FIG. 2. Gas chromatograms obtained from the volatiles of the intersegmental membranes (A) between the abdominal segments VIII and IX, and (B) between the segments VII and VIII. The samples were introduced via a solid-sampling technique onto a 25 m × 0.22 mm FSCC coated with SP-2340. The oven temperature was held at 60°C for 2 min and programmed to 195°C at 4°C/min. The hydrocarbon peaks are marked with a star. See Table 1 for abbreviations.

acid ($CH_3COOH_2^+$). This ion was used to recognize the acetate peaks in the RGC. The mass chromatogram for *m/z* 61 has eight maxima indicating peaks 2, 5, 7, 8, 13, 17, 21, and 24 were acetates. This evidence in combination with a systematic search for the corresponding M^+-CH_3COOH ions, indicated the

FIG. 3. presence of one isomer each of tetradecenyl, tetradecadienyl, hexadecyl, hexadecenyl, octadecyl, octadecadienyl, eicosyl, and docosyl acetates. Similarly the ion *m/z* 31 was used in conjunction with that due to M^+-H_2O to identify the primary alcohol peaks.

The volatile compounds identified from the gland are summarized in Table 1. Components were quantified by using a solution of *Z*11-16:Ac as an external standard. The total content of acetates and alcohols in the gland was 77 ng/female, of which octadecyl acetate, the major component, represented 42 ng.

Electrophysiological Studies. Although about 11 pheromone-like compounds are present in the gland, only three EAG signals were obtained when a

gland was subjected to GC-EAD. These three EAG signals appeared at retention times corresponding to those from Z9-14:Ac, Z9,E12-14:Ac, and Z11-16:Ac.

Of a number of mono- and diunsaturated acetates, alcohols, and aldehydes, known as phycitine sex pheromone components, Z9,E12-14:Ac evoked the highest amplitude when EAG recordings were performed. This tetradecadienyl acetate isomer is the main component of the pheromone complexes of *Cadra cautella*, *C. figulella*, *Ephestia elutella*, *E. kuehniella*, *Hypsipyla robusta*, and *Plodia interpunctuella* (all Phycitinae, see reviewing literature, Arn et al., 1986; Tamaki, 1987).

By single-cell recordings (ESG), two sensory cells specifically responding to Z9,E12-14:Ac and Z9-14:Ac were found in the sensory hairs. Cells with large spike amplitudes were activated by Z9,E12-14:Ac, and cells with small spike amplitudes by Z9-14:Ac.

Field Trials. Based on analytical and electrophysiological results, a series of baits were prepared and tested in the field for attractancy. The results are summarized in Table 2. The traps baited with a blend of Z9-14:Ac (250 μg),

13	3 Virgin Females						12
14	Blank					0	
15	Blank						0

[a]The traps 6, 7, and 8 captured four, five, and nine males of *Isotrias hybridana*, respectively. The field trials were carried out in the hills near Ebermannstadt, Oberfranken, Bavaria.

*Z*9,*E*12–14 : Ac (500 μg), and *Z*11–16 : Ac (250 μg) were successful in capturing numbers of males similar to those baited with virgin females. Trap 8 captured 31 males of *M. cribrella* in two nights. Although some traps baited with this formulation were even superior to those baited with virgin females, we must not forget that the female moths were calling males only for a short period of time during the night, whereas the synthetic baits were attractive throughout the day and night. Furthermore, the microenvironment of a trap is known to play an important role; however, in practice it is impossible to provide the same microenvironment to all the traps. It was interesting to find that baits composed of one or two components only, and those with *Z*9–14 : Ac, *Z*9,*E*12–14 : Ac, and *Z*11–16 : Ac in 1 : 2 : 2 and 1 : 1 : 2 ratios did not trap any males. By examining the genitalia of the trapped moths, it was found that exclusively males of *M. cribrella* had been caught in traps 6, 7, and 8. In addition, traps 6, 7, and 8 also captured a few males of a tortricid, *Isotrias hybridana.* For this species, it is already known that a 1 : 1 mix of *Z*11–16 : Ac and *Z*9–14 : Ac make an attractive formulation (Szöcs et al., 1983). However, no *Isotrias* males were found in the trap (No. 13) with virgin females of *M. cribrella.*

(Received September 1, 1986; accepted February 28, 1987)

Abstract—Ten volatile compounds derived from the cephalic glands of the fire bee *Trigona (Oxytrigona) mellicolor* were bioassayed for possible allomonal activities facilitating nest plundering. Two diketones, (*E*)-3-heptene-2,5-dione and (*E*)-3-nonene-2,5-dione, caused the honeybee *Apis mellifera* to display avoidance behavior and reduced defensive behavior. These diketones are produced in relatively large quantities in fire-bee cephalic glands.

Key Words—Fire bee, *Trigona (Oxtrigona) mellicolor*, *Trigona (Oxtrigona) tataira*, honeybee, *Apis mellifera*, Hymenoptera, Apidae, mandibular gland secretion, allomone, nest plundering, diketones, (*E*)-3-heptene-2,5-dione, (*E*)-3-nonene-2,5-dione.

INTRODUCTION

The exocrine secretions of stingless bees in the genus *Trigona* possess varied functions in the chemical ecology of these apids. *T.* (*Oxytrigona*) *mellicolor* produces a remarkable mandibular gland secretion (Kerr and Costa Cruz, 1961) which causes blistering lesions of up to 2 cm in diameter, over four times the length of the bee which inflicted it, when applied to the skin of humans (Wille, 1961; T.E. Rinderer, field observation). The pain caused by such lesions, in combination with the reddish-orange color of *T. mellicolor*, explains why the bee is frequently called the fire bee.

The fire bee is also remarkable for its ability to remove honey from the nests of honeybees (*Apis mellifera*) imported from both the palearctic and Ethiopian realms (Moure, 1946; T.E. Rinderer, field observation). During nest plundering, the fire bee produces a cephalic secretion which has a strong but, to humans, pleasant floral odor (Moure, 1946; Bian et al., 1984). Yet, during a nest-plundering episode, honeybees do not defend their nest but remain motionless on the comb, hang in a cluster of bees outside the entrance of the colony, or appear to "wander" in a seemingly disorientated manner over the surface of the comb. Cephalic extracts contain a variety of compounds that we were interested in evaluating as potential allomones that might facilitate nest plundering. This report describes the results of a honeybee bioassay to determine the allomonal activities of the components of fire-bee cephalic secretions identified by Bian et al. (1984).

METHODS AND MATERIALS

Assay for Primary Effects. Thirteen observation-hive colonies were prepared from established field colonies in Baton Rouge, Louisiana. These colonies were derived from sister queens of general European commercial stock that were permitted to open-mate from the same apiary. Each observation-hive colony contained the original queen, about 0.25 kg (2500) of her adult worker bee daughters, one brood comb (16 × 45 cm) containing the queen's worker brood (about half sealed and half unsealed) and one comb (16 × 45 cm) half-filled with honey and pollen. The observation hives were then left undisturbed for four days to allow them to return to normal organization and regulation (egg laying, colony defense, foraging, etc.).

Ten chemicals [(*E*)-3-nonene-2,5-dione, or (*E*)-3-n, (*E*)-3-heptene-2,5-dione, or (*E*)-3-h, 3-hepten-2-one, dodecyl acetate, 2-decanone, tetradecyl acetate, hexadecyl acetate, pentadecane, 2-heptanone, and tetradecane] found in fire-bee cephalic gland secretions and synthesized commercially or in our laboratories (Bian et al., 1984) were prepared separately as 1:500 dilutions by

weight in paraffin oil. Additionally, a mixture containing equal proportions of each by weight was prepared as a 1:500 dilution by weight in paraffin oil. In the bioassay, the diluted compounds were presented to the observation-hive colonies as 0.5 ml of solution in 7 × 11-mm "sleeve-type" rubber septa. Two control treatments were incorporated into the design: rubber septa with no added materials and rubber septa containing 0.5 ml of paraffin oil.

The effects of the 13 treatments (exposure to 10 compounds, a mixture of the 10 chemicals, and two controls) were tested in a randomized Latin-square design with the 13 colonies. The tests were conducted on 13 consecutive days, each rain-free and with similar temperatures (ca. 30°C).

For each test, a rubber septum was held in a firm steel wire loop, filled with 0.5 ml of the appropriate solution, and inserted from the top of the hive to the center area of one side of the brood comb. Prior to the test, this side of the observation hive was fitted with a standard grid to facilitate later measurements. After 2 min, the septum was withdrawn and the number of stings implanted in it was counted. The entire procedure was recorded on video tape for later evaluation. The maximum diameter (measured through the center of the top surface of the septum) of the area surrounding the septum that had no bees at the end of the 2 min was measured using the grid image to standardize measurements. Ten seconds after the septum was in place, the reaction of the first bee to approach the vial was observed and recorded. Such reactions were observed for a total of 10 bees identified at 10-sec intervals. Reactions included, from the least defensive to the most defensive: (1) rapidly withdrawing from the area, (2) slowly withdrawing from the area, (3) remaining in the area, (4) investigating the septum, (5) "buzzing" wings in response to the septum or its contents, and (6) attacking the septum either by biting or stinging it.

Bee responses were converted to a composite defensive scale by summing the numerical values (1 through 6) of the responses of the 10 bees and then rank-transforming the 169 sums (Conover and Iman, 1981).

These scores, the numbers of stings, and the diameters of areas without bees surrounding the septa at the end of the tests, were submitted to analyses of variance according to the Latin-square design for the main factors of chemicals, days, and colonies. Videotaping errors resulted in a few missing cells for defensive behavior and diameter of area. These missing cells were estimated using the method of Steel and Torrie (1980). The error degrees of freedom were reduced appropriately to reflect the number of observed values. Mean separation evaluations were based on Duncan's multiple-range tests.

Additional information was obtained by ranking the responses to the independent variables for each dependent variable. These ranks were then analyzed with a Friedman two-way analysis of variance in order to test the null hypothesis that the independent variables had generally similar effects for the three dependent variables in the analysis (Siegel, 1956).

Assay for Synergistic Effects. Seven additional observation-hive colonies were prepared and tested in a 7 × 7 Latin-square design by the procedures described for the first experiment. Based on the results of the first experiment, seven chemicals and mixtures were used; (1) (*E*)-3-n, (2) (*E*)-3-h, (3) 3-hepten-2-one, (4) a mixture of 1 and 2, (5) a mixture of 1 and 3, (6) a mixture of 2 and 3, and (7) a mixture of 1, 2, and 3.

RESULTS

Primary Effects. Significant and consistent trends were revealed by the analysis (Table 1). Two of the dependent variables, the number of stings in the septum and the intensity of the defensive responses, differed significantly among

TABLE 1. HONEYBEE RESPONSES TO FIRE BEE CEPHALIC COMPOUNDS[a]

Treatment	*N*	Diameter (cm) of comb area cleared of bees	Number of stings	Defensive scale

Colonies	12	3.07	0.0005	4.14	0.0001	3.96	0.0001
Sampling	132 (128)[b]						

[a] Average diameter of an area without honey bees surrounding an empty septum, a septum containing paraffin oil, a septum containing paraffin oil with each of ten chemicals, or a septum containing paraffin oil and all 10 chemicals; average number of stings delivered to the septa containing the treatments; average indexes of graded defensive responses (explained in text). For each dependent variable, values are significantly different if not followed by the same letter as determined by Duncan's multiple-range tests. Each set of statistical values from the analysis of variance in the lower part of the table is for the column above.

[b] Sampling df for number of stings and (diameter and defensive scale).

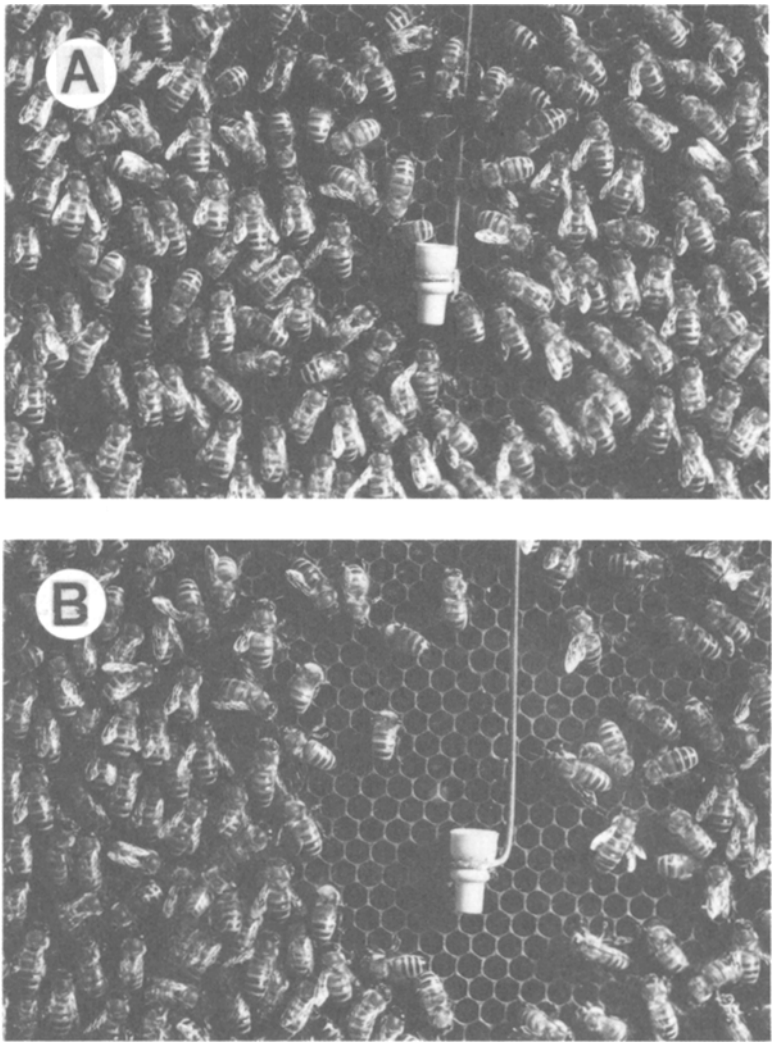

FIG. 1. (A) Area surrounding rubber septum containing paraffin oil vacated by bees. (B) Area surrounding rubber septum containing (*E*)-3-nonen-2,5-dione vacated by bees. Both A and B are responses after 2 min.

treatments, days, and colonies. The diameter of the area vacated by bees differed among treatments and colonies.

Analysis of the differences among treatments by Duncan's multiple-range tests identified strong allomonal activities by (*E*)-3-n and (*E*)-3-h. These two compounds cleared an area with a significantly larger diameter than was cleared by the other treatments (Figure 1). Also, of all the remaining treatments, the

mixture of compounds (which contained these two, but at one tenth the concentration) was most similar to them. Additionally, the septa containing these two compounds received the fewest numbers of stings, and the septa containing the mix of compounds received the next fewest. These three treatments also provoked the least intense defensive responses as measured by the defensive scale.

The Friedman two-way analysis of ranks confirmed the consistent effects of the two unsaturated diketones and the mixture containing them ($X_r^2 = 152.12$, $df = 12$, $p = 0.001$). (*E*)-3-n and (*E*)-3-h and the mixture of compounds had combined ranks of 6, 6, and 7, respectively. The next closest grouping was hexadecyl acetate and pentadecane with combined ranks of 13 and 14. The remaining treatments had combined ranks of 22–35.

Synergistic Effects. No significant or even suggestive differences were found to support the hypothesis that synergistic effects are elicited by mixtures of these compounds.

DISCUSSION

Generally, the chief honeybee response to the diketones was negative chemotaxis. Reductions in stinging and defensive behavior most probably stem from this negative chemotactic response rather than a second specific response. The reactive nature of the diketones (Michael addition) suggest that they may function as irritants, especially to sensitive antennal chemoreceptors.

The diketones also may have an important role in the defensive secretion of *T. mellicolor*. When added to the formic acid in this secretion (Roubik et al., 1987), the diketones may increase its ability to produce burning sensations and blistering either by increasing its solubility in epidermal lipids or facilitating nucleophilic additions by protonation of the carbonyl groups.

The possible roles of the diketones in both nest robbing and colony defense suggest that the existence of one behavioral potency made possible the evolution of the other. *T. mellicolor* has often been observed robbing the nests of *Apis mellifera* but not the nests of sympatric neotropical bees (Roubik et al., 1987). This simply may be a consequence of *A. mellifera* nests being more easily observed. However, *A. mellifera* lacks the elaborate entrance structure typical of neotropical stingless bee nests. Perhaps the importation of *A. mellifera* to the Americas provided a novel opportunity for the development of *T. mellicolor* nest plundering of comparatively unprotected nests. The possibility exists that nest plundering is a simple extension of other foraging-related behavior. Perhaps *T. mellicolor* has expanded the use of its nest-defense secretions to repel competitors from rich floral patches. If so, the use of the secretions in plundering the nests of recently introduced honeybees would be a further expansion of an already existing behavior.

Because the two diketones are so effective at repelling honeybees, they may have desirable commercial uses. Formulations may be developed to remove bees from hive chambers prior to honey harvesting or to reduce the incidence of persons being stung while handling bees.

Acknowledgments—We thank Robert Spencer for excellent technical assistance and an anonymous reviewer for especially useful suggestions.

(Received December 31, 1986; accepted March 3, 1987)

Abstract—The ability of cotton-top tamarins to discriminate between scents from conspecifics and those from other tamarin species, and between scents from conspecific individuals was tested. Cotton-tops scent mark with specialized skin glands in the circumgenital area. Females possess larger glands than males and show more scent-marking behavior. In the first experiment, subjects were presented with a glass rod scented with either material collected from the surface of the scent glands of a conspecific female, with scent material from a female of a related species, or with an unscented rod. Glass rods carrying scent from conspecifics were sniffed more frequently than rods carrying scent from related tamarin species or unscented rods. A second experiment offered a choice between two glass rods, one scent marked by a *Saguinus o. oedipus* female, the second one scent marked by a *Saguinus fuscicollis* female. Shelves carrying rods that had been scent marked by conspecifics were contacted more frequently than those carrying rods marked by heterospecific females. Scent marks from conspecific females were also sniffed more frequently. A third experiment compared the level of responses to rods carrying material collected from the scent glands of female individuals to which the subjects had been habituated with their responses to rods carrying scent from females to which they had not been habituated. Contacting and sniffing responses to the scents of novel females were higher than those to the scents of females to which the subjects had been habituated.

Key Words—Primates, callitrichids, scent marking, chemical communication, chemical signals, odor discrimination, cotton-top tamarin, *Saguinus oedipus oedipus*.

INTRODUCTION

In the South American callitrichid monkeys, chemical signals appear to play an important role in social communication. The small body size (180–800 g body weight) and the highly arboreal way of life (Hershkovitz, 1977) may have favored the use of chemical communication in these marmosets and tamarins. All species possess specialized scent glands and show a variety of scent-marking behaviors whose complexity rivals that seen in prosimians (Epple et al., 1986; Schilling, 1979). Scent-marking behaviors and their social contexts have been studied in a number of callitrichid species. These studies, recently reviewed by Epple et al. (1986), indicate that marking behavior and the signals deposited in this manner play important roles in a number of sexual and social interactions, among them pair bonding, infant–caregiver relationships, intergroup spacing, and intragroup dominance interactions.

Some of our own work has concentrated on the signal content and the chemical composition of the scent marks of the saddle-back tamarin (*Saguinus fuscicollis*).[1] We have shown that the scent marks of this species communicate the identity of species, subspecies, gender, and individual. Information on the endocrine condition and dominance status of males and on the age of the scent material also appears to be encoded in the marks (Belcher et al, 1986; Epple et al., 1979). The major volatile constituents of the scent marks, squalene and 15 esters of *n*-butyric acid, may be involved in encoding some of the messages listed above (Smith et al., 1985), although they are not the sole carriers of the communicatory information (Belcher et al., 1986).

The present paper reports on the first in a series of studies on the communicatory content and the chemical composition of the scent marks of another callitrichid monkey, the cotton-top tamarin, *S. o. oedipus*. The goal of these studies is a comparison of the behavioral and chemical aspects of scent communication in two closely related species. This may result in the detection of phylogenetic principles of encoding communicatory signals by means of chemical compounds in this primate family.

The morphologic appearance of the circumgenital scent gland of *S. o. oedipus* is similar to that of *S. fuscicollis*. The gland involves the labia majora in the female, the scrotum in the male, and extends into the suprapubic area as a pair of pubic cushions divided by a slight median sulcus (Perkins, 1969). It is deeply pigmented, slightly raised, and relatively hairless. According to our own observations, the perineal area also appears to be part of the glandular complex (Epple, unpublished). In the cotton-top tamarin, the gland is sexually dimorphic, being much larger in the female (Perkins, 1969). As in *S. fuscicollis* (Perkins,

[1]The genus *Saguinus* will be abbreviated (*S.*) in the remainder of the paper.

1966), it consists of an accumulation of holocrine and apocrine glands which are more numerous and more complex in the female (Perkins, 1969).

Cotton-top tamarins show two distinct patterns of scent marking as described by French and Snowdon (1981). Anogenital marking is performed in a sitting position ("sit rubbing," Moynihan, 1970) and results in the application of glandular secretion, urine, and perhaps genital discharge and fecal residues (French and Snowdon, 1981). Suprapubic marking ("pull rubbing," Moynihan, 1970) results in the application of skin secretions and other material adhering to the suprapubic part of the glands as the animals, assuming a sprawling position, rub this portion of the gland across the substrate. Both scent-marking patterns are much more frequenctly performed by females than by males (French and Snowdon, 1981; Wolters, 1978).

In the course of the present study, we tested the ability of the monkeys to discriminate among scents from closely related tamarin species and between scents from conspecific individuals. The pronounced sex differences in the structure of the scent glands and in the scent-marking behavior make it difficult to obtain scent material from males. Therefore, this study has used female cotton-top tamarins as scent donors.

METHODS AND MATERIALS

Housing and Maintenance. All cotton-top tamarins used as subjects lived as permanently cohabiting male–female pairs. Females of other tamarin species, which were used as donors of scent material, lived either in pairs or as breeding females in small families.

The animals were housed in stainless-steel mesh cages. The cages varied in size between 150 × 80 × 130 cm and 300 × 80 × 130 cm, depending on the number of animals in the group. The cage floors were located 85 cm above the floor of the rooms. All refuse fell out of reach of the monkeys and was collected on paper. All cages consisted of several interconnected compartments, each measuring 50 × 80 × 130 cm. They were equipped with wooden sleeping boxes, natural branches, and wooden resting shelves. All compartments were available to the animals most of the time. By inserting a sliding door made from stainless-steel mesh, it was possible to divide each cage into subunits, and temporarily separate an animal from its group mates for testing or scent collection without causing alarm or stress responses.

Each pair of cotton-top tamarins shared a small colony room with one or two groups of *S. fuscicollis*, but none of the colony rooms contained more than one pair of *S. o. oedipus*. The monkeys had no visual contact with tamarins belonging to other groups. However, even conspecific groups housed in different colony rooms exchanged calls, and the animals could probably smell other

monkeys in the colony. The animal rooms were maintained at a temperature of 26°C and 50% relative humidity. The rooms were lighted by means of fluorescent light for 12 hr a day. Infrared bulbs suspended over a shelf in the cage provided dim light during the night and an area of warmth which the animals prefer during periods of resting.

The monkeys received a mixed diet consisting of fruits, vegetables, small amounts of cooked meat, dairy products, monkey chow, and several types of cereal, supplemented with vitamins and minerals.

Subjects and Donors. Seven pairs of cotton-top tamarins were available. One of the males did not participate in the study because of his chronic bad health. With the exception of two females, all of the subjects participated in all three experiments. One female did not participate in experiment 1, the second female did not participate in experiments 2 and 3. Five of the *S. o. oedipus* female subjects, eight *S. fuscicollis* females, and three *S. l. labiatus* females served as donors of scent. None of the *S. o. oedipus* females was used as a scent donor for tests in which she or her male served as a subject.

Stimulus Materials and Scent Collection. The ability of the cotton-top tamarins to discriminate among different tamarin species and between conspecific individuals on the basis of scent was tested in three experiments. Natural scent marks and material collected from the surface of the circumgenital scent gland were offered as stimuli. Statistically significant differences in the responses of the tamarins to different scent types were interpreted as proof that the animals could discriminate among the stimuli.

Natural scent marks and material from the surface of the gland were collected on frosted glass rods. These rods were made by closing one end of a frosted glass tube (10 x 1.5 cm) to form a round smooth top. Between uses, the glass rods were cleaned in a chromic–sulfuric acid solution, rinsed with distilled water, followed by methanol and methylene chloride, and air-dried.

The glass rods could be inserted into holes drilled into heavy wooden shelves, and in this way mimicked small protruding twigs. The animals prefer to scent mark small protruberances and could be trained to mark these "glass twigs." After an extended period of training, all natural scent marks could be collected within a few minutes and used for testing immediately. To collect scent marks, clean glass rods were inserted into the holes of the wooden shelves and were removed immediately after the donor animals had scent marked them. The material collected in this way from cotton-top tamarins consisted almost exclusively of anogenital marks, since suprapubic marking was extremely rare. *S. fuscicollis* often combines anogenital and suprapubic marking, and some of the scent material collected from this species resulted from combined marking patterns (Epple et al., 1986).

At the start of the project, i.e., before the tamarins were trained to donate natural scent marks, material adhering to the surface of the gland was used as

stimulus scent. To collect this material, all donors were trained to allow their scent gland to be rubbed with the glass rod while receiving a reward. For this purpose, the clean glass rod was gently wiped over the whole surface of the gland. Each collection was completed within a few minutes. The material collected in this manner probably consisted of a mixture of glandular secretions, urinary residues, genital discharge, and environmental contaminants.

Scent Discrimination Tests. All subjects were housed and tested in cages consisting of five compartments. Three of the compartments were equipped for testing. In addition to natural branches, level wooden shelves ($7 \times 7 \times 80$ cm), which served as sample carriers, were suspended between the back and the front of the cages at a height of 65 cm above the cage floor. Each shelf was equipped with a hole into which a glass rod containing the scent sample could be inserted.

In experiments 1 and 3, only a single sample was presented to the animals. Therefore, only one sample carrier was present in the center of the testing area. In experiment 2, choice tests offering two samples were conducted. For these tests, the right and left compartments of each testing area contained one sample carrier while the center compartment did not contain a carrier. The wooden sample carriers were part of the permanent cage equipment. The cages and their equipment were washed in a cage washer at least once a month using hot water but no detergent.

The animals were allowed to use all five compartments when no tests were performed. During each test, the subject was confined to the three testing compartments, while its mate remained in the other part of the home cage. The duration of each test was 10 min for experiments 1 and 2 and 15 min for experiment 3. The total testing time was divided into intervals of 5 sec, indicated by an audible signal.

Three behavioral responses were recorded. (1) Contacting the wooden sample carrier: any physical contact with the surface of the shelf carrying the glass rod containing the sample; (2) sniffing the glass rod containing the sample: bringing the nostrils within 2 cm of the glass rod; most sniffs are performed with the muzzle actually contacting the scented tip of the rod, and usually an accelerated rate of inhalation can be observed; (3) scent marking the glass rod: anogenital marking of the glass rod in a sitting position; suprapubic marking was very rare and is not included in this category. The subjects received a score of one for each of these behaviors if they displayed the pattern during a given 5-sec interval, regardless of the frequency of display.

All animals were tested repeatedly in the course of each experiment (see below). The right–left position of the scent stimuli was counterbalanced across tests and across subjects. The order of testing of the subjects was determined at random for every experiment. The observer recorded the behavioral responses on check sheets while sitting in full view of the animals, approximately 2 m from the cage. In analyzing the results of each experiment, mean scores for

contacting, sniffing, and scent marking were computed for each subject. These data were analyzed by two-way (donor by sex) analysis of variance (experiment 1) and paired *t*-tests (experiments 1, 2, and 3). A significance level of $P \leq 0.05$ was accepted. Each animal was tested only once a day. All testing and all collection of stimulus material were done between 8 and 11 AM and 1 and 4 PM.

Experiment 1. The ability of cotton-top tamarins to discriminate between material from the surface of the circumgenital scent gland of conspecific and heterospecific females was tested. Each of the subjects was given 18 tests. During each test, a single glass rod which was either unscented (blank) or scented with glandular material from an adult female, was inserted into the sample carrier located in the center of the testing area. The following samples were presented in random order: (1) an unscented glass rod (blank), (2) a glass rod scented with material from the circumgenital gland of an adult female *S. o. oedipus*, (3) a glass rod scented with material from the corresponding gland of an adult female *S. fuscicollis*, and (4) a glass rod scented with the material from the corresponding gland of an adult female *S. l. labiatus* (it should be noted that *S. l. labiatus* lacks the pronounced suprapubic glandular ridges present in the other two species).

All subjects were familiar with the scent marks of *S. fuscicollis*. In addition to living in close proximity to this species, they had previously undergone training tests during which scent marks from conspecifics and from *S. fuscicollis* were offered on wood. *S. l. labiatus* scent was known to the subjects only as far as living in the same colony familiarized them with the odor of this species.

Each subject received three tests which presented scents from three different conspecific female donors, three tests each with scent from three different female donors of *S. fuscicollis* and *S. l. labiatus*, and nine tests with blanks. The order of stimulus presentation was determined at random. All tests lasted 10 min.

Experiment 2. The ability of the tamarins to discriminate between natural scent marks of adult *S. o. oedipus* and *S. fuscicollis* females was investigated. Each subject was given four choice tests. During each test, a glass rod that had been scent marked by a conspecific female and a glass rod that had been scent marked by a female *S. fuscicollis* were offered simultaneously. Two *S. o. oedipus* and two *S. fuscicollis* females served as donors for each subject. Scent marks from each pair of donors were presented twice. All tests lasted 10 min.

Experiment 3. The ability of the tamarins to discriminate between conspecific female individuals was tested. A habituation paradigm was used. It is based on the assumption that the animals will habituate to a scent stimulus which is presented several times in close succession, showing a decrease in investigatory responses. Investigatory responses should increase again when a novel stimulus is presented after the animals have habituated to the original one. The design

of this experiment required the presentation of up to three different fresh scent samples from each donor individual. Since donor females did not readily scent mark several glass rods in close succession, material collected from the surface of the gland was used as stimulus scent.

Each subject was given four tests. The tests consisted of three 5-min presentations of a single glass rod scented with a fresh sample of material from an adult *S. o. oedipus* female. A pause of 1 min separated the presentations. In two of the four tests, three different samples of scent material collected within a short period of time from the same individual were presented. In the two remaining tests, the first and the second glass rod carried samples from the same individual, while the third glass rod was scented with material from another female. Two adult females, A and B, served as donors for each subject. Each donor female was used for one test in which she donated all three samples (AAA, BBB), for one test in which she donated only the first and second sample, and for one test in which she donated only the third sample, (BBA, AAB). The order of the four tests on each subject was determined at random.

In analyzing the results of experiment 3, mean individual contacting, sniffing, and scent-marking responses to the third sample were compared between tests in which the third sample was from the same donor as the first and second sample and tests in which it was from a novel donor.

RESULTS

Figures 1–4 show the mean scores obtained in experiments 1–3 by males and females for contacting the sample carriers and for sniffing and scent marking the stimulus rods. These scores represent the mean number of 5-sec intervals in which the behavioral responses were displayed. The results of experiments 1 and 2 show that cotton-top tamarins distinguish the scent of conspecifics from that of other tamarin species, both on the basis of material obtained from the surface of the scent glands and on the basis of natural anogenital scent marks.

Two-way analysis of variance (donor by sex) showed that in experiment 1, in which stimuli were presented one at a time, the material obtained from the surface of the scent glands of the three species elicited significantly different levels of sniffing ($P = 0.03$). Paired comparisons by means of t test further showed that as a group, male and female subjects sniffed glass rods carrying scent material from *S. o. oedipus* females significantly more frequently than glass rods carrying *S. fuscicollis* ($P = 0.03$) or *S. l. labiatus* scent ($P = 0.01$) or blank rods ($P = 0.05$). There also were significant sex differences in contacting the sample carrier, in sniffing, and in scent marking. Male subjects contacted the sample carrier ($P = 0.01$) and sniffed the samples ($P = 0.003$) more

frequently than females, but females showed much more scent marking of the glass rod, regardless of whether it carried a sample or not ($P = 0.003$) (Figure 1).

When natural scent marks from *S. o. oedipus* and *S. fuscicollis* were presented simultaneously in experiment 2, male and female subjects contacted the shelves carrying rods marked by conspecific females significantly more frequently than those carrying rods marked by *S. fuscicollis* (male: $P < 0.01$; female: $P = 0.01$). Moreover, males ($P = 0.03$) and females ($P < 0.01$) sniffed glass rods with *S. o. oedipus* scent significantly more frequently than rods with *S. fuscicollis* scent. As in experiment 1, females showed significantly more scent marking than males ($P = 0.01$) but sex differences in the other responses were not observed (Figure 2).

The results of the habituation tests in experiment 3 are depicted in Figures 3 and 4. They show that the tamarins can discriminate between scent material from conspecific female individuals on the basis of material adhering to the surface of the scent gland. Figure 3 shows that the average number of intervals spent contacting the sample carrier and sniffing the sample by males and females as a group gradually decreased when the animals were offered three successive samples of material from the scent gland of the same individual. However, when the third scent sample was from a different individual than the first and second sample, sniffing and contacting scores obtained during the third sample presentation were higher than those obtained during the second sample presen-

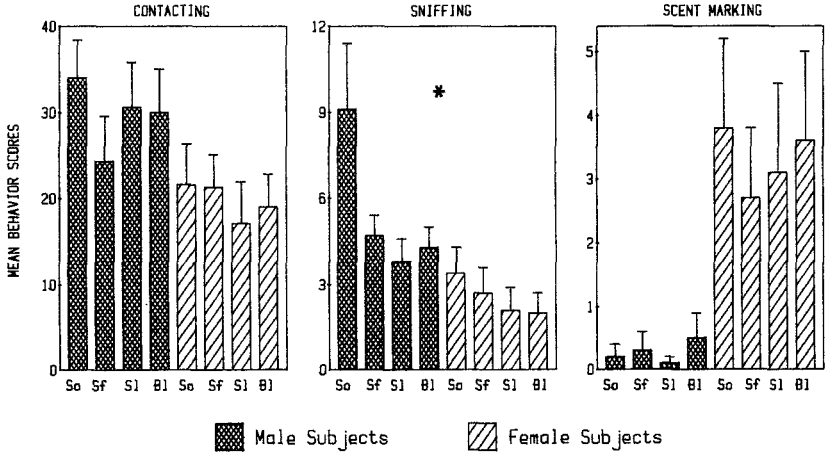

FIG. 1. Experiment 1: mean contacting, sniffing, and scent-marking scores ± SEM obtained by male and female subjects in response to single glass rods carrying gland material from *S. o. oedipus* (S.o.), *S. fuscicollis* (S.f.), or *S. l. labiatus* (S.l.) and to blanks (Bl). *Significant difference (ANOVA); P levels in text.

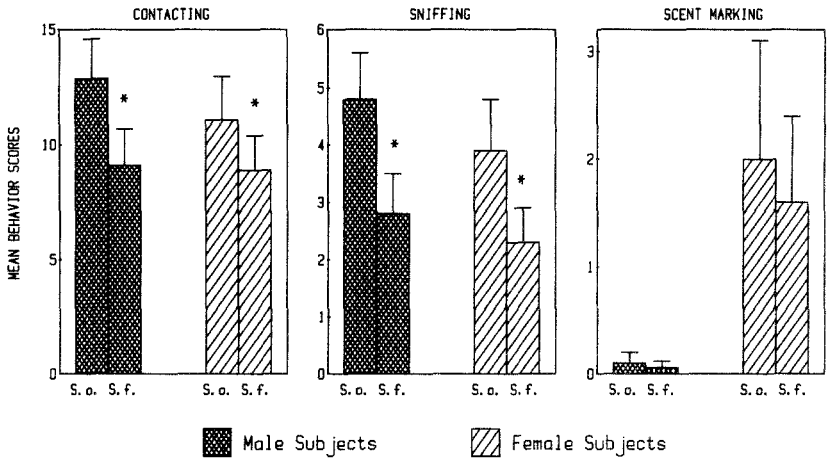

FIG. 2. Experiment 2: mean contacting, sniffing, and scent-marking scores ± SEM obtained by male and female subjects in tests offering a choice between glass rods carrying scent marks from *S. o. oedipus* (S.o.) and *S. fuscicollis* (S.f.). *Significant difference (*t* test); *P* levels in text.

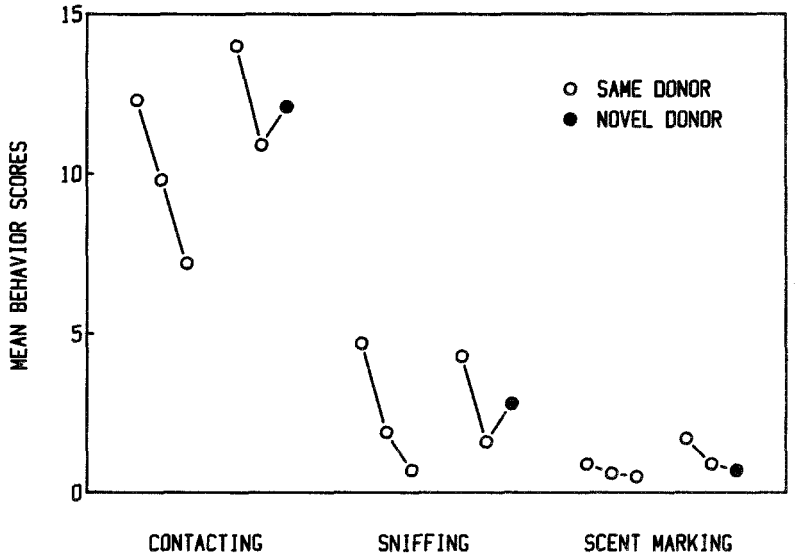

FIG. 3. Experiment 3: habituation curves showing mean contacting, sniffing, and scent-marking scores of male and female subjects as a group during three successive presentations of scent samples from female conspecifics. ○-○-○, the three glass rods carried scent from the same donor; ○-○-●, the first and second rods carried scent from the same donor; the third rod carried scent from a novel donor.

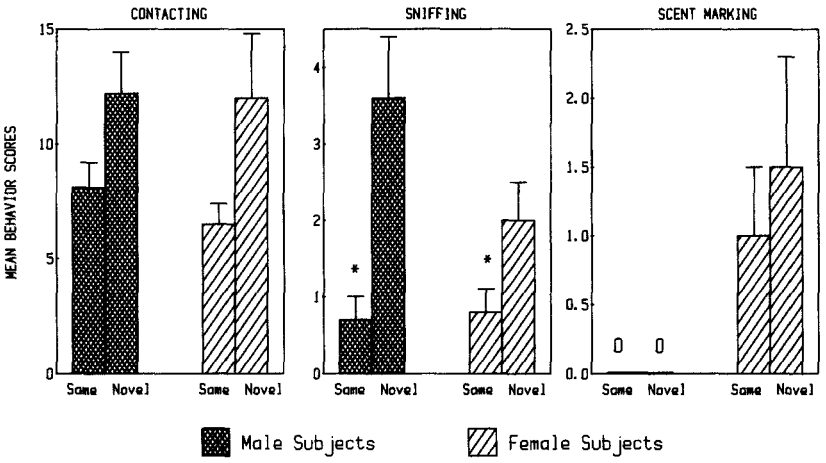

FIG. 4. Experiment 3: mean contacting, sniffing, and scent-marking scores ± SEM obtained by male and female subjects during the third of three successive presentations of scent samples from female conspecifics. Scores obtained during tests offering three successive samples from the same donor individual are compared with scores obtained during tests offering two samples from the same individual followed by a sample from a novel individual. *Significant differences (t test); P levels in text.

tation. In contrast to contacting and sniffing responses, there was little habituation and dishabituation of the scent-marking response.

Figure 4 presents the scores for contacting and sniffing obtained by males and females during the third sample presentation in experiment 3. Both sexes showed more sniffing of the sample during tests in which the scent donor was an individual to which the subjects had not been habituated during the first and second test (male: $P = 0.01$; female: $P = 0.02$). Males and females as subgroups did not discriminate between samples from the two donor individuals in terms of contacting the carriers. However, when the contacting scores of all subjects were analyzed as one group, contacting was significantly more frequent in tests offering the scent from an individual to which the subjects had not been habituated ($P = 0.01$). There were no sex differences in contacting and sniffing, but females showed significantly more scent marking than males ($P = 0.01$).

DISCUSSION

Studies on saddle-back tamarins (*S. fuscicollis*) have shown that this species can discriminate among a relatively large number of scent types. Conspecifics and other callitrichid species, subspecies of *S. fuscicollis*, males and

females, castrated and intact males, dominant and submissive males, and conspecific individuals are distinguished from each other on the basis of scent marks alone (Epple et al., 1979, 1986). The results reported in the present paper indicate that the scent of cotton-top tamarins communicates information similar to that contained in the scent marks of saddle-back tamarins. The natural scent marks and the material adhering to the scent glands of *S. o. oedipus* contain cues which facilitate species recognition. Material adhering to the surface of the glands also contains cues on which individual recognition can be based. Because of the difficulty in collecting a sufficient number of scent marks, we were not able to investigate the tamarins' ability to discriminate between individuals on the basis of their natural scent marks. However, it would not be surprising if the complex scent marks also serve to identify individuals, as was found to be the case in *S. fuscicollis* (Epple et al., 1979, 1986).

It would be interesting to establish whether natural scent marks and glandular material also contain cues for gender discrimination. In *S. fuscicollis*, gender discrimination is one of the most reliable responses to scent marks (Epple, 1974). Since male and female cotton-tops both possess scent glands, one would expect that they produce sexually dimorphic signals. However, because of the relatively small glands and the low marking activity of males, the stimulus material required for gender discrimination studies is difficult to obtain. Nevertheless, we recently have begun such studies and will report on them in due course.

Our studies show that chemical cues relating to species and individuality are present on the gland surface of an animal. These body scents may be important during interactions among individuals at close range. Chemical cues of similar signal content are also deposited in the environment, where they can influence the behavior of a recipient in the absence of the animal who deposited the scent mark. The chemical constituents of a scent mark deposited by a donor monkey may be somewhat different from those of the material adhering to the glandular surface. At present, we do not know whether both scents are equally attractive to the tamarins and whether similar communicatory signals in glandular material and in scent marks are based on similar chemical composition. It would be misleading to interpret the obvious differences in the intensities with which the subjects contacted, sniffed and scent marked the stimuli in experiments 1, 2, and 3 as an indication that glandular secretion differed from scent marks in attractiveness and/or chemical composition. Although most subjects participated in all experiments, the methods used in experiments 1–3 differed from each other in duration and in the number of scent stimuli offered simultaneously. Therefore the mean behavior scores obtained in the three experiments cannot be compared directly.

The present study confirms findings on pronounced sex differences in scent marking. French and Snowdon (1981), French and Cleveland (1984), French

et al. (1984), and Wolters (1978) found that females maintaining the breeding position in their groups showed much higher levels of anogenital and suprapubic marking than males of comparative social status. In our test situations, females also showed significantly more anogenital marking than males, while males showed more sniffing of female scents and more contacting of the sample carrier than females, at least in experiment 1. This result can be interpreted as supporting the suggestion of French and Snowdon (1981) that anogenital marking in female cotton-tops is primarily a means of communicating sexually relevant information. These authors observed an increase in anogenital marking by breeding females and in male sniffing of female genitalia and female scent marks around the time of suspected estrus (as dated from the timing of parturition). Suprapubic marking, a behavior rarely observed in the present study, has been found to be associated mainly with aggressive arousal of females, and French and Snowdon (1981) suggested that one of its functions is the promotion of intergroup spacing. From these observations, it appears possible that anogenital and suprapubic scent marks communicate somewhat different information (French and Snowdon, 1981).

Depending on the social context in which basic chemical messages relating to species, gender, and individual recognition are perceived, they can influence a wide variety of different sexual and social interactions (Epple, 1986; Epple et al., 1986). We expect that our continuing studies will provide additional information on the communicatory content and the chemical composition of the scent marks of *S. o. oedipus*. This work, together with our concurrent studies on *S. fuscicollis*, will lead to a broader understanding of chemical communication in primates.

Acknowledgments—Supported by the Deutsche Forschungsgemeinschaft. We thank Michael Schwibbe for assistance with the statistical analyses.

(Received December 9, 1986; accepted March 4, 1987)

Abstract—The Neo-Guinean pseudomyrmecine ant, *Tetraponera* sp. utilizes its modified sting to smear upon enemies a contact poison with strong deterring and toxic properties. The venom, which originates from the poison gland, contains a mixture of eight closely related, alkaloids (tetraponerine-1 to -8). The structure of tetraponerine-8 was established by an X-ray diffraction analysis and was reported previously. The structure of five other members of the series has now been determined by comparison of their spectral properties with those of tetraponerine-8 and of model compounds.

Key Words—*Tetraponera*, ant, alkaloids, poison gland, contact poison, tetraponerine, Hymenoptera, Formicidae, Pseudomyrmecinae.

INTRODUCTION

The Neo-Guinean pseudomyrmecine ant *Tetraponera* sp. is characterized by a defensive mechanism which is unique both in the morphology of the sting apparatus and in the structure of the venom alkaloids (Braekman et al., 1986). The modified sting is not a suitable injection device but is well adapted to deposit a liquid on a surface. GC analysis of the venom showed that it contains eight closely related derivatives named tetraponerine-1 to -8 (referred to here as T1 to T8). The structure of T8, one of the major constituents of the venom, has been determined as **1** by an X-ray diffraction analysis (Braekman et al., 1986). T8 is the first member of a new family of alkaloids based on the deca-

hydro-pyrido-(1,2-c) pyrrolo-(1′,2′-a) pyrimidine skeleton. In this paper, we report on the isolation and structure determination of five other alkaloids (T3 to T7) from *Tetraponera* sp. venom, which are derived from the same tricyclic ring system.

METHODS AND MATERIALS

Ants. Workers of *Tetraponera* sp. were collected near Bogia, along the north coast of Papua, New Guinea, and immediately placed in vials containing methanol. The venom of 250 individual workers was collected on bits of filter paper by "milking" the ants and was stored in hexane.

Chemical Analysis. Gas chromatographic analyses were performed on a Varian model 3700 equipped with a 25-m OV-1 capillary column, isothermally at 170°C. Gas chromatography–mass spectrometry was performed at 170°C on a Finnigan 2500 GC, coupled to a Finnigan 3000 D mass spectrometer.

Preparative gas chromatographic separations were realized on a Hewlett-Packard model 402 equipped with a 1.80-m column packed with 2% SE-30 on Chromosorb W, at 150°C. Thin-layer chromatographic (TLC) analyses were realized on Merck Al_2O_3 plates (eluent: hexane–AcOEt 8:2) or on SIL G Macherey Nagel plates (eluent: hexane–acetone–NH_4OH 25% 8:2:0.5). The plates were visualized by spraying with Dragendorff reagent. Silica gel column chromatographies were performed either by the "flash" technique (Still et al., 1978) (eluent: hexane–acetone–NH_4OH 25% 8:2:0.5) or on Merck Lobar columns (eluent: $CHCl_3$–EtOH 9:1).

Infrared spectra were obtained from neat liquid films with either a Unicam SP1000 or a Perkin-Elmer 237 infrared spectrophotometer. [^{1}H]- and [^{13}C]NMR spectra were obtained at 250 and 62.8 MHz respectively, using a Bruker WM 250 spectrometer. All spectra were recorded in C_6D_6, chemical shifts (δ) being expressed in parts per million (ppm) from internal TMS. High-resolution MS (HRMS) was performed on a Micromass 7070 F mass spectrometer.

Extraction of Ants and Purification of T3 to T7. TLC analyses of the hexane extract of the venom revealed the presence of a single orange spot on visualization (Al_2O_3) with Dragendorff reagent. Filtration of the hexane extract on alumina and evaporation of the solvent afforded 16 mg of alkaloidal mixture.

To obtain larger amounts of the venom constituents, several batches of *Tetraponera* workers were ground in CH_3OH and extracted three times with CH_2Cl_2. Typically, combined extracts of 1250 workers were evaporated under reduced pressure; the residue (161 mg) was redissolved into 15 ml of CH_2Cl_2 and extracted five times with 5 ml of 5% aqueous HCl. The acid layer was basified with NH_4OH (pH 10) and extracted with 5 × 5 ml of CH_2Cl_2. Drying and evaporation of the solvent afforded 70 mg of crude alkaloidal mixture. Capillary GC analysis of this mixture showed that it contained the same alkaloids as the venom. A series of silica gel column chromatographies (flash and Lobar),

followed by preparative GC afforded T3 (2 mg), T4 (1.1 mg), T5 (3 mg), T6 (3 mg), T7 (3 mg), and T8 (6 mg). The purity of these compounds was checked by capillary GC and TLC.

RESULTS

Capillary GC analyses of the *Tetraponera* sp. venom revealed the presence of eight components: T1–T8, numbered in order of increasing retention time. The relative proportions, given in Figure 1, were found to change slightly from

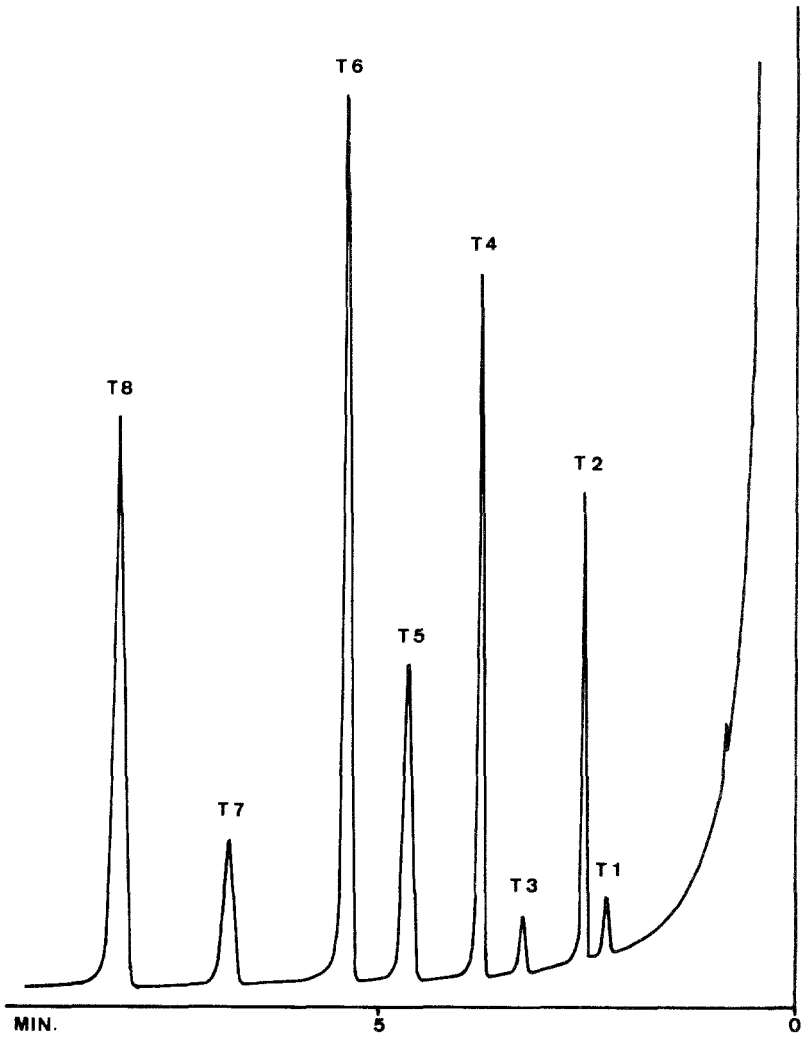

FIG. 1. Chromatogram of the crude secretion of *Tetraponera* sp. (OV-1, 170°C).

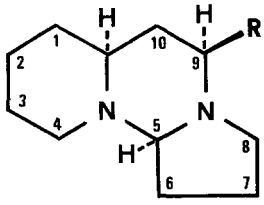
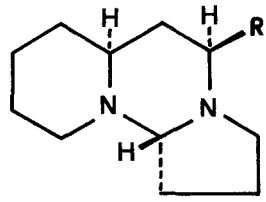
one collection to the other. Careful dissection of the Dufour and poison glands followed by TLC analyses of the hexane extract showed that these compounds are specific to the poison gland. GC-MS analysis of the mixture shows that these derivatives may be distributed into four pairs of isomers. The mass spectra of matched isomers are almost superimposable, suggesting that they are diastereomers. HRMS measurements established the empirical formula of three of the four pairs and indicated that each pair differs from the next one by a CH_2 unit. Moreover, a plot of the logarithm of the corrected retention times of the alkaloids versus the number of carbon atoms (Kovats, 1961) suggests that the eight compounds may be distributed into two series of homologs, one even (T2, T4, T6, and T8) and one odd (T1, T3, T5, and T7).

Six of these compounds could be isolated in small amounts by a combination of chromatographic methods. The structure of T8 has been established to be **1** by X-ray diffraction analysis (relative configuration 5S*, 9R*, 11S*) (Braekman et al., 1986). The structures of T3–T7 were deduced from a careful analysis of their spectral properties and will be discussed below.





1 (T8) R= n-C_5H_{11}

$C_{16}H_{30}N_2$ by HRMS (measured 250.239, calculated 250.241); [^{13}C]NMR: 85.4 (d, C-5), 62.6 (d, C-9*), 61.6 (d, C-11*), 51.3 (t, C-4), 49.7 (t, C-8), 37.6 (t, C-10), 34.2 (t, C-1), 32.6 (t, C-12$^+$) 32.2 (t, C-14$^+$), 29.3 (t, C-6), 25.8 (t, C-3), 24.9 (t, C-13°), 24.7 (t, C-2°), 22.9 (t, C-15), 19.9 (t, C-7), 14.2 (t, C-16)] shows that both compounds possess the same tricyclic ring system with identical configuration at C-5, C-9, and C-11 and thus differ only by the presence of an *n*-propyl side chain in T4 in place of the *n*-pentyl side chain of T8. This conclusion is based on the following arguments. The relative intensities of the Bohlmann bands at 2785–2700 cm^{-1} in the IR spectra of T4 and T8 are

the same, suggesting that the number of C–H bonds α to the nitrogen atoms and *trans* to the nitrogen lone pairs is the same in both compounds (Crabb et al., 1971). The mass spectra of both T4 and T8 show intense fragment ions at *m/z* 193.1714 ($C_{12}H_{21}N_2$), corresponding to side-chain cleavage between C-12 and C-13. Fragment ions arising from the tricyclic portion of the molecules (e.g., *m/z* 152, 96, 84) are found in the spectra of both compounds with practically the same relative intensities. The [^{1}H]NMR spectrum of T4 displays five 1H signals between 2.0 and 3.15 ppm, the chemical shifts and coupling constants of which are nearly identical to those of the corresponding deshielded protons of T8 (Table 2). Finally, the chemical shifts of the carbon atoms of the tricyclic ring system of T4 and of T8 are nearly the same, and those of the carbon atoms of the *n*-propyl chain of T4 are in good agreement with the δ reported for 2-propylpiperidine (Shamma and Lang, 1979). All these arguments point to structure 2 for T4.

Structure of T3 (3), T5 (4) and T7 (5). Table 1 shows that the mass spectra of T7 [oil; $KI^{OV\text{-}1}_{173^\circ} = 1809$; $C_{16}H_{30}N_2$ by HRMS (measured 250.239, calculated 250.241); [^{13}C]NMR: 75.9 (d, C-5), 57.1 (d, C-9), 53.7 (d, C-11), 51.4 (t, C-4*), 51.0 (t, C-8*), 34.6 (t), 32.9 (t), 32.7 (t), 31.3 (t), 30.9 (t), 27.7 (t), 26.9 (t), 25.6 (t), 23.6 (t), 22.6 (t), 14.7 (q, C-16)] and T8 are nearly superimposable, which suggests that these compounds are diastereomers. The IR spectrum of T7 also displays Bohlmann bands, but their relative intensities are lower than those of T8. This observation strongly suggests that the number of H atoms α to the nitrogen atoms and *trans* to the nitrogen lone pairs is smaller in T7 than in T8, implying that the two compounds differ by the configuration at one or more of the three chiral centers: C-5, C-9, or C-11.

On the basis of [^{13}C]- and [^{1}H]NMR arguments, we propose that T7 is the C-5 epimer of T8. In the [^{13}C]NMR spectrum of T7, the three most deshielded signals (δ 75.9, 57.1, and 53.7) attributable to C-5, C-9, and C-11, respectively, experience a strong upfield shift in comparison to the corresponding signals of T8 (Table 3).

The influence of the change from an equatorial to an axial alkyl group on the chemical shift of the quinolizidine carbon atoms was calculated by using 2α- and 2β-methylquinolizidine and 4α- and 4β-methylquinolizidine as model compounds (Tourwe and Van Binst, 1978; Lalonde and Donvito, 1974). The increments thus obtained were utilized to calculate the chemical shifts of the quinolizidine carbon atoms of 5-epi- and 9-epi-T8.

As can be seen from Table 3, there is a good agreement between the values calculated for the quinolizidine carbon atoms of 5-epi-T8 and those observed for the same carbon atoms of T7. These data strongly suggest that T7 and T8 are C-5 epimers and that the quinolizidine ring system is *trans*-fused in both compounds, as indicated by the chemical shifts of C-1 to C-4 (Tourwe and Van Binst, 1978). These conclusions are fully supported by the [^{1}H]NMR spectrum

TABLE 3. COMPARISON OF CALCULATED CHEMICAL SHIFTS FOR QUINOLIZIDINE CARBON ATOMS OF 5-EPI- AND 9-EPI-T8 WITH THOSE OBSERVED FOR T6–T8

	C-1	C-2	C-3	C-4	C-5	C-9	C-10	C-11
9-epi-T8	33.7	24.6	26.3	51.6	79.5	60.2	34.6	57.0
5-epi-T8	34.1	24.7	26.2	52.4	79.8	55.8	37.6	53.7
T8	34.2	24.7	25.8	51.3	85.4	61.6	37.6	62.6
T7	34.6	25.6	26.9	51.4	75.9	57.1	—	53.7
T6	—	—	—	—	83.4	64.2	—	59.7

of T7, which displays five protons in the 2.7–3.4 ppm region, whereas only two protons appear in the corresponding region of the T8 spectrum (Table 2). In T7, the HC-5 (3.33 ppm) is equatorial and *cis* to the lone pairs of both N atoms, which explains its deshielding. Furthermore, HC-4 (eq) and both HC-8, being *cis* to the nitrogen atom lone pairs, appear at about 3.0 ppm. The fifth signal at about 2.8 ppm is attributed to HC-11 which is deshielded (0.5 ppm) by a Van der Waals interaction with H_2C-6 (Bhacca and Williams, 1964).

Consequently, we propose structure **5** for T7, with the relative configuration 5R*, 9R*, 11S*.

Several attempts were made to correlate chemically T7 and T8 by cleavage of the *gem*-diamino function with reducing agents ($LiAlH_4$, $NaBH_4$, DIBAL-H, catalytic hydrogenation). These treatments led either to unchanged starting material or to complex mixtures.

Next, we turn to compound T3 [oil; $KI^{OV\text{-}1}_{173°} = 1627$; $C_{14}H_{26}N_2$ by HRMS (measured 222.208, calculated 222.210); [^{13}C]NMR: 75.5 (d, C-5), 56.7 (d, C-9), 53.0 (d, C-11), 51.0 (t, C-4*), 50.6 (t, C-8*), 34.3 (t), 33.3 (t), 32.2 (t), 30.6 (t), 26.6 (t), 25.2 (t), 22.2 (t), 20.7 (t), 14.5 (q, C-14)] and compound T5 [oil; $KI^{OV\text{-}1}_{173°} = 1713$; $C_{15}H_{28}N_2$ by HRMS (measured 236.223, calculated 236.225); [^{13}C]NMR: 76.5 (d, C-5), 58.3 (d, C-9), 54.1 (d, C-11), 51.0 (t, C-4*), 50.0 (t, C-8*), 33.2 (t), 32.5 (t), 31.6 (t), 30.2 (t), 30.1 (t), 27.4 (t), 23.2 (t), 22.0 (t), 20.4 (t), 14.4 (q, C-15)]. Their mass spectra (Table 1) and their Kovats indexes (KI) strongly suggest that they are the lower homologs of T7, possessing the same tricyclic skeleton as T7 but with an *n*-propyl or *n*-butyl side chain, respectively. The similarity observed between the [^{1}H]- and [^{13}C]NMR spectra of T3, T5, and T7 confirms this assumption. These data also demonstrate that the relative configuration at C-5, and C-11 must be the same in the three compounds.

Thus we propose structure **3** for T3 and **4** for T5.

Structure of T6. The mass spectrum (Table 1) of T6 [oil; $KI^{OV\text{-}1}_{173°} = 1751$; $C_{15}H_{28}N_2$ by HRMS (measured 236.223, calculated 236.225); [^{13}C]NMR: 83.4

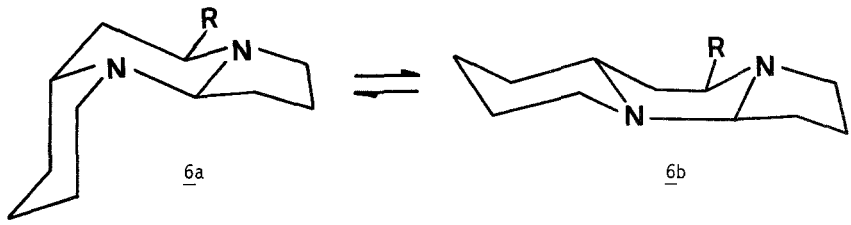

FIG. 2. The two most stable conformers of T6.

(d, C-5), 64.2 (d, C-9), 59.7 (d, C-11), 49.2 (t, C-4*), 45.9 (t, C-8*), 34.8 (t), 33.5 (t), 32.7 (t), 30.7 (t), 29.3 (t), 25.9 (t), 23.1 (t), 21.3 (t), 21.0 (t), 14.3 (q, C-15)] indicates the presence of a tricyclic system substituted at C-9 by an *n*-butyl side chain. The relative intensity of the Bohlmann bands in IR is similar to those observed in the spectra of T4 and T8. These observations, together with the KI of T6 led us to hypothesize that it could be the homolog between T4 and T8. However, its [^{1}H]- and [^{13}C]NMR spectra are clearly different from those of T4 and T8, thus precluding that it could possess the 5S*, 9R*, 11S* configuration. Moreover, since T6 is diastereomeric with T5, its configuration cannot be 5R*, 9R*, 11S*. Examination of Table 3 shows that the chemical shifts of C-5, C-9, and C-11 of T6 are very different from those calculated for 9-epi-T8 (5S*, 9S*, 11S*). It follows that T6 has structure **6**, possessing the 5S*, 9R*, 11R* configuration. Examination of molecular models shows that **6a** and **6b** are the two more stable conformers of T6 (Figure 2).

Conformation **6b**, in which the B ring adopts a boat conformation, is probably the preferred one since it has an overall shape that is very close to that of T4 and T8. This would best explain the behavior of T6 in gas chromatography and the intensities of the Bohlmann bands in IR.

Pure samples of compounds T1 and T2 could not be obtained. Nevertheless, the mass spectrum, obtained by GC-MS, suggests that they have the empirical formula $C_{13}H_{24}N_2$ (M^+ at *m/z* 208), which is compatible with a tetraponerine tricyclic skeleton bearing an ethyl side chain. The relative configuration of these compounds remains undetermined.

DISCUSSION

The presence of alkaloids in ants is well documented (Blum and Hermann, 1978; Jones and Blum, 1983). Several species belonging to the genera *Solenopsis* and *Monomorium* are well-known alkaloid producers. This is, however, the first report of saturated nitrogen heterocycles from the venom of a pseudomyrmecine ant. All other alkaloids of this type have been isolated from the myrmicine genera *Solenopsis*, *Monomorium*, and *Chelaner* (Jones et al., 1986).

Structurally, all ant alkaloids isolated till now were based on the pyrrolidine (Jones et al., 1982), piperidine (MacConnell et al., 1971; Jones et al., 1982), indolizidine (Jones et al., 1980, 1984), or pyrrolizidine (Jones et al., 1986) ring systems. Although based on piperidine and pyrrolidine rings, the tricyclic ring system of the tetraponerines has never been reported before in a natural compound.

The biosynthetic origin of ant alkaloids is still controversial. The presence of the same structural elements in the Myrmicinae alkaloids and in the tetraponerines could reflect the existence of a basic biogenetic scheme common to all these derivatives. However, it should be noted that the *Monomorium* and *Solenopsis* alkaloids, with one exception (Jones et al., 1982), all possess an odd-numbered carbon skeleton. This contrasts with the tetraponerine family where both odd- (T1, T2, T5, T6) and even-numbered (T3, T4, T7, T8) carbon skeletons are found. We plan to address the problem of the tetraponerine biosynthesis in the near future. The total synthesis of the tetraponerines is currently underway in our laboratory.

Acknowledgments—We thank Dr. B. Bolton (British Museum) and Dr. C. Baroni-Urbani (Natural History Museum, Basel) for identification of the ant species. We also thank Dr. R. Ottinger for the NMR spectra and Mr. C. Moulard for the HRMS. This work was supported by a grant (2.9001.86) from the Belgian Fund for Joint Basic Research.

PARTIAL INHIBITION OF PHEROMONE PRODUCTION IN *Dendroctonus ponderosae* (COLEOPTERA: SCOLYTIDAE) BY POLYSUBSTRATE MONOOXYGENASE INHIBITORS[1]

D.W.A. HUNT[2] and MICHAEL J. SMIRLE

Centre for Pest Management
Department of Biological Sciences,

(Received December 11, 1986; accepted March 4, 1987)

Abstract—Female and male mountain pine beetles, *Dendroctonus ponderosae* Hopkins, were treated topically with piperonyl butoxide or sesame oil, both of which are known to inhibit polysubstrate monooxygenase activity. Beetles then exposed to vapors of the host monoterpenes α-pinene and myrcene were found to contain reduced levels of the pheromones *trans*-verbenol and ipsdienol, as well as a buildup of monoterpene precursors. Polysubstrate monooxygenase enzymes appear to be at least partially responsible for the detoxification of host monoterpenes and for the production of terpene alcohol pheromones in this species.

Key Words—*Dendroctonus ponderosae*, Coleoptera, Scolytidae, pheromones, *trans*-verbenol, ipsdienol, allelochemicals, mixed-function oxidases, monooxygenase inhibitors.

INTRODUCTION

Many plants contain allelochemicals that are toxic to herbivorous insects. In response, these insects have developed several enzyme systems that metabolize plant allelochemicals to compounds that are less toxic and/or more easily excretable (Brattsten, 1977). The polysubstrate monooxygenases (also known

[1] Research supported in part by Natural Sciences and Engineering Research Council, Canada, Operating Grants A3881 and A7774.
[2] Present address: Department of Entomology, University of Wisconsin–Madison, Madison, Wisconsin 53706.

0098-0331/88/0200-0529$06.00/0

as mixed-function oxidases) are probably the most important of these enzyme systems. The products of monooxygenase-catalyzed oxidations of allelochemicals generally are not biologically active and often are excreted as glutathione conjugates.

The mountain pine beetle, *Dendroctonus ponderosae* Hopkins, is one example of an herbivorous insect that makes use of the metabolic products of allelochemical oxidation. This bark beetle breeds in the phloem of several *Pinus* species throughout western North America and thus is exposed to a variety of monoterpenes and other toxic compounds. The monoterpenes are converted to corresponding terpene alcohols and related compounds, and these are excreted by the insects. Female *D. ponderosae* are known to convert the monoterpene α-pinene to *trans*-verbenol (Hughes, 1973), an aggregation pheromone for this species (Pitman, 1971). Male *D. ponderosae* convert myrcene to ipsdienol (Hunt et al., 1986), which may act as an antiaggregation pheromone for this species (Hunt and Borden, 1988) (see Figure 1).

Although it has been hypothesized that polysubstrate monooxygenases are involved in the production of bark beetle pheromones (White et al., 1980), experimental evidence is inconclusive. Sturgeon and Robertson (1985) measured polysubstrate monooxygenase activity in midgut tissue from *D. ponderosae*, but did not evaluate the role of these enzymes in terpene metabolism and pheromone production. White et al. (1979) reported that microsomal fractions of *Dendroctonus terebrans* could produce α-pinene oxide, and other unidentified compounds, from α-pinene. White et al. (1979) hypothesized that α-pinene oxide may be the first step in the *in vivo* production of certain terpene alcohol pheromones of *Dendroctonus* species. No corresponding studies have been carried out on the oxidation of myrcene.

We have investigated the role of monooxygenase enzymes in the production of terpene alcohol pheromones in the mountain pine beetle. Our approach has been to use intact insects instead of homogenates and to assess the effects of the polysubstrate monooxygenase inhibitors piperonyl butoxide and sesame oil on the conversion of α-pinene and myrcene to their corresponding terpene alcohol pheromones. Monooxygenase inhibitors are widely used as insecticide synergists and have become a standard means of assessing the involvement of these enzymes in insecticide metabolism (Brattsten, 1979). As such, they lend themselves naturally to studies on allelochemical metabolism as well.

METHODS AND MATERIALS

Logs of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann, infested with the mountain pine beetle were obtained from the southwestern interior of

British Columbia. Their cut ends were sealed with hot paraffin wax, and the logs were stored at 4°C. Adult *D. ponderosae* were obtained by placing logs in cages at 27°C, collecting the emergent beetles, and storing them on moistened paper toweling at 2–4°C until required (two weeks maximum). When needed for experiments, beetles were rewarmed to room temperature, and active individuals were selected and their sex determined using the method of Lyon (1958).

Piperonyl butoxide (analytical grade, >95%; McLaughlin, Gormley, King Co., Minneapolis, Minnesota) or sesame oil (Sigma Chemical Co., St. Louis, Missouri) were diluted in acetone and 1 μl of a 20% solution (v/v) was applied to the pronotum of each insect. Control beetles received 1 μl of acetone on the pronotum. Then female beetles were exposed to the vapors from a vial containing 25 μl of distilled α-pinene (>99%; Aldrich Chemical Co., Milwaukee, Wisconsin) in a 500-ml jar (9 cm OD) for 24 hr at 22°C. Male beetles were exposed to myrcene vapors (>99%; Phero Tech Inc., Vancouver, British Columbia) under the same conditions.

A group of control beetles was exposed to monoterpene vapors at the same time and under the same conditions as each group of inhibitor-treated beetles. This ensured that control and treatment groups had identical exposure to monoterpene vapors and further ruled out factors such as beetle age from affecting the comparisons between inhibitor and control treatments.

To assess the effect of acetone treatments, groups of female and male beetles receiving 1 μl of acetone were compared to groups receiving no treatment. All groups were exposed to monoterpene vapors as previously outlined.

In all treatment and control groups, some insects died or appeared sick following monoterpene vapor exposure. All beetles that did not appear to be healthy were excluded from pheromone analysis. Extracting and analyzing only apparently healthy beetles avoided biasing the data, as more sick beetles were present in the inhibitor treatments than in the controls.

Abdomens from individual insects were excised and extracted in double-distilled pentane; each insect represented one replicate of the piperonyl butoxide, sesame oil, or acetone control treatments. Extracts were analyzed for terpene alcohol pheromones and their precursors on a Hewlett Packard 5880A gas chromatograph equipped with a capillary inlet system, flame ionization detector, and glass capillary column (30 m × 0.50 mm ID) coated with SP-1000 (Supelco, Inc., Bellefonte, Pennsylvania). 3-Octanol was added to the pentane used to extract the abdomens and was used as an internal standard. The compounds were identified by comparison of retention times with authentic standards, and selected samples were analyzed using mass spectroscopy to ensure proper identification of compounds.

Differences in the quantities of monoterpenes and pheromones were analyzed statistically using the Mann-Whitney U test, $P > 0.05$.

RESULTS

Female *D. ponderosae* that had been treated with sesame oil prior to α-pinene exposure contained lower levels of *trans*-verbenol than did acetone-treated controls (Table 1, experiment 1). A similar, but not statistically significant, effect occurred after beetles were treated with piperonyl butoxide (Table 1, experiment 2). Females that had been treated with sesame oil or piperonyl butoxide retained significantly higher levels of α-pinene than did acetone-treated controls (Table 1, experiments 1 and 2). Acetone-treated females contained levels of α-pinene and *trans*-verbenol that were not significantly different from those found in untreated beetles (Table 1, experiment 3).

Male *D. ponderosae* that had been treated with piperonyl butoxide, but not sesame oil, prior to myrcene exposure contained lower levels of ipsdienol than did acetone-treated controls (Table 2, experiments 1 and 2). However, males that had been treated with either inhibitor retained significantly higher levels of myrcene than did acetone-treated controls (Table 2, experiments 1 and 2). Acetone-treated males contained levels of myrcene and ipsdienol that were not significantly different from those found in untreated beetles (Table 2, experiment 3).

DISCUSSION

Unlike most bark beetles, which breed in weakened or dead host material, *D. ponderosae* attack vigorous host trees that are capable of a significant defen-

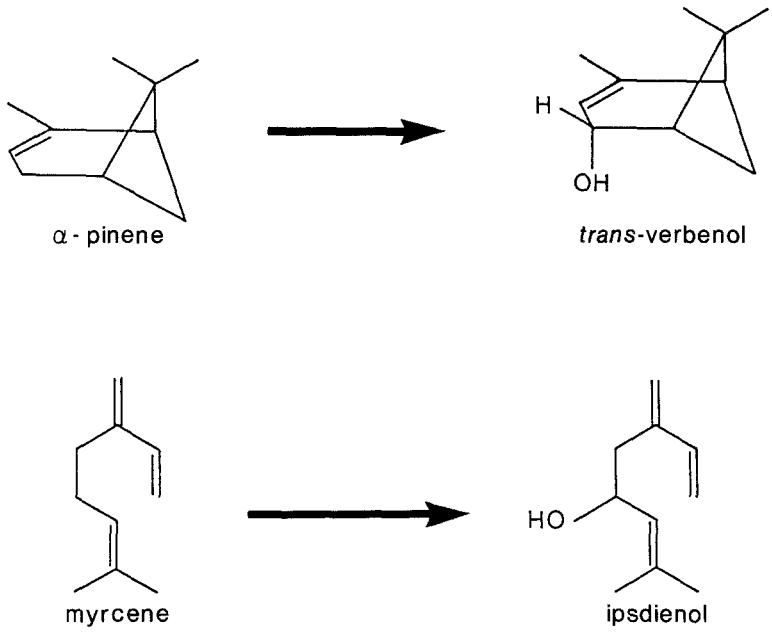

FIG. 1. Oxidation of α-pinene to *trans*-verbenol and myrcene to ipsdienol.

sive reaction. As a result, these insects are exposed to large amounts of resin containing a variety of substances known to be toxic to bark beetles (Smith, 1965; Reid and Gates, 1970; Coyne and Lott, 1976). Evidently, these insects require a rapid and efficient means of dealing with a wide range of toxic host substances.

Another result of *D. ponderosae* attacking healthy, resinous hosts is the need for rapid production of aggregation pheromones. At low attack densities host trees are capable of confining attacking adults within necrotic lesions containing high levels of monoterpenes and other toxic plant allelochemicals. Only through rapid mass attack are these insects able to achieve a density of attacking beetles sufficient to overwhelm the defensive capacity of the host (Raffa and Berryman, 1983).

Our findings that topical applications of piperonyl butoxide or sesame oil cause a decrease in the levels of certain terpene alcohol pheromones, along with a buildup in the levels of their monoterpene precursors, are supportive of the hypothesis that polysubstrate monooxygenases are involved in bark beetle pheromone production. Thus, the mountain pine beetle is able to detoxify host monoterpenes and produce the aggregation pheromone *trans*-verbenol rapidly and simultaneously using the same enzyme system. In doing so, the insects have

adapted to use the metabolic products of detoxification to produce a behavioral response, a strategy that is more energy efficient than producing pheromones *de novo* from precursors not found in the diet.

It is known that monoterpenes such as α-pinene and myrcene are potent and rapid inducers of cytochrome P-450-linked monooxygenases in certain insects (Brattsten et al., 1977). Such induction probably also occurs in *D. ponderosae* and greatly facilitates the rapid detoxification of host monoterpenes and the production of aggregation pheromones.

Polysubstrate monooxygenase inhibitors such as piperonyl butoxide possess some toxicity to insects, and it is possible that the reduction in pheromone levels and concurrent increase in precursors following inhibitor exposure could be due to sublethal toxicity. However, our dosages of piperonyl butoxide and sesame oil caused only low levels of beetle mortality (Tables 1 and 2); thus it appears unlikely that the reduction in terpene alcohol production is caused by general toxicity. In addition, a topical application of an insecticide, diazinon, at a dosage that approximated the LD_{50} for female *D. ponderosae*, did not decrease the production of *trans*-verbenol in females (authors' unpublished data). This is further evidence that the reductions in pheromone production are not due to sublethal toxicity.

There is evidence that microorganisms associated with certain bark beetle species can convert host tree monoterpenes into compounds that their insect hosts utilize as pheromones (Brand et al., 1975; Byers and Wood, 1981). However, there is also evidence that bark beetles devoid of readily culturable microorganisms can produce these terpene alcohol pheromones (Conn et al. 1984). It is possible that these reactions are being catalyzed by monooxygenase enzymes present in the insects, in their symbiotic microorganisms, or both. Further studies using polysubstrate monooxygenase enzymes *in vitro* are needed to address this question.

(Received May 30, 1986; accepted March 5, 1987)

Abstract—The feasibility of using the synthetic sex pheromone, disparlure, as a mating confusant of the nun moth (*Lymantria monacha* L.) was investigated on wild populations occurring in outbreak proportions in Poland and in low density in Czechoslovakia. The size of experimental plots ranged from 1 to 12 hectares. The amounts of pheromone applied were 10 or 20 g/hectare. Three types of slow-release formulations of a racemic mixture of disparlure were tested: (1) a spray formulation with latex as a carrier, (2) a tubing of natural rubber, and (3) sawdust of a porous material used for making tips of fiber-tip pens. All three pheromone formulations prevented significant numbers (98.6–100% in the low density situation, 90–96.2% during the outbreak) of the males from locating a discrete source of pheromone (a trap containing synthetic pheromone or a female) during the whole flight period, indicating long-lasting efficiency of the formulations.

Key Words—*Lymantria monacha*, Lepidoptera, Lymantriidae, pheromone communication, mating disruption, disparlure, slow-release formulations.

INTRODUCTION

In Central Europe, the nun moth, *Lymantria monacha* (L.) is one of the most economically important defoliators of coniferous trees, notably spruce and pine. Periodic population outbreaks have produced devastating results, as for exam-

0098-0331/88/0200-0537$06.00/0

ple in Czechoslovakia in 1917–1927 (Pfeffer, 1954), when an area of 105,000 hectares was damaged, and more recently in Poland, where some 6.3 million hectares of forested areas had to be chemically treated during 1978 through 1984 (Śliwa and Sierpiński, 1986). Smaller outbreaks have also been reported from Germany (Altenkirch, 1986), Austria (Schmutzenhofer, 1986), and Denmark (Jensen and Nielsen, 1984). In the search for alternative and environmentally more acceptable approaches to the management of this pest, a series of field trials was carried out at the same period in Germany (Altenkirch, 1985a), Austria (Schmutzenhofer, 1986), and in Poland and Czechoslovakia (Vrkoč et al., 1981, the present study) to investigate the feasibility of using the synthetic pheromone, disparlure (Schönherr, 1972), as a mating confusant.

In this paper we report on the experiments done on low-density populations in Czechoslovakia and during an outbreak of the pest in Poland. The objectives of the studies were to obtain information concerning (1) the performance of three different slow-release formulations of disparlure and (2) the ability of the disparlure treatment to disorient and/or confuse wild males that are seeking a discrete source of the sex attractant (a pheromone cap or a calling female).

METHODS AND MATERIALS

Pheromone Formulations. A racemic mixture of *cis*-7,8-epoxy-2-methyloctadecane (disparlure, Zoecon Corp., Palo Alto, California) was formulated into one of three carriers. The first carrier was an aqueous polystyrene–butadiene latex (density 0.9662, pH 10.5, dry weight 19.3%, contents of the bound styrene 24.6%, contents of the free styrene 2.9 g/liter): the desired hectare dose of disparlure (10 or 20 g) was dissolved in a mixture of 20 ml of 75% nonpolar emulsifier and 100 ml of benzene which was then thoroughly emulsified in 5 liters of the latex. In one experiment (Bobrowice, PL, 1984), a commercially available latex paint was used as a carrier. The second was a tubing of natural rubber, mixture No. 3263, CSN 2245.14 (Gumárne SNP n.p., Dolné Vestenice, Czechoslovakia). The length of the individual pieces was 30 cm, diameter 4 mm, wall thickness 0.5 mm. The desired hectare dose (10 g) of disparlure was dissolved in 200 ml of benzene and allowed to embed into 400 g of the tubing (approximately 170 pieces) in a tightly closed vessel for 12 hr, after which time the solvent was permitted to evaporate. The third carrier was a sawdust of the material used for making the tips of fiber pens (Kohinoor-Hardtmuth n.p., 07 Dačice, Czechoslovakia). It consists of curled polyamide fibers impregnated with polymerized epoxy resin, porosity 45%, density 1.1 g/cm^3, mean effective radius of the most frequently occurring pores 2.5 and 50 μm. The desired hectare dose (10 g) of disparlure was dissolved in a mixture of 200 ml of paraffin oil and 5 liters of petrolether, which was applied to 3 kg

of the fiber-tip sawdust in a closed container and allowed to embed into it overnight. The solvent was allowed to evaporate at room temperature.

Experimental Plots and Designs of Experiments. Application of disparlure against scarce populations of the nun moth were performed in Czechoslovakia, where the last outbreaks of the pest occurred in 1965–1968. Since then, the pest has been in a latency phase. In such a situation the catches of the pheromone survey traps are most frequently in the range of 100–500 specimens per plate trap and season. The presence of the pest cannot be detected by other means.

The first experiment was done in Čížová near Milevsko, S. Bohemia (alt. 460–490 m above sea level), where the 56- to 76-year-old stands were composed of 90% spruce and 10% pine. The experiment was done in 1981. Three square plots of one hectare each were delineated for the experiment. The shortest distance between the plots was more than 300 m. Racemic disparlure formulated into the latex was applied to two of them at the doses 10 and 20 g/hectare, respectively, by means of a motor-driven sprayer. The third plot served as an untreated control. In each plot, five traps with 0.1 mg of racemic disparlure were exposed and checked regularly throughout the whole flight period of the moths.

The second Czechoslovak experiment was performed in Dobříš, Central Bohemia (alt. 450–470 m) in 1983. Composition of the stands was 80% spruce, 20% pine; the age of the trees was 60–80 years. Racemic disparlure was formulated into rubber tubing and the porous fiber-tip sawdust. Pieces of tubing were manually stapled on tree trunks (approximately one piece per five trees) in a square area of one hectare, and the fiber-tip sawdust was spread manually over another one-hectare area 700 m away. Five traps with 20 μg of (+)-disparlure were exposed on each treated plot, and the same number of traps was placed on an untreated one-hectare control plot 800 m away. Trap catches were checked regularly throughout the whole flight period.

The third experiment was performed again in Dobříš at a nearby location (alt. 550–570 m) in 1984. Composition of the stands was 90% spruce and 10% pine, age of the trees was 65–70 years. Two plots (300 $\times$ 400 m) 2 km apart were delimited for the experiment. One of the plots was treated manually with the fiber-tip pen formulation of racemic disparlure (10 g/hectare), the other was left as an untreated control. Twelve traps with 20 μg of (+)-disparlure were evenly distributed over both areas together with four traps that were each provided with a virgin female. The females originated from pupae collected in Chocianow, Poland, where the nun moth occurred in outbreak proportions that season. The caged females were first exposed on August 7 and replaced by newly emerged ones on August 10 and 14. The virgin females of the last batch were left in traps till September 5. No freshly eclosed females were available later during the season. The catches were recorded until the end of the flight season.

Two other experiments were performed in Poland, where the most devastating European outbreak of the nun moth ever recorded occurred in 1978–1984. The first experiment was carried out in Karsznica near Ustka (alt. 50–60 m above sea level) in 1982. The experiment was performed during the eruptive phase of an outbreak that culminated in 1982 and 1983. An average of 47 females per tree trunk ($N = 6$) was found that season. Four one-hectare plots (100 × 100 m), 400 m apart, were delineated from a spruce (80%) and pine (20%) stand whose trees ranged in age from 70 to 85 years. In two of the plots, the latex formulation of racemic disparlure was applied by hand sprayer in parallel strips 10 m apart. Ten grams per hectare of synthetic pheromone was disseminated in plot A, while 20 g/hectare was applied to plot B. The remaining two plots were not treated and served as controls. Five traps baited with 0.1 mg of racemic disparlure and four traps baited with a virgin female were exposed on each plot. The females were exchanged at every check, i.e., once in three or four days.

The second Polish experiment was done in Bobrowice near Zielona Gora during the first year of population decline in 1984. An average of 0.1 female and 116 caterpillars were found on sample trees. Two plots 300 × 300 m each, 1.5 km apart, were delineated from a 100% pine forest whose trees were 70–95 years old, at altitudes of 80–100 m above sea level. On one of the plots, 10 g/hectare of racemic disparlure was applied with a manual sprayer. A hectare dose of the pheromone was dissolved in 100 ml of benzene and emulsified in 1.5 liters of the latex paint, to which 3.5 liters of water and 20 ml of a detergent were added. Sixteen pheromone traps with 0.1 mg of racemic disparlure were evenly distributed on each of the plots and checked regularly during the whole flight season.

Methods of Evaluation of Male Confusion Effects. The effect of disorientation and/or confusion of the males (E_d) was calculated from the decrease in catches of pheromone traps on treated plots as compared with those on untreated ones. In some cases, live virgin females also were used as a lure. The E_d was calculated from the formula $E_d = [(K - A)/K] \times 100$, where K = the males caught at the control plot, and A = the males caught at the treated plot. Two different traps were employed. In Czechoslovakia, tin plates, 50 × 50 cm, provided with the adhesive Chemstop I (Chemika, Bratislava, Czechoslovakia) on both sides, were hung on tree trunks 1.5 m above the ground. The pheromone dispenser or a small cage with the female was placed in the middle of the plate (Skuhravý et al., 1974). In Poland, dry traps of the lantern type were used (manufactured by Producent, Warszawa). The trap consists of a plastic funnel with an upper diameter of 18 cm that is covered with a roof, under which the bait is suspended. The moths that enter the trap through the gap between the roof and funnel fall into a plastic bag suspended under the funnel. The chemicals used as a lure were either commercially available pheromone dis-

pensers (Zoecon) for the gypsy moth containing 0.1 mg of racemic disparlure, or caps of natural rubber containing 20 μg of (+)-disparlure, which was synthetized in the Institute of Organic Chemistry and Biochemistry, Praha. In each experiment, the same type of lure and trap was used both in the treated and control plots.

RESULTS

Application of Disparlure at Low Population Densities. The results of a pilot experiment (Čížová, 1981), in which two doses of disparlure were formulated in the latex, are clear-cut. Not a single male was caught on either of the pheromone-treated plots, while 282 males were found in the traps on the untreated plot between July 30 (the day of spraying) and September 24.

In the second small-scale experiment (Dobříš, 1983) two other slow-release formulations were tested. As shown in Table 1, very few moths were captured on either of the treated plots at any time after applications of the pheromone (E_d = 98.0% and 99.8% for rubber and fiber-tip sawdust preparations, respectively), whereas over 600 males were found in traps on the control plot. All differences between the catches on the untreated and on both treated plots were significant ($P < 0.05$) or highly significant ($P < 0.01$, t test).

The following year, a large-scale experiment was performed at the same location with disparlure being formulated only into the fiber-tip sawdust. Catches to the control pheromone traps as well as to the traps baited with virgin females

TABLE 1. MALES OF *L. monacha* CAUGHT BY PHEROMONE TRAPS (20 μg OPTICALLY ACTIVE DISPARLURE IN DOBŘÍŠ EXPERIMENT IN 1983 (MEAN PER TRAP AND DAY ± SD)

Date checked[a]	Untreated plot (1 hectare) (N = 5)	Plots (1 hectare) treated with 10 g of racemic disparlure formulated into	
		Rubber tubing (N = 5)	Fiber-tip sawdust (N = 5)
July 26	54.8 ± 16.3	0.4 ± 05	0
July 28	37.6 ± 10.3	0.6 ± 0.5	0
August 2	17.6 ± 4.4	0	0
August 5	1.6 ± 1.1	0	0.2 ± 0.4
August 10	1.2 ± 0.4	0.4 ± 0.9	0
August 16	4.6 ± 0.9	0	0
August 24	6.6 ± 3.2	0	0
September 21	1.0 ± 1.4	0	0

[a] The pheromone treatment was done on July 22.

were significantly higher on the untreated plot than on the pheromone-treated one, E_d being 99.1% and 98.8%, respectively (Table 2). The following season (1985), the same set of disparlure-baited traps (0.1 mg/trap) was exposed on both plots during the entire flight period. Mean catch per trap (±SD) in the control plot was 174.0 ± 105.2 males per season, whereas that in the plot treated in 1984 was 80.3 ± 50.9. The differences are not significant.

Application of Disparlure During Outbreak Population Densities. The differences in the catches of the traps exposed in Karsznica on the disparlure-treated and control plots are illustrated in Figure 1. For both doses applied, the catches on treated plots were significantly ($P < 0.05$) or highly significantly ($P < 0.01$) lower (t test) than those from control plots, except for some checks after August 23, when the flight period was already ending and very few moths were captured on either plot. Calculated from the data summarized for the whole season, the E_d was 92.0 and 95.0% in pheromone- and female-baited traps, respectively, in plots treated with 10 g of disparlure per hectare, and 94.2 and 90.5% in plots treated with 20 g of disparlure.

In the second experiment, carried out in Bobrowice, only 91 males were caught into 16 pheromone traps on the disparlure-treated plot during the whole flight period of the moths, versus 2388 males on the control plot, thus making the $E_d = 96.2\%$. The differences between the catches on the treated and control

[a] Racemic disparlure (10 g/hectare) formulated in latex was applied on July 31.

plots were highly significant ($P < 0.01$, t test) throughout the whole flight period (Table 3).

DISCUSSION

Disparlure, the sex pheromone of the gypsy moth (Bierl et al., 1970), has been recognized as a sex attractant in the nun moth also (Schönherr, 1972), and later it was found in the female of the latter species (Bierl et al., 1975). The synthetic pheromone has been used in survey traps for many years for detection and prognosis of the nun moth in Central Europe (Altenkirch, 1985a, b; Schmutzenhofer, 1986; Skuhravý et al., 1974; Maksymov, 1978; Apel et al., 1984; Jensen and Nielsen, 1984). Synthetic disparlure was also tried as an attractant for the control of the moths by trapping off the males (Boness et al., 1974) and as a mating confusant in several countries (Vrkoč et al., 1981; Altenkirch, 1985a, 1986; Schmutzenhofer, 1986). The results were mostly encouraging. Racemic disparlure also has been extensively tested in the United States as a confusant of males of the introduced gypsy moth populations with the aim of finding environmentally acceptable methods of halting the spread of the introduced pest (for review see Doane and McManus, 1981; Plimmer, 1982;

Schwalbe et al., 1983). The rationale for using the sex pheromone as a controlling agent against the nun moth in Europe comes from different premises and a different strategy should be adopted. The nun moth is a native species in the palearctic region, occurring in sparse populations all over the continent and making only occasional outbreaks, presumably as a result of ecological disturbances caused by man. Therefore, there is no reason for fighting the sparse autochthonous populations in ecologically balanced environments. Instead, the population levels of the moths should be closely watched for signs of incipient outbreaks and controlling measures applied only after a population buildup is detected.

The present paper investigates feasibility of using racemic disparlure as a mating confusant in the nun moth under the conditions of low and high population densities. Three types of slow-release formulations were tested: a spray formulation with latex as a carrier, a tubing of natural rubber, and a sawdust of porous material used for manufacturing tips of fiber-tip pens. All of them appeared suitable for the purpose. Providing that 10–20 g/hectare of disparlure were disseminated over the experimental plots (with their size ranging from 1 to 12 hectares), the disparlure concentration in the atmosphere remained high enough to interfere with the males' ability to find a discrete source of sex attractant (i.e., a dispenser loaded with racemic or optically active disparlure or a calling virgin female) for the whole flight season, which may extend for four to five weeks. In sparse density populations (approximately 10 females/hectare), the confusion effect was very high (98.6–100%) at all pheromone formulations and both doses applied. This finding is encouraging with respect to the potential use of the tested formulations in preventing the onset of a population outbreak.

A somewhat different situation appeared during the outbreak period. Although the catches of the pheromone and female baited traps of the disparlure-treated plots were significantly suppressed, the confusion effects were lower (90–96.2%) than during the non-outbreak period. These findings support the hypothesis made for the gypsy moth (Beroza and Knipling, 1972), and often also considered for other moth species, that synthetic sex attractants may have limited value as a practical measure to disrupt mating in medium or dense populations because their effectiveness will be influenced by the density of the target pest population.

With respect to the technical feasibility of dissemination of the active material, latex and the fiber-tip sawdust appear to be convenient carriers. The sawdust has particularly promising properties because it is composed of small particles that are easy to spread aerially by conventional applicators of solid materials. Moreover, it is a cheap waste by-product of the pen industry.

Questions concerning the impact of pheromone treatment on the reproduc-

tive efficiency of wild females were not addressed by the present study. Their understanding is, however, of prime importance for the confusion method to become operational. More research along this line will have to be done in the future.

(Received December 4, 1986; accepted March 5, 1987)

Abstract—Extracts of Scandinavian birch (*Betula pendula* Roth) buds and internodes of varying twig diameters have been investigated for their inhibitory effect on ruminant digestibility in vitro. The predominant inhibitory effect was observed in extracts containing the phenol platyphylloside, 5-hydroxy-1,7-bis-(4-hydroxy-phenyl)-3-heptan-one-3-O-β-D-glucopyranoside. Isolation of the pure compound and incubation with rumen inocula showed that digestibility was negatively related to the concentration. Significant effect was measured below the concentration naturally occurring in birch (0.8% of dry matter). Another isolated compound, the closely related rhododendrin, 4-(4-hydroxyphenyl)-2-butanol-2-O-β-D-glucopyranoside, did not depress digestibility within the concentrations found in birch. An important phenol of buds, apigenin-4′,7-dimethylether, did not have any measurable effect on digestibility, while a nonphenolic fraction of bud extract had a slight inhibitory effect on digestibility. Implications for browsers feeding on birch are briefly discussed.

Key Words—Phenol, platyphylloside, digestibility, plant defense, ruminant, birch.

INTRODUCTION

Plants produce a number of structurally different secondary metabolites of which at least some must be regarded as part of a chemical defense against foraging

0098-0331/88/0200-0549$06.00/0

animals (Freeland and Janzen, 1974; Feeny, 1975; Swain, 1977; Rosenthal and Janzen, 1979). Studies on boreal tree–herbivore interactions demonstrate that food selection by boreal vertebrate herbivores may be explained, to some extent, by the occurrence of certain antinutritional or deterrent compounds in the plant (Pehrson, 1980, 1981; Bryant and Kuropat, 1980; Bryant, 1981a,b; Bryant et al., 1983; Palo et al., 1983; Palo, 1984). Herbivores of the boreal forest depend on birch as a main feed source during both winter and summer. However, different animals such as moose (*Alces alces*), hare (*Lepus timidus*), beaver (*Castor fiber*), and certain birds (*Tetranoidae*) utilize birch differently. All species feed selectively on different anatomical fractions and locate their feeding activity at different heights within the tree (Pullianen, 1972; Salo, 1973; Svendsen, 1980; Pehrson, 1980; Danell et al., 1987).

It seems reasonable to assume that the feeding behavior of the species studied is related to the presence of compounds that make the birch unpalatable, toxic, and/or indigestible (Bryant and Kuropat, 1980). Birch is rich in phenolic compounds, which are more or less associated with high biological activity (Palo, 1984). No doubt phenols have properties that ought to make them suitable as defense substances. Low-molecular-weight phenols are often sufficiently lipid soluble to enter animal cells, and polyphenols may interact with plant and animal macromolecules in the digestive system. Tannins and lignin are mostly found in long-lived tissues and plants growing on poor soils, and they are thought to act in a dosage-dependent fashion. Short-lived plants on richer soils tend to synthesize compounds that are active in lower concentrations, e.g., alkaloids, phenolic glycosides, and cyanogenic glycosides (Feeny, 1975; Cates and Orians, 1975; Rhoades, 1979; Coley et al., 1985).

Recent investigations have shown, that phenolic extracts of birch depress ruminant in vitro digestibility, and phenols in birch may be involved in metabolic disturbances in hares (Palo et al., 1983; 1985; Palo, 1985). However, the chemical basis of these effects was not known. The aim of the present investigation was to isolate and identify the compounds(s) responsible for the depressing effect on ruminant in vitro digestion.

METHODS AND MATERIALS

Twigs from Scandinavian birch (Betula pendula, Roth.) (Betulaceae) were collected in April, before leafing, at a site northeast of Uppsala, Sweden, and were separated into two groups with diameters of 0–1.5 mm and 1.5–5 mm, respectively. The twigs, either with or without buds, were dried at 40°C for 72 hr and then milled to pass a 1-mm sieve. Separate buds were stored at −20°C.

High-performance liquid chromatography (HPLC) was performed on a Waters chromatograph using either an analytical (Chrompac CP-TM-spher C

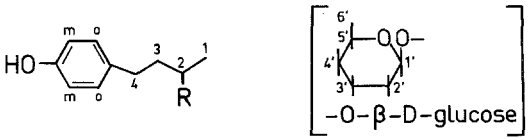
18, 4.6 × 250 mm) or semipreparative column (HiChrom Spherisorb S 10 ODS, 8 × 500 mm). Phenols were detected at 280 nm. Proton nuclear magnetic resonance spectra ([^{1}H]NMR) were recorded at 89.6 MHz on a Jeol Fx 90 Q spectrometer. Values are given relative to tetramethylsilane (TMS) as internal reference, [^{13}C]NMR spectra were recorded at 22.5 MHz. Sugars were determined with gas chromatography (GC) according to Theander and Westerlund (1985). Thin-layer chromatography (TLC) was performed on Merck HF-254 silica gel plates using the following solvents: (A) chloroform–methanol–water (80:15:1, v/v); (B) chloroform–methanol–water (40:15:2, v/v); (C) chloroform–butanone–acetic acid (10:7:2, v/v); and (D) petroleum ether (bp 40–60°C)–ethyl acetate (3:1, v/v). Phenols were detected by spraying the plates with diazotized sulfanilic acid (Fluka AG. CH. 9470) in 10% sodium carbonate (w/v), followed by 50% sulfuric acid (v/v). Catechin and leukoanthocyanins were detected with vanillin in 37% hydrochloric acid.

Some samples were hydrolyzed with pectinase (Sigma Chemical Co., No. P4625, 1.1 units/mg), which is known to have a high glycosidase activity, by incubating 5–15 mg in 2 ml water with 1 mg of enzyme added. After 20 hr in the dark at room temperature, the solution was extracted with 2 × 2 ml ethyl acetate. The organic phase was dried over anhydrous sodium sulfate and evaporated to dryness. All evaporations were made under reduced pressure below 40°C.

Isolation of Major Phenols from Different Fractions

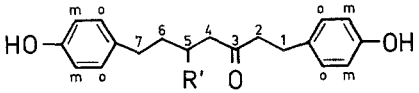
Twigs with Buds. Flour (100 g) from twigs (< 1.5 mm) was extracted with 80 ml acetone for 30 min in an ultrasonic bath in room temperature. The acetone was decanted and the flour extracted again with 80 ml acetone–water 1:1 (v/v). The two extracts were combined, the acetone was evaporated, and the aqueous phase extracted with petroleum ether (40–60°C). The remaining aqueous phase was lyophilized to a powder (8.5 g), which was dissolved in 96% ethanol and eluted on a Sephadex LH-20 column (30 × 880 mm) using (1) water, (2) 30% aqueous ethanol v/v, (3) 60% ethanol, and (4) 96% ethanol. The fractions were monitored by TLC using eluent A. Seven fractions were collected: I:1 (1.87 g); I:2 (0.45 g); I:3 (0.10 g); I:4 (0.5 g); I:5 (0.53 g); I:6 (0.49 g); and I:7 (0.64 g). Fractions I:1–4 were eluted with H_2O, fractions I:4–5 with 30% ethanol, fractions I:5–7 with 60% ethanol, and I:7 also with 96% ethanol. Part (0.3 g) of fraction I:5 was refractionated on silica (Merck Kiselgel 60, 0.040–0.063 mm, column size 20 × 300 mm) using eluent A. After examination of the fractions with TLC, one pure fraction (90 mg), later shown to be platyphylloside (Figure 1, structure 3) (cf. fraction III:4 below) was collected.

Buds. Buds (91 g, 69% dry matter) from twigs 1.5–5 mm in diameter were



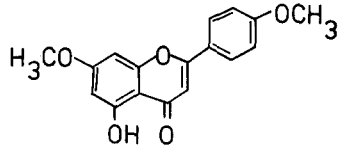
1: R = -O-β-D-glucose; Rhododendrin

2: R = H ; Rhododendrol



3: R' = -O-β-D-glucose; Platyphylloside

4: R' = H ; Platyphyllone



5: Apigenin - 4',7 - dimethylether

FIG. 1. Structural formulas of phenols isolated from birch. Numbers and letters on carbon atoms refer to [^{1}H]NMR spectra.

extracted with 3 × 200 ml acetone in a homogenizer, and the liquid was filtered and evaporated. The residue was suspended in 500 ml water and extracted with 2 × 100 ml hexane and 3 × 250 ml ethyl acetate. The two organic phases were dried over sodium sulfate and evaporated, yielding 9.0 and 11.7 g, respectively. Part (4 g) of the solid residue from acetate extract was chromatographed on a silica column (50 × 500 mm) with ethyl acetate–petroleum ether 40–60°C, 1:1 as an eluent. The fractions were monitored with TLC, eluent C. Seven fractions were collected: II:1 (0.1 g); II:2 (0.7 g); II:3 (0.4 g); II:4 (0.3 g); II:5 (0.1 g); II:6 (0.2 g); and II:7 (0.2 g). Fraction II:5 consisted almost exclusively of one compound. Part of it was recrystallized from acetone, yielding yellow needles (mp 174–175°C, not corrected) (cf. Wollenweber and Egger, 1971; Wollenweber, 1975). TLC eluent D: R_f = 0.38. Color with diazotized sulfanilic acid followed by 50% sulfuric acid: was dark yellow. The substance (Figure 1, structure 5) was identified as apigenin-4',7-dimethylether with [^{1}H]NMR (cf. Biftu and Stevenson, 1978).

Twigs without Buds (Internodes). Flour (100 g) made from internodal segments with a diameter of 1.5–5 mm was extracted with 600 ml ethanol (96%)

in an ultrasonic bath for 15 min. The solution was filtered, and the twig residue was washed with 100 ml ethanol. The combined ethanol phases were evaporated (10.9 g) and chromatographed on Sephadex LH-20, column size 4 × 50 cm using (1) water, (2) 30% aqueous ethanol (v/v), (3) 60% ethanol, (4) 96% ethanol, and (5) pure acetone as solvents. The fractions were monitored with TLC (eluent A) and seven fractions collected: III:1 (115 mg); III:2 (299 mg); III:3 (82 mg); III:4 (634 mg); III:5 (197 mg); III:6 (1273 mg); and III:7 (237 mg). Fractions III:1–2 were eluted with water, fractions III:3–5 with 30% ethanol, fractions III:5–7 with 60% ethanol, and fraction III:7 also with 96% ethanol and acetone.

Part (5 mg) of fraction III:2 was purified with semipreparative HPLC, mobile phase: linear gradient 52–100% aqueous methanol, 2.0 ml/min for 30 min; retention time was 14.3 min; yield was 4 mg. TLC, eluent A, $R_f = 0.35$, color with diazotized sulfanilic acid: yellow, darkens to red. [^{1}H]NMR (D_2O): 1.22 (1-CH_3, d, $J = 6.2$ Hz), 1.6–2.0 (3-CH_2, m), 2.65 (4-CH_2, t, $J = 7.6$ Hz), 3.0–4.0 (2-H and 2′-H to 6′-H, m), 4.50 (1′-H, d, $J = 7.6$ Hz), 6.85 (2 *m*-H, d, $J = 8.7$ Hz), 7.20 (2 *o*-H, d, $J = 8.7$ Hz). The compound was determined to be rhododendrin (Figure 1, structure 1).

Another part (15 mg) of fraction III:2 was enzymatically hydrolyzed and one product identified with GC as glucose. The aglycone (Figure 1, structure 2) was purified with semipreparative HPLC, mobile phase: linear gradient 36–100% aqueous methanol, 3.0 ml/min, 15 min; retention time 19.4 min. TLC eluent A: $R_f = 0.43$, eluent B: $R_f = 0.91$. Color with diazotized sulfanilic acid followed by 50% sulfuric acid: orange with darker contours. [^{1}H]NMR agreed with data for rhododendrol (Terasawa et al., 1973).

Fraction III:4 was almost chromatographically pure and was not further purified. TLC eluent A: $R_f = 0.17$, eluent B: $R_f = 0.52$. [^{1}H]NMR (CD_3OD): δ 1.6–1.9 (6-CH_2, m), 2.4–2.9 (1-, 2-, 4- and 7-CH_2, m), 3.0–4.0 (5-H and 2′-H to 6′-H, m), 4.27 (1′-H, d, $J = 7.3$ Hz), 6.69 (4 *m*-H, d, $J = 8.4$ Hz), 6.98 (2 *o*-H, d, *J* 8.5 Hz), 7.01 (2 *o*-H, d, $J = 8.5$ Hz). The compound was identified as platyphylloside (Figure 1, structure 3). [^{13}C]NMR agreed with data of Ohta et al. (1985). A small amount (6 mg) of the substance was enzymatically hydrolyzed and the sugar moiety identified as glucose with GC. TLC analysis of the aglycone gave $R_f = 0.65$, 0.91, and 0.78 for eluents A, B, and C, respectively. [^{1}H]NMR agreed with data for platyphyllone (Figure 1, structure 4), peviously called platyphyllonol (Terasawa et al., 1973, 1984; Nomura, 1981).

Determination of Digestibility In Vitro

The technique employed was essentially that of Palo (1985). Plant extracts or isolated substances were mixed with 500 mg of milled hay or flour from

birch twigs of diameter 1.5–5 mm in triplicate in glass filter tubes and dried at 40°C for 12 hr. The concentration of plants extracts or pure phenols was similar to that naturally occurring in birch twigs of diameter 0–1.5 mm. The tube contents were then incubated for 96 hr at 38°C with buffered rumen liquor taken from a goat fed hay (den Braaver and Eriksson, 1967). After incubation, the indigestible residues were recovered by filtration, washed with water and acetone, dried at 100°C for 24 hr, ashed at 600°C for 2 hr, weighed, and the in vitro organic matter digestibility (IVOMD) was calculated.

Twig fractions I: 1–7, bud fractions II: 1–7, crude hexane and ethyl acetate extracts of buds were tested for effects on IVOMD of hay. Substances isolated from internodes were tested at different concentrations on flour from twigs of 1.5–5 mm diameter.

Statistical analysis was performed using the Mann-Whitney U test (Siegler, 1956). Values of probability below 0.05 were considered as significant.

RESULTS

The effect of fractions I: 1–7 (twigs with buds) on IVOMD of hay is presented in Figure 2. Fraction I: 1, containing mostly low-molecular-weight car-

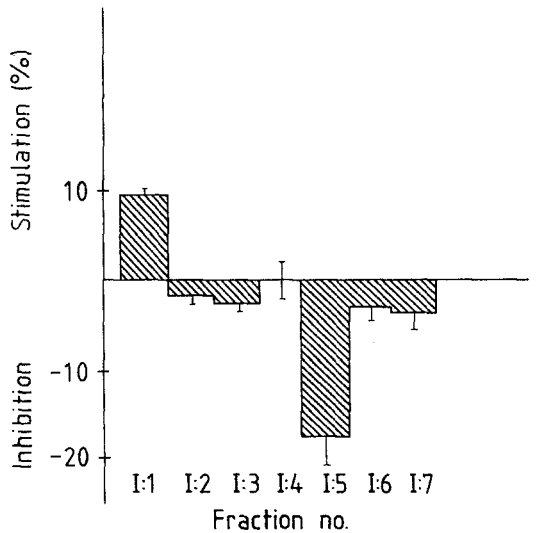


FIG. 2. Effect on in vitro organic matter digestibility of different fractions of an acetone–water extract of birch twigs including buds. Means and standard deviation ($N = 4$).

bohydrates and phenolic acids, stimulated IVOMD, while fraction I:5 has a strong inhibitory acitivity (Figure 2). This encouraged further studies on the latter fraction.

Qualitative analysis of catechins and leukoanthocyanins in fractions I:1–7 were made by spraying TLC plates with vanillin–hydrochloric acid. Fractions I:1–4 lacked catechin derivatives, while fractions I:5–7 contained vanillin-reactive substances (in increasing amounts). No correlation could be found between digestibility reduction and vanillin reactive substances.

In order to study the distribution of the compounds inhibiting IVOMD, internodes and buds were extracted separately. In fractions III:2 and III:4 one major phenolic compound was isolated from each.

Compounds Found. The [^{1}H]NMR spectrum of the substance in III:2 showed one *p*-substituted aromatic ring and four types of aliphatic protons in addition to signals from sugar protons. The NMR shift for the proton bound to the anomeric carbon showed that the sugar was aliphatically linked. The integral revealed a monoglycoside. The substance was identified as rhododendrin, which was confirmed by decoupling of the aliphatic protons. Enzymatic hydrolysis gave glucose identified with GC. [^{1}H]NMR data of the glycoside and the aglycone confirmed the compounds to be rhododendrin and rhododendrol respectively.

Fraction III:4 from internodes contained, as determined by TLC and HPLC, one major compound and minute amounts of impurities. [^{1}H]NMR data showed two almost equal, *p*-disubstituted aromatic rings in addition to 18 aliphatic protons. Decoupling of the aliphatic proton signals confirmed the structure to be platyphylloside. As for rhododendrin, the sugar moiety was aliphatically linked β-glucose. Although it has not been shown for either of the two compounds, we take for granted that it is the D-enantiomer of glucopyranose. The glycoside of fraction III:4 was identical to the major component of the active fraction I:5.

Buds contained a number of ethyl acetate soluble compounds not present in internodes. Fraction II:5 from buds crystallized spontaneously, and the substance was identified as apigenin-4′,7-dimethylether by [^{1}H]NMR.

Biological Effects Observed. The effect of the isolated compounds on IVOMD was studied at or below concentrations occurring in the plant material. The natural concentration of rhododendrin is about 0.3% in fine twigs. Neither rhododendrin nor rhododendrol had any effect on IVOMD. Platyphylloside, which has a concentration of 0.8% in fine twigs (based on dry matter), strongly affected digestibility in vitro (Figures 2 and 3). The reduction of IVOMD was directly proportional to the concentration of platyphylloside within the range studied and was significant even at concentrations below those found in fine twigs. Buds, which constitute about 7% of the twig weight, contained the

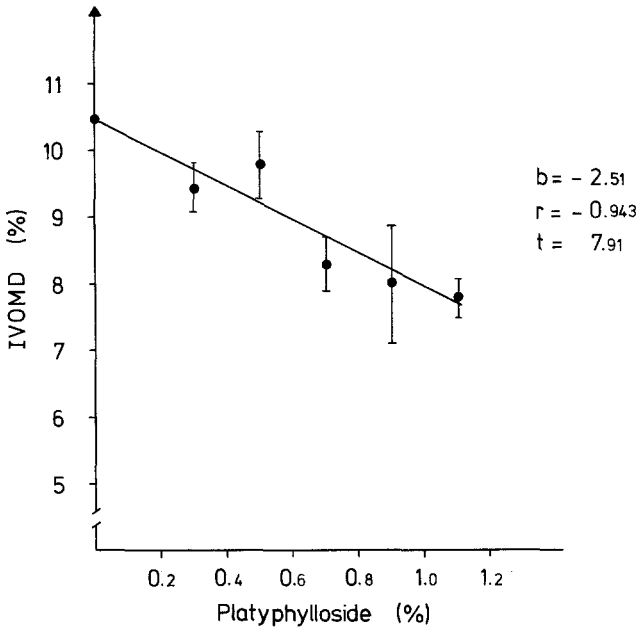

FIG. 3. The effect of addition of platyphylloside to twig flour on its in vitro organic matter digestibility. Mean and standard error ($N = 6$).

phenol, apigenin-4′,7-dimethylether, showing no effect on IVOMD. However, the ethyl acetate fraction II:1 of buds, containing mostly nonphenolic compounds had a certain depressive effect. The hexane fraction lacked effect on IVOMD.

DISCUSSION

This study confirms earlier observations that extracts of birch twigs contain substances that depress digestibility in goat rumen liquor (Palo, 1985; Palo et al., 1985). Buds contained several nonphenolic lipophilic substances not present in internodes. These were not further analyzed in this study, but a preliminary investigation of the hexane extract established that the triterpenoid, papyriferic acid, was not present in buds or internodes. This compound has been suggested as the primary defense compound in Alaskan paper birch (*B. papyrifera*) and has been shown to deter browsing by snowshoe hare (*L. americanus*) and also to depress cellulose digestion in ruminants in vitro (Reichard et al., 1984; Risenhoover et al., 1985). This does not exclude the possibility that the depression of IVOMD by the nonphenolic fractions may be partly due to some other isoprenoid substance(s). In view of the relatively modest effect of different

bud extracts on IVOMD and the fact that buds constitute only 7% of the twig weight, the overall effect of buds was considered to be small.

It is apparent from this study, that the compounds in birch that primarily depressed digestibility are found in water extracts of internodes. The platyphylloside, occurs in the fraction exhibiting the largest inhibitory effect on IVOMD.

Rhododendrin is a well-known birch phenol and was first reported by Archangelski (1901). As shown in the present study, the substance did not have any measurable effect on in vitro digestibility even at concentrations well above those found naturally. The only other study so far on possible effects of rhododendrin is by Santamore and Vettel (1978) in relation to attacks of the bronze birch borer (*Agrilus anxius*). They did not find any relationship between the concentration of rhododendrin in different birch species and the attack pattern of the insect.

Platyphylloside was originally isolated from Japanese birch (*B. platyphylla*) by Terasawa et al. (1973, 1984) and has not previously been identified in Scandinavian birch. About 80% of the observed depression of IVOMD by twig extracts in our experiments could be explained by the effect of this compound. It is very likely that the observations by Palo (1985) and Palo et al. (1985) of the inhibitory effect by water extracts from birch on IVOMD could be explained primarily by the occurrence of platyphylloside. Further support for the effect of platyphylloside is provided by the fact that its concentration shows the same seasonal decline in spring as catechin. (Palo et al., 1985; K. Sunnerheim, unpublished data). Thus the earlier reported effects on IVOMD of birch extracts and their variation with season (Palo, 1985; Palo et al., 1985) can most probably be ascribed to the presence of platyphylloside.

Results from in vitro studies may not be applicable directly to the situation in the living animal; nevertheless the mechanism of action on rumen microbes would qualitatively be the same. The rate of degradation of fibrous material in the rumen is important for the passage rate of food and hence for food intake. Although the rate of digestion has not been measured in detail in this study, we have indications that even the rate was decreased when the "total" digestibility was depressed. Substances such as platyphylloside, which depress digestibility, may thus reduce both the available energy per unit feed and the energy supply per unit time.

The optimal defense theory, as proposed by Rhoades (1979) states that the type of defense would be governed by the plant's apparency to herbivores in evolutionary time. Two major classes of defense compounds, quantitative and qualitative defenses, have been evolved. These are effective against specialist and generalist herbivores, respectively (Feeny, 1975). Polyphenols are regarded as a typical quantitative defense with a general antinutritional action (Swain, 1977, 1979).

Substances such as alkaloids and phenolic glycosides fall into the category of qualitative defense associated with a specific toxic action (Rhoades, 1979). Here we have shown that the polyphenolic fraction of birch does not exhibit the proposed action on digestibility; on the contrary, a phenolic glycoside has been shown to have the main antinutritional effect. Other observations on green alder (*Alnus crispa*), willows (*Salix* spp.), and paper birch have shown that phenolic glycosides and isoprenoids are responsible for defense properties against hares in these species (Bryant et al., 1983; Reichard et al., 1984; Tahavanainen et al., 1985).

The results of this study give further support to our hypothesis that deterrence by woody decidous plants against vertebrate herbivores is related to specific substances rather than groups of compounds.

Acknowledgments—We thank Dr. H. Graham for valuable discussions; Mr. R. Andersson for recording the NMR spectra; and Mrs. E. Fuchs, Miss E. Söderberg, and Miss Aili Henriksson for skillful technical assistance.

The study was supported by grant 517/82 and 560/85 from the Swedish council for forestry and agricultural research.

CHEMICAL ASPECTS OF HOST-PLANT SPECIFICITY IN THREE *Larrea*-FEEDING GRASSHOPPERS

R.F. CHAPMAN, E.A. BERNAYS, and T. WYATT[1]

Department of Entomology and Division of Biological Control
University of California, Berkeley, California 94720

(Received October 15, 1986; accepted March 6, 1987)

Abstract—The host-selection behavior of three species of grasshopper feeding on creosote bush, *Larrea tridentata*, in southern California was investigated. The species were *Bootettix argentatus*, which is monophagous; *Ligurotettix coquilletti*, oligophagous; and *Cibolacris parviceps*, polyphagous. The monophagous species is stimulated to bite by nordihydroguaiaretic acid (NDGA), a compound that is characteristic of the host plant and that may comprise up to 10% of the dry weight of the leaf. Host specificity of *B. argentatus* is enhanced by deterrent responses to compounds present in the surface waxes of all non-host-plant species. Both the oligophagous and polyphagous species are deterred by NDGA at naturally occurring concentrations. Their association with *Larrea* is probably based on tolerance of the plant chemicals rather than on dependence on specific chemicals. Factors other than the chemistry of the plant probably also contribute to the specificity of *B. argentatus* and *L. coquilletti*.

Key Words—Creosote bush, *Larrea*, nordihydroguaiaretic acid, grasshoppers, monophagy, *Bootettix*, *Ligurotettix*, *Cibolacris*, Orthoptera, Acrididae, host selection, feeding deterrence.

INTRODUCTION

Creosote bush, *Larrea tridentata*, is widespread in the Mojave and Sonoran deserts in North America. Associated with it is a guild of herbivorous insects exhibiting varying degrees of specificity for the plant (Schultz et al., 1977). Rhoades (1977a, b) demonstrated that the resin which coats the outer surface

[1] Present address: Cleppa Park Field Research Station, University College, Cardiff, Newport NP1 9YT, U.K.

0098-0331/88/0200-0561$06.00/0

of *Larrea* leaves has an antidigestibility effect in vitro and obtained correlative evidence for an in vivo effect in the proscopiid grasshopper, *Astroma quadrilobatum* Mello-Leitao. While an antidigestibility effect may be the adaptive (ultimate) reason for the failure of many species to eat *Larrea* and for the specificity of some insects, it does not account for the present-day responses of insects to the plant, since some species reject it without feeding, while others are adapted to feeding on it.

In this paper we describe some of the chemical factors affecting the selectivity of three species of grasshoppers that exhibit different degrees of specificity on *Larrea*: *Bootettix argentatus* Bruner which is monophagous, *Ligurotettix coquilletti* McNeill which is oligophagous, and *Cibolacris parviceps* Walker which is polyphagous. We are concerned with establishing whether the monophagy of *B. argentatus* is determined largely by host-plant chemistry, as opposed to other ecological factors, and what sense organs are involved in selection.

METHODS AND MATERIALS

Nearly all the studies were made in 1984, 1985, and 1986 at the Boyd Deep Canyon Desert Research Center which is 10 km south of Palm Desert, Riverside County, California. The climate and flora of Deep Canyon are typical of the Colorado Desert, and the tetraploid race of *Larrea tridentata* is dominant over the alluvial plain and lower slopes of the canyon. The three species of grasshoppers feeding on *Larrea* are all relatively common.

Behavior on Plants. Observations on the feeding behavior of *Bootettix argentatus* and *Ligurotettix coquilletti* were made in open-fronted clear-plastic boxes 30 cm tall, 16 cm wide, and 8 cm deep. The open front allowed for ease of access and observation. A sprig freshly cut from the test plant was placed in a vial of water centrally on the floor of the box. Insects were transferred to the plant from vials and allowed a few seconds to settle down before others were added. The behavior of each individual was recorded continuously. In fact, most of the time the insects were stationary, and it was possible to observe and record the behavior of five insects simultaneously. Tests continued for 1 hr or until the insects left the plant, if this was earlier. Approximately equal numbers of observations were made by each observer on each plant to counteract the effects of possible observer bias. Insects were only used once in any one experiment, and they were allowed at least 24 hr in the stock cage with access to *Larrea* before being used in any other experiment. Only adults or last-instar nymphs were used.

Since *B. argentatus* feeds during the daytime (Otte and Joern, 1977), it

was tested during the day in subdued light usually at 30.0–32.5°C (range 27.5–35°C). Insects, previously collected in the field, were taken directly from stock cages containing fresh *Larrea* foliage for one series of tests simulating natural conditions (0 hr deprivation). Since selectivity of grasshoppers declines with increased time without food (Chapman and Bernays, 1977), a second series of experiments was carried out with insects deprived of food for approximately 20 h. This extreme condition provided a more rigorous test of specificity.

L. coquilletti feeds at night (Otte and Joern, 1977) and so was tested at night using red light. Under these conditions, the insects were not readily disturbed, although they could see the light and occasionally responded to it. A weak response to red light by *Locusta migratoria* L. has been recorded by Chapman (1954) and Cassier (1960). These insects were deprived of food for about 10 hr during the day to simulate normal feeding conditions; they were tested between 2000 and 2300 hr, usually at 30.0–32.5°C (range 27.5–35°C).

Cibolacris parviceps was tested behaviorally only on *Larrea*. Its readiness to feed on other plants was investigated by giving individual insects in 250-ml containers a sprig of a test plant for about 15 hr, starting at sunset. The occurrence or absence of feeding was recorded the following morning at about 0900 hours. Between tests the insects were fed on *Encelia farinosa*, a commonly occurring plant in the habitat on which they fed readily.

Preparation of Plant Extracts. Extracts of the resin on the surface of *Larrea* leaves were made using methanol, chloroform, or hexane as solvents. In each case, leaves were picked from freshly cut branches of *Larrea* plants on which *B. argentatus* was known to be present. This reduced the likelihood of selecting leaves from a bush which, for some reason, was unpalatable to this species. Bushes are known to vary in their palatability to *L. coquilletti*, and the same may be true for *B. argentatus*. Extracts were made from nine bushes. Dead leaves and reproductive parts were not included. Chloroform extracts were made by immersing the fresh leaves for 1 min at room temperature; with methanol, the leaves were immersed for 1 hr at room temperature; with hexane, they were soaked overnight at 8°C. These extracts were made from separate batches of leaves; they were not sequential. The times chosen for extraction were such that as much resin as possible was removed without the extract becoming contaminated by chlorophyll, as judged by its color. It was thus assumed that the chemicals in the extracts were largely limited to those present on the surface of the leaves. Although NDGA, when pure, is relatively insoluble in chloroform, the solubility of other resin components resulted in the bulk removal of the resin. As a result, the chloroform extract contained a high concentration of NDGA (up to 50% dry weight).

After the period of extraction, the extract was filtered, air-dried, and weighed. The residue of the leaves was oven-dried and weighed so that a mea-

sure of the dry-weight concentration of resin removed from the leaves was obtained. Subsequently the dried extracts were redissolved in the same solvents to give dry-weight concentrations on sucrose-impregnated glass-fiber disks that ranged from one to five times those on the plant.

For one series of experiments, the concentration of NDGA in a methanol extract was reduced by fractionation on an LH20 Sephadex column with methanol. Fifteen fractions were collected, and each one was examined for the presence of NDGA by comparison with the standard using thin-layer chromatography (Macherey-Nagel, Polygram SIL G/UV254, $CHCl_3$–MeOH–H_2O, 13:7:4). Fractions in which no NDGA could be demonstrated were pooled and the solvent removed. This was the NDGA-reduced fraction.

Some of these extracts were tested against all three species. Additional extracts were prepared for assay with *L. coquilletti*. This species habitually occupies some *Larrea* bushes but not others (Otte and Joern, 1975; Greenfield and Shelly, 1985). For convenience, these are called "good" and "bad" bushes, respectively. One good and one bad bush was selected by Dr. M. Greenfield on the basis of his observations. Leaf samples from each bush were oven-dried at 75°C for 3 hr and then extracted for 1 hr in methanol followed by 5 min in chloroform. In this case the extractions were sequential. Extraction in methanol reduced the dry weight of the leaves from the good bush by 14%, compared with 20% from the bad bush. Chloroform extraction resulted in a further reduction by 1.6% and 0.9%, respectively.

The concentration of NDGA in the extracts dissolved in methanol was determined on an Eyela PLC-5 liquid chromatograph system (Tokyo Rikatikai) at room temperature using a YMCA-PACK, AM-302 ODS reverse-phase column (15 cm × 6 mm) (Yamamura Chemical) equipped with Uptight precolumn (2 cm × 2 mm) (Upchurch Scientific). The mobile phase was methanol–water (7:3) at a flow rate of 1.25ml/min. The eluent was monitored by a built-in UV detector at 254 nm, and the amount of NDGA was quantified by comparison with a standard curve.

Surface extracts of nonhost plants from the habitat were made by dipping leaves into chloroform for 30 sec. Extracts were air-dried and leaves oven-dried to obtain a dry weight concentration. The extracts were tested at five times the concentration on the leaf surface because they are absorbed through the disk so that the concentration on the surface of the disk is less than the concentration applied (Woodhead, 1982).

Behavioral Observations on Responses to Plant Extracts. The responses of *B. argentatus* to contact with plant extracts or to their odor was observed in transparent plastic domes 8 cm in diameter and 3 cm high. These were made from inverted plastic champagne glasses with the stem cut off. The hole which remained served as an entry point for the insect; it was sealed with parafilm

during tests. The floor of the chamber was made of a double layer of wire gauze (1 mm mesh) on which were two semicircles of filter paper (Whatman No. 1). These were pleated so that the free edges were readily accessible to the insect for biting; *Bootettix argentatus* typically starts to feed at the edge of a leaf and had difficulty biting the edge of a disk flat on the floor of the chamber. The filter paper was untreated in control or odor experiments or treated with a chloroform surface extract of one of the test plants. In the odor experiments, a filter paper with the test extract or 1.5 g of fresh *Larrea* leaves was beneath the floor so the insect was not able to touch the extract or leaves, although the odor entered the experimental dome.

The observations were made in red light to minimize the effects of disturbance and the behavior of each insect was recorded at 30-sec intervals for 15 minutes at 28–31°C. Insects were previously deprived of food for about 21 hr (range 17–25 hr) generally at 19–23°C. They were allowed at least 15 min to acclimate at 30°C before being tested. During each experimental session two sets of insects were watched by different observers. A fresh insect was used for each treatment, and the sequence of treatments was randomized. Equal numbers of each treatment were observed by each observer in each session to minimize bias. Experiment 1 was carried out in Deep Canyon, experiment 2 at Berkeley using insects recently collected in the Mojave Desert.

Feeding Responses to Plant Extracts. The feeding responses of insects to plant extracts were determined in experiments in which the extract was added to a glass-fiber disk (Whatman GF/A, 2.1 cm diameter) already containing 5% dry weight of sucrose. Sucrose and extracts were each added to the disks in 100 μl of the appropriate solvents. This amount was just sufficient to impregnate the whole disk. Different dry weight concentrations, approximating those on leaves, were obtained by adjusting the concentrations of the solutions. The disks were air dried after addition of sucrose and after addition of the extract.

Insects were tested individually in a choice experiment in which the test disk was paired with a second sucrose-impregnated disk additionally treated with solvent only. The amounts of the two disks eaten after 24 or 48 hr were determined by weighing. The disks were presented in plastic boxes 20 × 10 × 3 cm high with gauze insets at either end. The disks were mounted on inverted thumb tacks 5 cm from each end of the box and 1.2 cm above the floor so that the insects had easy access to the edges. A pad of wet cotton was placed centrally in the box, equidistant between the disks, to provide drinking water.

In assays with extracts of good and bad bushes against *L. coquilletti*, test disks, one from each plant, were paired. Experiments were conducted in an incubator at 30°C and in darkness since some of the extracts were colored.

Commercially available NDGA (Sigma Chemical Company, St. Louis, Missouri) was tested in the same way as the extracts, being applied to the disks

in methanol. In one experiment NDGA was added to glass-fiber disks (Whatman GF/C) without sucrose; control disks in this case were treated with solvent only (no sucrose).

RESULTS

Feeding on Larrea. All three species fed readily on *Larrea* after a period of deprivation or, in the case of *B. argentatus*, even when taken directly from the host plant (Table 1). The duration of a meal was about 5 min for all species for periods of food deprivation of 10–20 hr, and in the case of *B. argentatus* and *L. coquilletti*, nearly all the insects remained on the plant in the observation box for the hour of the experiment. More than half the *C. parviceps* left the plant.

Effects of Extracts of Larrea. Leaves of *Simmondsia*, a woody shrub similar in size to *Larrea* and present in the habitat, were completely rejected by *B. argentatus* without any attempt at biting (Table 2, and see Table 6), but all the insects tested, bit, or nibbled at the leaves when these were painted with a chloroform extract of the surface resin of *Larrea* leaves. This extract did not, however, increase the palatability of *Simmondsia* leaves for *L. coquilletti*, which nibbled, but rarely fed on the plant.

Chloroform extracts added as 29–37% dry weight to sucrose-impregnated glass-fiber disks were phagostimulatory to *B. argentatus* in two of three tests (Table 3). These extracts contained 20–50% dry weight of NDGA, giving 5–16% dry weight of NDGA on the disks.

The methanol extract of *Larrea* leaf surface did not influence the selection of *B. argentatus* for sucrose impregnated glass-fiber disks in four experiments, but was a feeding deterrent for both *L. coquilletti* and *C. parviceps*. However,

when most of the NDGA and related compounds in the extract were removed by column chromatography, reducing the NDGA concentration on the disks to 1.5%, it lost its deterrence to *L. coquilletti*.

A methanol extract of a *Larrea* bush that was habitually occupied by *L. coquilletti* (good bush) was compared in a choice experiment with one from a bush that was not commonly occupied (bad bush) (see Otte and Joern, 1975; Greenfield and Shelly, 1985), both extracts being presented at about 22% dry weight on sucrose-impregnated glass-fiber disks. The extract from the good bush was eaten by *L. coquilletti* in significantly greater quantities than that from the bad bush (Table 4), although the total amount consumed (mean of 1.2 mg/insect) was much less than in any experiment that included a sucrose-impregnated disk as a control (range of means 6.5–10.5 mg/insect, five experiments). We conclude that the extract from the good bush was deterrent to *L. coquilletti*, but less so than that from the bad bush. The dry weight concentrations of NDGA on the disk were 4% and 6%, respectively. Chloroform surface extracts of the same two bushes made after the methanol extracts did not differ in palatability and were not deterrent (10.8 mg eaten per insect, Table 4). The disks contained less than 0.002% NDGA.

A hexane extract, containing less than 0.5% NDGA, of *Larrea* leaf surface was phagostimulatory for *B. argentatus* and *L. coquilletti* and had no effect on *C. parviceps* (Table 3).

Effects of NDGA. NDGA increased the acceptability of *Simmondsia* leaves to *B. argentatus* (Table 2) and was stimulating at all concentrations from 0.005%

to 20% dry weight on sucrose-impregnated glass-fiber disks (Figure 1). The degree of phagostimulation increased from 0.005% to 5% dry weight of NDGA ($t = 3.81$, $P < 0.001$), but there was no significant difference between 5% and 10% dry weight. In experiments using 6% or 13% NDGA on glass fiber disks (GF/C) without sucrose, the insects almost invariably nibbled at the test disks, but not the controls (13 of 14 and nine of 10, respectively), but the amounts of material consumed in 24 hr were negligible. The average amounts eaten were less than 0.2 mg in both experiments, and the biggest feed was 0.4 mg, compared with 3.5 ± 1.1 mg ($\bar{X} \pm$ SE, $N = 11$) in a parallel experiment with a choice between 5% sucrose and blank disks.

Both *L. coquilletti* and *C. parviceps* were deterred by 5% and 10% NDGA on glass-fiber disks (Figure 1), and in both cases significantly fewer insects fed on the test disks with the higher (10%) concentration of NDGA (*Ligurotettix*, $P = 0.009$; *Cibolacris*, $P = 0.005$; Fisher's exact test). At concentrations of 0.5% dry weight and below, *C. parviceps* did not distinguish between test and

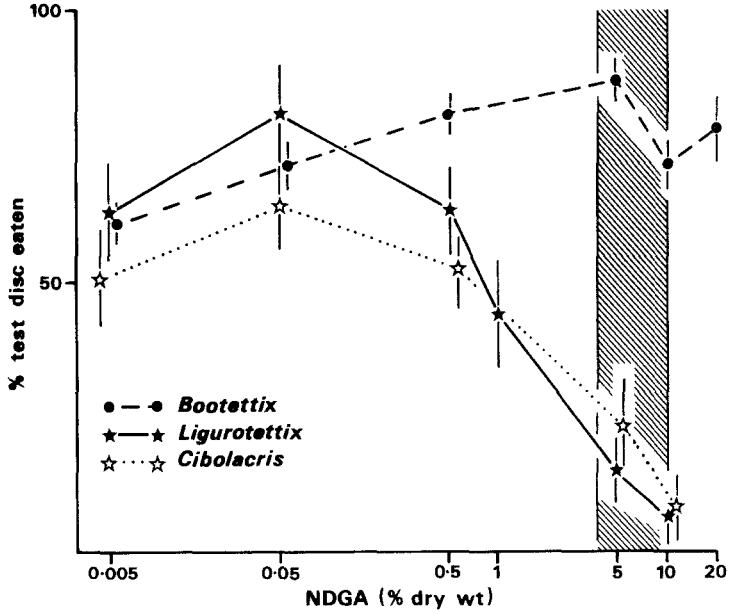

FIG. 1. Responses of each species to different concentrations of NDGA on sucrose-impregnated glass-fiber disks. Ordinate shows the amount of test disk consumed as a percentage of the total consumption by weight (test + control disks): 50% indicates no preference; >50%, phagostimulation; <50%, deterrence. Each point is based on a minimum of 16 insects. Results are of tests lasting 48 hr except for 20% which was only 24 hr. Vertical lines indicate standard errors. Hatched area shows range of normally occurring concentrations on *Larrea* leaves.

control disks. In the case of *L. coquilletti*, however, the pooled data for 0.005–0.5% dry weight indicate a significant phagostimulatory effect (Wilcoxon signed-ranks test, $P < 0.01$).

Behavioral Responses. Observations on the behavior of *B. argentatus* were carried out to determine which sensilla were involved in acceptance of the host plant. Normally, before starting to feed, a grasshopper tests the chemical quality of the potential food by touching it with the palps, "palpating," and biting. Rejection of the plant may follow either of these activities, or the insect may go on to feed. A chloroform extract of the leaf surface on filter paper induced more palpation and biting than was observed on untreated filter papers in two separate experiments (Table 5). The higher level of response with the extract may have resulted from information received via contact chemoreceptors on the tarsi or from olfactory receptors, probably on the antennae. When presented only with the odor of the extract or of *Larrea* leaves, significantly more palpation and biting occurred with the odor than without it in one experiment, but not in two others.

Responses to Other Plants. B. argentatus did not feed on any of 19 other plant species, most of which were common in the habitat at Deep Canyon. Undeprived insects rarely palpated and even after a 20-hr deprivation only a few insects palpated, bit, or attempted to nibble (Table 6). Other species of

[a] Minus indicates none in this category.

Zygophyllaceae, the family to which *Larrea* belongs, were no more acceptable than plants from other families. Only on the grass, *Aristida*, was a sustained attempt at feeding made by one insect. This individual chewed at a leaf blade for 8 min, but during this time, although the leaf tissue was crushed, hardly any was removed. One other insect also nibbled and one bit on the *Aristida*. With nearly every plant offered, a majority of the insects left the plant within the duration of the experiment (1 hr) without apparently palpating on the surface. Only the tarsi had made contact with the leaves.

Surface extracts of 11 of these species were tested in choice tests on sucrose-impregnated glass-fiber disks. In all cases, the extracts were strongly deterrent and, apart from *Beloperone* and the grasses, virtually no feeding occurred on the test disks (Table 7). The chloroform extracts of *Encelia* and *Hyptis* on filter papers did not, however, influence behavior in observations lasting 15 min (Table 5).

In contrast with *B. argentatus*, one or more individuals of *L. coquilletti* bit or nibbled at all the different plants offered, and three species, *Atriplex*, *Lycium*, and *Fagonia*, were readily eaten by most insects tested. Individual insects also fed on the grasses (Table 6). *L. coquilletti* commonly left the plants on which it did not feed.

The feeding responses of *C. parviceps* were only tested on eight plant species in five families. It ate all the plants (Table 6), although not always in large amounts.

DISCUSSION

Analysis of gut contents has revealed that *Bootettix argentatus* is strictly monophagous on *Larrea*; *Ligurotettix coquilletti* is oligophagous, although *Larrea* commonly constitutes a major host plant; and *Cibolacris parviceps* is polyphagous, feeding on *Larrea* only to a limited extent and not, in general, being dependent on it (Otte and Joern, 1977; Joern 1979). The present results demonstrate that the different relationships of these species with *Larrea* are at least partly governed by the chemical characteristics of the plant, extending the work of Rhoades (1977a), who clearly showed the importance of the leaf-surface resin in selection by *C. parviceps* and had circumstantial evidence relating the resin content of the leaves to acceptability by *B. argentatus* and *L. coquilletti*.

The sticky resin covering the leaves of *Larrea* may comprise 26% or more of the dry weight of the young leaves, sometimes falling to around 10% on older leaves of the same sprig and also varying between bushes. Phenolic aglycones comprise over 80% of the resin and the major component is nordihydroguaiaretic acid (NDGA), so that this single compound constitutes 4–10% of the dry weight of the leaf in samples taken from Deep Canyon (Greenfield et al., 1987). The resin also contains a range of flavonoid aglycones (Mabry et al., 1977; Rhoades, 1977a). In addition, Seigler et al. (1974) recorded the presence of a range of wax esters (even-numbered, C_{46}–C_{56}), most of which were from the external surface of the stems, but some of which were probably also on the leaves.

In the present experiments, *B. argentatus*, even after 20 hr without food, fed only on *Larrea*; none of the other plants from the habitat was eaten, and they were almost invariably rejected by the insect without biting. Clearly the insect responds to the surface chemicals or to the odors of the plants. The importance of the surface resin is confirmed by the fact that a chloroform extract of the surface induced the insects to bite and nibble at leaves of *Simmondsia* to which it was applied and to feed on sucrose-impregnated glass-fiber disks. The extract used in these experiments contained 50% dry weight of NDGA, which itself was a stimulant over a range of concentrations from 0.005–20% dry weight of the disks. The experiments in which NDGA was presented without sucrose suggest that it is a biting factor since, although virtually all the test disks were bitten, very little was ingested. These experiments were carried out with GF/C disks, not GF/A as in all other experiments, so it is possible that the failure to ingest was related to the physical differences of the disk, although we consider this unlikely.

The hexane surface extract was also phagostimulatory at 5% dry weight. This extract contained less than 0.025% NDGA, which may have produced the positive effect, although the presence of other phagostimulants cannot be excluded. Although the methanol surface extract contained NDGA at relatively high concentrations, it was not phagostimulatory. Presumably the effects of the NDGA were offset by unidentified deterrents.

The behavioral observations using a chloroform extract show that palpation and biting are induced by tarsal contact and/or olfaction. The much stronger response on contact suggests that contact chemoreception of the resin is of primary importance, but a response to odor occurred in one of three experiments, so that an olfactory response cannot be ruled out, especially since the odor presented was that of the surface extract and so will, presumably, have contained only a proportion of the many volatiles known to be present in *Larrea* (Mabry et al., 1977). An electroantennogram could be recorded from an antenna stimulated by the odor of leaves, so the odor was perceived by the insect, although the antennogram did not differ in magnitude from that produced by the leaves of nonhost plants (Wyatt, unpublished).

When presented with nonhost plants, nearly all the *B. argentatus* left the plants without attempting to feed or even palpating. This may have been due to the lack of specific phagostimulants characteristic of the host or to deterrent effects of the nonhosts. The behavioral experiments with *Encelia* and *Hyptis* provided no evidence of rejection, although the longer-term disk tests show that the surface extracts of all the nonhosts, including *Encelia* and *Hyptis*, contained feeding deterrents. This was true even of the two grass species tested, but on these more than half the insects did feed on the test disk, whereas with extracts of most other plants no feeding occurred at all. Mature grasses are generally low in biochemically active plant secondary compounds (Bernays and Barbehenn, 1987), although some strains of *Cynodon* are cyanogenic (this was not tested), and it is significant that the only nonhost on which *B. argentatus* made sustained attempts to feed was the grass *Aristida*. In this case, the combination of the fibrous food and specialized mandibles of the insect (Chapman, unpublished) apparently resulted in a mechanical barrier to feeding.

We conclude that the specificity of *B. argentatus* to *Larrea* involves a positive response to NDGA. This is the first example of an acridid adapted to respond positively to a characteristic host-plant chemical, although probably other instances are to be expected in other monophagous species (Bernays and Chapman, 1978). This parallels the suggestion by Rhoades (1977b) that the *Larrea* resin provides feeding cues to the monophagous caterpillar of the moth *Semiothisa colorata*. The specific response to NDGA in *Larrea* is complemented by the deterrent responses to surface compounds of nonhost plants, a combination similar to that exhibited by many relatively specific phytophagous insects (Chapman and Bernays, 1977). This is not to suggest that the chemical

cues are solely responsible for the specificity of *B. argentatus*. The insect is cryptic in *Larrea* foliage, and it probably responds to visual features of the plant (Otte, 1981).

Ligurotettix coquilletti exhibits a disjunct oligophagy. Otte and Joern (1975, 1977) recorded seven plants in the gut contents including *Larrea*, *Atriplex*, *Simmondsia*, and grass, and Ball et al. (1942) recorded feeding on *Franseria* (=*Ambrosia*) *dumosa*. Diet breadth, however, was more restricted within any one locality (Otte and Joern, 1977). In the current experiments, this species occasionally nibbled at *Simmondsia*, but did not eat it even when it was coated with the surface extract of *Larrea*. It did, however, eat *Atriplex*, *Lycium*, and *Fagonia* as well as *Larrea*. Populations are known to exist in areas in which *Larrea* is absent, and *Atriplex* and *Lycium* are the dominant shrubs (Greenfield, personal communication); clearly it is not dependent on any one plant species.

Methanol extracts of *Larrea* leaf surface were deterrent to *L. coquilletti*, even that from a good bush normally inhabited by this species. This extract was, however, less deterrent than that from a normally uninhabited bush. Rhoades (1977a) observed that the resin content of *Larrea* leaves from unoccupied bushes was, on average, higher than that of occupied bushes. This was also true in our case, but in the experiment the two extracts were present in similar dry weight concentrations (22–23%) on the glass-fiber disks. Our experiment suggests that the significant difference to the insects is the composition of the resin rather than, or perhaps, as well as, its quantity on the leaf. The disks from the good bush contained 4% dry weight of NDGA, compared with 6% in the disks from the bad bush. Over this range of concentrations, the deterrent effect of NDGA changes rapidly (Figure 1), and this could account for the differences in amounts eaten. Greenfield et al. (1987), in a parallel study of *L. coquilletti*, recorded longer meals on foliage with low NDGA–resin ratios.

The hexane extract of *Larrea* leaves is phagostimulatory. The compound responsible has not been identified, although low levels of NDGA, similar to those in the extract, are phagostimulatory.

L. coquilletti is cryptic on the stems of *Larrea*, and Otte and Joern (1977) point out that it is equally cryptic on the stems of *Atriplex* and *Simmondsia*. The same is true of *Lycium*. This suggests that visual cues may be important in host-plant selection by this species, although concealment on the nonhost, *Encelia*, seems equally effective (Greenfield, personal communication). If so, the chemical aspects of selection may be permissive rather than providing key sign stimuli. That the insect is not dependent on specific chemical signals, at least in the initial stages of selection, is suggested by the frequency with which biting and nibbling occur on nonhost plants. These are all ultimately unpalatable, but the deterrence in many cases depends on the internal constituents of the plant, not primarily on its surface properties.

Cibolacris parviceps is polyphagous (Otte and Joern, 1977; Rhoades,

1977a; Joern, 1979), feeding on a wide range of plants from numerous families. In the current experiments, all the extracts of *Larrea* leaf surface, as well as NDGA, were deterrent. Rhoades (1977a) and Schultz et al. (1977) showed that this species feeds preferentially on the oldest *Larrea* leaves, presumably those with the lowest resin contents. Removal of the resin with ether greatly enhanced the palatability of both young and old leaves and eliminated the differential between them (Rhoades, 1977a). The implication is that *C. parviceps* is able to tolerate *Larrea*, rather than having a specific response to it.

Bernays and Chapman (1978) suggest that polyphagous Arididae are, in general, less sensitive than oligophagous species to deterrence by plant secondary compounds, some of which may even become phagostimulatory. Host range and amounts eaten by these insects are determined by the balance between phagostimulatory and deterrent properties of a plant for that species of grasshopper. The results with *C. parviceps* are consistent with this thesis, although the meager data do not allow any more certain conclusions to be drawn.

All three species of grasshopper studied are Gomphocerinae (Jago, 1971), a subfamily comprised almost entirely of grass-feeding taxa. Otte and Joern (1977) discuss the evolutionary pressures that may have led to the current habits of these *Larrea*-feeding species. They envisage a series of steps in which insects fed on shrubs when grasses were no longer available, through the ability to feed entirely on a range of shrubs, and finally to specialization on *Larrea* associated with its high level of spatial and temporal predictability. It seems evident that the chemical relationships between the insects and the plant are largely a consequence of the pressures of desertification. *B. argentatus* have evolved a dependence on the plant, and at least one specific chemical is stimulatory over a wide range of concentrations. In contrast, it seems that both *L. coquilletti* and *C. parviceps* tolerate *Larrea*, but the requirement of *L. coquilletti* for suitable stems for concealment has perhaps become associated with a more limited tolerance of other plants than is true for *C. parviceps*. Thus the first exhibits oligophagy, the second polyphagy.

Acknowledgments—We are greatly indebted to Michael Greenfield for sharing his knowledge of *Larrea* as a grasshopper habitat with us, and to Alan and Vic Muth for making the facilities at Deep Canyon freely available to us. We also appreciate the assistance received from Drs. G. de Boer, K. Downum, I. Kubo, D. Light, D. Stanley-Samuelson, and Mr. R. Wrubel. Thanks are due to the UK AFRC Wain Fellowships for financial support of T.W.

GYPSY MOTH[1] MATING DISRUPTION: Dosage Effects

CHARLES P. SCHWALBE and VICTOR C. MASTRO

U.S. Department of Agriculture, APHIS
Otis Methods Development Center
Otis ANG Base, Massachusetts 02542

(Received July 25, 1986; accepted March 9, 1987)

Abstract—Small (1-hectare) plots in a dense gypsy moth (*Lymantria dispar*) infestation were treated with 5, 50, or 500 g racemic disparlure, and effects on male trap catch and mating behavior were studied. Capture of males in traps baited with 1, 10, 100, or 1000 μg (+)-disparlure declined as disruptant dosages increased. Traps with high levels of attractant caught moths when capture in those with lower baitings was dramatically reduced. While all disruptant dosages reduced trap catch, it was reducd at least 95% at all attractant levels at the 500-g disruptant application rate. Visual estimates indicated that male moth density was similar in treated and control plots; female mating success was reduced 6.5, 34.5, and 84% in plots with 5, 50, and 500 g/hectare disruptant, respectively. The duration of precopulatory and copulatory periods was similar for all females that were observed mating, regardless of disruptant treatment. It is proposed that reduced trap catch and female mating success are due to effects of atmospheric synthetic disparlure (disruptant) camouflaging natural attractant point sources.

Key Words—Gypsy moth, *Lymantria dispar*, Lepidoptera, Lymantriidae, disparlure, mating disruption.

INTRODUCTION

The development of techniques for disrupting pheromone communication in Lepidoptera has received considerable research effort in the last decade, but field trials have often been empirical and application rates have been restricted to those that were presumed to be "economically feasible" in the real world. For the gypsy moth, determining potential effectiveness of the technique has

[1] Lepidoptera: Lymantriidae.

0098-0331/88/0200-0581$06.00/0

been hindered further: in dense infestations where direct population measurement is accurate (through egg mass, larval and pupal counts), populations have not been significantly affected by disparlure treatment (Granett, 1976). Other studies with gypsy moth (Schwalbe, et al., 1979) and Douglas-fir tussock moth, *Orgyia pseudotsugata* (Sower and Daterman, 1977), have shown mating disruption to be inversely density-dependent. In low-density populations, direct census is difficult and imprecise and, therefore, the degree of control achieved by a disruptant treatment cannot be accurately quantified. Most field tests with gypsy moth have evaluated only disruptant dosages below 50 g/hectare; it may be theorized that the technique will be more effective against denser populations when the airborne concentration of disruptant is increased.

The purpose of the experiments in this report was to evaluate the degree of communication and mating disruption effected by vastly different atmospheric concentrations of disruptant.

METHODS AND MATERIALS

Gypsy moth mating-disruption field studies typically have been conducted on 16-hectare (or larger) plots with treatments applied by aircraft. Most controlled-release formulations that have been devised are appropriate for applying ca. 50 g disparlure (or less) per hectare. Formulation volume and cost of material render tests of greater application dosages impractical; consequently, it was necessary to miniaturize our experimental design such that a wide range of disruptant dosages could be studied.

Square, 1-hectare plots were established near Cotuit, Massachusetts. In the year of the test (1981), this site harbored a "dense" gypsy moth population that resulted in ca. 50% defoliation of oak trees. Plots were separated from one another by at least 1.5 km. Transect lines running through the plots at 10-m intervals resulted in 100 grid points in each plot. Relative airborne concentrations of racemic disparlure (disruptant) were achieved using 2.5-cm-wide Hercon tape containing 3.1 mg racemic disparlure/cm^2. A strip of tape was stapled in loops 1.5–2.5 m high on a tree at each grid point. By using strips 6.4, 63.5, and 635 cm long, plots were treated with 5, 50, or 500 g disparlure/hectare, respectively. Based upon laboratory measurements of emission rates from similar strips, daily disparlure release in the three plots was estimated at 15, 150, and 1500 mg/hectare (B.A. Leonhardt, personal communication).

Large-capacity traps fashioned out of 1.9-liter milk cartons were used to trap males in the test plots. Traps were baited by dispensing 1, 10, 100, or 1000 μg (+)-disparlure in 100 μl *n*-hexane onto 1 × 1-cm-diameter cotton wicks. These wicks were replaced every three days during the course of the studies. Laboratory emission tests indicate that, for the first three days, 10-, 100-, and

1000-μg wicks release ca. 2, 18, and 33 μg/day, respectively (Schwalbe, unpublished). Four traps of each dosage (16 traps total) were placed on a 4 $\times$ 4 grid arrangement (20 m between traps) in each plot. One trap of each dosage was randomly positioned on each line. Traps within each line were rerandomized with each observation. Pieces of dog collars 8.9 cm long and containing 8.37% (by weight) dichlorvos (Zoecon Corp., Palo Alto, California.) were suspended within the traps to kill the moths that entered. Traps were checked and rerandomized, and all captured males were counted daily. Populations were monitored in the four plots for five days (July 19–23, 1981) to give baseline trap catch prior to treatment. Treatments were applied to three plots on the evening of July 23, 1981, and traps were checked daily until July 29, 1981, to determine the effects of disruptant on capture.

Periodically throughout the day on July 31 (1130–1600 hr), observers walked slowly through the center 10 $\times$ 10-m sector of each plot and counted all male moths seen. This provided a visual census of male moth density in the plots.

Tests were also performed to determine mating activity in the plots. On July 28 and 31, and August 3, fifteen 1-day-old laboratory-reared female moths were placed on trees in each of the plots and collected three to four days later. That mating had occurred was concluded if the moth laid embryonated eggs. If an egg mass was not laid or the eggs were not embyonated, it was assumed the female had not mated. On each day that females were released, all females were observed continuously from 1130 to 1600 hr; incidence of mating, time to initiate mating, and duration of copulation were recorded.

RESULTS

Summaries of the number of male moths captured in traps baited with 1-1000 μg (+)-disparlure are presented in Figure 1A–D. Traps baited with 1–1000 μg (+)-disparlure typically yield a dose–response curve in which, as bait concentration increases, trap catch also increases to a peak at ca. 100 μg (+)-disparlure; traps baited with 1000 μg capture at about the same level as those with 10 μg pheromone. While the total number of moths captured in the various plots varied somewhat because population densities were different, the pretreatment dose–response curves were similar in all plots.

In the control plot, treatment catches were similar to pretreatment catches in traps baited with 1, 10, and 100 μg (+)-disparlure, indicating that no major change in adult population density occurred during the course of the test (Figure 1A). Traps containing 1000 μg pheromone captured 30.6% fewer moths in the presence of disruptant (61.6 moths/trap/day) than pretreatment (88.7/trap/day); the reason for this is not known.

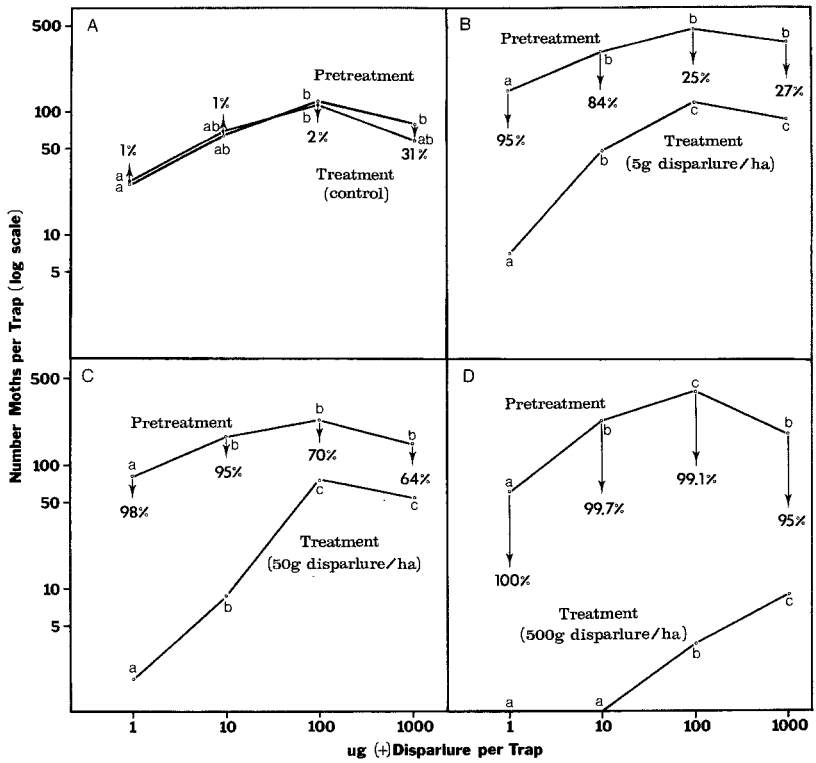

FIG. 1. (A–D) Daily number of male gypsy moths captured in four traps baited with 1, 10, 100, and 1000 μg (+)-disparlure before and after treatment of plots with 5, 50, and 500 g disparlure/hectare. Values shown below arrows on pretreatment curves are percent change in trap catch following application of disruptant. Pretreatment curves are from five daily trap readings (July 19–24, 1981); treatment results are from the six days following disruptant application (July 25–29, 1981).

In the plot treated with 5 g racemic disparlure/hectare, a general reduction in trap catch from pretreatment levels was observed in (Figure 1B). Catch in traps baited with 1 μg was suppressed to a greater degree (95%) than that in traps with 10, 100, or 1000 μg (+)-disparlure (reductions of 84, 25, and 27%, respectively). Traps containing 1000 μg (+)-disparlure caught fewer moths (89.2 males/trap/day) than traps baited with 100 μg (121 males/trap/day). While catch at both concentrations of attractant was reduced similarly, the typical "peak" of the dose–response curve was observed at the 100 μg concentration.

Increasing the application rate to 50 g racemic disparlure/hectare resulted in a further overall reduction in trap catch (Figure 1C). In this case, catch in the 1- and 10-μg traps was reduced appreciably (98 and 95%, respectively)

TABLE 1. AVERAGE NUMBER OF MALE GYPSY MOTHS OBSERVED IN CENTER 100 m^2 OF 1 ONE-HECTARE PLOTS TREATED WITH VARYING AMOUNTS OF RACEMIC DISPARLURE (COTUIT, MASSACHUSETTS, 1981)

	Treatment			
	Control	5 g/hectare	50 g/hectare	500 g/hectare

[a]Means followed by the same letter are not significantly different at the 5% level according to Duncans multiple-range test.

compared with the 100- and 1000-μg traps, which were reduced only 70 and 64%, respectively. As in the 5-g disruptant/hectare plot, traps baited with 100 μg (+)-disparlure caught more moths than any other trap type.

When the disruptant treatment was 500 g/hectare, the trap catch pattern changed dramatically. No moths were capture in traps baited with 1 μg (+)-disparlure, and those baited with 10 and 100 μg had catches reduced 99.7% and 99.1%, respectively, from pretreatment levels (Figure 1D). A reduction of 95% in trap catch was recorded in traps baited with 1000 μg (+)-disparlure. The treatment dose–response curve in this plot was unique from other treatments in that the 100-μg traps caught fewer moths than those baited with 1000 μg.

Results of visual census of male moths taken on July 31 indicate that more moths were present in the treated plots than in the control plot (Table 1).

In the control plot, all recaptured female moths were mated (Table 2). Successful mating was observed in 93.5, 65.6, and 16% of the females col-

Copulatory period (min)	64	80	60	–

lected in plots treated with 5, 50, and 500 g disparlure/hectare, respectively. Females that were mated during the observation periods were located by males as soon after release as those in the control plot (Table 3). There were simply fewer cases of mating in the treated plots and, in fact, none were observed in the 500 g/hectare plot. The duration of observed copulations was also similar, at ca. 60–80 min.

Native, unmated, and calling females could be commonly observed in the plot treated with 500 g/hectare, but searches in the environs around that plot only yielded mating or ovipositing female moths. As indicated in Table 1, male moths were present in all plots, but mating of females was noticeably rare in the plot with the 500 g/hectare treatment.

DISCUSSION

The results of these studies give insight into the mechanism of mating disruption effected by atmospheric permeation with racemic disparlure: atmospheric disparlure appears to camouflage attractant point sources. This is indicated by the finding that low disruptant levels caused substantial reductions in catch by traps baited with small amounts of attractant. Traps containing higher concentrations of attractant were consistently less affected. As disruptant treatments were increased from 5 to 50 to 500 g/hectare, catch in traps baited with increasing concentrations of attractant was consecutively reduced. If reduced trap catch was the result of males spending more time orienting to "competing" disruptant tapes (false-trail-following), treatment trap catch would have been generally reduced at all trap-bait concentrations. In effect, moth density would simply appear lower and the shape of the dose–response curves would have been similar to those before treatment. Indeed, such was not the case, as the shape of the treatment curves was very much influenced by disruptant concentration. Additionally, the racemic disparlure disruptant is a weak attractant, and

male moths would not be expected to spend much time searching such sources (Cardé, et al., 1977), nor were they observed doing so in this study. In tests with the western pine shoot borer, *Eucosma sonomana*, Daterman et al. (1982) obtained somewhat similar results, and they concluded that males were unable to locate trap baits because disruptant particles were more attractive. In such cases where the synthetic pheromone is used as the disruptant, false-trail-following (taken in the context where males were actually diverted and temporarily occupied by attractant point sources) is a tenable theory.

Adult male moth density (based on visual census) was higher in treated plots than in control plots. This rules out the possibility that high airborne levels of disruptant cause males to leave the treatment area, resulting in reduced trap catch and mating incidence. This contradicts a previous report (Granett and Doane, 1975) that moths are less numerous in areas with high airborne disparlure levels than in untreated areas. The differences observed here are thought to be due to plot location, but the possibility that moths were attracted to the treated plots cannot be ruled out. Note that pretreatment trap catch was higher in treated plots, suggesting higher local population density (Figures 1A–D).

The rarity of female mating in the plot treated with 500 g/hectare indicates that even at very high male moth densities (the daily pretreatment catch in four traps with 100 μg (+)-disparlure was 401 males in this plot), mating can be reduced. The frequent observation of unmated, calling native females in high-density sites is unusual. In high-density populations, female mating typically occurs within a few hours of eclosion and within minutes of placement (Doane, 1968). This finding suggests that the mating disruption technique could be effective in populations denser than previously hypothesized (Schwalbe et al., 1979; Cameron, 1973). Most literature on this subject alludes to the applicability of the technology to "low-density" populations.

Based upon laboratory emission measurements from disruptant dispensers similar to those used in this test, 1.5 g released/hectare/day (in the 500 g/hectare plot) was necessary to substantially reduce mating success at the high population densities in which these tests were run. Improvements in controlled-release formulations may offer new opportunities to develop the mating disruption technique for managing gypsy moth populations.

The limited observations indicating that the precopulatory period of female moths was similar in the control, 5 g, and 50 g/hectare plots is intriguing and suggests that those females that attracted mates produced enough attractant to be readily perceptible above atmospheric levels by males. There is considerable variation in pheromone production among individual females (Charleton and Cardé, 1982). Camouflaging was implicated as the mechanism of disruption in tests with pink bollworm moths (*Pectinophora gossypiella*) (Doane and Brooks, 1980) and Oriental fruit moths (*Grapholitha molesta*) (Cardé, 1980). If camouflaging is the governing principle in this mating disruption system, increasing

atmospheric concentrations should mask the presence of increasing proportions of the female population. Obviously, those that release perceptible amounts of pheromone should attract males, at least at high moth densities where long range plume-following is not necessary for locating females. Indeed, in dense populations, females may be located (via tactile cues) and mated before they commence calling (Cardé and Hagaman, 1984). The evidence that population control can be affected at low densities with lower (and economical) disruptant rates is still incomplete, however.

Acknowledgments—We thank Drs. Ring Cardé and Gary Daterman for reading the manuscript and providing helpful comments.

FERULATE ESTERS OF HIGHER FATTY ALCOHOLS AND ALLELOPATHY IN *Kalanchöe daigremontiana*

MURALEEDHARAN G. NAIR, MELVIN D. EPP, and BASIL A. BURKE

The Plant Cell Research Institute, Inc.
6560 Trinity Court, Dublin, California 94568

(Received November 3, 1986; accepted March 10, 1987)

Abstract—Ferulate esters of normal C_{22}–C_{30} alcohols were found in the root extract of *Kalanchöe daigremontiana* and the free *n*-C_{30} alcohol, triacontanol, was found on the leaves. Ferulic acid was isolated from the vermiculite in which plants were grown. Whole plant and tissue culture experiments were done to investigate the role of ferulic acid as an allelochemical and of triacontanol as a plant growth regulator in *K. daigremontiana* and other bioassay systems. No positive growth responses to triacontanol were observed, but inhibitation of growth response of plantlets by ferulic acid was seen.

Key Words—*Kalanchöe daigremontiana*, triacontanol, ferulate esters, ferulic acid, tissue culture, allelopathy.

INTRODUCTION

Mature plants of *Kalanchöe daigremontiana* (Crassulaceae) have been shown to display an allelopathic influence on the growth and development of their own plantlets (Groner, 1974) as well as on other species of plants (Groner, 1975). Extracts of *K. daigremontiana* were shown to have an inhibitory effect on the germination and survival rates of various plant seedlings (Groner, 1975). The phenolic glucoside, bryophyllosid, was suspected to be one of the allelopathic agents present in *K. daigremontiana* (Karsten, 1965). In another context, Williams and Smith (1984) have reported that the leaves of this plant were toxic to chicks at a dosage of 8–12 mg/g body weight, but the toxic principles were not chemically characterized. Several other phenolic components and flavonoid glycosides isolated by Gaind and Gupta from the leaves of *K. daigremontiana* were not characterized fully (Homans and Fuchs, 1970; Gaind and Gupta, 1971).

0098-0331/88/0200-0589$06.00/0

These authors did, however, analyze the sterols and alkanes present in the leaves (Gaind and Gupta, 1971).

In addition to the toxicity mentioned in these reports, *Kalachöe* species exhibit the phenomenon of asexual reproduction and are usually grown as curiosities because of the plantlets borne on leaf margins. The scientific explanation for this phenomenon has led to several investigations for plant growth regulation and for hormonal requirements during in vivo and in vitro propagations of *Kalanchöe* species (Smith and Nightingale, 1979; Kazaryan and Gevorkyan, 1985).

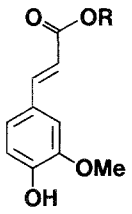
The allelopathic effect of the mature *K. daigremontiana* plant on its own plantlets is thus stimulatory as well as inhibitory. These effects, particularly the former, prompted us to investigate this phenomenon further, and to look for a possible chemical explanation (Burke, 1985; Nair and Burke, 1986). Furthermore, the availability of tissue culture methods involving *Kalanchöe* species (Thomas and Stobart, 1971; Smith and Nightingale, 1979) provided us with an opportunity to shorten the experimental time and to compare the effects of plant tissue in vitro with whole plants.

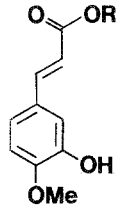
METHODS AND MATERIALS

General. Kalachöe daigremontiana were grown in the greenhouse in a bedding mix (20% peat, 15% sand, 15% red cinder, and 50% fir bark) supplied by Shelton Transfer, San Jose, California, and were harvested at eight months of age. In experiments aimed at extracting the potting medium, vermiculite was substituted for the bedding mix. Over the growth periods, the greenhouse temperature varied between a minimum of 15° C at night and a maximum of 28° C in the day. The relative humidity values ranged from 40% to 50% at night to 20% to 30% in the day. [^{1}H]- and [^{13}C]NMR spectra were done on a Varian XL-300 spectrophotometer, 300 MHz for proton and 75 MHz for carbon. High-resolution mass spectra (70 eV) were obtained on VG analytical 7070E spectrometer. GC analyses were conducted on a Perkin-Elmer Sigma 2000 gas chromatograph and OV-1 and DB-5 capillary columns, 25 m long and 0.25 mn in diameter. Unless specified, all GCs were done under gradient conditions with an initial temperature of 150°C, held for 2 min, and the temperature raised to 310°C at a rate of 10°C/min, and held for another 20 min. Both the detector and injector temperatures were 300°C. IR and UV spectra were recorded on Perkin-Elmer 1420 and Perkin-Elmer Lambda 5 spectrophotometers, respectively. To test for growth enhancement by triacontanol, three tissue culture bioassays were used measuring variations in fresh and dry weight of callus and suspension cultures. Unless otherwise indicated, the triacontanol was dissolved

in acetone and added to the media before autoclaving. The acetone concentration before autoclaving for all treatments including the control was 1%.

Extraction of Potting Medium and Isolation of Ferulic Acid. The vermiculite (200 g) in which the *K. daigremontiana* was grown was Soxhlet extracted in the dark with methanol for nine days. The methanol solution, evaporated to dryness in vacuo, gave a brown gum (610 mg) which showed seed germination and growth inhibition against lettuce and cress (Goldsby and Burke, 1987). This crude gum was triturated with chloroform, and removal of the solvent yielded a brown solid (240 mg), which, upon TLC purification (silica plates, 4:1 $CHCl_3$–MeOH) and activity-directed bioassay based on the inhibition of germination of lettuce and cress seeds, resulted in a UV-positive band, compound 1. This band was further purified by HPLC on a C18 column (5% ODS, MeCN–





1 R = H

2 R = $C_{22}H_{45}$

3 R = $C_{24}H_{49}$

4 R = $C_{26}H_{53}$

5 R = $C_{28}H_{57}$

6 R = $C_{30}H_{61}$

7 R = $C_{28}H_{57}$

H_2O, 60:40) and shown to be ferulic acid (30 mg) by spectral data and by comparison with authentic ferulic acid. In an attempt to evaluate the presence of other phenolics, the crude gum was silylated and the product subjected to GC-MS analysis. The result indicated only ferulic acid as the silyl derivative. Other minor, less polar components in the crude soil extract, which were also UV-positive on the TLC plates, did not yield silyl derivatives and were not acids or phenolics. They were not characterized. The natural and commercial samples of ferulic acid were also assayed for seed germination activity on cress and lettuce seeds.

Extraction of Roots and Isolation of Ferulate Esters. Fresh roots (wet weight 35 g) were blended with acetone (600 ml) and the resulting extract evaporated to dryness (520 mg) in vacuo. The crude extract was bioassayed using

the seed germination activity of cress and lettuce seeds as mentioned above. Since there was no activity, the UV-positive bands on TLC (silica plates, 4:1 $CHCl_3$–MeOH) were purified by TLC and the resulting product, A, (29 mg) appeared as a single spot. An attempt at further purification of this portion of HPLC was not successful.

Product A. Amorphous solid, UV (MeOH) 326 and 203 nm and with KOH in MeOH, 387 and 207 nm; IR ($CHCl_3$) 3540 (OH), 1700 (carbonyl), 1640 (olefinic), 1600 (aromatic) cm^{-1}; [^{1}H]NMR ($CDCl_3$) indicated that product A is a mixture of ferulate esters of higher fatty alcohols and sterols: The signals are δ 0.86 (3H, t, J = 6 Hz, CH_3), 0.96–1.50 (br s, CH_2), 1.69 (2H, m, CH_2), 4.16 (2H, t, J = 6 Hz, OCH_2), long chain alkyl; 5.50 (m, H-6), 3.70 (m, H-3) free sterols; 5.85 (1H, bs, exchanged with D_2O, OH), 6.26 (1H, d, J = 16 Hz), 6.91 (1H, d, J = 8 Hz, H-5), 7.07 (2H, overlapping signals, H-2, H-6), 7.58 (1H, d, J = 16 Hz), ferulate moiety. [^{13}C]NMR ($CDCl_3$) ppm, 167.38 (C=O), 144.60 (C-α), 123.03 (C-β), 146.0, 130.0 (aromatic C—O); 127.03, 115.62, 114.64, 109.18 (aromatic C), 76.57 (O—CH_2); 31.91, 29.69, 29.59, 29.54, 29.44, 29.35, 29.29, 28.75, 25.98, 22.68 (CH_2s of the fatty alcohol); 14.13 (CH_3 of fatty alcohol) 139.21, 121.23 (C-5, C-6 sterols) 72.86 (C-3 sterols); HRMS, *m/z*:6, 614.528 ($C_{40}H_{70}O_4$, M^+, req. 614.527); 5, 586.492 ($C_{38}H_{66}O_4$, M^+, req. 586.481); 4, 558.462 ($C_{36}H_{62}O_4$, M^+, req. 558.465); 3, 530.434 ($C_{34}H_{58}O_4$, M^+, req. 530.434); 2, 502.4034 ($C_{32}H_{54}O_4$,M^+, req. 502.402); 194.057 ($C_{10}H_{10}O_4$), and 177.058 ($C_{10}H_9O_3$) for the ferulate fragments. Mild alkali hydrolysis of product A afforded ferulic acid, found to be identical to an authentic sample.

Synthesis of Ferulate Ester with C_{22} Alcohol. Ferulic acid (4-hydroxy-3-methoxycinnamic acid), 194 mg, and behenyl alcohol, *n*-$C_{22}H_{45}OH$, (326 mg) were dissolved in dry benzene (100 ml) and a drop of conc. H_2SO_4 added as catalyst. Water formed during the reaction was removed using a Dean Stark appartatus. The product on purification by TLC afforded a white solid, 135 mg, UV (MeOH) 326(ϵ = 4930), 202 (ϵ = 7630) nm, shifting with KOH in MeOH, 387 (ϵ = 7496), IR ($CHCl_3$) 3540 (OH), 1700 (C=O), 1640 (C=C), 1600 (aromatic) cm^{-1}; [^{1}H]NMR ($CDCl_3$) δ 0.86 (3H, t, J = 6 Hz, CH_3), 0.96–1.50 (br s, alkane CH_2), 1.69 (2H, m, CH_2), 4.16 (2H, t, J = 6 Hz, OCH_2), 5.85 (1H, bs, exchanged with D_2O, OH), 6.26 (1H, d, J = 16 Hz, Hα), 6.91 (1H, d, J = 8 Hz, H-5), 7.07 (2H, overlapping signals, H-2 and H-6), 7.58 (1H, d, J = 16 Hz, Hβ); [^{13}C]NMR ($CDCl_3$) ppm, 167.38 (C=O), 144.60 (C-α), 123.03 (C-β), 146.0, 130.0 (aromatic-C—O), 127.03, 115.62, 114.64, 109.18 (Ar—C), 76.57 (O—CH_2), 31.91, 29.69, 29.59, 29.54, 29.44, 29.35, 29.29, 28.75 25.98, 22.68 (CH_2 of the alkane side chain), 14.13 (CH_3); EI-MS*m/z*: 502 (100) M^+, 194 (85), 177 (65).

Extraction of Leaves of Isolation of Triacontanol. Leaves of *K. daigre-*

montiana were removed from the stem (130 g wet weight) and blended with acetone in a Waring blender. The extract (600 ml) was dried *in vacuo* under reduced pressure to yield a crude gum (6.5 g) which was dissolved in methanol and filtered. The methanol-insoluble precipitate (1.32 g) was water soluble and tested positively for oxalates. The methanol-soluble portion was evaporated to dryness and stirred with $CHCl_3$. Removal of $CHCl_3$ gave a green gum (2.7 g). All extracts were bioassayed against cress and lettuce seed germination. The extracts were further purified by TLC on silica plates and assayed for seed germination activity on cress and lettuce seeds.

Fresh leaves of *K. daigremontiana* (100 g) were washed with $CHCl_3$. The wash was evaporated to dryness in vacuo. This crude extract (250 mg) was redissolved in acetone and the solution cooled and filtered. The residue (29 mg), product B, was analyzed by GC and found to be triacontanol, [^{1}H]NMR ($CDCl_3$), δ 1.01 (3H, t, CH_3), 1.5 (52H, bs, CH_2), 2.78 (4H, m, CH_2), 3.82 (2H, t, J = 2 Hz, O—CH_2), 4.20 (1H, s, exchanged with D_2O, OH). This was identical to the [^{1}H]NMR spectrum of the standard triacontanol.

Whole Plant Experiments with Standard Ferulic Acid, Extracts from Potting Medium, and Water-Soluble Fraction from Leaf Extract. Ferulic acid, the crude extract of the potting medium in which the *K. daigremontiana* plants were grown, and the water-soluble portion containing oxalates from the leaf extracts of the same plant were dissolved in DMSO–H_2O (1:99) to obtain concentrations of 50 and 250 ppm (pH ~5.5). Ten plantlets were placed on filter paper in a Magenta box after weighing. Solutions (10 ml) of the test compounds were placed on the filter paper and kept in the growth chamber. Each concentration had three replicates with 10 plants. Fresh weights were recorded on day 0, 7, and 14. On day 14 the plantlets were sacrificed for dry weights. These results were evaluated against controls.

Whole Plant Experiments with Triacontanol. K. Daigremontiana plantlets obtained from the leaves of matured plants were used for the assay. Triacontanol was dissolved in acetone (1 mg in 100 ml). Aliquots (1 ml) of this solution were mixed with 9 ml of Hoagland's solution in a test tube. A filter paper was placed on the surface of each solution and one plantlet was placed on the filter paper. A control was set similarly. There were 10 replications for both. The plantlets were kept in a growth chamber at 25°C under a 16:8 hr light–dark photoperiod. Each plantlet was weighed at day 0, 7, 14, and 21. On day 21, they were sacrificed to obtain the dry weight.

In another experiment, triacontanol was sprayed on the plantlets. Five plantlets were placed on a filter paper in a sterilized container which already contained 10 ml of Hoagland's solution. Triacontanol (1 mg) was dissolved in $CHCl_3$ (0.5 ml) and made up in water to achieve 1 mg in 100 ml (Ries and Wert, 1982). This solution was warmed, while stirring, in order to displace the

$CHCl_3$, cooled to room temperature, and sprayed uniformly on the plantlets in the container (Ries and Wert, 1982). Ten such pots containing five plantlets each were set. A control of 10 pots minus triacontanol was also set. All the pots were kept in the growth chamber, and their weights were recorded at 0, 7, 14, and 21 days. On day 21, plantlets from each pot were sacrificed to get the dry weight.

Tissue Culture Experiments with Triacontanol. Calluses were obtained from leaves of *K. daigremontiana* grown on MS medium (Murashige and Skoog, 1962) modified with Nitsch's vitamins and supplemented with 10 mM α-naphthalene acetic acid and 1mM *N*-6-benzyladenine (Karp and Sink, 1976). The calluses were transferred six or more times before being used in the bioassay. Ten pieces of callus tissue, averaging 0.12–0.16 g each, were placed on 30 ml medium in 100 × 15-mm Petri dishes. The plates were maintained under constant low light of 39 μE/sec/m^2 at 27°C. After 14 days, the mass of callus per plate was determined collectively. Ten plates were weighed for each treatment. The initial callus weights at day 0 were substracted from the weights at day 14; consequently the data describe the growth in grams during 14 days. The callus per plate was dried, and dry mass expressed as a percentage of fresh mass. In the second experiment *N*-6-benzyladenine was replaced by triacontanol.

The hypocotyls of aseptically germinated sunflower seedlings *Helianthus annuus* L. (variety Mammoth Grey Stripe) were sliced 2 mm thick and grown on MS medium with 4.4 mM *N*-6-benzyladenine (Greco et al., 1984). The individual slices averaged 5.3 mg. The plates were cultured for two weeks under low constant light of 39 μE/sec/m^2 at 27° C. Fourteen plates with 10 hypocotyl calluses per plate were weighed per treatment. For fresh weight determinations, the calluses were weighed individually, and for dry weights, the 10 calluses per plate were combined.

Suspension cultures of alfalfa (*Medicago sativa* L.) (variety Caygo UC) were grown in SH medium (Schenk and Hildebrandt, 1972) supplemented with 25 mM α-naphthalene acetic acid and 10 mM kinetin (Stuart and Strickland, 1984). Approximately 200 mg fresh weight of cells were inoculated into 20 ml of medium in 125 ml Delong flasks. The flasks were placed on a gyratory shaker at 125 rpm at 28°C in the dark. The cells were collected after 7 or 14 days with gentle vacuum on weighed filter disks and washed with 10 ml of distilled water. For each data point, the contents of five flasks were individually weighed. The fresh and dry weights of the cells were determined.

Bioassays were developed using tissues *K. daigremontiana* because triacontanol was found on its leaves, and such tissues would provide a useful comparison between whole plants and plant tissue in cultures. Alfalfa also has been

shown to produce triacontanol. Sunflower was an additional source of tissue for the study of initiation of callus formation.

RESULTS AND DISCUSSION

The earlier chemical investigations of the biologically active chemicals associated with *K. daigremontiana* have indicated the presence of nontoxic levels of oxalates, alkaloids, and nitrates in the leaves (Williams and Smith, 1984), but these studies have not defined the allelochemicals that were produced in the vermiculite in which *K. daigremontiana* plants were grown nor those that affected the plants whose development and growth were inhibited (Groner, 1975). Our investigation on the allelopathy of *K. daigremontiana* has identified an allelochemical in the potting medium, a conjugate of this compound in the roots, and a reported plant growth regulator in leaves of this plant.

In order to identify the allelochemicals in the potting medium, *K. daigremontiana* plants were grown in the greenhouse for eight months using vermiculite. Nutrients were added over the growth period to ensure growth. The vermiculite in which the plant had grown was extracted with cold methanol. Removal of the solvent gave very little residue. Soxhlet extraction of this vermiculite in the dark with methanol for nine days gave a brown gum, the $CHCl_3$-soluble portion of which was purified. This purification was guided by our bioassay against cress and lettuce seeds. Ferulic acid, compound 1 (0.05% to the total extract) was obtained. This was distinguished from isoferulic acid by comparison of the UV spectrum and the base shift with that of the latter, by GC-MS of the silyl derivative, and by direct comparison to an authentic sample of ferulic acid. Silylation of the total extract did not indicate any other phenolics. Bioassy of ferulic acid against *K. daigremontiana* plantlets and in our sensitive evaluation against lettuce and cress seeds showed significant activities. Evaluation of activity against lettuce and cress is particularly useful as a preliminary indicator of activity because of the high percentage of germination and the speed with which these seeds germinate.

The Soxhlet extraction of a blank vermiculite on which no plant was grown, but which was processed similarly, gave no such product. The very low yield of ferulic acid from the rooting medium is to be expected since organics tend to bind very strongly and sometimes almost irreversibly to such medium (Dalton et al., 1983; Nishimura et al., 1984).

The roots of the same plant which were grown in vermiculite gave a mixture of products when extracted with acetone. Bioassay of the crude root extract and a purified fraction, product A, on seed germination of cress and lettuce, and the assay against the fungus, *Cladosporium herbarum* (Homans and Fuchs, 1970), did not show any activity. Despite the lack of activity, product A was

evaluated because, like ferulic acid, it showed strong UV absorption on TLC plates. Product A consisted mainly of *n*-alkyl-3-methoxy-4-hydroxy cinnamates, compounds 2–6. Spectral data (UV, IR, [^{1}H]NMR, and MS) of this mixture indicated the presense of traces of stigmasterol and campesterol, in addition to the ferulate esters. The HPLC and TLC methods of separation used did not achieve separation of the sterols from the ferulate esters. However, the presence of these esters and sterols coexisting in the above purified fraction of root extract, product A, was established by fractional separation under MS conditions (Figures 1 and 2) and by GC. The total ion current (TIC) showed separation into these two groups of compounds (Figure 1). The broad peak centered at scan 63 (Figure 2) represented the ferulate esters showing mass measurements of 502, 530, 558, 586, and 614 as molecular ions, M^+, for these esters and 194 for the ferulic acid fragment. Similar mass measurements of the other peaks centered at scan 45 showed molecular ions, M^+, at 412 and 400, and a spectrum which indicated stigmasterol and campesterol, respectively. High-resolution mass spectra on the mixture confirmed this distribution of compounds. A selective ion chromatogram indicated that ions at *m/z* 194 and 177 for the ferulic acid moiety coincided with the TIC of the ferulate esters and were not related to the sterols. The sterols were thus free sterols. UV and base shift comparisons supported the presence of ferulate (4-hydroxy-3-methoxy cinnamate) rather than the isomeric 3-hydroxy-4-methoxy cinnamate. The [^{1}H]- and [^{13}C]NMR spectra (see Methods and Materials) of this mixture supported the

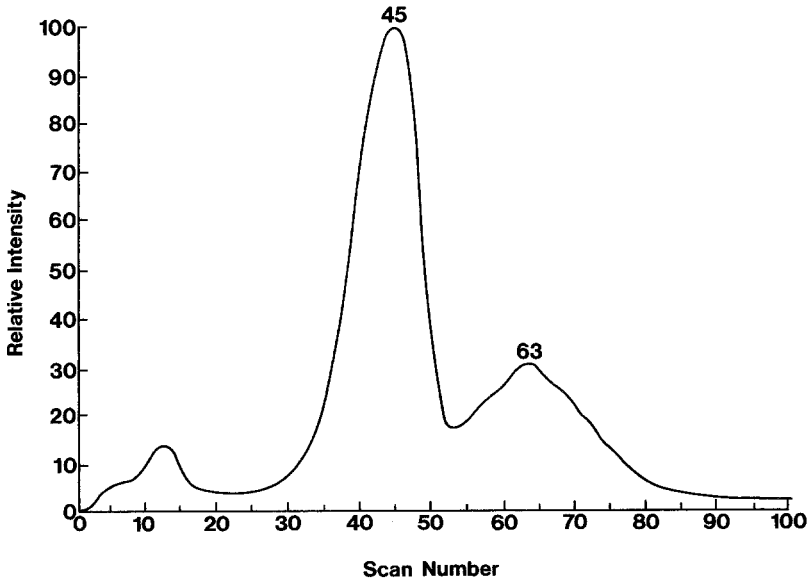


FIG. 1. Total ion current (TIC) of EI mass spectrum (70 eV) of product A.

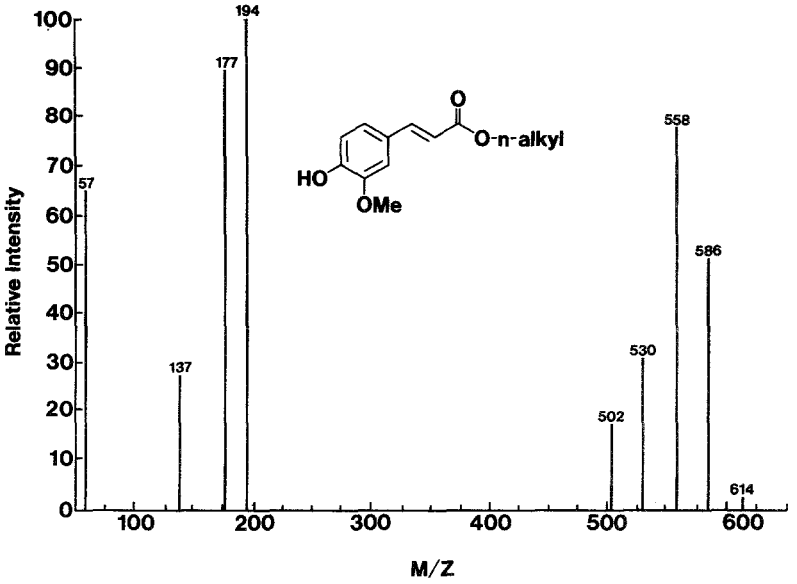

FIG. 2. EI mass spectrum (70 eV) of scan 63 of the TIC obtained from product A.

assignments from MS and UV data. In particular, the [^{1}H]NMR signal at δ 3.70 is characteristic of H-3 of a free sterol, while the triplet at δ 4.16 supports the primary ester of the fatty alcohols.

In order to verify this further, one of the ferulate esters $C_{22}H_{45}OH$ was synthesized from behenyl alcohol and ferulic acid. MS of the purified product (Figure 3) showed the expected molecular ion of 502 as the highest mass. The rest of the spectrum was similar to the spectrum of the mixture of esters. Also, other spectral data such as the IR, UV, [^{1}H]NMR, and [^{13}C]NMR were similar to that of product A. Since the molecular ion, M^+, at 502, is the base peak in this single-component spectrum, the relative ratio (8, 17, 44, 29 and 2) of the molecular ions of compounds 2–6 in the mixture of esters is a very good indication of the relative percent proportion in which these esters (C_{22}, C_{24}, C_{26}, C_{28}, and C_{30}) exist naturally in the roots of *K. daigremontiana*.

The presence of ferulic acid and ferulate esters in the rooting medium and roots, respectively, prompted us to reinvestigate (Williams and Smith, 1984) the leaves of *K. daigremontiana* for the existence of related substances. Acetone extraction of the fresh leaves revealed an extremely high concentration of water solubles (20% of the total extract by weight). Seed germination bioassay on cress and lettuce seeds of the crude extract exhibited a moderate level (40%) of inhibition of germination at 250 ppm level. When the dried acetone extract was reconstituted by trituration with methanol, the methanol-soluble portion was inactive in our bioassay against cress and lettuce seeds. However, the residue

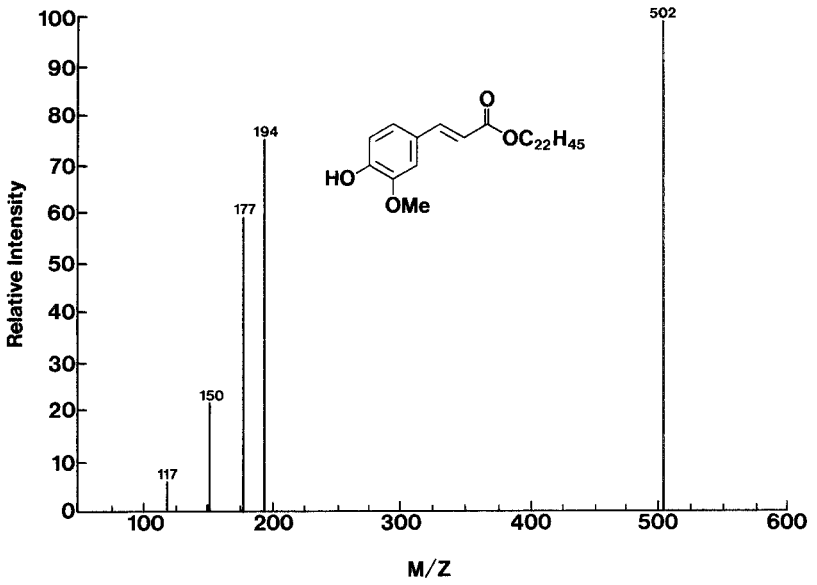

FIG. 3. EI mass spectrum (70 eV) of the synthetic ferulate ester, *n*-docosanyl-4-hydroxy-3-methoxycinnamate, compound 2.

that was water soluble and consisted largely of oxalates was toxic and inhibited the seed germination of cress and lettuce at the 250 ppm level. A fungal bioassay using the saprophyte, *C. herbarum*, was negative (Homans and Fuchs, 1970).

Alkanes of chain length varying from 22 to 35 were reported earlier in the leaves of *K. daigremontiana* (Gaind and Gupta, 1971). We therefore extracted the epicuticular leaf surfaces. Fresh leaves were washed with $CHCl_3$ and solvent then removed in vacuo. The colorless extract was redissolved in acetone and cooled. A precipitate thus formed, product B, which was filtered off and analyzed by GC. Both the crude leaf washings and the partially purified product B contained triacontanol, the C_{30} normal alcohol. Crude leaf washing contained alcohols of chain lengths C_{22}–C_{30} and the sterols. Product B contained sterols as well.

Ferulic acid is a well-known allelopathic agent (Putnam, 1983; Dalton et al., 1983; Liebl and Worsham, 1983). It has been suggested by Liebl and Worsham (1983) in their studies with prickly sida that the activity of ferulic acid as an allelochemical may be enhanced by microbial decarboxylation to its styrene derivative, a compound which is even more potent than ferulic acid. Triacontanol is a reported plant growth regulator (Ries and Wert, 1982) and is now found as a conjugate of ferulic acid in the roots and as a component of the leaves. No free ferulic acid was detected in the roots. It therefore seems that

the allelopathic activity of this plant is due to the ferulic acid exuded into the soil from the roots. This further suggests that the ferulic acid which is sequestered as esters with the long-chain fatty alcohols in the roots is nontoxic to the host plant, but the esters are cleaved to yield ferulic acid which is free to act in the soil as an allelochemical. Triacontanol, on the other hand, may act as a plant growth regulator (PGR). To examine this PGR effect of triacontanol on *K. daigremontiana*, tissue culture (Table 1) and whole plant experiments (Figures 4 and 5) were conducted.

In the tissue culture bioassays, there was no reproducible increase in the wet or dry weights during the two-week growth cycles with calluses of *K. daigremontiana* or of sunflower hypocotyls, or of suspension cultures of alfalfa (Table 1). In experiment 1, calluses of *K. daigremontiana* on media with the hormone, *N*-6-benzyladenine, increased the fresh weight by four fold. No effect was evident when treated similarly with triacontanol. The calluses of *Kalanchöe* on media without hormones showed a 30% decrease in fresh weight, but again there was no appreciable growth response to triacontanol. These results suggest that triacontanol cannot replace the hormonal requirements of this tissue. The hormone-supplemented portion of the first experiment was repeated with similar results. The dry weights did not show any response to triacontanol. The growth of the sunflower calluses was not enhanced with additions of triacontanol. When the concentration of tricaontanol was 10^{-5} M there appeared to be a slight growth inhibition with a marginal increase in percent of dry matter (Table 1).

With suspension cultures of alfalfa, no growth enhancement by triacontanol was observed. An analysis of variance for each day, as well as two-sample *t* tests, did not indicate any statistical differences between controls and triacontanol treatments. The standard deviations are large enough to mask possible minor differences in response.

Whole plant experiments with individual plantlets of *K. daigremontiana* treated with triacontanol at the roots did not show any significant difference in the fresh or dry weights (Figure 4). In addition, plantlets sprayed with triacontanol suspension (Ries and Wert, 1982) did not show any difference in the fresh or dry weights (Figure 5). Solubility of triacontanol is a major problem in conducting bioassays and may have contributed to the lack of any positive results for PGR activity of triacontanol.

Young plantlets treated with ferulic acid and crude ferulic acid extracts, isolated from the substrate in which the plantlets of *K. daigremontiana* were grown, showed considerable inhibitory effects on their growth (Figure 6). Plantlets treated with total potting medium extract and with ferulic acid had their roots decayed and the leaves chlorotic. In contrast, aqueous portions containing oxalates derived from the acetone extracts from leaf extracts showed no such activity but showed more root growth than the control, a result significantly different from that of inhibition shown in the seed germination assay.

TABLE 1. BIOASSAYS FOR GROWTH ENHANCEMENT WITH TRIACONTANOL[a]

Tissue and treatment	Triacontanol (M)				
	0	10^{-11}	10^{-9}	10^{-7}	10^{-5}
Kalanchöe callus, average growth in 14 days					
Experiment 1, with/without *N*-6 benzyladenine					
Fresh weight with *N*-6-benzyladenine (g ± SE)	4.87 ± 0.32	4.92 ± 0.42	4.38 ± 0.45	4.82 ± 0.41	4.67 ± 0.40
Fresh weight without hormone (g ± SE)	0.97 ± 0.08	0.93 ± 0.08	0.95 ± 0.09	0.95 ± 0.07	0.94 ± 0.10
Experiment 2, with *N*-6-benzyladenine					
Fresh weight (g ± SE)	4.16 ± 0.26	3.91 ± 0.28	3.74 ± 0.22	4.24 ± 0.33	3.65 ± 0.26
Dry weight as a percent of fresh weight (% ± SE)	4.5 ± 0.2	4.2 ± 0.04	4.3 ± 0.04	4.2 ± 0.1	4.2 ± 0.1
Sunflower callus, average growth in 14 days					
Fresh weight per hypocotyl slice (mg ± SE)	207.4 ± 8.2	199.9 ± 8.1	211.9 ± 9.3	203.5 ± 6.7	171.5 ± 7.3
Dry weight as a percent of fresh weight (% ± SE)	5.2 ± 0.3	5.3 ± 0.3	5.3 ± 0.3	5.4 ± 0.3	6.5 ± 0.5
Alfalfa suspension cultures, average per flask					
Day 0					
Fresh weight (mg ± SE)	190 ± 12.5				
Dry weight (mg ± SE)	25 ± 3.8				
Day 7					
Fresh weight (mg ± SE)	744 ± 125.0		702 ± 108.0	804 ± 141.0	661 ± 89.0
Dry weight (mg ± SE)	70 ± 10.0		64 ± 8.7	65 ± 8.3	54 ± 8.0
Day 14					
Fresh weight (mg ± SE)	1188 ± 427.0		2115 ± 463.0	1864 ± 629.0	1890 ± 570.0
Dry weight (mg ± SE)	89 ± 34.0		159 ± 26.9	134 ± 36.6	130 ± 37.9

[a] See text for experimental details.

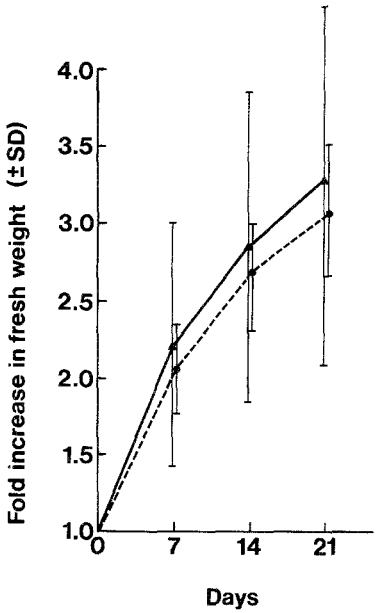

FIG. 4. Comparison of growth at days 7, 14, and 21 of plantlets of *K. daigremontiana* grown on filter paper impregnated with triacontanol (1 ppm). The fresh weight of the plantlets is expressed as -fold increase over weight at day 0 ± SD. Solid line, treated with triacontanol; dashed line, control.

In other bioassays against lettuce and cress seeds, fractions containing ferulate esters were noninhibitory. By contrast, ferulic acid showed good allelopathic activity, inhibiting 100% of seeds at 250 ppm concentrations during the seed germination assays. It is very clear that the allelopathic influence shown by *K. daigremontiana* can be attributed to free ferulic acid which, when sequestered as the nontoxic acid conjugates with the long-chain fatty alcohols, is not toxic to the host plant. These ferulate esters (compounds 2–6) are unprecedented as natural products, although the isoferulate of octacosanol, *n*-octacosanyl 3-hydroxy-4-methoxycinnamate, compound 7, isolated from the stem bark of *Erythrina senegalensis*, *E. glanca*, and *E. mildbaedii* (Fomum et al., 1986) has been reported since the completion of this work. The free ferulic acid presumably acts on young *K. daigremontiana* and other plantlets but is ineffective on the parent. Dalton et al. (1983) have indicated that ferulic acid is bound most tightly to the topsoil, where the concentration of organic matter is greatest. It is here perhaps, where ferulic acid becomes concentrated, that it is most effective on young plantlets or germinating seeds, because the young roots are in contact with this bound allelochemical.

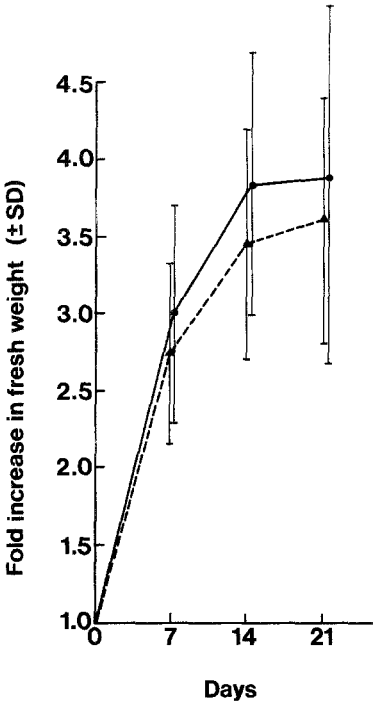

FIG. 5. Comparisons of growth at days 7, 14, and 21 of plantlets of *K. daigremontiana* after foliar spray with a solution of triacontanol (1 ppm). The fresh weight of the plantlets is expressed as -fold increase over weight at day 0 ± SD. Solid line, treated with triacontanol; dashed line, control.

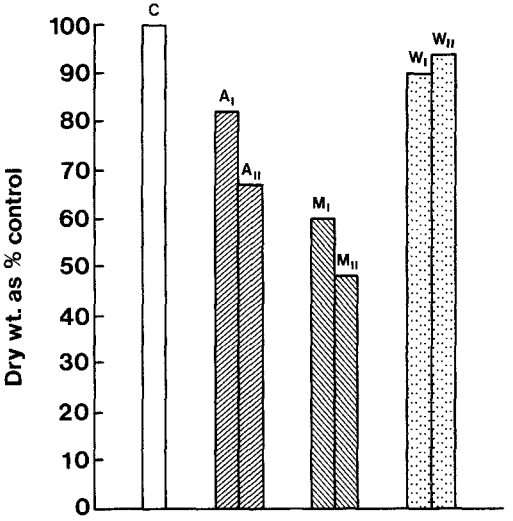

FIG. 6. Growth of plantlets of *K. daigremontiana* in solutions of ferulic acid, water-soluble portion containing oxalate and crude extract of the soil at 50 (I) and 250 (II) ppm concentrations. Data expressed as percent of control after 14 days. C = control, A = ferulic acid, M = methanol extract of the soil, W = water-soluble portion containing oxalates.

(Received December 18, 1986; accepted March 12, 1987)

Abstract—(*Z*)-11-Tetradecen-1-yl acetate, (*E*)-11-tetradecen-1-yl acetate, and (*Z*)-11-tetradecen-1-ol were previously reported as the sex pheromone in New York strains of the oblique-banded leafroller, *Choristoneura rosaceana* (Harris), and (*E*)-11-tetradecen-1-ol was tentatively identified in female tip extracts. For Okanagan Valley strains of *C. rosaceana*, an additional component, (*Z*)-11-tetradecenal, was identified from female tip extracts by splitless capillary gas–liquid chromatography and mass spectroscopy and was strongly stimulatory in electroantennogram studies. In field tests, 3 mg of 96.5:2:1.5 (*Z*)-11-tetradecen-1-yl acetate, (*E*)-11-tetradecen-1-yl acetate, and (*Z*)-11-tetradecen-1-ol (containing approx. 1% *E* isomer) was not as attractive as female-baited traps, and significant numbers of European leafroller *Archips rosanus* L. were attracted. The above blend with 1% (*Z*)-11-tetradecenal added was significantly more attractive than traps baited with

[1] Lepidoptera: Tortricidae.

female *C. rosaceana*, but *A. rosanus* males were still attracted. Increased percentages of (*Z*)-11-tetradecenal up to 4% caused increased catches of *C. rosaceana* and decreased catches of *A. rosanus*. Low amounts of (*E*)-11-tetradecen-1-ol and (*E*)-11-tetradecenal male also contribute to increased specificity of the synthetic pheromone blend to *C. rosaceana*.

Key Words—Oblique-banded leafroller, *Choristoneura rosaceana*, Lepidoptera, Tortricidae, sex pheromone, (*Z*)-11-tetradecen-1-yl acetate, (*E*)-11-tetradecen-1-yl acetate, (*Z*)-11-tetradecen-1-ol, (*E*)-11-tetradecen-1-ol, (*Z*)-11-tetradecenal, (*E*)-11-tetradecenal.

INTRODUCTION

The oblique-banded leafroller (OBLR), *Choristoneura rosaceana* Harris, was first reported attacking apples in British Columbia in 1922 by Venables (1924). It was a serious pest of apple until 1926 when the outbreak collapsed, apparently due to the activity of parasites (Venables and Gillespie, 1926). Increased damage occurred from 1934 to 1937 (Buckell, 1937). Mayer and Beirne (1974) surveyed unsprayed orchards and native host sites in 1972 but found only very low populations of OBLR. Since 1979, however, OBLR has become an important pest of apples in the Okanagan and Similkameen Valleys (Madsen and Procter, 1982).

In 1979, preliminary attempts to monitor OBLR populations in the Okanagan Valley of British Columbia were made using a bait containing only (*Z*)-11-tetradecen-1-yl acetate (Z11-14:Ac) (Conrel Co., Needham Heights, Massachusetts) (Madsen and Madsen, 1980). Better captures of OBLR were obtained with a formulation for the European leafroller (ELR) *Archips rosanus* (L.) (Zoecon Corporation, Palo Alto, California) containing an 85:15 mixture of Z11-14:Ac and (*Z*)-11-tetradecen-l-ol (Z11-14:OH) (Roelofs et al., 1976). Traps containing another bait for OBLR in plastic capsules[9] (Zoecon Corporation, Palo Alto, California) caught few males in orchards under an integrated pest management (IPM) program in 1980, even though high levels of damage were found in 1979 (Vakenti and Peters, 1981).

Differences in response to ratios of pheromone components occur between strains of the fruit-tree leafroller (FTLR), *Archips argyrospilus* (Walker) (Roelofs et al., 1974). The response of a New York strain is dependent upon the correct *Z*:*E* ratio and the presence of a synergist, while the British Columbia strain is less specific. Specificity was linked to the presence of the sympatric species, the red-banded leafroller, *Argyrotaenia velutinana* (Walker) in New York (Roelofs et al., 1974). Similarly, ELR males in British Columbia

[9] Identity and amount of pheromone blend used in the plastic capsule formulation is not available from the company.

responded to a wide range of Z11–14:Ac and Z11–14:OH ratios, but in the Netherlands it responded better to a 90:10 acetate–alcohol mixture (Roelofs et al., 1976). However, tests in the Okanagan Valley with modifications of the ratios and amounts of the pheromone blend for eastern OBLR populations, *Z*- and *E*11–14:Ac in a 95:5 ratio and ca. 5% Z11–14:OH (Hill and Roelofs, 1979) failed to improve catches of OBLR or to eliminate cross-attraction of ELR.

We report the results of a project initiated to investigate and reevaluate the pheromone chemistry and bioactivity for OBLR in the Okanagan Valley of British Columbia.

METHODS AND MATERIALS

Insects. OBLR larvae were obtained from laboratory colonies maintained on broad beans (16:8 hr light–dark, 25°C, 60% relative humidity) or field collected and individually reared on excised apple leaves or artificial diet. Pupae were held at room temperature and natural photoperiod until adult eclosion. Emergent adults were held at 5°C until used in traps or laboratory experiments.

Analytical Procedures. Solvents were distilled and/or filtered through activity I alumina prior to use. The compounds used in this work were purchased or synthesized by standard methods. Commercial Z11–14:Ac (Albany International Co., Needham Heights, Massachusetts), was purified from a 1% *E* isomeric impurity by liquid column chromatography on 20% $AgNO_3$–silica gel. The purified acetate was used to obtain Z11–14:OH by hydrolysis, and the latter was converted into (Z)-11-tetradecenal (Z11–14:Ald) by oxidation with pyridinium chlorochromate. All compounds used were >99% pure as determined by splitless capillary gas–liquid chromatography (SC-GLC).

Abdominal tips of individual OBLR females, 1–3 days old, 2–4 hr into the scotophase, were excised and washed with freshly distilled analytical reagent grade heptane (3 μl) as described by Klun et al. (1979). Extracts were prepared by covering several excised tips with heptane and storing these for two to four days in a sealed glass ampoule at room temperature. The heptane extract was removed and washed twice with a 5% aqueous sodium bicarbonate solution (50 μl) to remove free fatty acids prior to analysis.

SC-GLC was performed on a Hewlett-Packard 5880A instrument. The fused silica columns used were (A) a 50-m, 0.2-mm-ID Carbowax 20 M (Hewlett-Packard, Avondale, Pennsylvania) and (B) a 30-m, 0.25-mm-ID DB-1, a cross-linked methyl silicone (J&W Scientific, Inc., Rancho Cordova, California). Column A was programmed at 40°C isothermal for 2 min, 30°C/min to 150°C, then 2°C/min to 210°C. Column B was operated at 80°C isothermal for 2 min, 10°C/min to 180°C, then 2°C/min to 240°C. The injector was main-

tained at 200°C with a helium carrier gas flow of 1 ml/min. A flame ionization detector was operated at a temperature of 250°C. The detection limit for (*E*)-11-tetradecen-1-yl acetate (*E*11–14 : Ac) admixed with Z11–14 : Ac under these conditions was 5% *E* in 95% *Z* for column A and 1% *E* in 99% *Z* for column B.

Double-bond position was established as described by Bierl-Leonhardt et al. (1980). The combined washes from 35 female tips were mixed with *m*-chloroperbenzoic acid (30 μg) in methylene chloride (50 μl) and sealed in a glass ampoule at 25°C. After two days, the mixture was diluted with heptane (50 μl), washed three times with a 5% aqueous sodium bicarbonate solution (50 μl), and once with water (50 μl). An aliquot was chromatographed on column B and the remainder analyzed by mass spectroscopy.

Mass spectroscopic analysis, (SC-GLC-MS), was performed on combined washes or extracts by splitless injection into a Hewlett-Packard 5985B GLC-MS, fitted with either a 30-m × 0.32-mm-ID DB-1 or a 15-m × 0.25-mm ID Carbowax C20 M column using electron impact ionization.

Electrophysiological Studies. Electroantennograms (EAGs) were performed to determine response of male OBLR antennae to functional groups of a monounsaturated (Δ11) 14-carbon chain. Standard EAG techniques (Roelofs, 1976) were used and excised antennae were suspended between AgCl-coated silver electrodes (Arn et al., 1975) in a humidified, heated stream (1 liter/min) of compressed medical air. Chemical stimuli (10 ng) were placed on filter paper in 5 ml of air, which was injected in 1 sec into the air stream 10 cm from the antenna. One antenna was used for all test compounds with a 2- to 3-min exposure to clean airflow between stimulus presentations. Solvent controls (hexane) and nonpheromonal standard stimuli (14 : Ac) were presented throughout the test series. Responses to solvent controls (hexane) prior to and after test stimuli were averaged and subtracted to correct for mechanical and solvent stimulation. Data were normalized to a standard (14 : Ac) to correct for decline in EAG amplitude as an antennal preparation aged. Data presented are based on 20 antennal preparations. Compounds tested were: Z11–14 : Ac, *E*11–14 : Ac, Z11–14 : Ald, (*E*)–11-tetradecenal, (*E*11–14 : Ald), Z11–14 : OH, and (*E*)-11-tetradecen-1-ol (*E*11–14 : OH). All compounds were >99% pure as determined by capillary gas chromatography.

Field-Trapping Procedures. In all field experiments using virgin OBLR females, a yellow, cylindrical trap (Proverbs et al., 1966) was used. This trap was effective for leafrollers (Madsen and Vakenti, 1973) and could hold females alive for up to seven days. In other experiments, Pherocon 1C traps or a similar trap from a local supplier (Ecoyoos Consulting Services, Osoyoos, British Columbia) were used. Traps were spaced at a minimum between-trap distance of 8 m within rows and were hung in apple trees at a height of 2 m. To avoid contaminated trapping surfaces that would have decreased trap efficiency (Shep-

herd, 1979; Westigard and Graves, 1976), trap bottoms were replaced if catches exceeded 10 moths/trap. Except where otherwise noted, all chemical baits were formulated on rubber cap dispensers (Arthur H. Thomas Co., Philadelphia, Pennsylvania) which were pinned inside the top portion of the trap. Details of the experimental design are reported in Tables 1–5.

1982 Field Studies. In two orchards in Cawston, British Columbia, the following formulations of OBLR pheromone were compared: three dosages (1, 3 and 5 mg) of *Z*- and *E*11–14:Ac at a 93:2 ratio and 5% *Z*11–14:OH (Hill and Roelofs, 1979), and an *A. rosanus* formulation (Zoecon AROS) containing 5 mg of an 85:15 mixture of *Z*11–14:Ac and *Z*11–14:OH (Table 1). In one orchard, another blend (Albany OBLR) formulated in a Conrel fiber packet (Hill and Roelofs, 1979) was tested. All treatments were compared against unbaited control traps and trap catches were recorded weekly.

In the Entomology Research Orchard (Agriculture Canada, Summerland, Research Station, Summerland, British Columbia), traps baited with one of seven blends of *Z*11–14:Ac, *E*11–14:Ac, and *Z*11–14:OH were compared against traps baited with OBLR females (5/trap) and unbaited controls (Table

[c] *Z*11–14:Ac, *E*11–14:Ac, and *Z*11–14:OH in a 90:5:5 blend prepared in laboratory from materials obtained from Farchan Co. Willoughby, Ohio; based on OBLR pheromone determination by Hill and Roelofs (1979).

[d] *Z*11–14:Ac and *Z*11–14:OH in a 85:15 blend; based on *Archips rosanus* pheromone determination by Roelofs et al. (1976).

[e] Probably *Z*11–14:Ac, *E*11–14:Ac, and *Z*11–14:OH in a 90:5:5 blend (Hill and Roelofs, 1979) formulated in a packet of 10 microtubules by Albany International Co., Needham Heights, Massachusetts. Not tested in Zebroff Orchard.

2). [Z11–14:Ac obtained from Albany International Co., Needham Heights, Massachusetts; Z11–14:OH prepared from Z11–14:Ac containing up to 1% *E*11–14:Ac. Solvent used in preparation of mixtures unless otherwise noted, was 1,2-dichloroethane. Blends prepared at the Summerland Research Station.]

Another experiment was conducted from August 16 to September 15, 1982, in the Still Orchard, Cawston, British Columbia to compare lower amounts of *E*11–14:Ac blended with increasing amounts (1.5, 3.0, and 6.0%) of Z11–14:OH to catches in traps baited with OBLR females ($N = 5$, randomized complete block design).

1983 Field Studies. Three experiments were done in 1983, but only the results of experiment 1 are reported in Table 3. In experiment 1, eight blends of Z11–14:Ac, *E*11–14:Ac, and Z11–14:OH with the amounts of *E*11–14:Ac kept at $<3\%$ and Z11–14:OH at $\leq 2\%$ were compared against OBLR females. A 3-mg bait was used because little difference was found between a 3- or 5-mg dosage (Table 1). A second experiment tested similar blends (low *E*11–14:Ac and Z11–14:OH), but the blends were not compared against traps baited with virgin females (8 × 8 Latin square, traps checked weekly from June 6 to August 8). At the Zebroff Orchard, Cawston, British Columbia (experiment 3), eight blends prepared in the laboratory were tested to determine if the *E*11–14:Ac

component was critical for increased attraction of OBLR males. Purified Z11–14:Ac alone, Z11–14:Ac from Albany International (up to 1% E11–14:Ac as determined by SC-GLC) with either no E11–14:Ac or 2 mg E isomer plus up to 15% E11–14:OH, purified Z11–14:Ac + 2% E11–14:Ac + E11–14:OH and Z11–14:Ac + 2% E11–14:Ac + E11–14:OH were compared (8 × 8 Latin square; traps checked weekly, June 7 to August 3).

1984 Field Tests. In three experiments in 1984 (Table 4), the presence of an additional component, Z11–14:Ald, was assessed. In experiment 1, standard OBLR blend alone (3 mg Z11–14:Ac, E11–14:Ac, Z11–14:OH) or with three dosages of Z11–14:Ald, and 0.03 mg of the standard blend alone or with three dosages of Z11–14:Ald were tested in comparison to traps baited with virgin females.

The effect of greater amounts of Z11–14:Ald on the catch of OBLR and ELR was tested in experiments 2 and 3 by adding 0.5–8.0% Z11–14:Ald to the standard 3-mg OBLR blend. In experiment 2, these treatments were compared against traps baited with 1 to 4-day-old virgin females.

The effects of adding two additional minor components possibly present in female OBLR, E11–14:OH and E11–14:Ald, on the catches of OBLR and ELR were tested by adding them in low amounts to the standard OBLR blend + 1% Z11–14:Ald and comparing it to standard OBLR + 1% Z11–14:Ald, standard ELR blend, and a blank control (Table 5).

To ensure that the Z11–14:Ald component of the OBLR bait was not being destroyed by air oxidation, 0.1 or 1.0% 2,6-di-*t*-butyl-4-hydroxytoluene (BHT) was added to blends containing aldehyde and compared to the aldehyde blend without BHT. This antioxidant has been included at various concentrations in aldehyde baits by some investigators (Nesbitt et al., 1977; Klun et al. 1980). The treatments were examined in a 3 × 3 Latin square layout in a 2-hectare cherry block at the Mennell Orchard, Cawston, British Columbia. Numbers of captured males were recorded weekly from July 27 to October 4, 1984.

Statistical Analysis. Electrophysiological data were subjected to an arcsin transformation and then analyzed by ANOVA and Duncan's multiple-range test (Duncan, 1951).

Field-test data were transformed (e^{y+1}) when necessary and subjected to analysis of variance using computer programs (ACTS AOV or LATIN SQ). The assumptions of ANOVA were tested graphically and with Bartlett's test. Means were separated with Duncan's multiple-range test (ACTS Duncan) (Duncan, 1951).

A curve-fitting program (Spain, 1982) was used to determine "best-fit" regression lines and statistics from the data to illustrate graphically differences in catch levels of OBLR in response to changing amounts of E11–14:Ac and Z11–14:OH in blends.

RESULTS

Compounds Produced by Virgin Females. Individual female ovipositor tip washes analyzed by SC-GLC indicated the presence of two major components with retention times on columns A and B corresponding to Z11-14 : Ac and Z11-14 : OH, as reported by Hill and Roelofs (1979). Individual washes seldom contained more than 20 ng of Z11-14 : Ac. A minor component (1–1.5%) was detected fairly consistently on column B, identical to the retention characterstics of the *E*11-14 : Ac. Epoxidation of combined tip washes resulted in new peaks in the SC-GLC traces corresponding to the retention times for authentic samples of *Z*- and *E*11-14 : Ac epoxides. Analysis by SC-GLC confirmed the identity of the Z11-14 : Ac epoxide, but the mass spectrum of the minor *E* isomer was obscured by an impurity.

Another minor component (up to 1%), corresponding to Z11-14 : Ald was occasionally apparent in SC-GLC traces of individual washes. Single-ion monitoring of SC-GLC-MS traces for ions of *m/e* 70, 98, and 192 provided further evidence for a tetradecenal structure. Extracts prepared over a four-day period exhibited enhanced levels of this component, and SC-GLC retention times of this material on both columns were consistent with those for Z11-14 : Ald. A mass spectrum of this substance obtained by SC-GLC-MS analysis of these extracts was identical to that of authentic Z11-14 : Ald.

Electrophysiological Responses. Z11-14 : Ac, the major pheromone com-

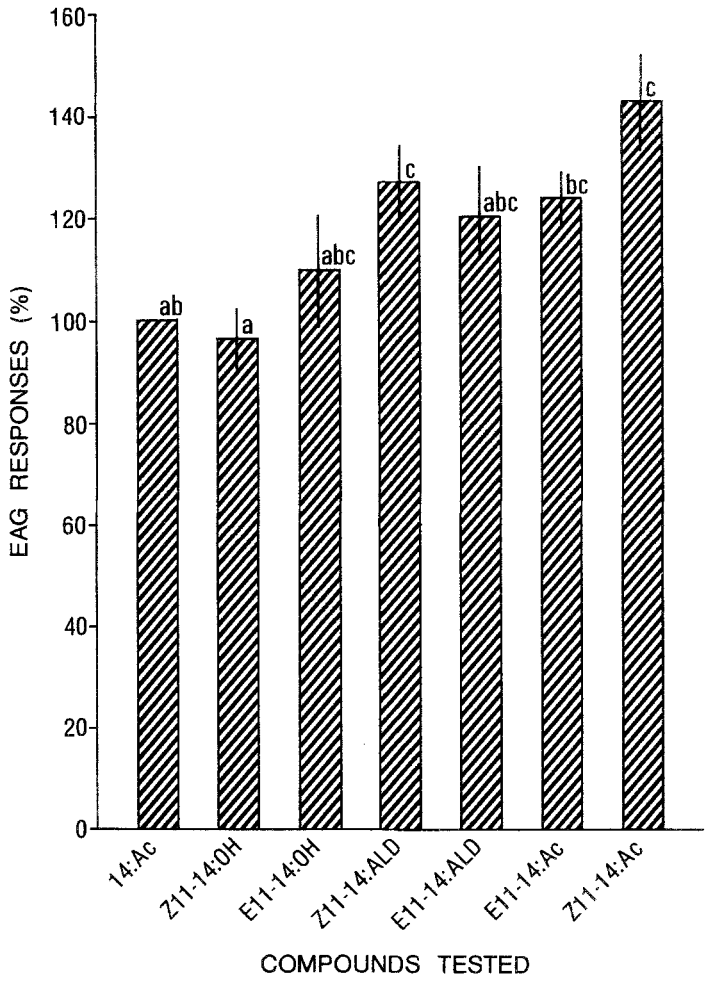

FIG. 1. EAG responses of 20 male *C. rosaceana* to a series of monounsaturated (Δ11) 14-carbon aldehydes, acetates, and alcohols. Responses were compared to a standard, 14 : Ac, and converted to percentages. Bars indicate ± 1 SE of the mean. Bars identified by the same letter are not significantly different, Duncan's multiple-range test, $P < 0.05$.

ponent, and the newly identified Z11–14 : Ald were the most stimulating of the six components tested (Figure 1). An intermediate response was obtained to *E*11–14 : Ac, but neither it nor the other standard bait component, Z11–14 : OH, were more stimulatory than the 14 : Ac standard. The mean EAG response (minus that to the solvent controls) to the nonpheromonal standard, 14 : Ac, was 537 $\pm$ 83.3 μV.

1982 Field Tests. The Zoecon AROS lure was as effective in catching OBLR males as 3 or 5 mg of the 90:5:5 blend of Z11–14:Ac, E11–14:Ac, and Z11–14:OH formulated in the laboratory (Table 1). As also found by Madsen and Madsen (1980), very few *A. rosanus* males were captured in the two orchards in Cawston; therefore, the species specificity of these blends could not be evaluated.

The 1-mg laboratory blend on rubber cap dispensers gave poor results in both orchards (Table 1). The Albany OBLR lure was effective for two weeks but catches were low after the second week.

When the percentages of Z11–14:Ac, E11–14:Ac, and Z11–14:OH in a 5-mg bait were varied, the two most effective blends (94.2:2.8:3.0 and 93.3:1.0:5.7 of the above components, respectively) were those that contained the lowest percentage of E11–14:Ac (Table 2). However, these two treatments also caught the highest numbers of ELR males. While traps baited with these two blends captured more OBLR males than traps baited with virgin females, the biological effectiveness of the females was questionable because of their age (1–7 days old prior to being placed in the field for seven days).

The blend containing 5.4% E11–14:Ac and 5.4% Z11–14:OH was comparable to the Zoecon AROS and Albany OBLR lures (Table 1), attracting fewer OBLR but almost equal numbers of ELR and OBLR (Table 2). Blends which caught the fewest ELR males also caught the fewest OBLR males.

When increasing amounts of Z11–14:OH (up to 6%) were blended with 1% or 2% E11–14:Ac and large amounts of Z11–14:Ac, the most effective treatment consisted of 2% E11–14:Ac and 1.5% Z11–14:OH, but significantly fewer males (Duncan's multiple-range test, $P < 0.05$) were captured than with traps baited with 10 OBLR females. Increasing the percentage of Z11–14:OH did not improve catch levels of OBLR.

At a percentage of 5.7% Z11–14:OH in the blend, the highest ELR catch occurred at Summerland (Table 2). Previous studies on *A. rosanus* found that catches did not differ significantly with acetate–alcohol ratios up to 50:50 (Roelofs et al., 1976). Therefore, increased amounts of Z11–14:OH in the blend would decrease specificity for OBLR. On the other hand, higher amounts of E11–14:Ac in the blend reduced catches of both species (Table 2).

1983 Field Tests. The catches of *C. rosaceana* and *A. rosanus* in only one orchard with blends containing 1–3% E11–14:Ac are presented in Table 3 (experiment 1) and Table 2. In experiment 1, a blend containing E11–14:Ac and Z11–14:OH at 2.0 and 1.5% or 1.0 and 0.5%, respectively, attracted the most OBLR and the ratio of OBLR to ELR males captured was ca. 1.0. Traps baited with OBLR females were significantly more effective than these blends. In experiment 2, the most attractive blend to OBLR, with a OBLR to ELR capture ratio >1, was also one containing 2% E11–14:Ac and 1.5% Z11–14:OH. More OBLR males were captured in response to a blend containing

1% *E*11–14:Ac and 2% *Z*11–14:OH but high numbers of ELR were also captured. In both experiments, *E*11–14:Ac at >2% appeared inhibitory to *A. rosanus* males but OBLR catches were also reduced (Table 3). Also, maintaining the percentage of *Z*11–14:OH at <2% appeared critical to obtaining increased catches of OBLR.

The relative importance of the two minor components, *E*11–14:Ac and *Z*11–14:OH was further demonstrated in experiment 3 at the Zebroff Orchard, (Table 4). While the major component, *Z*11–14:Ac alone captured many OBLR males, the addition of either 2% of the *E*11–14:Ac or 1.5% of *Z*11–14:OH substantially increased catches. The best catches were obtained when all three components were present in a 96.5:2:1.5 blend. Again, a high percentage of *Z*11–14:OH (15%) with *Z*11–14:Ac appeared to inhibit positive orientation by OBLR. Captures of OBLR in several experiments were pooled and compared against changing amounts of *Z*11–14:OH and *E*11–14:Ac in the blend. These results are graphically presented in Figure 2, which indicates the optimum percentages of *Z*11–14:OH and *E*11–14:Ac.

After two years of field tests, the optimum blend for OBLR was concluded to consist of a 96.5:2:1.5 blend of *Z*11–14:Ac (purified), *E*11–14:Ac, and *Z*11–14:OH. While large numbers of *C. rosaceana* could be attracted with this blend, it still was not competitive with five virgin OBLR females. Moreover, the specificity was poor if traps with this blend were deployed in orchards with high populations of *A. rosanus*. The blend was adequate for determining the distribution and flight activity of OBLR (Madsen et al., 1984), but results of its use for monitoring populations in orchards could be difficult to interpret, particularly if endemic female OBLR densities increased in certain orchards (Reidl and Croft, 1974). Nonetheless, it was used as a standard blend for further research in 1984.

1984 Field Tests. The numbers of OBLR males captured increased with 0.1 and 1.0% *Z*11–14:Ald added to 3 mg of the standard three-component pheromone blend (Table 4, experiment 1). The addition of 1.0% *Z*11–14:Ald to the standard blend resulted for the first time in more OBLR males captured than in traps baited with virgin females. The numbers of *A. rosanus* did not decrease with the addition of up to 1.0% of the aldehyde, but the higher catches of OBLR caused the OBLR–ELR ratio to increase.

The species specificity increased as more *Z*11–14:Ald was added to the standard OBLR blend (Table 4, experiment 2). These data suggest that a blend containing between 2 and 8% *Z*11–14:Ald would combine the advantages of superior attractiveness to OBLR and minimal attractiveness to ELR. In experiment 3 (Table 4), the blend with 8% *Z*11–14:Ald continued to perform well, both with respect to OBLR catches and species selectivity.

The results obtained late in the OBLR and ELR flight periods with the addition of 0.03% *E*11–14:OH and 0.02% *E*11–14:Ald to the four-component

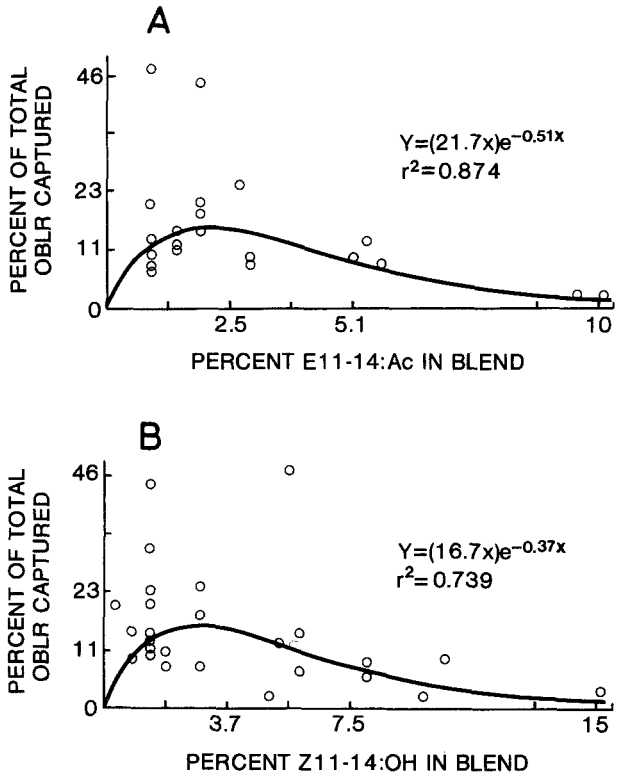

FIG. 2. Maxima function curves (with equations) describing the influence of changing percentages of *E*11–14 : Ac (A) and *Z*11–14 : OH (B) on catches of OBLR males in traps baited with different synthetic pheromone blends. Captures with each blend are expressed as a percentage of the total OBLR catch in an experiment to allow comparison of data from several experiments.

blend above suggest that these two minor components might impart even higher specificity for OBLR without lowering the attractiveness to OBLR males (Table 5). These percentages were chosen in an attempt to match the *Z*:*E* ratio found with the more abundant Δ11–14 Acs. Further studies are necessary to validate a species selective, six-component blend during peak flight periods of OBLR and ELR.

No apparent degradation of *Z*11–14 : Ald at the 1% level on the rubber caps with the standard OBLR blend were observed as there were no significant differences in the numbers of males captured from July 27 to October 4, 1984, between lures treated with 0.0, 0.1, and 1.0% BHT.

DISCUSSION

The addition of Z11–14 : Ald to the three-component standard OBLR blend (confirmed by EAG responses as well as field tests) supports the hypothesis that a major pheromone component for *C. rosaceana* was yet to be found. Similar seasonal and diurnal activity periods for OBLR (unpublished results) and ELR (AliNiazee, 1976) would demand pheromonal species specificity as demonstrated by female OBLR and blends containing Z11–14 : Ald, and possibly E11–14 : Ald and E11–14 : OH. [Peak hourly catches for OBLR in synthetic pheromone traps occurred from 2200–2300 hr, similar to ELR catches in female-baited traps (AliNiazee, 1976). Mixed ELR and OBLR populations were found on 16 native hosts in a recent survey.]

In the eastern United States, Hill and Roelofs (1979) found that the three-component blend of Z11–14 : Ac, E11–14 : Ac, and Z11–14 : OH was the most attractive bait for OBLR. The optimal ratio of the three components was 90 : 5 : 5 (Roelofs and Novak, 1981), considerably different from the 95.5 : 2 : 1.5 blend that we found to be optimal. In contrast to our results, Hill and Roelofs (1979) did not find Z11–14 : Ald in female tip extracts, and increased trap catches were not achieved with the addition of the aldehyde. Thus, geographic variation in pheromone content, as found for other moths such as *Archips argyrospilus* (Walker) (Roelofs et al., 1974), *Agrotis segetum* (Schiff.) (Arn et al., 1982), and *Ostrinia nubilalis* (Hübner) (Klun et al., 1973), appears to occur in *C. rosaceana*. In British Columbia, *C. rosaceana* feeds on a wide range of deciduous hosts that overlaps in distribution with the coniferous hosts of other *Choristoneura* species such as *C. occidentalis* Freeman, *C. biennis* Freeman, and *C. orae* Freeman. Possibly, additional pheromone components are required to impart specificity between a greater number of sympatric species in British Columbia than in New York State. In eastern Canada, Z11–14 : Ald was reported to be an effective attractant for *Choristoneura conflictana* and the addition of 1.0% Z11–14 : Ald to Z11–14 : Ac increased captures of *C. rosaceana* (Weatherston et al., 1976). Our findings support the above authors' hypothesis that reinvestigation of extracts from female OBLR would reveal the presence of Z11–14 : Ald.

In 1983 and 1984, experiments on monitoring populations of *C. rosaceana* were conducted in the Okanagan Valley using the standard three-component OBLR blend. High numbers of males can be trapped in orchards that sustain little or no fruit damage (Madsen et al., 1984). For practical monitoring considerations, replacing the three-component blend with a more attractive and species-selective six-component blend might further complicate the interpretation of numbers of moths caught. However, the problem of contamination of traps with ELR would be solved.

In mating disruption studies with *C. rosaceana* in New York State, Roelofs and Novak (1981) found that the n ural blend (90:5:5 *Z*11–14:Ac, *E*11–14:Ac, *Z*11–14:OH) gave the best disruption of male orientation to traps in small test plots. Our better understanding of the sex pheromone complement of *C. rosaceana* in British Columbia will make it possible to optimize the disruption technique for this locale.

GLUCOCAPPARIN VARIABILITY AMONG FOUR POPULATIONS OF *Isomeris arborea* NUTT.

(Received November 3, 1986; accepted March 12, 1987)

Abstract—Glucocapparin (methylglucosinolate), a putative defense compound, was found to vary between desert and nondesert populations of *Isomeris arborea* (Capparaceae): Plants from desert populations contained greater concentrations than nondesert plants in four of the five organs analyzed. Immature leaves at desert sites had average glucocapparin concentrations of 9.2 mg/g and 8.4 mg/g, while nondesert sites averaged 6.0 mg/g and 4.6 mg/g. Mature leaves from desert sites had average concentrations of 12.8 mg/g and 7.9 mg/g; leaves from plants at nondesert sites contained approximately one third to one half of those concentrations. A similar pattern was observed in capsule walls and seeds but not in flower buds; for these, nondesert plants contained a slightly higher concentration of glucocapparin. Our studies show that nitrogen and glucocapparin concentrations fluctuate throughout the year and contribute to the observed variability among populations during any particular season. Glucocapparin may fluctuate seasonally as much as 37% in immature leaves and 78% in mature leaves. In a controlled experiment, glucocapparin concentration varied inversely with nitrogen fertilizer treatment. The plants treated with fertilizer lacking nitrogen ranged from 10.1 mg/g to 10.9 mg/g glucapparin, which was roughly twice the concentration of those supplied with 20 mM nitrogen in the fertilizer.

Key Words—Capparaceae, chemical defense, glucocapparin, glucosinolate, *Isomeris arborea*.

INTRODUCTION

According to some current theories of defensive secondary compounds, glucosinolate–myrosinase systems can be expensive to maintain (cf. Rhoades, 1979). One would reasonably expect, therefore, that the same species growing

0098-0331/88/0200-0623$06.00/0

in areas of different resource availability would be found to differ in concentration of defensive compounds and that these differences would be variable within individuals in response to changing resource availability (Coley et al., 1985). Although these predictions are straightforward, relatively few studies have focused on determining whether or not they are met or what environmental resources might be involved.

Ecological research on the concentration of plant defensive compounds has focused on differences due to elevation (De Araujo, 1976; Jones, 1977), moisture gradients (Louda and Rodman, 1983a,b; Louda et al., 1987), and disjunct distribution (Wisdom and Rodriguez, 1982); few studies describe the variation in defensive compounds among plant populations. We report here our studies of the concentration of glucocapparin found in the organs of plants from four distinct populations of *Isomeris arborea* Nutt.

I. arborea is well suited to studying variation in defensive compounds both among populations and within individuals. Although restricted to southern California and northern Baja, it occurs in a diversity of plant communities, including creosote bush scrub, valley grassland, and coastal sage scrub. Stands of *I. arborea* within these communities may contain hundreds of bushes, but they are often small in area and widely separated with little opportunity for gene flow among them. The plant communities themselves are even more disparate (Munz, 1968; Barbour and Major, 1977).

Within California, *I. arborea* is the only woody member of the Capparaceae. Plants of this family produce glucosinolates, with some known to contain as many as four or five (Kjaer and Thomson, 1963). All of the organs of *I. arborea* that have been examined (immature and mature leaves, flower buds, capsule walls, seeds) (Blua and Hanscom, 1986), however, contain only glucocapparin (= methylglucosinolate), which eliminates the complication of having to assay for several compounds and to consider possible interactions among them.

Concentrations of phytotoxins (such as glucocapparin, in species which have been studied, generally increase in plants exposed to a variety of environmental stresses (McKey, 1974; Rhoades, 1979). On the other hand, concentrations of digestibility-reducing compounds in some perennials generally decrease with environmental stresses (Rhoades, 1979). *I. arborea* is unusual because it is a perennial containing a defensive compound commonly found in annual species (Blua and Hanscom, 1986). Our studies (unpublished) show that *I. arborea* is subjected to water and nitrogen stress of different magnitudes, depending on the population in which it is found. We predict the glucocapparin in stressed *I. arborea* will behave in a manner similar to that in other phytotoxin-containing plants growing under various degrees of environmental stress.

Although the geographic populations of *I. arborea* are uniform with respect to the presence of the same glucosinolate, they show significant quantitative

variation in several other physiologic and morphologic traits (Tobiessen, 1976; Iltis, 1957), and four subspecies are described in the taxonomic literature (Munz, 1968). This suggests that we could also expect to find differences in glucocapparin concentration among populations. We further hypothesized that glucocapparin concentration would be plastic within individuals from the same population, varying in response to availability of important resources. To test these ideas, we sampled several widely separated natural stands and also grew plants from a single population under different, controlled greenhouse conditions.

METHODS AND MATERIALS

Collection of Plant Material. Plant material was collected from four sites within southern California, representing the four plant communities where *Isomeris arborea* is most frequently found: Yaqui Well in the low desert and Short Canyon in the high desert, both of which are creosote bush scrub plant communities; Bakersfield, a valley grassland plant community; and Sorrento Valley, a coastal sage scrub plant community. The precise locations were: (1) Yaqui Well: junction of State Highway 78 and county road S3, 0.1 miles southwest of Tamarisk Grove Campground, Anza Borrego State Park, San Diego County; (2) Short Canyon: 1 mile west of U.S. Highway 395 at Brady's convenience station, 0.3 miles north of the junction of State Highway 14 and U.S. highway 395, Kern County; (3) Bakersfield: 6 miles east of Oildale at the edge of the Poso oil field, Kern County; and (4) Sorrento Valley: Flint Kote Road, Torrey Pines State Preserve, San Diego County.

Immature (not fully expanded) and mature leaves, flower buds, capsule walls, and seeds were collected from five plants in each of the four populations and from an additional five plants in the Sorrento Valley population. All vegetative organs and flower buds were collected in the late spring (May). Capsule walls and seeds were collected as they became available in spring and summer. In addition, leaves from ten Sorrento Valley plants were collected in winter (November), early spring (March), late spring (May), and summer (August). Each time plant material was collected, it was immediately placed on Dry Ice and transfered to a freezer for storage prior to analysis.

Greenhouse Experiment. To test the hypothesis that leaf glucosinolate concentrations increase with water and nitrogen stress, a completely randomized 3 $\times$ 2 factorial experiment was used. One factor was the application of three nitrogen levels in the fertilizer: 0, 2, and 20 mM nitrogen in a modified Van de Elst solution. Our preliminary studies showed that the application of these concentrations resulted in low, intermediate, and high leaf Kjeldahl nitrogen in our test plants. Total Kjeldahl nitrogen (TKN) was measured with an automated spectrophotometer (Technicon Auto Analyzer II, Terrytown, N.Y.).

The second factor was the difference in amount of water supplied. Individual plants considered unstressed were irrigated with deionized water daily, while those comparatively water stressed were irrigated twice weekly. A difference in the degree of stress was monitored by measuring dawn water potential with a vapor pressure osmometer (Wescor No. 5100B, Logan, Vermont).

Four *I. arborea* clones of similar size and development were used as replicates within each combination of nitrogen concentration and irrigation treatment. Plants were grown in full sunlight in five-gallon pots containing U.C.II(C) soil mixture. All plants were allowed in equilibrate at their assigned nitrogen concentration for two weeks before withholding water from water-stressed plants. Treatments lasted eight weeks, at which time immature and mature leaves from each plant were collected for glucosinolate and TKN analysis and dry weight determination.

Glucocapparin Analyses. Glucocapparin was identified and quantified by methods described by Blua and Hanscom (1986).

Statistical Procedures. Although a conventional two-way ANOVA, with the main effects being location and plant organs, would appear to be an appropriate method of data analysis, we took a sample of each of the five plant organs that were studied from each of five plants at each site. Thus, the 25 samples taken at each site are not independent. Therefore, we chose to analyze our data in two parts: (1) a one-way ANOVA for differences among sites was carried out on the means taken across organs for each plant, with the five resulting plant means at each site serving as replicates, and (2) at each site, a randomized block ANOVA was carried out to test for differences among organs, with the plants serving as blocks. Thus, in this second analysis, the data from each site were treated separately. This statistical analysis precludes the possibility of testing the interaction term for significance, and we will present evidence along different lines in our results that suggest that the pattern of differences among organs is not the same at different sites.

The greenhouse experiment was designed to be analyzed with ANOVA to detect significant differences in the glucocapparin content of immature and mature leaves from plants treated with the three nitrogen and the two irrigation levels. The following statistical model (Montgomery, 1984) is consistent with the experimental design:

$$y_{ijkm} = \mu + \alpha_j + \beta_k + \gamma_m + P_{i(jkm)} + (\alpha\beta)_{jk} + (\alpha\gamma)_{jm} + (\beta\gamma)_{km} + (\alpha\beta\gamma)_{jkm} + E_{ijkm}$$

where α_j, β_k, and γ_m are the effects associated with nitrogen fertilization, irrigation treatment, and leaf age class respectively; and $P_{i(jkm)}$ is the unique contribution associated with the ith plant nested in nitrogen fertilization j, irrigation treatment k, and leaf age class m. Interaction effects are shown in parenthesis.

E_{ijkm} is the error of measurement associated with determining Y_{ijkm}, the glucocapparin concentration of leaves of age class m from plant i grown under nitrogen fertilization j with irrigation treatment k.

RESULTS

Differences Among Field Sites and Among Organs. Of the organs examined, mature seeds contained the highest concentrations of glucocapparin at all four sites (Table 1). Because these concentrations were so consistently high relative to those of the other four organs, a separate one-way ANOVA for differences among sites just for mature seeds was carried out. This analysis indicated that mean concentrations of glucocapparin in mature seeds did not differ significantly among sites. In contrast, a one-way ANOVA among site means, calculated across all organs exclusive of mature seeds, indicated highly significant differences among sites ($F = 32.1$; $df = 3, 16$; $P < 0.001$; Table 1).

The randomized block ANOVA to test for differences among organs (excluding seeds) at each site indicated that the organ means were highly significantly different at all four sites. At each site the capsule walls were consistently lowest in glucocapparin concentration, with the mean across populations of 2.5 mg/g fresh weight. But there was little similarity in the pattern of glucocapparin concentrations of immature leaves, mature leaves, and flower buds among the different sites. The differences among these three organs were slight and probably not significant for Sorrento Valley (the coastal site) and Short Canyon (high desert). The mean across these three organs at Short Canyon, however, was nearly 70% higher than the mean across organs at Sorrento Valley. The means for Yaqui Well (low desert), in contrast, ranged from 3.4 mg/g for flower buds, which was the lowest value for any of these three organs at

any site, to a high of 12.8 mg/g for mature leaves, which was the highest value. The situation for the Bakersfield site was different from any of the others, with mature leaves having a concentration of only 3.8 mg/g, while flower buds and immature leaves at Bakersfield differed little from one another and had intermediate concentrations of glucocapparin. From the differences in these patterns at each site, taken together with the difference among sites of means across organs, we infer that there is an interaction between site and organ.

Seasonal Patterns. Data obtained at Sorrento Valley several times during the year indicated that glucocapparin concentration in leaves changed significantly as the growing season progressed into the drier summer months (Table 2). Again, the pattern of differences was not straightforward: the interaction term between leaf age and season was significant, and season, as a main effect, was highly significant. But leaf age as a main effect was not significant. For both immature and mature leaves, the period of greatest concentration of glucocapparin in the samples occurred during the summer, although Tukey's procedure for unplanned multiple comparisons (Steel and Torrey, 1980) indicated that collection date was significant only for mature leaves ($P = 0.01$). The increase in mature leaves was quite pronounced, with glucocapparin concentration in summer being 78% higher than in late spring.

Greenhouse Experiment. Total Kjeldahl nitrogen and leaf dry weight increased as higher concentrations of nitrogen were supplied in the fertilizer treatment (Table 3), which was anticipated. Glucocapparin concentration declined with increasing concentrations of nitrogen in the fertilizer (Table 3). In addition, immature leaves contained a greater glucocapparin concentration than mature leaves, which agrees with our earlier observations of plants from this population grown under greenhouse conditions (Blua and Hanscom, 1986). No trend in glucocapparin concentration with respect to irrigation treatment was observed in this experiment, even though the water potential of well-watered plants was consistently higher than that of the water-stressed plants. All com-

binations of interactions between nitrogen fertilization, irrigation treatment, and leaf age class was found to be insignificant.

DISCUSSION

The mean glucocapparin concentrations were found to vary significantly among four *Isomeris arborea* populations. The differences in values between plants in the desert and in the nondesert populations were especially obvious: the glucocapparin concentration in the coastal sage scrub (Sorrento Valley) and valley grasslands (Bakersfield) populations were similar but quite different from their counterparts in the desert (Yaqui Well and Short Canyon). Our data suggest that plants growing in different populations respond to environmental driving variables that are unique to those environments, particularly the availability of key resources such as soil nitrogen, perched ground water, and perhaps other resources not covered in this study. In controlled experiments conducted in other laboratories, glucosinolate concentration responded to environmental factors such as water stress (Bible et al., 1980), nitrogen (Freeman and Mossadeghi, 1972), soil sulfate (Josefesson, 1970), and soil type (Ju et al., 1980). We speculate that two key variables, soil nitrogen content and the water resources available to the plants during the growing season, differed from population to population and thereby contributed to the glucocapparin concentration observed among the four *I. arborea* populations studied.

The presence of herbivores may constitute another factor that leads to variability in concentration of plant toxins among populations of a plant species. Rhoades (1979) lists several studies in which the concentration of a toxin increased in as little as 12 h after the plants producing them were attacked by herbivores. The direct effect of herbivores on the concentration of glucocapparin in *I. arborea* was not tested in this study. However, herbivore load is not independent of other stresses and may have been a contributing factor to the results we obtained. It is unclear to us at this point how to separate the direct effects of herbivory from indirect effects, such as the change in plant water potential, and other driving variables that come about as a result of the physical injury to the plant by the herbivores.

Because of seasonal extremes, neither herbivores nor plants remain active throughout the year in the desert populations. But the effect of herbivory may be just as great during the growing season, even though the herbivore load may be much lighter than in populations, such as the coastal sage scrub, where herbivores and growth of plants occur throughout the year. The combined effects of herbivory and relatively more extreme environmental stresses may have led to a higher mean glucocapparin concentration in desert plants.

In controlled experiments, glucocapparin concentration in *I. arborea* var-

ied inversely with nitrogen fertilizer treatment (Table 3). This trend was observed in annual species (Eaton, 1942; Trzebny, 1964; Josefsson, 1970) and has now been confirmed in *I. arborea*, which differs from many other perennials in that it contains a toxin as a chemical defense. The adaptive significance of this phenomenon is subject to speculation, and it may be that toxins are relatively common in fast-growing tropical trees. We observed a decline in the production of glucocapparin when nitrogen was not a limiting factor during rapid growth. This is partially explained by Eaton's (1942) observation that the production of many metabolites increased at a greater rate than glucosinolate when nitrogen was not a limiting resource.

Water stress and its interaction with nitrogen fertilizer treatment were not found to influence glucocapparin concentration in *I. arborea* (Table 3). In contrast to our observations, Louda et al. (1987) found an increase in the glucosinolate concentration of an annual caper growing in a dry environment. Their data were in agreement with those of Wolfson (1980, 1982), and Louda and Rodman (1983a,b). We were unable to recreate the degree of water stress in our greenhouse plants that we observed in field specimens (Wilford-Beanan, 1985), and the evidence, by inference from the field studies cited, is that water stress may likewise trigger an increase in glucocapparin concentration.

Glucocapparin concentration may vary inversely with leaf age or may be static upon leaf maturation (full leaf expansion). The temporal variation in glucocapparin in mature leaves observed in the Sorrento Valley population may represent variation in mean leaf age rather than a seasonal fluctuation of glucocapparin. In a study of Brussels sprouts (Cruciferae), mature and "old" leaves contained statistically similar concentrations of allylisothiocyanate, whereas immature leaves had much higher concentrations (VanEmden and Brashfor, 1969). In our study, the glucocapparin concentration observed in mature leaves increased significantly when the plants were most stressed (Table 2). Again, the evidence suggests that environmental stresses, particularly availability of key resources, is the driving factor for fluctuations of toxins in *I. arborea*.

It is noteworthy that glucocapparin concentration in young leaves did not vary significantly through the growing season. We speculate that *I. arborea* has evolved a capacity to buffer the physiologic environment of immature leaves and other tissues which are undergoing development because developing tissues would experience more stress from environmental extremes than mature tissues. Immature leaves may also have a higher glucocapparin concentration because they are not fully expanded, resulting in the toxin being more concentrated. As the leaves mature, glucocapparin concentration declines and then rises as environmental stress increases.

Coley et al. (1985) argue that resource availability is the major determinant of the amount and type of a plant's chemical defense. Their evidence indicates that plant species which grow slowly because of resource limitations evolve

"immobile defenses" such as polyphenols and fiber, and plants that are capable of fast growth when resources are abundant evolve "mobile defenses." The defensive chemistry of *I. arborea* is consistent with their views. First, *I. arborea* grows rapidly, with a net assimilation rate of over 400 mg dry matter/dm^{-2}/day (unpublished data), when the plants are treated with fertilizer with a high nitrogen content and in the absence of herbivory. Secondly, *I. arborea* contains a "mobile defense," glucocapparin (Blua and Hanscom, 1986), the concentration of which fluctuates depending upon the environment in which it is found. Finally, among the four populations we studied, glucocapparin concentrations were highest in plants growing in populations in which the environmental stresses were most evident. More specifically, our controlled studies point to nitrogen as the variable that is most related to glucocapparin concentration. We speculate that selection pressure will favor plants which increasingly invest in defensive chemicals during times of resource limitation.

Acknowledgments—The authors wish to thank Joe Verfailie for doing nitrogen determinations, Pat Hanscom for helping with statistical analyses, and an anonymous reviewer who improved the manuscript. Our special thanks to the managers of Torrey Pines State Preserve. ATTRACTION OF ADULT *Diabrotica* (COLEOPTERA: CHRYSOMELIDAE) TO CORN SILKS AND ANALYSIS OF THE HOST-FINDING RESPONSE

BRIAN PRYSTUPA, C.R. ELLIS, and P.E.A. TEAL[1]

(Received October 29, 1986; accepted March 31, 1987)

Abstract—Volatile chemicals from corn silks attracted *Diabrotica virgifera virgifera* LeConte and *D. barberi* (Smith and Lawrence). The behavioral response of both species of beetles to the host plant was typified by four distinct phases: perception, random movement, orientation to the source, and search with reorientation. The perception phase was composed of stationary behaviors, while the random, orientation, and search phases were composed of directed and nondirected movements. Each of the movement phases had a characteristic response pattern composed of the ratio of upwind, lateral, and downwind walking and flight movements, which affected net displacement of the beetle in the flight tunnel. The perception phase occurred within and between the other phases and was responsible for initiating changes from one movement phase to another (based on the presence or absence of volatiles from corn silks). Host finding was flexible, and the response pattern fit a flow-chart type of response, rather than a single stereotyped sequence of behaviors.

Key Words—Rootworm adults, *Diabrotica* spp., Coleoptera, Chrysomelidae, attraction, corn, flight tunnel, ethograms, host finding, bioassay.

INTRODUCTION

Although the northern corn rootworm, *Diabrotica barberi* (Smith and Lawrence), and the western corn rootworm, *D. virgifera virgifera* LeConte, have long been pests of corn, little is known about their host-finding behavior and

[1] Present address: Insect Attractants, Behavior and Basic Biology Research Lab, USDA, ARS, Gainesville, Florida 32604.

host-mediated chemical ecology. The two species are closely associated with corn due, in part, to their restricted larval host range (Branson and Ortman, 1971) and adult feeding behavior (Branson and Krysan, 1981). Larvae feed on the roots of corn, but they have no long-range ability to distinguish these roots from those of nonhost plants and are restricted in the distance they are able to travel in search of hosts. Selection of a suitable host is dependent upon the oviposition habits of the adult female (Branson and Krysan, 1981).

The feeding behavior of adults of the two species differs significantly but reflects their close association with corn (Branson and Krysan, 1981). Newly emerged *D. v. virgifera* adults initially feed on corn leaves, but then move to the pollen-bearing tassels, silks, and young kernels, when these food sources become available (Ball, 1957; Hintz and George, 1966). When pollen becomes unavailable and the silks dry, *D. v. virgifera* remains in the cornfield and resumes leaf-feeding (Ludwig and Hill, 1975). A short time after the silks dry, *D. v. virgifera* disperses between cornfields (Hill and Mayo, 1980), although a small number of beetles feed on cucurbits and other plants (Metcalf et al., 1982; Ferguson et al., 1983). Conversely, *D. barberi* adults do not feed on the leaves, but feed on the pollen, silks, and young kernels of corn (Ludwig and Hill, 1975). When pollen becomes unavailable and the silks begin to dry, *D. barberi* females leave the cornfield to feed on the pollen of other plants nearby, but many return to corn to oviposit (Cinereski and Chiang, 1968). Several days after the silks have dried completely, *D. barberi* disperses to other plants more distant from the cornfield, including weedy oats and soybeans (Hill and Mayo, 1980; Matin and Yule, 1984).

The preference of both species for corn tissues, the behavioral change from leaf-feeding to pollen- and silk-feeding by *D. v. virgifera*, and the ability of weed-feeding *D. barberi* females to relocate corn for oviposition suggest the existence of feeding (Bruss, 1981) and oviposition (Cinereski and Chiang, 1968; Branson and Krysan, 1981) attractants in corn. This field evidence is further supported by laboratory reports that their activity is affected by corn silks (Bruss, 1981).

The confirmation of chemical attractants in corn to adult rootworms and an understanding of host-finding behavior are vital to any study of the chemical ecology of corn rootworms. Further, such information should prove useful for monitoring and trapping field populations. The objectives of this paper are to determine that corn silks produce volatile attractants, and to describe the host-finding behavior of adult *D. barberi* and *D. v. virgifera.*

METHODS AND MATERIALS

Adult Collection and Holding. Beetles were collected from cornfields near the University of Guelph, Guelph, Ontario. Beetles were tested over a two-

week period beginning when the first few gravid females were found and continuing over the time when beetles were feeding on the pollen of nearby weeds and presumably returning to the cornfields to oviposit. Adults were collected 24 hr prior to testing and housed in 30 × 30 × 30-cm Plexiglas cages. All cages were kept in a room that was well lit with natural light to maintain the light–dark cycle experienced by beetles in the field. Beetles were not isolated by species or sex, but they were held as collected to minimize handling. Beetles were starved for 24 hr prior to testing to predispose them to host finding. A moist paper towel was provided as a source of water, and cages were held in a room with high humidity. Tests were conducted during the morning and early evening to coincide with the 6–10 AM and 5–10 PM periods of maximum locomotive activity found by VanWoerkom et al. (1980). Test individuals were selected on the basis of good color, anatomic completeness, and normal walking and flight activity.

Source of Volatiles. Three whole ears of corn with mature silks were used as the source of volatiles for most tests. Mature silks were >7 cm long, yellow in color, and many individual silks often had a faint brown streak down their length indicating recent pollination. These silks had the characteristic odor of corn. Ears were collected from fields ca. 20 min prior to their use in assays. Ears were replaced with fresh ones every hour during assays.

Silks were also removed from the corn ears and tested separately to identify the source of volatiles and to eliminate visual effects of corn ears. The silks from three ears were strapped lengthwise to three 4 × 8-cm strips of 20-mesh aluminum screen. The strips with silks were suspended at the upwind end of the flight tunnel 8 cm from the top and 10 cm apart. Fresh silks were used for every group of 10 bioassays.

A 500-ml flask that contained silks from three ears was also used as a source of volatiles. The flask was placed outside the tunnel and concealed from view with aluminum foil. Two glass funnels 5 cm in diameter at the mouth were positioned at the upwind end of the flight tunnel and connected to the flask by Teflon tubing.

In all tests, the volatiles were pulled through the tunnel at 0.33 m/sec. using a centripetal exhaust fan. This system pulled air through the flasks containing corn silks at a rate of 1 liter/min. The dimensions of the odor plumes were estimated using smoke emitted from heated paraffin wax in the flasks or directly behind the corn ears or silks. The odor plumes were similar for the three treatments.

Bioassays. Two assay systems were used to study host-finding behavior. The first, which was used to determine the existence of volatile attractants from corn, used a 1.2 × 0.4 × 0.4-m Plexiglas flight tunnel. The upwind two thirds of the tunnel was divided into two 0.2 × 0.7-m chambers to provide a two-choice test. Airstreams from the time chambers mixed downwind in the release area. At least 2 min before each bioassay, groups of 10 beetles of mixed sex of

either *D. barberi* or *D. v. virgifera* were placed in a release cage, 5 × 5 × 12 cm, positioned ca. 15 cm from the downwind end of the tunnel. Three ears of corn with silks were used as a source of volatiles in one of the upwind chambers; the second chamber was left unbaited. Fresh beetles were used for each replication, and the baited and control treatments were randomly assigned to either side of the chamber. Bioassays were performed in a greenhouse to provide natural light. The types of behaviors displayed and the number of beetles that located the odor source following each release were recorded on videotape for a 10-min period.

A second assay system used the same 1.2 × 0.4 × 0.4-m Plexiglas flight tunnel, but it was not divided into two chambers and treatment and control beetles were tested separately. This system was used to record the frequency and sequencing of particular behaviors of individual beetles so that comprehensive ethograms could be constructed. Individual beetles were released in the downwind end of the tunnel as in the previous test, and their behaviors were recorded on videotape for a 5-min period. All aluminum screens, Plexiglas, and release cages were thoroughly rinsed with methanol after each series of 10 bioassays. This same assay system was used with funnels connected to a flask of silks as a source of volatiles.

Videotapes of beetle responses from both bioassays were transcribed from a television monitor using both stop-action and standard-speed modes. Species, sex, date of assay, and the occurrence and sequence of all behaviors were tabulated.

Statistical Analysis. Treatment differences for the flight tunnel bioassays were tabulated using chi-square analysis with Yates' correction for continuity. For analysis, behaviors in the flight tunnel were classified as random phase when no volatiles were present, orientation phase when beetles were in an odor plume, and search phase when beetles had left an odor plume and until it was reentered. Frequencies of walking (WW) and flight behaviors (HPF) were compared for the three phases using an analysis of variance.

An ethogram was constructed by tabulating the frequencies of all observed behaviors in first-order, preceding–following, transition matrices. Each cell in the matrix was tested using chi-square analysis, and standard normal deviates were calculated and applied to a binomial test for individual transitions (Teal et al., 1981). Transitions with deviates having probabilities of $P < 0.05$ were used to construct an ethogram of the most probable sequence involved in host finding.

RESULTS AND DISCUSSION

Role of Volatiles in Host Finding. During initial tests using groups of 10 beetles and whole ears of corn as a source of attractants, all the beetles flew ($N = 300$), with 91.7% flying upwind (Table 1). The 12 beetles (4%) that initially

flew downwind subsequently flew at least part way up the tunnel. Eventually, 73.3% of the beetles found the corn during the 10-min bioassay period, while 26.7% of the beetles remained in the unbaited chamber ($P < 0.05$). In an assay system similar to ours, but without attractants, VanWoerkom et al. (1983) found that upwind flights of WCR were always uncommon. We assume that the higher percentage of upwind flights in our study was due to the attractancy of corn.

In subsequent 5-min assays with individual beetles, in which whole ears of corn were used as bait ($N = 75$), 96% of the beetles flew; 55.6% of them initially flew upwind, while 74.6% were at least half way up the flight tunnel at the end of the assay (Table 2). Eventually, 61.3% of all beetles found the corn ears (Table 2). *Diabrotica v. virgifera* were significantly better at finding the corn (28/36 = 77.8%) than were *D. barberi* (18/39 = 46.2%) (Table 3). Males of both species were equally adept as females in finding the corn. In the untreated controls, 92.9% of the beetles flew ($N = 85$), but only 7.6% of these beetles flew upwind, and only 32.9% reached the upwind end of the flight tunnel (Table 2).

Two additional treatments were used to eliminate all volatiles except those from silks and to eliminate any visual attraction due to color, shape, or orientation of the ears. In the first, where corn silks were strapped to aluminum screens, all the beetles flew at least half way up the flight tunnel ($N = 20$), and 75% of all beetles found and fed on the silks (Table 2). In the second treatment in which silks were in a hidden flask, upwind flight occurred 55.6% of the time ($N = 30$), and 70% of the beetles landed on the glass funnel that was the source of silk volatiles (Table 2). These results clearly demonstrated that volatiles from corn silks were attractive to *D. barberi* and *D. v. virgifera*.

The beetles first walked upward to the edge of the release container where they could encounter a directional airflow that carried volatile substances. After reaching the upper edge, the beetles paused temporarily (P), waved their antennae (PW), or walked about the edge of the cage while waving their antennae (WW). The latter two behaviors were often repeated several times and were interrupted by a third behavior, head held up without antennal movement (HU). Flight usually followed the head up position.

The preflight behaviors were similar to those reported by VanWoerkom et al. (1983) for *D. v. virgifera* in the absence of any attractant. The "hind legs bent as if crouching" behavior reported by VanWoerkom et al. (1983) is equivalent to the head up (HU) behavior that we report. They found that without attractants, flight was instantaneous at wind speeds up to 0.5 m/sec, whereas flight was seldom instantaneous in our tests at wind speed of 0.33 m/sec with corn as an attractant. Instead, one or more PW and HU behavioral sequences occurred with a minor amount of WW behavior. The PW and HU behaviors appeared to be perceptory behaviors and were followed by upwind flight by 97% of beetles tested in groups of 10 and by 75% of individual beetles. How-

[a]Beetles were tested individually in an undivided flight tunnel. Numbers analyzed by chi-squared with Yates' correction. Percentages for a species and in the same column that are followed by different letters are significantly different ($P < 0.05$).

ever, only 1% of beetles flew upwind in the absence of attractants (Van-Woerkom et al., 1983). More importantly, their beetles did not orient themselves facing into the wind until wind speeds were greater than 2.0 m/sec. At a wind speed of 0.33 m/sec, most beetles in our tests oriented themselves upwind when exposed to corn volatiles.

After taking flight upwind, most beetles flew only a short distance. These 10- to 20-cm flights were called hop flights (HPF). This type of behavior was more common than flight up the entire length of the tunnel, called full flight (FF). Beetles typically proceeded upwind by a series of HPF and WW movements. Upwind HPF and WW were interspersed with several pauses (PW), during which time the beetles lifted their heads (HU), lifted their elytra (E), passed their foretarsi through their mouthparts (FT), rubbed their hind legs against each other (HL), and extended their hind wings (HW). These stationary behaviors also appeared to be perceptory behaviors, since they were usually followed by corrections (changes) in the direction of movement. Perception phases, consisting of one or more stationary behaviors, occurred infrequently, usually three to four times, in beetles that entered the chamber baited with the corn ears. These beetles were typically less diverse in their behavior than beetles that entered the unbaited chamber. Behavior included three to four HPF upwind and three to four WW upwind sequences, before ending up on the corn silks. Beetles that entered the unbaited chamber typically displayed the perceptory phase more than 10 times. Beetles in the unbaited chamber (random phase) displayed a higher proportion of lateral and downwind directed HPF and WW behaviors (Table 4). Apparently, after losing the attractant, the corrective movements are lateral and downwind relative to the airflow. In most cases, this action led the beetles out of the unbaited chamber and back into the release area where the two airstreams mixed and where they could reorientate to the corn. Thus, although initial upwind flights left 59% of the beetles in the unbaited chamber, ultimately 73.3% of the beetles ($N = 300$) found the corn ears (Table 1). The same host-finding responses were shown by beetles tested individually in the undivided flight tunnel. Beetles that flew upwind often flew past the source of volatiles, but subsequently paused and then made downwind and lateral WW and HPF movements that eventually placed them back in the plume of volatiles. A large part of successful host finding appeared to be due to this ability to relocate the volatile plume in the airstream and then reorientate to the source.

Most beetles that failed to respond to the volatiles from corn, and most of those in the controls, walked about the release area in all directions. Many beetles also flew downwind or laterally, so that net displacement in the flight tunnel was downwind.

Sequential Analysis of Host-Finding Behavior. The observations above were confirmed by analysis of 190 successful host-finding sequences using individual beetles. Host-finding behavior was complex. *Diabrotica barberi* and *D.*

TABLE 4. MEAN NUMBERS OF WALKING WITH ANTENNAE WAVING (WW) AND HOP FLIGHT (HPF) BEHAVIORS PER *Diabrotica* ADULT CLASSIFIED ACCORDING TO PHASE OF HOST-FINDING BEHAVIOR AND DIRECTION OF MOVEMENT

Behavior[a]	Phase of behavior[b]	*N*	Direction of movement		
			Upwind	Lateral	Downwind
Walking with antennae waving (WW)	Random	50	2.56	2.88	1.28
	Orientation	51	4.71	1.41	0.27

	Orientation	52	1.33	0.58	0.02
	Search	34	0.68	0.15	0.27

[a] The interaction between both WW and HPF behaviors and direction of movement was significant ($P < 0.001$).

[b] Phase response: random, in the absence of host volatiles; orientation, in the presence of host volatiles; search, host volatiles present but behaviors recorded after beetles had left the odor plume and until they reentered it.

v. virgifera located the volatile source using three movement phases: random activity, orientation to the source, and search with reorientation. The existence of these three distinct movement phases was confirmed in two ways. First, each phase had a characteristic response pattern composed of the ratio of lateral, upwind, and downwind WW and HPF movements (ANOVA: $P < 0.001$) (Table 4). Also, first-order, preceding–following, transitions were calculated and found to be distinct for behaviors in each of the three movement phases.

Sequential analysis of host-finding behavior was accomplished by first tabulating the frequencies of transitions from one behavior to the next, then consolidating the frequencies into a transition probability matrix using only first-order transitions. Self-transitions (i.e., when, after a predetermined time interval, the beetle remains in the same behavioral state) were not included in these matrices (the behavior was recorded as having occurred once). The chi-square value for the expected frequency of transition, based on the chance association of the two behaviors, was then calculated. The expected and observed frequency transitions were then tested by chi-square for any significant deviation from random. Standard normal deviates (Z) were calculated by taking the square root of the final chi-square value and applying it to a binomial test by selecting only those deviates with values of $Z = 1.96$–2.56 (for $P < 0.05$) or higher (more significant). Transitions with deviates yielding probabilities of $P < 0.05$ were used in construction of an ethogram to indicate the most probable behavioral sequence. A separate ethogram was constructed for each of the random,

orientation, and search phases (Figure 1). Each phase was characterized by the types of behavior shown by the beetles and by the conditional probability of occurrence of each preceding–following transition. As evidenced by the occurrence of several significant "following" behaviors and the low conditional probability of each multiple transition, host-finding behavior was not "stereotyped," but was instead plastic (Baker and Cardé, 1979).

In the random phase, the WW behavior occurred upwind and laterally more frequently than downwind, while HPF movements were more frequently directed downwind and laterally (Table 4). First-order transitions indicated that the conditional probability of flight was significant in all directions, as was WW (Figure 1A). This combination of HPF and WW usually resulted in serpentine movement with no net displacement of the beetles from the release area (79% of beetles), although downwind flight was also common (11%). Perception behavior was complex in the random phase. Inactivity was common, and beetles often went through a series of diverse stationary behaviors over a lengthy period of time. The perceptory behaviors of beetles occurred after WW in any direction and were followed by a change in the direction of movement.

Orientation was characterized by lateral and downwind HPF and WW occurring at much lower frequencies than upwind HPF and WW (Table 4). Also, first-order transitions indicated that the conditional probability of the HU to HPF upwind transition was high, as was the transition to WW upwind from HPF in any direction (Figure 1B). However, the response of beetles remained plastic, with both vertical and lateral HPF behaviors being significant occurrences. This combination of WW and HPF movements resulted in a net displacement of the beetles upwind. Host finding during the orientation phase involved only a few behaviors relative to the random phase. Transitions from one behavior to the next occurred quickly, with little interruption by lateral or downwind movements, and with few perceptory pauses. Also the entire sequence of stationary behaviors occurred less often and the perception phase had a lower diversity of stationary behaviors (boxes Figure 1A and B). The fewer pauses during orientation suggest that WW involves some perception and that PW was probably initiated by a lack of odors. Also, the perception phase occurred only after WW in both the random and orientation phases, further suggesting that beetles perceive odors while WW.

The search phase occurred only after an orientation phase. Search behavior was characterized by more frequent lateral WW than upwind and downwind WW, and downwind and upwind HPF occurring more frequently than lateral HPF (Table 4). This combination of WW and HPF resulted in displacement of the beetles downwind, lateral, or both, and thereby helped the beetles to relocate the odor plume. While searching, most beetles found the volatile source by reorienting with only one or two upwind HPF or WW movements. First-order transitions confirmed behavioral observations, whereby beetles leaving

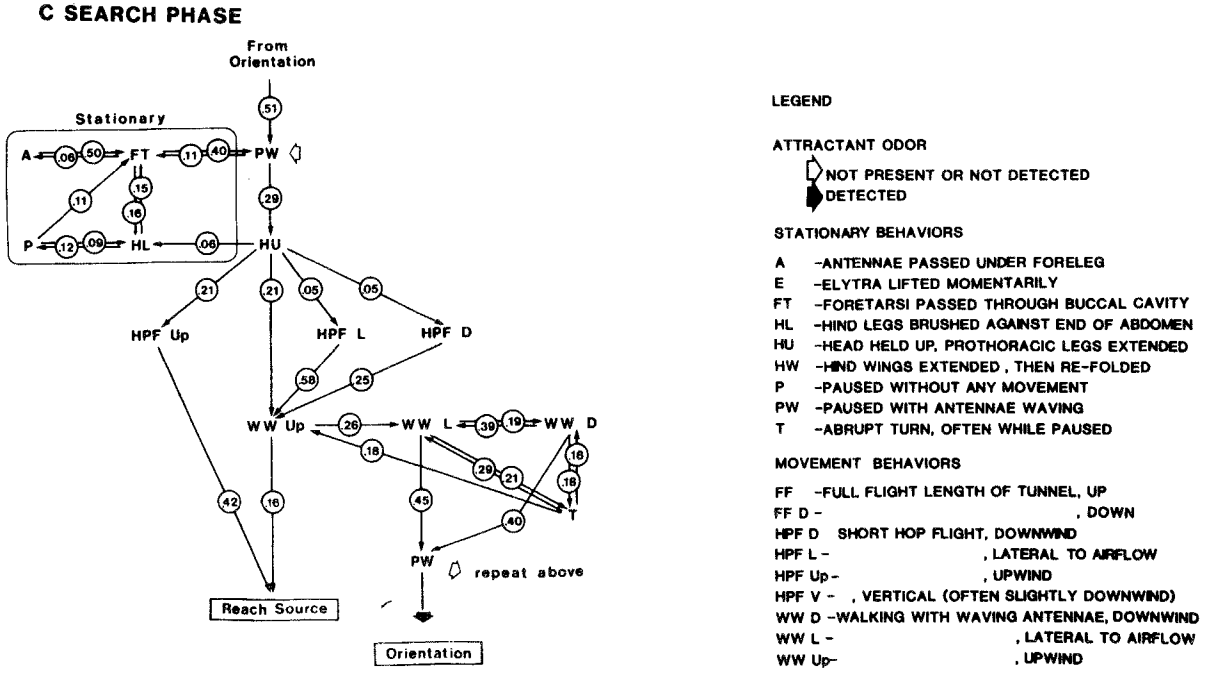

FIG. 1. Ethogram of the response of *Diabrotica* to the presence or absence of silk volatiles in a flight tunnel: (A) random—volatiles absent; (B) orientation—volatiles present; (C) search—volatiles present but beetles not in the odor plume. Circled values are the conditional probabilities of occurrence.

the odor plume paused, then flew upwind directly to the source of volatiles ($P = 0.12$), but most beetles flew downwind or laterally, then proceeded upwind by WW ($P = 0.71$) (Figure 1C). Beetles that did not encounter the odor plume when WW upwind subsequently moved laterally or downwind. Beetles WW in all directions frequently turned (T), presumably in an attempt to relocate the odor plume, again suggesting that the WW behavior was perceptory and initiated changes in the direction of movement.

A perception phase is used during the orientation behavior of other insects. Linn and Roelofs (1983) reported that at certain points in the flight sequence, male *Grapholitha molesta* (Busck) were very sensitive to changes in the chemical signal. They interpreted these "key" behaviors in the sequence as points at which males made decisions with respect to this type of mechanism when locating their host (Hawkes et al., 1978). Flies that overshoot the odor source land, then change their flight behavior to relocate the odor plume. The PW–HU sequence and the other concurrently occurring stationary behaviors of *Diabrotica barberi* and *D. v. virgifera* appear to be the key behaviors during which these beetles made decisions about their subsequent movement pattern. The ratio of directional movements following the PW–HU sequence was the same as that prior to this sequence whenever the chemical signal remained unchanged. When the chemical signal was changed, as when the beetles encountered corn volatiles in the airstream or moved out of the volatile plume, the ratio of directional movements following the PW–HU sequence and the conditional probabilities of movement in different directions (Figure 1) also changed. Therefore, changing the chemical signal had the effect of changing the net displacement of the beetles through the flight tunnel at the next perceptory phase. Moreover, the frequency of the perception phase itself was found to be significantly higher (ANOVA: $P < 0.05$) during the random phase and search phases than after the orientation phase, perhaps as a result of the same change in chemical signal.

Orientation to a host plant is commonly thought to involve zigzag flight, much like that observed when moths proceed up a plume of sex pheromone (Shorey, 1973). However, Hawkes et al. (1978) reported that *Delia radicum* orientates to its host without using zigzag flight. Instead, *D. radicum* uses a series of short upwind flights and landings in the odor plume, interspersed with a small amount of walking. The principal effect of the host odor was to increase the take-off rate and to direct flight upwind. Similarly, Dindonis and Miller (1980) reported that *Delia antiqua* (Meig.) uses a series of short flights when relocating the volatile plume from a nontransient emitter. They suggested that these short flights, punctuated by frequent landings, prevented the fly from straying far from the area where it was last stimulated by the odor. This behavior would maintain a high probability of restimulation, provided wind direction was not exceedingly variable (Dindonis and Miller, 1980). Both species of corn

rootworms frequently used short flights (HPF) and walking (WW), punctuated by the PW–HU sequence, to locate the source of volatiles during bioassays in a flight tunnel. Long flights (FF) up the entire length of the flight tunnel occurred infrequently ($P = 0.17$). Thus it appears that the host-finding behavior of these beetles has some similarities with that used by *D. radicum* and *D. antiqua*.

The random and search phases of host finding differed in the pattern of directional movements and net displacement of the beetle through the flight tunnel, even though both phases were initiated by the absence of silk volatiles. This implies that the beetles can differentiate between the absence of attractants, and the absence of attractants given their previous detection. In this study, beetles that overshot the odor plume switched their behavior from orientation to plume relocation, as indicated by the change in the ratio of directional movements (Table 4), and the change in the conditional probabilities of these movements (Figure 1). Hawkes et al. (1978) reported that female *Delia radicum* flying in a plume of host volatiles land as soon as they overshoot the odor source. Females then turn downwind, circle, and reenter the plume. This behavior is similar to the search phase of host finding used by *Diabrotica barberi* and *D. v. virgifera*. The search phase was responsible for 37.3% of successful host finding over that realized by beetles using orientation alone (24.0%), based on bioassay where 61.5% of beetles found the corn ears (Table 2).

Modeling Host-Finding Behavior. Given the perceptory role of stationary behaviors, the characteristic pattern of directional movement behaviors in each of the random, orientation, and search phases that followed perception (Table 4), and ethograms of the most probable transitions (Figure 1), we produced a simplified model of the host-finding response. Starting from any movement or stationary phase, the behavioral response and net displacement of the beetle can be predicted (Figure 2). At the next perceptory phase, which occurred frequently in the absence of an attractant odor, there was a high probability that the beetle would WW downwind, laterally, or upwind in about equal proportion if no attractant was detected (Table 4) (Figure 1A). If an attractant odor was detected, then there was a high probability that the beetle would make HPF and WW movements in an upwind direction (Table 4) (Figure 1B). This behavior usually placed the beetle on the corn silks. If the beetle overshot or walked out of the odor plume (loss of attractant odor), subsequent movement was characteristic of the search phase (Figure 1C). Searching beetles paused and performed stationary behaviors, then made HPF and WW movements in a lateral and downwind direction (Table 4) (Figure 1C), often with several repetitions. This behavior usually placed the beetle back in the odor plume. One or two upwind reorientation movements, HPF or WW, completed the search phase, placing the beetle on the corn silks (Figure 1).

The establishment that corn silks contain volatile chemical attractants for

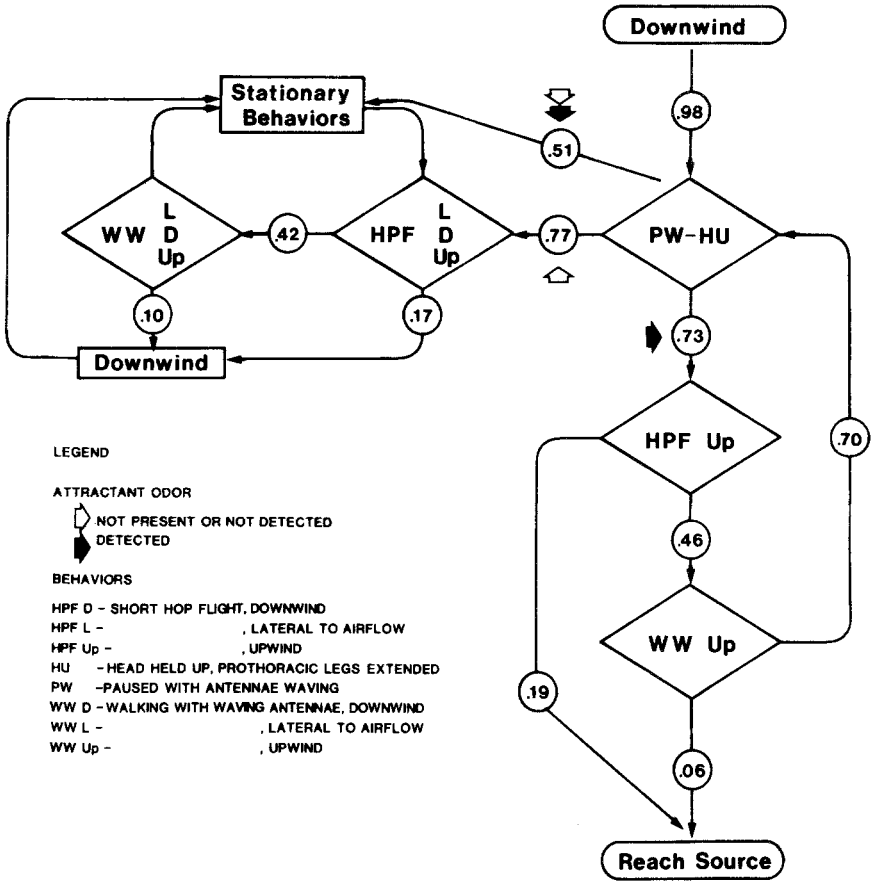

FIG. 2. Computer flow-chart equivalent of the ethograms (Figure 1) of host finding by *Diabrotica*.

Diabrotica beetles and the full description of host-finding behavior should facilitate further studies. Identification of biologically active compounds from corn silks may have an important application in trapping or monitoring programs for these important agricultural pests.

TRAIL-FOLLOWING BEHAVIOR OF *Reticulitermes hesperus* BANKS (Isoptera: Rhinotermitidae)

J. KENNETH GRACE,[1] DAVID L. WOOD,[2] and GORDON W. FRANKIE[2]

(Received November 25, 1986; accepted March 14, 1987)

Abstract—The behavior of *Reticulitermes hesperus* Banks pseudergates (workers) was assessed on artificial trails containing different concentrations of sternal gland extract. On nongradient trails, more pseudergates were recruited to trails of greater pheromone concentration, they traveled a greater distance without pausing, and their rate of locomotion increased over that observed on trails of lesser concentration (positive orthokinesis). Of the individuals pausing before completing trails of high concentration, fewer left the trails or reversed direction (negative klinokinesis) than on trails of lower concentration. Termites walking down concentration gradients failed to complete these trails to the low-concentration termini. At a point representing an average decrease of slightly more than 10-fold in the original concentration of pheromone, individuals reversed their direction of travel and returned to the high-concentration terminus. Termites walking up pheromone gradients proceeded to the high-concentration termini without reversing direction. *R. hesperus* pseudergates are thus able to orient along a gradient of trail pheromone by longitudinal klinotaxis.

Key Words—Termite, *Reticulitermes hesperus*, Isoptera, Rhinotermitidae, pheromones, trail following, orientation.

INTRODUCTION

Reticulitermes spp. (Isoptera: Rhinotermitidae) establish chemical trails with pheromones secreted by the sternal gland, an epidermal gland located in the anterior portion of the fifth abdominal segment beneath the fourth abdominal sternite (Mosconi-Bernardini and Vecchi, 1964; Smythe and Coppel, 1966;

0098-0331/88/0200-0653$06.00/0

Quennedey, 1971; Liang et al., 1979). The trail pheromone of *Reticulitermes virginicus* Banks was identified by Matsumura et al. (1968) as *cis*-3,*cis*-6,*trans*-8-dodecatrien-1-ol. This compound is attractive to other *Reticulitermes* spp. (Matsumura et al., 1972) and has been implicated as the pheromone of *Reticulitermes lucifigus* var. *santonensis* (Feytaud) (Ritter and Coenen-Saraber, 1969) and *Reticulitermes speratus* Kolbe (Honda et al., 1975). It may also be closely related to that of other species (Howard et al., 1976) or represent one component in a multicomponent trail pheromone (Kaib et al., 1982; Prestwich et al., 1984).

Traniello (1982) and Hall and Traniello (1985) consider termite trail-following behavior to consist of both recruitment and orientation components. Additionally, there are two aspects to orientation: orientation to the lateral boundaries of the trail space (cf., Bossert and Wilson, 1963) and orientation along the longitudinal axis of the trail. With respect to longitudinal orientation, we describe here the concentration-dependent responses elicited by *Reticulitermes hesperus* Banks pseudergates by different concentrations of sternal gland extract on artificial trails. Orientation responses were evaluated both on trails drawn with single concentrations of sternal gland extract and on trails containing discrete (incremental) concentration gradients of extract.

The significance of evaluating trail orientation with respect to pheromone gradients lies in the intriguing possibility that differences in pheromone concentration could indicate directionality on trails. Although behavioral assays with *Hospitalitermes sharpi* (Holmgren) (Jander and Daumer, 1974), *R. flavipes* (Runcie, 1983), and *Trinervitermes trinervoides* (Sjöstedt) (Tschinkel and Close, 1973) indicated that these species could not distinguish the direction of their nest from the direction of foraging areas, these assays employed short segments of naturally laid trails. Any differences in trail pheromone concentration over a short distance might not be sufficient to elicit changes in termite orientation. Leuthold (1975) suggested, based on observations of grass-feeding termites, *Trinervitermes* spp., that orientation could be facilitated by the presence of a pheromone gradient over an extensive network of trails.

These studies emphasize mechanisms of individual termite orientation. Rather than attempting to draw conclusions about behavior to unknown stimuli on natural trails, we chose to define the behavioral responses to a series of known stimuli on artificial trails. Thus, with the individual behavioral parameters established, investigation of the unknown natural stimuli, in the appropriate social context, can follow.

METHODS AND MATERIALS

Source of Insects and Gland Extracts. In behavioral assays we used undifferentiated *R. hesperus* pseudergates (workers) older than the third instar (as

determined by size) from two colonies. One of these was removed from severely infested Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) wood substructure framing in a home in Alameda County, California (Oakland). The other colony was from a Douglas-fir soil-retaining board on the grounds of a University of California family housing complex in the same county (Smyth). After collection, termites were removed from the wood and placed in plastic trays containing a small block of the Douglas-fir, damp cotton, and several pieces of Whatman No. 1 filter paper as feeding substrates. These trays were maintained in a humidity chamber at 94 ± 5% relative humidity, 21–25°C (Grace, 1986). Individuals from the two colonies were kept separate from each other and assayed only with extracts of pseudergates from the same colony.

Stock sternal gland extracts containing trail pheromone (1× dilution) were prepared by removing the fourth and fifth sternites from 10 *R. hesperus* workers (immobilized by exposure to Dry Ice) and extracting these sternites in 1 ml dichloromethane (Baker analyzed) for 24 hr. Tenfold (0.1×), 100-fold, and several lesser dilutions (0.0625× and 0.03125×) were prepared from the stock solution. Artificial trails containing higher concentrations of trail pheromone than the stock solution were prepared by repeatedly overlaying trails with the stock solution.

Assay Conditions. Each artificial trail consisted of a straight 100, 150, or 200-mm line, 1–2 mm in width, drawn on Monroe No. 41 parchment tracing paper (5 × 25 cm) with a microliter syringe containing 1 μl of extract per 50 mm of trail. A thin, uniform line of solvent could be more readily applied to this particular paper than to others that were tested. Preliminary tests indicated that trails drawn on this paper with pure solvent and with extracts of the paper itself did not elicit any noticeable behavioral response (e.g., trail following, arrestment, repellence). A light pencil line on the underside of the paper served as a guide for extract application and as a reference during the assay. Our extract application rate of the stock glandular extract (1×) at 1 μl/50 mm of trail was equivalent to a concentration of 2×10^{-4} glandular equivalents (GE) per millimeter of trail.

The papers were placed on a glass surface and uniformly illuminated by overhead fluorescent lighting (13.5–19.5 foot-candles). All assays were performed at ambient conditions (21–25°C, 35–45% relative humidity), which were standardized throughout each experiment by regulating the laboratory temperature. In each assay, an artificial trail was drawn with extract and the solvent allowed to evaporate for ca. 15 sec. A single *R. hesperus* pseudergate was gently deposited from a small glass vial onto one end of the trail. Timing of the assay and measurement of distance traveled on the trail was begun when the insect moved a distance greater than one body length in any direction. In experiments where distance traveled on the trail was the critical parameter, only the distance traveled on new (previously untraveled) portions of the trail was considered. The points of initiation and termination of locomotion along the trail

axis were marked lightly in pencil at the base of the paper for later measurement. In all of our experiments, a new trail was drawn for each individual assay, and each insect and each trail were used only once to prevent any effects from behavioral conditioning or trail reinforcement.

Orientation on Nongradient Trails. Two experiments were performed on nongradient artificial trails drawn with different dilutions of sternal gland extract. The first experiment was designed to determine whether a concentration-dependent relationship existed in the response to artificial trails and longitudinal orientation upon them. We recorded the distance traveled in 0.5, 1.0, 2.0, or 3.0 min by pseudergates from the Oakland colony on 200-mm artificial trails of either stock (1×), 0.1× or 0.01× dilute extract and control trails of dichloromethane. Any movement along the trail axis was scored as a positive response, with the short movements recorded along the control trails representing the background level of behavioral "noise" in the assay. Twenty-five individual assays were performed for each time interval with each of the three concentrations of glandular extract and the dichloromethane control, for a total of 16 independent treatments.

Our second experiment was conducted to examine concentration-mediated differences in orientation behavior following initiation of trail following. Pseudergates from the Oakland and Smyth colonies were deposited at one end of 150-mm trails containing glandular extract (from their respective colony-mates) in either 10×, 1×, or 0.1× concentration. Trails of the 0.01× concentration and solvent controls were not included in this experiment since these elicited very little or no trail following in the first experiment. We recorded the distance traveled on each trail without pausing or leaving the trail, the time taken to travel that distance (rate of locomotion), and the behavior of those that did not immediately complete the 150-mm trail (i.e., continuing forward after pausing on the trail, leaving the trail, or reversing direction). Thirty individuals from each colony were tested with each of the three concentrations of glandular extract.

Orientation on Gradient Trails. Three separate experiments were performed on artificial trails consisting of a concentration gradient of sternal gland extract. In the first experiment, a pseudergate from the Oakland colony was deposited at either the high or the low concentration end of a 100-mm artificial trail containing a 20-fold arithmetic gradient of either the stock 1× sternal gland extract or its 10-fold dilution. These 0.1×–2× and 1×–20× arithmetic gradients were created by repeatedly overlaying successive 5-mm increments of the trail with either the stock 1× extract or the 0.1× dilution. Thus, individuals deposited at one end of the trail were initially either walking up or down a steep gradient of trail pheromone. Under these conditions we recorded the number of termites completing trails in a 3-min period, the time taken to complete trails, and the number reversing their direction of travel before reaching the end of the trail. Behavior of pseudergates walking up or down a pheromone gradient was

compared to behavior on nongradient trails containing only the 1× extract or the 0.1× dilution. Twenty-five individual assays each were performed walking up the gradient, down the gradient, and on nongradient trails of the 1× stock extract, while 20 individual assays in each of these three treatments were performed with the 0.1× dilution.

A second experiment was performed to supplement observations made during the first experiment with respect to the distance traveled by individuals walking down a pheromone gradient before reversing their direction of travel. Twenty-five pseudergates from the Oakland colony were individually tested walking down 20-fold gradients (100 mm in length) and on nongradient artificial trails drawn with 0.0625× and 0.03125× dilutions of the stock extract. These dilutions were based upon the earlier observation that a 0.01× dilution of the stock extract elicited very little trail following. The proportions of individuals completing trails and reversing direction without completing trails were compared on gradient and nongradient trails at each dilution.

Our third experiment measured the behavior of 30 pseudergates each from the Oakland and Smyth colonies walking either up or down a 10×–1×–0.1× incremental logarithmic pheromone gradient in individual assays on 150-mm artificial trails. We compared the distances traveled without reversing direction and the proportion of pseudergates in each treatment completing trails without reversing direction.

Analyses. Statistical analyses employed two-tailed t tests and analysis of variance (ANOVA) with the rank transformation (SAS Institute, 1982). This ANOVA is equivalent to the Kruskal-Wallis test with the F approximation (Conover and Iman, 1981; Quade, 1966). Comparison of means was performed with the Tukey-Kramer method (Kramer, 1956) or the Ryan-Einot-Gabriel-Welsch (REGW) multiple F test ($\alpha \leqslant 0.05$). Proportions were compared with multiple Z tests using Bonferroni's inequality to maintain $\alpha \leqslant 0.05$ (Dixon and Massey, 1983).

RESULTS

Orientation on Nongradient Trails. In the first experiment on nongradient trails, the proportion of pseudergates initiating trail following increased significantly as the concentration of glandular extracts increased (Table 1). With the 23% overall response recorded to the dichloromethane control trails representing random movements, almost twice as many individuals (41%) responded to the 100-fold (0.01×) dilution of glandular extract. The number of respondents increased significantly (90% and 99%) at the 0.1× and 1× concentrations. Conversely, there was no apparent relationship between the length of the exposure time and the number of individuals responding to trails (Table 1).

The mean distance traveled on the 200-mm trails by responding pseuder-

[a] 1× = 10 sternal glands per milliliter dichloromethane, applied at the rate of 1 μl per 50 mm of trail. Control = dichloromethane.
[b] Total percent recruited in all four time periods (N = 100). Different letters indicate that each proportion is significantly greater than the one appearing immediately below it in the column (one-tail Z test of proportions, $\alpha \leq 0.05$).
[c] N = number of pseudergates (Oakland colony) recruited to trails in 25 individual assays with each concentration of extract in each time interval. SEM = standard error of the mean. Means in the same column followed by different letters are significantly different (ANOVA of ranks, Tukey-Kramer test, $\alpha \leq 0.05$).

gates also increased with increasing concentration of glandular extract (Table 1). Of the 100 total termites tested with each dilution of glandular extract, 88 completed trails drawn from the stock 1× concentration, 32 completed trails at the 0.1× concentration, and none completed trails of 0.01× concentration or the dichloromethane alone. There was no statistically significant relationship (ANOVA, $\alpha \leqslant 0.05$) between the distance traveled and the length of the exposure period. This can be attributed to the relatively short length of the trail (200 mm) and the rapidity with which trail following was initiated under our assay conditions.

Results from our second experiment (Table 2) indicate that differential movement along trails of different pheromone concentration is due, at least in part, to concentration-dependent differences in rates of locomotion. Individuals from both the Oakland and Smyth colonies walked faster on trails of 1× and 10× concentrations of glandular extract than on trails of 0.1× concentration. Oakland pseudergates also walked faster on 10× than on 1× trails.

The distance traveled without pausing, reversing direction, or deviating from the 150-mm trail was also greater at higher concentrations of glandular extract (Table 2). The mean distances traveled by pseudergates from both colonies at the 1× and 10× concentrations differed significantly from the distances traveled on trails of 0.1× concentration.

Individuals that did not immediately complete the 150-mm trails evidenced three behaviors: (1) continuing forward on the trail after pausing, (2) leaving the trail, or (3) turning around and reversing their direction of travel on the trail. Combining the results from both colonies (Figure 1), 28% of the pseu-

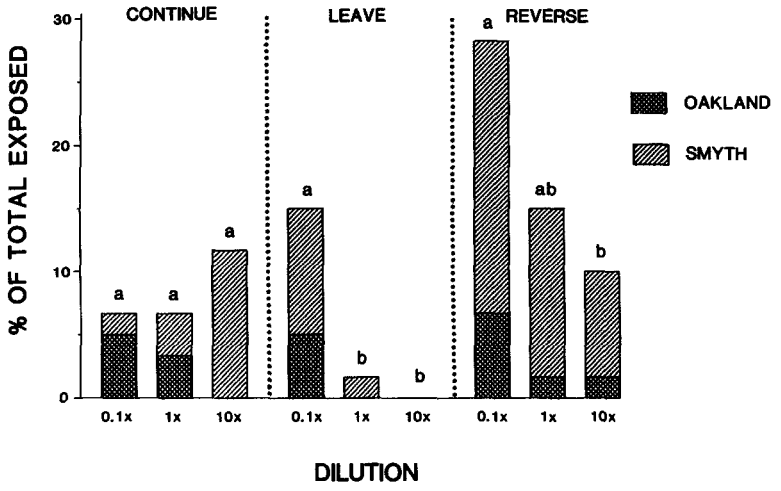

FIG. 1. Behavior of *Reticulitermes hesperus* pseudergates after pausing on 150-mm artificial trails drawn with three different dilutions of sternal gland extract. Thirty individuals from two colonies (Oakland and Smyth) were tested with each dilution ($N = 60$). Different letters over bars in each category indicate that proportions are significantly different (two-tail Z test of proportions, $\alpha \leqslant 0.05$).

dergates on trails of low 0.1× concentration of glandular extract reversed their direction of travel, in contrast to 15% of those on trails of 1× concentration and 10% of those on trails of 10× concentration. Significant differences occurred between the 0.1× and 10× concentrations. Although fewer termites left the trail in each treatment than reversed direction, the relationship to pheromone concentration was similar to that observed for directional reversals. However, the proportion leaving the trail at both the 1× and 10× concentrations was significantly different from the 0.1× concentration. More individuals continued forward after pausing on trails of the 10× concentration than was the case with either of the lower two concentrations, although these differences were not statistically significant.

Orientation on Gradient Trails. R. hesperus pseudergates on artificial trails containing a 20-fold gradient of pheromone exhibited significant differences in behavior when compared to pseudergates on trails of constant pheromone concentration (Table 3). In the 3-min assay period, fewer individuals walking down a pheromone gradient completed the 100-mm trails than was the case with those walking up a gradient or on nongradient trails of 1×, 0.1× or 0.0625× pheromone concentration. With the more dilute sternal gland extract (0.1×), more individuals walking up a 20-fold gradient completed the trails than did those walking on nongradient pheromone trails. This significant difference did not

	No gradient	60a	18 ± 1a	20b

[a] Termites (Oakland colony) were tested walking up or down 20-fold (20–1) arithmetic gradients and on nongradient trails corresponding to the pheromone concentration found at the low end of the gradient trails.

[b] 1× = 10 sternal glands per milliliter dichloromethane, applied at the rate of 1 μl per 50 mm of trail.

[c] Proportions within each concentration followed by different letters are significantly different (Z test of proportions, $\alpha \leqslant 0.05$).

[d] Means within each concentration followed by the same letter are not significantly different (ANOVA of ranks with Tukey-Kramer test, or t test of ranks, $\alpha \leqslant 0.05$). SEM = standard error of the mean.

[e] $N = 25$ (1×), or $N = 20$ (0.1×). Termites were observed for 3 min. Those reversing direction could return to complete the trail.

[f] $N = 25$. Termites were observed until they either completed the trail, reversed direction, or left the trail.

appear in tests with the 1× extract, suggesting the presence of an upper limit for pheromone perception and response under our assay conditions. With those termites completing trails, the time taken to do so did not differ significantly with respect to the trail gradient.

More termites walking down a 20-fold pheromone gradient reversed their direction of travel before (or without) completing the trail than did those walking up a gradient or on nongradient trails (Table 3). This difference was significant at every dilution of gland extract assayed. Thus, the response to a negative gradient was not to wander off the trail as the pheromone concentration decreased, but to reverse direction and walk in the direction of increasing concentration. The proportion of pseudergates completing nongradient trails declined to 60% with the 0.03125× dilution (Table 1). However, half of these

individuals (five) did not respond to the low concentration of pheromone at all, while the 11 termites not completing the gradient trails all reversed direction after initially responding to the trails and walked back to the high concentration termini.

The similarity in the distances traveled by termites down gradient trails of different pheromone concentration before reversing direction (Table 4) indicates that this is not a static klinokinetic response to an absolute threshold level of trail pheromone. Rather, the turning response appears to be initiated by a particular proportional decrease in the original concentration of pheromone detected. However, the relatively small sample size and high degree of variability in individual responses indicate that further trials are necessary to substantiate this hypothesis.

Termites exposed to logarithmic gradients on the artificial trails behaved similarly to those on arithmetic gradients (Table 5). Very few of the pseudergates walking down the 10×–1×–0.1× gradient completed the trails to the low-concentration termini. Rather, they reversed direction and walked back up the pheromone gradient. Although the mean distances traveled down the gradient trails at which these reversals occurred differed significantly between the

TABLE 5. RESPONSES OF *Reticulitermes hesperus* PSEUDERGATES ON 150-mm LOGARITHMIC GRADIENT TRAILS[a]

Colony	Trail gradient	Percent completing trail[b]	Time to complete trail (sec ± SEM)[c]	Percent reversing direction[b]
Oakland	Down	17a	29 ± 2a	83a
	Up	90b	24 ± 2a	10b
Smyth	Down	0a	—	100a
	Up	73b	32 ± 3	27b

[a] 30 pseudergates from each colony were tested walking either up or down 150-mm trails containing three 10-fold dilutions of sternal gland extract in successive 50 mm increments (0.1×-1×-10×). Termites were observed until they either completed the trail, reversed direction, or left the trail.
[b] Proportions from the same colony in each column followed by different letters are significantly different (Z test of proportions, $\alpha \leqslant 0.05$).
[c] Means for the Oakland colony are not significantly different (*t* test of ranks, $\alpha \leqslant 0.05$). SEM = standard error of the mean.

Oakland and Smyth colonies (Table 6), identical concentrations of pheromone (e.g., 1×) were associated with both of these mean distance values. With respect to the gradient, this 1× concentration represents a 10-fold decrease in the amount of pheromone to which the pseudergates were initially exposed. Summing the results from the Oakland and Smyth colonies, slightly more termites starting at the 10× terminus reversed direction when they encountered the 1× portion (29 workers) of the trail than the 0.1× portion (22 workers). This variation in individual response agrees with our observations on arithmetic gradients

TABLE 6. DISTANCES TRAVELED BY *Reticulitermes hesperus* PSEUDERGATES BEFORE REVERSING DIRECTION ON 150-mm LOGARITHMIC GRADIENT TRAILS[a]

Colony	Mean distance ± SEM (mm)[b]	
	Down gradient	Up gradient
Oakland	86 ± 7a (N = 25)	25 ± 6b (N = 3)
Smyth	65 ± 5b (N = 30)	48 ± 11b (N = 8)

[a] Termites were tested walking up or down 150-mm trails containing three 10-fold dilutions of sternal gland extract in successive 50-mm increments (.1×-1×-10×).
[b] Means in the same column followed by different letters are significantly different (*t* test of ranks, $\alpha \leqslant 0.05$). SEM = standard error of the mean.

(Table 4) and suggests that the mean proportional decrease in trail pheromone needed to trigger a turning response is slightly in excess of a 10-fold change.

DISCUSSION

Although termite trail pheromones may consist of multiple chemical components, as suggested by Kaib et al. (1982), Traniello (1982), Traniello and Busher (1985), Runcie (1983) and Prestwich et al. (1984), certain aspects of trail-following behavior appear to be modulated quantitatively. The behavior of *R. hesperus* on nongradient trails of sternal gland extract indicates that initiation of trail following, rate of movement (orthokinesis), and distance traveled without any variation in behavior are directly related to the concentration of the compound(s) eliciting trail following. Reversing direction on the trail (klinokinetic behavior), and propensity to leave the trail, on the other hand, are negatively related to pheromone concentration. The positive orthokinesis we observed is in agreement with the suggestion by Prestwich et al. (1984) that the speed of termite trail-following may be related to discrimination of pheromone. Van Vorhis Key et al. (1981) also suggested from their work with *Iridomyrmex humilis* that speed of locomotion might be a relevant factor in trail-following assays; they subsequently (Van Vorhis Key and Baker, 1982) incorporated locomotory rate into their index of anemotaxis induced in *I. humilis* by trail pheromone.

Our laboratory assays were designed to illuminate individual orientation in response to specific chemical stimuli. Initiation of trail following in response to sternal gland extracts is one component of, but not necessarily analogous to, termite recruitment to trails under field conditions. Other social and environmental stimuli are likely of great importance in affecting their behavior. However, concentration-dependent responses in initiating trail following, rate of locomotion, distance traveled without leaving the trail, and a reduced klinokinetic response would all be advantageous to *R. hesperus* in locating the nest after a disturbance or in enhancing foraging efficiency. More individuals could be recruited to well-traveled trails, presumably containing a higher concentration of pheromone, and would be able to reach the nest or forage more rapidly. Individuals encountering trails of low pheromone concentration would tend to leave these trails or reverse direction on them, increasing their probability of encountering a well-traveled trail and minimizing the time spent following old and possibly unprofitable trails.

Detection of a change in pheromone concentration by *R. hesperus* pseudergates is dependent upon successive longitudinal sampling of trail increments and temporal processing of this information. This orientation mechanism has been referred to as longitudinal klinotaxis (Ewer and Burrell, 1950; Kennedy,

1978) to distinguish it from lateral klinotaxis, or side-to-side sampling. Orientation to the lateral boundaries (edges) of the trail-space may involve either lateral klinotaxis or tropotaxis, independent of orientation along the longitudinal axis of the trail. Kennedy (1986) recently proposed the alternative label schemakinesis to emphasize the internally programmed, self-steered basis of this response to longitudinal gradients.

The ability to detect and respond to changes in trail pheromone concentration suggests the possibility that differential deposition of pheromone could indicate directionality on natural trails. Such a mechanism does not necessarily require that individuals have the ability to vary the amount of pheromone deposited. As Leuthold (1975) has suggested for grass-harvesting termites, concentration of termite activity in particular areas of a gallery network could passively polarize the system in an additive fashion. Although behavioral studies to date have not documented the existence of pheromone gradients on termite trails, chemical analyses of trail increments may prove useful in this regard. Identification of the trail pheromone(s) is crucial to such investigations.

Concentration-dependent responses to crude glandular extract do not imply that a single component is responsible for eliciting the multiple behaviors comprising the trail-following response. Traniello (1982) and Traniello and Busher (1985) suggested that both an ephemeral recruitment component and a very persistent orientation component were present in glandular extracts from the termite *Nasutitermes costalis* (Holmgren). Similarly, additional components in the pheromone blend may excite locomotion or suppress klinokinesis. Researchers must develop assays designed to measure these single behaviors rather than a general trail-following response if such semiochemicals are to be isolated and identified.

(Received January 6, 1987; accepted March 23, 1987)

Abstract—The role of leaf lipids in food plant selection by larvae of *Manduca sexta* was investigated by measuring preference responses in a two-choice preference test using glass fiber filter paper disks laced with extract (test) or water (control). The larvae respond to the petroleum ether extract of whole leaves of the host-plant *Lycopersicon esculentum* (tomato) extract in a concentration-dependent manner. At "natural concentration" it is the most strongly stimulating extract or compound yet tested using the disk test. This response is affected by food plant experience of the larvae, suggesting stimulation by plant-specific compounds in the extract. The extract contains volatile compounds that attract the larvae. In contrast, it does not promote continued feeding on an agar–cellulose diet that incorporates the extract. Also stimulating are the extracts of leaf surfaces of two hosts, *L. esculentum* and *Solanum pseudocapsicum*, and two acceptable nonhosts, *Brassicae napus* and *Vigna sinensis*, indicating the presence of nonpolar feeding stimulants at the leaf surface. However, similar leaf-surface extracts of the unacceptable plant *Canna generalis* were inactive, although the surface extraction process renders this plant acceptable. Leaf-surface extracts of *L. esculentum*, *S. pseudocapsicum*, and *B. napus* evoke feeding responses that are qualitatively comparable to those of their corresponding leaves. However, no such parallel is found for surface extracts of *V. sinensis* and *C. generalis*. Thus, nonpolar compounds at the leaf surface of host and some acceptable non-host-plant species strongly stimulate feeding and hence must play an important role in food selection by the tobacco hornworm.

Key Words—*Manduca sexta*, Lepidoptera, Sphingidae, feeding preference, leaf lipid extracts, plant surface, hosts, nonhosts.

INTRODUCTION

Larvae of the tobacco hornworm, *Manduca sexta* (Johan.), feed only on some members of the family Solanaceae (Madden and Chamberlin, 1945; Yamamoto and Fraenkel, 1960a). Many studies have tried to elucidate the chemical basis of this specificity by testing various host-plant extracts and fractions thereof, as well as some solanaceous allelochemicals (Yamamoto and Fraenkel, 1960b; Fraenkel et al., 1960; Howard, 1977). These studies showed that only polar constituents of host plants are important in stimulating feeding. Bordner et al. (1983) presented a tentative structure of one polar host-recognition factor.

In contrast to the above studies on polar compounds, Morgan and Crumb (1928) and Städler and Hanson (1978) demonstrated that nonpolar material extracted from host leaves also stimulated feeding; moreover, the feeding responses to the extracts resemble very closely those of their corresponding leaves (Städler and Hanson, 1978). de Boer and Hanson (1982) showed that nonpolar feeding stimulants of a host plant are neutral lipids. Many of these lipids can be found on the outer surface of the leaves and, upon contact, may signal the palatability of the plant to the insect before it initiates feeding (Chapman, 1977; Woodhead and Chapman, 1986). Following these leads, the present investigation attempts to characterize the feeding responses of *Manduca sexta* to nonpolar extracts of both host and nonhost plants.

METHODS AND MATERIALS

Larvae of the tobacco hornworm, *Manduca sexta* (Johan.) (Lepidoptera, Sphingidae) were reared from eggs obtained from a culture maintained on an artificial diet (Yamamoto, 1969) at the U.S.D.A. at Beltsville, Maryland. Larvae were reared on cut foliage of tomato, *Lycopersicon esculentum* Mill. var. Better Boy and Jerusalem cherry, *Solanum pseudocapsicum* L. var. Jubilee. The rearing conditions were 16:8 hr light–dark and 27 ± 3°C. Tests were done in the light at the same temperature.

Bioassays. The preference test of Städler and Hanson (1978) was used to assay the feeding preferences of the larvae. Four test and four control disks of glass fiber filter paper (Whatman GF/A, 14 mm in diameter) were placed in ABAB . . . order around the circumference of transparent containers (10 cm in diameter). The floor of the containers was a layer of paraffin wax into which were inserted pins holding the disks ca. 5 mm above the substrate. Small retainers (3 mm in diameter) punched from acetate sheets (or Teflon when chloroform was used as solvent) kept the disks from sliding down the pin. A wire screen covered a moist piece of filter paper on the floor of the container. A freshly moulted fifth-instar larva, starved for 12–24 hr after the moult, was placed in the center of the container. The containers were covered with transparent lids

to maintain high humidity. When the larva had eaten approximately 50% of the total area of either test or control disks, the experiment was stopped and the area consumed of each disk was estimated visually. Larvae were tested only once, then discarded.

The test disks were laced with 0.1 ml of the test solution which is enough to wet each disk completely. The control disks received 0.1 ml of solvent only. After evaporation of the organic solvent from test and control disks, each disk was wetted with 0.1 ml distilled water because *Manduca* does not eat dry disks. The evaporating solvents apparently left no active residue; when larvae were given a choice between filter paper disks pretreated with hexane or chloroform and untreated disks, no difference in feeding preferences could be demonstrated.

The difference in food choices between test and control disks is expressed by a choice index (range -100 to $+100$) which measures the mean percent of total consumption of test disks minus that of control disks. Since the consumption scores were not normally distributed, a two-tailed Mann-Whitney test was used for the analysis of the raw scores to determine the significance of difference in food choices (*P*-choice). Most tests were carried out with 20 larvae or more.

To examine whether feeding responses to plant extracts are plant-specific, two groups of larvae were used in preference tests. Each group was reared on a different food plant species which induces feeding preferences specific for the rearing plant (Jermy et al., 1968; de Boer and Hanson, 1984) and their extracts (Städler and Hanson, 1978).

In some experiments, differences in disk texture could interfere with chemosensory-based feeding responses, such as choices between leaves and certain dewaxed leaves (chloroform treatment makes the leaves less turgid). In these cases, the leaf disks were presented in a "sandwich" (analogous to the test designed by Jermy, 1966), in which the leaf disk was placed between two glass fiber disks. These disks were then wetted with 0.2 ml of distilled water which "bonded" the multilayered disks into one integral substrate. Two layers of glass fiber filter paper disks spotted with 0.2 ml distilled water were used as control disks in these experiments.

The feeding continuation test of de Boer et al. (1977) was used to screen for compounds that promote continued feeding. The leaf extract was incorporated in a 4% agar–4% cellulose diet at concentrations equivalent to $0.5\times$ and $0.1\times$ on filter paper disks, whereas the control diet only received the solvent. The extract was added to cellulose, and the solvent was allowed to evaporate before mixing with warm agar. The same was done with the solvent for control diet. Larvae were placed individually on either the test or control diet in a no-choice situation and their production of fecal material (dry weight) over a 24-hr period was measured as an indication of the amount of food consumed. The significance of differences between feces production of the larvae on the test diet and those on the control diet was determined using Student's *t* test.

The orientation test (modified from Saxena and Schoonhoven, 1978) examined the presence of attractants or repellents in the extract by observing turning behavior of individual larvae towards a filter paper disk treated with extract or distilled water (control). A freshly moulted fifth-instar larva, starved for 24–48 hr, was allowed to climb on the bars of an aluminum grid, tilted upwards at about a 45-degree angle. At a right angle intersection, a control and a test disk were positioned approximately 0.5 cm from the center bar on which the larva was walking. After reaching the test intersection, the larva could turn to the control or the test disk or continue its movement along the center bar. The larva was not allowed to contact the disks. The choice of each larva was recorded and the larva discarded. The position of the test and control disks was randomized, and the experiment was run under red light conditions to avoid interference of visual stimuli. Choice scores from at least 30 larvae were averaged, and the means were analyzed for differences between test and control turns using the binomial test.

Extractions. Leaves of *L. esculentum* were freeze-dried before extraction with petroleum ether at room temperature. The extract was filtered and the solvent was removed. Leaf-surface extracts were made by dipping whole leaves in hexane or chloroform at room temperature for periods of either 30 sec or 2 min as indicated for each experiment. The solvent was agitated gently by a magnetic stirring bar to facilitate the removal of the surface lipids. This method removes lipids from the leaf surface with very little contamination by internal leaf lipids (Hamilton and Hamilton, 1972). The "natural concentration" of the extract was determined by two methods. For the "area method," the surface area of the leaves extracted, compared to that of a filter paper disk, determined the proportion of the extract to be spotted on each filter paper disk. For the "weight/volume method," the water content of the leaf was determined by drying a sample of leaves. The weight of all leaves extracted, corrected for percentage water content, yielded the concentration in milligrams of extract per milliliter of water. Both methods yielded similar results. All dried extracts were stored below 0°C in the dark.

The following plant species were used for extraction of phytochemicals: tomato, Jerusalem cherry, cowpea (*Vigna sinensis* Savi. var. Black-eyed Pea), rape (*Brassica napus* L. var. Dwarf Essex), and canna (*Canna generalis* Bailey var. Rosamond Cole). All plants were grown in the campus greenhouse; in addition, canna was grown outdoors.

RESULTS

Whole-Leaf Extract of Host Plant. The extract of *L. esculentum* at the natural concentration is 0.61 times as stimulating as fresh leaves (Figure 1). Thus the leaf chemicals that stimulate larvae to feed are partially extracted by

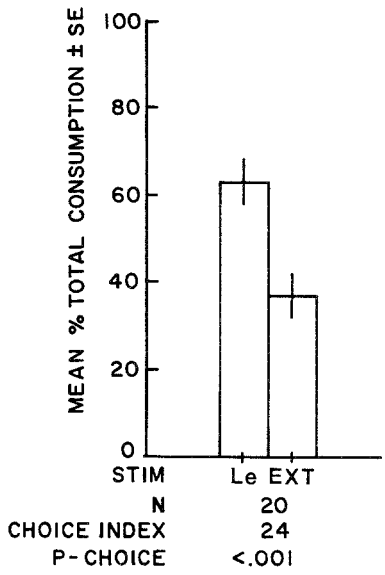

FIG. 1. Food choice between leaf disks of tomato, *L. esculentum* (Le), and filter paper disks laced with a petroleum ether extract of freeze-dried tomato leaves (EXT). The leaf disks were sandwiched between two moistened paper disks. The tomato extract is only slightly less preferred than whole leaves. Columns represent mean percentage of total consumption scores, with bars representing ± SEM. Choice index is the difference between consumption scores (%) on the two choices, and P-choice is the probability that this could occur by chance (Mann-Whitney test). Abbreviations: STIM, stimuli in choice tests; N, number of test repetitions (animals).

petroleum ether. Larvae reared on *L. esculentum* show a maximal preference for the natural concentration of the extract (Figure 2A). A threshold response is seen at 100-fold dilution (0.01×). The supranormal concentration (10×) is slightly less stimulatory than the natural concentration. Larvae that were reared on another host plant (*S. pseudocapsicum*) and therefore were not "induced" on *L. esculentum* show a completely different concentration–response curve for the extract of *L. esculentum* (Figure 2B); the stimulation of feeding in general is much weaker and the concentration–response curve is flatter. Moreover, the extract inhibits feeding slightly but significantly at 0.1× concentration.

In the orientation test, a significant number of larvae turned more often towards the disk with 3.3× extract than to the control disk ($P < 0.001$, $N = 93$). This signifies attractive volatiles in the extract. At lower extract concentrations (0.33× and 0.033×), no significant attraction could be demonstrated.

In the continuous feeding test, the larvae consumed equal amounts of the control diet and the diet with 0.5× and 0.1× extract ($P > 0.05$, $N = 40$; $P > 0.10$, $N = 38$, respectively). Thus, the petroleum ether extract of leaves of

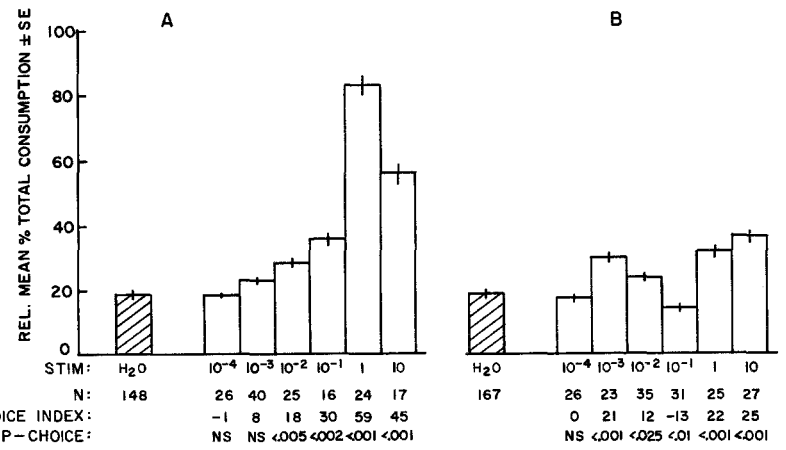

FIG. 2. Feeding responses to a petroleum ether extract of leaves of *L. esculentum* (Le) by larvae reared on: (A) *L. esculentum* or (B) *Solanum pseudocapsicum* (Sp). Each extract concentration (1 = natural concentration) was tested vs. water in two-choice bioassays. Response to each concentration was normalized to the grand mean of water consumption. A strong, dose-dependent stimulatory effect was seen at the natural concentration for Le-reared larvae; this was much weaker for Sp-reared larvae. Abbreviations: see Figure 1.

L. esculentum contains compounds that attract the larvae, but it does not seem to stimulate continued feeding on an agar–cellulose diet at the concentrations tested. This failure was examined by testing the validity of this bioassay using a known stimulant (sucrose, 0.1 M) incorporated into the diet. Larvae consumed twice as much of this diet compared with control diet, thereby confirming an earlier report (de Boer et al., 1977). Furthermore, because of the possibility that the active principle may be thermolabile and thus inactivated during preparation of the diet, we examined heat-pretreated (60°C for 3 min) extract (0.5×) in the standard filter paper disk feeding preference test. The results showed that larvae still strongly prefer this preheated extract over water ($P < 0.001$, choice index = 67, $N = 24$). Thus, it is unlikely that the active principle was destroyed by heat.

Leaf-Surface Extracts of Host and Nonhost Plants. Leaf-surface extracts using two different solvents (hexane and chloroform) were tested in the two-choice preference bioassay with water as control. The results in Figure 3A show that larvae strongly prefer host-plant extracts to water. Thus a feeding stimulant comparable to that seen for the whole-leaf extract (Figure 2A) can be obtained from just the leaf surface.

Leaf-surface lipids were similarly extracted from two weakly acceptable nonhosts (*Brassica napus* and *Vigna sinensis*) and one unacceptable nonhost

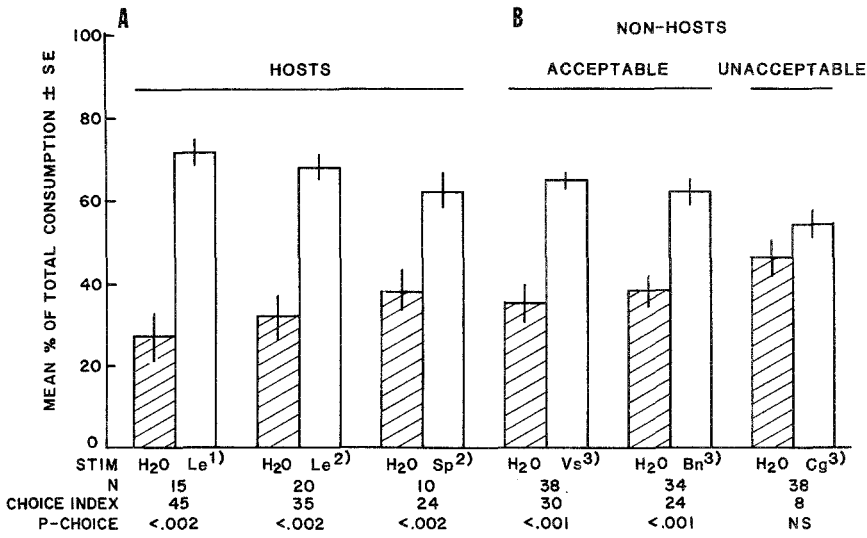

FIG. 3. Feeding responses to leaf-surface extracts of different plant species. Each extract was tested vs. water in a two-choice test. All larvae were reared on leaves of Le, except for those tested on Sp which were reared on Sp. The leaf-surface extracts of acceptable plants (Le, Sp, Vs, Bn) stimulate feeding, whereas that of the unacceptable plant (Cg) is neutral. Abbreviations: Le, *L. esculentum*; Sp, *S. pseudocapsicum*; Vs, *Vigna sinensis*; Bn, *Brassicae napus*; Cg, *Canna generalis*. Extraction procedures: 1) 120-sec dip in hexane; 2) 30-sec dip in chloroform; 3) 30-sec dip in hexane. Details as in Figure 1.

(*Canna generalis*). Extracts from the acceptable nonhost plants are stimulatory, whereas the extract of the unacceptable plant is neutral (Figure 3B).

The stimulating effectiveness of the leaf-surface extracts of *L. esculentum* was examined in a concentration–response series. Larvae show an increased preference for the chloroform and hexane leaf surface extracts at increasing concentrations (Figure 4). At higher than natural concentrations (3.3×) a slightly reduced stimulation is seen. Thus, the leaf-surface extract of *L. esculentum* stimulates feeding in a concentration-dependent manner just as does the extract of whole leaves (Figure 2A).

After surface extraction of acceptable leaves, the remaining leaf ("dewaxed leaf") still elicits feeding, but usually less strongly than the untreated leaf (Figure 5), suggesting that some stimulatory compounds have been removed. The only exception found is for *L. esculentum* dewaxed with hexane instead of chloroform (Figure 5, first pair of columns); dewaxed and untreated leaves are equally acceptable, irrespective of whether the dewaxing period lasts 30 sec (standard) or 120 sec.

In contrast, dewaxed leaves of the unacceptable *C. generalis* elicit much

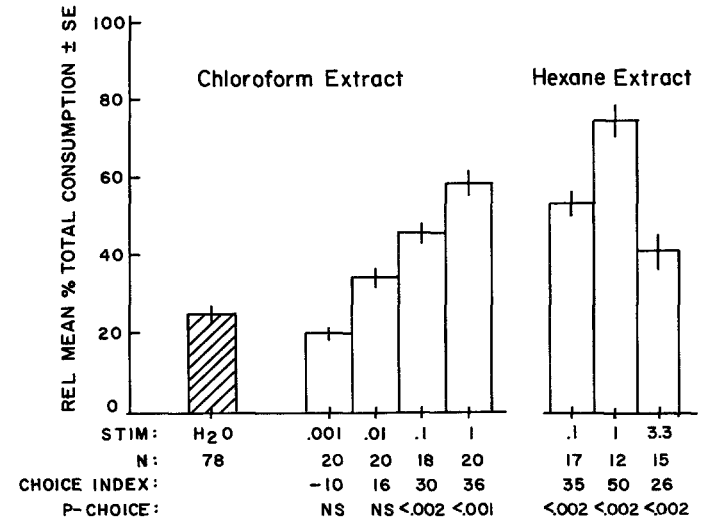

FIG. 4. Feeding responses to leaf-surface extracts of tomato (*L. esculentum*). The extract was obtained by dipping leaves in chloroform (30 sec) or hexane (120 sec) and tested at different concentrations vs. water in two-choice tests. Both leaf-surface extracts stimulated feeding in a concentration-dependent manner. Details as in Figures 1 and 2.

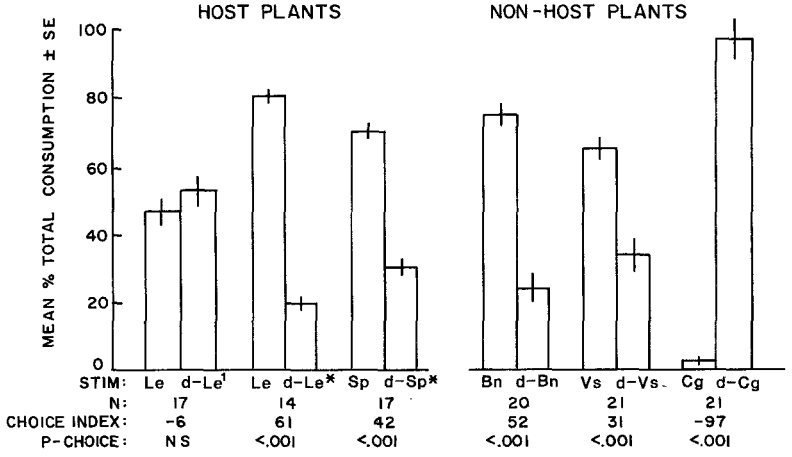

FIG. 5. Change in leaf acceptability following surface extraction. Larvae were given a choice between normal and dewaxed leaf disks. Leaves were dewaxed by dipping in hexane or chloroform (*) for 30 or 120 sec (¹). In experiments using chloroform for dewaxing, the leaf disks were presented between two moistened filter paper disks (sandwich method). Removal of leaf surface material generally decreased feeding on acceptable species (Le, Sp, Bn, and Vs) and increased feeding on the unacceptable species (Cg). Details as in Figures 1 and 3.

more feeding than untreated leaves (Figure 5, last pair of columns). This suggests that a deterrent principle in the leaf waxes of this plant is being extracted. However, no such feeding-deterrent activity could be demonstrated (Figure 3, last pair of columns). To control for possible textural changes brought about by the dewaxing process, an experiment was performed using leaf disks sandwiched between two filter paper disks; however, the larvae still prefer dewaxed leaves over untreated leaves (choice index = -96, $P < 0.001$, $N = 7$). Thus unacceptability of *C. generalis* must be due to chemical rather than physical factors.

Reconstitution experiments in which the leaf-surface extract of *C. generalis* was added back to its dewaxed leaves did not restore the unacceptability of *C. generalis*. Other experiments showed that merely spotting fresh leaf disks with solvent (and permitting it to evaporate) also rendered them acceptable. Thus, the feeding deterrent activity must be destroyed by the solvent used, and the strongly deterrent character of *C. generalis* is lost in the surface-extraction process.

The question arises whether the leaf-surface chemicals are qualitatively representative of the entire leaf in eliciting feeding behavior of *M. sexta*. To test this, normal leaf disks were paired with filter paper disks wetted with water in two-choice tests; the results are compared to those of the corresponding surface extracts in Figure 3. Table 1 shows that the feeding scores of the surface extracts of *L. esculentum*, *S. pseudocapsicum*, and *B. napus* are comparable with those of their corresponding leaves (all are stimulatory), whereas those of *V. sinensis* and *C. generalis* are totally different. Thus the leaf-surface extracts do not always elicit feeding responses qualitatively similar to those of the corresponding leaves.

Specific activities (discrimination per milligram extract) of all extracts stimulating feeding were compared at natural concentrations (1×), using water

TABLE 1. COMPARISON OF FEEDING RESPONSES OF *M. Sexta* LARVAE TO FRESH LEAVES VS. SURFACE EXTRACTS[a]

Plant	Choice index			
	Whole leaves	*N*	Surface extract	*N*
L. esculentum	67	24	45	15
S. pseudocapsicum	34	24	24	10
B. napus	44	20	24	34
V. sinensis	−32	27	30	38
C. generalis	−100	21	8	38

[a]Leaves and extracts were each tested vs. water in two-choice tests. See Figure 3 for details.

TABLE 2. COMPARISON OF SPECIFIC ACTIVITIES OF VARIOUS EXTRACTS OF DIFFERENT PLANT SPECIES FOR FEEDING STIMULATION BY LARVAE OF *M. sexta*.[a]

Plant	Extract		Natural concentration (mg/ml)	Choice index[b]	Specific activity[c]	*N*
	Leaf part	Solvent				
L. esculentum	whole	petether	2.8	59	21	24
	surface	hexane	0.3	45	149	15
	surface	chloroform	1.3	35	27	20
S. pseudocapsicum	surface	chloroform	0.3	24	80	10
B. napus	surface	hexane	4.8	24	5	34
V. sinensis	surface	hexane	0.4	30	75	38

[a] See Figures 2 and 3 for details.
[b] Measured at natural concentration (1×).
[c] Specific activity = choice index/mg extract.

as the common control. Table 2 shows that the hexane leaf-surface extract of *L. esculentum* has the highest specific activity of the extracts tested, indicating relatively few contaminants (neutral and/or inhibitory compounds) and/or high concentration of stimulant(s). Hence, this extract seems most promising for further isolation and identification of the nonpolar feeding stimulatory principle(s).

DISCUSSION

The petroleum ether extract of whole leaves of *L. esculentum* clearly stimulates feeding in the tobacco hornworm. This finding confirms Städler and Hanson's (1978) results showing that nonpolar extracts elicit feeding. Using the disk test, the extract accounts for about 61% of the stimulatory activity of whole tomato leaves, indicating that the extraction was incomplete and/or that compounds other than nonpolar chemicals also contribute to the attractiveness of this food plant. Polar compounds and compounds of intermediate polarity also show feeding stimulatory activity (Yamamoto and Fraenkel, 1960b; Städler and Hanson, 1978).

Feeding stimulation by this simple extract is remarkably strong. The optimal feeding responses to the extract is four times that of the water control (Figure 2A) and twice that of the common stimulant sucrose at optimal concentration (Städler and Hanson, 1978). Thus, the petroleum ether extract of *L. esculentum* leaves is the most strongly stimulating extract or compound so far tested using this preference test. A supranormal concentration shows lower feeding activity

than a normal concentration, indicating a saturation in the stimulatory response of the larvae, or perhaps the presence of deterrent compounds that become effective at higher concentrations. Indeed, feeding deterrent activity was shown in one of the fractions of this extract (de Boer and Hanson, 1982).

In contrast to the unimodal concentration–response curve obtained with *L. esculentum*-reared larvae, a bimodal response to the same extract is found with larvae reared on *S. pseudocapsicum* (Figure 1B). These larvae are stimulated to feed less strongly than larvae reared on *L. esculentum* and are slightly deterred from feeding by the 0.1× extract. The latter demonstrates the presence of a deterrent in the extract to which *S. pseudocapsicum*-reared larvae respond but to which the larvae reared on *L. esculentum* do not respond. This difference in feeding preference of these two groups of larvae illustrates clearly an induction of feeding preference for some component(s) of the *L. esculentum* extract. These findings agree with those of Städler and Hanson (1978), who also found an induction of feeding preference for a nonpolar extract of *L. esculentum* using tobacco hornworm larvae reared on the same two plant species. Thus, the extract of *L. esculentum* contains compounds determining the specific "chemosensory profile" of this plant recognized by larvae that have been induced to prefer this plant.

The disk preference test measures larval feeding responses that are the end result of activation of one or more distinct behavioral acts, such as orientation, biting, continued feeding, and cessation of feeding. This bioassay cannot determine which component of feeding behavior is elicited by the extract. For this reason, two other bioassays were used to examine the effect of the extract on orientation behavior and continued feeding of the larvae.

The orientation test showed that the petroleum ether extract of *L. esculentum* leaves contains volatile compounds which attract the larvae. Apparently the active chemical(s) must have a low volatility because the extract had been dried twice and still elicited an attraction from 0.5 cm away. These results support and complement those of a study on the chemosensory basis of food selection in *M. sexta*, which shows that olfaction plays a role in the discrimination between *L. esculentum* and certain other plants (Hanson and Dethier, 1973; de Boer and Hanson, 1987a).

In contrast, no stimulation of continued feeding could be demonstrated by this extract using larvae in the 24-hr feeding test. Experiments using sucrose as the stimulant showed that the bioassay is functional in detecting feeding stimulatory activity. Heat treatment, such as that during diet preparation, does not inactivate the extract. Several possibilities for the lack of activity can be suggested: Perhaps the active principle is inactivated by the ion-exchange properties of the agaropectine, a constituent of agar; the active principle may bind to the agar or cellulose and thus not be available to stimulate the larval chemore-

ceptors; the extract contains no compounds that elicit long-term feeding, only attraction, short-term biting, and swallowing; and the animals may adapt to the presence of the stimulus over 24 hr.

The above results demonstrate the importance of using more than one bioassay to screen for behaviorally active compounds. But because the filter paper disk preference test appeared to be the most sensitive, further studies to monitor feeding stimulatory activity were done using this bioassay.

Since the first contact of the larva with its food occurs at the leaf surface, which contains mainly lipids, further study was focused on the role of leaf-surface lipids in food-plant selection. These compounds have been reported to affect feeding in several phytophagous insect species (Chapman, 1977; Woodhead and Chapman, 1986). The leaf alcohols *n*-hexacosanol and *n*-octacosanol promote feeding in silkworm larvae, *Bombyx mori* (Mori, 1982). Lipid-soluble material from the surface of *Poa annua* leaves stimulates biting in nymphs of *Locusta migratoria* (Bernays et al., 1976). In contrast, this insect is strongly deterred from feeding by surface material of sorghum leaves, which was shown to be mainly due to the compound *p*-hydroxybenzaldehyde (Woodhead, 1982). Klingauf et al. (1971) demonstrated that the insect *Acyrthosiphon pisum* is stimulated to probe longer by certain alkanes of the leaf surface of *Vicia fabae*. The above studies suggest a relationship between the leaf cuticular compounds and feeding stimulations, as we found for the tobacco hornworm.

One of the interesting findings is that leaf-surface extracts of hosts as well as acceptable nonhosts contain feeding stimulatory compounds on the leaf surface, whereas that of the unacceptable plant *C. generalis* did not affect feeding at all. The failure of the reconstitution experiment confirms that no deterrent is extracted. Nevertheless, the dewaxing process or just adding solvent to the leaf makes this plant acceptable (although still less acceptable than wet filter paper or tomato leaves; de Boer and Hanson, unpublished). This effect is the more remarkable because untreated leaves of this plant deter feeding so strongly that the larvae starved to death rather than consume any leaf material. A possible explanation for the reduced deterrency following dewaxing is that repellent odors were removed. The presence of such odors was suggested by the results of an orientation experiment in which larvae preferred turning towards a "neutral" plastic disk instead of a leaf disk of *C. generalis* ($P < 0.05$, $N = 77$). It is also possible that the solvent used for dewaxing destroys a strong deterrent.

One remarkable result is that, despite large texture differences between leaves and filter paper, some leaf-surface extracts on filter paper mimic the whole leaf in feeding responses as well as they do (Table 1). This indicates that nonpolar compounds in the leaf surface are major contributors to the feeding stimulation. In contrast, larvae apparently do not recognize the leaf-surface extract of *V. sinensis* as faithfully representing whole leaves of this plant. In fact, the extract stimulates feeding, whereas the whole leaf is slightly deterrent.

Apparently, interior chemicals or other unidentified factors play a major role in feeding on *V. sinensis*.

Jermy (1966) suggested that the oligophagous character of phytophagous insects is mediated mainly by plant compounds having feeding inhibitory activity in nonhost plants. Indeed, feeding in *M. sexta* is inhibited by various deterrents (de Boer et al., 1977; Städler and Hanson, 1978; de Boer and Hanson, 1987b). However, the strong stimulation of feeding by lipid extracts signifies the importance of feeding stimulants for food selection as well. Botanical specificity, on the other hand, does not seem to be conferred by these surface lipids.

In conclusion, lipid extracts of leaves contain attractants and feeding stimulants for larvae of *M. sexta*. The primary repository of these stimulants can be found at the leaf surface of two hosts and two acceptable non-host-plant species. In contrast, no activity was found in leaf-surface chemicals of an unacceptable nonhost plant. The results of this study underscore the importance of leaf-surface lipids in food plant selection by the tobacco hornworm.

Acknowledgments—We would like to thank Drs. J. Kaplanis and J. Svoboda of the U.S.D.A., Beltsville, Maryland, for supplying eggs of the tobacco hornworm, R. Barnett of the U.M.B.C. greenhouse for all plant material, and Dr. K.-H.A. Rösler of the Department of Medicinal Chemistry and Pharmacognosy at the University of Maryland at Baltimore for assistance and use of his facilities. We are also indebted to R. Stevens, L. Sachs, D. Klein, J. Kirgan, J. Glaser, C. Cearley, N. Wiley, and Dr. S. Kogge for their valuable assistance and to Dr. R.F. Chapman for helpful comments on the manuscript. We gratefully acknowledge the support of NSF grant BNS-7914043 and USDA grant 5901-0410-9-0246-0.

(Received December 1, 1986; accepted March 25, 1987)

Abstract—Moths belonging to the species *Spodoptera sunia* have been recognized as a new pest of cotton in Central America. By means of electrophysiologic investigations, solid sample injection gas chromatography, and combined gas chromatography–mass spectrometry, (*Z*)-9-tetradecenyl acetate, (9*Z*,12*E*)-9,12-tetradecadienyl acetate, (*Z*)-9-tetradecen-1-ol, and (*Z*)-11-hexadecenyl acetate, in a ratio of 100:5:31:20, were identified in the pheromone gland of female insects. These substances should serve as a base for the development of a pheromone-monitoring system for this lepidopteran pest.

Key Words—Sex pheromone analysis, *Spodoptera sunia*, solid sample injection, Lepidoptera, Noctuidae.

INTRODUCTION

Members of the genus *Spodoptera* (Lepidoptera: Noctuidae, Amphypyrinae) appear worldwide. A number of species of this genus are known as pests that cause damage to cereals, field crops, grasses, and flowers. Over the last few years, especially in Central America, *Spodoptera sunia* Guenée has been recognized as a new pest of cotton, showing resistance or at least insensitivity

[1] Pheromones, 60. Pheromones 59: Bestmann, H.J., Attygalle, A.B., Brosche, T., Erler, J., Platz, H., Schwarz, J., Vostrowsky, O., Wu Cai-Hong, Kaissling, K.E. and Chen Te-Ming. 1987. *Z. Naturforsch.* 42c:631–636.

towards a wide range of standard insecticides. It is likely that *S. sunia* may have experienced a favorable selection pressure, due to the extensive use of certain pesticides, resulting in a steady increase of its population.

The correct identification of a pest species is one of the most important requirements in deciding the appropriate method of control. It is rather tedious, or even impossible, to differentiate young larvae of *S. sunia* from those of other sympatrically occurring species of *Spodoptera*, because of the overlapping color patterns of their larval skin. The development of a species-specific lure for capturing males of *S. sunia* can be useful to monitor selectively the presence of this species among other pests.

In the literature, no information on the pheromone of *S. sunia* was found. Therefore, a determination of the composition of its female sex pheromone complex appeared useful. By means of electrophysiologic studies, solid sample injection gas chromatography of isolated pheromone glands, and combined gas chromatography–mass spectrometry, the chemical structures of the pheromone components were determined. The analytic results will be useful in formulating a synthetic lure for monitoring the abundance and distribution of this lepidopteran pest.

METHODS AND MATERIALS

Insect Material. Spodoptera sunia moths were reared on a semisynthetic diet at Hoechst AG, Frankfurt. The strain, originating from Colombia, has been maintained as a laboratory colony for several years.

The larvae were allowed to pupate and were sexed prior to hatching. The segregated sexes were placed in plastic boxes containing moist sawdust and maintained on a reversed 15 : 9 hr light–dark cycle. After emergence, the female insects were observed carefully during the scotophase under a red darkroom lamp to observe the calling behavior and period.

Electroantennography. Using the electroantennogram (EAG) technique (Schneider, 1957) with male moth antennae, the stimulus potentials evoked by a large number of pheromone and pheromone-like chemicals (filter paper strips loaded with the test chemicals) were measured, and the response amplitudes were compared with each other. The test compounds selected were those known as noctuid sex pheromones, especially those identified from females of other species of *Spodoptera* (for recent reviews, see Tamaki, 1987; Arn et al., 1986; Bestmann and Vostrowsky, 1981).

Encapsulation of Pheromone Glands. The samples were prepared according to the method described by Attygalle et al. (1987). The pheromone glands of 2- to 4-day-old female moths were excised during the period of maximum calling activity. One to five glands prepared in this way were sealed in a soda

glass capillary (2 cm × 2 mm) and used for immediate analysis or stored at −20°C.

Gas Chromatography. Capillary gas chromatography with flame ionization detection was performed on a Packard-United Technologies 438A instrument equipped with a splitless injector and Shimadzu Chromatopac C-R3A data system. Columns and temperature programs were: (A) fused silica capillary column coated with SP-2340 (100% cyanopropyl silicone, Chrompack, 25 m × 0.22 mm), 2 min at 60°C, 60–195°C at 4°/min; and (B) fused silica capillary column coated with CP-19 (chemically bonded 50:50 phenyl–methyl silicone, Chrompack, 12 m × 0.2 mm), 2 min at 60°C, 60–270°C at 10°/min.

Samples sealed in glass tubes were chromatographed by a solid sample injector (Attygalle et al., 1987).

Gas Chromatography–Mass Spectrometry. A Finnigan 9502 gas chromatograph, fitted with a Grob-type split–splitless injector and a solid sampler, linked to a Finnigan 3200E quadrupole mass spectrometer with a Data System 6000 was used: (C) fused silica capillary column coated with SP-2340 (50 m × 0.22 mm), 4 min at 60°C, 60–195°C at 6°/min, splitless injection by a solid sampler, split-vent was kept closed for 1 min.

RESULTS AND DISCUSSION

Electrophysiological Studies. In order to obtain some information about the chemical nature of the sex pheromone of *S. sunia*, electrophysiologic studies were carried out. A series of mono- and diunsaturated aldehydes, alcohols, and the corresponding acetates was employed as the stimulus sources, and the EAG amplitude evoked by each compound was measured. Of all the compounds tested, (9*Z*,12*E*)-9,12-tetradecadienyl acetate was the most active. It could evoke response amplitudes of 1.6 mV and 2.9 mV, for doses of 0.2 μg and 2 μg at the stimulus source, respectively. This tetradecadienyl acetate isomer is known as a pheromone component of *Spodoptera eridania* (Jacobson et al., 1970; Teal et al., 1985), *S. exempta* (Beevor et al., 1975), *S. exigua* (Persoons et al., 1981; Steck et al., 1982; Tumlinson et al., 1982), *S. litura* (Nesbitt et al., 1973; Tamaki et al., 1973), and *S. littoralis* (Tamaki, 1987).

In a few species of Spodoptera, (9*Z*,11*E*)-9,11-tetradecadienyl acetate is known as a pheromone component (Nesbitt et al., 1973). However, this tetradecadienyl acetate isomer was about 100 times less active than (9*Z*,12*E*)-9,12-tetradecadienyl acetate in releasing EAG activity. This was determined by comparing the loadings required, at the stimulus source, by the two compounds to evoke the same EAG response.

The second most effective test chemical was (*Z*)-9-tetradecenyl acetate (0.6 mV and 2.0 mV at 0.2 μg and 2.0 μg, respectively). This compound is often

found in the pheromone complexes of other species of Spodoptera (Steck et al., 1982, and references cited above).

Analysis of Gland Volatiles. Under our laboratory conditions, *S. sunia* females showed maximum calling activity ca. 7 hr after the beginning of the dark period. During the calling period, which lasts for about 20–30 min, the females raise their wings slightly and expose the ovipositors. Various parts of the abdominal tip of 3-day-old female moths were excised during the calling period and analyzed by GC for their pheromone content. Almost all the components of the sex pheromone complex were found only in the ventral side of the intersegmental membrane, between the VIIIth and IXth abdominal segments (densely stippled area in Figure 1). This area becomes enlarged and bulbous during the calling period.

The segments VIII and IX, and the intersegmental membrane between segment VII and VIII contained no detectable amounts of pheromone-like substances. The dorsal region of the intersegmental membrane contained only traces of pheromone components, which may be due to contamination. Steinbrecht (1982) has obtained similar results by EAG evaluations of hexane extracts made from different parts of the abdominal tip of *S. exempta.*

The section of the intersegmental membrane, containing the highest concentration of volatile pheromone components, was dissected carefully under a binocular microscope and sealed in a glass capillary to be used for GC-MS analysis by a solid sample injector (Attygalle et al., 1987).

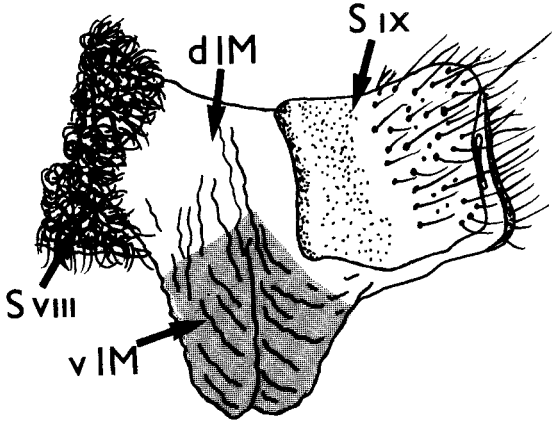

FIG. 1. An illustration of the abdominal tip of a female *Spodoptera sunia* (S VIII = 8th abdominal segment; S IX = 9th abdominal segment; dIM = intersegmental membrane, dorsal side; vIM = intersegmental membrane, ventral side). The pheromones are located during the calling period only in the ventral side (densely stippled area) of the intersegmental membrane.

Figure 2 shows a reconstructed gas chromatogram (RGC, top chromatogram in the figure) from a GC-MS analysis of three "pheromone glands" on column C. All the signals were well resolved for accurate integration of peak areas. Complete EI-mass spectra of the four pheromone-like components could be obtained using only three female glands. The identification of the chromato-

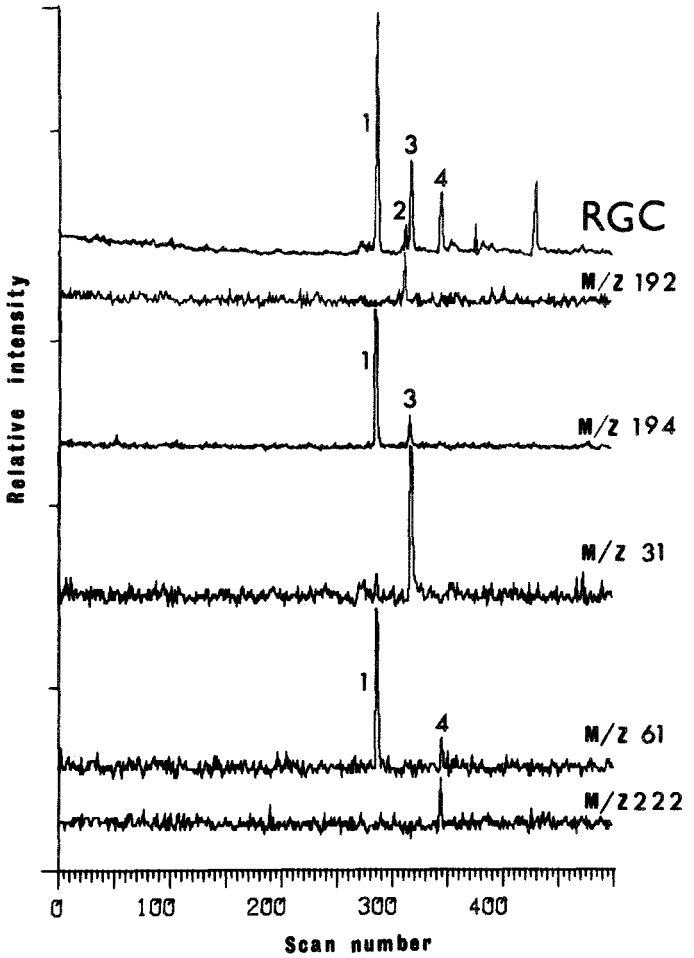

FIG. 2. A reconstructed gas chromatogram (RGC) and four mass chromatograms for m/z = 192 ($C_{14}H_{24}^+$), m/z = 194 ($C_{14}H_{26}^+$), m/z = 31 ($CH_2{-}OH^+$), and m/z = 61 ($CH_3COOH_2^+$). 1 = (*Z*)-9-tetradecenyl acetate, 2 = (9*Z*,12*E*)-9,12-tetradecadienyl acetate, 3 = (*Z*)-9-tetradecen-1-ol, and 4 = (*Z*)-11-hexadecenyl acetate. Three glands from 3-day-old females were chromatographed on a 50 m × 0.22 mm FSCC coated with SP-2340 via a solid sample injection technique.

graphic peaks was achieved by mass chromatographic analysis of characteristic fragment ions, and elucidation of mass spectra by the method of Horiike and Hirano (1982). Under identical mass spectroscopic conditions, the spectra of a series of *Z* isomers of tetradecenyl acetate and hexadecenyl acetate were measured, and the intensities of various peaks in each ion cluster of these spectra were compared to those obtained from peaks 1 and 4 in Figure 2. This way peaks 1 and 4 could be identified tentatively as 9-tetradecenyl acetate and 11-hexadecenyl acetate. The stationary phase SP-2340 (columns A and C) can resolve essentially all the positional and geometric isomers of monounsaturated compounds found in pheromones (Heath and Tumlinson, 1984). This was verified by using a standard mixture containing all positional isomers of tetradecenyl acetate. Furthermore, column A could afford baseline separations of four geometric isomers of 9,12-tetradecadienyl acetate.

A mass chromatographic search for characteristic ions known for previously identified pheromone components from other species of *Spodoptera* was made. The results are shown in Figure 2. The main component of the *S. sunia* pheromone complex was found to be (*Z*)-9-tetradecenyl acetate (1). This was corroborated by the coincidence of the maximum of abundance of fragment ions $m/z = 194$ ($C_{14}H_{26}^+$, generated by the elimination of acetic acid) with that of $m/z = 61$ due to protonated acetic acid $CH_3COOH_2^+$. A small amount of the diunsaturated (9*Z*,12*E*)-9,12-tetradecadienyl acetate (2) was also found (mass chromatogram of $m/z = 192$, $C_{14}H_{24}^+$, in Figure 2).

The second major component, 3, is (*Z*)-9-tetradecen-1-ol, as shown by the contemporal appearance of ion $m/z = 194$ ($C_{14}H_{26}^+$, generated by the elimination of H_2O) and $m/z = 31$ ($CH_2{-}OH^+$) in the corresponding mass chromatograms in Figure 2. The third major component, signal 4 in the figure, was found to be (*Z*)-11-hexadecenyl acetate (mass chromatogram $m/z = 61$, $CH_3COOH_2^+$, and $m/z = 222$, $C_{16}H_{30}^+$).

The identification of the four peaks was confirmed by a comparison of retention times obtained from columns A and B with those of authentic samples. The relative amounts of (*Z*)-9-tetradecenyl acetate, (9*Z*,12*E*)-9,12-tetradecadienyl acetate, (*Z*)-9-tetradecenol, and (*Z*)-11-hexadecenyl acetate were 100, 5, 31, and 20, respectively. In 3-day-old females, the major component, (*Z*)-9-tetradecenyl acetate, represents about 30 ng/insect. This amount is several times more than that reported for *S. exempta* by EAG estimations (Steinbrecht, 1982; Beevor et al., 1975).

The two acetates, (*Z*)-9-tetradecenyl acetate, 1, and (9*Z*,12*E*)-9,12-tetradecadienyl acetate, 2, are common to almost all other known pheromone complexes from this genus. However, a recent analysis by Tumlinson et al. (1986) shows that the latter component plays no role in the pheromone blend of *S. frugiperda*. (*Z*)-11-Hexadecenyl acetate, 4, has been found only in *S. eridania* (Teal et al., 1985) and *S. frugiperda* (Tumlinson et al., 1986), and this may be

an essential sex attractant component necessary for speciation and isolation. (*Z*)-9-tetradecenol, 3, gave at least 100 times lower EAG responses than those from 2 with male *S. sunia* antennae and could be considered rather as a biosynthetic precursor. Alcohols corresponding to pheromone acetates are often found in more comprehensive pheromone analyses, especially in those carried out by a solid sample injection technique. In at least a few examples, the biosynthetic role of the alcohols as precursors of pheromone acetates (Bestmann et al., 1987) and aldehydes (Teal and Tumlinson, 1986) has been established. Nevertheless, since (*Z*)-9-tetradecenol has also been identified in other *Spodoptera* species (Steck et al., 1982; Tumlinson et al., 1982; Mitchell et al., 1983; Teal et al., 1985), the possible role of the alcohol in the pheromonal communication of *S. sunia* can be evaluated only by field trails.

Based on the compounds identified as the major components of the pheromone gland of *Spodoptera sunia*, extensive field experiments, to be conducted in Central and South America, are planned for the development of a monitoring method that can be incorporated into integrated pest control.

(Received February 20, 1987; accepted March 25, 1987)

Abstract—Secretion from glands was observed when cercariae of *Schistosoma mansoni* were exposed to certain lectins. Lectins from *Maclura pomifera*, *Pisum sativum*, and *Triticum vulgaris*, were effective at 7.5 μg/ml. The effects of cercarial gland secretion caused by *T. vulgaris* agglutinin and *Arachis hypogaea* agglutinin were blocked by pretreatment with the inhibiting glycan. Discharge of glands was not visualized after exposure of miracidia to lectins. The distribution of five labeled lectins was determined on live miracidia and cercariae. Only *T. vulgaris* agglutinin generally labeled the cercarial and miracidial bodies. Specific labeling occurred with the other lectins on the anterior, in glands or on their secretions, in flame cells in both stages, and on an unidentified ring of cells in miracidia. The possible mechanisms involved in changes caused by the lectins are discussed.

Key Words—*Schistosoma mansoni*, lectins, cercariae, miracidia, secretions, surface carbohydrates.

INTRODUCTION

Sugars can occur generally as receptors in biologic systems (Monsigny et al., 1983), and recent studies with nematodes have shown that the carbohydrate moieties of glycoproteins function in the reception and recognition of chemotactic signals (Zuckerman and Jansson, 1984; Bone and Bottjer, 1985). Exposure of worms to mannosidase and sialidase completely inhibits normal

[3]Permanent address: Department of Microbial Ecology, University of Lund, Lund, Sweden.

0098-0331/88/0200-0691$06.00/0

chemotaxis (Jansson et al., 1984), while partial inhibition results from treatment with the mannose/glucose-specific lectin concanavalin A (Con A) or the sialic-specific lectin *Limulus polyphemus* agglutinin (limulin) (Jeyaprakash et al., 1985). Electrophysiologic measurements of receptors are possible in large invertebrates (Dusenbery, 1980), but are impractical in small invertebrates. However, the demonstration that mannosyl (McClure and Zuckerman, 1982) and sialyl (Spiegel et al., 1982; Jansson and Nordbring-Hertz, 1984) residues are proximate to the cephalic sensillae of four nematode species, when combined with the behavioral changes caused by molecules reacting with sugars, suggests that sugars are almost certainly involved in chemotactic responses in nematodes.

When miracidia of *Schistosoma mansoni* approach snails, their behavior changes (MacInnis, 1965). Certain fatty acids, particularly 2-tetradecanoic acid, stimulate cercarial penetration (Haas, 1984). These compounds may act on glycoprotein receptors. Therefore, the effects of lectin exposure on miracidia and cercariae were investigated, and labeled lectins were used to determine if the sites of receptors could be identified.

METHODS AND MATERIALS

Organisms. A Puerto Rican strain of *S. mansoni*, originally obtained from the Center for Tropical Diseases, University of Lowell, Massachusetts, was maintained in albino *Biomphalaria glabrata* and Charles River CD1 mice. Miracidia were hatched from eggs released by homogenization of infected murine livers, and cercariae were collected by placing patent snails in a small quantity of dechlorinated tap water under a bright light for 2 hr. Both miracidia and cercariae were used within 1 hr of collection.

Lectin Studies. Twenty-five to 50 miracidia or 50–100 cercariae were incubated in 0.1 ml of 5 mM Tris (pH 7.2) buffer or buffer plus lectin (see Table 1 for lectins tested) in multiwell tissue culture plates at room temperature for 0.5 hr. Two drops of Lugol's iodine were added to each well for observation of gland discharge in both lectin-treated and untreated miracidia and cercariae.

The unlabeled lectins tested for their physiologic effects, their abbreviated names, and their sugar specificities are as follows: *Arachis hypogaea*, PNA, *d*-galactose and beta-(1-3)*N*-acetyl galactosamine; *Concanavalia ensiformis*, Con A, alpha-*d*-glucose and alpha-*d*-mannose; *Griffonia simplicifolia*, GS1, *d-n*-acetyl glucosamine; *Glycine max*, SBA, alpha-*d-n*-acetyl galactosamine and *d*-galactose; *Limax flavus*, LFA, sialic acid; *Limulus polyphemus*, LPA, sialic acid; *Maclura pomifera*, MPA, alpha-*d*-galactose; *Pisum sativum*, PSA, alpha-*d-n*-acetyl glucosamine and *d*-mannose; *Solanum tuberosum*, STA, beta(1-4)*d-n*-acetyl glucosamine; *Triticum vulgaris*, WGA, beta-*d-n*-acetyl glucosamine;

Ulex europaeus, UEA-1, alpha-1-fucose and *d-n*-acetyl glucosamine. Lectins were tested from 500 μg/ml down to 7.5 μg/ml in 5 mM (pH 7.2) Tris buffer.

For the labeling trials, both fluorescein (FITC) and tetramethyl rhodamine isothiocyanate (TRITC) conjugates of Con A, LFA, LPA, PNA, and WGA were tested. Concentrations were 25 μg protein/ml in 5 mM Tris buffer, pH 7.2. The specificity of the lectin was established by preincubation with the appropriate inhibiting saccharide. Miracidia or cercariae were placed on microscope slides and the label visualized on a Nikon fluorescence microscope equipped with FITC and TRITC filters. For photography, labeled miracidia and cercariae were immobilized by warming the slides immediately before photography.

To test further for sialic acid, ^{125}I-labeled LFA was prepared by the chloramine-T reaction (Talmage and Claman, 1967) according to Kahane and Tully (1976). This procedure is more sensitive than the fluorescent technique and should indicate even small numbers of sialic acid molecules. The test was performed on heat-inactivated cercariae.

Labeling was attempted also with WGA, UEA, PNA, and LFA conjugated with ferritin. Live miracidia and cercariae were treated with lectin conjugate at 25 μg/ml in 5 mM Tris buffer, pH 7.2, as described by Zuckerman et al. (1979). Then the specimens were fixed, embedded in araldite, and processed for transmission electron microscopy (TEM) by standard procedures. Micrographs of random sections through specimens were taken on a JEOL 100S electron microscope operated at 80 kV.

Tegumental damage to *S. mansoni* adults after binding of Con A or *Ricinus communis* agglutinin can occur (Simpson and McLaren, 1982). Therefore the cercariae and miracidia were examined for similar damage after treatment with lectins. Miracidia or cercariae were exposed first to 250 μg/ml PNA or WGA, which was greater than the doses causing gland discharge in cercariae. Then specimens were prepared for TEM as described previously. The untreated cercariae and miracidia were used for controls.

Lectins and *N,N*-diacetyl chitobiose penta-*o*-acetate were purchased from EY Laboratories (San Mateo, California), with the exception of unlabeled LPA, *d*-(+)-galactose and alpha-methyl-D-mannoside which were from the Sigma Chemical Co. (St. Louis, Missouri).

RESULTS AND DISCUSSION

A range of lectins caused discharge of glands in cercariae (Figure 1 and Table 1). WGA at 15 μg/ml resulted in discharge of glands of 91% of cercariae, but prior incubation of cercariae in 5 μg/ml of the specific blocking agent *N,N*-diacetyl chitobiose penta-*o*-acetate reduced this to 5% compared with 1% in untreated controls. In similar tests, 300 μg/ml galactose blocked 30 μg/ml PNA (Figure 1B) and 125 μg/ml alpha-methyl-D-mannoside blocked 30 μg/ml Con A, demonstrating the specificity of the binding of these lectins to chemoreceptors. However, 300 μg/ml *d*-galactose did not block 30 μg/ml MPA and 250 μg/ml *N,N*-diacetyl chitobiose penta-*o*-acetate did not block 30 μg/ml PSA, indicating that the binding of these two lectins may be nonspecific. The same lectins used on cercariae were tested on miracidia (except STA) at 500 μg/ml. No discharge of glands was visible before or following addition of Lugol's iodine, and more sensitive techniques may be required to visualize secretions as they occur. Some miracidia died or rounded up and swam more slowly in the two highest doses of GS1, but attempts to block this effect with a similar concentration of *N,N*-diacetyl chitobiose penta-*o*-acetate were not successful, suggesting that the effect of GS1 on miracidia is nonspecific.

To determine if the position of possible receptors could be identified, live active miracidia and cercariae were incubated in FITC and TRITC conjugated lectins (Figure 2, Table 2). Both miracidia and cercariae (Figure 2E and F) were labeled by LPA and LFA, which suggested the presence of sialic acid. In competitive displacement trials fluorescent Con A, WGA, and PNA were displaced, indicating that *n*-acetyl glucose and galactose were on the surface. Ferritin-labeled WGA also labeled densely the surface glycocalyx or miracidia (Figure 3) and cercariae. The position of the miracidial plates was visualized following the WGA (Figure 2B) and Con A fluorescent treatments. No labeling of miracidia or cercariae was observed with the PNA, LFA, or UEA ferritin

conjugates, but it is probable that if fucose residues occur on only localized surface areas of these schistosome stages, the residues would not be detected using this technique. Transmission electron microscopy of miracidia and cercariae exposed to 250 μg/ml WGA or PNA did not reveal damage to the tegument.

With three exceptions, all of the tested lectins induced discharge of cer-

carial glands (Figure 1B). Three of the active lectins (WGA, MPA, and PSA) caused significant discharge at the lowest dose tested, 7.5 μg/ml, indicating a very high sensitivity of the cercariae to lectin exposure. Linder (1985, 1986) used fluorescent lectins to visualize secretions as cercariae moved over skin lipids on a slide. However, our results suggest that the lectins affected the cercariae and, therefore, the events observed did not represent the normal situation.

The uniform distribution of *n*-acetyl glucosamine over the whole miracidial surface (Figure 2A), but not under the plates which are shed (Figure 2B), suggests that the lectin is not reaching most of what becomes the surface of the sporocyst. The labeling patterns found in our study agree with those of Samu-

elson and Caulfield (1985), who used Con A, but disagree with those of Murrell et al. (1978), who reported that Con A but not WGA bound generally to cercariae. Lectins can, however, reach other structures. PNA labeled a ring of cell- or pore-like structures of unknown origin which must be rich in galactose or galactose-like molecules (Figure 2C and D). LFA, which is specific for sialic acid or one of its analogs, labeled a number of structures and presented an enigma (Figure 2E and F). One of the proofs of the presence of sialic acid is the ability to displace the lectin with sialic acid, but this did not occur in tests with both the fluorescent and iodinated conjugates. Sialic acid has been reported in a number of helminths using indirect methods, but conclusive chemical determinations have not been undertaken (Schauer, 1982). We conclude that the labeling observed with LFA does not prove the presence of sialic acid in the schistosome stages examined.

The relationship of glycans localized on the cuticular surface proximate to nematode chemosensilla was discussed by Zuckerman and Jansson (1984) and has been shown to be important in chemoreception by the animal parasite *Trichostrongylus colubriformis* (Bone and Bottjer, 1985). Based on the current work, several receptors with different recognition sugars are involved in the triggering of gland discharge. This could explain why skin lipids cause almost complete discharge of the preacetabular glands (Austin et al., 1972), but relatively little occurs with 2-tetradecanoic acid (Haas, 1984). In *Caenorhabditis elegans*, enzymatic digestion of surface mannosyl residues interrupted the nematode's response behavior to a food source, supporting the view that this surface sugar derives from sensilla exudates and that sugars are the recognition molecules of receptors positioned within the chemosensilla. Based on the present results, we propose that galactosyl residues associated specifically with the chemosensilla of *S. mansoni* cercariae are critical to the recognition of the mammalian host. The role of galactose and related residues has precedent as being vital in molecular recognition between organisms, one example being the report of *n*-acetylgalactosamine on the nematode cuticle surfaces being critical in the recognition of the nematode by the nematophagous fungus *Arthrobotrys oligospora* (Nordbring-Hertz and Mattiasson, 1979). A better understanding of the molecular basis of chemical recognition by schistosomes is needed, but the abundance of surface sugars complicates the use of lectins to identify the structures or to try to purify the receptor molecules.

(Received November 21, 1986; accepted March 27, 1987)

Abstract—Samples of female coyote urine were taken once or twice each week during the winter and spring for two years. Headspace analysis was employed with Tenax GC trapping and GC-MS. Tenax trapping was started in less than 1 hr after sampling, and mild conditions were used to minimize losses of highly volatile and labile compounds. Thirty-four compounds were identified. They include sulfur compounds, aldehydes and ketones, hydrocarbons, and one alcohol. The principal constituent is methyl 3-methylbut-3-enyl sulfide, which usually comprised 50% or more of the total volatiles observed. The concentration of many constituents varied widely. This appeared to be quasiperiodic for five of the constituents, with a period of a few weeks, and with pronounced maxima at the peak of estrus. Apparently these compounds are 3-methyltetrahydrothiophene, methyl 3-methylbutyl sulfide, octanal, dodecanal, and bis(3-methylbut-3-enyl) disulfide. One or more of these compounds may have pheromonal activity in coyote relationships.

Key Words—Canidae, coyote urine, volatiles, estrous urine, urine volatiles.

INTRODUCTION

Deposition of urine is one of the means of communication used by coyotes (Bekoff and Wells, 1986). Among other functions, it appears to be important in mating behavior; scent marking is a common act performed during courtship

0098-0331/88/0200-0701$06.00/0

rituals. It has long been known by trappers that the odor of urine collected during estrus is more attractive to coyotes than is urine taken at other times.

A number of studies have been made to identify the volatile chemicals present in the urine and in other secretions of canids. The tenative identification of several carboxylic acids, sulfides, and other compounds in coyote estrous urine has been reported by Murphy et al. (1978), and by Teranishi et al. (1981). The analytic approach was to use liquid–liquid extraction first, to separate the constituents into acid, base, and neutral fractions. No more recent analytic work with this approach has been done by these authors. However, one of the original findings was that the acid fraction was more attractive than the others. This finding was one of the factors that led to a comprehensive program of testing the attractancy of both a series of aliphatic carboxylic acids and their trimethylammonium salts (Fagre et al., 1983).

Urine of the red fox, collected during the winter season (breeding season), has been reported to contain several unusual volatile compounds, including two sulfides and two terpene-derived ketones (Jorgenson et al., 1978). Urine from captive red foxes has been studied by Bailey et al. (1980). They found some of the same compounds and also methyl 3-methylbutyl sulfide, and related their concentrations to the reproductive state of the animal. Wolf urine has been investigated by Raymer et al. (1986). They reported over 70 compounds, including eight sulfides and disulfides found also in other canids, and showed the dependence of some of them on reproductive hormones. Studies of the volatile constituents of female dog urine (*Canis familiaris*) have been made by Schultz et al. (1985). Major constituents found were two aliphatic sulfides. The list of minor constituents includes disulfides, trimethylamine, and other compounds.

Studies of the volatile constituents of coyote and dog anal sac secretions during estrus have been made by Preti et al. (1976). The major constituents reported were low-molecular-weight (C_2–C_6) carboxylic acids and trimethylamine. These same compounds, along with putrescine and cadaverine, have been reported as principal volatile constituents of red fox anal sac secretions by Albone et al. (1974).

Goodwin et al. (1979) studied vaginal secretions of the dog during the state of estrus and reported the presence of methyl *p*-hydroxybenzoate in samples taken on days of full estrus only. They described pheromonal activity for this compound. However, when similar testing was done by other investigators (Kruse and Howard, 1983), no pheromonal activity was observed.

The present paper reports on the identification and relative amounts of some of the volatile constituents of female coyote urine obtained from early winter well into spring of two years. These periods included the normal mid-winter estrous season. The analyses were run on vapors from the headspace of

fresh urine samples at room temperature. Gas chromatography (GC) and gas chromatography combined with mass spectrometry (GC-MS) were employed.

METHODS AND MATERIALS

Collection of Urine Samples. Three female coyotes were kept in separate but adjoining 9-m^2 outdoor pens, each with a small shelter at one end. These animals were maintained on a standard diet of commercial dog food, dry kibble, and water. Coyote 1 was 3 years old and had pups in April of the previous year. Coyote 2 was 3 years old and never had pups. Coyote 3 was 2 years old and never had pups. Coyote 3 failed to donate urine after March 2 of the first season. Only coyote 1 was used in the second season.

Samples were collected early in the morning, usually twice each week from early January through March, then irregularly until early June in the first season (1981). Samples were taken from December 21 to April 26 in the second season (1982). For each collection, a clean pan, 20 cm wide, 25 cm long, 5 cm deep, was placed on the ground near the sheltered area of the pen and left there. The coyote usually sniffed and scent marked the pan, donating a urine sample, within a few minutes. Often, three or four scent-marking episodes were needed to obtain enough volume for analysis, but all samples were collected within a half hour of the initial urine donation. The urine was then poured into a glass bottle, stoppered, and kept in an ice bath until the start of the analysis, which was usually about 30–60 min later. The volume of sample varied from 3 to 30 ml during the first season. Generally, larger donations of urine were made during the second season. A 10-ml sample was taken each time for a GC analysis, and in 12 instances, the remainder, 9–42 ml, was used for GC-MS analysis.

Headspace Analysis. Purified nitrogen was passed over the surface of the urine sample. Entrained volatiles were carried by the gas into a 0.6-cm-diam., 7.5-cm-long stainless-steel tube packed with Tenax GC where they were adsorbed by the Tenax. The adsorbed volatiles were subsequently back-flushed into a liquid-nitrogen-cooled cold trap. The cold trap was flash-heated with a beaker of glycerol at 140°C or a heat-gun to move the volatiles into the GC column. Once the volatiles were loaded on the column, the GC run was done as usual. A stainless-steel open-tubular column, 0.75 mm ID and 150 m long, coated with methyl silicone oil containing 5% Igepal, was used. Details of the apparatus and procedure have been previously described (Schultz et al., 1971, 1985). An integrator–plotter, Hewlett-Packard model 3385A, was employed to trace the chromatogram and determine peak areas.

GC-MS. The procedure for trapping and back-flushing the volatiles for GC-MS was essentially the same as that described above. The GC column and

operating conditions of flow rate and temperature program were similar. The mass spectrometer was a Finnigan model 4500 equipped with an INCOS data system.

Separate runs on mixtures of pure paraffinic hydrocarbons from C_5 to C_{16} were made with the same GC and GC-MS systems and operating conditions as used with the urine volatiles in order to minimize the possibilities of mismatching any of the peaks and to permit calculation of retention indices.

RESULTS AND DISCUSSION

A list of identified constituents of the headspace vapor from female coyote urine is shown in Table 1. Peak numbers in column 1 refer to peaks in the chromatograms in Figures 1 and 2. Except where noted otherwise, all of these compounds were identified by matching their mass spectra and Kovats indices with those of authentic compounds. By far the most prominent constituent was methyl 3-methylbut-3-enyl sulfide (peak 46). This compound was synthesized by one of the authors (D.J.S.) using published methods (Wilson et al., 1978). The mass spectrum of the synthetic compound closely matched that of peak 46. In nearly half the urine samples, this compound amounted to 50% or more of the total volatiles observed. This compound has been reported to be a constituent of the urine of the red fox (*Vulpes vulpes* L.) during the winter season (Jorgenson et al., 1978) and of the wolf (*Canis lupus*) (Raymer et al., 1986). This compound, or perhaps a closely related isomer, was found also in the urine of the domestic dog (Schultz et al., 1985) but only as a minor constituent. Conversely, methyl propyl sulfide and methyl butyl sulfide were found to be major constituents of female beagle urine but only minor constituents of coyote urine. The other sulfur compounds in Table 1 are related to the three discussed above.

It was not surprising to find carbonyl compounds since they have earlier been found to be urine constituents (Matsumoto et al., 1973). Those in Table 1 comprise incomplete homologous series of aldehydes and methyl ketones from C_3 to C_{12}, but constituents were found in both of these classes only at the C_4 and C_5 levels. Hydrocarbons were represented by several terpenes, paraffins, 1-undecene, and toluene. Only one alcohol was found in substantial quantity, 3-methylbut-3-en-1-ol, which was always present, with relatively little variation in concentration. It might be one of the precursors of some of the sulfur compounds.

The most striking feature of the data is the great variation in concentration and ratios of concentrations of one constituent to another, with numerous ups and downs separated by only a few days. For the largest constituent, methyl 3-methylbut-3-enyl sulfide (peak 46), the concentration varied widely with time,

TABLE 1. COYOTE URINE VOLATILE CONSTITUENTS

Peak number[a]	Compound name	Kovats index	
		Found	Determined or literature

87	Dodecanal	1391	1391
90	Bis(3-methylbut-3-enyl) disulfide	1441	1437

[a] Peak numbers refer to the chromatograms in Figures 1 and 2.
[b] Probably an artifact.
[c] Tentative.

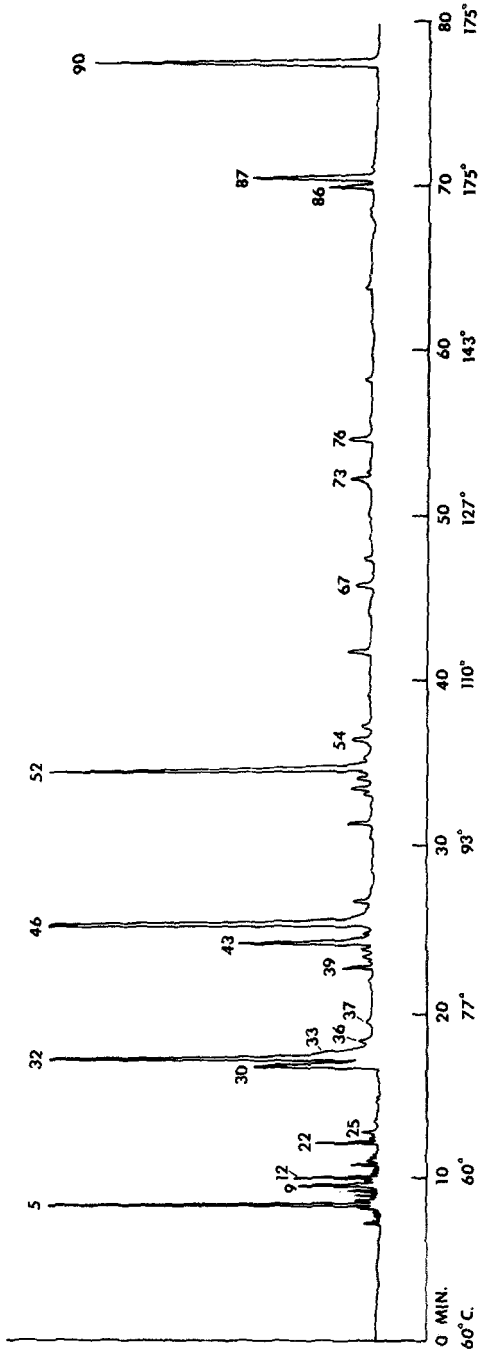

FIG. 1. Chromatogram of headspace volatiles from female coyote urine, coyote 1, on February 25, first year. Column: methyl silicone.

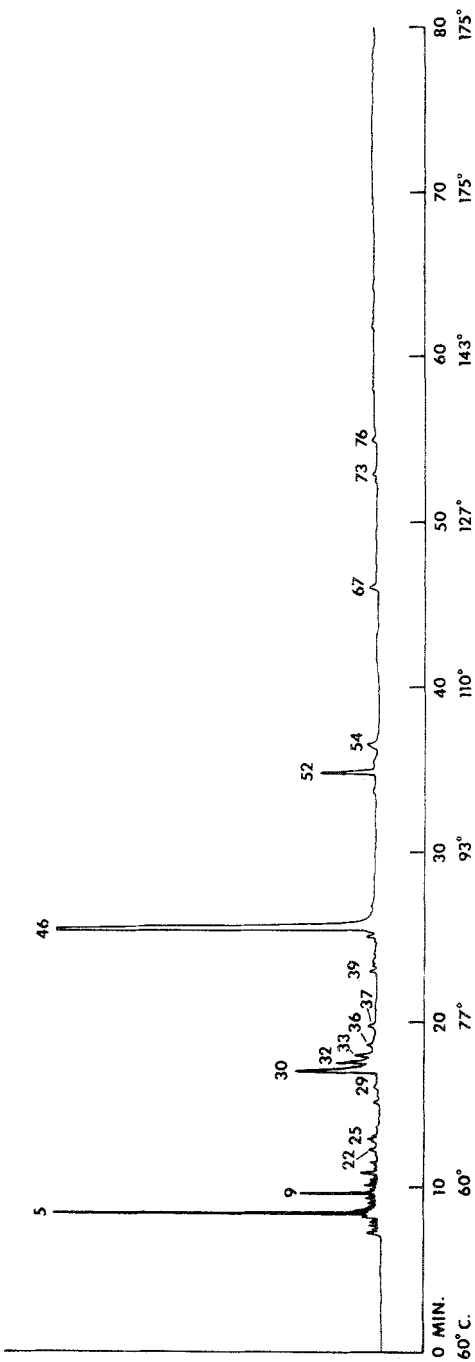

FIG. 2. Chromatogram of headspace volatiles from female coyote urine, coyote 1, on February 13, first year. Column: methyl silicone.

but there was no apparent relationship between its concentration and the state of estrus. Several of the other constituents varied from zero to moderate or fairly high concentrations. For example, the chromatogram of Figure 1 shows a fair number of substantial peaks. (Peak areas, measured in counts by the automatic integrator, are roughly proportional to concentrations of the constituents in the urine headspace; response factors were not determined.) This chromatogram is for coyote 1 on February 25, first season. The chromatogram for the same coyote on February 13 is shown in Figure 2. Peaks 43, 86, 87, and 90 are at, or near, zero, and peaks 32, 39, and 52 are much smaller than they are in Figure 1. However, in this particular comparison, peak 46 was nearly the same size, 20,300 vs. 21,000 counts.

Five of the constituents, with one or more of the coyotes, show patterns that suggest the variation is quasiperiodic. Plots of the first-year data for 3-methyltetrahydrothiophene (peak 39), methyl 3-methylbutyl sulfide (peak 43), and dodecanal (peak 87) are shown in Figures 3, 4, and 5, respectively. 3-Methyltetrahydrothiophene and dodecanal show maxima at intervals of a few weeks. Methyl 3-methylbutyl sulfide shows only two maxima, both in February. [Bailey et al. (1980) reported that the concentration of this compound in urine of the male red fox was significantly increased in February.] The other constituents that suggest a quasiperiodic variation are octanal (part of peak 52) and bis(3-methylbut-3-enyl) disulfide (peak 90). These five constituents showed pronounced maxima within, or near, the last week of February, which appeared

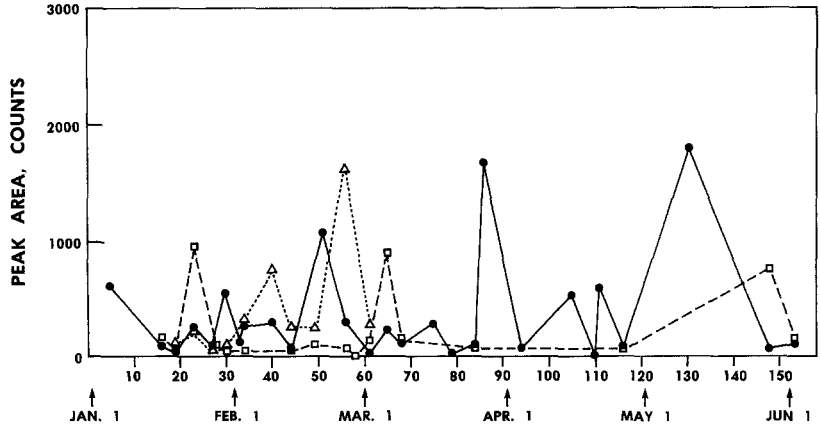

FIG. 3. Variation in concentration of 3-methyltetrahydrothiophene (peak 39) in the headspace with date, first year. Solid circles, coyote 1; squares, coyote 2; triangles, coyote 3.

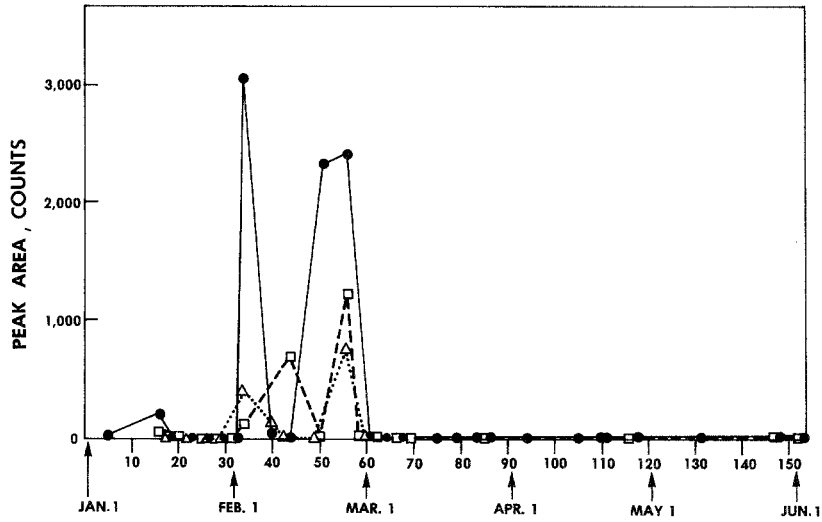

FIG. 4. Variation in concentration of methyl 3-methylbutyl sulfide (peak 43) in the headspace with date, first year. Legend is as in Figure 3.

to be the height of the estrous season, as judged by sexual behavior of male–female pairs in nearby pens.

In the second year, when samples were available from only one of the coyotes, 1, similar variations were observed. The data for 3-methyltetrahydrothiophene (peak 39) are plotted in Figure 6. There is good agreement of the pattern compared with that for this compound with the same coyote in the first year (see Figure 3). However, from the samples collected, methyl 3-methylbutyl sulfide gave no substantial peak in February. High concentrations might have occurred within the five- or nine-day gaps when no samples were taken. Dodecanal gave only one substantial peak all season. This was in one of the GC-MS runs, and the identification as dodecanal was definite. The peak area, calculated with a conversion factor, was 1450 counts. In agreement with data of the first year, this peak was observed in a sample taken on February 26.

In the data presented above, there is a suggestion that the variations in concentration of these five constituents reflect hormonal cycles. However, this hypothesis is very tentative. Before it could be established, many more analyses would be required, with many more animals and more frequent sampling.

One of the other aliphatic aldehydes, nonanal (peak 67), is noteworthy. In the first year, its peak area varied between zero and 1920 counts, but on January 16, the sample from coyote 1 showed a very high peak of 23,000 counts.

In the first year, consistency of the numerical data was only fair, due mainly to the use of urine samples of different volumes. However, we believe that discrepancies from this cause are not serious enough to change any of the con-

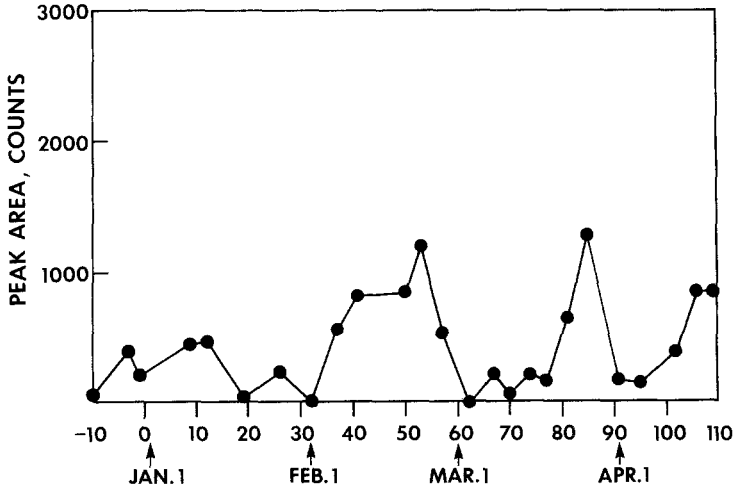

FIG. 6. Variation in concentration of 3-methyltetrahydrothiophene (peak 39) in the headspace with date, second year, for coyote 1.

clusions of this paper. In the second year, the urine sample volume was consistent at 10 ml.

No information was obtained about the possible presence of carboxylic acids, phenolic compounds, or mercaptans in the urine headspace because the GC column used does not permit the passage of small amounts of these compounds as definite peaks.

Some aldehydes, including octanal, nonanal, and dodecanal, have been shown to be coyote attractants (Scrivner et al., 1984), but further behavior studies are necessary to establish whether any of the compounds identified in coyote estrous urine have pheromonal activity.

(Received August 11, 1986; accepted March 31, 1987)

Abstract—The emission of species-specific odors by *Pristiphora erichsonii* and *P. wesmaeli* is accompanied by a characteristic defensive behavior called "snap bending." When the larvae are disturbed, blends of volatile compounds are emitted from ventral glands. The odor of *P. erichsonii*, a colonial species, is composed of bornyl acetate, borneol, *trans*-pinocarveol, myrtenol, benzaldehyde, and tetradecyl, hexadecyl, and octadecyl acetates, whereas that of the solitary *P. wesmaeli* is composed of 3-carene-10-al, linalool, myrtenal, and benzaldehyde. The role of these compounds in the defensive behavior of the larvae is discussed.

Key Words—Larch sawfly, *Pristiphora erichsonii*, Hymenoptera, Tenthredinidae, 3-carene-10-al, benzaldehyde, bornyl acetate, larval snap-bending.

INTRODUCTION

Larvae of the larch sawflies, *Pristiphora erichsonii (Hartig)* and *Pristiphora wesmaeli* (Tischbein) (Hymenoptera, Tenthredinidae), produce characteristic scents, easily distinguished by human olfaction. Upon being disturbed, the larvae emit the scents and quickly flex their abdomens to attain a characteristic stiff S-shaped posture, called "snap-bending" ("Schnickender haltung," Nägeli, 1935) (Figure 1).

[1] Hymenoptera: Tenthredinidae.

0098-0331/88/0200-0713$06.00/0

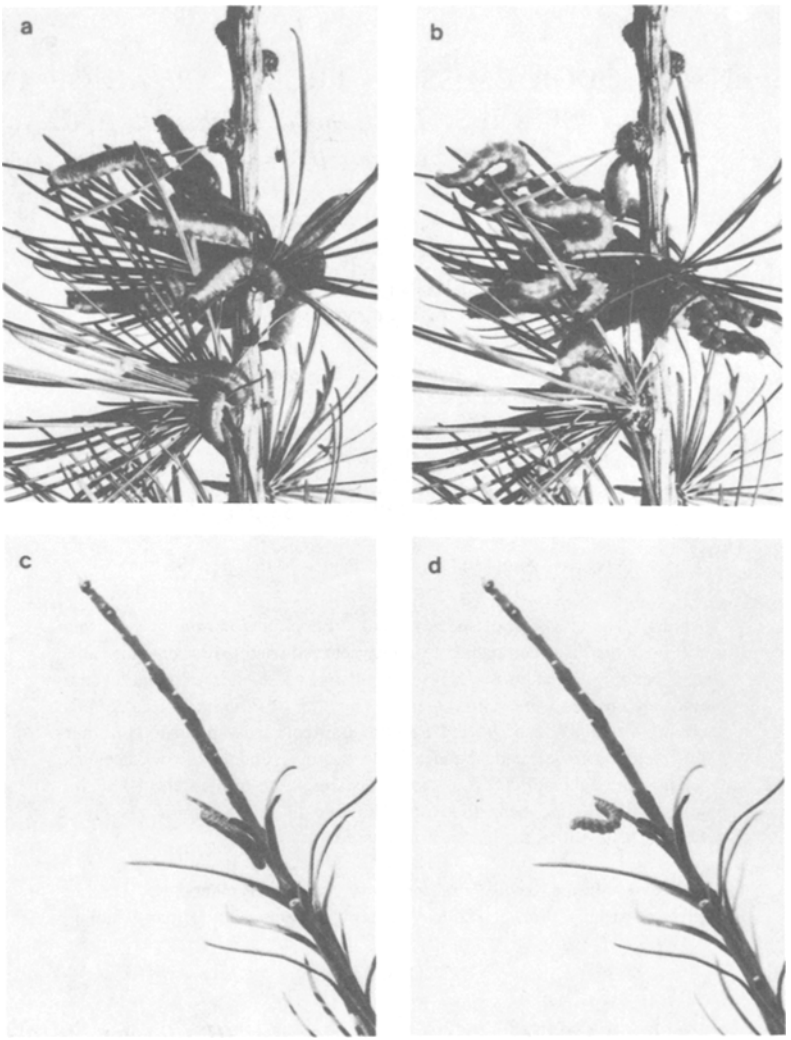

FIG. 1. A colony of *Pristiphora erichsonii* larvae (a, b) and a single *P. wesmaeli* larva (c, d) on needles of *Larix decidua* in the field. In a and c the larvae are feeding undisturbed, while in b and d the same larvae are shown in the snap-bending posture.

Glands producing volatile secretions are situated ventrally on the first seven abdominal segments in several Tenthredinidae (Yuasa, 1923; Maxwell, 1955; Boevé and Pasteels, 1985). The glands on the second to seventh segments are protrusile, those on the first segment are not. It has been suggested that the latter produce the odor emitted by snap-bending larvae (Benson, 1950, p. 76).

The sympatric *P. erichsonii* and *P. wesmaeli* differ in several respects, including feeding and oviposition behavior. *P. erichsonii* attack needles growing from tufts produced the preceding summer, whereas *P. wesmaeli* feed only on the long shoot needles initiated the same summer. Larvae of *P. erichsonii* live colonially with the most pronounced aggregation during the early instars, while *P. wesmaeli* larvae are solitary (Pschorn-Walcher and Zinnert, 1971). *P. wesmaeli* larvae are light green with two somewhat lighter bands along the body, and they exhibit homochromy in that they resemble larch needles. *P. erichsonii* larvae are greyish-green with a black head and are easier to discover at distance.

We have isolated compounds from the secretions which emanate from gland cells of the first abdominal segment of each species of sawfly larvae. The volatile components have been identified in an attempt to understand the role of these volatiles in the behavior related to the different life histories of these two species.

METHODS AND MATERIALS

Feeding larvae of *P. erichsonii* and *P. wesmaeli* were collected from *Larix* spp. near Uppsala in eastern Sweden or near Vårgårda in southwestern Sweden during the years 1975, 1979–1981, and 1985. In the laboratory, the larvae were fed with fresh foliage of *Larix decidua* (Miller).

To collect the volatiles emitted from the first abdominal segment, the larvae were induced to snap-bend and the glandular openings were wiped with 3 × 12-mm pieces of filter paper held with forceps. This procedure was repeated four to six times for each larva, with at least 12 h of undisturbed feeding between collections. The filter papers were immediately extracted in either redistilled pentane or pentane:ethyl acetate (95 : 5 v/v). The extracts were stored at −20°C and concentrated by evaporation at 42°C. Analyses were made on a coupled gas chromatograph–mass spectrometer (GC-MS), Finnigan 4021, San Jose, California. Glass capillary columns coated with either FFAP/OV-17 (6 : 5) (0.3 mm × 33 m) or Superox FA (0.25 mm × 56 m) or a fused silica column coated with OV-351 (0.2 mm × 25 m) were used. All compounds were identified by comparing their retention characteristics and mass spectra with those of synthetic reference compounds. The mass spectra were scanned from *m/e* 31 to

300, and, for the quantitative determinations, the area under each peak in the reconstructed ion chromatogram was measured. A response factor of 1.0 was used for all compounds.

The gas chromatographic phases were purchased from Alltec Assoc. Bellefonte, Pennsylvania and Supelco Inc. Deerfield, Illinois. The 3-carene-10-al was derived was derived by oxidation of 3-carene-10-ol synthesized as described in Lanne et al. (1987).

In a series of experiments at the laboratory, groups of the bug *Anthocoris nemorum L.* (Heteroptera, Anthocoridae) were placed one by one in Petri dishes (diameter 70 mm) containing a piece of filter paper with synthetic compounds (0.5–1 μg of each compound). As control, insects were studied in the same situation but without odors added to the filter paper. Three replicates were made of each test.

RESULTS

The gland on the ventral side of the first abdominal segment of *P. erichsonii* larvae was studied by light microscopy and was found to consist of a thin layer of glandular cells in a pocket. The gland is not protrusible, but the glandular pocket was observed to open and close regularly while the larvae were snap-bending. The secretions from these glands of *P. erichsonii* and *P. wesmaeli* were analyzed.

Gas chromatograms of the volatiles from the two species (Fig. 2) show that they are made up of several different compounds (Table 1). Benzaldehyde was the only compound common to both species, although present in different relative amounts. In *P. erichsonii*, the four oxygenated monoterpenes found in appreciable amounts were bornyl acetate, borneol, myrtenol, and *trans*-pinocarveol. Of these, bornyl acetate was the major component. The *P. wesmaeli* secretion contained three other oxygenated monoterpenes: linalool, myrtenal, and 3-carene-10-al. The mass spectrum of 3-carene-10-al, the major compound in *P. wesmaeli*, was compared with that of the synthetic reference (Figure 3). The *P. erichsonii* secretion also contained straight-chain tetradecyl, hexadecyl, and octadecyl acetates. Individual larvae of *P. erichsonii* and *P. wesmaeli* contained on the average 50 ng bornyl acetate and 1 ng 3-carene-10-al, respectively. Different instars of *P. erichsonii* and *P. wesmaeli* were analyzed. Third and fifth instars were compared for *P. erichsonii*. These analyses, based on 150 larvae of each instar, showed that none of the components in the secretion differed more than a few percent relative to the main component, bornyl acetate. Three groups of *P. wesmaeli* were analyzed, the first (120 larvae) consisted of a mixture of second- and third-instar larvae, the second group (75 larvae) consisted of third-instar larvae, and the third group (41 larvae) a mixture of fourth- and fifth-instar larvae. For *P. wesmaeli*, the amount of linalool and myrtenal did not differ more than 3% relative to 3-carene-10-al.

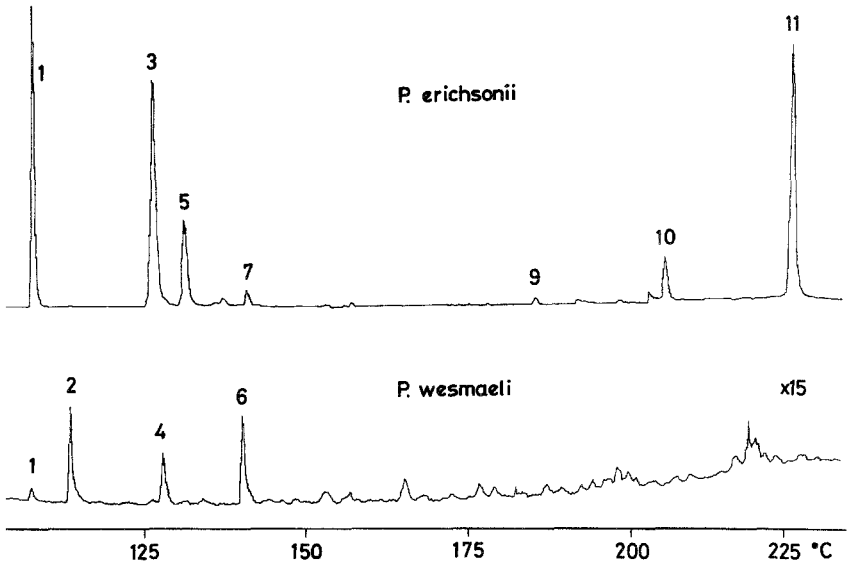

FIG. 2. Examples of capillary gas chromatograms of volatile secretions from *P. erichsonii* and *P. wesmaeli*. The GC column was coated with FFAP/OV-17 (see Methods and Materials). Compound 8 was not evident in this analysis as it coeluted with bornyl acetate on this particular column.

TABLE 1. VOLATILE COMPOUNDS IDENTIFIED IN GLANDULAR SECRETION OF *Pristiphora erichsonii* AND *P. wesmaeli* LARVAE

No.	Compounds	Relative amount[a]	
		P. erichsonii[b]	*P. wesmaeli*[c]

[c] Mean value of three extracts of instars 1–5. Seventy-six larvae were analyzed.

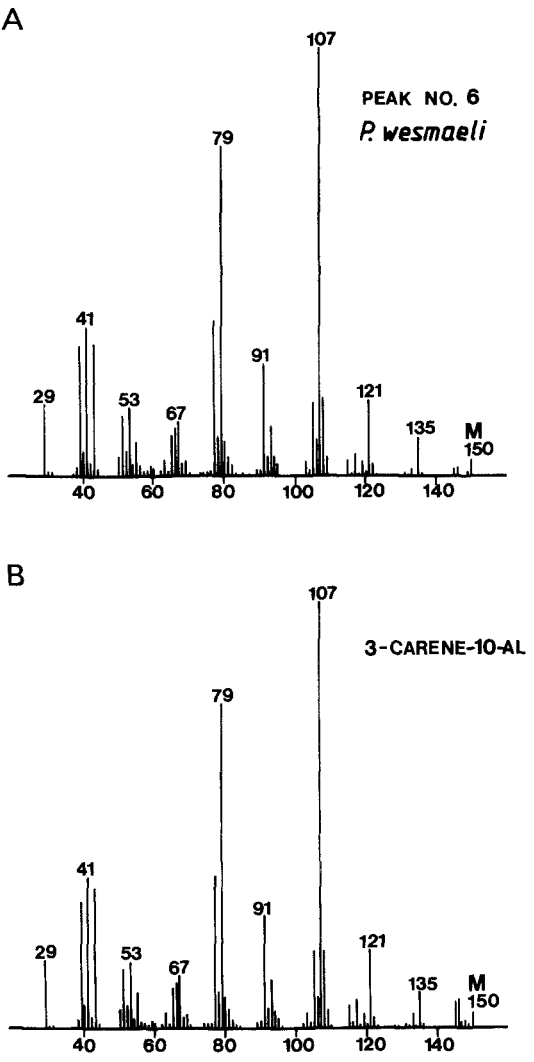

FIG. 3. Mass spectra of (A) compound 6 in *P. wesmaeli*, and (B) synthetic 3-carene-10-al.

Needles of *Larix sibirica* (Ledebour) and *L. decidua* were extracted and analyzed. Bornyl acetate, the only detectable volatile compound common to both *P. erichsonii* larvae and needles, was present in trace amounts in *L. sibirica*.

Mechanical or visual stimuli were used to evoke snap-bending and odor

emission under experimental conditions in the field and in the laboratory. Under natural conditions in the field, attacks by heteropteran predators such as *Orius* sp., *Anthocoris nemorum*, and *Ligyrocoris silvestris* L., were observed to release snap-bending behavior and odor emission. The attacking insects normally reacted to the behavior and excretions of the larch sawfly larvae by retreating and then grooming their antennae. When the predator *A. nemorum* was exposed to compounds found in the secretion of *P. erichsonii* in the laboratory, the insects were alerted and increased the intensity of their activities. They groomed their antennae, twitched, ran around, and attempted to fly. A mixture of borneol, bornyl acetate, myrtenol, and tetradecyl and hexadecyl acetate evoked a strong response, and when the compounds were tested one by one; hexadecyl acetate gave the strongest response. Benzaldehyde also stimulated the insects but only for a short while.

DISCUSSION

The spectrum of defense mechanisms known for larvae of Tenthredinidae include: (1) rapid changes in position (Figure 1b and d); (2) hiding (Figure 1a and c); (3) camoflage (homochromy) (Figure 1a and c); (4) display, which may be aposematic (Figure 1b and d); and (5) deterrence. Coupling between these modes of defensive behavior is common and augmentative (Benson, 1950). Glandular ejections of ill-smelling or protective liquids by sawfly are effective against spiders, which are chemotactically sensitive (Bristowe, 1941). Recently, Boevé and Pasteels (1985) have shown that the secretions from Nematinae sawfly larvae with well-developed ventral glands in the abdominal region protect the larvae from attacks by ants. Our field observations of *A. nemorum* and other heteropteran predators also show that the sawfly larval secretions protect the larvae from predators. Furthermore, our laboratory experiments indicate that the predators are affected by the glandular compounds of *P. erichsonii*.

The patterns of oxygenated monoterpenes found in the larch sawfly larvae show great similarity to the patterns of such compounds found in the hindguts of many bark beetles. In bark beetles, many of the oxygenated monoterpenes were originally suggested to result from detoxification of host terpenes (White et al., 1980), but the compounds are known now, in some cases, to be used as aggregation pheromones (Wood, 1982; Borden, 1982). The ability to oxygenate host monoterpene hydrocarbons is widespread in several insect orders. Two plausible precursors of *trans*-pinocarveol, myrtenol, and myrtenal are α-pinene and β-pinene, while 3-carene is probably the precursor of 3-carene-10-al. These three monoterpene hydrocarbons are present in many conifers (Karrer, 1976). It is also possible that the insects selectively sequestered some of the trace oxygenated monoterpenes that can be present in a conifer host (Heemann and

Francke, 1977). If this is the case for the larch sawflies, the different amounts of monoterpenes in *P. erichsonii* and *P. wesmaeli* should reflect their different choices of food.

Most studies of larval odors have dealt with defensive secretions (for a review see Blum, 1981). The Tenthredinidae *Neodiprion sertifer* (Geoffrey) larvae, upon being disturbed, perform a type of snap-bending similar to that of larch sawfly larvae, but their heads are lifted rather than their abdomens. In this disturbed situation, they discharge the content of diventricular pouches in their foreguts. These pouches contain sequestered host-plant terpenoic resins (Eisner et al., 1974) that deter predators.

Boevé et al. (1984) and Boevé and Pasteels (1985) have investigated eight species of Tenthredinidae, subfamily Nematinae, all of which have glands that produce secretions repellent to ants. These glands are situated ventrally on the second to seventh abdominal segments and are protrusible. The authors have, as have we, isolated the secretions by wiping the glands with pieces of filter paper. Seven compounds were identified by analysis of these secretions: *trans*-2-hexenol, *trans*-2-hexenal, *trans*-4-oxo-2-hexenal, geranial, neral, *cis*- and *trans*-dolichodial, and benzaldehyde. Since the openings of the gland we have studied and the protrusible glands that Boevé and coworkers investigated are closely situated on the larvae, it cannot be ruled out that the benzaldehyde we found could have been produced in the eversible glands on the midabdominal region rather than in the glands of the first abdominal segment.

Several authors have reported varying compositions of the secretions of papilionids from the different larval instars (Seligman and Doy, 1972; Burger et al., 1978; Honda, 1980). We did not observe this phenomenon. However, we did not try to determine whether there are differences in the amounts of volatiles in the different instars.

In contrast to *P. wesmaeli*, the aposematic *P. erichsonii* larvae are colonial, and simultaneous snap-bending can occur. It may be possible, therefore, that the volatiles not only have a deterring effect on predators but also may have an effect in alarming the whole colony. If all the larvae in a colony snap-bend simultaneously, very large amounts of deterring compounds would be released, and the visual scaring-off effect would be complemented.

Acknowledgments—We are grateful to R. Unelius and P. Baeckström for providing a sample of 3-carene-10-al. A.-B. Wassgren is acknowledged for discussions of stationary phases and for preparing the capillary columns; G. Wife, Dr. E. Hallberg, and Prof. Å. Franzén for doing scanning electron and light microscopy of larval glands; and P. Ödman for revising the language.

Book Review

Chemical Signals in Vertebrates 4; Ecology, Evolution, and Comparative Biology.
D. Duvall, D. Muller-Schwarze, and R. M. Silverstein (eds.).
New York and London: Plenum Press, 1986. $95.00, 742 pp.

This volume, the proceedings of a conference held in July of 1985, is a surprisingly thorough and well-balanced survey of the current status of the field of chemical communication in vertebrates. There are a total of 54 papers included, distributed into sections as follows: General Considerations, four; Chemistry, four; Fishes, five; Amphibians, five; Reptiles, seven; Birds, two; Mammals, 27. Although half the chapters concern mammals, this volume includes much more work on nonmammalian vertebrates than any other general reference of which I am aware.

A large proportion of the chapters in this book include substantial amounts of review material, further enhancing its value as a reference. As one engaged in research on mammalian chemical communication, I found many such chapters on nonmammalian vertebrates to be particularly interesting and informative. On fishes there are valuable reviews on alarm signals and their evolution by Smith; reproductive pheromones by Stacey, Kyle, and Lily; and chemosensory orientation and homing (including an update on salmon homing) by Johnsen. On amphibians there are interesting reviews on salamander courtship pheromones by Houck, kin recognition in toads and frogs by Waldman, and a combined experimental and review paper on territoriality in salamanders by Jaeger. For reptiles there is a review of snake pheromone trails by Ford; lizard pheromones by Cooper and Vitt; homing and orientation in aquatic amphibians and reptiles, especially sea turtles, by Owens, Comuzzie, and Grassman; and, from Garstka and Crews, a summary of their extensive examination of pheromones and reproduction in garter snakes. Wenzel reviews information on the olfactory system and some of its functions in procellariiform birds (albatrosses, fulmars, petrels, shearwaters), a fascinating group that contains 10 of the top 12 avian species in terms of the size of the olfactory bulb.

A number of the 27 papers on mammals also have a broad scope. Three areas in which chemical signals influence endocrine function are reviewed: Vandenbergh on the suppression of ovarian function, Keverne and Rosser on

0098-0331/88/0200-0723$06.00/0

pregnancy blocking, and Drickamer on puberty-influencing signals in house mice. Other relatively broad summaries not mentioned elsewhere in this review include that by Wysocki, Bean, and Beauchamp on the mammalian vomeronasal system; Fadem on chemical communication in marsupials and monotremes, and Doty on cross-cultural studies of taste and smell among humans.

It is difficult to generalize about a book that covers such a broad spectrum of species and issues, but two themes seemed to emerge from this collection. The first, probably intended by the organizers of the conference, was a widespread concern with evolutionary issues. This concern was the explicit focus of a number of articles and was clearly an issue of importance in a host of others. In addition to the chapters mentioned elsewhere in this review, papers with a strong evolutionary bias include those by Maderson on the characteristics and evolution of the tetrapod skin as a source of chemical signals, Graves et al. on den location as an adaptive feature in rattlesnakes, Gosling on the economics of territorial scent marking, and Jannet on scent glands of *Microtus*. Adams and Johnsen reported on the similarities and differences in the chemical control of feeding in herbivorous and carnivorous fish, and Dawley considered chemical isolating mechansims in salamanders.

As a second theme, it seems clear that virtually all researchers in the field now accept, at least implicity, that most chemical signals in vertebrates are likely to be complex mixtures of components and not single substances and that the perceptual processes underlying communication are likely to be similarly complex. Jemiolo, Andreolini, and Novotny, for example, identified several components from urine of house mice that may be important in the delay of puberty in that species; the effects can be obtained when these substances are presented in normally ineffective urine but, apparently, not when presented alone. Muller-Schwarze et al. reported that responses of beavers to artificial scent marks from other beavers was maximal when the stimulus contained both castoreum and anal gland secretions, less to either secretion alone, and lower still to fractions of these components. The most through work on the complexity of the chemical signals comes from studies of scent communication in marmosets and tamarins, reported by Epple, Belcher, and Smith. They show, for example, that the same chemical compounds are found in the scent secretions of males and females of two different subspecies but that the ratios of these compounds differed. Animals of a particular species and sex maintained consistent ratios over long periods of time, thus suggesting that such quantitative differences could be used for species and gender recognition. For gender recognition, the entire range of volatiles may be necessary; splitting the volatiles into two fractions resulted in loss of gender-specific responses from marmosets. All three of these studies suggest the importance of a complex chemical mixture that is necessary for communication. Galef's experiments further show that the olfactory signal itself must appear in the proper context—in this case in order

for an observer rat to be influenced by the odors of food that another has eaten they must come from the head region of a live (but not necessarily mobile) rat. Surprisingly, the odors do not necessarily come from food particles on the surface of the body—rats that have been tube-fed provide sufficient stimuli for other rats so that they alter their food preference.

The rich panorama of observation and experimental results ranges from fish to elephants (Rasmussen et al.) and is bound to be educational for almost any reader. The highlights will vary for different readers; for me they included relatively concrete examples of behavior as well as the latest analytical approaches to chemical communication. What could be a more striking (although not exactly a subtle) example of chemical signaling behavior than the male salamanders that slap their scent gland directly over the nares of the female they are courting? In other species the males first abrade the skin of females, and then rub the gland on this abraded area (reported by Houck). Equally amazing, and perhaps not unique, are the demonstrations that the sexual contact pheromone of female garter snakes is a lipid produced in the liver (!) and transported in the blood to specialized vessels (but not to glands) in the skin (Garstka and Crews). Ford reports experiments on the classic issue of the directionality of scent trails and comes up with a new mechanism by which this can occur: he shows that snakes can determine the directionality of a trail by discrimination of the higher concentration of scent on the side of objects that the snake has pushed off from, and that are therefore in the direction that the trail-laying snake was going. In the course of their review on homing and orientation, Owens, Comuzzie, and Grassman report earlier studies by Manton in which green sea turtles remembered an arbitrary discrimination for at least one year, results that should be more generally known. Except for homing studies, aspects of olfactory memory have been largely ignored, yet a variety of observations suggest that many animals have phenomenal abilities in this domain.

Other striking discoveries are reported. Schreibman et al present results that document the amazing growth and differention of olfactory structures in platyfish that are correlated with reproductive development. Mason and Clark demonstrate that the plants selected by starlings for their nest material on the basis of chemical cues are effective in inhibiting the growth of ectoparasites and bacteria. Porter shows that spiny mice recognize their siblings and that they do so by learning their chemical signatures. He has demonstrated that experience with one sibling is sufficient to permit young to recognize other siblings but that experience of an individual with its own odor is not. Cues from the mother are also sufficient: siblings reared apart treat one another as siblings if they are nursed by the same mother but not if they are nursed by different mothers. Perhaps the most biologically hi-tech research included is that on discrimination of closely related strains of house mice: Beauchamp, Gilbert, Yamazaki, and Boyse report that inbred, congenic mice with a mutation in one gene in the

major histocompatibility compex, which results in a substitution of 3 amino acids on one protein, can still be discriminated from the original strain on the basis of chemical cues! Furthermore, experiments on the source of the strain-distinctive odors have shown that they originate from cells in the hematopoietic system. When mice have this entire system destroyed by irradiation and then receive bone-marrow transplants from donors of either the same inbred strain or a heterozygote strain, the recipient smells like animals of the donor type to other mice. Thus, marrow cells that are involved in cell recognition within the body are also involved in production of substances that allow mice to discriminate between closely related individuals on the basis of odor cues.

I strongly recommend this book as a reference to anyone interested in this field. The book is large (684 pages of text plus 57 additional pages of indexes) and, although not actually encyclopedic, it does cover an impressive range of topics. Most chapters are clear and offer insights into the current state of the art and science of chemical communication in vertebrates.

WHAT IS CHEMICAL ECOLOGY?[1]

Clive G. Jones
Institute of Ecosystem Studies
The New York Botanical Garden
Mary Flagler Cary Arboretum
Box AB, Millbrook, New York 12545

What is chemical ecology; what direction should it take in the future; and what can chemical ecologists do to promote, facilitate, and advance the science? I will present a personal viewpoint and do not seek consensus. A debate on these issues may be valuable and would indicate what diversity of opinions exists about our science. Pluralism in opinion and approach usually promotes vigorous science when the issues are aired openly. My comments should not be construed as criticism of past work or approaches. Here I will suggest that the body of studies in the *Journal of Chemical Ecology* reflects the current definition of chemical ecology stated in the journal and in the statement of purpose of the International Society of Chemical Ecology. I will argue for a broadening of our approach and for the explicit inclusion of more ecology.

Let me first state my personal perspective. I do not consider chemical ecology to be an autonomous discipline, but see it rather as an approach to ecology—viewing ecological interactions from a chemical perspective. Chemistry is a valuable tool or probe for increasing ecological understanding because it frequently plays a crucial role, is discrete and quantifiable, and is often manipulable. This approach is not necessarily restricted to any one level of ecological organization, and it strives to understand the role of the chemistry together with the diversity of physical, biotic, and historical factors that shape ecological interactions. Although such an approach is integrated within ecology, the science remains clearly identifiable because of its unique perspective—much in the same way that physiological ecology and ecological genetics retain their identities.

In order to examine some current emphases in chemical ecology, I sur-

0098-0331/88/0200-0727$06.00/0

veyed a total of 305 papers published in the *Journal of Chemical Ecology* in 1985 and 1986. I categorized papers into approaches or areas of study that constituted their main focus (Table 1). The bulk of papers (84%) dealt with methods, natural-products chemistry, biochemistry, pharmacology, toxicology, behavior, and organismal biology. These papers contained very little reference to ecology. The remainder dealt with some ecological aspects; the majority (12%) concerned studies of autecology or species pair interactions. There were very few papers dealing with higher levels of ecological organization, such as population or community ecology, and none addressing ecosystem ecology. The few papers on community ecology all dealt with allelopathy. Evolutionary ecology papers (primarily plant–insect coevolution) were limited in number (1%); there was only one review paper, and there were no papers that were primarily conceptual or theoretical. Studies that attempted to examine the relative importance of chemical factors versus other ecological factors were very rare (1%). Almost all studies dealt with identified or partially characterized and/or isolated organic compounds (92%). A few were nonchemical (7%), where no specific compounds were directly involved or no isolation and/or fractionation was attempted); and only 1% addressed inorganic compounds.

Clearly, studies of natural-products chemistry, studies within organisms, behavior, and organismal-level studies dominate over ecological studies in the journal. The current balance of papers appears to reflect the statement of purpose of the *Journal of Chemical Ecology*, the official organ of the International Society of Chemical Ecology (ISCE). "The *Journal of Chemical Ecology* (and

ISCE) is devoted to promoting an understanding of the origin, function and significance of natural chemicals that mediate interactions within and between organisms.'' The statement of purpose recognizes that the study of chemical interactions is central to our science. Isolation and identification of compounds, and determining their mode of action, are also explicitly stated. The word ''significance'' implies that we should also examine nonchemical phenomena in order to understand the importance of the chemical phenomena. ''Interactions within... organisms'' validates suborganismal and behavioral approaches; and ''interactions... between organisms'' may imply some aspects of autecology or species interactions. There is no reference to ecology in the statement.

It is ironic that a journal and a society that use the word ecology in their titles should have statements of purpose that lack any specific reference to ecology. Perhaps the relative dearth of ecological papers in the journal is a reflection of the statement. Authors of manuscripts involving chemistry that have a more ecological emphasis may not consider submitting to the journal as a consequence. A brief examination of such journals as *Ecology* and *Oecologia* over the last three years shows that an increasing number of more ecologically oriented papers involving chemistry are appearing there, rather than in the *Journal of Chemical Ecology*. Although studies of natural-products chemistry or biochemistry are essential to chemical ecology, they are not necessarily, in themselves, chemical ecology, just as an ecological study alone is not chemical ecology. While the *Journal of Chemical Ecology* cannot, nor should, publish all papers that cover the entire range of studies from natural products chemistry to ecology, our science may be better served if there was a broader and more balanced representation of approaches in the journal, and if the journal contained the very best examples of chemical ecology.

Chemical ecology is a new and relatively small area of science that can ill afford fragmentation into different camps. Much more is to be gained by broadening our science and encouraging a multiplicity of approaches and perspectives. A broad approach might increase membership of the society and readership of the journal. We would all gain additional insight and perspective that would improve our own studies. Ultimately we might increase the impact of our field of science to both basic and applied research. I argue that this can be done without diluting our discipline or excluding scientists whose individual contributions to chemical ecology may lie at opposite ends of a spectrum.

How could these lofty goals be accomplished? A few suggestions come to mind, and no doubt the creative readership of the *Journal of Chemical Ecology* and members of ISCE can come up with many better ideas. We could alter the statement of purpose of the journal and the society to broaden scope and more explicitly include ecology (e.g., ''...devoted to promoting ecological understanding of the origin, function, and significance of naturally occurring organic and inorganic chemicals and the interactions that they mediate.'') We could

increase the editorial board of the journal to reflect a wider range of approaches. We could change our statement of editorial policy to explicitly welcome submission of papers in areas that we feel are currently underrepresented and actively solicit submission of papers in these areas. Outside of the journal, we could find ways to promote broad, multidisciplinary interest and collaboration, such as occasional joint meetings of ISCE with organizations of similar size and scope that have mutually beneficial aims. We could provide funds to students through ISCE to attend meetings, do research in underrepresented areas, or build bridges between different approaches within our science. We could carefully balance the structure of ISCE meetings to reflect our diversity and actively solicit the attendance of scientists who do not currently attend.

Chemistry is important in most ecological interactions. Roles include: exploitation of resources by producers, consumers and decomposers; communication and defense within and between species; dynamics of populations; organization of communities; and structure and function of ecosystems. Exploring, understanding, and integrating the diverse roles of chemistry in the operation of ecological systems is an exciting, important challenge and a new frontier in chemical ecology. The approach to these complex problems is necessarily diverse, multidisciplinary, and collaborative. It includes a mixture of approaches with techniques ranging from the elucidation of the structure of natural products, biochemical and behavioral assays, to quantitative analysis and experimental manipulation of such parameters as organismal, population, community, or ecosystem characteristics. Most importantly, it requires the interaction of scientists with diverse talents and backgrounds. Chemical ecology grew out of the mutualistic desires of the chemist and ecologist to work together, and we have been very successful at developing these collaborations. As our discipline matures, we should not lose sight of the reasons for and benefits from these interactions and continue to keep a broad perspective that is the essence of our future productivity and success.

Acknowledgments—I thank Gunnar Bergström, Murray Blum, Thomas Eisner, Brad Hawkins, Jean Langenheim, John Lawton, Gene Likens, Wendell Roelofs, and other members of ISCE for discussion and critical comment; John Lawton and Richard Firn for their hospitality at York. Announcement

INTERNATIONAL CONFERENCE ON CHEMICAL SIGNALS

The 5th International Conference on Chemical Signals in Vertebrates will take place in Oxford, England, August 8–10, 1988. Sessions will include semiochemistry, reproduction and primers, neurophysiology and anatomy, social and spatial organization, predators and prey, and applications. Inquiries should be addressed to the conference chairman, Dr. David Macdonald, Department of Zoology, South Parks Road, Oxford, England, U.K. 0X1 3PS.

BIOLOGICAL SUPPRESSION OF NITRIFICATION BY SELECTED CULTIVARS OF *Helianthus annuus* L.

IBRAHIM S. ALSAADAWI

Department of Botany, Faculty of Agriculture and Biology
Nuclear Research Center
P.O. Box 765, Baghdad, Iraq

(Received January 22, 1987; accepted April 6, 1987)

Abstract—The allelopathic potential of different cultivars of *Helianthus annuus* against nitrification was studied using the soil incubation method. The results indicated that aqueous extracts and residues of roots and shoots of all test cultivars significantly reduced the nitrification rate in soil. However, cultivars Local and Citosol were found to be more inhibitory to nitrification than others.

Key Words—Allelopathy, *Helianthus annuus*, nitrification inhibition, biological control.

INTRODUCTION

The nitrification process is considered important to the regulation of nitrogen leaching in soils. Such leaching may severely reduce the productivity of plants and cause great losses in the energy requirement for growing crops (Alexander, 1977; Rice, 1984). Moreover, it is reported to increase water pollution and disease incidence in plants (Huber et al., 1977; Alexander, 1977; Rice, 1984). In attempting to enhance utilization of nitrogen fertilizers, nitrification inhibitors have been extensively used.

Inhibition of nitrification by allelopathic plant species has been reported in natural and manipulated ecosystems. Greenland (1958) found that low levels of nitrate under grassland were due to suppression of nitrification by toxic materials exuded from grass roots. Neal (1969) reported that aqueous root extracts of 12 grasses and forbs were inhibitory to the nitrifying organisms *Nitrosomonas* and *Nitrobacter*. Rice and Pancholy (1972, 1973, 1974) revealed that nitrification is significantly inhibited by climax species. The phenolic com-

0098-0331/88/0300-0733$06.00/0

pounds identified from soil under climax vegetation were found to be inhibitory to *Nitrosomonas* and *Nitrobacter*. Lodhi (1981) indicated that the aboveground parts of corn in a corn field significantly reduced ammonium oxidation. Moore and Waid (1971) reported that root exudates of rye grass, wheat, lettuce, salad rape (*Brassica napus*), and onion were inhibitory to nitrification. Root exudates of rye grass, wheat, and onion had the most pronounced and persistent inhibitory effects. Alcohol extracts of neem seeds were successfully used as nitrification inhibitors in agricultural land in India (Sahrawat and Parmar, 1975). Subsequent work on the neem plant showed that leaf residues and defatted neem seed cake can also be used as inhibitors of nitrification (Santhi et al., 1986). AlSaadawi et al. (1986) evaluated several cultivars of *Sorghum bicolor* for their ability to inhibit nitrification and found that aqueous extracts and decaying residues significantly inhibited nitrification. Some cultivars appeared more inhibitory than others.

Helianthus annuus is one of the important crops in the world. It is reported to be an allelopathic species (Wilson and Rice, 1968; Hall et al., 1982) and has considerable variations for this trait (Leather, 1982, 1983). However, most of the research activity concerning the allelopathic potential of this species or its cultivars against weeds and crops, and information concerning the allelopathic activity against nitrification, is not available. Therefore, the present work was conducted to determine the allelopathic activity of *H. annuus* against nitrification and to find out whether differences in allelopathic activity among selected cultivars exist.

METHODS AND MATERIALS

Plant and Extract Preparations. Five seeds each of *Helianthus annuus* cultivars Local, Pemir, Peredovik, Record, Citosol, and Cheremn were planted in plastic pots, each containing 7 kg of loamy soil. The pots were placed under field conditions and watered with tap water whenever necessary. At the flowering stage, plants of all test cultivars were harvested, separated into shoots and roots, and air-dried for several days under shade. The air-dried shoots and roots were ground to pass a 2-mm sieve.

Five grams of roots and tops of each cultivar were Soxhlet extracted with 500 ml methanol for 10 hr. The methanol extract of each treatment was evaporated to dryness in a flash evaporator at 50°C. The residues of each treatment were dissolved in 250 ml of distilled water to make a final concentration of 2% of the original weight of roots or shoots. The controls were prepared in the same manner except that plant materials were ommitted.

Biological Activities of Sunflower Cultivars Against Nitrification. For extract bioassays, soil with characteristics listed in Table 1 was collected to a

TABLE 1. SOME PHYSICAL AND CHEMICAL PROPERTIES OF SOIL USED FOR NITRIFICATION EXPERIMENTS

Soil property	Value[a]
pH (saturation extract)	8.5
EC (saturation extract, mS/cm at 25°C)	3.8
NH_4-N (ppm)	12.4
NO_3-N (ppm)	9.3

Sand (%)	39.7
Silt (%)	38.5
Clay (%)	21.8

[a] Each value is an average of three replications.

depth of 10 cm in April 1986. The soil was mixed thoroughly, air-dried under shade, and passed through a 2-mm sieve. Samples of 100 g of the air-dried soil were placed in 100-ml plastic beakers, and the beakers were preincubated at 28°C under darkness for seven days before adding the substrate $(NH_4)_2SO_4$.

After incubation, each beaker of the control treatment received 12 ml of an appropriate concentration of $(NH_4)_2SO_4$ necessary to make the nitrogen concentration added 300 ppm. Treatments were run in the same manner, except that aqueous solution of $(NH_4)_2SO_4$ was replaced by an equal amount of extract solution of roots or shoots of the test cultivars containing the same amount of $(NH_4)_2SO_4$ as was added to each control pot. All beakers were covered with perforated polyethylene sheets to allow aeration and incubated at 28°C under darkness. The experiment was arranged in a randomized complete block design with four replications.

The amounts of NH_4 nitrogen and NO_3 nitrogen were measured at 0, 4, 8, and 12 days after incubation using the MgO-Devarda alloy method (Bremner, 1965).

For residue bioassays, 1 g of powder of roots or shoots of each test cultivar was mixed with 100 g of soil and placed in a 100-ml plastic beaker. Control treatments were made by mixing 1 g of peat moss with 100 g of soil to keep the organic matter the same (AlSaadawi et al., 1985). Each beaker received 12 ml of aqueous solution containing enough $(NH_4)_2SO_4$ to make the NH_4 nitrogen added 300 ppm. The incubation conditions, experimental design, and measurements of NH_4 and NO_3 nitrogen were the same as mentioned in the previous experiment.

RESULTS

In all bioassay experiments, the amounts of NH_4 nitrogen converted in the incubated soil was significantly correlated with the amount of NO_3 nitrogen produced over the periods of incubation (Table 2). All bioassay experiments revealed significant correlation between NH_4 nitrogen converted and NO_3 nitrogen produced.

Shoot extracts of all test cultivars significantly reduced nitrification rates at all incubation periods (Table 3). However, the reduction was significantly different among the extracts of the test cultivars at the first and second periods of incubation. Shoot extracts of Cheremn cultivar had the greatest ability to reduce nitrification when compared to the shoot extracts of other cultivars. At the third period of incubation, shoot extracts of all test cultivars revealed the same potential of nitrification inhibition.

Root extracts of all test cultivars significantly reduced the nitrification rate at all incubation periods (Table 4). Root extracts of Citosol and Cehremn cultivars caused greater inhibition than those of others at all incubation periods except at four days.

Shoot residues of all cultivars significantly inhibited the nitrification rate at all incubation periods (Table 5). Shoot residues of all cultivars except Citosol revealed the same ability of nitrification inhibition at the first period of incubation. However, at the second and third incubation periods, shoot residues of some cultivars exhibited greater inhibitory action than others.

Root residues of all cultivars caused significant inhibition of nitrification at all periods of incubation. The inhibitory potential of test cultivars was the

DISCUSSION

The high correlation between ammonium converted and nitrate produced in all bioassay experiments suggests that the soil incubation method is very useful in studying nitrification under laboratory conditions. The high correlation also indicates that almost all the ammonium converted is biologically oxidized to NO_3 via bacterial nitrification. A similar observation was reported by AlSaadawi et al. (1985, 1986), who studied the allelopathic potential of sorghum cultivars against nitrification by the soil incubation method. In all bioassay experiments, 12 days were found to be enough to convert about 95% of ammonium added.

Aqueous extracts of roots and shoots of all test cultivars inhibited nitrification, indicating that the extracts have water-soluble nitrification inhibitors. This explanation is further substantiated by the decaying residues, in which the decaying roots and shoots of the cultivars revealed significant inhibition to nitrification. No attempts were made to isolate, identify, and quantify the inhibitors. However, several reports on the allelopathy of *Helianthus annuus* showed that numerous phenolic compounds occur in different parts of sunflower plants (Wilson and Rice, 1968; Hall et al., 1982). Most of these compounds were found to inhibit nitrifying bacteria and thus the nitrification process (Rice and Pancholy, 1974). It is possible that variations in the inhibitory potential among the test cultivars resulted from different amounts of inhibitor(s) in the test species. Fay and Duke (1977) evaluated the allelopathic potential of 3000 accessions of

Avena sp. germ plasm against weeds, and they found that the most allelopathic accessions contained three times the concentration of the allelopathic agent scopoletin as was present in a commercial oat cultivar.

These results suggest that *Helianthus annuus* is inhibitory to nitrification in soil, and this may help augment the nitrogen efficiency of the added fertilizer. Barnes and Putnam (1983) reported that *H. annuus* has potential as a smother crop or a cover crop in no-tillage systems. The residues of smother crops are used to reduce soil erosion, improve water retention, and control weeds when the smother crop used is highly allelopathic. This study suggests another possible advantage for no-tillage cropping in that the residues of the smother crop can also inhibit nitrification. No definite conclusion can be drawn until field evaluations are made. However, such findings should be taken into consideration since a reduction in the requirement for commercial nitrification inhibitors could be possible by using allelopathic cover crops.

(Received January 28, 1987; accepted April 6, 1987)

Abstract—Ozonolysis, dithioether derivatization, and EI and CI mass spectrometry were used to establish the location of the double bond in the side chain of the two major anacardic acids in geranium (*Pelargonium hortorum*) trichome exudate. The point of unsaturation was shown to be between C-5 and C-6 counting from the methyl end of the side chain, contradicting the earlier hypothesis that the olefinic bond was probably at the 9–10 position based upon expected biosynthetic considerations. The two major components are thus 6-[(*Z*)−10′-pentadecenyl]salicylic acid ($C_{22}H_{34}O_3$) and 6-[(*Z*)-12′-heptadecenyl]salicylic acid ($C_{24}H_{38}O_3$). This may indicate that the precursor of these anacardic acids is a saturated fatty acid since the location of a double bond at the 5–6 position is unusual among the unsaturated fatty acids. Capillary GLC and HPLC of the trichome exudate indicated the presence of small amounts of other anacardic acid analogs possessing such features as odd numbers of carbon atoms and saturated side chains.

Key Words—Trichome, geraniums, *Pelargonium*, defensive agents, anacardic acids, double-bond location, insect resistance.

INTRODUCTION

Previous work (Gerhold et al., 1984; Craig et al., 1986) on the mite resistance chemicals produced by geraniums indicated that the trichome exudate was a mixture of two components, namely, *o*-pentadecenyl salicylic acid (A) and *o*-heptadecenyl salicyclic acid (B) (Scheme 1). The position of the *cis* double bond

0098-0331/88/0300-0743$06.00/0

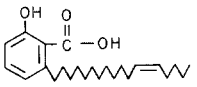
Compound B (C_{24}) 60 %



SCHEME 1.

in the side chain was not determined but was postulated to be nine carbons from the methyl end of the chain, corresponding to that of the commonly occurring unsaturated fatty acid. This study is concerned with determination of the double-bond location in both compounds and analysis of the exudate using the greater resolving power of capillary gas chromatography.

METHODS AND MATERIALS

Plant Source. Geraniums were maintained in a greenhouse environment using standard cultural practices. The geranium variety used (71-17-7) was previously determined to be mite resistant by Stark (1975).

Exudate Collection. Exudate was collected by two different methods. The first method (pressing a microscope slide against the leaf surface) was performed as described by Gerhold et al. (1984). The slide was rinsed with methylene chloride, and this extract was concentrated to a small volume and used directly for analysis. The second method used was a simple dip of the flower pedicel and sepals in methylene chloride. The sample was then treated in a manner similar to the microscope slide collection.

HPLC Separation. Preparative high-pressure liquid chromatography (HPLC) was used to isolate the individual anacardic acids. HPLC was performed using a Waters model ALC/GPC 244 with 6000A pumps, a model 480 variable wavelength UV detector, a WISP 710A automatic injector, and a data module. For preparative HPLC, a 60 cm × 10 mm C_{18} Bondapak Porasil B column (25–75 μm particle size) was used to achieve separation of up to 250 μg per injection of exudate. The solvent used was 5% 0.1 N acetic acid–95% acetonitrile mobile phase at 3 ml/min. The central two thirds of each of the peaks representing the two compounds was collected. Solvent was removed using a flash evaporator at 40°C. The sample was redissolved in acetonitrile and evaporated again several times until no odor of acetic acid could be detected. The sample was then weighed, redissolved in methylene chloride, and stored at −20°C. Chromatographic analysis of the isolated compounds on GLC and HPLC (25 cm × 4 mm C_{18} Spherisorb ODS Column, 5 μm particle size, 20% 0.1 N acetic acid–80% acetonitrile) revealed that the individual compounds isolated were >98% pure.

Capillary Chromatography. A Varian 2700A gas chromatograph equipped with a flame ionization detector was used for all analyses. For the GLC analysis and subsequent GC-MS analysis of the aliphatic aldehyde portion of the ozonolysis product, a 30 m × 0.53 mm RTX-1 (Restek Corp., Port Matilda, Pennsylvania, cross-bonded 100% dimethyl polysiloxane) column operated at 110°C with a gas flow of 10 ml/min was used. For the analysis of the underivatized compounds, the dimethylated derivatives, the dithioether derivatives, and the aromatic aldehyde portion of the ozonolysis products, a 20 m × 0.53 mm RTX-5 (Restek Corp., cross-bonded 95% dimethyl–5% diphenyl polysiloxane) column operated at a temperature program of 260–300°C with a gas flow of 10 ml/min was employed.

GLC-MS Analysis. Mass spectral analysis of the aliphatic aldehyde products of ozonolysis was performed using chemical ionization (CI) with methane as the ionizing gas. Electron impact mass spectral (EI) analysis was performed on the underivatized anacardic acids, the dimethylated derivatives, the ozonolysis-produced aldehyde containing the aromatic ring, and the dithioether derivative. All GLC-MS analyses, both EI and CI, were performed using a Finnigan model 3200 GLC-MS mass spectrometer. Probe samples were analyzed on a Kratos model MS–950.

Methylation. Methylation of both compounds was achieved by treating a small amount of the pure compound (0.1–1 mg) dissolved in a few drops of methanol with an ethereal solution of diazomethane. The reaction required overnight treatment at room temperature to methylate the phenolic moiety in agreement with Gellerman and Schlenk (1968).

Ozonolysis. Ozonolysis was performed using a microozonizer kit (Supelco, Inc., Bellefonte, Pennsylvania) for ozone generation. The reaction was carried out in an acetone–Dry Ice bath and was continued until a yellow color appeared in a KI indicator solution. Approximately 0.1–0.3 mg of methylated anacardic acid dissolved in 0.5 ml of methylene chloride was ozonized in each trial. Reduction of the ozonide to the aldehyde was achieved using a threefold excess of triphenyl phosphine (Stein and Nicolaides, 1962). Methyl oleate and palmitate were ozonized as controls to check the procedure.

Dimethyl Disulfide (DMDS) Derivatization. DMDS derivatization was performed on the methylated compounds according to the procedure of Buser et al. (1983). An aliquot of the anacardic acids (0.05–0.1 mg) was dissolved in 1.75 ml of hexane. DMDS (2.5 ml) and iodine solution (0.25 ml of a 60 mg I_2/ml diethyl ether) were added to the reaction vial, and the reaction was allowed to run overnight at ca. 40°C. Iodine was included as an initiator in the free radical addition reaction. After completion, 2.5–5 ml of sodium thiosulfate (5% solution in water) was added to the reaction mixture for removal of the iodine. The organic phase was removed and concentrated for subsequent GLC and GC-MS analysis.

RESULTS AND DISCUSSION

Chromatographic Analyses. HPLC analysis of the exudate revealed primarily compounds A and B, identified by Gerhold et al. (1984). A small broad peak (<1%) of the total material (absorbing at 208 nm) which eluted after compound B was collected and analyzed by mass spectroscopy, revealing a spectrum similar to those of compounds A and B, but apparently produced by C_{22} and C_{23} compounds with saturated side chains. Peaks for molecular ions and fragments representing losses of water and CO_2 and a base peak of 108 *m/z* are present to substantiate this conclusion. Trace amounts of other compounds also produce small "shoulder" peaks on the peaks produced by compounds A and B in both HPLC and GLC chromatograms. The presence of small amounts of compounds with minor structural differences from compounds A and B is not surprising and has been shown to occur with anacardic acids in the *Anacardiaceae* as well (Yalpani and Tyman, 1983; Tyman et al., 1984; Gellerman and Schlenk, 1968). The length of the side chain as well as the number and position of double bonds are all somewhat variable in extracts from the *Anacardiaceae*, usually showing a predominance of one or two of the variations.

GLC mass spectral results from a crude trichome collection (microscope slide method) indicated the presence of C_{22}, C_{23}, C_{24}, and C_{25} homologs with saturated side chains, as well as C_{18}, C_{23}, and C_{26} homologs with unsaturated side chains, all representing less than 1% of compounds A and B. In all probability, the other minor peaks associated with the trichome exudate represent similar modifications.

Mass Spectral Analysis. The mass spectrum of isolated compound A (EI, probe) is presented in Figure 1A. Methylation stabilizes the aromatic portion of the molecule preventing the loss of the carboxylate group during GLC (Figure 1B). Molecular ions were observed at *m/z* 374 and *m/z* 402 for A and B, and significant peaks occurred at M-31 and M-32, indicating losses of CH_3O- and CH_3OH, respectively. The mass region from 100 to 200 *m/z* is nearly identical for the two compounds A (C_{22}) and B (C_{24}). The base peak occurs at *m/z* 161 produced by loss of water from the ion produced by α-cleavage of the side chain from the aromatic ring (*m/z* 179). Substantial peaks occur at *m/z* 148 and *m/z* 121, indicating losses of $-OCH_3$ and $-\overset{\overset{O}{\|}}{C}-OCH_3$, respectively, from the *m/z* 179 fragment. These data are consistent with those reported earlier (Gerhold et al., 1984).

Mass spectral analysis of the lower-molecular-weight straight-chain aldehyde products of ozonolysis was somewhat ambiguous. Although a large amount of pentanal was present in the reaction product, smaller amounts of hexanal and the corresponding alcohols of both compounds were present. In addition, isomers of both compounds, as well as dimers representing the condensation products of both pentanal and hexanal, were present. Reducing the time between

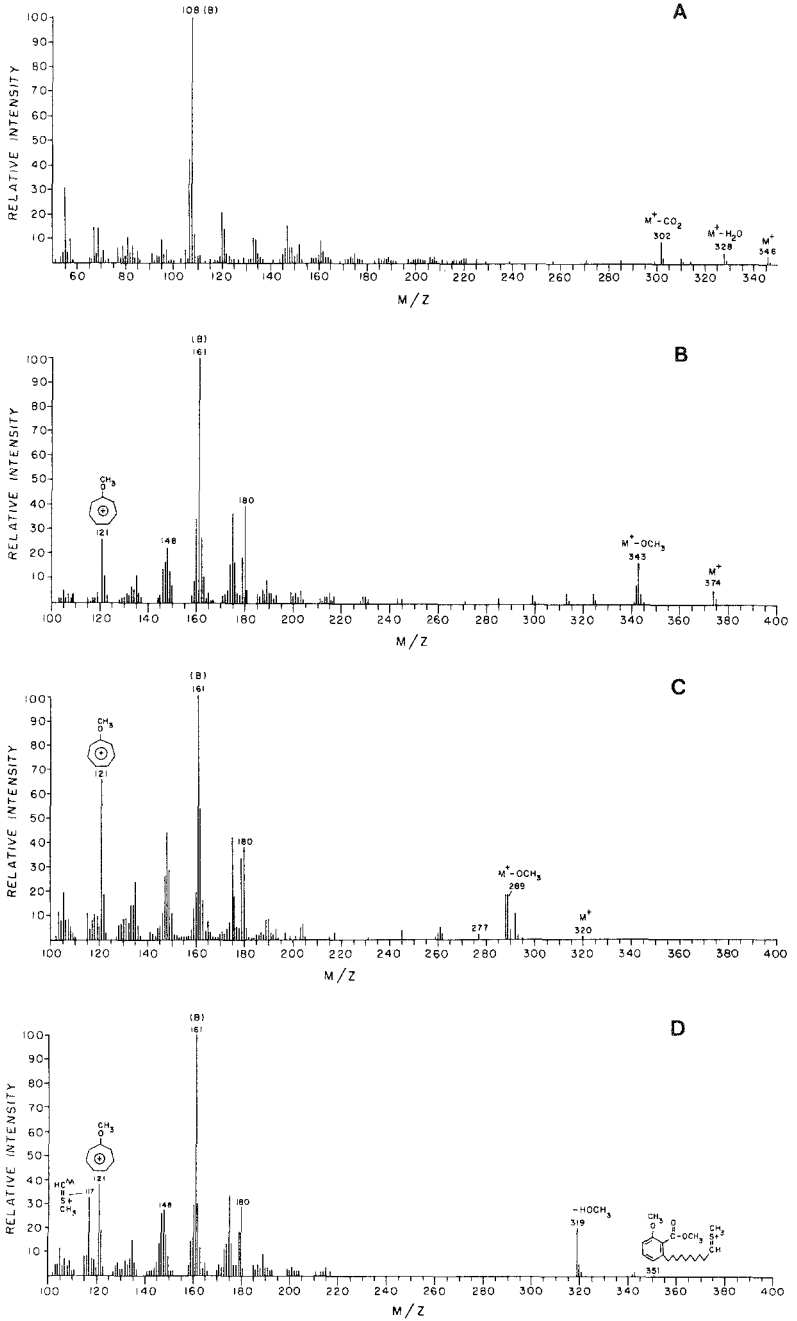


FIG. 1. EI Mass spectra of isolated and derivatized C_{22} anacardic acid from geranium (compound A); (A) isolated compound (probe); (B) methylated derivative; (C) aldehyde product possessing the chain and aromatic ring after ozonolysis of compound A; (D) dithioether derivative of compound A.

ozonolysis and mass spectral analysis resulted in a less complex product. It should be noted that ozonolysis of chromatographically pure oleic acid as a control sample also produced small amounts of C_8 and C_{10} aldehydes in addition to the expected C_9 aldehyde.

In order to resolve this ambiguity, the larger-molecular-weight aldehydes containing the aromatic portions of the molecules were analyzed by GLC-MS. GLC capillary analysis produced a single high-molecular-weight peak for each anacardic acid ozonized. GC-MS analysis then showed the aldehyde to represent a molecule with a side chain five carbon units shorter than the parent compound in both cases, implying no other positional isomers present for the double bond (Figure 1C). The mass region from 100 to 200 *m/z* remained, for practical purposes, identical to that of the methylated but unozonized compound. For compound A, a molecular ion of *m/z* 320 and significant peaks of *m/z* 288, 289, and 261 (loss of CH_3O-, CH_3OH, and $-CO-CH_3$, respectively) are all consistent with a compound having a 10-carbon straight-chain aldehyde moiety, indicating that the double bond of the parent compound occurred between carbons 10 and 11 of the side chain (counting from the ring) (Figure 1C). Results from ozonolysis of compound B are entirely analogous with corresponding peaks occurring 28 mass units higher. Thus, in B, the double bond lies between carbons 12 and 13 of the side chain.

DMDS derivatization of the methylated anacardic acids produced compounds with a methyl thioether group attached to the carbons joined by the double bond. GC analysis of the dithioether derivative of both A and B indicated a single pure product and no evidence for positional isomers of the double bond. The presence of the methyl thioether groups on adjacent carbons renders the bond between them susceptible to cleavage during mass spectral fragmentation (Buser et al., 1983), thus enabling the determination of the original double-bond location. As with the ozonolysis products, the region of the spectrum between *m/z* 100 and *m/z* 200 is essentially identical with that of the methylated compound with one notable exception (Figure 1D). That exception is the large increase of a previously very minor peak at *m/z* 117. This is the fragment expected from the cleavage of the bond between the adjacent methyl thioether groups for the instance when the bond occurs five carbons from the methyl end of the side chain. Although the molecular ion was not detected, a small peak at $M-117$ and a large peak at $M-117-CH_3OH$ were detected, providing further support for the location of the bond five carbons from the methyl end. The excellent correspondence of the ions from the lower mass end of the spectrum with that of the dimethyl ether ester before DMDS derivatization is good evidence that only the desired derivatization occurred and the aromatic portion of the molecule remains intact. Figure 2 depicts the mass spectral fragmentation of the DMDS and ozonide derivatives relative to compound A.

The results of this investigation indicate that the double-bond location pro-

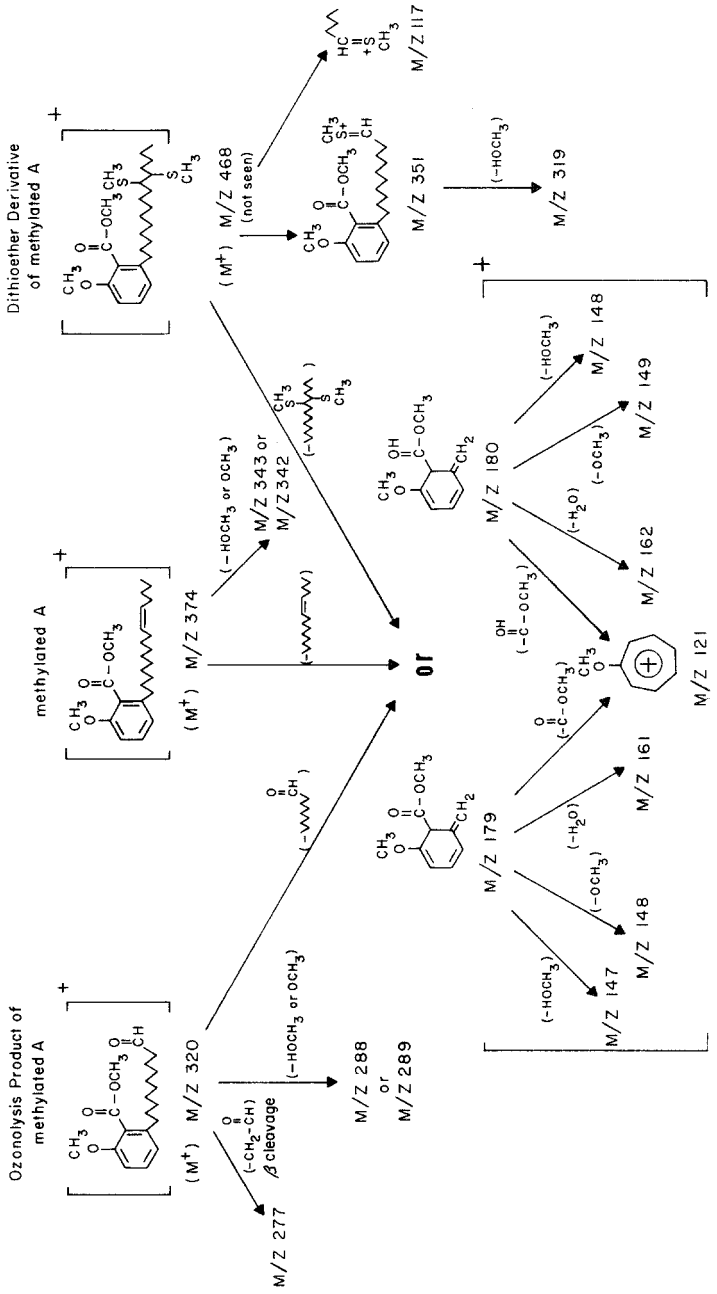

FIG. 2. Mass spectral fragmentation scheme of methylated compound A and of ozonized and dithioether-derivatized products.

posed by Gerhold et al. (1984) for the anacardic acids of geranium is incorrect. This location was based upon the premise that oleic acid and palmitoleic acid might be the precursors from which compounds A and B were synthesized. Establishment of the double-bond location occurring five carbons from the end of the side chain may be an indication that a saturated fatty acid is the precursor for these two compounds. This somewhat unusual double-bond location may provide insight into the proposed biosynthetic scheme which has been suggested to occur by way of a polyketide intermediate that undergoes cyclization via an intramolecular aldol type condensation (Geissman, 1963; Gerhold, 1984). It seems unlikely that the additional two carbon units in the side chain of compound B over that of A occur as the result of condensation and subsequent reduction of an extra acetate unit. A more likely prospect is that the anacardic acid synthetase system will accept a range of fatty acid precursors and that compounds A and B are the result of the respective processing of C_{16} and C_{18} fatty acids by the enzyme system. Desaturation of the alkenyl side chain may occur external to the anacardic acid synthetase system (the enzyme system may be specific for this double bond position). Alternatively, desaturation may be performed as part of the anacardic acid synthetase system either as the initial step in the pathway or as the final step in synthesis on the completed anacardic acid carbon skeleton. In any case, the enzyme(s) desaturates the molecules a fixed number of carbon units from the methyl end of the chain, a fairly rare occurrence since most double bonds are inserted relative to the carboxyl end of the molecule in fatty acids.

(*Received January 29, 1987; accepted April 6, 1987*)

Abstract—Material extracted from hyphae of *Fusarium avenaceum*, isolated from foliage of balsam fir, *Abies balsamea*, was toxic to spruce budworm larvae when incorporated into insect diet. The major insecticidal component of the toxic fraction was identified by chemical and spectroscopic methods as enniatin complex, rich in enniatin A/A_1. Possible ecological implications of these observations are considered.

Key Words—Enniatins, cyclodepsipeptides, *Fusarium avenaceum, Abies balsamea*, balsam fir, *Choristoneura fumiferana*, Lepidoptera, Tortricidae, spruce budworm, insecticide, toxin.

INTRODUCTION

The spruce budworm, *Choristoneura fumiferana* (Clem.), is one of the most destructive defoliators of the spruce–fir forests in eastern North America. Population levels of the insect in New Brunswick have been observed to oscillate, with major outbreaks followed by dramatic declines occurring in 30 to 40-year cycles (Greenbank, 1963; Royama, 1984). Royama (1984) suggested that, besides parasitoids and probably diseases, a complex of unknown causes con-

0098-0331/88/0300-0753$06.00/0

tributed to mortality during collapse of a budworm population. Discussions among N. Whitney (Biology Department, University of New Brunswick), T. Royama, E. Eveleigh (Canadian Forestry Service—Maritimes), and one of us (D.B.S.) resulted in the suggestion that phylloplane fungi may have a role in the unknown causes of budworm mortality.

Recently a body of information has accumulated suggesting that plant–fungal associations can provide some protection to the plant against phytophagous insects (Carroll, 1986; Hinton and Bacon, 1985; Siegal et al., 1985). In New Brunswick, Miller et al. (1985) reported that balsam fir trees infested with spruce budworm had a different phylloplane fungal community than budworm-free trees, and some fungi from infested trees were toxic to larvae when ingested. It is possible that this plant–fungal association may result in adverse effects on the spruce budworm, comparable to reported cases where plants are protected from phytophagous insects by endophytic fungi (Carroll, 1986; Clay et al., 1985).

One phylloplane fungus toxic to budworm was *Fusarium avenaceum* (Miller et al., 1985). This fungus is known to be a pathogen of a wide range of plants, including conifers (Booth, 1971). It occurs mainly in the soil as a saprophyte, but it can infect the roots of susceptible plants, and it has been isolated from foliage (Miller et al., 1985). It was also reported to colonize an insect pest of grain (Miczulski and Machowicz-Stefaniak, 1977) and can grow saprophytically on budworm larvae (D.B.S., unpublished data). Other *Fusarium* species (e.g., *F. lateritium*) associated with insects produce biochemicals toxic to insects (Claydon and Grove, 1984; Grove and Pople, 1980). The purpose of this study was to investigate the biochemical basis of the toxicity of *F. avenaceum* to spruce budworm larvae.

METHODS AND MATERIALS

Instrumentation. Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Pye Unicam PU 9516 infrared spectrophotometer, and ultraviolet spectra on a Philips PU 8800 UV/Vis spectrophotometer. Proton and carbon magnetic resonance spectra were run on a Varian XL-200 instrument. Optical rotations were measured using a Perkin Elmer 241 polarimeter. High-resolution mass spectra were provided through the courtesy of Dr. A. Hogg, University of Alberta.

Stock Cultures. Fusarium avenaceum (Corda ex Fr.) Sacc. (isolate No. 120, FA120) isolated from balsam fir foliage (Miller et al., 1985) was kept on 2% malt extract agar (MEA) slants. In an attempt to preserve the physiological traits, several slants were made from a culture subcultured only twice from the original isolate. These slants were used for subsequent culturings of the fungus.

A culture of FA120 is deposited in the herbarium at the Biosystematics Research Centre, Ottawa, Ont. (DAOM No. 196490).

Culture Conditions. FA120 was grown as described by Miller et al. (1985). A MEA stock culture was macerated in 50 ml of sterile, distilled water and 2.5 ml of the suspension was added to a 250-ml Erlenmeyer flask containing 50 ml of the following medium: NH_4Cl (3 g), $FeSO_4 \cdot 7H_2O$ (0.2 g), KH_2PO_4 (2 g), peptone (2 g), yeast extract (2 g), malt extract (2 g), and glucose (20 g) in 1-liter distilled water. Flasks were placed on a rotary shaker (220 rpm) at 28°C for two days. The resulting inoculum was homogenized and added (5%, v/v) to 1-liter Roux bottles containing 400 ml of a medium consisting of glucose (20 g), yeast extract (5 g), and peptone (5 g) per liter distilled water. Cultures were incubated at 28°C in the dark for 14 days.

Extraction of Metabolites and Isolation of Enniatins. Mycelia were harvested by vacuum filtration (Whatman No. 1 paper) and freeze-dried in preparation for extraction (2 liters culture medium yielded 16 g of hyphae, dry weight). The culture filtrate was extracted immediately. Freeze-dried hyphae (10 g) were ground in a mortar, then extracted with methylene chloride (CH_2Cl_2) (45 ml) at ambient temperature using a Polytron homogenizer. The resulting slurry was filtered at the pump on Whatman No. 1 filter paper, and the residual hyphal powder reextracted twice with 45-ml portions of CH_2Cl_2. The combined filtrates were filtered through celite, then evaporated to dryness on a rotary vacuum evaporator affording 1.659 g of extract. In an initial attempt to separate lipids from more polar material, the CH_2Cl_2 extract was partitioned between hexane (75 ml) and methanol–water (1 : 1, v/v) (100 ml). The upper layer was separated, dried over $MgSO_4$, and evaporated to yield 1.208 g of hexane extract. The lower phase was evaporated in vacuo giving 0.183 g of aqueous methanol extract.

The hexane extract, dissolved in carbon tetrachloride (CCl_4), was applied to a column of silica gel (Baker, average particle diameter 40 μm) packed in CCl_4. Material eluted with CCl_4–ether (3 : 2) was monitored by thin-layer chromatography (TLC) [silica gel plates, eluent CCl_4–ether (1 : 1), spots rendered visible with iodine vapor], and three major fractions were thus separated.

Fraction 1, $R_F \sim 0.85$, was further purified by preparative TLC on silica gel. Characterized as an unsaturated fatty acid fraction on the basis of its spectra, this material was not investigated further.

The principal component of fraction 2, $R_F \sim 0.51$, also further purified by preparative TLC on silica gel, was identified as ergosterol by comparison of melting point and spectra with those of an authentic sample.

The third fraction (502 mg), $R_F \sim 0.23$, showed ions in the mass spectrum at m/z inter alia 681.4560 (3.90%) (M^+ enniatin A), 667.4393 (4.35%) (M^+ enniatin A_1), 653.4235 (2.04%) (M^+ enniatin B_1), 228.1598 (8.41%) ($C_{12}H_{22}NO_3$), 214.1443 (2.63%) ($C_{11}H_{20}NO_3$), 100.1125 (100%) ($C_6H_{14}N$),

86.0973 (40.91%) ($C_5H_{12}N$). This fraction was crystallized from ethanol–water at −50°C. (In cases where material from the column did not appear homogenous on TLC, it was further purified by preparative TLC before recrystallization.) Colorless needles (312 mg) consisting principally of enniatin A (major component) and enniatin A_1 plus *N*-methylleucine containing enniatin(s) (minor components) were obtained. This material was toxic to spruce budworm larvae in the bioassays (Table 4, see below). The crystallized product had mp 120–121°C, $[\alpha]_D^{20}$ − 88.9° (c 1.04, $CHCl_3$); IR (KBr) 2970, 2935, 2880, 1735, 1665, 1465, 1415, 1385, 1380, 1370, 1305, 1260, 1185, 1150, 1130, 1115, 1095, and 1015 cm^{-1}; [^{1}H]NMR (200 MHz, $CDCl_3$, major peaks) δ 0.84–1.09 (36H, m), 1.26–1.44 (6H, m), 1.87 (occluded H_2O), 2.08 (3H, m), 2.28 (3H, m), 3.12 (9H, s), 4.67 (3H, d, J = 9.5 Hz), 5.13 (3H, d, J = 8.3 Hz). [^{13}C]NMR data (major peaks) and tentative assignments are presented in Table 1. Mass spectrum inter alia *m/z* 681.4568 (3.85%) ($C_{36}H_{63}N_3O_9$, M^+ enniatin A), 667.4406 (1.44%) ($C_{35}H_{61}N_3O_9$, M^+ enniatin A_1), (enniatin B <1%), 455.3116 (3.17%) ($C_{24}H_{43}N_2O_6$), 228.1596 (7.76%) ($C_{12}H_{22}NO_3$), 100.1126 (100%) ($C_6H_{14}N$), 86.0973 (10.76%) ($C_5H_{12}N$).

The enniatin complex was the major component of the aqueous methanol extract and could similarly be isolated by column chromatography and crystallization. This product, however, consistently contained a contaminant, absent in the hexane extract, which was visible as a superimposed dark spot when the TLC plate was sprayed with anisaldehyde reagent and heated (Krebs et al.,

1969). The contaminant, identified as ergosterol peroxide by its spectra and by comparison with an authentic sample (cf. Windaus and Brunken, 1928), could be separated from the enniatin fraction by elution with methanol through a column of Sephadex LH-20.

Hydrolysis of Recrystallized Enniatins (Mainly Enniatin A). A portion (104 mg) of the recrystallized fraction was heated under reflux with 6.1 M HCl (4.0 ml) in a nitrogen atmosphere for 20 hr. The resulting solution was evaporated to dryness in vacuo, and the residue was redissolved in water (15 ml). The solution was extracted four times with ether (10 ml each), and the combined extracts were washed with brine, dried over Na_2SO_4, and evaporated to dryness under reduced pressure. The product, essentially homogenous on TLC, was crystallized from benzene–petroleum ether (bp 35–52°C), yielding colorless crystalline material, mp 63–64°C, identified as D-2-hydroxyisovaleric acid by its optical rotation and by comparison of its solution spectra with those of an authentic sample of racemic 2-hydroxyisovaleric acid.

The aqueous solution, containing the ether-insoluble hydrochloride salts of *N*-methylamino acids, was evaporated to dryness. The residue was redissolved in the minimum volume of water, and the solution adjusted to pH 7 by addition of triethylamine. After addition of an excess of absolute ethanol, the solution was cooled to −50°C. The white precipitate that separated was collected at the pump and washed with cold ether–ethanol mixture. The product was analyzed by chromatography on cellulose plates (Brinkman Polygram cel 300 UV_{254} 0.1 mm), *tert*-amyl alcohol–acetic acid–water (20:1:20), with detection by buffered (pH 7) ninhydrin (Audhya and Russell, 1973). By comparison with standards, the amino acid products of the hydrolysis were identified, in order of increasing R_F, as *N*-methylvaline, *N*-methylisoleucine, and *N*-methylleucine. Visual inspection of the spots indicated that *N*-methylisoleucine was the predominant amino acid, and that *N*-methylvaline and *N*-methylleucine were minor products. A variety of solvent systems was tested in an attempt to distinguish the threo and erythro forms of *N*-methylisoleucine. Although marginal differences in R_F were observed using the above solvent system, the presence of both diastereoisomers in the hydrolysis mixture could not be rigorously established but may perhaps be inferred from the research of others (Audhya and Russell, 1974).

Bioassay. Hyphae, extracts from hyphae and culture filtrate, and crystalline product from FA120 were tested for toxicity to spruce budworm in an assay where larvae were reared on a meridic diet (McMorran, 1965) containing these materials. On a wet weight basis, the concentrations used were hyphae (1%), extracts (0.04%), and crystalline product (0.04% and 0.004%). The hyphae were ground to a powder and mixed well with freeze dried diet, while extracts and crystalline material were dissolved in approximately 30 ml of CH_2Cl_2, mixed thoroughly with diet, then the solvent evaporated under vacuum. In each

case 0.1 g of treated, dry diet was loaded into conical, plastic vials (8 × 38 mm inside diameter, 4.0 ml capacity) and rehydrated to 80% with sterile distilled water (0.4 ml) (A. W. Thomas, Canadian Forestry Service—Maritimes, Fredericton, New Brunswick, personal communication). Controls had diet either untreated, or treated with CH_2Cl_2 and the solvent evaporated. Laboratory stock spruce budworm larvae (second instar) from the Forest Pest Management Institute, Sault St. Marie, Ontario, were put singly into vials. The vials were capped, inverted, and incubated at 25 ± 2°C under intermittent light (16 hr light–8 hr dark) for 14 days.

After incubation, larval survival was recorded, the survivors were killed by freezing, then the instar determined by measuring head capsule width, and dry weight was recorded after freeze drying.

Fir Foliage Inoculations. Balsam fir foliage up to 3 years old was harvested from seedlings. Approximately 10 g of needles was put into a 250-ml Erlenmeyer flask with 5 ml distilled water and autoclaved. A culture of FA120 was macerated as described above and 2 ml of the inoculum suspension was added to each flask. These cultures were incubated at 25°C in the dark for eight weeks. After incubation, the cultures were extracted and checked for the presence of enniatins.

RESULTS AND DISCUSSION

Hyphae and hyphal extracts of FA120 were toxic to spruce budworm larvae when incorporated into a meridic insect diet at 1 and 0.04%, respectively (Tables 2 and 3, see below). Some toxic material was also present in the extract of the fungal culture filtrate (Table 2), but was not investigated because of the paucity of material. The biological activity was associated with a major fraction

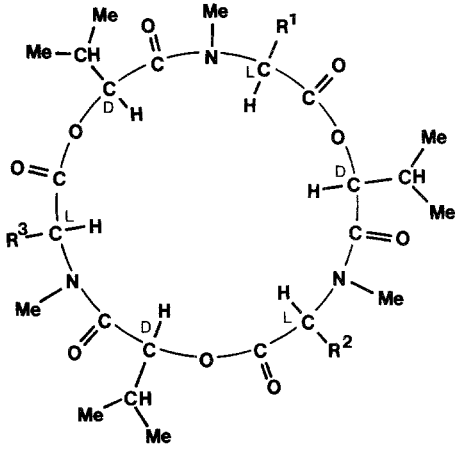
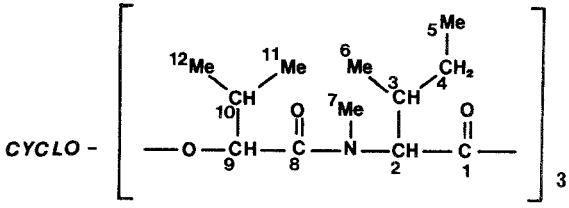
with physical properties and spectra characteristic of the cyclodepsipeptide enniatins (Russell, 1966). Other components of the hyphal extract identified were an unsaturated fatty acid fraction, ergosterol, and ergosterol peroxide. The latter was toxic to spruce budworm cells at 10 ppm (C. Clark, Biology Department, University of New Brunswick, personal communication). Ergosterol peroxide fed to budworm larvae at concentrations up to 400 ppm had no toxic effects.

The enniatins are a group of cyclohexadepsipeptide antibiotics produced by various *Fusarium* species including *F. lateritium* and *F. sambucinum* (Cook et al., 1948; Russell, 1966). These compounds are ionophores possessing the general structure 1 (Figure 1), in which the R groups may be Pr^i, Bu^s, or Bu^i.



1



Enniatin A

FIG. 1. Structures of enniatins.

They are normally isolated as complexes which may contain enniatin A (R^1 = R^2 = R_3 = Bu^s), A_1 (R^1 = R^2 = Bu^s, R^3 = Pr^i), B_1 (R^1 = Bu^s, R^2 = R^3 = Pr^i), and B (R^1 = R^2 = R^3 = Pr^i) (Audhya and Russell, 1974). The presence of *N*-methylleucine in hydrolysates of natural enniatin mixtures suggests the existence of a series of enniatins containing this amino acid in place of one or more *N*-methylisoleucine residues (enniatin C has R^1 = R^2 = R^3 = Bu^i). While the enniatin complex has often defied attempts at separation, enniatin B has been obtained pure from a *Fusarium* species (Plattner and Nager, 1948), and enniatin A has been purified by chromatography of mycelial extracts of *F. sambucinum* (Audhya and Russell, 1974). The latter authors demonstrated that their "pure" enniatin A contained both threo and erythro diastereoisomers of *N*-methylisoleucine.

Chromatography of hyphal extracts of FA120 yielded a fraction whose mass spectrum showed molecular ions corresponding to enniatins A, A_1, and B_1, with A_1 slightly more abundant than A. After recrystallization, B_1 was no longer detected in the mass spectrum, and the relative abundance of the molecular ion of A was significantly enhanced relative to that of A_1. [Ions $(C_6H_{14}N)^+$ and $(C_5H_{12}N)^+$ derived from *N*-methylisoleucine and *N*-methylvaline residues, respectively (cf. Wulfson et al., 1964) are also diagnostic in this regard, with the caveat that *N*-methylleucine residues may also give rise to a $(C_6H_{14}N)^+$ ion. Indeed, minor peaks at 37.97(t), 23.31(q), and 21.56(q) ppm in the [^{13}C]NMR spectrum suggested the presence, in low concentration, of compound(s) containing the *N*-methylleucine residue.] Acid hydrolysis of the recrystallized enniatin mixture gave, as expected, D-2-hydroxyisovaleric acid, and a mixture of the amino acids *N*-methylisoleucine, *N*-methylvaline, and *N*-methylleucine, in which the former predominated, and the other two were minor products. It can be concluded that enniatin A (Figure 1) is the principal component of the recrystallized fraction from FA120.

To our knowledge, enniatin B (Tirunarayanan and Sirsi, 1957; Minasyan et al., 1978) and "avenacein" (mp 139°C) (Cook et al., 1948) are the only cyclohexadepsipeptide metabolites previously reported from *F. avenaceum*.

The results of bioassays showing the effects on spruce budworm larvae of FA120 hyphae, a culture filtrate extract, crude hyphal extracts, and crystalline enniatins (see above) are presented in Tables 2–4. Table 3 gives results for hexane and aqueous methanol fractions which had their origin in an initial attempt to separate the crude hyphal extracts into lipids and more polar material by solvent partition. Enniatins were present in both phases and were, in fact, the major components of the (smaller) aqueous methanol fraction. The toxicity data in Table 3 reflect differences in relative concentrations of enniatins in the lipid and polar fractions as well as a dose–response relationship that is not expected to be linear.

The recrystallized enniatin A-rich fraction showed pronounced toxicity to spruce budworm larvae at a concentration of 0.04% (400 ppm) in the diet. The toxicity was manifested as mortality or retarded development (Table 4). At the conclusion of this assay, the larvae were found on the lid or side of the rearing vial. Those that were not dead showed weak movements only, and little evi-

dence of feeding was observed (food in the gut or frass in the vial), suggesting that the toxicity may be accompanied by feeding deterrent effects. Little evidence of toxicity was observed at 0.004% (40 ppm) and larval dry weight was not significantly different from that of the controls (Table 4); however, the enniatin A-rich fraction caused damage to spruce budworm cell cultures at concentrations as low as 5 ppm (C. Clark, Biology Department, University of New Brunswick, personal communication).

The enniatins, like other cyclodepsipeptides, are ionophores capable of forming complexes with alkali metal cations. Their antibiotic and other biological properties appear to be associated with their ability to affect ion transport across membranes (Shemyakin et al., 1965), and this may account for the observed toxicity to spruce budworm cells at low concentration.

While the phytotoxicity and antibiotic properties of the enniatin complex are well known, and other cyclodepsipeptides such as beauvericin (Hamill et al., 1969) and bassianolide (Kanaoka et al., 1978) from the entomopathogenic fungus *Beauveria bassiana*, are known to have insecticidal activity, only one previous report was found in which the effects of the enniatin complex on insects were investigated. Grove and Pople (1980) reported that enniatin complex and enniatin A from *F. lateritium* had moderate insecticidal activity—an order of magnitude lower than carbaryl—when injected into adult *Calliophora erythrocephala* (blowfly) and *Aedes aegypti* (mosquito) larvae. Comparison of these data with the toxicity of enniatins to spruce budworm larvae (Table 4) is complicated by differences in the test insects and in the methods of dosing and by the deterrent effects of the material on budworm feeding.

It is apparent that enniatins can affect spruce budworm larvae adversely at concentrations that might be produced by *F. avenaceum* on budworm-infested foliage, although preliminary attempts to isolate enniatins from (detached and autoclaved) foliage inoculated with the fungus were inconclusive.

Jensen (1977) suggested that production, by microorganisms like fungi, of biochemicals toxic to insects was advantageous to the fungus in habitats where it was subjected to predation by the insect. Likewise, Carroll (1986) suggested that trees harbor fungi that produce insecticidal toxins in the foliage, thereby reducing predation by insect herbivores. The results reported here may lend support to these ideas. If this is the case in the balsam fir–spruce budworm system, then the presence of *F. avenaceum*, and perhaps other phylloplane fungi, might cause budworm mortality contributing to the "unknown" death syndrome described by Royama (1984).

Acknowledgments—We thank Dr. D. W. Russell (Dalhousie University) for providing reference samples of *N*-methylamino acids and a specimen of enniatin complex from *F. sambucinum*. We have benefited from useful discussions with him and with Dr. A. Taylor (Atlantic Regional Laboratory, National Research Council of Canada).

Abstract—The heartwood of bald cypress, *Taxodium distichum* (L.) Rich., resisted feeding attack by the Formosan subterranean termite, *Coptotermes formosanus* Shiraki. Hexane-extracted heartwood, however, was consumed at >12 times the amount of sound heartwood eaten. A bioassay using *T. distichum* sapwood as a feeding substrate was employed to assess the antitermitic activity of successive hexane, acetone, and methanol extracts of heartwood shavings and isolates derived from the active hexane extract. Two fractions, eluted from the crude hexane extract by liquid chromatography, significantly reduced termite feeding compared to the parent extract, while a third fraction was less active than the original hexane extract. Each fraction contained one major component. All three components were structurally related diterpenes. The two most active heartwood constituents were identified by GC-MS and NMR as ferruginol and manool, while the third and least active, but most prevalent, compound in heartwood was identified as nezukol. Results of bioassays suggest that these allelochemicals act principally as feeding deterrents with accompanying termite mortality due to starvation.

Key Words—Taxodiaceae, *Taxodium distichum*, bald cypress, Isoptera, *Coptotermes formosanus*, Rhinotermitidae, Formosan subterranean termite, antitermitics, feeding deterrents, diterpenes, nezukol, ferruginol, manool.

INTRODUCTION

Oshima (1919) first demonstrated that natural products occurring in termite-resistant woods were more essential in conferring resistance than the woods' physical qualities. Unlike cellulose and lignin, these allelochemicals do not contribute to the structural integrity of wood, are solvent extractable, and occur in relatively small amounts, usually in heartwood (Wolcott, 1953; Sandermann and Dietrichs, 1957; Bultman and Southwell, 1976). A number of diverse compounds from resistant wood species have been reported to be toxic to termites, including the acetylenic sesquiterpenoid, chamaecynone, from *Chamaecyparis pisifera* D. Don (Saeki et al., 1973); 7-methyljuglone, a naphthoquinone from *Diospyros virginiana* L. (Carter et al., 1978); and the iridoid glycoside, loganin, from *Guettarda speciosa* L. (Yaga and Kinjo, 1985). Termite repellents in wood include an unknown saponification-deactivated compound from *Eucalyptus microcorys* F. Muell. (Rudman and Gay, 1961) and 2-furfuraldehyde from *Pinus sylvestris* L. (Becker et al., 1971). Scheffrahn and Rust (1983) isolated free carboxylic acids from *Pinus lambertiana* L. wood which deter termite feeding, and Carter et al. (1981) presented evidence that some Nearctic woods contain unknown compounds that are toxic to gut symbionts of termites. Most of these and other antitermitic agents in resistant woods probably encompass several categories of activity (Becker et al., 1972; Carter and Dell, 1981).

Bald cypress, *Taxodium distichum* (L.) Rich., is a widespread North American conifer ranging from Delaware to the Florida Keys and west to Texas (Harlow and Harrar, 1969). Bald cypress heartwood has been reported to resist attack by the drywood termite, *Cryptotermes brevis* (Walker) (Wolcott, 1957), and three subterranean rhinotermitid species, including *Coptotermes formosanus* Shiraki (Smythe and Carter, 1970a). In one case, bald cypress timbers used to construct buildings in Florida remained free of damage for over three centuries, although adjoining native woods were heavily damaged by termites (Ellis, 1936). Organic extracts of bald cypress heartwood deposited onto filter paper reduced feeding and increased mortality of *Reticulitermes flavipes* (Kollar) (Carter and Smythe, 1972, 1974). The compounds mediating this antitermitic activity were not identified.

We now report the chemical nature of major antitermitic compounds isolated from *T. distichum* heartwood and their activity against the Formosan subterranean termite, *C. formosanus*.

METHODS AND MATERIALS

Wood and Termites. T. distichum heartwood used in this study was seasoned "old-growth" lumber (7–21 annual rings/cm) collected in central Florida prior to 1944 and stored under indoor conditions until this study (1986). A

portion of wood was processed into shavings, for later extraction by use of a Wiley Mill. Construction grade *T. distichum* sapwood (2–4 rings/cm), also grown in Florida, was obtained from a commercial dealer. Foraging groups from three colonies of *C. formosanus* were harvested from field traps located in Hallandale, Florida, and separated from wood and debris by published methods (Tamashiro et al., 1973; Su and Scheffrahn, 1986) over the course of this study. Freshly collected (< 1 week) workers (larvae of at least third instar, 2.9–3.8 mg/individual) and soldiers (in foraging group proportions) were used in bioassays.

Bioassays. Four feeding and mortality tests were conducted to assess the antitermitic activity of (1) sound and hexane-extracted heartwood, (2) successive solvent extracts of heartwood shavings, (3) fractions of heartwood hexane extract eluted from a silica-gel column, and (4) purified major components isolated from deterrent fractions in (3). Bald cypress sapwood was used for the feeding bioassay substrate as it was found to be one of the most preferred woods in a related study (Scheffrahn and Su, unpublished). For tests 1–3, wood slices (35 × 19 × 1.2 mm thick, ca. 500 mg) were cut so that the plane of the large surface was perpendicular to the grain. Slices were oven dried at 100°C for 2 hr, transferred to airtight vials, and weighed. In accordance to the exact weight of each slice, gravimetrically determined concentrations of test solutions were deposited by pipet to yield a 2% (wt solute/wt wood) slice retention after drying. Solution concentrations were adjusted to permit saturation of slices without runoff. Wood slices were placed on the bottom of 74-ml cylindrical ointment jars and covered with 25 cm^3 of cleaned sand and 6 ml of water. Eighty-eight workers and six, three, or five soldiers (tests 1, 2, and 3, respectively) were placed on the moist sand. Foragers from the same colony were used in bioassays 2 and 4, while termites from two different colonies were used in tests 1 and 3. Jar lids were loosely fitted and experimental units were stored in the dark at 29°C for two weeks.

Surviving workers were counted, and wood slices were brushed free of sand, redried, and reweighed to determine dry weight loss resulting from worker feeding. Survivors were transferred to fresh jars provisioned with untreated sapwood slices for an additional two weeks to observe for latent effects from exposure to test materials.

The fourth bioassay was conducted to determine activity of the major component isolated from each of three fractions of the hexane heartwood extract. Because quantities of these pure isolates were limited, a small-scale version of the original bioassay procedure was adopted. Test isolates were deposited at 1% (w/w) on 12-mm-diam × 1.2-mm-thick sapwood disks weighing ca. 55 mg. Disks were placed in the bottom of 40-ml jars to which were added 10 cm^3 sand, 2.5 ml water, and 40 *C. formosanus* workers. Wood consumption and worker mortality were assessed after three days.

Treatments in all four bioassays were replicated four times. Feeding and mortality control units contained untreated sapwood, while starvation controls containing no wood were included to determine mortality due solely to starvation. For each bioassay, wood consumption (mg) and worker mortality (%) at each time period were subjected to analysis of variance. Significant differences among means were detected by Student-Newman-Kuels test at $\alpha = 0.05$ (Steel and Torrie, 1980).

Extraction, Isolation, and Identification. Bald cypress heartwood shavings (240 g) were extracted successively with hexane, acetone, and methanol (ca. 2.7 l each) for 8 hr each using a side chamber extractor (2200 ml capacity to siphon) to yield extractives at 4.0, 1.0, and 2.7% w/w, respectively. A 780-mg portion of crude hexane extract, concentrated in vacuo, was eluted with $CHCl_3$–hexane (1 : 1) from a 2- × 40-cm glass column which was slurry packed with 50 g of silica gel 60 (70–230 mesh). Thin-layer chromatography (TLC) of fractions was performed on Kodak chromatogram sheets coated with silica gel. Sheets were developed with 20% $CHCl_3$ in hexane and visualized with iodine vapor. Similar fractions were combined to produce three major fractions. Fraction yields were measured gravimetrically by solvent evaporation of 1-ml volumes.

Gas chromatography (GC) was performed with a Tracor 540 chromatograph equipped with a flame ionization detector and a DB-5 fused silica capillary column (J & W Scientific, 30 m × 0.325 mm ID; 0.25 μm film thickness) with helium as carrier at a flow of 29 cm/sec. Oven temperature was programmed from 150°C to 260°C at 5°C/min with injection port at 200°C and detector at 300°C. Further purification of components B and C for [^{1}H]- and [^{13}C]NMR analyses was accomplished by GC with a Hewlett Packard 5890A instrument fitted with a thermal conductivity detector using helium at 40 ml/min as carrier. Glass columns, 1.8 m × 6.4 mm OD × 4 mm ID, packed with 10% Silicone GE SE-54 (100–120 mesh) and 10% Silar-10C (100–120 mesh) on Gas Chrom QII (Alltech Associates, Inc.) were temperature programmed from 170°C to 260°C at 4°C/min and from 100°C to 230°C at 5°C/min with 15 min final hold to elute components B and C, respectively. Effluents corresponding to the major peaks were collected by a 15-cm × 1.5-mm glass tube fitted to the detector effluent port with a sleeve of Teflon tubing.

[^{1}H]- and [^{13}C]NMR spectra were obtained with a JOEL FX-200 instrument at 200 and 25 MHz, respectively, in $CDCl_3$ and TMS added as internal standard. GC-mass spectrometry of the crude hexane extract was performed on a DB-5 fused-silica bonded-phase capillary column (J & W, 15 m × 0.32 mm ID) with a temperature program from 100°C to 230°C at 5°C/min interfaced with a Finnigan 4021 MS system. EI spectra were obtained with a source temperature of 250°C and an electron energy of 70 eV. CI spectra were obtained with a reagent gas (methane or isobutane) at a pressure of 0.2 torr, a source

temperature of 150°C, and an electron energy of 70 eV. MS of ferruginol was obtained with a VG ZAB-1FHF mass spectrometer by direct probe at 70 eV.

RESULTS

C. formosanus workers consumed over 12-fold more of the hexane extracted *T. distichum* heartwood slices than sound heartwood (Table 1). Sapwood slices were eaten only slightly more (ca. 15%) than extracted heartwood. Nevertheless, this difference was significant. Mortality was significantly higher after the two-week exposure and two-week postexposure period for workers exposed to intact heartwood. When termites were exposed to sapwood slices treated at 2% with successive solvent extracts of heartwood shavings, only the hexane extract significantly reduced feeding below control levels, while acetone and methanol extractives had no effect on wood consumption (Table 2). Mortality on the hexane treatments was intermediate between the starved termites and the other treatments at two weeks. Both feeding and survival on hexane extract treatments were lower than levels on other extracts or control treatments even after returning the termites to untreated sapwood substrate for two weeks. The combined results in Tables 1 and 2 indicated that the antitermitic compounds in bald cypress heartwood could be extracted with, and retain activity in, hexane.

Three major fractions in the elution order A, B, and C were obtained by silica-gel chromatography of the hexane extract in yields of 40, 4.7, and 4.8%, respectively, of the total crude solids. Bioassay results of these fractions, an ethyl acetate–methanol column strip, and the original hexane extract are given in Table 3. Fractions B and C reduced feeding at levels significantly below their parent extract. Fraction A and the strip elution were significantly less active

than the original extract. None of the deposited fractions induced mortality levels beyond those of the unfed termites either immediately after the two-week exposure or two weeks thereafter when termites were transferred to untreated sapwood slices.

GC and TLC analyses of fractions A–C indicated that each contained a single major component also designated A, B, and C. Respective TLC R_f values were 0.68, 0.28, and 0.36, and GC retention times were 15.5, 19.3, and 14.2 min with purities (based on percent area) of 99, 89, and 79%, respectively.

GC-MS (EI and CI) spectra revealed the molecular weight of component A to be 290. Identification was established by [^{1}H]- and [^{13}C]NMR, as well as by its melting point (42–43 °C). The spectral data (within ± 0.08 ppm) and melting point of A agreed with literature values (Corbett and Smith, 1967; Rao et al., 1982) for nezukol (8β-hydroxysandaracopimar-15-ene) (Figure 1A). Spectrometric data for component A (nezukol) were as follows: EI-MS, *m/z* 290 (M^+, $C_{20}H_{34}O$, 12%), 275 (M − CH_3, 75), 272 (M − H_2O, 9), 257 (M − CH_3 − H_2O, 20), 247 (2), 221 (5), 205 (10), 193 (9), 179 (26), 165 (10), 149 (14), 137 (20), 136 (23), 123 (27), 121 (23), 109 (48), 95 (51), 81 (65), 69 (65), 55 (88), 43 (58), 41 (100); [^{1}H]NMR (200 MHz, $CDCl_3$) δ 0.84 (s, 3H, methyl), 0.86 (s, 3H, methyl), 0.99 (s, 3H, methyl), 1.21 (s, 3H, methyl), 4.78 (d, 1H, J_{cis} = 9 Hz, vinyl, 4.85 (d, 1H, J_{trans} = 18 Hz, vinyl), 5.73 ppm (dd, 1H, J_{trans} = 18 Hz, J_{cis} = 9 Hz, vinyl); [^{13}C]NMR (25 MHz; $CDCl_3$) δ 15.6, 17.0, 17.8, 18.4, 21.6, 24.3, 33.3, 33.5, 36.4, 37.2, 38.1, 39.4, 42.1, 43.5, 51.5, 56.6, 57.0, 72.5, 108.5, 151.6 ppm. Multiplicities were determined by the INEPT experiment (Morris and Freeman, 1978) and agree with assignments made by Rao et al. (1982).

Component B was identified by EI-MS and [^{1}H]NMR as ferruginol (Figure 1B) based on published spectral values (Wenkert et al., 1976; Dev. et al., 1985) and proton coupling experiments. The [^{13}C]NMR data were also consistent with the ferruginol structure. Spectrometric data for component B (ferruginol) were as follows: EIMS, *m/z* 287 (M + 1, 23), 286 (M^+, $C_{20}H_{30}O$, 100), 272 (14), 271 (67), 229 (12), 215 (11), 201 (32), 189 (35), 187 (13), 175 (40), 163 (12), 159 (10), 149 (19), 147 (14), 137 (11), 109 (11), 95 (10), 83 (13), 81 (10), 69 (53), 57 (14), 55 (13), 43 (18), 41 (10); [^{1}H]NMR (200 MHz, $CDCl_3$) δ 0.91 (s, 3H, methyl), 0.94 (s, 3H, methyl), 1.2 (d, 6H, methyls), 2.84 (m, 2H, $-CH_2$-7), 3.11 (m, 1H, isopropyl−CH−Ar), 4.62 (s, 1H, −OH), 6.63 [s, 1H, H−Ar (C-14)], 6.83 ppm [s, 1H, H−Ar (C-12)]; [^{13}C]NMR (25 MHz; $CDCl_3$) δ 19.3, 21.6, 22.6, 22.7, 24.8, 26.8, 29.7, 29.7, 33.3, 33.4, 37.5, 38.9, 41.7, 50.4, 111.0, 126.6, 127.3, 131.4, 148.7, 150.7 ppm.

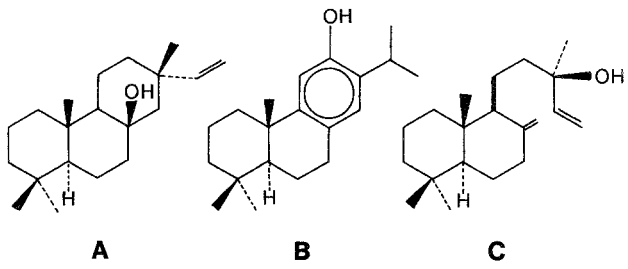

FIG. 1. Major components in the hexane extract of *T. distichum* heartwood: nezukol (A), ferruginol (B), and manool (C).

Component C was identified by GC-MS (EI and CI) as manool (Figure 1C), which was further supported by comparison of [^{13}C]NMR data of the purified material with literature values (Almqvist et al., 1975). Spectrometric data for component C (manool, $C_{20}H_{34}O$) were as follows: CI-MS (CH_4), *m/z* 331, 319, 291 (M + 1); EIMS, *m/z* 272 (M - H_2O, 3), 257 (M - H_2O − CH_3, 27), 244 (3), 229 (2), 204 (7), 203 (7), 189 (14), 177 (16), 175 (12), 161 (12), 148 (10), 147 (10), 137 (93), 123 (39), 121 (34), 109 (40), 107 (43), 95 (89), 93 (58), 81 (96), 79 (48), 71 (52), 69 (66), 55 (77), 43 (93), 41 (100); [^{1}H]NMR (25 MHz; $CDCl_3$) δ 0.68 (s, 3H, methyl), 0.80 (s, 3H, methyl), 0.87 (s, 3H, methyl), 1.28 (s, 3H, methyl), 4.47 (bs, 1H, vinyl), 4.80 (bs, 1H, vinyl), 5.06 (d, 1H, vinyl), 5.21 (d, 1H, vinyl), 5.92 ppm (dd, 1H, vinyl); [^{13}C]NMR (25 MHz; $CDCl_3$) δ 14.5, 17.7, 19.4, 21.7, 24.5, 28.0, 33.6, 33.6, 38.4, 39.1, 39.9, 41.4, 42.2, 55.6, 57.3, 73.7, 106.3, 111.6, 145.2, 148.8 ppm.

Results of bioassays with the pure isolates (Table 4) were in general agreement with those of the fractions from which they were derived (Table 3). Ferruginol and manool reduced feeding at an equal level of significance with only minute termite grazing evident on the wood disks. At 1% w/w, nezukol did not significantly reduce feeding below control levels. At 8% w/w, feeding on nezukol-treated disks was similar to crude extract deposits of 1%. Again, as in the initial bioassay (Table 1), termites consumed 12-times as much extracted heartwood as untreated heartwood. Because of the abbreviated bioassay period, no significant differences in mortalities for any of the treatments were observed.

TABLE 4. WOOD CONSUMPTION BY AND MORTALITY OF *C. formosanus* WORKERS EXPOSED 3 DAYS TO PURE ISOLATES OF *T. distichum* HEARTWOOD HEXANE EXTRACT AND HEARTWOOD DISKS[a]

Isolate (ww) or wood	Extracted from wood (%)	Consumption (mg)	Mortality (%)
Ferruginol 1%	0.2	2.2 a	1.7 a

DISCUSSION

Known as "the wood eternal" (Wolcott, 1957), bald cypress heartwood has long been recognized for its durability in service. Wolcott (1950) was first to investigate the resistance of this wood to termite attack. Results from his feeding studies using *C. brevis* implied an allelochemic resistance mechanism. He observed that increased "gum" content in heartwood was related to increased resistance. Wolcott (1950) classified *T. distichum* sapwood as "very susceptible" to attack by *C. brevis*. Smythe and Carter (1969) exposed the eastern subterranean termite, *R. flavipes*, to bald cypress heartwood blocks and observed poor survival (0–22%) after eight weeks, but when provisioned with pine sawdust as an alternative food source, survivorship was high (81%). We interpret their results to indicate that termite mortality in treatments with heartwood alone was a result of starvation, and not toxicity, as was speculated by Smythe and Carter (1969). Results of further tests by Smythe and Carter (1970a,b), using *C. formosanus*, *Reticulitermes virginicus* (Banks), and *R. flavipes* varied with wood source, but overall poor survival of termites exposed to bald cypress heartwood blocks or its sawdust was evident. *C. formosanus* workers, however, did not avoid contact with heartwood sawdust in a repellency bioassay (Smythe and Carter, 1970b).

Carter and Smythe (1972, 1974) verified that allelochemicals played an important role in bald cypress resistance by using filter paper as a bioassay substrate to test heartwood extracts against *R. flavipes*. As reported in our study, they found antitermitic activity to be greatest in the nonpolar (pentane) extract. Carter and Smythe (1972, 1974) did not quantify feeding but assessed extract activity based on mortality observed after eight weeks of continuous exposure to treated filter papers. Although 70 and 100% mortality were reported by Carter and Smythe (1974) at four and eight weeks, respectively, on pentane extract deposits; 94 and 100% mortality occurred in their starvation controls. This suggests again that mortality resulted from starvation in the bald cypress extract treatments. The role of bald cypress heartwood constituents as toxicants to gut symbionts was suspected after defaunation of intestinal protozoa was observed in *R. flavipes* workers exposed to pentane extract deposits (Carter, 1976) and reduction of symbiont populations in guts of *C. formosanus* workers exposed to *T. distichum* heartwood blocks (Carter et al., 1981). Cause and effect, however, are uncertain, as defaunation of essential protozoa in *R. flavipes* can occur after one week of induced starvation (Carter, 1976).

The antitermitic activity of manool, ferruginol, and to a lesser extent, nezukol against *C. formosanus* and occurrence of these compounds in bald cypress heartwood explain the findings reported in previous studies of bald cypress heartwood–termite interactions. Our study focused on a single source of heartwood and, although we identified and tested the three major components

in the hexane extract, over 20 compounds were detected by GC in the crude extract. Heartwood extractives are known to vary quantitatively and qualitatively along a radial sector of a single bole (Rudman, 1964), among trees in one area, or among geographically isolated tree populations (Rudman and Gay, 1964). In addition to allelochemical content, the physical characteristics of wood influence, to a lesser extent, feeding behavior. Behr et al. (1972) demonstrated an inverse relationship between amount consumed by *R. flavipes* and the specific gravity and hardness of wood. Likewise, Bultman et al. (1979) observed a general trend for decreased feeding by *C. formosanus* with increased density among 42 species of wood. The density of sapwood and extracted heartwood used in our study was 0.49 and 0.59 g/cm^3, respectively. This may explain why control feeding on untreated sapwood slightly surpassed the quantities of extracted heartwood consumed (Tables 1 and 4).

It is interesting to note that fresh core samples of heartwood removed from living bald cypress trees release 2-furfuraldehyde in concentrations sufficient to retard development of silkworm, *Bombyx mori* L., larvae (Jones et al., 1981a). This compound has an inhibitory effect on enteric microorganisms in *B. mori* and thus may decrease their nutritional contribution (Jones et al., 1981b). 2-Furfuraldehyde, isolated from *P. sylvestris* wood, was found to repel the subterranean termite, *Heterotermes indicola* (Wasmann), from treated inert substrates (Becker et al., 1971). 2-Furfuraldehyde deposits evaporate from wood within several days, losing their potency. Although 2-furfuraldehyde was not detected in our well-seasoned heartwood sample, the presence of this or unknown volatile compounds in heartwood used in other studies may have additionally influenced bioassay results.

HOST-PLANT ACCEPTANCE BY GEOGRAPHIC POPULATIONS OF THE COLORADO POTATO BEETLE, *Leptinotarsa decemlineata*
Role of Solanaceous Alkaloids as Sensory Deterrents

GLENN D. HARRISON and B.K. MITCHELL

Department of Entomology

(Received December 1, 1986; accepted April 9, 1987)

Abstract—We used a detailed analysis of feeding behavior to investigate the role of solanaceous alkaloids as sensory-based feeding deterrents for the Colorado potato beetle, *Leptinotarsa decemlineata* (Say). Experiments were conducted on three geographic, host-adapted populations of beetles to determine whether evolutionary changes in host use have been accompanied by behavioral adaptations to alkaloids. Solanine and tomatine, steroidal glycoalkaloids found in two regional host plants, did not reduce leaf consumption or significantly alter behavior patterns of newly emerged beetles, including those from populations that normally will not feed on plants containing the compounds. Atropine, a tropane alkaloid found in several taxonomically related nonhost species, caused a significant increase in sampling behavior (indicating direct action on the sensory system) and reduced acceptance of treated potato leaves. We propose that variable acceptance of host plants among regional populations of *L. decemlineata* has evolved independently of adaptations to alkaloids at the sensory level. To establish that secondary compounds such as atropine influence host choice in nature, field observations are needed to confirm that beetles routinely encounter, and sample, nonhost species.

Key Words—*Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, feeding deterrents, host recognition, host-adapted populations, host races, solanine, tomatine, atropine, alkaloids, chemoreception.

INTRODUCTION

This paper describes experiments designed to clarify the role of solanaceous alkaloids as feeding deterrents for the Colorado potato beetle *Leptinotarsa*

0098-0331/88/0300-0777$06.00/0

decemlineata (Say). An oligophagous species that feeds on the alkaloid-bearing Solanaceae, *L. decemlineata* has served as a case study in developing theories regarding the defensive function of plant secondary compounds (e.g., Fraenkel, 1959; Harborne, 1982). Although it has long been recognized that food-plant selection in *L. decemlineata* is based on a complex of stimuli (Jermy, 1961), several studies have stressed an important role for alkaloids as feeding deterrents and toxins. The alkaloids are thought to restrict the host range of the beetles and reduce feeding on "resistant" plants (Stürckow and Löw, 1961; Hsiao and Fraenkel, 1968; Hsiao, 1974; Sinden et al., 1978, 1980; Dimock and Tingey, 1985). In several papers, authors imply, or explicitly state, that alkaloids act directly on the chemosensory system to inhibit feeding. As a result, it has become generally accepted that alkaloids exert a strong influence on the host choice behavior of *L. decemlineata*. However, this conclusion is based largely on long-term feeding experiments using beetles confined on alkaloid-treated diets or leaves. Because alkaloids and other toxic compounds may reduce feeding after consumption, such methods do not demonstrate involvement by the sensory system, nor do they indicate how beetles would behave if they were free to leave an unacceptable host.

In this paper, we focused on the influence alkaloids have on initial host-plant acceptance and first-meal feeding. Newly emerged, unrestrained beetles were videotaped as they approached and contacted leaves infiltrated with alkaloids to levels equaling or exceeding those reported in the literature. When new adults first contact a plant, they perform a series of stereotyped sampling behaviors, the durations of which vary according to food-plant preference (Harrison, 1987). Our approach here was to correlate any reduction in feeding on alkaloid-treated plants with changes in sampling behavior, thereby demonstrating effects of the compounds at the sensory level.

Experiments were conducted on three geographic populations of *L. decemlineata* from North America that use different local hosts. Within these populations varying degrees of specialization in larval digestive efficiency (Hsiao, 1978) and adult food-plant preference (Harrison, 1987) have evolved. One of our objectives in this study was to determine whether these changes in adult behavior have been associated with adaptations to specific alkaloids at the sensory level. Our intent was not to provide an extensive list of foreign substances that might deter feeding, but to concentrate on a small number of ecologically meaningful compounds and ask whether they influence host acceptance among regional populations of beetles.

METHODS AND MATERIALS

Collection sites for beetles (and their dominant regional host plants) were: Benson, Arizona (*Solanum elaeagnifolium* Cav.); Edmonton, Alberta (*Solanum*

tuberosum L.); and Beltsville, Maryland (*Lycopersicon esculentum* Mill). Beetles were reared on their respective regional hosts under conditions described previously (Mitchell and Harrison, 1984). Plants were grown in a greenhouse equipped with supplemental lighting at 16 : 8 light–dark.

Experiments were conducted using newly emerged, unfed adults of both sexes. Behavior was recorded using an apparatus designed to allow videotape monitoring of unrestrained beetles (Harrison, 1987). Each beetle was allowed free access to a leaf until 3 min without feeding elapsed. This time interval is a good indicator of the end of the first meal (Harrison, unpublished data). Leaf area consumed was measured using a Licor Area Meter, model 3100 (accuracy = 1 mm^2).

Leaves were treated chemically by passive transpiration. Leaf petioles were cut with a sharp razor blade, weighed, immersed in a 5-ml test tube containing the alkaloid solution, and sealed with Parafilm. Because the alkaloids used were nonvolatile, they accumulated in leaves as transpiration occurred. From a knowledge of the percent water content of each plant species (Table 1) and the concentrations of test solutions, we determined the approximate level of alkaloid accumulating in a leaf by weight loss of the alkaloid solution. As a rule, we replaced the amount of water in each leaf with an equal amount of alkaloid solution. Therefore, we estimate that the concentration of alkaloid added to each leaf approximately equaled that of the test solution.

To determine whether alkaloids were being distributed throughout the treated leaves, several leaf petioles were placed in a solution of fluorescein, a water-soluble fluorescent dye, and periodically viewed under UV light. After 30 min, dye was visible in all parts of the leaves. Because treating leaves with alkaloids took 2–4 hr, we concluded that the test solutions were distributed evenly within the leaves.

Control leaves were placed in deionized water for the same length of time as treated leaves before being used. Control and treated leaves were interspersed randomly in time during the experiments. All alkaloids were obtained from Sigma Chemical Co. (St. Louis, Missouri).

TABLE 1. TOTAL GLYCOALKALOID (TGA) LEVELS AND PERCENT WATER CONTENT OF LEAVES FROM THREE SOLANACEOUS HOST PLANTS OF *Leptinotarsa decemlineata*

Plant	Water (%)[a]	TGA (mg/g dry wt)
Solanum tuberosum (potato)	91	5.2 (approx 0.5 mM)
Solanum elaeagnifolium	86	0.85 (approx 0.08 mM)
Lycopersicon esculentum (tomato)	88	7.8 (approx 0.8 mM)[b]

[a] Calculated by subtracting dry weight from wet weight. Dry weight determined by oven-drying ten leaves at 100°C for 24 hr.

[b] From Sinden et al. (1978); flowering plants grown at 16:8 light–dark.

Total Glycoalkaloid Determinations. In order to treat leaves to a desired total glycoalkaloid (TGA) level, natural levels of glycoalkaloid in two of the *Solanum* species used in this study were measured using techniques described by Fitzpatrick and Osman (1974), and Fitzpatrick et al. (1978) (Table 1). TGA levels for *L. esculentum* were approximated using values reported by Sinden et al. (1978).

To verify that alkaloids were accumulating in treated leaves at the desired concentrations, we also measured the TGA content of a group of alkaloid-treated leaves. With the high levels of alkaloid present in treated leaves, a precipitate formed in a separation phase resulting in a TGA value of only 70% of that predicted. However, in accuracy tests of these techniques, recovery rates of standards were highly variable and ranged from 46% to 78% (Coxon, 1984). Given a minimum 22% loss, analysis of treated leaves therefore accounted for at least 92% (= 70 + 22) of the predicted alkaloid content.

Behavioral Analysis. Definitions of the behavioral measures used are as follows (for complete descriptions, including illustrations, see Harrison, 1987):

Examine is defined as time spent by beetles on the leaf surface beginning with first leaf contact and ending with transition to *macerate*. Beetles typically palpate and move their antennae over the leaf surface during this period. This measure was included to determine whether alkaloid treatments induced changes in leaf surface properties that may have affected subsequent feeding.

Macerate is a period following *examine* during which the leaf edge was "squeezed" by repetitive movements of the mandibles. Because plant saps containing alkaloids are first encountered at this time, variations in macerating behavior can be used to investigate action of alkaloids on the gustatory system. Duration of the first (preingestive) macerating bout and frequency of macerating bouts during the test period were recorded. On preferred plants, this behavior was usually followed by feeding.

Feeding behavior was quantified by first comparing the number of beetles to reject leaves as food. For beetles that did feed, the amount consumed, feeding rate, and number of feeding sites on the leaf were measured.

Data collected as frequencies were analyzed using G tests. To compare the number of sampling and feeding sites among treatment groups using this statistic, data were separated into groups of one (the usual pattern on primary hosts) and greater than one. The remaining data were analyzed using one-way analysis of variance (ANOVA). All probabilities reported are based on directional (one-tailed) tests. Statistics were calculated with the aid of BMDP statistical software (Dixon, 1983).

Experiment 1. This experiment was designed to compare effects of three alkaloids within a single beetle population. Beetles from Alberta were individually videotaped on *S. tuberosum* (potato) leaves treated with deionized water (control), or with a 2 mM solution of solanine, tomatine, or atropine. The steroidal glycoalkaloid, solanine, is a principal alkaloid in *S. tuberosum* and many

other tuber-bearing *Solanum* species (Schreiber, 1979; Gregory et al., 1981). Tomatine, also a steroidal glycoalkaloid, occurs in relatively high concentrations in many *Lycopersicon* species (including tomato) where it is often the only alkaloid present (Roddick, 1974). Atropine, a tropane alkaloid, is found in several genera of Solanaceae (e.g., *Atropa* and *Datura*; Evans, 1979) that are not regularly used as hosts by *L. decemlineata*.

Experiment 2. Irrespective of their geographical origin, feeding by adult beetles on tomato is significantly lower than on primary *Solanum* hosts (Bongers, 1970; Harrison, 1987). In this experiment, we tested the hypothesis that reduced feeding on tomato is caused by its resident alkaloid—tomatine—acting as a sensory deterrent. Tomato-reared beetles from Maryland were randomly assigned to leaves treated with either 2 mM tomatine or water. This concentration of tomatine has been correlated with a reduction in feeding by beetles from Maryland on certain *Lycopersicon* species (Sinden et al., 1978).

Experiment 3. When reared as larvae on their regional host, *S. elaeagnifolium*, most adult beetles from Arizona will not feed on potato leaves on first contact (Harrison, 1987). In this experiment, we asked whether solanine was a factor in this initial rejection of potato. Beetles were randomly assigned to *S. elaeagnifolium* leaves treated with either 0.5 mM solanine or water. This concentration of solanine was double that normally found in greenhouse-grown potato leaves (Table 1).

RESULTS

Experiment 1. Of the three alkaloids tested, atropine had the most pronounced effect on beetles, with 40% refusing to feed despite repeated sampling (Table 2). Interestingly, beetles that fed consumed as much as those offered control leaves, although their feeding rate was somewhat (but not significantly) lower. There was also an increase over controls in the duration of the first macerating bout on atropine-treated leaves ($F = 7.94$, $df = 1$, $P < 0.01$) and a trend toward increased numbers of sampling and feeding sites. These changes in behavior indicate that atropine did act via the sensory system to inhibit feeding.

Increasing the solanine concentration in potato leaves fivefold did not influence the beetles' behavior. Leaf consumption was not reduced, and there was no increase in plant sampling.

Although first-meal feeding on tomato by beetles from Alberta is negligible (Harrison, 1987), tomatine had no significant effect on these beetles when infiltrated into potato leaves. Duration of the first macerating bout ($F = 0.18$, $df = 1$, NS, using square root transformation) and its variance ($F = 2.54$; $df = 9,9$, NS) did not differ from controls. There was no overall reduction in first-meal feeding or in feeding rate.

Experiment 2. Increasing the existing tomatine content in tomato leaves by

[b] Definitions as in Table 2.

2 mM to yield an estimated TGA level of 2.8 mM did not change the behavior of beetles from Maryland (Table 3). Having one beetle reject a tomatine-treated leaf was not unusual because two of 12 beetles tested on untreated tomato leaves in a previous experiment did the same (Harrison, 1987). Consumption of tomatine-treated leaves did not differ from controls, and there were no consistent trends in other variables measured.

Experiment 3. Sampling and feeding behavior by beetles from Arizona did not change with the addition of 0.5 mM solanine to their regional host plant *S. elaeagnifolium* (Table 4). This TGA level represents twice that normally found in potato (which the beetles largely reject) and several times the amount estimated in their regional host *S. elaeagnifolium* (Table 1).

DISCUSSION

In this study we used a direct behavioral approach to investigate the role of solanaceous alkaloids as sensory-based feeding deterrents for *L. decemlineata* adults. This function has long been implied for a number of alkaloids, including tomatine, but our findings indicate that neither solanine nor tomatine act on the sensory system to influence food-plant acceptance, even when these compounds are tested at relatively high concentrations.

Using the same experimental protocol as employed here, Harrison (1987) demonstrated that most beetles from Arizona will not feed on potato despite repeated sampling. In the present study, however, solanine did not inhibit feeding by beetles from Arizona on their regional host, *S. elaeagnifolium*. It is therefore unlikely that solanine is a cause of the initial rejection of potato by these beetles. Increasing the solanine level in potato leaves approximately fivefold also did not alter the behavior of beetles from Alberta which feed locally on potato.

Perhaps more surprising are the results obtained with tomatine. Tested at levels characteristic of "resistant" tomato varieties (Sinden et al., 1978), tomatine did not inhibit first-meal feeding by beetles from two populations. Also, there were no significant changes in sampling behavior that would indicate tomatine acted on the sensory system. In a recent electrophysiological study (Mitchell and Harrison, 1985), we found that tomatine and solanine have similar effects on chemosensory cells in adult beetles. After long applications, both compounds elicit bursting activity (first reported by Stürckow, 1959) associated with cell injury. There is no evidence of alkaloid-sensitive cells or "deterrent receptors" (Dethier, 1980; Schoonhoven, 1982) in *L. decemlineata*. Although cell injury is potentially one of the mechanisms by which alkaloids could disrupt feeding (Schoohoven, 1982; Mitchell and Sutcliffe, 1984), there is no indication that tomatine or solanine had this effect in the present study.

Our results do not necessarily contradict studies reporting inhibition of

adult feeding by tomatine. The reduced consumption reported by Stürckow and Löw (1961) and the reduction in feeding rate reported by Sinden et al. (1978) were both based on long-term feeding bioassays. A postingestive accumulation of tomatine affecting general activity levels (including feeding) may be responsible for these results. Similarly, slower growth and development by *L. decemlineata* larvae on tomatine-treated diets (Hsiao and Fraenkel, 1968; Hsiao, 1974) probably results from the compound's toxicity. This conclusion is supported by the observation that surviving larvae actually eat more tomato than potato to complete development (Latheef and Harcourt, 1972), suggesting that tomatine at nominal levels may not inhibit larval feeding via the sensory system.

It would be interesting to know if the same general conclusion applies to acetylated *Solanum* glycoalkaloids, the leptines. Sinden et al. (1986) recently reported dramatic reductions in feeding in both field and laboratory experiments when high-leptine-content individuals of *S. chacoense* were compared with low-leptine-content individuals from the same clone. Their experiments were not designed to differentiate sensory-mediated and longer-term deterrent effects of the alkaloids. In their laboratory choice experiments, adult beetles always consumed some of the high-leptine leaf disks, but within 2 hr a significant reduction in feeding could be measured. The leptines could have been acting via the sensory system, as atropine did in this study, or they could have been acting internally, following initial consumption. Unfortunately purified leptine samples were not available when the studies reported here were carried out.

Kogan (1976) has proposed that *L. decemlineata* may be physiologically adapted to steroidal alkaloids but not to tropane alkaloids, thereby allowing expansion of the beetles' host range to include tomato but not, for example, *Datura* or *Atropa* species. This hypothesis is supported by results of the present study, in that atropine (a tropane alkaloid) apparently caused a sensory-based inhibition of feeding. However, these results must be interpreted with caution. For oligophagous insects, conclusions regarding the role of deterrent compounds cannot be made from laboratory studies alone because visual and olfactory cues may be sufficient to preclude routine contact with many nonhosts in the field (Prokopy and Owens, 1983; Visser, 1986). Moreover, nonhost plants that are encountered may be rejected on the basis of leaf structure properties before plant fluids that normally contain secondary compounds are first sampled (Harrison, 1987). To establish that nonhost compounds such as atropine naturally deter feeding in *L. decemlineata*, we need to know if these compounds are routinely contacted by beetles in nature. This could be accomplished through a detailed study of the foraging behavior of adult beetles.

Recent studies have shown that the perception of host plants by *L. decemlineata* is based on an integration of complex stimulus patterns. Selective, upwind orientation to *Solanum* species is dependent on precise ratios of green-leaf volatiles which form an appropriate blend or "Gestalt" for the insects (Ma

and Visser, 1978; Visser and Avé, 1978). Food-plant acceptance involves a complex of stimuli as well, and beetles may be capable of discriminating among closely related *Solanum* species by examining the surface of their leaves (Harrison, 1987). These findings, and the results of the present study, indicated that selective host-choice behavior by beetles may occur independently of alkaloids. While acknowledging that many plant secondary compounds probably restrict host choice, either by direct action on the sensory system or by postingestive means, we hypothesize that specificity for *Solanum* hosts (Tower, 1906; Hsiao, 1981; May and Ahmad, 1983) is maintained primarily by the beetles' sensory system, which is selectively tuned to plants containing the appropriate combinations of "positive" stimuli.

(Received March 6, 1987; accepted April 22, 1987)

Abstract—Headspace components from strawberry foliage have been isolated by nitrogen entrainment and Tenax trapping. Traps were eluted with hexane, and components were analyzed by gas chromatography–mass spectrometry. Fifteen compounds were identified by comparison with authentic standards, *trans*-2-hexenal, 1-hexanol, *trans*-2-hexen-1-ol, *cis*-3-hexen-1-ol, hexyl acetate, *cis*-3-hexenyl acetate, 6-methyl-5-hepten-2-ol, 1-octanol, 1-octen-3-ol, linalool, α-terpineol, methyl salicylate, ethyl salicylate, benzyl alcohol, and 2-phenylethanol. The relative amounts of these components were compared at flowering and after fruit harvest when plants were more resistant to the two-spotted spider mite, *Tetranychus urticae* Koch. The predominant components, *cis*-3-hexen-1-ol and its acetate, did not change markedly between the sampling periods, but methyl salicylate increased approximately 10-fold after fruit harvest. Methyl salicylate at low concentrations under bioassay conditions did not affect mite behavior. The biosynthetic relationship of this compound to other phenols which have been implicated in plant resistance is discussed.

Key Words—*Fragaria ananassa*, two-spotted spider mite, *Tetranychus urticae*, Acari, Tetranychidae, headspace compounds, methyl salicylate, seasonal resistance.

INTRODUCTION

The twospotted spider mite (TSSM), *Tetranychus urticae* Koch, can be a serious pest for a large number of crop plants including strawberry. In early work with strawberry–TSSM interaction we observed that strawberry plants are susceptible to attack in the preflowering and flowering period (April–May) but become resistant after fruit harvest (mid- to late June) (Dabrowski et al., 1971). Volatile compounds have been implicated in plant–parasite interactions (Seigler, 1983), and mites respond to certain volatile compounds in bioassays (Rodriguez et al., 1976). One of the most recently developed methods for assaying volatiles from plants is headspace trapping. In one approach to this procedure volatiles emitted by plant material are entrained in a stream of gas flowing over foliage and are adsorbed on a porous polymer such as Tenax. After a trapping period of several hours, the volatiles are eluted from the Tenax with a solvent and separated by gas chromatography.

In the present experiments, strawberry leaves from several cultivars were bioassayed for susceptibility to mites at flowering and after fruit harvest. At the same time, fresh foliage was analyzed for the compounds present in headspace samples trapped on Tenax to determine the types of volatiles emitted. Comparisons were made between the headspace volatiles trapped during the two periods.

METHODS AND MATERIALS

Plant Material. Fully expanded leaves were harvested at flowering (late April to early May) and after fruit harvest (mid- to late June) from field-grown strawberry *Fragaria* × *ananassa* Duch. plants and used the same day for bioassay or headspace analysis.

Scanning electron micrographs were made of the top and bottom surfaces of freshly harvested leaves.

Detached Leaf Disk Bioassay. Disks (44 mm diam.) were cut from fresh strawberry leaves and placed on moist paper in Petri dishes. Tanglefoot was applied around the cut edges of each disk, and five teneral female TSSM were placed on the leaf disk surface. The dishes were placed in continuous photoperiod at 23°C for one week, after which the number of TSSM progeny were counted. There were five replications for each test conducted.

Headspace Analysis. One hundred grams of freshly harvested foliage was used for each headspace analysis. Each leaf was cut into two to three pieces and placed in a 5-liter round bottom flask which was immersed in a water bath maintained at 30°C. A stream of nitrogen (high purity, compressed) was filtered through a molecular sieve and passed over the foliage via Teflon tubing at a flow rate of 500 ml/min for 20 hr. The stream of gas containing the entrained volatiles passed from the flask into 1.5 g of Tenax (Alltech, Inc.) packed in a

glass tube attached to the flask. Prior to use, each Tenax trap was washed with 50 ml of hexane and then conditioned for 1 hr at 250°C using filtered nitrogen at 500 ml/min. After headspace vapor adsorption, the Tenax was removed from the tube and eluted with 15 ml of hexane (Burdick and Jackson Co.). The hexane eluate was concentrated to approximately 1 ml using a microstill with a Vigreux column. Aliquots of the hexane concentrate were submitted to gas chromatographic analysis as described below.

GC-MS Analysis and Quantitation. Headspace samples were separated using a 60-m × 0.32-mm Supelcowax 10 fused silica capillary column held isothermal at 60°C for 1 min and then programmed at 3°C/min to 220°C. GC-MS was carried out using a Hewlett Packard model 5985A instrument operated at 70eV. Identification of components was based on comparisons of mass spectra and cochromatography with authentic standards. Headspace component peaks were integrated electronically, and octadecane was used as an external standard for quantitation. Two headspace analyses were performed for each of the three cultivars at both sampling periods, and the average values for the peak areas were calculated.

RESULTS AND DISCUSSION

Observations in previous years of strawberry plants grown in the field have shown that mite populations build up during the preflowering and flowering period and then decline significantly after fruit harvest. Results from leaf disk bioassays utilizing field-grown plants in 1985 (Table 1) also showed that the plants were susceptible at flowering and relatively resistant to TSSM approxi-

TABLE 1. BIOASSAY DATA SHOWING NUMBER OF PROGENY SEVEN DAYS AFTER PLACING FIVE TENERAL FEMALE *T. urticae* ON STRAWBERRY LEAF DISKS

mately two to three weeks after fruit harvest. This confirmed our observations with intact plants in the field. It was determined that the plants were still susceptible to mites during fruit harvest but became resistant in about two weeks postharvest (end of harvest was about June 1). When bioassays were performed in 1986 (Table 1), similar susceptibility at flowering and resistance following fruit harvest were observed. Sampling in late May during the mid-period of fruit harvest showed that the plants were still susceptible. This confirmed the 1985 data and indicated that a period of about two to four weeks following fruit harvest is critical in the development of resistance. Harvesting the fruit removes a metabolic sink for the leaf photosynthate, and this process may alter the metabolism of the plant and concurrently increase resistance. In addition, environmental factors such as temperatures, water availability, and photoperiod may also function in the development of resistance.

In some plants, leaf trichomes have been associated with the production of volatile compounds (Loomis and Croteau, 1980). The volatile 2-tridecanone is believed to be secreted by trichomes of the wild tomato (*Lycopersicon hirsutum*) and is toxic to certain insects (Williams et al., 1980). It was considered of interest to determine the trichome characteristics of the strawberry leaves used in these studies, and scanning electron micrographs indicated the presence of two types of trichomes on the cultivars (Figure 1). The most prominent was a long slender structure that narrowed to a pointed tip and did not appear to be secretory. The second was quite small in comparison but possessed a globular-

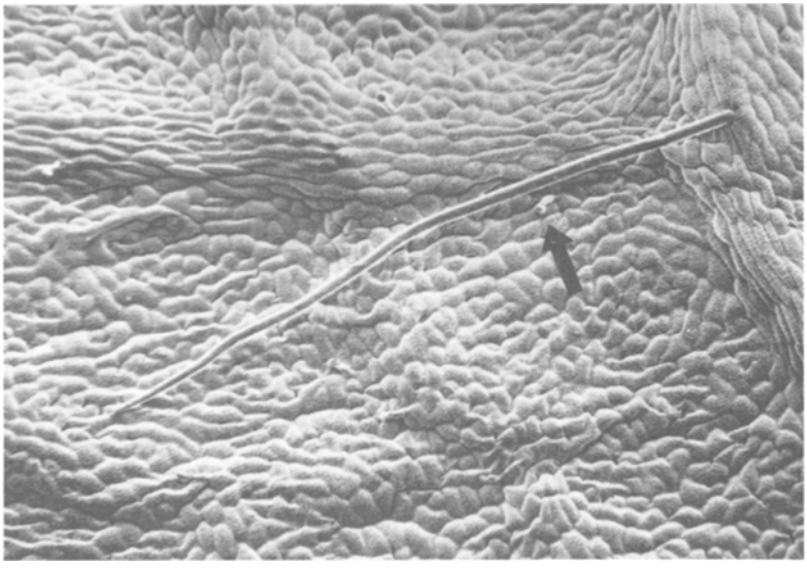

FIG. 1. Scanning electron micrograph (×150) of the lower surface of a leaf removed from a flowering plant (Scott) showing large and small (arrow) trichomes.

shaped tip that may indicate the structure was secretory. General observations of the leaves did not indicate dense populations of trichomes on the cultivars although exact counts were not done.

Table 2 lists the compounds that were identified in a headspace sample from strawberry leaves. Among these compounds were *cis*-3-hexen-1-ol and its corresponding acetate ester, which were the most abundant compounds trapped by this procedure. This result was similar to those reported for intact foliage headspace from other plants (Buttery et al., 1984, 1985). Among the headspace components with pleasant odors were the terpenoid linalool (floral odor) and methyl salicylate (wintergreen). In addition to monoterpenes, the headspace sample also contained a component believed to be a sesquiterpene (mol wt 204) with major ions in decreasing intensity at *m/e* 41, 93, 69, 55, 79, 91, 77, 107, 119, and 123. The biosynthesis and secretion of volatile and nonvolatile terpenes has been associated with trichomes in some plant species (Loomis and Croteau, 1980).

Alcohols and esters accounted for the majority of compounds identified under the trapping conditions used. The yield of strawberry headspace components was estimated at around 5–10 ppm (fresh weight basis), which was

greater than the yields obtained from other plants such as wheat and tobacco that were examined by this method in preliminary experiments. The compounds identified accounted for greater than 80% of the total quantity of the headspace samples trapped from the cultivar Redchief in these experiments.

In the present experiments nitrogen was used in the headspace analysis procedure to prevent oxidation of the trace quantities of compounds entrained and trapped on Tenax. Recent experiments (T.W. Kimmerer, University of Kentucky, personal communication) showed that the volatiles acetaldehyde and ethanol increased in leaves, and alcohol dehydrogenase, which reduces acetaldehyde, increased in tree roots under a nitrogen atmosphere. In future experiments, it would be interesting to compare the types of strawberry headspace components entrained in air to those in an inert gas such as nitrogen.

Interestingly, several of the compounds found in the headspace analysis, including 3-hexen-1-ol, methyl salicylate, and linalool, were also found in an earlier study when foliage was subjected to steam distillation (Kemp et al., 1968). One notable difference was that the major component found in the steam distillate, nonanal, was not identified among the headspace volatiles, although it may have been present in relatively small amounts. A similar result was observed with tobacco tissue earlier (Andersen et al., 1986). Perhaps this compound is compartmentalized and not readily released into the headspace. Also, 1,2-dihydro-1,1,6-trimethylnaphthalene, found in distillates (Stoltz et al., 1970), was not detected in the headspace samples; the low volatility of the compound compared to the other components isolated may account for this result. This rather unusual type of hydrocarbon, which is probably formed from a carotenoid, was recently reported as a component of volatiles from black tea (Mick and Schrier, 1984). In addition to studies on foliage, numerous studies have been carried out on the isolation and identification of the aroma components from strawberry fruit (Winter and Willhelm, 1964; McFadden et al., 1965; Tressl et al. 1969; Pyysalo et al., 1979). All of the compounds found in the foliage headspace have also been found in strawberry fruit.

A comparison of the quantities of the headspace components of the cultivar Scott at flowering and after fruit harvest is presented in Table 2. From these data it can be seen that some headspace components such as the C_6 components apparently decreased, while others such as 1-octen-3-ol and benzyl alcohol increased. However, one of the most marked changes occurred for methyl salicylate, which increased approximately 10-fold from flowering to postharvest and became a major component in the postharvest headspace components. These compositional changes from flowering to postharvest were found in the three cultivars tested as shown for the representative compounds in Table 3. Similar changes occurred for ethyl salicylate with increased amounts in Redchief; however, generally this compound was a minor constituent of the samples. The accumulations of the salicylate esters may reflect their increased synthesis or greater release from bound forms in plants later in the season.

TABLE 3. RATIO OF AMOUNTS OF SOME HEADSPACE VOLATILES AFTER FRUIT HARVEST TO THOSE AT FLOWERING FOR THREE CULTIVARS IN 1985

Compound	Cultivar		
	Scott	Redchief	Sunrise
3-Hexen-1-ol	0.7	1.0	1.0
1-Octen-3-ol	4.1	3.1	5.3
Linalool	0.6	0.5	0.8
Methyl salicylate	13.0	12.6	8.1
Ethyl salicylate	13.7	37.7	8.5
Benzyl alcohol	2.1	1.3	2.3
2-Phenylethanol	0.7	0.6	0.9

In a bioassay used previously to test attractancy or repellency of strawberry essential oils (Rodriguez et al., 1976), a "standard essential oil mixture" (SEOM) was utilized that contained the compounds in relative proportions of strawberry foliage essential oil. The SEOM formed the base for other test mixtures containing varied levels of other compounds such as methyl salicylate. In those bioassay tests, the SEOM containing varied levels of methyl salicylate generally attracted TSSM females at concentrations of 0.001% and repelled them at 1.0%. Currently, in preliminary tests using this bioassay but testing only methyl salicylate per se, the compound failed to elicit attractancy at the dilutions tested. It is interesting that salicylates are phenolic compounds believed to be formed through the shikimic acid pathway via benzoic acid (Klambt, 1962). Many phenolics are synthesized in plants, and frequently members of this class are repellents, feeding deterrents, and toxins and have been generally associated with plant resistance to herbivores (Levin, 1976; Feeny, 1976; Stipanovic, 1983). Nonvolatile phenols can account for a significant portion of plant tissue weight (Andersen and Todd, 1968; Feeny, 1970) and function as defense factors against herbivores. The build-up of the volatile salicylates may be accompanied by similar accumulations of nonvolatile phenols, and the possible role of this class of compounds as determinants of mite resistance of strawberries merits further study.

RESPONSES OF MALE CODLING MOTHS (*Laspeyresia pomonella*) TO CODLEMONE AND OTHER ALCOHOLS IN A WIND TUNNEL

R. PREISS and E. PRIESNER

Max-Planck-Institut für Verhaltensphysiologie

(Received January 30, 1987; accepted April 28, 1987)

Abstract—The primary pheromone (*E,E*)-8,10-dodecadien-1-ol (I, codlemone), 11 further alcohols, and binary blends of both were evaluated for attractiveness as defined by the percentage of *L. pomonella* males showing oriented upwind flight terminated by landing at the source within 10 min after release. Sources of I were attractive from 10^{-5} μg to 10^{1} μg, with approx. 70% males responding at 10^{-3}–10^{-1} μg. Most other alcohols also showed attractiveness, but the dose–response curves differed greatly with respect to the range of effective lure doses as well as the maximum response level reached at any dose. (*E,E*)-7,9-Undecadien-1-ol (III) revealed a dose–response curve similar in shape to I but shifted towards higher concentrations. (*E,E*)-8,10-Tridecadien-1-ol (II) and (*E*)-8,10-undecadien-1-ol (IV) exhibited threshold values of 10^{-5} μg (same as for I) and were effective over, respectively, seven and nine decades of source load, but they did not reach a response level of 40% at any test amount. (*E*)-9,11-Dodecadien-1-ol (VI) and the monoenes (*E*)-8-, (*E*)-10-, and (*Z*)-10-dodecen-1-ol (VIII–X) showed weak attractivity restricted to one to three test doses. Upwind approaches that broke off a few centimeters from the source were rarely seen in tests with I but frequently occurred with some of the analogs. When combined with 10^{-3} μg of I, all alcohol analogs showed "inhibitory" properties, although the amounts required to obtain a significant lowering of response differed by up to 10^{5}-fold. This amount was the lowest (10^{-4} μg) for the positional isomer VI, and the highest (10^{1} μg) for undecan-1-ol (XI) and dodecan-1-ol (XII). With some mixtures, the presence of the inhibitor appeared to cause an alteration in landing behavior. No synergistic effects were seen in these tests. The results are briefly considered with respect to the sensory perception of the test stimuli and the involvement of minor components in the female pheromone blend.

INTRODUCTION

Virgin female codling moths, *Laspeyresia pomonella* (L.) (Tortricidae: Olethreutinae), release a sex pheromone whose major component has been partially identified as (*E*,*E*)-8,10-dodecadien-1-ol by Roelofs et al. (1971) and Beroza et al. (1974). The synthetic compound (codlemone) is highly attractive to conspecific males; potential minor pheromone constituents have recently been isolated from the effluvia of calling females, as will be considered further below, but synergistic effects over and above codlemone alone have not yet been demonstrated in the field. However, several investigators have reported a decrease of captures of codlemone-baited traps due to the addition of certain other chemicals. A lowering effect of codlemone stereoisomers was recognized early (Roelofs et al., 1971, 1972), although 8,10-dodecadienol samples containing less than 50% of *E*,*E* isomer still retained attractivity. Arn et al. (1974) reported a reduction of codlemone trap captures due to admixture of certain monounsaturated alcohols and acetates in a 1 : 1 ratio. Hathaway et al. (1974) and George et al. (1975) demonstrated strong inhibitory effects for several (*E*,*E*)-8,10-dodecadienyl esters and ethers; the most potent codlemone inhibitors found by these authors were the acetate and ethyl ether analogs, which in amounts of 5% of the pheromone almost abolished trap captures. The mode of behavioral action as well as sensory perception of these various attraction-modifiers remain unexplored.

We have studied behavioral and sensory responses of male codling moths to the primary attractant (codlemone), selected parapheromones (nonpheromonal compounds showing attractivity), and attraction modifiers (increasing or decreasing the response to codlemone or a parapheromone). A wind-tunnel assay was used in conjunction with field trapping tests and electrophysiological recordings from single receptor cells. The wind-tunnel setup was designed to quantify attractive as well as inhibitory or synergistic properties of test compounds, as measured by the percentage of orientation flight responses elicited from a male test population by single compounds and compound mixtures, respectively. This study describes the laboratory behavioral setup and presents results for codlemone and 11 further alcohols.

METHODS AND MATERIALS

Insects. Pupae of *L. pomonella* were obtained from Eidgenössische Forschungsanstalt, Wädenswil, Switzerland, and Bundesanstalt für Pflanzenschutz, Vienna, Austria. The two cultures originated from local wild populations and were reared on semisynthetic diets. The pupae as well as the eclosed male moths were kept under continuous light (ca. 1500 $\pm$ 10 lx) at room temperature (ca.

23°C) until the experiments, which were carried out using 43- to 73-hr-old moths. Care was taken to avoid contact of the males with female odor or synthetic pheromone prior to testing.

Chemicals. The following 12 alcohols (abbreviation and code number are in parentheses) will be treated in this study: (*E*,*E*)-8,10-dodecadien-1-ol (*E*8,*E*10–12:OH, I, codlemone); (*E*,*E*)-8,10-tridecadien-1-ol (*E*8,*E*10–13:OH, II); (*E*,*E*)-7,9-undecadien-1-ol (*E*7,*E*9–11:OH, III); (*E*)-8,10-undecadien-1-ol (*E*8,10–11:OH, IV); (*E*,*E*)-6,8-decadien-1-ol (*E*6,*E*8–10:OH, V); (*E*)-9,11-dodecadien-1-ol (*E*9,11–12:OH, VI); (*Z*)-8-dodecen-1-ol (Z8–12:OH, VII); (*E*)-8-dodecen-1-ol (*E*8–12:OH, VIII); (*Z*)-10-dodecen-1-ol (Z10–12:OH, IX); (*E*)-10-dodecen-1-ol (*E*10–12:OH, X); undecan-1-ol (11:OH, XI); and dodecan-1-ol (12:OH, XII).

Compounds I–V were generously supplied by the Laboratoire des Médiateurs Chimiques INRA/CNRS at Brouessy; VI, by the Tropical Products Institute, London; and VII–X by the Institute for Pesticide Research, Wageningen. Steric purity was 99% or better at receipt; possible isomerization was not checked continuously. The saturated analogs XI and XII were obtained commercially in purissimum quality (Fluka Chemicals, Neu-Ulm, BRD). The chemicals were serially diluted in *n*-heptane and applied onto the dispenser in amounts ranging from 10^{-6} to 10^{3} μg. All samples were stored at −18°C.

Flight Tunnel. The flight tunnel (115 × 50 × 50 cm) was of clear PVC and had a flight compartment of 80 cm. Its upwind and downwind ends were closed with a perlon screen (mesh width 2 mm); the side walls were covered with black cardboard up to a height of 35 cm, with white cardboard beyond. The floor consisted of a stationary black-and-white chessboard pattern (each black and white square 2 × 2 cm). Air was sucked through the tunnel by means of a ventilator (air speed: 0.3 m/sec, measured at the center of the flight compartment), its outlet leading outside the building. The flight tunnel was diffusely illuminated from above by means of eight 60-W bulbs with a light intensity of about 1500 lx (measured at the center of the flight compartment), dimmable down to 15 lx by means of a variable resistor.

Stimulus Application. The chemicals were applied on a flat cotton pad (weight: 3 ± 0.5 mg; diameter 1 cm^2) in 10-μl amounts from the serial dilutions. The pad was positioned in the center of a glass tube (diameter 2.5 cm) whose tapered outlet (diameter 1 cm) touched the upwind screen of the flight compartment from outside, 30 cm above the tunnel floor. The chemical(s) was actively blown into the flight compartment by means of a pump (60 liter/hr) connected with the glass tube. The difference between stimulus and wind-tunnel air velocity equalized after a few centimeters, as indicated by substituting the odor source with a smoke source (NH_4Cl) as well as by measurement with a hot-wire anemometer.

In tests for inhibitors, two identical glass tubes were connected one behind the other; the first was loaded with codlemone, the second with a test analog.

Testing Procedure. An experiment was started by placing a cotton-screen cage (10 × 8 × 8 cm) containing 10–12 males into the flight compartment at 65 cm from the upwind end of the tunnel, at the same height as the pheromone applicator. The moths were then "activated" by "artificial dusk," during which light intensity was halved, by 5-min intervals, down to about 15 lx. During these 30 min of "activation" clean air was continuously applied to the moths from the glass tube applicator. The cotton pad loaded with the test substance was then positioned within the glass tube, and after a further 30 sec the cage with the males was opened. This procedure ensured that before opening the cage, the males had already perceived the test substance(s). During the following 10 min, males landing at the source were counted; in addition, the time interval between opening the cage and landing was recorded for each moth. Landed males were sucked out from the flight compartment to avoid double counts. Males that did not "activate" (as indicated by the lack of walking movements or wing fluttering) or that were sitting on the floor of the tunnel at the end of the 10-min registration period were not taken into account. Each male was tested only once.

A test formulation that elicited no landing at the source in three replicated runs (each including 10–12 males) was not tested further. All other formulations were investigated in five runs, and mean values and standard deviations of responses were calculated for these five replications.

Between experimental series, the level of male activity and the optimal functioning of the experimental setup was verified by control tests of 10^{-3} μg of I (about 70% of responding males). After each test, glass tubes and pheromone applicators were washed with *n*-hexane and oven-dried at 100°C; clean air was sucked through the tunnel for at least 30 min before starting the next test.

RESULTS

Male Behavioral Actions. Little motor activity of the males in the release cage was noted as long as full lights were on (1500 lx). When subjected to the "artificial dusk," most males were observed walking while fanning wings and/or attempting to fly. Once synthetic pheromone (I) or parapheromone was added to the air stream, these activities were further enhanced and additional males—in most cases all—became "active."

On opening the cage, in the presence of stronger stimuli (e.g., 10^{-3}–10^{-1} μg of I), most males immediately oriented towards the odor source, whereas with weaker stimuli (e.g., 10^{-5} or 10^{-4} μg of I) most males first distributed

themselves throughout the flight compartment, outside the odor plume. However, because of frequent spontaneous flights, they accidentally restored contact with the plume and orientation flights towards the source were then induced. These differences in behavior are reflected by a different time distribution of landings at the source, as considered further below. Landings usually occurred directly on the glass tube outlet (touching the upwind screen of the flight compartment) or within 2 cm from it, both with strong and weak stimuli. In control experiments (pure air applied only), this landing place was not preferred to any other parts of the tunnel walls. However, with many pheromone–inhibitor blends, males frequently stopped their approach flight before reaching the source; the distance from the source at which the flight broke off usually increased with the dose of inhibitor. These parameters were not systematically evaluated, since very short upwind flight approaches were not surely distinguished from spontaneous flights.

Flight tracks in response to stronger stimuli usually were rather straight upwind, with cross-wind excursions not exceeding approx. 2 cm. With weaker stimuli, convoluted flight tracks with enlarged cross-wind excursions in both the horizontal and vertical plane, partly resulting in a "spiral flight," dominated. It is noteworthy that with most attractant–inhibitor blends, flights that were terminated by landing at the source were not obviously different from those with the respective amount of codlemone alone: the "inhibitor," therefore, primarily affected the number of approach flights, rather than the flight pattern itself.

Attraction Response to Codlemone. "Successful flights" (i.e., approach flights terminated by landing at the source) were induced over the range of 10^{-5}–10^{1} μg of I (Figure 1); the lowest test amount of 10^{-6} μg did not elicit any such response. On increasing the source load from 10^{-5} to 10^{-3} μg, the proportion of responding males increased to 70%. The dose–response curve then formed a plateau extending over three decades of source load; with further increase, from 10^{-1} μg up to 10^{1} μg, the percentage of successful flights strongly decreased (and may be expected to become zero at 10^{2} μg, not tested).

Except for the lowest attractive amount of 10^{-5} μg, most responding males reached the source within the first 1 min of registration (Figure 2). The high value of responses at 10^{-3}–10^{-1} μg is evidently due to upwind starts within this first 1-min interval, i.e., starts directly from the release cage shortly after opening. However, even within this plateau of the dose–response curve, the increase of lure dose from 10^{-3} to 10^{-1} μg further shifted responses towards the very beginning of the registration period; with 10^{-2} and 10^{-1} μg of I some males reached the source only 5 sec after release. (These very short response times are not apparent from the histograms because of their class interval). With lure doses of 10^{0} and 10^{1} μg, too, the few males that responded all arrived at

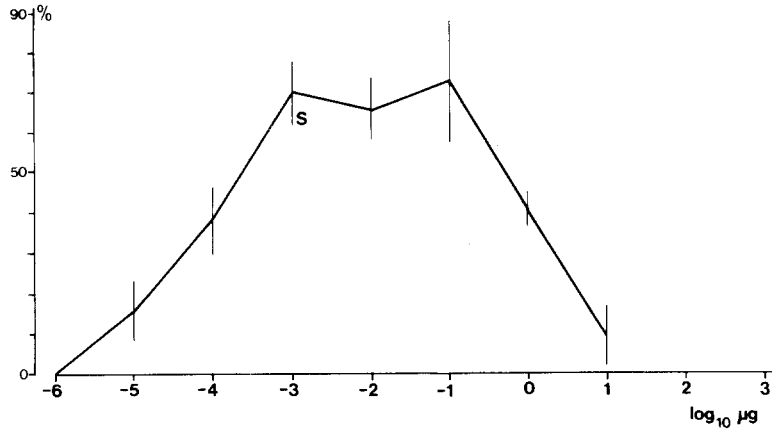

FIG. 1. Response of male *L. pomonella* towards eight different amounts of codlemone (I) in a wind tunnel. Values represent percentage (mean ± SD) of males displaying orientation flight completed by landing on the source, within 10 min of registration (S denotes standard response to 10^{-3} µg, used as the reference in tests on compound mixtures, presented in Figure 5).

the source within 1 min; the strongly reduced efficacy of these very high doses is, thus, obviously a result of the lack of responses after this interval.

Attraction Response to Analogous Alcohols. The mono- and diunsaturated alcohol analogs were tested for attractancy in the same manner as used for I. All of these, with the exception of the *Z*8 monoene (VII), elicited approach flights terminated by landing at the source. Compound VII was tested at 10^{-4} and 10^{-3} µg in eight runs; only one male (of 96 tested) displayed an approach flight, but this flight stopped 2 cm from the source. Among the other eight alcohols, the attractant power, as measured by both the threshold dose and the peak value of responding males, was highly different (Figure 3). Although some analogs (e.g., *E*8,10–11:OH, IV) showed very low threshold values of 10^{-5}–10^{-4} µg, none of these reached a peak value of 70% as measured for I.

With respect to this peak value, *E*7,*E*9–11:OH (III) was the most potent analog. This compound yielded a dose–response curve similar to that of I but shifted towards a dose about 100-fold higher and not exceeding response values of 50% at the plateau, which again extended over three decades of lure dose (Figure 3). The C_{13} homolog (II) showed a lower threshold value than found for III, differing by less than 10-fold from the codlemone (I) threshold. Attractive properties of II, as measured by the number of responding males, extended from 10^{-5} to 10^{3} µg, thus covering a broader range of effective lure dose than found with any other test compound during the present study. However, the

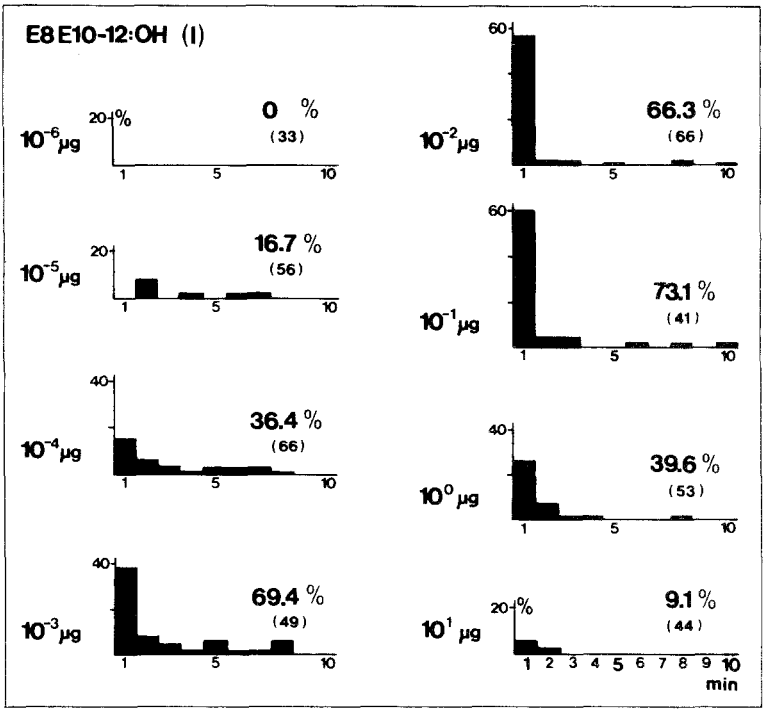

FIG. 2. Time distribution of orientation flight responses of male *L. pomonella* to codlemone (I) sources (same data as in Figure 1, specified for 1-min intervals; number of "activated" test males given in parentheses).

slope of the dose–response curve for II is much flatter compared to the dose–response curve for I or III, not forming a plateau and not reaching a response value of 40% at any test dose (Figure 3).

An even flatter dose–response curve applies to *E*8,10–11 : OH (IV); despite the very low threshold, responses to this compound did not reach a level of 20% at any test amount (Figure 3). The two other dienes, V and VI, showed response curves restricted to two or three decadic steps of stimulus amount and not exceeding a peak value of 10%. The threshold doses for these two compounds differed about 10^4-fold, thus totally separating the range of effective lure dose (Figure 3). Response curves restricted to a narrow range of lure dose were also obtained for the *Z*10 and *E*10 monoenes (IX and X). In the experiments with X, however, the number of approach flights that stopped shortly (1–5 cm) before reaching the source was strongly increased within the range of 10^{-3}–10^0 µg, exceeding by approx. sixfold the number of flights completed by

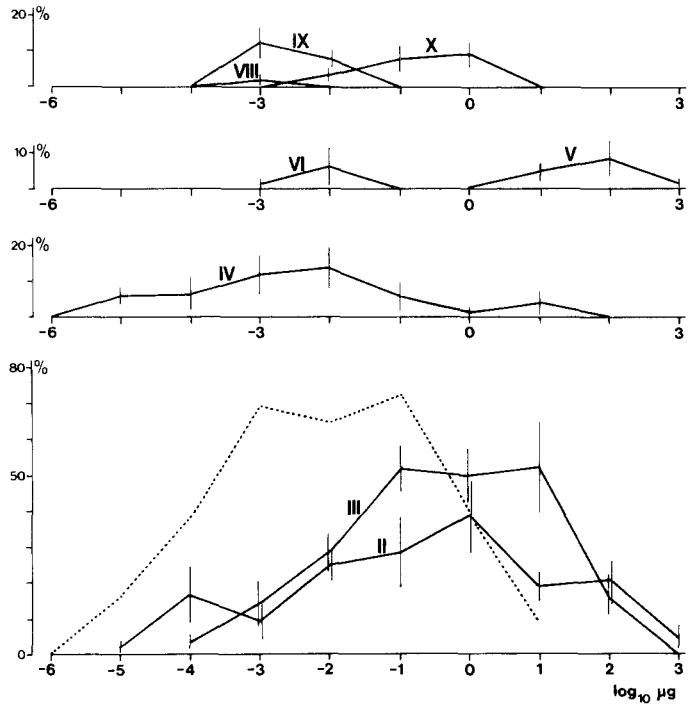

FIG. 3. Response (as in Figure 1) of male *L. pomonella* to nonpheromonal alcohols II–IX (dotted line shows response to I, taken from Figure 1).

landing at the source. These incomplete flights, however, were not counted because of the predetermined parameters for evaluation of responses. The dose–response curve for X, therefore, might not sufficiently reflect the compound's real attractivity. Finally, with the *E*8 monoene (VIII), tested in the range of 10^{-4}–10^{-2} µg, only one male arrived at the source (Figure 3). This compound is, therefore, almost as ineffective as the *Z*8 isomer (VII), mentioned above.

Time distributions of landings are exemplified in Figure 4 for two analogous compounds, *E*7,*E*9–11:OH (III) and *E*8,*E*10–13:OH (II). The dose–response curve for III is similar to that of I, as pointed out above. The data presented in Figures 2 and 4 show that the time distributions are also similar between I and III when corresponding parts of the two dose–response curves are compared. Thus, at low lure doses of III (10^{-4} and 10^{-3} µg), landings were more or less equally distributed over the 10-min period, whereas with increasing lure dose, the time interval from release until landing continuously decreased (Figure 4). In the range of the plateau of the dose–response curve, 10^{-1}–10^{1}

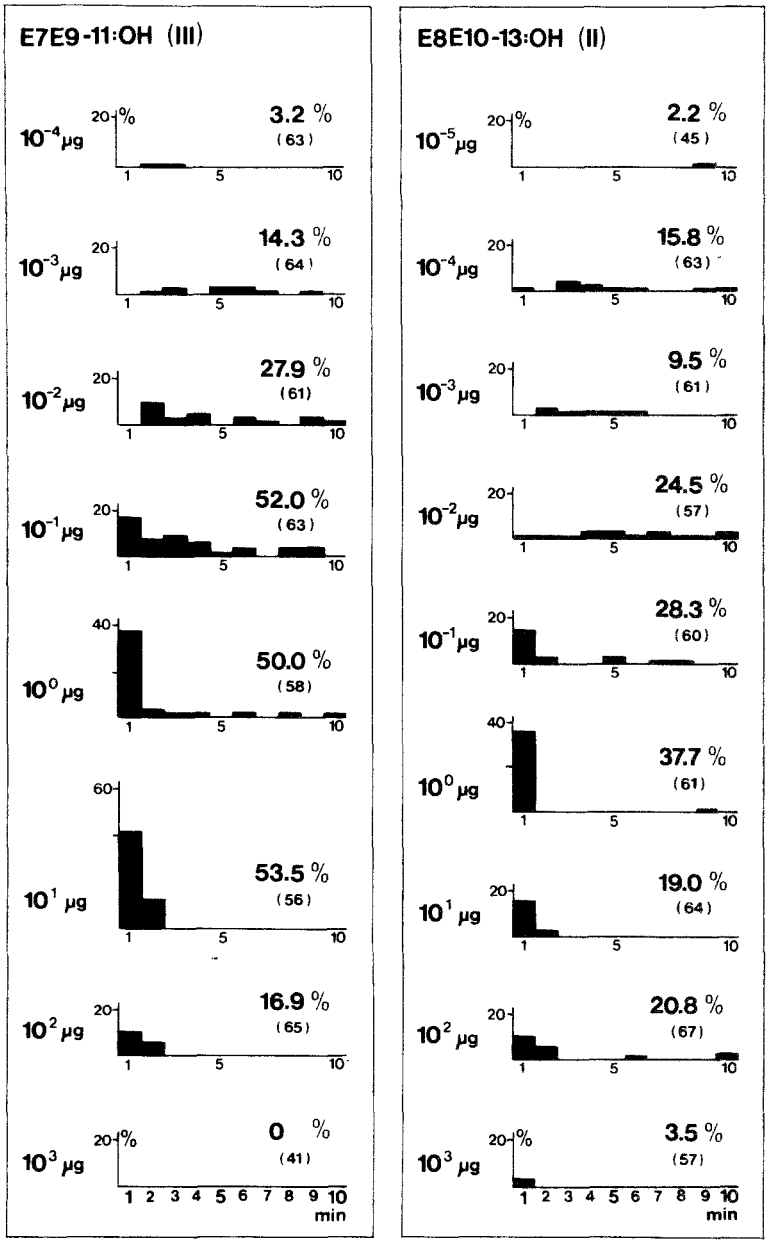

FIG. 4. Time distribution (as in Figure 2) of orientation flight responses of male *L. pomonella* to nonpheromonal alcohols III and II.

μg, responses during the first 1-min interval became dominant. This closely compares to respective parts of the codlemone (I) dose–response curve.

For compound II, which has revealed a flattened dose–response curve lacking a plateau (Figure 3), the decrease in response times with increasing lure dose is evident also (Figure 4). Thus, males preferentially arrived at the source during the first 1 min of registration at 10^{-1}–10^{3} μg of II but not at 10^{-5}–10^{-2} μg (Figure 4). Closer comparison between I and II is precluded by the different shapes of the dose–response curves, but it is noteworthy that at the peak value of II, 10^{0} μg, almost all (22 of 23 responding) males arrived within the first 1 min, although the response rate was only 37.7%. By comparison, 10^{-4} μg of I revealed a response rate of 36.4%, but more than half the arrivals occurred after the first 1-min interval (Figure 2).

In the case of compounds with only a weak attractivity, restricted to a narrow range of lure doses (compounds V, VI, IX, X), the landing responses were irregularly distributed over the 10-min period, with only a weak preference for the first 1-min interval.

Inhibitory Effects of Analogous Alcohols. The alcohols II–XII were also tested for their ability to reduce the number of oriented flights towards a source of codlemone (I) when simultaneously delivered with it into the same airstream. All binary mixtures considered here were made with 10^{-3} μg of I, the onset of the plateau of its dose–response curve (Figure 1).

All alcohols were effective in reducing responses to 10^{-3} μg of I. Among the 11 compounds, however, the threshold doses required to obtain a significant lowering in the number of responding males differed up to 10^{5}-fold (Figure 5). Furthermore, the slope of the "inhibition curves," as measured from the first significant lowering up to the total abolishment of responses, varied greatly; total inhibition required an increase of dose of less than 10^{2}-fold for some analogs (e.g., XI and XII) but more than 10^{5}-fold for others (e.g., II). With three compounds, II, III, and V, total inhibition was not obtained even on addition of 10^{3} μg (the highest stimulus amount used in this study).

The *E*9,11–12:OH (VI) was the most inhibitory alcohol. This positional isomer of the pheromone significantly reduced responses as a 10% admixture to 10^{-3} μg of I, although a further 10^{3}-fold increase of stimulus amount was required to abolish responses totally (Figure 5A). A similar flat "inhibition curve," but shifted towards 10^{4}-fold higher doses as compared to VI, was obtained for *E*8,*E*10–13:OH (II) (Figure 5A). However, as was apparent from a comparison with the "attraction curve" of this compound (Figure 3), within the range of 10^{-1}–10^{3} μg of II, the number of responding males did not significantly differ whether or not 10^{-3} μg of I was added. Similarly, with admixture of 10^{1}–10^{3} μg of *E*7,*E*9–11:OH (III) to 10^{-3} μg of I, the number of responding males was the same as for the respective amount of III alone.

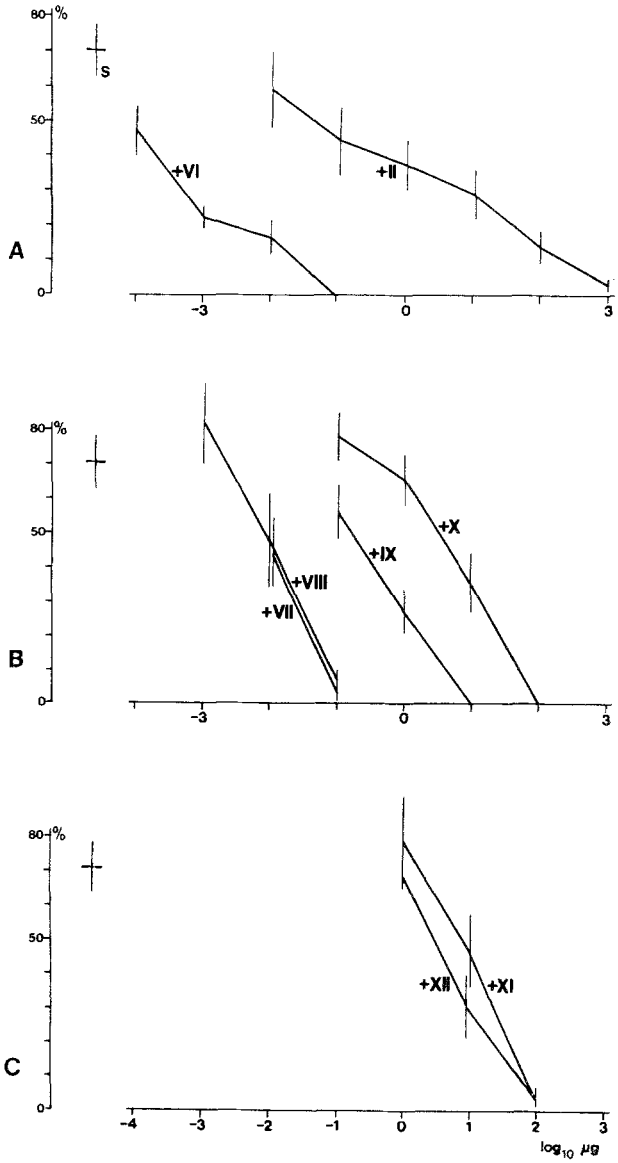

FIG. 5. Response of male *L. pomonella* to binary mixtures of 10^{-3} µg of I with varying amounts (abscissa) of alcohols II–XII (bar at upper left indicates response to 10^{-3} µg of I alone, taken from Figure 1).

The "inhibitory curves" obtained for the monounsaturated alcohols VII–X were, by comparison, much steeper, reaching total inhibition of responses to I within two decadic steps of stimulus amount (Figure 5B), although the threshold doses were up to 10^5-fold above that of *E*9,11–12 : OH (VI). The same holds for the saturated analogs XI and XII (Figure 5C).

The C_{10} homolog (V) showed the least inhibitory properties of all alcohol analogs listed. With 10^1 μg of V added to 10^{-3} μg of I, the number of responding males was significantly reduced; however, even in the presence of 10^3 μg, about 30% of the test males successfully oriented towards the 10^{-6}-fold lower amount of I present in the mixture (results not specified by figures).

Approach flights not terminated by landing were generally found to be more frequent in experiments with binary mixtures than with 10^{-3} μg of I alone. The inverse, however, was found with the *E*10 monoene (X): In the presence of 10^{-3} μg of I, the number of flights that stopped before reaching the source was far lower as compared to tests with X alone, where uncompleted flights predominated over flights terminated by landing.

DISCUSSION

Mating flights of male codling moths in the field usually occur within 1 hr before and after sunset (Wong et al., 1971; Batiste et al., 1973a,b; Mani et al., 1974). This periodicity is reflected by a pronounced circadian rhythm of male responsiveness to female sex pheromone in laboratory tests. Castrovillo and Cardé (1979) and Arn et al. (1985) studied pheromonal behavioral responses in *L. pomonella* males kept under a 16 : 8 hr light–dark photoperiod, using a tube olfactometer and a wind tunnel, respectively. In their studies, responses towards synthetic female pheromone were highest within the first 3 hr of scotophase. However, even with males at a circadian stage 3 hr prior to scotophase, the full level of 70–80% of upwind orientation responses could be induced by lowering light intensity from 1500 to 15 lx (Castrovillo and Cardé, 1979).

In the present work, "artificial dusking" was used throughout to induce high pheromonal responsiveness in the *L. pomonella* males. Differing from the procedure applied by the above authors, the males were kept in continuous light (1500 lx) from the late pupal stage until test, including 43–73 hr of adult life. Various tests (R. Preiss, unpublished results) showed that *L. pomonella* males, submitted to this pretreatment followed by the 30 min "dusking," revealed the same level of approx. 70% orientation flight responses towards 10^{-3} μg of codlemone (I), irrespective of the actual time of day. This permitted us to conduct our test program around the clock.

In our experiments and those of Arn et al. (1985), males had to orient by flight within an odor plume, whereas in the experiments of Castrovillo and Cardé (1979), moths had to walk upwind within an homogeneous odor stream.

The dose–response curves for I as measured by the two different methods both run through a maximum, although only in our experiments did the dose–response curve form a pronounced plateau, extending over three decadic steps of lure dose. Within this plateau the only observed effect of increased lure dose was a reduced response time as measured from male release until landing at the source.

In all three studies, the dose–response curves strongly declined at very high lure doses. The cause of this "overdose effect" is unknown. In our wind-tunnel experiments, the overdose stimuli primarily affected the number of approach flights rather than the flight pattern itself; e.g., flights stopping before reaching the source were not found to occur more frequently at these high doses.

Further comparison of the dose–response curve for I (Figure 1 and 2) with those obtained by other researchers with tube olfactometers (Castrovillo and Cardé, 1979) or wind tunnels (Arn et al., 1985; Einhorn et al., 1986) is limited by a number of factors, including the spatial arrangement of the experimental setup, the type of odor dispenser used, the kind of behavioral action(s) evaluated, and the predetermined time of observation. Unpublished wind-tunnel results showed that rubber caps (such as used by Arn et al., 1985) release olefinic test compounds at an approx. 10^3-fold lower rate compared to filter papers or cotton pads; this could explain in part the marked difference in threshold dose for I between the study of Arn et al. (1985) and ours. Arn et al. also evaluated the percentage of males completing orientation flight by landing at the source. However, in their tests males that did not take off within 1 min after release or that touched parts of the tunnel wall other than the odor source were taken as nonresponding (and discarded). This differs from our arrangement in which males were allowed to start or restore contact with the plume during flight over the entire 10-min exposure period.

The olfactometer study of Castrovillo and Cardé (1979) evaluated male upwind orientation within a period restricted to 30 sec, which resulted in a high threshold value (10^{-2} μg) for I. We are fully aware that, in our setup too, the number of males reaching the source (and thus, the attractivity of the compound as given in the Results section) strongly depended on the predetermined duration of the exposure period following male release. Restricting exposure to, e.g., 1 min would have resulted in a higher threshold dose and a lower percentage of responding males, as can easily be seen from the time distribution of responses to I (Figure 2). With analog II, the flat dose–response curve would, in the case of a 1-min exposure period, start at a higher lure dose and the maximum at 10^{-2} μg would become more pronounced. Conversely, in the case of unlimited exposure time, the percentage of responding males would theoretically approach 100% for any effective lure, if other limiting factors would not interfere. In our wind-tunnel experiments, some males were indeed found to approach the source even after the 10-min exposure period.

It also should be kept in mind that, in our wind-tunnel assay, orientation flight is measured over only a short distance (< 1 m). It is conceivable that a field bioassay, where orientation towards the odor source over greater distances is evaluated, should be even more sensitive in discerning the more effective attractant. In fact, whereas some of the alcohol analogs mentioned in this paper induced a considerable rate of orientation flight towards the source (mostly terminated by landing at the source), in field experiments these same compounds in lure doses of up to 1000 μg revealed only poor, if any, captures of *L. pomonella* males (E. Priesner and E. Mani, unpublished results). Likewise, threshold values for inhibitory effects of compounds in admixture to codlemone were lower in field experiments than in the wind-tunnel tests. Thus, Hathaway et al. (1974) found that the addition of undecanol (XI) to codlemone (I) in a ratio of 20 : 1 reduced trap catches of *L. pomonella* males by approx. 50%. In our wind-tunnel tests a more than 1000-fold overdose of XI over I was required to reduce orientation flight responses (Figure 5B). A lower threshold dose for field as compared to wind-tunnel responses was also found for some other codlemone inhibitors, including some highly potent ester and ether analogs of codlemone (E. Priesner and R. Preiss, in preparation).

It was interesting to find that most test alcohols elicited attraction responses from *L. pomonella* males when offered as single compounds, but also reduced responses to I when simultaneously delivered with it into the same airstream. This shows that the same chemical in the same test species may be classified as both an "attractant" and an "inhibitor," depending on the kind of behavioral test.

In this context the reduction of the percentage of responding males at overdose stimulus amounts must again be considered. This phenomenon was not only found with I where responses declined from 73% at 10^{-1} μg to 10% at 10^{1} μg (Figure 1); it similarly occurred with other more attractive analogs, such as *E*7,*E*9–11 : OH (III) and *E*8,*E*10–13 : OH (II) (Figure 3). Accordingly, "inhibition curves" such as obtained for binary mixtures between higher amounts of III or II with 10^{-3} μg of I (codlemone) cannot be considered as reflecting responses evoked by the very low amount of I present in these mixtures: These "inhibition curves" are not different from the respective parts of the "attraction curve" of the analogous compound alone, and thus evidently represent the decreasing response to overdose stimuli of these compounds themselves, apparently unaffected by the admixture of the very small amount of I (see Figures 3 and 5A for compound II).

Contrary to this, the dose–response curves obtained for the binary mixtures of the other eight alcohol analogs with 10^{-3} μg of I can be considered as "true inhibition curves": these curves (Figure 5) are fully separated from the respective "attraction curves" of the test compounds alone (Figure 3) and should thus

merely reflect the response to the portion of 10^{-3} μg of I present in the test mixtures, continuously reduced due to the dose of the other mixture component.

We have attempted to interpret the various attractive and inhibitory effects shown by the 11 test alcohols by considering their mode of sensory perception by types of receptor cells present on the male antenna. Electrophysiological recordings (E. Priesner, in preparation) have shown that the olfactory hair sensilla (s. trichodea) on male antennae of *L. pomonella* contain three different types of alcohol-sensitive receptor cells that are specific, respectively, to *E*8,*E*10–12:OH (I), *Z*8,*E*10–12:OH (a codlemone stereoisomer, not considered in this study), and *E*9,11–12:OH (compound VI of this report). No further types of alcohol receptors were found. Each test alcohol produced its own particular pattern of nerve impulse activity across the three cell types. Thus, codlemone acted upon its own type of specialist cell but also elicited weak responses from the two other cells. Similarly, other more attractive alcohols, such as II, III, and IV, had their main stimulatory effect on the codlemone cells.

We were, therefore, surprised to find that even a compound such as analog VI, which is primarily perceived via its own type of specialist cell, did induce orientation flight responses. Yet, in the electrophysiological measurements, compound VI at higher doses evoked nerve impulse discharges from the codlemone receptor cells as well, at a rate approximately 100-fold below the key stimulus (I). In the wind-tunnel experiments too, compound VI revealed a response threshold value shifted approximately 100-fold from the codlemone (I) threshold (Figures 2 and 4). These and further results are leading us to propose that the various attractive effects of test chemicals observed in the wind-tunnel tests should be triggered via excitation of the codlemone receptor cells, eventually counteracted according to simultaneous activation of further cell types. Results of the electrophysiological analysis, and a detailed interpretation of wind-tunnel and field trapping results in terms of receptor responses, will be presented elsewhere (E. Priesner, in preparation).

The codling moth sex pheromone, long considered to be a single-component attractant system, appears to include additional (secondary) components as evidenced from male behavioral responses to live females or female extracts in comparison to synthetic codlemone (Bartell and Bellas, 1981; Einhorn et al., 1984; R. Preiss, unpublished results) and the results of chemical analyses. Einhorn et al. (1984), Arn et al. (1985), and Guerin et al. (1985) isolated from extracts of pheromone glands of unmated *L. pomonella* females a number of further compounds, including the following eight alcohols (in parentheses, percent amount relative to I): *E*8,*Z*10–12:OH (3–5%), *Z*8,*E*10–12:OH (0.5%), *E*9–12:OH (4–9%), *E*8–12:OH (0.8%), 10:OH (0.2%), 12:OH (30–50%), 14:OH (10–17%), 16:OH (2–13%), and 18:OH (4%). These eight alcohols were also present, at similar proportions, in effluents emanating from calling

females (Arn et al., 1985). In wind-tunnel tests conducted by the latter authors, 12:OH (XII) when added to I appeared to enhance flight responses, whereas the other alcohols in relative amounts such as found in the extracts had no apparent synergistic effects (Arn et al., 1985; Einhorn et al., 1986). The data presented by Arn et al. suggest that the addition of XII "widens" the dose range over which males are optimally attracted to I, thus "restoring" male responses to both too low or too high an amount of the primary attractant. However, as also stated by Arn et al., the addition of XII to the nonoptimal dose of I mainly caused an improvement of the orientation flight itself (leading more males up to the source), rather than an increase in the number of males starting a flight response.

We have not studied, in our wind-tunnel experiments, additions of XII to amounts of I lower than 10^{-3} μg or greater than 10^{-1} μg (the plateau of its dose–response curve); however, a "restoring" effect such as found by Arn et al. is unlikely to occur in our setup, where orientation flights towards different test amounts of I (including those below and above the dose–response plateau) almost all led up to landing at the source (the main dose effect of I in our setup being the number of males starting a flight response, not the flight pattern itself). Electrophysiologically, we did not find a cell type specialized for compound XII; rather, this saturated analog at higher test amounts excited all three types of alcohol receptors mentioned above. It is also noteworthy that compound XII did not show synergistic effects in field trapping tests (Einhorn et al., 1984; Arn et al., 1985).

The compounds specifically acting on the two other types of alcohol receptors mentioned above were *Z*8,*E*10–12:OH and *E*9,11–12:OH. Behaviorally, the *Z*8,*E*10–12:OH showed strong modifying effects on male responses to I, not considered in this report, but the extremely low amount of this stereoisomer found in the female gland effluents makes it an unlikely candidate for a secondary pheromone constituent. The occurrence of the *E*9,11 positional isomer (compound VI of this study) in the *L. pomonella* female pheromone, and its modifying effects in field trapping tests, have not yet been reported.

Acknowledgments—We are grateful to Drs. K. Russ (Vienna) and E. Mani (Wädenswil) for their continuous supply of *L. pomonella* pupae over a period of six years, and Drs. C. Descoins (Brouessy), D. Hall (London), and S. Voerman (Wageningen) for generously supplying the test chemicals. We particularly acknowledge the skillful assistance in the wind-tunnel experiments of A. Hofer, B. Huber, W. Kolbinger, S. Schmidt, J. Schuler, and B. Stagge. We thank Dr. H. Arn (Wädenswil) and our collegues at Seewiesen for their constructive comments, and Dr. L. Williams for correcting the English.

CHEMICAL TRAIL MARKING AND FOLLOWING BY CATERPILLARS OF *Malacosoma neustria*

STEVEN C. PETERSON[1]

Department of Entomology
Agricultural University at Wageningen
6700 EH Wageningen, The Netherlands

(Received February 23, 1987; accepted May 11, 1987)

Abstract—Chemical trail marking and following by gregarious caterpillars, *Malacosoma neustria* L. (Lepidoptera: Lasiocampidae), was studied in the laboratory. As in other species of *Malacosoma*, larvae deposit a trail pheromone from a sternal secretory site when searching the host for food. Larvae in the vanguard of foraging columns establish chemical trails as they explore new territory. Marking behavior diminishes as successive unfed foragers utilize the trail. These exploratory trails are subsequently overmarked by fed larvae returning to the tent. Other foragers follow the trails of fed larvae in preference to trails of unfed larvae. Thus, like the eastern tent caterpillar, *M. americanum*, successful foragers of *M. neustria* recruit colony-mates to feeding sites. The chemical activity of both recruitment and exploratory trails degrades slowly, suggesting that the trail pheromone of *M. neustria* is a nonvolatile substance. Caterpillars of *M. neustria* readily follow the nonvolatile trail pheromone which has been identified from *M. americanum*, 5β-cholestane-3,24-dione.

Key Words—Trail pheromones, trail marking, 5β-cholestane-3,24-dione, tent caterpillars, *Malacosoma nuestria* L., Lepidoptera, Lasiocampidae, recruitment, leader-follower behavior.

INTRODUCTION

Despite recent advances in research on trail pheromones of caterpillars, the chemical basis of silk trail following has been established for only a few species (reviewed in Fitzgerald and Peterson, 1988). The most thoroughly studied of these is the eastern tent caterpillar, *Malacosoma americanum* (F.), which pro-

[1] Current address: Department of Biological Sciences, University of Maryland, Baltimore County, Catonsville, Maryland 21228.

0098-0331/88/0300-0815$06.00/0

duces a steroidal trail pheromone, 5β-cholestane-3,24-dione, from a sternal secretory site (Fitzgerald and Edgerly, 1982; Crump et al., 1987). Another North American species of tent caterpillar, *M. disstria* Hübner, also deposits a chemical marker (Fitzgerald and Costa, 1986), which suggests that chemical trail marking is common in *Malacosoma*. This paper investigates chemical trail marking and following in a third species of tent caterpillar, *M. neustria* L.

Caterpillar trail pheromones may serve to maintain aggregations or to facilitate exploration (Fitzgerald and Costa, 1986), but they can also function as recruitment signals to indicate pathways leading to food (Fitzgerald, 1976; Fitzgerald and Peterson, 1983). *M. americanum* is the only caterpillar reported so far to use its chemical marker to recruit colony-mates to food finds (Fitzgerald, 1976). Eastern tent caterpillars forage from a stable, centrally located tent. Larvae mark trails during exploration of new territory, and the trails are reinforced (overmarked) by fed larvae as they return to the tent. These recruitment trails lead directly to food and are followed preferentially by hungry larvae (Fitzgerald, 1976).

Here the hypothesis that *M. neustria* caterpillars produce a chemical marker which recruits others to food sources was tested in the laboratory. Experiments were done to (1) localize the site of secretion of the trail marker, (2) observe the marking behavior of fed and unfed larvae, (3) test the preference of larvae for trails of fed caterpillars, (4) investigate aging of the trail, and (5) test the responses of caterpillars to the trail pheromone identified from *M. americanum*.

METHODS AND MATERIALS

Insects. Malacosoma neustria is a polyphagous species widespread in Europe and Asia (Stehr and Cook, 1968). Unhatched egg masses were collected from oak (*Quercus robur* L.) near Almere, The Netherlands. Eggs were stored at 6°C and 80% relative humidity. Egg masses were removed from refrigeration, hatched, and larvae were kept in plastic rearing containers. Young leaves of apple (*Malus* sp.) or oak were provided daily. All experiments were conducted at a controlled temperature of 21°C.

Y-Maze Bioassay. Comparisons of trails were made using a Y-maze procedure modified after Fitzgerald and Edgerly (1979). Groups of larvae (N = 8–10) established trails across long strips of 3-mm-wide white filter paper, suspended horizontally between two rods. The strips were then cut into 3-cm-long sections and assembled into Y mazes, with a 60° angle between the arms. The maze was attached with masking tape to the bottom of a glass Petri dish, which was cleaned periodically with 90% ethanol to prevent contamination by pheromone and silk. The choices of caterpillars were tested by placing third-instar larvae one at a time on the stem of the maze and allowing them to crawl to the choice point. A choice for either side was granted if the caterpillar completely

passed onto one of the branches. The arms of the maze were replaced after each replicate, but the stem was reused. To exclude artifacts due to side preferences, the position of experimental and control branches was alternated. To prevent direct overhead light from influencing the behavior of the larvae, experiments were conducted in the closed end of a cardboard box which was open at one end to allow observation. The box was laminated with sheets of white filter paper to further eliminate visual cues.

Secretory Site. Caterpillars of *M. americanum* and *M. disstria* produce their trail pheromone from a sternal cuticular site between the anal prolegs on the tip of the last abdominal segment. To lay a trail, the abdomen is pressed against the substrate as the caterpillar walks (Fitzgerald and Edgerly, 1982; Fitzgerald and Costa, 1986). Third- and fourth-instar caterpillars of *M. neustria* were observed with a hand lens to determine whether they laid trails in this manner. Larvae were allowed to crawl onto the filter-paper strips spontaneously without handling by connecting the strips to the rearing container. Larvae were fed ad libitum up to 6 hr before the experiments or were kept chilled overnight without food. Experiments were initiated when most of the larvae in the group were observed to be active.

In each of the 18 replicates of this experiment, the degree of trail marking was estimated for the first, fifth, and tenth larva to cross the trail as each traversed the middle 10 cm of the 30-cm-long strip. Since larvae do not always maintain continuous marking, their behavior was classified according to the approximate amount of time they were observed with their tip in contact with the trail: marking (>50% of the time with tip in contact with the trail), discontinuous marking (>5% but <50% tip contact), and not marking (<5% tip contact).

Tests to determine the site of pheromone secretion were conducted using the "tip-wiping" method (Fitzgerald and Edgerly, 1982; Fitzgerald and Costa, 1986). A folded piece of filter paper was wiped across the last abdominal segment of a single large (fourth-instar) caterpillar to make a residue trail of 3 cm length. As a control, surface residue was wiped from the same caterpillars' anus onto a different piece of filter paper. A smaller caterpillar (second-instar) was placed at one end of the test trail and another was placed at one end of the control trail. Each was observed to determine whether it followed the crease to the trail terminus within 3 min. The test was repeated 16 times.

A second experiment was carried out by obstructing the abdominal tip of eight fourth-instar caterpillars with liquid plastic (New Skin, Beecham Properties, St. Helen's, England). Control caterpillars ($N = 8$) were treated with New Skin on the abdomen between the first pair of abdominal prolegs. The trails made by treated insects were compared to the trails made by control caterpillars using the Y-maze test protocol described earlier.

Recruitment. Recruitment behavior was tested by comparing the overmarking of trails by fed and unfed caterpillars and observing the response of

other caterpillars to these trails in choice tests. One paper strip was connected at the far end to a sprig of foliage, and a control strip was connected to a bare wooden rod. Test and control trails were made simultaneously by letting eight starved larvae per trail traverse each strip. Larvae were allowed to crawl onto the strips without handling. Three of these larvae were allowed to visit the feeding site (or the site without food) and return to the starting point. The overmarking of trails by each group of three larvae was observed on their return. The strips were then cut, and the trails of fed and unfed caterpillars were compared using the Y-maze bioassay. A section of the trail of fed larvae was used as the stem of the Y-maze in all tests. The experiment was repeated six times using apple foliage and four times using oak foliage.

Trail Aging. The trails of other species of *Malacosoma* degrade slowly, but differences between trails of fed larvae and trails of unfed larvae of *M. americanum* persist over a period of 6 hr (Fitzgerald, 1976; Fitzgerald and Costa, 1986). *M. neustria* trails were aged at room temperature and were compared with fresh trails using the Y-maze bioassay as previously described. Eight larvae traversed each strip to establish a test trail. After 2 hr of aging, the test trail was compared to a fresh trail prepared in the same manner. The 2-hr-old test trail was then aged for an additional 4 hr (for a total of 6 hr of aging) and compared to a second fresh trail. The same sections of the aged trail were used in the comparison with fresh trails at 2 and at 6 hr. To avoid contamination, larvae were prevented from crawling more than midway onto a trail arm. The used arms of the Y maze were reversed, and the unused half was abutted to the stem of the Y for the subsequent test. Fresh and aged exploratory trails were compared in two separate tests, as were fresh and aged recruitment trails in which three of the eight larvae were allowed to feed and return. A section of the fresh trail was used as the stem of the Y maze in each of these tests.

In addition, aged trails of fed larvae were compared with aged trails of unfed larvae at 2 and at 6 hr using the protocol already described. A section of the fed caterpillars' trail was used as the stem of the Y maze in each of the tests.

Response to Chemicals. The response of *M. neustria* caterpillars to the trail pheromone of *M. americanum*, 5β-cholestane-3,24-dione, was tested. A stock solution of 0.1 mg pheromone/ml solvent was made by dissolving the synthetic substance in methanol (Merck). In addition, a 0.1 mg/ml solution of 5β-cholestan-3-one was also tested. This compound, which differs from the identified trail pheromone by lacking an oxygen at C-24, elicited trail following in caterpillars of *M. americanum* but was not a component of their secretion (Crump et al., 1987).

Test compounds were applied to white paper using microcapillary pipetes calibrated to deliver 4 μl in a 2-mm-wide streak onto a 10-cm length of paper. A positive response was recorded when the caterpillar walked from one end of the trail to the other. Responses of caterpillars to 5β-cholestane-3,24-dione were

tested at five trail dosages ranging from 0.001 to 0.1 mg/ml (N = 20 at each dosage). As a control, 20 larvae were tested with pure methanol. In addition, the responses of 20 larvae to trails prepared from 0.1 mg/ml 5β-cholestan-3-one were also tested.

Statistical Analysis. Results were analyzed using a G test (Sokal and Rohlf, 1981), either testing for significant differences between treatments or for a difference from the expected 1 : 1 ratio in the Y-maze tests.

RESULTS

Exploratory Marking and Secretory Site. Malacosoma neustria larvae were observed dragging their abdominal tips against the substrate. When 10 larvae were let onto a 30-cm-long paper strip and the marking of the first, fifth, and tenth larva in the column was observed, the frequency of marking declined with caterpillar order (Figure 1). The caterpillars often crossed the paper strip without reversing direction, so that columns of foragers were evidently led by larvae in the vanguard. Although larvae were sometimes reluctant to initiate a trail independently of other caterpillars, only 11 of 180 larvae (6.1%) reversed direction after passing 15 cm onto the strip.

The abdominal tip was determined to be the site of marker secretion by the wiping test. All larvae tested followed the 3-cm residue trail to its terminus

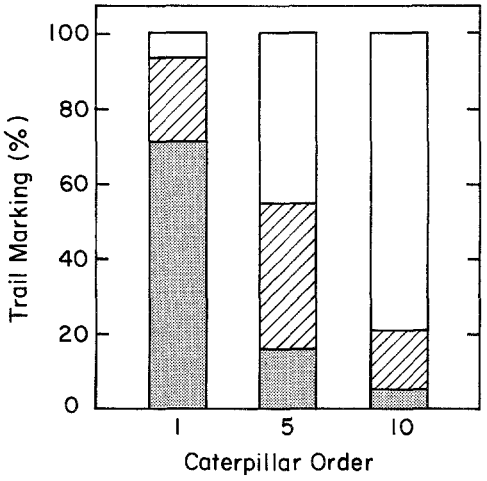

FIG. 1. Percentage of *M. neustria* trail marking as a function of order on the trail. Shading = marking; cross-hatch = discontinuous marking; open = not marking (see text). The frequency of marking vs. not marking is significantly greater for caterpillars at position 1 than for caterpillars at position 10 ($P < 0.005$, two-way comparison G test), N = 18 tests.

($N = 16$; time to follow trail = 25.5 ± 11.0 sec, mean ± SD). Only one of 16 larvae followed the control trail in the 3-min test period.

Furthermore, in two separate Y-maze tests, larvae were able to discriminate trails made by control caterpillars from trails made by caterpillars with their abdominal tip covered with New Skin. In the first test, 17 of 18 larvae chose the control trail and in the second test all 18 larvae chose the control trail ($P < 0.005$, G test).

Recruitment. The results of the recruitment experiments are given in Table 1. Caterpillars returning after feeding overmarked their trails, but unfed larvae did not overmark. Overmarking occurred to apple as well as to oak foliage. In Y-maze tests, significantly more larvae chose the trails of fed larvae over the trails of unfed larvae.

Trail Aging. The results of the trail aging experiments are given in Table 2. Both exploratory and recruitment trails were only slightly less attractive than fresh trails of the same type after 2 hr of aging, but after 6 hr the fresh trails were clearly favored. Recruitment trails were strongly preferred over exploratory trails at 2 hr and at 6 hr of aging.

Chemical Trail Following. Larvae of *M. neustria* readily followed the pheromone of *M. americanum*. The response of caterpillars diminished with

decreasing concentration of 5β-cholestane-3,24-dione, from 100% positive response at 0.1 mg/ml until no response was observed at 0.001 mg/ml (Figure 2). No response was observed to the methanol control, out of 20 larvae tested. In addition, all 20 larvae tested followed a trail of 0.1 mg/ml 5β-cholestan-3-one.

DISCUSSION

The results demonstrate a chemical trail marking system in *Malacosoma neustria* remarkably like that of its congener, *M. americanum*. The similarities include: (1) marker secretion from the abdominal tip, (2) conspicuous dragging of the abdomen when marking a trail, (3) overmarking of exploratory trails by fed larvae returning to the group, (4) preference by foragers for overmarked trails, (5) gradual deterioration of pheromone activity, together with (6) persistence of differences between exploratory and recruitment trails.

The similarity of the two species is further indicated by their positive responses to 5β-cholestane-3,24-dione, the pheromone identified from *M.*

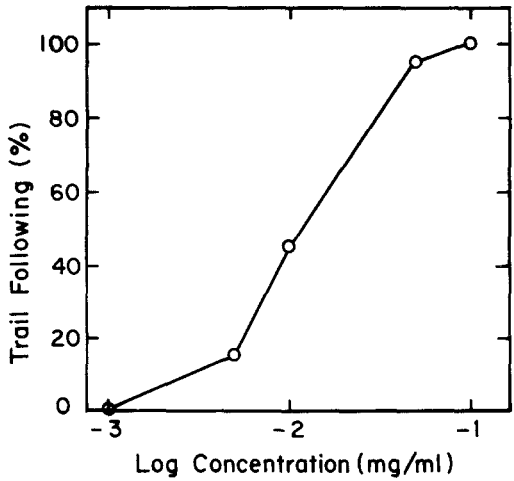

FIG. 2. Percentage of *M. neustria* following a 10-cm-long trail of 5β-cholestane-3,24-dione (N = 20 at each concentration).

americanum, and to 5β-cholestan-3-one. The gradual fade-out of the *M. neustria* trail pheromone is an indication that it is a high-molecular-weight, nonvolatile substance, like the pheromone of *M. americanum*.

The only outstanding difference between *M. americanum* and *M. neustria* trail-marking systems noted here is the apparent leader–follower behavior of *M. neustria* caterpillars. Both *M. americanum* and *M. disstria* explore unmarked substrates in groups, advancing only short distances together before turning back (Edgerly and Fitzgerald, 1982; Fitzgerald and Costa, 1986). Here, *M. neustria* larvae explored more independently. In addition, since the lead caterpillar consistently marked and those that followed marked less (Figure 1), larvae in the vanguard of foraging columns appeared to play a more active role in the establishment of exploratory trails than those in the rear. However, it is not known whether certain caterpillars are more likely to lead than others. Wellington (1957) reported leader–follower behavior in *M. californicum pluviale* Dyar and attributed this to individual differences in activity level. Laux (1962) also described activity differences in larvae of *M. neustria*, as did Greenblatt and Witter (1976) for *M. disstria*. However, these studies have been criticized on the basis of inappropriate experimental methods and statistical analysis (Edgerly and Fitzgerald, 1982; Papaj and Rausher, 1983). Moreover, in an extensive study of *M. americanum*, activity levels of caterpillars varied, but there was no indication that caterpillars assumed discrete behavioral roles (Edgerly and Fitzgerald, 1982). Larvae of *M. disstria* were also reported to diminish their marking behavior as successive waves of foragers utilized the trail (Fitzgerald and Costa, 1986).

M. neustria is only the second species of lepidopterous larvae reported to recruit to food. The fact that *M. americanum* has a well-developed recruitment system but *M. disstria* does not was attributed to differences in foraging systems by Fitzgerald and Costa (1986) and Fitzgerald and Peterson (1988). *M. americanum* larvae forage from a centrally located resting place to which they return after feeding. In contrast, *M. disstria* moves repeatedly from one resting–feeding site to the next, a syndrome described as "nomadic" by Fitzgerald and Costa (1986). Preliminary field observations of *M. neustria* suggest that it too has a central-place foraging system like that of *M. americanum* and uses its web as a resting site between periodic forays to food. This supports the conjecture of Fitzgerald and Peterson (1988) that gregarious caterpillars with central-place foraging systems may commonly exhibit recruitment behavior.

Acknowledgments—The author thanks the National Science Foundation for support of this research with a NATO Postdoctoral Fellowship; and L.M. Schoonhoven of the Agricultural University at Wageningen, The Netherlands, and W.M. Herrebout of the University of Leiden, The Netherlands, for facilities, encouragement, and other assistance. T.D. Fitzgerald, D. Crump, and R. Silverstein kindly supplied the chemicals. The cooperation of P. Roessingh and T.F. Mueller is also gratefully acknowledged. Thanks to T.D. Fitzgerald, P. Roessingh, and anonymous reviewers for helpful comments on the manuscript.

(Received March 3, 1987; accepted May 11, 1987)

Abstract—The *Solenopsis invicta* trail pheromone is synthesized by the Dufour's gland and is released through the sting apparatus. The recruitment subcategory of the *S. invicta* trail pheromone was shown to be composed of a mixture of the orientation pheromone, (*Z*, *E*)-α-farnesene and an unidentified homosesquiterpene consisting of three rings and one double bond (C−1). C−1 is present in worker Dufour's glands at only 75 pg per worker equivalent. This is the first report that demonstrates that different exocrine products from the same gland control different subcategories of behavior related to mass recruitment.

Key Words—*Solenopsis invicta*, Hymenoptera, Formicidae, imported fire ant, Dufour's gland, trail pheromone, pheromone, (*Z*, *E*)-α-farnesene, sesquiterpene.

INTRODUCTION

Ant trail pheromones represent one of the most elaborate known forms of chemical communication in social insects (Wilson, 1971) and were discussed in recent reviews of the behavior and chemistry of mass recruitment (see Hölldobler, 1978; Attygalle and Morgan, 1985). Trail pheromones are essential components of efficient foraging and mass recruitment by *Solenopsis invicta* Buren (Wilson 1962b) and are a good example of trail pheromone complexity. Wilson (1959) reported that the Dufour's gland was the source of fire ant trail phero-

mones and that the contents of the gland were emitted through the sting onto the substrate on which the trail-laying worker walks. The pheromone attracts workers who then orient (move) along the trail (Wilson, 1962a). Depending on the context, the Dufour's gland contents also released colony emigration, alarm recruitment, or settling behavior (Wilson, 1962c).

The investigation of the chemical nature of fire ant trail pheromones began with Wilson (1959), who recovered bioassay active material from a steam distillate of whole ants. However, the crude material was not stable over long periods of time (Walsh et al., 1965). Barlin et al. (1976) characterized the trail pheromone of *S. invicta* as a sesquiterpene hydrocarbon, based on analogy with gas chromatograph (GC) and GC-mass spectrometric (GC-MS) data for *Solenopsis richteri* Forel. This was confirmed by Vander Meer et al. (1981), who isolated (*Z,E*)- and (*E,E*)-3,7,11-trimethyl-1,3,6,10-dodecatetraene (α-farnesenes) and two homofarnesenes later identified as (*Z,E*)- and (*E,E*)-3,4,7,11-tetramethyl-1,3,6,10-dodecatetraene (Alvarez et al., 1987). An allofarnesene was also reported (Williams et al., 1981); however, we synthesized and tested this compound in our laboratory and showed that it did not induce trailing behavior (Williams, 1985).

The isolation of the farnesenes and homofarnesenes in the previous research was directed by a bioassay that specifically measured the orientation response of ants (movement along a trail). However, these compounds were ineffective in a bioassay designed to measure worker recruitment or attraction associated with the trail pheromone. We report here the isolation and partial identification of the Dufour's gland components from *S. invicta* that recruit workers to a trail.

METHODS AND MATERIALS

Point Source Recruitment Bioassay. Ten positions were marked symmetrically on the bottom of a plastic tray (7 × 44 × 56 cm) along a circle radiating 20 cm from the tray center. Queenright colonies consisting of one to three Williams nests (Banks et al., 1981) were reared from queens collected around Gainesville, Florida, and used in the bioassays. The cells were placed on top of each other in the center of the plastic tray. In addition, workers in the foraging arena of the mother colony tray were transferred to the bioassay tray. Each test colony contained approximately 25,000–75,000 workers. The ants were given at least 1 h to equilibrate in their new surroundings. Blotter paper squares (2 × 2 cm) with 1.5-cm-diam. circles marked in the center were placed on slightly larger aluminum squares. Up to eight test samples, a Dufour's gland extract standard, and a solvent blank (volume applied = 5 μl; one worker equivalent, WE) were applied to the paper squares and placed randomly on the numbered positions. The ants responded to active test samples by aggregating on the treated spots, often chewing the paper (see Wilson 1962c). The number of

ants aggregated within a 1.5-cm circle on the blotter paper squares were counted at 5-min intervals for 30 min. The sum of the six counts was regarded as the result for each position. Each test was replicated using six different *S. invicta* colonies. Experiments were evaluated by ranking sample responses based on Dufour's gland standard = 100 and solvent blank = 0. This method of scoring was used to minimize the day-to-day variability of the responsiveness of the ants. Using this method, if a sample response is greater than the Dufour's gland control, its ranking is greater than 100. Likewise if a sample's score is less than the solvent control, then its ranking will be less than 0.

Olfactometer Bioassay. The olfactometer (modeled after a design by Vander Meer et al., 1979) consisted of two 24/40 ground glass joints (Figure 1b); each ring was sealed to one of the arms of a 5-cm Y tube such that 1 cm of each Y-tube arm extended through the male half of one of the ground glass joints (Figure 1 d). A 5-cm piece of 0.6-cm-ID tubing was ring sealed 1 cm into the female half of the ground glass joints (Figure 1, a and e). A baffle (Figure 1c) at the center of the Y tube controlled air streams and prevented premature mixing of the sample, and gave the ants a clearer choice. The baffle also narrowed the openings to the choice chambers to the minimum size required

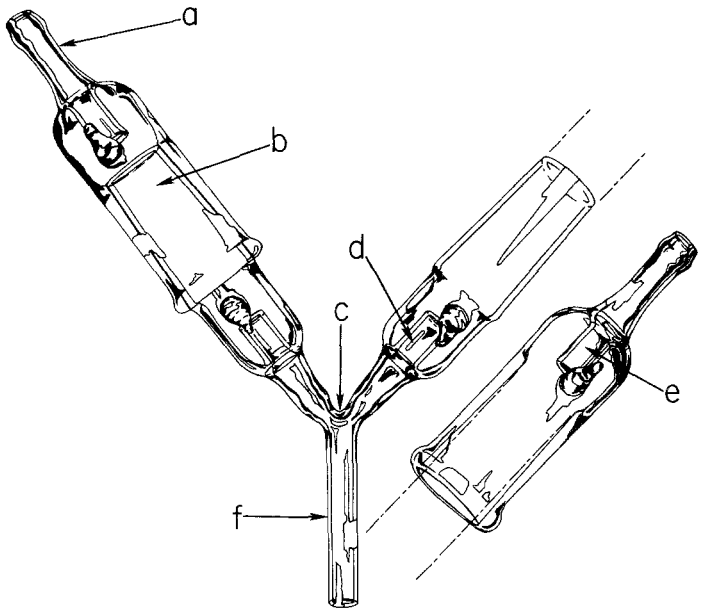

FIG. 1. Drawing of Y tube used in recruitment bioassays. Unit consists of two 24/40 ground glass joints ring-sealed to a Y stem. Legend: a, air inlet tube; b, sample chamber; c, baffle; d, ring seal tube (front); e, ring seal tube (rear); f, entrance stem.

for passage of a major worker. A test sample (10 μl/WE) and a solvent blank (10 μl) were applied to two filter paper strips (0.3 × 2.5 cm, Whatman No. 1), air dried, and each placed in one of the choice chambers (Figure 1, b). Compressed air (breathing air quality) was split into two streams and passed into the two choice chambers. Each stream was regulated to 0.2 liters/min. for a total effluent flow rate of 0.4 liters/min. Approximately 50–70 ants from laboratory colonies were confined in a 2.5-cm piece of 0.9-cm-ID Tygon tubing sealed at one end with wire gauze. The open end of the tubing was attached to the entrance stem (Figure 1, f). The initial choice of the first 20 ants that walked down the entrance tube and into one of the arms of the Y tube was recorded. Ants that were not trapped in a choice chamber and came back to the entrance stem were not counted if they made another choice. After each test, the olfactometer was rinsed with acetone and dried. Each test sample was retested with worker ants from the same colony, but the choice chamber in which the sample and control were placed was reversed. This procedure eliminated any bias inherent in the individual olfactometers. A complete replicate was the sum of the results from the two tests. Data were analyzed statistically by a chi-squared test, and comparisons between means were made with the Newman-Keuls test.

Gas Chromatography. Gas chromatography (GC) was performed on a Varian 3700 gas chromatograph equipped with a flame ionization detector (FID). Small-scale preparative GC work was carried out using the FID and a 10:1 glass splitter. The effluent was collected in glass capillary tubes and eluted into vials with hexane. The GC columns used are designated as follows: Column A—DB-1 (J and W Scientific, Inc.), fused silica, 0.322 mm ID × 15 m, 0.25 μm film thickness; Column B—Superox (SGE, Inc.), glass, 0.5 mm ID × 27 m; Column C—OV-101 on 120/140 Gas Chrom Q (Applied Science), 4 mm ID × 1.8 m; Column D—3% OV-17 (Applied Science, Inc.) on Gas Chrom Q (120/140 mesh). Quantitative data were obtained with a Varian CDS 401 data processor and paraffin internal standards.

Dufour's Gland Extract. Dufour's glands were extirpated in water from randomly chosen worker ants and macerated in hexane. Pooled Dufour's gland extracts were used to determine parameters for recruitment pheromone isolation, GC quantification, and as standards in all bioassays.

Dufour's Gland Extract Column Chromatography. Dufour's gland extract (100 WE in 150 μl hexane) was applied to a 1.5-cm × 0.4-cm bed of silica gel (37–53 μm, Whatman, Inc.) and eluted sequentially with 6 ml each of hexane, methylene chloride, and methanol to separate the solute into hydrocarbon, nonpolar lipids, and polar lipids, respectively (Christie, 1973). The solvent for each fraction was evaporated under a stream of nitrogen to a volume of 0.5 ml and used in the point source recruitment bioassay.

Preparative GC of Dufour's Gland Extract. A Dufour's gland extract (100 WE) was separated into fractions by preparative gas chomatography (FID, 10:1

splitter, column C), 145°C for 22 min then 145–250°C at 10°C/min. Two procedures were used: (1) The mixture was separated into a volatile region (solvent front through the retention time of heptadecane) and a nonvolatile region (everything beyond heptadecane). (2) Individual fractions were collected at 1-min intervals for the first 21 min. Fractions 1–10 were from the solvent front to just after the elution of heptadecane. Fraction 22 contained all material eluted beyond 22 min. The fractions were collected in capillary tubes cooled with Dry Ice, and the sample was eluted into a 2-ml vial with 500 μl of hexane. These fractions were used for subsequent bioassays.

Isolation of Non-Dufour's Gland Saturated Hydrocarbons. The postpharyngeal gland (located in the head) is a rich source of species-specific hydrocarbons (Vander Meer et al., 1982). Five postpharyngeal glands were extirpated and crushed in 150 μl of hexane. This solution was applied to a Pasteur pipet silica column and eluted with hexane to isolate only the hydrocarbons (Christie, 1973). The hexane eluent was evaporated to a small volume and quantitatively analyzed by GC.

Extraction of Worker Ants. Whole worker ants (904 g, an estimated 904,000 workers at 1 mg per individual) were rinsed two times in hexane (1.5 liters) for 15 min and filtered. The ants were then homogenized in hexane (1.5 liters) for 2 min using a Virtis blender at a medium setting. The homogenate was filtered over a bed of Celite and the residue washed and filtered several times with fresh hexane. The filtrate was concentrated under vacuum to 200 ml. The insoluble residue was further homogenized with methanol (1.5 liters), filtered, washed several times with fresh methanol, and the combined filtrate was concentrated under vacuum to 200 ml. The hexane fraction was analyzed by thin-layer chromatography (TLC) using Polygram sil G/UV_{254} precoated plastic sheets (Macherey-Nagel, 40 × 80 mm) and an eluting solution for lipid separation (Christie, 1973).

Fractionation of Hexane Extract. The hexane extract (200 ml) was fractionated by gravity column chromatography on silica gel (800 g, Analtech; 35–75 μm). The sample was sequentially eluted with hexane (2 liters), methylene chloride (1.5 liter), and methanol (1 liter). These fractions were designated G-1, G-2, and G-3, respectively. The three fractions were concentrated under vacuum to 200 ml. The hexane eluent (G-1) was further concentrated under vacuum to yield 3.2 ml of a colorless liquid.

Separation of Saturated and Unsaturated Hydrocarbons. An aliquot (30 μl, 8500 WE) of the total hydrocarbon fraction (G-1) above was diluted in hexane (1 ml) and chromatographed using silver nitrate-impregnated silica gel (10% $AgNO_3$, Adsorbosil-LC-Ag, Applied Science, Inc., State College, Pennsylvania; 1.3 × 23 cm bed size). The sample was eluted stepwise with 0–50% ethyl ether in hexane (1 ml/min; 8.5 ml/fraction). Twenty fractions (Ag) were collected, and each was filtered through sodium chloride to remove potentially

interfering AgCl. The percentage of ethyl ether was increased based on GC analysis (column A) of fractions: fractions 1–6, hexane; fractions 7–11, 5% ethyl ether; fractions 12–16, 10% ethyl ether; fractions 17 and 18, 20% ethyl ether; and fractions 19 and 20, 50% ethyl ether. The fractions were designated Ag-1 to Ag-20.

Isolation of Active Components. Preparative GC of active fractions was carried out on columns C or D using an FID and 10:1 split. Kovats indices (KI) were calculated and coinjections made on columns A and B. Chemical ionization (C1) GC-MS were obtained on a Finnigan model 1015 SL upgraded to a 3200 GC-MS system. Hydrogenations (10% Pd/C in hexane) were carried out using a Supelco, Inc. microhydrogenator.

RESULTS

Preliminary studies using Dufour's gland extracts indicated that the active components of the recruitment pheromone were hexane soluble and could be eluted from a silica gel gravity column with hexane (Table 1). These physical properties defined the active components as hydrocarbons (Christie, 1973). Preparative GC of the Dufour's gland hexane extract yielded full bioassay activity from only the volatile region (solvent front through *n*-C-17 paraffin) of the chromatogram (Table 1). However, all pheromone activity was lost on preparative GC of the volatile region into 10 one-minute fractions. Recruitment pheromone activity was regenerated on recombination of all 10 fractions, which suggested a multicomponent pheromone system.

It was not practical to continue the elucidation of the recruitment trail pheromone complex using Dufour's gland extracts, since extirpation of adequate numbers of glands would be too labor intensive. Therefore, we extended the separation procedures developed for Dufour's gland extracts to the isolation of

TABLE 1. POINT SOURCE BIOASSAY OF COLUMN CHROMATOGRAPHY AND PREPARATIVE GAS CHROMATOGRAPHY FRACTIONS OF DUFOUR'S GLAND EXTRACTS

Sample[a]	Recruitment ranking[b]

bioassay-active materials from whole ant extracts (Figure 2). Whole ants were first rinsed with hexane to remove cuticular hydrocarbons, which would add to the contamination of the hydrocarbon trail pheromone components. Then the ants were extracted sequentially with hexane and methanol. Analytical thin-layer chromatography of the hexane extract showed a complex mixture of substances with a range of polarities. Following the procedure used for Dufour's gland extracts, the whole ant hexane extract was separated into hydrocarbons, nonpolar lipids, and polar lipids (G-1 to 3) by sequential elution with hexane, methylene chloride, and methanol, respectively, from a silica gel column (Christie, 1973). Point source bioassays of the three fractions clearly showed that pheromone activity was only in the hexane fraction (G-1, Figure 2), which corresponded to hydrocarbons.

GC analysis of hydrocarbon fraction G-1 showed that the vast majority of hydrocarbons were the known saturated normal, methyl, and dimethyl branched

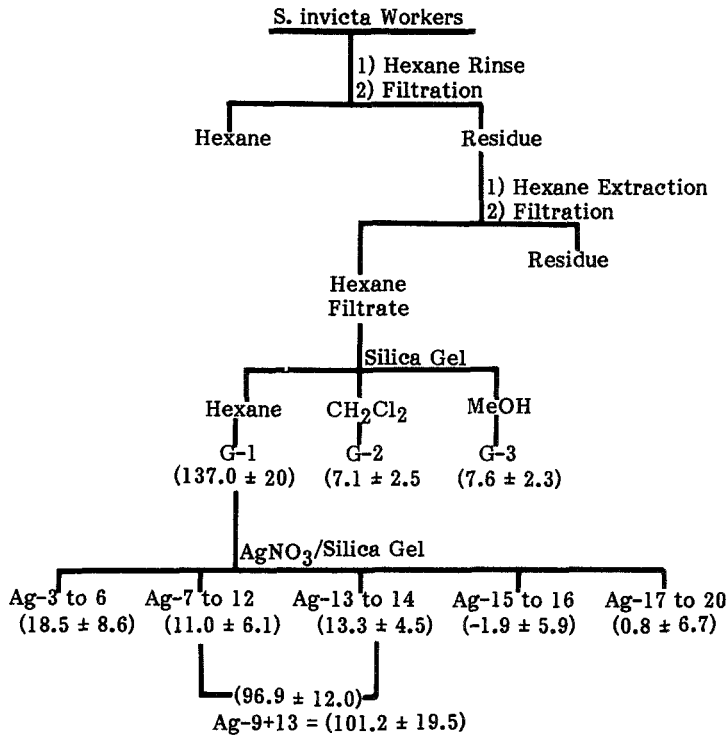

FIG. 2. Separation flow chart for the isolation of the *S. invicta* trail recruitment pheromone from worker extracts. Point source bioassay results are shown in parentheses (mean ± SE, $N = 6$) for the indicated fraction. Ranking is based on response to Dufour's gland = 100 and the response to the solvent blank = 0.

compounds specific to *S. invicta* (Lok et al., 1975; Nelson et al., 1980; Thompson et al., 1981). Our previous work on the trail orientation pheromone indicated that at least a part of the recruitment pheromone might be an unsaturated hydrocarbon. Consequently, to separate hydrocarbons with varying degrees of unsaturation, the total hydrocarbon fraction G-1 was chromatographed on a silver nitrate-impregnated silica gel column and eluted with hexane containing increasing amounts of diethyl ether. A total of 20 fractions were collected. The fractions were grouped into the following five categories based on changes observed in the GC chromatograms of each fraction: Ag-(3–6), Ag-(7–12), Ag-(13–14), Ag-(15–16), and Ag-(17–20). Point source bioassays of the five groups showed that none of the individually tested groups approached the activity induced by the Dufour's gland standard (Figure 2). However, bioassay results for various combinations of the five groups indicated that Ag-(7–12) in the presence of Ag-(13–14) gave full Dufour's gland activity (Figure 2). In addition, when these two groups were combined with the saturated hydrocarbon group (isolated in Ag-3, by GC analysis), activity greater than Dufour's gland was generated. These results led to detailed bioassay investigation of fractions within the Ag-(7–12) and Ag-(13–14) groupings. The combination of Ag-9 and -13 gave activity equivalent to that of Dufour's gland extracts, and these fractions were selected for preparative GC.

Ag-9 was initially separated into four major GC sections, Ag-(9A–D). Bioassays, always with an equivalent amount of Ag-13, indicated that only Ag-9C was active. Ag-9 was GC prepped again (Table 2), subdividing the active zone, Ag-9C, into four fractions, Ag-9(C-1 to C-4). The active area contained a single peak that was a minor component in Ag-9. This component was designated C-1. It was homogeneous on two capillary GC columns (KI 1640 on

[a] All samples and Dufour's gland extracts were tested at 1 WE. All fractions were bioassayed with an equivalent amount of Ag-13.

[b] Mean response (± SE) based on Dufour's gland response = 100 and solvent response = 0 (N = 6).

column A and 1796 on column B). Knowing where to look on the GC chromatogram facilitated the discovery of C-1 in Dufour's gland extracts. Quantitative analysis of *S. invicta's* Dufour's glands (from a pooled sample of 100) showed that component C-1 was present at about 75 pg per worker. GC-MS of C-1 showed it to have a molecular weight of 218, indicative of a C_{16} hydrocarbon with four degrees of unsaturation (rings and/or double bonds). Hydrogenation followed by GC-MS showed the uptake of two hydrogens, which means that the compound has three rings and a single double bond.

Preparative GC of Ag-13 monitored by bioassays in combination with active monoene fraction, Ag-9, led to the isolation of a component (Table 3) that was shown to be identical to (*Z,E*)-α-farnesene, the major trail orientation pheromone, by direct comparison with a synthetic sample (Vander Meer et al., 1981). (*Z,E*)-α-Farnesene is present in the Dufour's gland of *S. invicta* at about 6 ng per worker (Vander Meer et al., 1981).

Results of the Y-tube olfactometer tests (Table 4), confirmed those of the point source bioassay in that a combination of (*Z,E*)-α-farnesene and component C-1 was required for attraction. Neither component had significant activity when tested alone. In the specific behavior of attraction, the mixture was indistinguishable from an equivalent amount of Dufour's gland extract. Therefore, the combination of (*Z,E*)-α-farnesene and C-1 (at a ratio of 6 ng:75 pg/WE, respectively) is responsible for the attraction or recruitment of worker ants. However, in the point source bioassay, the two-component mixture elicited only 85% of the activity found with an equivalent amount of Dufour's gland extract. The two natural homofarnesenes did not enhance the activity of C-1 in the olfactometer bioassay (Table 4).

Other components known to be present in Dufour's gland extracts, hep-

TABLE 3. POINT SOURCE RECRUITMENT BIOASSAY RESULTS FOR PREPARATIVE GAS CHROMATOGRAPHY FRACTION Ag-13

Preparative GC fraction[a]	Recruitment ranking[b]

tadecane, nonadecane, homofarnesenes, and five heptacosanes, (Vander Meer et al., 1981; Barlin et al., 1976), were inactive in the point source bioassay by themselves and at physiological levels did not enhance the activity of the (*Z*,*E*)-α-farnesene and C-1 mixture.

DISCUSSION

Ant recruitment systems use a wide variety of mechanisms ranging from the tandem running first reported for *Leptothorax acervorum* (Möglich et al., 1974) to the multiple recruitment systems of the African weaver ant *Oecophylla longinoda* (Hölldobler and Wilson, 1978). Tandem running is initiated when the recruiter or calling ant releases an attractive secretion from its poison sac through the sting. When the responding worker touches the calling ant, tandem running occurs. Only a single nestmate is recruited, and it is suggested that tandem running is the evolutionary precursor to odor trail communication. Tandem running has since been observed in ponerine (Hölldobler and Traniello, 1980) and formicine (Hölldobler, 1974) ant species. At the other end of the spectrum is the highly evolved and complex weaver ant system, which involves multiple glandular secretions combined with a variety of tactile signals to cope with a large number of context related recruitment situations (Hölldobler and Wilson, 1978). Examples of recruitment mechanisms that fit in between the two extremes mentioned above have been reviewed by Hölldobler (1978). In examples where more than one gland is involved in recruitment, it is likely that more than one chemical or blend of chemicals is required; i.e. *Myrmica rubra* lays an odor trail with its poison sac contents and deposits attractive spots with the contents of its Dufour's gland (Cammaerts-Tricot, 1974).

S. invicta has a highly evolved and efficient mass recruitment system with

the Dufour's gland as the sole source of the chemicals responsible for releasing this behavior (Wilson, 1959, 1962a,b). *S. invicta* is, to our knowledge, the first example reported in which different chemicals produced in the same exocrine gland control subcategories of trailing behavior. The mass recruitment behaviors elicited by the Dufour's gland contents include attraction, orientation (Wilson, 1962c), and orientation priming (Vander Meer et al., submitted). In addition, depending on the context, Dufour's gland secretions can elicit colony emigration, alarm recruitment, and settling (Wilson, 1962c).

While it was clear that Dufour's gland secretions had multiple functions, it was not evident until this report that different chemical combinations originating from the same gland released different behaviors. This was because previous research on the trail pheromone of *S. invicta* did not differentiate between subcategories. The bioassay usually consisted of streaking test material on a piece of paper and then substituting it for a portion of an already established trail to a food source (Barlin et al., 1976; Jouvenaz et al., 1978; Vander Meer et al., 1981; Williams et al., 1981). This was a good bioassay that gave unambiguous results; however, only the orientation element of the total trail pheromone response was measured. This became clear when the activity of the orientation components was compared to Dufour's gland extracts in two bioassays designed to quantify the recruitment subcategory of the trail pheromone. These initial observations demonstrated that the chemicals isolated and identified as having orientation activity did not, by themselves, elicit recruitment.

In addition to attraction, the point source bioassay measured the settling or aggregation (Wilson, 1962c) behavior of the workers to Dufour's gland extracts or test samples. This bioassay could effectively test up to 10 samples at one time and was used to guide the chemical separation and isolation of the bioactive components. Initially, a combination of three classes of hydrocarbons (saturated, monoenes, and di- to tetraenes) was found to give the best bioassay results; however, quantitative analysis of the saturated hydrocarbon fraction showed that there were exceptionally large amounts of the species-specific saturated hydrocarbons (53 μg/WE) ubiquitous to *S. invicta* (Vander Meer et al., 1982). Previously Thompson et al. (1981) showed that three to four times less material (10–20 μg) released aggregation and biting behaviors in *S. invicta* workers. However, quantitative analysis of these same hydrocarbons from Dufour's gland extracts showed that the hydrocarbons were present at only 16–20 ng per worker. Bioassays of the active unsaturated classes of hydrocarbons, along with the saturated hydrocarbons at the low concentrations found in the Dufour's gland, did not enhance the activity of the unsaturated fractions. Consequently, we felt justified in removing the saturated hydrocarbons from consideration as components of the recruitment part of the trail pheromone.

Further point source bioassays and chemical separations led to: (1) the isolation of a single homosesquiterpene, C-1, with three rings and a single dou-

ble bond, that was present in minute amounts (ca. 75 pg/Dufour's gland WE) and (2) the previously isolated orientation pheromone, (*Z*,*E*)-α-farnesene (ca. 6 ng/Dufour's gland WE). The combination of the two isolated chemicals at physiological concentrations gave 85% of the recruitment activity of an equivalent amount of Dufour's gland extract. These results confirmed that different behaviors associated with the trail pheromone are elicited by different combinations of chemicals derived from the Dufour's gland.

The recruitment point source bioassay was very useful during the isolation and purification of the recruitment pheromone complex, due to its simplicity and reproducibility. However, this bioassay detected multiple behaviors (e.g., attraction, aggregation, and mastication). This problem was avoided by using a Y-tube olfactometer bioassay (Figure 1), which measured only worker attraction. The response of the ants to a mixture of C-1 and (*Z*,*E*)-α-farnesene was indistinguishable from the response to an equivalent amount of Dufour's gland extract (based on the amount of (*Z*,*E*)-α-farnesene). Therefore, this mixture is responsible for the attractive properties of the Dufour's gland contents. Interestingly, the two homofarnesenes did not enhance the attractive qualities of C-1, which indicates an as yet unknown function for these compounds.

The chemistry of ant trail pheromone systems has been the subject of research for many years (Attygalle and Morgan, 1985). Several leaf-cutting ants use methyl 4-methylpyrrole-2-carboxylate produced in their poison gland (Riley et al., 1974). In another *Atta* and several *Myrmica* species, 3-ethyl-2,5-dimethylpyrazine (Cross et al., 1979; Evershed et al., 1982), is the trail following substance. Another pyrazine, 2,5-dimethylpyrazine is a trail following pheromone of *Tetramorium caespitum* (Attygalle and Morgan, 1983). The true trail pheromone of the pharoah's ant was identified as (+)-(3*S*,4*R*)-3,4,7,11-tetramethyltrideca-(6*E*,10*Z*)-dienal (faranal; Ritter et al., 1977). Another aldehyde, (*Z*)-9-hexadecenal is part of the trail pheromone complex of *Iridomyrmex humilus* (Van Vorhis Key and Baker, 1982). Several fatty acids found in the rectal fluid of *Lasius fuliginosus* (Huwyler et al., 1975) and *Pristomyrmex pungens* (Hayashi and Komae, 1977) have been demonstrated to be trail pheromones.

In all of the known examples cited above, a trail-following (i.e., orientation) bioassay was used to measure the ants' response to isolated chemicals. The results presented in this paper demonstrate the pitfalls inherent when a single bioassay is used to measure a complex behavioral event (i.e., trailing or mass recruitment) and that care must be taken to devise bioassays that clearly define the behavior of interest. We have shown for the first time that different exocrine products release different behaviors associated with mass recruitment and that subcategories of trailing behavior can be controlled by different blends of chemicals produced in the same exocrine gland.

(Received December 1, 1986; accepted May 15, 1987)

Abstract—The high leaf surface pH in cotton (*Gossypium hirsutum*) var. Acala SJ2 was bioassayed against *Spodoptera littoralis* larvae. Weight gain and leaf consumption of the larvae feeding on leaves devoid of alkalinity, due to daily washing, were recorded. Untreated cotton, with a leaf surface pH of 9.5–10.0 was used as control. The gland exudates contained potassium and magnesium cations, and the gland surface and intergland leaf areas were rich in calcium and phosphorus and low in K or Mg. The role of this plant antibiosis in the insect–host-plant relationship is discussed.

Key Words—Leaf surface pH, *Gossypium hirsutum*, cotton, *Spodoptera littoralis*, Lepidoptera, Noctuidae, larval weight, leaf consumption, alkaline glands exudation, ion microanalysis.

INTRODUCTION

An alkaline leaf surface is an uncommon character in the plant kingdom. However, in cotton species and varieties (Smith, 1923; Oertli et al., 1977; Harr et al., 1980) and in a few other malvaceous species (Harr et al., 1984), a high pH, ranging from 9.0 to 11.0, has been recorded. This alkalinity originates from multicellular epidermal glands, exuding magnesium and potassium cations (Ellman and Entwistle, 1982). This alkalinity has shown antimicrobial activity by inactivating insect nuclear (Andrews and Sikorowski, 1973; Young et al., 1977) and cytoplasmatic (Ali and Sikorowski, 1986) polyhedrosis viruses

[1] Contribution No. 1885-E 1986 series, from the Agricultural Research Organization, The Volcani Center, Bet Dagan, Israel.

applied to the plant, but the effect of this plant antibiosis against insects is unknown. Therefore, the feeding capacity of *Spodoptera littoralis* larvae on *Gossypium hirsutum* var. Acala SJ2 was recorded in comparison with the feeding on the same cotton devoid of alkalinity by leaf washing. In addition, the ion profile of the leaf surface was analyzed to characterize the phylloplane activity against the larva.

METHODS AND MATERIALS

The commercial cotton (*Gossypium hirsutum*) var. Acala SJ2 was planted in pots in a greenhouse at 25–35°C and 60–80% relative humidity with 16:8 hr light–dark photophase. A sand–peat mixture, 1:1, fortified weekly with an aqueous nutrient mixture was supplied to the plants. In the field the cotton was raised in an ARO experimental field plot in Bet Dagan.

Leaf washing to eliminate the leaf surface alkalinity was carried out as follows: potted cotton plants were bent aside to be dipped in 0.06% aqueous polyoxyethylene sorbitan monooleate (Tween 80) solution for 15 min. The solution was stirred to increase the washing action on the leaves. Then the plants were washed with glass-distilled water and dried with an air blower. Unwashed leaves were used as the control.

The pH of the washed and the unwashed leaves was measured on both leaf surfaces by means of Radiometer electrodes G242C and K401 connected to a portable pH meter. The intact leaf was fixed flat, 300 ml bidistilled water was pipetted on the leaf surface, and the electrodes were immersed in the water, touching the leaf. The pH was recorded after 5 min. Since 10 min of recording did not increase the pH by more than 20%, the recording time throughout the work was exactly 5 min. The same pH reading technique on intact leaves was used in the laboratory and in the field. Four leaves sampled in three different plants in a single pot were used for pH measurements in a bioassay.

Larvae were obtained from an insect colony bred on an alginate diet (Navon, 1985). Neonates were caged singly on the washed and on the control plants, placed in the greenhouse (30–35°C; 16:8hr light–dark photophase. The larvae were transferred daily onto freshly washed and onto untreated plants. The pH measurements 24 hr after washing showed that the surface alkalinity was not restored. The cage was made of two glass cylinders (15 mm diam. × 5 mm). The outer side of each of the cylinders was closed with a 300-mesh metal screen used for ventilation. The two cylinders were held together on both sides of the leaf by a hair clip. Similarly, third-instar larvae weighing 8 mg were caged by two plastic cylinders (32 mm diam. × 18 mm), closed with a 150-mesh metal screen (Navon et al., 1987). The two units were held together by an uncoiled wire clip. The feeding period was four, five, and 7 days, after

which the unconsumed leaf area of the cage diameter was cut and measured with a Li-Cor area meter, model 3100 (Li-Cor, Inc., Lincoln, Nebraska. The leaf area from cages without larvae was used as the control. The leaf area consumed by the larvae was determined by subtracting the leaf area which remained after feeding from that of the control leaves. Between 10 and 15 larvae were used per experiment, with four or five replicates.

The leaf surface-ion profile was analyzed as follows: Young cotton leaves of potted plants with an average size of 22 ± 1 cm^2 were fixed in aqueous 3% glutaraldehyde solution, dehydrated in alcohol series, washed in acetone, and dried with CO_2 in a critical-point dryer. Then the leaf preparation was coated with gold. The alkaline glands were observed and counted in a Stereoscan 180 scanning electron microscope (SEM). Ion microanalyses of the glands' content and surface were conducted by an energy dispersing spectra (EDS) technique using a Proxan cation analyzer (Elscint, Haifa, Israel).

RESULTS AND DISCUSSION

Table 1 shows that the high pH of the leaf surface of cotton in the field was similar to that of the greenhouse plants: both were close to pH 10 on the leaf underside. Washing the leaf caused a drop in the surface pH by 2.7 units. For comparison, in another malvaceous species, *Hibiscus rosa-sinensis*, the leaf surface pH was below neutral.

Table 2 shows that the weight of the neonates was doubled when they fed for seven days on washed leaves in comparison to feeding on untreated cotton.

TABLE 1. LEAF SURFACE pH OF COTTON DEVOID OF ALKALINITY FOLLOWING WASHING[a]

Plant species	Leaf treatment	pH units (means ± SE) of leaf surface	
		Upper side	Under side
G. hirsutum var. Acala SJ2			
Greenhouse plants	Washing	7.1 ± 0.4b*	7.2 ± 0.4b
	Control	9.8 ± 0.2a	9.9 ± 0.2a
Field plants	Washing	7.2 ± 0.6b	7.4 ± 0.4b
	Control	9.4 ± 0.2a	9.9 ± 0.2a
Hibiscus rosa-sinensis	Washing	6.7 ± 0.1c	6.3 ± 0.1c
	Control	6.8 ± 0.04c	6.5 ± 0.1c

[a] Within each column, means followed by a common letter do not differ significantly ($P < 0.05$), according to ANOVA and Duncan's new multiple-range test.

TABLE 2. EFFECT OF DAILY WASHING OF COTTON LEAVES ON *Spodoptera littoralis* LARVAL WEIGHT GAIN AND CONSUMPTION[a]

Leaf treatment	Feeding period (days)	Larval weight gain (mg ± SE)	Leaf area consumed (cm^2 ± SE)
Neonate larvae			
Washing	7	5.1 ± 0.7a	6.5 ± 0.4a
Control	7	2.5 ± 0.3b	3.5 ± 0.4b
Third-instar larva			
Washing	3	36.0 ± 3.3c	5.2 ± 0.4c
Control	3	27.0 ± 3.0c	4.1 ± 0.6c
Washing	4	50.5 ± 3.6b	7.0 ± 0.4b
Control	4	40.8 ± 4.5b	5.2 ± 0.7c
Washing	7	72.0 ± 6.8a	11.8 ± 0.9a
Control	7	57.7 ± 4.9b	7.7 ± 0.7b

[a] Within each column, means followed by a common letter do not differ significantly ($P < 0.05$), according to ANOVA and Duncan's new multiple-range test.

Feeding capacity was increased by 1.8 times on the washed cotton. Similarly, third-instar larvae grew significantly faster on the cotton with the neutral pH within at least seven days. At shorter feeding periods, this pH effect was not significant. This experiment shows that, for both larval stages, the cotton leaf from which the alkalinity has been washed off was more acceptable than the control cotton pH close to 10.0.

Figure 1 shows that the ion content in the exudates released from the gland punctured by the SEM electronic beam, was rich in potassium and magnesium and poor in calcium, with twice as much K as Mg. On the gland surface, phosphorus content was markedly higher than that of Ca, K or Mg. On the intergland leaf surface, Ca was most abundant, whereas potassium and magnesium were very low. Sulfur was equally represented in all the ion analyses. In cv. Deltapine 16, raised in an aqueous medium (Ellman and Entwistle, 1982) phosphorus was missing, but the ion profile of the glands edudates was as in Acala SJ2.

Potassium and magnesium are abundant elements in plant tissues. These cations, more than others, are required in artificial diets by phytophagous insects (Dadd, 1970). In a suitable *S. littoralis* diet (Levinson and Navon, 1969), K and Mg were major elements in the mineral mixture (Beck et al., 1968). Therefore, it is expected that the larvae will accept high amounts of the two cations offered at neutral pH, but would tolerate less the cations in an alkaline milieu, such as the cotton leaf surface. SEM observations revealed that the glands 20–30 μm in size were evenly distributed on the leaf surface and veins, and the mean distribution of these glands was 0.118 ± 0.02 (SE) per mm^2 leaf surface.

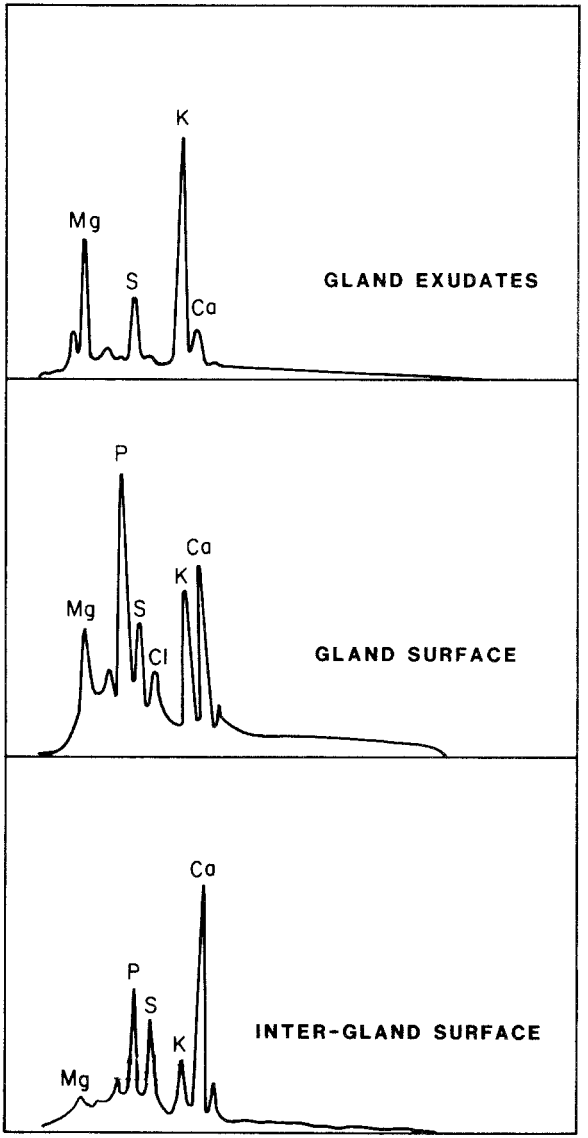

FIG. 1. Ion microanalysis of gland exudates, gland surface, and intergland surface in cotton (*Gossypium hirsutum*) var. Acala SJ2.

The leaf area consumed by the neonate at a single meal was 0.2 ± 0.03 mm^2, an area larger than the distance between glands. This explains the observation that the neonates could not avoid ingesting the glands. In spite of the high leaf-surface pH, *S. littoralis* is regarded as a serious cotton defoliator. Nevertheless, it seems that the alkaline phylloplane, in addition to other plant antibioses, could prolong the larval period on this crop. This leaf surface effect may be increased, even beyond that recorded in commercial cotton; a leaf surface pH of 11.0 was determined in the malvaceous species *Kitaibelia vitiifolia* (Harr et al., 1984). Possibly, cotton cultivars with similar phylloplane alkalinity could be selected to increase cotton resistance to larval pests.

Acknowledgments—We thank Mr. Liora Salame and Mrs. Sara Keren for their valuable assistance in the laboratory and field work.

(Received March 23, 1987; accepted May 18, 1987)

Abstract—*Lemna gibba* L. G3, (duckweed) was used as a bioassay organism to test the allelochemical effects of salicylic acid (SA), ferulic acid (FA), and umbelliferone (UM). Growth rate (K), dry weight (DW) and total chlorophyll (CHL) production were measured after seven days of growth. The bioassay procedure used 50 ml of E medium with and without sucrose in 125-ml Erlenmeyer flasks plus the selected concentration of allelochemical. At concentrations of 50 μM and greater, SA caused inhibition of K and DW production in *L. gibba* G3, while the threshold for CHL reduction was 20 μM. FA inhibited the DW and CHL production at 100 μM when the compound was autoclaved in E medium containing sucrose. Treatments of UM were least toxic with an inhibition threshold of 500 μM for K and DW production in medium without sucrose. UM did not reduce CHL production until 750 μM. In some cases, different thresholds of inhibition were observed depending on the presence or absence of sucrose and tartaric acid in the medium, and whether or not the chemicals were autoclaved with the medium.

Key Words—Allelopathy, allelochemical, duckweed, *Lemna gibba*, salicylic acid, ferulic acid, umbelliferone, growth rate, chlorophyll.

INTRODUCTION

Allelopathy, or the biochemical interaction between all types of plants including microorganisms (Rice, 1984), produces marked impacts in a variety of terrestrial and aquatic ecosystems (Mandava and Rao, 1984; Putnam, 1983). The specific chemicals involved in many allelopathic situations remain obscure, but allelochemical activity has often been attributed to several secondary plant products such as simple phenolic acids, coumarins, terpenoids, flavonoids, alkaloids, cyanogenic glycosides, and glucosinolates (Putnam and Duke, 1978). Acid phenolics, such as salicylic acid, have long been recognized as plant growth inhibitors (Leopold, 1964). The series of cinnamic acids are also common inhibitors, both as the free acids and the closely related lactones. Abundant among these are ferulic acid, which belongs to the series, and the naturally occurring coumarin, umbelliferone, which is one of the lactone group (Robinson, 1980). Some of the natural inhibitors may also increase growth through a synergistic effect promoting auxin-induced growth at low concentrations (Leopold, 1964). However, the mode of action of the numerous potential allelochemicals may not be the same (Einhellig and Rasmussen, 1979).

Currently, there is considerable interest in developing strategies for capitalizing on allelopathy in agricultural production either by avoiding negative impacts or by exploiting allelopathic mechanisms for additional pest control and in approaches to growth regulation (Putnam, 1983). These challenges enhance the necessity for finding organisms that are sensitive and can be used for identifying allelochemical activity and mechanisms of action if they are not difficult to propagate in bioassays.

Previous work using *Lemna minor* 5 and *Lemna obscura* 7133 demonstrated that these two species provided sensitive bioassays of allelochemicals (Einhellig et al., 1985; Leather and Einhellig, 1985). Inhibition of growth and reproduction was detected in the range of 50–1000 μM for the allelochemicals tested. It was suggested that other *Lemna* species be evaluated for use as bioassays and that certain members of this genus have unique features that may be particularly appropriate for considering some mechanisms of allelochemical action.

Lemna gibba L. is among the largest of the duckweeds, and its fronds are characterized by being swollen or gibbous on the abaxial side. It has rapid growth, relative structural simplicity, and can be grown in aseptic culture which simplifies work with organic compounds (Hillman, 1961; Steinberg, 1943; Walsh and Palmer, 1979). As with the other Lemnaceae, it is easily cloned and can be maintained in controlled temperature, light, and nutritional conditions more easily than most other angiosperms. The plant consists of a frond with two reproductive pockets at the pointed or proximal end from which new fronds and a root are produced (Blodgett, 1904). The frond is formed by chlorenchy-

matous cells separated by large intercellular spaces that are filled with air and other gases responsible for the gibbosity (Blodgett, 1904; Hillman, 1961). The predictability of morphological and physiological characteristics suggests *L. gibba* would be suitable to be used as a bioassay organism.

The objective of this research was to study *L. gibba* G3 as a bioassay for allelochemicals and to consider any impact on chlorophyll production as a potential indicator of interference.

The known allelochemicals salicylic acid, ferulic acid, and umbelliferone were tested for effects on this species. Salicylic acid was included because others (Cleland and Ajami, 1974; Cleland and Tanaka, 1979, 1982; Tanaka et al., 1979) have reported its alteration of growth and flowering in *L. gibba* G3.

METHODS AND MATERIALS

Culture Conditions. The aquatic duckweed, *Lemna gibba* L. strain G3 maintained aseptically, was used exclusively in this research. All cultures were grown in cotton-stoppered 125-ml Erlenmeyer flasks with 50 ml of E medium (Cleland, 1979), prepared at a pH of 4.6, and sterilized by autoclaving (15–20 min) Clones containing a total of 12 fronds were transferred to each flask using a culture loop. The cultures were allowed to grow for seven days in an environmental chamber at 28°C under constant (236 μE/sec/m^2) fluorescent and incandescent light.

The allelochemicals, salicylic acid (SA; 2-hydroxybenzoic acid), ferulic acid (FA; 4 hydroxy-3-methoxycinnamic acid), and umbelliferone (UM; 7-hydroxycoumarin), were added as the dry chemical to the medium in the first experiments prior to autoclaving and in later experiments after autoclaving. Four replications in a completely randomized design were prepared for each treatment.

To determine the effects of organic amendments on the response of *L. gibba* G3 to allelochemicals, E medium with and without sucrose and tartaric acid was prepared with known concentrations of the allelochemicals and autoclaved. Cultures were prepared using plants grown in complete E medium. In another experiment, E medium with and without sucrose was prepared and autoclaved, then the allelochemicals were added to the medium after autoclaving. In order to test the effects of prior conditioning of the plants, half the cultures were prepared using *L. gibba* G3 that had been grown for a minimum of two weeks in complete E medium; the other half of the cultures utilized plants previously grown without sucrose and tartaric acid. Controls were cultured according to each experimental protocol but without the allelochemical.

Data Collection. Cultures were inspected daily and, on day 7, fronds were

removed from the flasks, counted, each placed in a test tube, and the CHL extracted. The fronds were immersed in 5 ml of 95% ETOH for 24 hr, then the ETOH–CHL solution was decanted into a second container. The fronds were soaked again twice in fresh ETOH for 2-hr periods. Solutions were combined from each extraction, most of which occurred in the first 24 hr, and adjusted to a final volume of 20 ml. The ETOH–CHL solutions were kept in darkness at room temperature and, immediately following the extraction sequence, absorbances (A) of each CHL extract were read using spectrophotometry at 665 and 649 nm and values for CHL-a, CHL-b, and total CHL were determined (Wintermans and DeMots, 1965; Einhellig and Rasmussen, 1979).

The fronds were allowed to air-dry in a hood at room temperature for one week, then weighed (DW). The growth rate (K) was calculated according to Hillman (1961):

$$K = \frac{\log_{10}(F_d) - \log_{10}(F_0)}{d}$$

where F_0 is the initial frond number and F_d the final frond number obtained from the count on day 7, and d the number of days.

All experiments were repeated at least once. The results were analyzed by the Student's t test.

RESULTS AND DISCUSSION

Lemma gibba G3 showed high sensitivity to SA. In preliminary range-finding tests in which concentrations between 100 and 1000 μM were applied, an almost complete inhibition of frond production, indicated by the growth rate (K), and biomass production (DW) was observed in E medium, with and without sucrose (data not presented). Daily inspection of the cultures showed that 24 hr after treatment, all the fronds exhibited bleaching or the loss of CHL. Four days after treatment, there was a small degree of recovery detected at 100 and 500 μM SA. A few daughter fronds began to grow, and several morphological changes were apparent. Plants were small in size, different in shape, had brown-yellow edges, and very small (<0.5 cm) or no roots. This growth might have occurred because the uptake of SA is rapid and linear for at least the first 24 hr (Ben-Tal and Cleland, 1982). These investigations determined that there was virtually no transfer of SA from the mother to daughter fronds, indicating that the SA was apparently sequestered within the cells. In this way the oldest generation absorbs some of the compounds, thus lowering its concentration in the medium and allowing the daughter fronds to resume some growth.

Results of experiments to test the effects of allelochemicals on *L. gibba*

G3 in E medium with and without organic constituents are shown in Table 1. The threshold for inhibition of all measured attributes was reached at a lower concentration with SA than with FA or UM. In cultures containing sucrose and tartaric acid, inhibition was typically greater. The inhibition threshold was lower for total chlorophyll production, where a 50% reduction occurred with 20 μM SA compared to a 70 μM threshold for those plants tested in medium without organic amendments. The threshold for FA-induced chlorophyll reduction was also lower in cultures with organic amendments; 100 μM vs 750 μM without amendments. These differences between the two culture media are contrary to

those found by Einhellig et al. (1985) using *L. minor* 5 in small volume bioassays for allelochemicals. Their results showed that culturing duckweed without organic amendments resulted in lower thresholds of inhibition. Perhaps the larger size of *L. gibba* G3 and the greater volumes of medium utilized in the tests presented here are factors that influenced these results. Unlike SA and FA, treatments of UM were most inhibitory (500 μM, DW) in cultures without sucrose.

At the lowest concentration of FA and UM tested, stimulation of K, DW, and CHL was apparent (Table 1). CHL production was significantly stimulated in sucrose cultures with 100 and 500 μM UM. It has frequently been reported that inhibitory allelochemicals are often stimulatory at very low concentrations (Rice, 1984). Leather and Einhellig (1985) reported stimulation of *L. obscura* 7133 by several allelochemicals.

In a few instances where tests were conducted in medium without sucrose, preconditioning of the *L. gibba* G3 for two weeks prior to the test affected the threshold of inhibition (Table 2). Using cultures taken from stock grown without organic amendments, the SA threshold for affecting DW and CHL was slightly lower than when the stock culture had been grown with sucrose and tartaric acid. Conditions of growth for *L. gibba* G3 prior to transferring to flasks with FA and UM did not appear to make a substantial difference in the inhibitory effects of these treatments. Likewise, stimulation of K was obtained with 500 μM UM under both culture preconditions.

Although the experimental design and conduct of tests at different times does not allow direct statistical comparisons, the apparent effect of autoclaving SA is noteworthy. The thresholds of inhibition were lower for K, DW, and CHL when tested without organic amendments in the first experiments (Table 1) than those obtained under similar conditions in the second experiment shown in Table 2 (from stock W/S). It is possible that decomposition by heat enhanced the effects of SA. Similar results were reported for gibberellic acid (GA_3) on *Lemna* (Pieterse, 1976). Further study to determine the action of heat on SA is necessary. Comparisons between Tables 1 and 2 show autoclaving caused no apparent effect on the action of FA. The threshold for inhibition of DW by UM was slightly lower when this allelochemical was in the medium during autoclaving. We attribute this lower threshold to greater solubility of UM resulting from the heat during autoclaving.

Morphological changes occurring at and above the threshold of inhibition were similar to those observed and previously described for the preliminary tests with SA. At 500 μM FA and UM, bleaching was apparent, but was not severe. The fronds were smaller than in controls, not well developed, and clumped (daughter fronds did not separate from mother fronds). Fronds were less gibbous and had shorter (0.5 cm or less) or no roots. At 1000 μM FA and UM, the pattern of injury was similar but much more severe than at 500 μM. The

[c] Treatments were prepared using stock plant material from cultures maintained without sucrose.

colonies were more clumped than with 500 μM treatments. Nevertheless, morphological changes were less than the same concentrations of SA.

L. gibba G3 responses to the three allelochemicals (SA, FA, and UM) tested showed good sensitivity. The threshold levels for inhibition were at slightly higher concentrations than for other species of duckweed, but generally they are lower than for other bioassays commonly used in the study of allelopathy (Einhellig et al., 1985; Leather and Einhellig, 1985, 1986). SA was the most potent inhibitor of the three allelochemicals tested, causing growth alter-

ations at micromolar concentrations well below those observed for FA and UM. The action of SA diminishing CHL production was the most sensitive indicator. The three compounds generally produced similar responses in *L. gibba* G3 at the minimal concentrations at which they began affecting the plant for all the parameters tested. Responses were found to be more easily identified and consistent in all tests performed with E medium not enriched with sucrose and tartaric acid. The enrichment, however, sometimes resulted in more severe inhibition of *L. gibba* G3 by the allelochemicals. Although values for CHL-a and CHL-b were determined, there were no differences in threshold levels of inhibition from total CHL caused by allelochemicals tested, nor were there differences in the ratio of CHL-a to CHL-b (data not shown).

Because of its size and the volume of medium required for growth, *L. gibba* G3 was not suitable as a bioassay organism under the conditions reported earlier (Einhellig et al., 1985; Leather and Einhellig, 1985) but could be used in the further study of allelochemical interactions and mechanisms. Its physical characteristics of predictable size, shape, gibbosity, pigmentation, and root length exhibit adequate sensitivity to the effects of substances on the plant even before the analysis of data. Effects on CHL production are readily apparent by inspection, and quantification of CHL was easily obtained. Effects on CHL were the most sensitive indicator of the allelochemical effects in the case of SA.

Acknowledgments—We thank Dr. Charles F. Cleland, Smithsonian Environmental Research Center, Rockville, Maryland, for the cultures of *L. gibba*.

Abstract—Materials eliciting increased tongue flicking and prey attack in garter snakes were isolated from both earthworm and fish prey. New extraction methods based on chloroform–methanol mixtures are valuable adjuncts to the more typical aqueous preparations. Both high- and low-molecular weight components from earthworms and fish were active. The similarity between the active chemicals in these two classes of prey was established using several methods of analysis. These included chromatography, carbohydrate and amino acid analyses, and nuclear magnetic resonance.

Key Words—Chemoreception, garter snakes, *Thamnophis sirtalis*, chemical cues, vomeronasal system, *Lumbricus terrestris, Pimephales promelas.*

INTRODUCTION

The prey of garter snakes (*Thamnophis*) is quite diverse and includes earthworms, fish, slugs, leeches, salamanders, frogs, and rodents. However, some garter snake species specialize more than others on certain kinds of prey (Carpenter, 1952; Drummond, 1983), even when several prey classes are available in the habitat. The occurrence of such prey preferences is not limited to adult snakes but is also shown by ingestively naive newborn snakes.

Snakes of the genus *Thamnophis*, as well as many others, use chemical cues to discriminate among various prey items (Burghardt, 1970, 1980; Arnold,

0098-0031/88/0300-0855$06.00/0

1981). Surface chemicals can be easily removed from various prey and used to elicit feeding responses. The most common method involves presenting aqueous prey extracts to snakes with cotton swabs and recording both the number of tongue flicks and the latency of any prey attack. Extensive comparative studies show that newborn snakes may also respond to a wide range of prey chemicals highly correlated with the normal prey preferences of the species in the laboratory and field. Several studies have addressed the sensory mechanisms by which snakes detect prey chemical cues and the tongue–vomeronasal system appears largely responsible (Burghardt, 1970; Halpern and Kubie, 1984).

The wide range of inter- and intraspecific variability in the chemical responsivity of snakes to various prey, coupled with the strong genetic component underlying neonatal preferences (Burghardt, 1969, 1970; Arnold, 1981), makes this system a prime candidate for the study of evolutionary mechanisms of prey preference and chemosensory releasing mechanisms, as well as the partitioning of feeding behavior among diverse prey by sympatric guilds of related snakes. To fully carry out this task, however, more precise information is needed on the specific chemicals in various prey that snakes use in selecting prey.

To date, the chemistry of prey recognition has been limited to analysis of aqueous extracts (warm water washes) of earthworms (*Lumbricus terrestris*). Sheffield et al. (1968) showed that the nonvolatile components were critical in eliciting prey attack. Fractionation using Sephadex chromatography provided active components in at least two different molecular-weight ranges: substances more than 5000 daltons and fractions (in the vitamin B_{12} marker range) of about 1350 daltons, although the larger component was more effective. More recently, Halpern et al. (1984) have also investigated earthworm extracts in an attempt to identify active materials. They unequivocally report only a single nonvolatile component with a molecular weight in excess of 65,000 daltons. Recently, they have shown the similarity of the chemical composition of this fraction to the collagen found in earthworm cuticle (Halpern et al., 1986; Kirschenbaum et al., 1986). These workers used, it should be noted, a bioassay based only on relative tongue-flick rate and duration measures, not the more definitive attack measure (snakes tongue flick in response to many kinds of stimuli, not just food-related ones).

The ability of garter snakes to discriminate among extracts from different prey implies that different cues are recognized. However, even within the same species, initial and experience-altered preferences show that individual snakes discriminate the chemical cues from different prey. In the present study, we compare the effective chemicals from two diverse prey: a fish, the fathead minnow, and the well-studied nightcrawler earthworm. We tested Eastern garter snakes, a species that eats fish and worms both in the field and in captivity. The main question we seek to answer here is how similar or different chemically are the effective chemical cues from such diverse prey taxa.

METHODS AND MATERIALS

Animals

Freshly obtained earthworms (*Lumbricus terrestris*) and fish (fathead minnows, *Pimephales promelas*) were used to obtain the extracts. The predator species were primarily wild-caught or laboratory-reared Eastern garter snakes (*Thamnophis sirtalis*) from Michigan (Wayne County) stock with a few tests also including local (Knox county, Tennessee) animals. All animals were tested in their home cages, which varied depending on their size from plastic boxes to 60-liter aquaria. Snakes were tested at a temperature of 25 $\pm$ 2°C.

Prey Extraction Procedures

Aqueous Prey Extractions. Preparation of aqueous prey extracts followed Burghardt (1969). We extracted prey animals for 2 min with a ratio of 3 g of prey to 10 ml of distilled H_2O at 60°C. The solution was decanted and centrifuged for 10 min at 2500 rpm. The aqueous extract was then frozen or lyophilized to preserve activity. The amount of material obtained from prey ranged from 2 to 3 g/liter. References to this aqueous extract obtained from the earthworm and fathead minnow will be referred to as AQ-EW and AQ-FM, respectively. In the codes for test extracts, the extraction procedure is indicated first with the type of prey extracted (EW or FM) listed after the dash.

Methanol–Chloroform Extractions of Aqueous Extract. The lyophilized aqueous extract (0.71 g) was extracted for 15 min with 100 ml of 1 : 4 methanol–chloroform. The solution was filtered and extracted with 100 ml of 1 : 1 methanol–chloroform. The two solutions were combined and evaporated to dryness (Wold and Selset, 1977). Approximately 6% and 23% by mass of the materials obtained from this AQmc extraction from earthworm and fathead minnow, respectively, were soluble in the methanol and chloroform extracts. From this extraction procedure, there were materials that were soluble and insoluble in the methanol–chloroform solutions. The soluble compounds were labeled $AQmc_{sol}$-EW and $AQmc_{sol}$-FM and the insoluble compounds $AQmc_{insol}$-EW and $AQmc_{insol}$-FM.

Methanol Extractions of Aqueous Extract. The lyophilized aqueous extract (1.75 g) was extracted for 15 min with 75 ml of methanol. The insoluble materials were filtered with a fine glass frit and extracted again in the same manner. The insoluble compounds were extracted four additional times for 10 min with 25 ml of methanol and filtered between each extraction. All the methanol extracts were combined and evaporated to dryness. Approximately 24% and 52% by mass of the material extracted was soluble in the methanol extractions from the earthworm and fathead minnow aqueous extracts, which are labeled AQm_{sol}-EW and AQm_{sol}-FM, respectively.

Chloroform–Methanol Prey Extractions. In this procedure, 1000 g of prey was extracted for 4 min at 23°C with a solution containing 2000 ml of methanol and 1000 ml of chloroform. The solution was decanted and the prey extracted again with 1000 ml of chloroform. After 4 min, the second solution was decanted from the prey, combined with the first, and filtered with a coarse glass frit to remove particulate matter. The filtered solution was poured into a 5-liter separatory funnel and extracted with 1000 ml of distilled H_2O. The resulting emulsion was allowed to stand at 4°C, during which time it separated into two layers. After two days, the biphasic solution was allowed to warm to room temperature. The water layer was removed and filtered with a medium glass frit. Both the water and organic layers were evaporated to dryness. About 3–5 g of material were obtained per kilogram of prey, and 31% and 40% by mass of these materials were obtained from the earthworm and fathead minnow water layers, respectively. This extraction procedure is referred to as the CM extraction. The materials from the organic layer were coded CMo-EW and CMo-FM. Those from the water were labeled as CMw-EW and CMw-FM.

Chromatographic Separations

All chromatographic separations, unless otherwise stated, were conducted on a low-pressure liquid chromatography system. The system included an FMI lab pump (model RP-SV), Laboratory Data Control refractive index detector (model 1107H), and a Scientific Manufacturing Industries, fraction collector (model 12050).

Bio-Gel P-10 and P-2, 50–100 mesh and Sephadex G-200 filtration gel, 40- to 120-μm particle size were utilized. For all gel filtrations, the column-packing material was swollen and eluted with 10% ethanol in distilled water. The column size used for the analytical separations was 1.1 × 30 cm, and for the preparative separation was 3 × 23 cm. The flow rates for the analytical and preparative columns were approximately 0.4 ml/min and 1.4 ml/min, respectively. The pressure in the system was maintained below 4 psi in all cases. The fraction collector was adjusted to collect fractions at time intervals of 5 min for the analytical separations and 15 min for the preparative separations. The sample injections ranged from 30 to 40 mg for the analytical separations, while 0.50 g was used for the preparative separations.

Sephadex A-25 (diethylaminoethane anion exchange resin), 40- to 120-μm particle size, was packed in an analytical column. The exchange resin was utilized in the chloride form. The column was eluted with water and a step gradient of NaCl solution from 0.25 M to 1.0 M in increments of 0.25 M. The flow rate was 1.0 ml/min.

An analytical silica gel column was packed with Silica Gel 60 (particle

size 0.04–0.063 nm) from EM Laboratories Inc. The column was filled with 17 g of silica and vibrated until the packing material finished settling. The column was packed and eluted with 3:2 methanol–chloroform by volume. The flow rate of the system was 0.5 ml/min.

Silica gel separations were also conducted with gravity eluted (3 × 75 cm) columns. Silica gel, 60–200 mesh (60 g) (J.T. Baker Chemical Co.) was packed with 3:2 methanol–chloroform. The sample (0.30 g) dissolved in methanol was then evaporated until dry with 5 g of silica applied to the top of the silica column and the column eluted with 3:2 methanol–chloroform. In the separation of the fathead minnow material, the column was subsequently eluted with 3:2 methanol–chloroform that was saturated with H_2O.

Silica Thin-Layer Chromatography (TLC). Silica gel G (type 60, EM Laboratories Inc.) was used. The TLC plates were eluted with 3:2 methanol–chloroform or 3:2 methanol–chloroform saturated with water. Separations were visualized using iodine vapor or by treating the plate with an alpha-naphthol–sulfuric acid solution (1.0 g of alpha-naphthol dissolved in 5 ml of concentrated sulfuric acid diluted after 24 hr with 95 ml of ethanol) to detect carbohydrates. After spraying with the alpha-naphthol–sulfuric acid solution, plates were heated in a drying oven at 140°C for 2 min. Carbohydrates were visualized as purple spots on the TLC plate.

Dialysis Procedure

Sixty-four centimeters of 6000–8000 molecular weight cutoff dialysis tubing was boiled for 10 min in 950 ml of 2% sodium bicarbonate with 1 mM of disodium ethylenediamine tetraacetate in water. The dialysis tubing was cooled to room temperature in the solution, and two knots were tied in the bottom of the tubing. Aqueous prey extract (18 ml) was poured into the dialysis tubing and then was enclosed by tying two additional knots at the upper end. The filled dialysis membrane was inserted into a beaker containing 100 ml of distilled water and allowed to stand at 4°C for 24 hr. The dialysis solution was changed every 24 hr for three days.

Analysis of Active Components

Molecular Weight Estimates. Materials that were not retained by the Bio-Gel P-10 gel filtration column were estimated for molecular weight on a Sephadex G-200 column (1.1 × 30 cm). G-200 resin, 40- to 120-μm particle size, was reconstituted and packed with water. A mixture of molecular weight standards was used for calibration (Bio-Rad). The molecular weight standards and samples were eluted with water at a flow rate of 3.2 ml/hr. The fractioning range of Sephadex G-200 for globular proteins is rated from 5000 to 600,000

daltons (Grodon and Richard, 1972). In this study the upper limit for fractionation was assumed to be 600,000 daltons; however, the lower limit was estimated to be 17,000 daltons since the 1350- and 17,000-molecular-weight markers had the same retention volume. A graph was plotted of $\log_{10}$ of the molecular weight marker versus its K_{av} value ($K_{av} = (V_e - V_0)/(V_t - V_0)$ where V_e is the elution of the molecular weight marker, V_0 is the void volume of the column, and V_t is the total volume of the column). A least-squares approximation was made to obtain the best linear correlation, and this was used as a calibration plot to estimate the molecular weights of the unknown samples.

Components that were retained by the Bio-Gel P-10 gel filtration column were calibrated for molecular weight on a Bio-Gel, 50–100 mesh, P-2 column (1.1 × 30 cm). The column was packed with water, and the flow rate for the separation was 1.1 ml/min. The low-molecular-weight samples and the gel filtration standards that were used to calibrate the G-200 column were injected and eluted with water. Bio-Gel P-2 has the fractioning range of globular proteins of 100 to 1800 daltons. No calibration plot was obtained from the Bio-Gel P-2 column since sufficient standards were not available.

Sugar Analysis. Samples analyzed for carbohydrates were derivitized by the following method: 2.0 ml of aqueous 2 N trifluoroacetic acid was added to 30 mg of sample and the solution heated for 2 hr at 120°C. The hydrolyzed solution was evaporated to dryness and treated with 3 ml of water. The water was evaporated to dryness, and this procedure was repeated twice. The sample was reconstituted with 3 ml of water containing 25 mg of $NaBH_4$ and stirred for 16 hr. The $NaBH_4$ solution was acidified with Dowex 50W-X2 to pH 2 and filtered with a fine glass frit. The water from the filtrate was removed by codistillation with four 5-ml portions of methanol. Next, 3 ml of a 1 : 1 mixture of pyridine and acetic anhydride was added and the sample stirred for 16 hr. The pyridine, excess acetic anhydride, and other by-products of the reaction were removed from the sample by codistilling with four 5 ml portions of toluene. With each codistillation, the mixture's concentration was increased, finally evaporating the sample to dryness. The mixture was reconstituted with 300 μl of methylene chloride for gas chromatography (GC) and gas chromatography–mass spectrometric (GC-MS) analysis (Jansson et al., 1976).

Standards of sugars were derivitized in the same way as the samples analyzed for carbohydrates except that the hydrolysis with 2 N trifluoroacetic acid was omitted. The following sugars were used as standards in the amounts indicated: glucose (4.8 mg), galactose (2.0 mg), mannose (1.8 mg), xylose (4.1 mg), arabinose (1.9 mg), and myoinositol (2.2 mg). The standard was reconstituted with 900 μl of methylene chloride for GC and GC-MS analysis.

Gas chromatography was conducted with 0.4-μl sample injections using a 1.8-m × 2-mm-ID glass column containing 3% SP-2330 on 100–120 Supel-

coport. The samples were injected at an initial temperature of 180°C with an initial temperature hold of 6 min. The temperature ramp rate was 2°C/min to a final temperature of 240°C. The nitrogen carrier gas was at a flow of 20 ml/min, and a flame ionization detector was employed. The identity and concentrations of the unknown sugars were determined by comparing retention times and peak areas to known sugar standards of known concentrations.

GC-MS analysis was employed to confirm the identity of the acetylated sugars using Hewlett Packard models 5710H GC and 5980H MS. The same type of column and separation parameters were utilized for the GC-MS as for the GC separations with a helium flow rate of 25 ml/min and sample size of 10 μl. Electron impact was used at an ionization potential of 25 eV.

Amino Acid Analysis. Samples for amino acid analysis were reconstituted with water at a concentration of 1.0 mg/ml. An estimated 10 nm of compound from the 1.0 mg/ml sample was inserted into a small vacuum vial along with constant boiling HCl (0.4–1.0 ml). The resulting solution was frozen with liquid nitrogen and vacuum sealed. The vial was heated to 105°C and after 23 hr the sample was frozen and the vial opened and dried under vacuum over KOH. The sample was analyzed by the Analytical Services Facility at the University of Tennessee, Knoxville, using a reverse-phase column with a high-pressure liquid chromatograph. A precolumn derivitization method was used with phenol isothiocyanate for detection at 254 nm. A 0–60% acetonitrile gradient program was run at 37°C.

Nuclear Magnetic Resonance. Proton and carbon-13 nuclear magnetic resonance (NMR) of mixtures were obtained using a NT 200-WB Nicolet NMR. All samples were submitted for analysis in D_2O with acetonitrile as the reference. Presaturation experiments were conducted with all samples to reduce the HOD peak found in all proton magnetic resonance spectra.

Bioassay Procedures

The number of snakes tested in each bioassay varied between five and 12, depending on the number of extracts and the number of responsive snakes available for testing. Typically each snake was tested only once on each stimulus in a given bioassay session, in a counterbalanced fashion. Occasionally, when fewer snakes were available due to heavy recent feeding, illness, or skin shedding, suitable snakes were tested twice on each stimulus but with reversed stimulus orders. Snakes were never run on a bioassay more than once a week, usually the day before their weekly scheduled feeding.

After several bioassays, the snakes were screened a few hours before the bioassay by testing their responsiveness to aqueous extracts of the prey chemical stimuli being tested in that bioassay. Such screening resulted in a more discrim-

inating bioassay, since nonresponsive snakes were eliminated and were thus excluded from the statistical evaluation. It was also found that the snakes were more responsive if they were fed on half food rations one to two weeks before the bioassay. The food rationing technique usually resulted in a three-week feeding schedule where the snakes were given all the food they could eat every third week, and their food supply was reduced by half on the first and second weeks.

All extracts were reconstituted in distilled H_2O to a concentration representing, as nearly as possible, that found in the original extracts, less estimated losses on columns, etc. The number of stimuli in each bioassay ranged from three to seven, always including a distilled-water control and an AQ or CM extract of the prey being tested. All tests were conducted blind.

In the bioassay, a 15-cm wooden cotton-tipped swab was dipped in the extract and introduced into the snake's home cage about 2 cm from its head. It remained in that position as closely as possible (by following snake movements) for 30 sec or until the snake gave an open-mouth attack. The number of tongue flicks directed towards and away from the swab and the latency of any attacks were recorded. If the snake did not tongue flick in 10-15 sec after being presented with a stimulus, the end of the swab was brushed lightly on the snake's back to induce the snake to emit at least one tongue flick. For any bioassay series, the time between tests was kept constant, usually about 10-15 min and never less than 7 min. This basic methodology has been used in many studies (e.g., Sheffield et al., 1968; Burghardt, 1969, Arnold, 1981).

The working definition of an active component was a compound or mixture of compounds that both (1) elicited a minimum of two prey attacks by two different garter snakes of the same species and (2) exhibited a tongue flick–attack score statistically greater than water. Due to an initial shortage of garter snakes, the first criterion of this definition was relaxed if a replicate test series demonstrated statistical significance using the tongue flick–attack score and a subsequent bioassay based on the results led to satisfaction of the first criterion.

Statistical analysis to distinguish active from inactive stimuli was accomplished by comparing the extract data to distilled water controls and to the AQ or CM extract. The water control represented no activity, whereas the extract represented strong activity. The basic data for the statistical analyses were the number of attacks, attack latency time, and the number of tongue flicks each snake exhibited toward each stimulus. These were combined into a tongue flick–attack score (Burghardt, 1969) in which any attack received a higher score than any number of tongue flicks.

A two-way analysis of variance (repeated measures—stimulus $\times$ subjects) was run on the data for all the extracts tested in the bioassay excluding data from snakes that neither attacked any stimulus nor gave at least five tongue flicks toward at least one stimulus. If the variances were not homogeneous

(Hartley's F-Max test), a square root transformation was performed before all parametric tests. A nonparametric Friedman's two-way analysis of variance (ANOVA) was also performed. If the overall ANOVAs were significant, planned comparisons of prey extracts with water were made. A nonparametric Wilcoxon signed rank-matched pairs test (or a dependent *t* test if the number of subjects was six or fewer) was calculated. One-tailed *P* values are presented since, in all cases, only an increase in responsivity over water was being evaluated. All statistical calculations were performed using the Statgraphics package (Version 1.1) on an IBM-PC.

RESULTS

Only bioassay results for the major separations on which final conclusions are based will be detailed.

Separations of Earthworm Extracts

The lyophilized aqueous earthworm extract was separated on an analytical Bio-Gel P-10 gel filtration column which fractionates globular proteins from 1800 to 20,000 daltons (Gordon and Richard, 1972). However, this extract contained materials that did not pass through the column and prevented its reproducible and repeated use. In an attempt to remove the contaminants before the separation, the lyophilized material (AQ-EW) was extracted with methanol and chloroform to obtain $AQmc_{sol}$-EW. This extract was moderately active.

The material that was insoluble in the methanol–chloroform extract ($AQmc_{insol}$-EW) was separated on the P-10 gel filtration column and two major fractions of compounds were obtained. The first fraction was a multicomponent mixture ($AQmc_{insol}$-EW-HMW_{P10}) eluting close to the void volume of the column, indicating a molecular weight of at least 20,000 daltons or greater. The second fraction contained a mixture of compounds ($AQmc_{insol}$-EW-LMW_{P10}) that eluted close to the column volume, indicating a molecular weight of approximately 1800 daltons or less. Both fractions were active, although the low-molecular-weight fraction was shown to be active only for the second test.

Since it was found that the methanol–chloroform extracts from the lyophilized aqueous extracts ($AQmc_{sol}$-EW) were active, another extraction method was developed using methanol as the extraction solvent. Methanol was chosen since it was assumed that the active components were polar because of their solubility in water. The materials extracted by methanol from the lyophilized aqueous extracts were coded AQm_{sol}-EW and were active, as seen in Table 1.

The materials obtained from AQm-EW were separated on the Sephadex A-25 column. The column was injected with 0.47 g of material that had been reconstituted with water. All activity occurred in the material eluting at the void

volume of the column, which was clearly active. Of eight snakes tested, five attacked the swab (as compared to eight attacks to the AQ-EW). The first fraction, which included all of the compounds eluting at the void volume of the column, contained 71% by mass of the materials injected on the column.

The active material obtained from AQm_{sol}-EW was applied to a silica low-pressure liquid chromatography column. No active fractions could be obtained when eluting with 3:2 methanol–chloroform. In view of later results it was assumed that the active components from the extract were destroyed by the acidic packing material or adhered to the column.

Since it was observed that some active components from the lyophilized aqueous extract of the earthworm could be extracted with methanol, a procedure was sought that would directly extract the prey with organic solvents. A procedure of Blight and Dyer (1959) fulfilled these requirements, and our adaptation of this procedure is referred to as the CM extraction.

Extraction of the prey with organic solvents followed by extraction of the organic layer with water provided active material easier to chromatograph. The organic layer from the chloroform–methanol prey extract (CMo-EW) contained no activity (Table 2), whereas the water layer was very active. The compounds obtained from the water layer were separated on the preparative Bio-Gel P-10 column into two fractions: a multicomponent high-molecular-weight fraction ($CMw\text{-}EW\text{-}HMW_{P10}$) eluting at the void volume of the column and a low-molecular-weight fraction ($CMw\text{-}EW\text{-}LMW_{P10}$) eluting approximately at the volume of the column. Both the low- and high-molecular-weight fractions were active, as seen in Tables 2 and 3.

[c] Wilcoxon signed rank-matched pairs test, $N = 7$.

Separations of Fathead Minnow Extracts

Fathead minnows were extracted as described in Sheffield et al. (1968). As in the case of the earthworms, chromatographic separation of this material was complicated by column clogging, and it was submitted to many of the same procedures to provide workable materials. Application of trhe AQmc extraction to the fathead minnow lyophilized aqueous extract provided soluble ($AQmc_{sol}$-FM) compounds that were active (Table 4). Chromatography was conducted on the insoluble material in the chloroform–methanol extractions ($AQmc_{insol}$-EW) using a Bio-Gel P-10 analytical gel filtration column and two fractions were obtained. A high-molecular-weight fraction ($AQmc_{insol}$-FM-HMW_{P10}) eluted at the void volume of the column, and the low-molecular-

[a] Five *Thamnophis sirtalis* were each tested once each on five different stimuli; one subject omitted.
[b] Square-root transformation on all data for parameteric statistics. Overall two-way ANOVA results for stimuli: Friedman's, $\chi^2 = 10.38$, $df = 12$, $P < 0.05$; $F = 5.26$, $df = 4, 12$, $P = 0.01$.
[c] Dependent t test, $df = 3$.

regions from the earthworm A-25 separation. The active compounds (AQm-FM-void vol_{A25}) from the fathead minnow were eluted at the void volume of the column and amounted to 64% by mass of the compounds that were injected.

The soluble material obtained from the extraction (AQm_{sol}-FM) was separated on a low-pressure liquid chromatography silica gel column. The extract (150 mg) was reconstituted with 4 ml of 3:2 methanol–chloroform, injected on an analytical silica column and eluted with 3:2 methanol–chloroform. One active fraction (Table 6) (AQm_{sol}-FM-$Silica_1$) was obtained that had an R_f by silica gel TLC of 0.48 when eluting with 3:2 methanol–chloroform. This fraction had a carbohydrate component that was visualized by the alpha-naphthol–sulfuric acid solution.

The active material (AQm_{sol}-FM-$Silica_1$) could not be reisolated using gravity-eluted silica columns. When such a column was eluted with 3:2 methanol–chloroform, no active fraction was obtained from AQm_{sol}-FM. Next, the same column that was eluted with 3:2 methanol–chloroform was eluted with 3:2 methanol–chloroform that was saturated with water. This later elutent provided an active component labeled AQm_{sol}-FM-$Silica_2$. The activity of the fraction is shown in Table 7. This active component had an R_f by silica gel TLC of 0.08 when eluted with 3:2 methanol–chloroform. This material was visualized using the alpha-naphthol sulfuric acid solution, thus indicating a carbohydrate component.

The CM extraction was implemented on the fathead minnow in the same manner as with the earthworm. The organic layer (CMo-FM) from the extraction, in contrast to EW, was slightly more active than water (Table 8). The water layer contained most of the activity. A dependent t test was performed comparing responses to the water and organic layers. The t test showed that the

water layer was significantly more active than the organic layer ($t = 4.30$, $P < 0.01$, $df = 5$).

A Bio-Gel P-10 separation was conducted on the active water layer (CMw-FM). Two fractions were obtained from the preparative P-10 column. A high-molecular-weight fraction (CMw-FM-HMW_{P10}) eluted at the void volume of the column, and a low-molecular-weight fraction (CMw-FM-LMW_{P10}) eluted approximately at the volume of the column. Both fractions appear as unsymmetrical peaks in the chromatogram and thus must be multicomponent mixtures. Both fractions are active as indicated in Table 9.

Silica gel chromatography was conducted on the low-molecular-weight components from the CM fathead minnow extraction (CMw-FM-LMW_{P10}). No

[a] Seven *Thamnophis sirtalis* were tested once each on four different stimuli.
[b] Square-root transformations on all data for parametric test. Overall two-way ANOVA results for stimuli: Friedman's, $\chi^2 = 13.29$, $df = 18$, $P < 0.005$; $F = 17.76$, $df = 3, 18$, $P < 0.001$.
[c] Wilcoxon signed rank-matched pairs test, $N = 7$.

active fractions were found when a gravity-eluted silica column was eluted with 3 : 2 methanol–chloroform and 3 : 2 methanol–chloroform that was saturated with water.

Analysis of Active Components

The bioassay results clearly reveal the biological similarities in the extracts of the two prey. A number of chemical similarities have also been found, although the materials from the two species are clearly different by a number of criteria.

Aqueous Prey Extracts (AQ). Aqueous extracts of both the earthworm and fathead minnow were active. Other similarities in the AQ prey extracts are that the methanol–chloroform extracts from the lyophilized extracts are also active. The high- and low-molecular-weight components of the AQmc extracts from these prey also showed definite activity documented by an increase in the tongue flick–attack score. These similarities are noteworthy since the earthworm and fish are from different phyla and live in different environments.

The mass composition of the AQmc extract obtained from both prey is shown in Figure 1. There are similarities in the solubility properties of these prey extracts, that is, the amount of material obtained per liter of extract is similar for both, and the majority of the material from the AQmc extracts was insoluble in the methanol–chloroform solutions.

Chloroform–Methanol Extracts (CM). As observed with the AQ extractions, the CM extractions gave similar results for both fathead minnow and earthworm. The active components from both were primarily in the water layer of the CM extraction. The high- and low-molecular-weight materials from the water layer elicited prey attacks from both the earthworm and fathead minnow

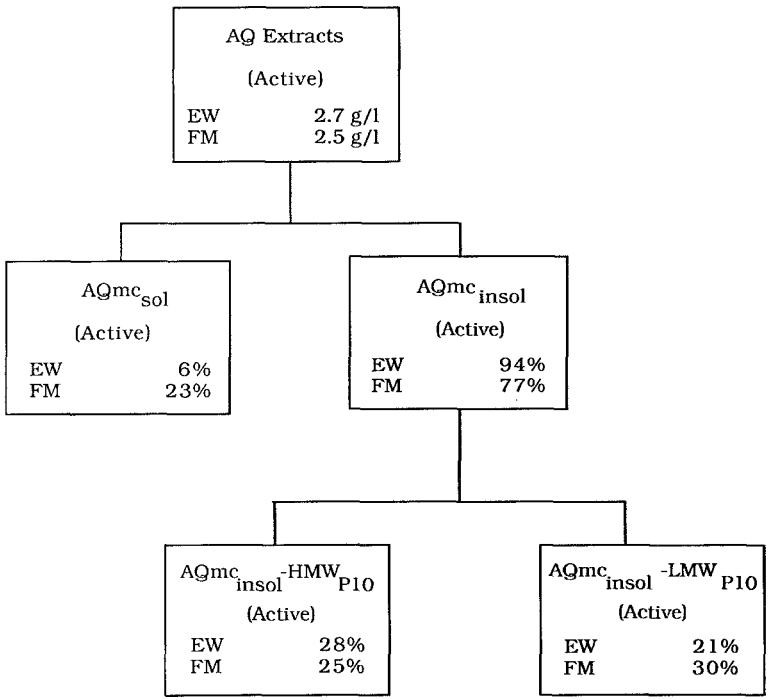

FIG. 1. Percent composition of aqueous prey extract. AQ, aqueous; EW, earthworm; FM, fathead minnow; mc, subsequent methanol–chloroform extraction; sol, soluble; insol, insoluble; HMW, high-molecular-weight fraction; LMW, low-molecular-weight fraction; P10, gel filtration column used.

(Tables 2, 3, and 8). The low-molecular-weight materials from each extract consisted of six times more material by mass than the high-molecular-weight materials. The percent composition by mass of the CM extraction for both prey is shown in Figure 2.

Molecular Weight Estimates. Molecular weight estimates of the high- and low-molecular-weight materials from the CM extraction for both the earthworm and fathead minnow were made. The high-molecular-weight materials were estimated on the basis of a molecular weight calibration plot obtained from Bio-Rad gel filtration standards on a Sephadex G-200 column. In the estimation of the high-molecular-weight materials from the CM extraction of both prey, the Sephadex G-200 column separated the material into two distinct fractions. In the case of the earthworm, the major constituent had an estimated molecular weight of 432,000 daltons. The minor constituent partially adhered to the col-
