Figure 6 shows graphs of *AI* against distance up or downhill for each of the four meadow species studied by Carral et al. (1988). The remaining species were not studied because of their low density, and indeed, it is questionable whether the density of *P. pratensis* was sufficient for the results for this species to be very meaningful. Figure 7 shows the distances for which there was a statistically significant difference between uphill and downhill *AI* (irrespective of the statistical significance of *AI*s compared). According to the classification of Table 2, it can be seen that the pattern presented by *T. repens* was type 2 (indifference–indifference, implying no interaction), with perhaps a slight tendency to type 9 (positive–negative, implying hormone-like interaction). The other species exhibit evident negative affinity for *R. obtusifolius*, with uphill–downhill asymmetries of type 7 in the cases of *L. perenne* and *P. pratensis* (negative > negative, implying hormonal or toxic allelopathy) and, in the case of *D. glomerata*, type 7 or 6 (negative–exclusion, with the same implication).

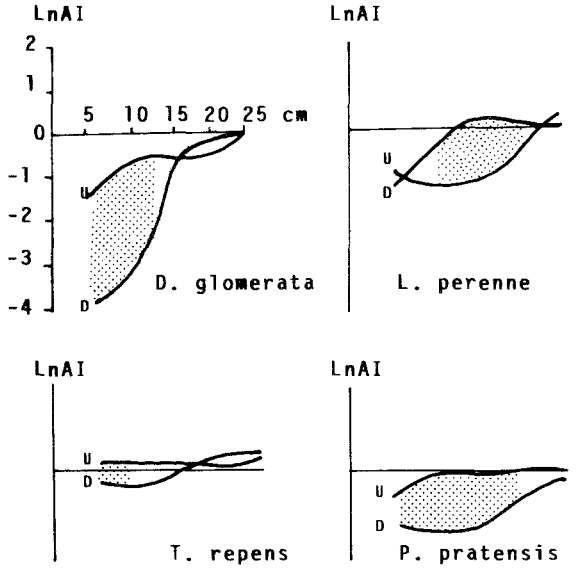

FIG. 7. Influence of distance uphill (U) and downhill (D) from *Rumex obtusifolius* on the *AI* between this primary species and four meadow species. Shading indicates distances at which the difference between the two curves is statistically significant ($P < 0.05$).

In view of the above results, we conclude that analysis of the small scale slopewise distribution of hypothetical receptors relative to a hpothetical emitter species is a simple, valid means of detecting the existence of allelopathic processes prior to subsequent research on the routes by which allelochemical agents are released, their chemical composition, the relationship between environmental factors and allelopathic efficiency, or the development of bioassays which adequately reflect natural conditions.

Editor's Note

The fourth annual meeting of the International Society of Chemical Ecology was held on July 13–17, 1987, at the University of Hull, England. This represented the first meeting of the society outside of North America since its founding in 1983. In keeping with the practice of the previous meetings, four symposia were featured, highlighting recent progress in diverse aspects for chemical ecology. These were: The Veracity of Bioassays in Chemical Ecology, Chemical Ecology and Plant Protection, The Applications of Chemical Ecology, and Biochemical Mechanisms and Defense Compounds. As official journal of the society, the *Journal of Chemical Ecology* is dedicating this issue to the proceedings of those symposia.

Each invited symposium paper has undergone peer review in accordance with the standard review policy of the Journal. We are grateful to the Chairman of the meeting, D. A. Jones, for his assistance in coordinating receipt of the manuscripts and to the following reviewers: G. J. Bakus, M. R. Berenbaum, U. Blum, J. M. Bradow, J. P. Bryant, B. C. Campbell, J. Cane, P. J. Canney, P. F. Dowd, S. R. Gliessman, A. E. Hagerman, M. B. Isman, K. F. Haynes, J. A. Juvik, I. Kubo, A. F. Moldenke, D. H. Netzly, F. Plapp, T. Robinson, J. R. Shann, C. M. Smith, J. N. M. Smith, J. F. Sutcliffe, N. M. Targett, and E. W. Underhill.

We acknowledge the cooperation of Plenum Publishing Corporation in producing extra copies of this issue to accommodate registrants of the meeting and others interested in the proceedings under this single cover.

PLANT POLYPHENOLS (*syn.* VEGETABLE TANNINS) AND CHEMICAL DEFENSE—A REAPPRAISAL

EDWIN HASLAM

Department of Chemistry, University of Sheffield
Sheffield, S3 7HF, United Kingdom

(Received September 15, 1987; accepted February 16, 1988)

Abstract—Many of the hypotheses adumbrated to rationalize the role of natural products in plant–herbivore interactions have focused attention on plant polyphenols (syn., vegetable tannins). Contemporary interpretations of the importance of plant polyphenols rest largely on the assumption that they act via their capacity to bind to proteins. The central proposition of plant–herbivore interactions, namely that plants, as a response to environmental pressures, have evolved the strategem of a chemical armory appropriate to the challenges they face, is examined in the context of plant polyphenols—their ability to complex to protein and their possible function as structural polymers.

Key Words—Plant polyphenols, vegetable tannins, biosynthesis, structure-activity relationships, protein complexation, proanthocyandidins, structural polymers.

INTRODUCTION

In comparison with the ubiquitous intermediates of primary metabolism, an infinitely greater body of natural products such as alkaloids, phenols, polyenes, polyacetylenes, terpenes, and polyphenols (tannins) occurs sporadically throughout the plant kingdom. Despite a great deal of thought, speculation, and research, they still frustrate all attempts to fit them readily into the general framework of higher plant metabolism and hence the economy of the producing organism. Because of their apparently secondary role, these substances are frequently referred to as secondary metabolites; as Bu'Lock (1980) perceptively noted, they express the individuality of species in chemical terms.

Over the past 30 years, a substantial literature has accumulated that sug-

0098-0331/88/1000-1789$06.00/0

gests a great many of these secondary substances are intimately concerned in the complex interactions between plants and their environment and that this is the raison d'dêtre for their existence. Various workers, most notably Fraenkel, Ehrlich and Raven, Feeny, Rhodes, Janzen, and Cates, among others, were responsible for the emergence of this view that secondary substances play the leading role in the determination of patterns of plant utilization by herbivores. This theory, which has an immediate intuitive appeal, has gained increasing prominence and has stimulated an exponential increase in work in this area over the past decade. However, the development of these ideas into a comprehensive theory of plant and animal coevolution sit, in the intellectual sense, far less comfortably, in particular the central proposition that plants, as a response to environmental and ecological challenges, have evolved the strategem of a chemical armory appropriate to the pressures that they face.

The intellectual effect of this theory has been hypnotic. However, should the metabolic significance of particular secondary metabolites be sought exclusively in terms of its relationship with predators, competitors, and its environment or in the context also of the plant's internal economy? This alternative perspective is given prominence here in relationship to the purported role of plant polyphenols (syn., vegetable tannins) in chemical defense. There is, as yet, no compelling evidence that tannins have any function in the physiological processes of plants, and, since Feeny's seminal papers (1968, 1970) on the deleterious effects of dietary tannins on the feeding of the larvae of the winter moth (*Operophtera brumata*) on oak, the view has developed that tannins constitute a unique quantitative defense. Feeny surmised that polyphenols are characteristic of the chemical defense of apparent plants and act as dosage-dependent barriers even to predators that may, in other circumstances, feed on such plants. The relevant physiological effects of polyphenols upon herbivores derive, it has been assumed, from their ability to complex with proteinaceous materials. Polyphenols thus have a harsh, astringent taste and produce in the mouth a feeling of constriction, dryness, and roughness. These effects are thought to be due specifically to polyphenol complexation with superficial glycoproteins within and without the epithelium and, it is believed, that they thereby render many plant tissues repellent and unacceptable as food sources to potential predators. The same interactions also undoubtedly influence and decrease the dietary value of nutritionally important forage crops such as sorghum and various categories of fodder tree leaves. This, it is believed, constitutes a second mode of chemical defense mediated by vegetable tannins.

The past decade has not only witnessed an explosive growth of interest in this area, but it has also quite clearly shown that the situation in nature, "on the ground," is much more complex than had been anticipated. Experiments on insects have thus demonstrated that, while plant tannins may deter many insects from feeding, others may be quite impervious to their deleterious effects.

Most significantly, however, their chemical complexity and heterogeneity means that they do not lend themselves to ready quantitative assessment, and this, in the author's view, has produced a confused picture of their real significance—both evolutionary and ecological.

If tannins are so generalized in their action, it is very difficult to rationalize this generality with the very wide structural diversity found among the plethora of plant polyphenols—particularly those of the hydrolyzable tannin class based on gallic acid and its derivatives (Figure 1). If these particular metabolites are the end products of energy-demanding syntheses and are not a capricious whim of nature, then it is reasonable to assume that there has been positive selection for their production. If it is the interaction of tannins with proteins and other biological macromolecules, particularly their effect on enzymic processes, that underlies their widely assumed ecological significance, then some correlation should exist between polyphenolic metabolites and their ability to complex with proteins. This proposition is discussed below as is a reinterpretation of Feeny's classic papers on the seasonal changes in oak (*Quercus robur*) leaf tannins.

DISCUSSION

The word tannin has a long established and extensive usage, particularly in the botanical literature, but a firm definition of what constitutes a vegetable tannin is not easy to give. The original implications of the word clearly indicate a plant material that produces leather from hide. Probably the most acceptable definition is still that of Bate-Smith and Swain (1962). They adopted the earlier ideas of White and classified vegetable tannins as "water-soluble phenolic compounds having molecular weights between 500 and 3000 and, besides giving the usual phenolic reactions, they have special properties such as the ability to precipitate alkaloids, gelatin and other proteins." Many still prefer the description "tannin," which they find valuable simply because of its lack of precision. Scientifically and terminologically plant polyphenol is to be preferred for this class of higher plant secondary metabolite.

Plant polyphenols are broadly divisible into two major groupings—the proanthocyanidins and the polyesters based on gallic and/or hexahydroxydiphenic acid and their derivatives (Haslam, 1981). As they were recorded in the earlier literature, the former category corresponds to that of the condensed tannins and the latter to the hydrolyzable tannins. Plant polyphenols possess several distinctive molecular characteristics that set them apart. Not only do they carry a multiplicity of phenolic groups, but their molecular weights encompass a wide range. Proanthocyanidins have been described up to 20,000 in molecular weight, and esters of gallic acid and its derivatives are found with molecular weights in the region of 3000 daltons. Bate-Smith and Swain (1953) and Bate-

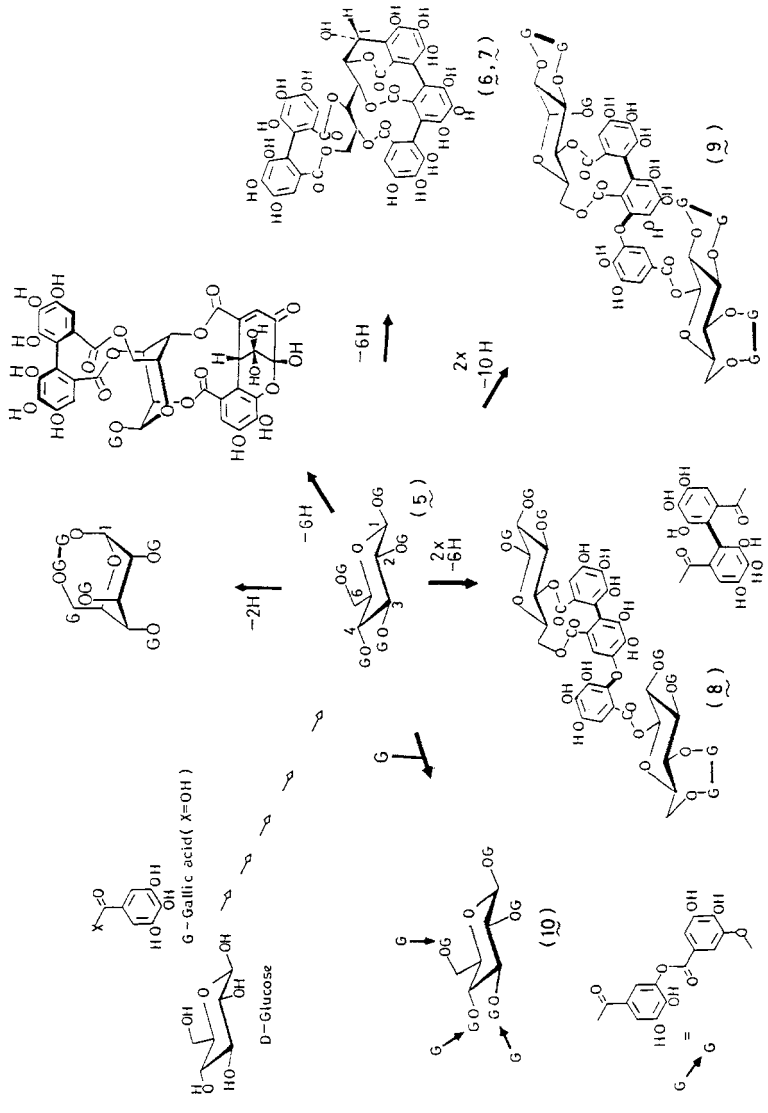

FIG. 1. Gallic acid metabolism in higher plants.

Smith and Metcalfe (1957) first drew attention to the very close similarity in the recorded systematic distribution between leucoanthocyanins (as proanthocyanidins were generally referred to at that particular time) and the diverse class of substances known in the botanical literature as "tannins." These authors suggested that proanthocyanidins were most commonly responsible for the range of reactions which, up until that point, had been attributed to the presence of tannins in plants. Subsequent detailed work, in which polyphenolic metabolites have been isolated from plant materials and identified, has given credence to that view.

Polyphenol–Protein Complexation. Although C_6–C_1 phenolic acids are found in plants and microorganisms, their occurrence is nevertheless sporadic and often constitutes something of a taxonomic speciality. In this respect, one of the most familiar examples is the willow family (Salicaceae) in which derivatives of salicyclic acid are found. Hydroxybenzoic acids and benzoic acid itself are consistently located throughout the plant kingdom esterified to both terpenoid and alkaloid structures. Likewise, although the various hydroxycinnamic acids (*p*-coumaric, caffeic, ferulic, sinapic) are ubiquitous in higher plants, they are normally found only as mono- and occasionally as bisesters with polyols (e.g., chlorogenic acid). In direct contrast to the hydroxybenzoic acids and the hydroxycinnamic acids, gallic acid and the biosynthetically derived hexahydroxydiphenic acid, are both widely distributed and found in a range of esterified forms. The occurrence of gallic acid has been noted in some 20 or so plant families and one freshwater alga in ester forms which vary from the very simple monoesters such as β-D-glucogallin (**1**), theogallin (**2**), and the flavan-3-ol gallates (**3**, **4**)—all found, for example, in young green tea shoots (*Camellia sinensis*)—to the complex soluble polyesters with D-glucose, whose molecular weights span the range 500–3000 (Figure 1). These polyphenols constitute the hydrolyzable tannins, and they are almost uniquely confined to dicotyledons. They are, in general, freely soluble plant metabolites and as such may be expected to contribute to taste and palatability and nutritional effects of plant materials in which they occur.

A routine feature of gallic acid metabolism in a great many plants is the oxidative coupling of appropriately oriented galloyl ester groups in a particular metabolite to give derivatives of hexahydroxydiphenic acid—usually referred to generically as ellagitannins. Intramolecular covalent bonding of this type produces, from a conformationally flexible and mobile galloyl ester precursor, a more rigid and compact molecular structure. The apotheosis of this effect is seen in the derivation of the diastereoisomeric phenolic metabolites—vescalagin and castalagin, in *Quercus* and *Castanea* sp., by oxidative transformation of the pivotal biosynthetic intermediate β-pentagalloyl-D-glucose (**5**). The latter has a flexible disk-like structure in which the galloyl ester groups are displayed on the periphery of the molecular surface; vescalagin (**6**) and castalagin (**7**) have

SCHEME 1.

propeller-shaped conformations, compact and rigid. Where intermolecular oxidative coupling of galloyl ester groups occurs, this also produces phenolic metabolites of increased molecular size (dimers, trimers, etc.). It is perhaps significant that the major biosynthetic thrust in plants is towards the formation of these highly convoluted structures (e.g., vescalagin, castalagin, geraniin) (Figure 1) or the dimers and trimers. Thus, for example, in the Rosaceae plant family, the leaves of *Rosa* sp. and *Filipendula ulmaria* (meadowsweet) contain as the principle phenolic metabolite rugosin-D (**8**). Similarly in *Rubus* sp. (blackberry and raspberry), *Geum* sp., and *Potentilla* sp., the dimer (**9**) predominates. Likewise, the familiar polygalloyl ester, tannic acid (**10**), in which additional galloyl ester groups are linked as depsides to β-pentagalloyl-D-glucose (**5**), dominates the metabolic profile of *Rhus* sp., *Cotinus* sp., and some *Acer* sp. The astringency of all these plant tissues, it is assumed, is attributable in very large part to these polyphenolic galloyl esters.

The primary reaction whereby astringency develops in the palate is, according to Bate-Smith (1954), by precipitation of glycoproteins in the mucous secretions of salivary glands. The efficacy of polyphenol binding to protein derives from the fact that polyphenols are multidentate ligands able to bind simultaneously (via different phenolic groups) at more than one point to the protein surface. When polyphenols cause precipitation of proteins from solution, two situations may be envisaged. At low protein concentrations, the polyphenol associates at one or more sites on the protein surface, to give a monolayer

that is less hydrophilic than the protein itself (Figure 2a). Aggregation and precipitation then ensue. Where the protein concentration is high, the relatively hydrophobic surface layer is formed by complexation of the polyphenol onto the protein and by cross-linking of different protein molecules by the multidentate polyphenols (Figure 2b). Precipitation then follows as above. This tendency to cross-link protein molecules at higher protein concentrations explains the changing stoichiometry of the aggregates with changing protein concentrations—observation first hinted at by Sir Humphrey Davy. More polyphenol is thus required to precipitate proteins from dilute solution than from concentrated solutions.

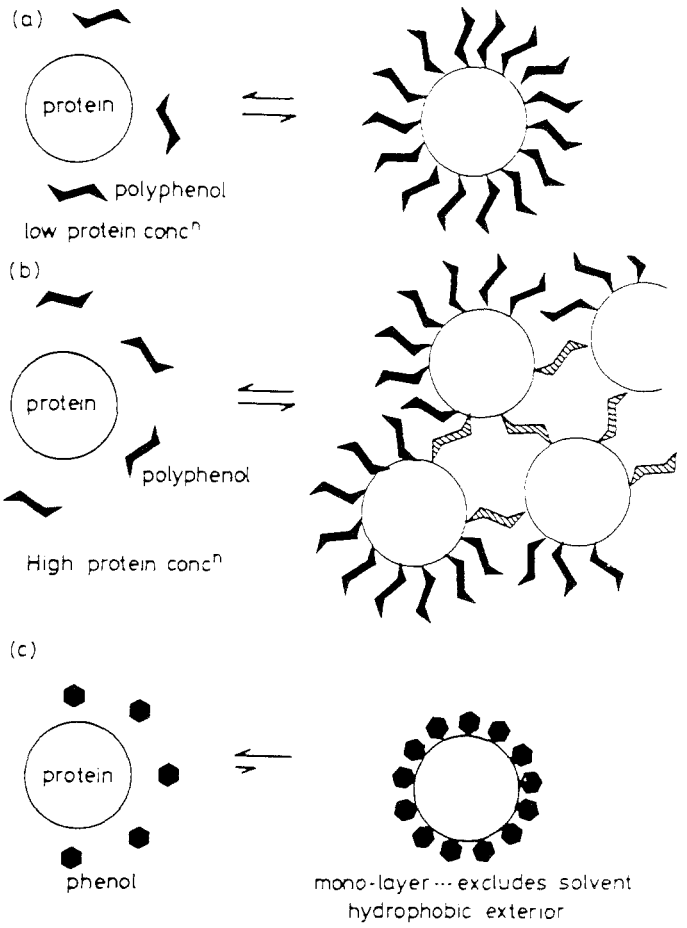

FIG. 2. Protein precipitation by phenols and polyphenols.

An interesting corollary of this hypothesis is that simple phenols such as pyrogallol should also be capable of precipitating proteins from solution if they can be maintained in solutions at concentrations sufficient to push the equilibrium in favor of the protein–phenol complex and thus form a hydrophobic layer of simple phenol molecules on the protein surface (Figure 2c). For many simple phenols, the limit is provided by their solubility in water, but it can be achieved with, for example, bovine serum albumin (BSA, 3×10^{-5} mol/kg) and pyrogallol (1 mol/kg). Clearly, such factors are important when assessing the total astringency of some plants rich in comparatively simple phenolic compounds.

Various studies of polyphenol complexation and, in particular, the delineation of structure–activity relationships have been carried out in recent years. Although as a subgroup the proanthocyanidins are most commonly responsible for the range of reactions generally attributed to tannins in plants, many of these particular studies have been most conveniently pursued with a series of biosynthetically interrelated esters of gallic acid (Figure 1). They are accessible in homogeneous forms and differ systematically in phenolic content, solubility, molecular size, and conformation. Polyphenol complexation with proteins may be studied in solution or by an investigation of the precipitation process which ultimately ensues after extensive complexation (Figure 2). Various physiocochemical techniques are appropriate to such analyses (Figure 3), and there is a broad, although not exact, comparability in the information derived from the various types of measurement (Figure 3). They show that a given polyphenol may exhibit substantially different affinities for different proteins. Hagerman and Butler (1981) have shown for example that flexible "open" proteins and those rich in the amino acid proline bind polyphenols more effectively than compact globular proteins. However, for a given series of polyphenols, their comparative behavior with one protein generally parallels the behavior with other quite different proteins. On the basis of present information, the associative process appears to be a surface phenomenon. Whether there are preferred modes of association and preferred binding sites is not yet entirely clear.

The effectiveness of plant polyphenols as complexing agents derives from the fact that they are polydentate ligands with a multiplicity of potential binding sites provided by the numerous phenolic groups and aryl rings on the periphery of the molecule (Beart et al., 1985). Because of the propinquity of these groups in the polyphenol, cooperativity of complexation to the protein surface is observed. Likewise, because of their molecular size and structure, polyphenols form stable cross-linked structures with different protein molecules (Figure 2). Molecular size is critically important as a determinant of the ability of a polyphenol to bind to protein—as inferred in Bate-Smith and Swain's definition of a vegetable tannin. Thus in the galloyl-D-glucose series, the efficacy of association with protein is enhanced with the addition of each galloyl ester group (di → tri → tetra → penta) and reaches a maximum in the flexible disklike

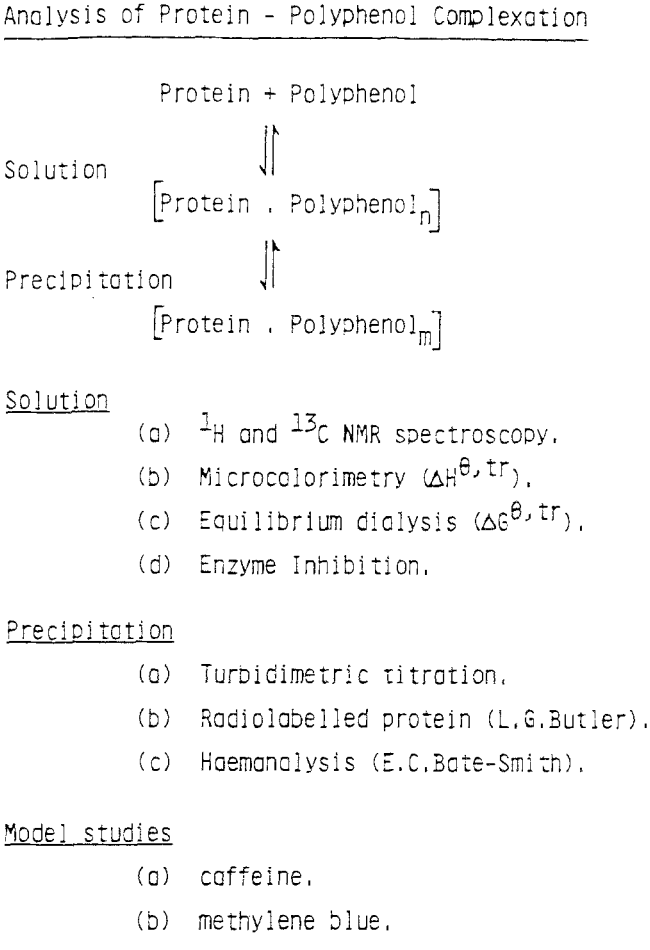

FIG. 3. Protein–polyphenol association.

structure of β-penta-*O*-galloyl-D-glucose (**5**). Further metabolism of this intermediate often substantially lowers its powers of association. Equally significant as molecular size of the polyphenol is conformational mobility and flexibility. In the galloyl D-glucoses, when vicinal galloyl ester groups are constrained by the biosynthetic intramolecular formation of biphenyl linkages and the generation of hexahydroxydiphenoyl ester groups, the loss in conformational freedom is reflected in a reduced capacity to bind to protein. The apotheosis of this effect is seen in the case of the unique open-chain D-glucose derivatives vescalagin and castalagin, metabolites of *Quercus* sp. (**6**, **7**). These rigid virtually inflexible, propeller-shaped molecules are in a sense analogs of β-penta-*O*-galloyl-D-

glucose (Figure 1), but on a molar basis they are bound much less effectively to protein than (**5**). Parenthetically, in this context, the observed "relatively lower astringency" of the proanthocyanidins compared to other polyphenols may be explained, in part, in terms of the conformational restraints imposed by restricted rotation about the repeating 4, 8 or 4, 6 interflavan bonds. Collectively, these results fully complement those of Hagerman and Butler (1981), who showed that proline rich and conformationally mobile proteins have high affinities for polyphenols. Thus, complementarity between the polydentate ligand (polyphenol) and the receptor (protein) is maximized by conformational flexibility in both components. What is not yet clear is whether there is specificity in the association with the protein (surface) or whether the binding is entirely random in nature.

The results show, however, that there is a very wide variability in the protein-complexing capabilities of the polyphenolic biosynthetic "end products" (**6–10**). There is no clear consistent pattern nor is any correlation discernible between the apparent metabolic cost to the plant of its synthesis of a particular polyphenol and the subsequent capacity of that polyphenol to complex with protein and hence that polyphenol's astringency. The dimer (**8**) binds more strongly to protein than (**5**), but frequently the protein-complexing ability of the polyphenols (e.g, **6**, **7**, **9**, and **10**) is diminished when compared to that of the key biosynthetic intermediate, β-penta-*O*-galloyl-D-glucose (**5**) from which they are presumably derived. In such cases, the plant's subsequent chemical manipulation, its embroidery of the intermediate (**5**), is quite clearly counterproductive vis-à-vis the synthesis of metabolites with enhanced astringency. If, as Rhoades (1979) has suggested, there has been positive selection for the production of such metabolites, then this does not appear to be based solely, if at all, on the capacity of these polyphenols to bind to protein.

While it may well be argued that polyphenol complexation with protein is not, as has been assumed, the critical property of polyphenols operative in plant defense, this work does suggest, at the very least, some reappraisal of the earlier hypotheses outlined above. The patterns of gallic acid metabolism outlined (Figure 1) represent a classic example of the biosynthetic prodigality evident throughout secondary metabolism. One key metabolite (gallic acid) is visualized as being formed. This then undergoes a wide range of chemical modifications (often oxidative in character), leading to a plethora of secondary metabolites, each one only slightly different from the next. The evidence presently available suggests that although the retention of polyphenolic synthesis such as this in certain taxa may confer an advantage, a secondary benefit, on the plant and may well be the basis of selective pressures, it does not appear to support the proposition that the purpose of polyphenol metabolism is to generate specifically agents for the plant's defense. On the basis of this reasoning, protection, if it exists, would be a consequence of polyphenol formation, not a cause.

Polymeric Proanthocyanidins and Structure of Tissues. The classical experiments of Feeny in the 1960s on the feeding of larvae of the winter moth on leaves of oak underpin the view that tannins play a major role in plant–herbivore interactions. In the intervening period, however, defining the exact status of tannins as defensive chemicals in plants has proved more difficult to establish. Feeny (1970) and Feeny and Bostock (1968) studied the changes in tannin content of oak (*Quercus robur*) leaves throughout a growing season. This plant species is heavily infested by insects in spring but is rarely subject to serious predation after mid-June. Feeny and Bostock (1968) showed that the level of hydrolyzable tannins remained roughly constant throughout the season but that condensed tannins (proanthocyanidins) did not appear until late May. They concluded that the period of highest insect attack on oak leaves (early spring) corresponds to the time when the total tannin content is at a minimum and condensed tannin is virtually absent. Scalbert and Haslam (1987) have recently reexamined this problem and have provided an alternative interpretation of the experimental data.

The predominant polyphenols of the vegetable tannin class in the leaf of *Quercus robur* L. are, at all stages of growth, undoubtedly those of the hydrolyzable (ellagitannin) group (Figure 4), tellimagrandin 2 (**11**), casuarictin (**12**), peduncalagin (**13**), vescalagin (**6**), and castalagin (**7**). In terms of the ability of soluble extracts of oak leaves to complex and precipitate dietary and other proteins, this group of compounds (**6**, **7**, **11–13**) is undoubtedly of greatest significance. If quantitative changes in the vegetable tannins of oak leaf tissue have a direct causal relationship with changes in insect predation, then it might be anticipated that these changes would be quantitatively reflected in the prinipal group—those of the hydrolyzable class (**6**, **7**, **11–13**). Minor qualitative changes occurred, but major qualitative and quantitative changes in the principal ellagitannins of oal leaf were not observed in two growing seasons.

Consistent with the results of Feeny (1970) and Feeny and Bostock (1968), the most significant changes among the polyphenols (tannins) takes place among the comparatively minor group (in oak)—the various proanthocyanidins of which by far the greater proportion are bound, apparently indissolubly, to plant tissue. The early observations of Sir Robert and Lady Robinson (1935) on the "insoluble" proanthocyanidins of plant tissues, confirmed by subsequent workers in this field, are directly relevant to this question. Thus, for example, Hillis and Swain (1959) have shown that the "leuco-anthocyanins" of plum leaves can be divided into three classes, the first two being successively extractable with absolute, followed by aqueous methanol, and the third, remaining in the residue, being nonextractable by these or other neutral solvents. Likewise, Bate-Smith (1973a, b), in an investigation of the proanthocyanidins of herbaceous Leguminosae, noted that in most of the species examined the amount extracted, even under the most favorable conditions, is only a small proportion of the total present. These observations are of considerable relevance to the questions sur-

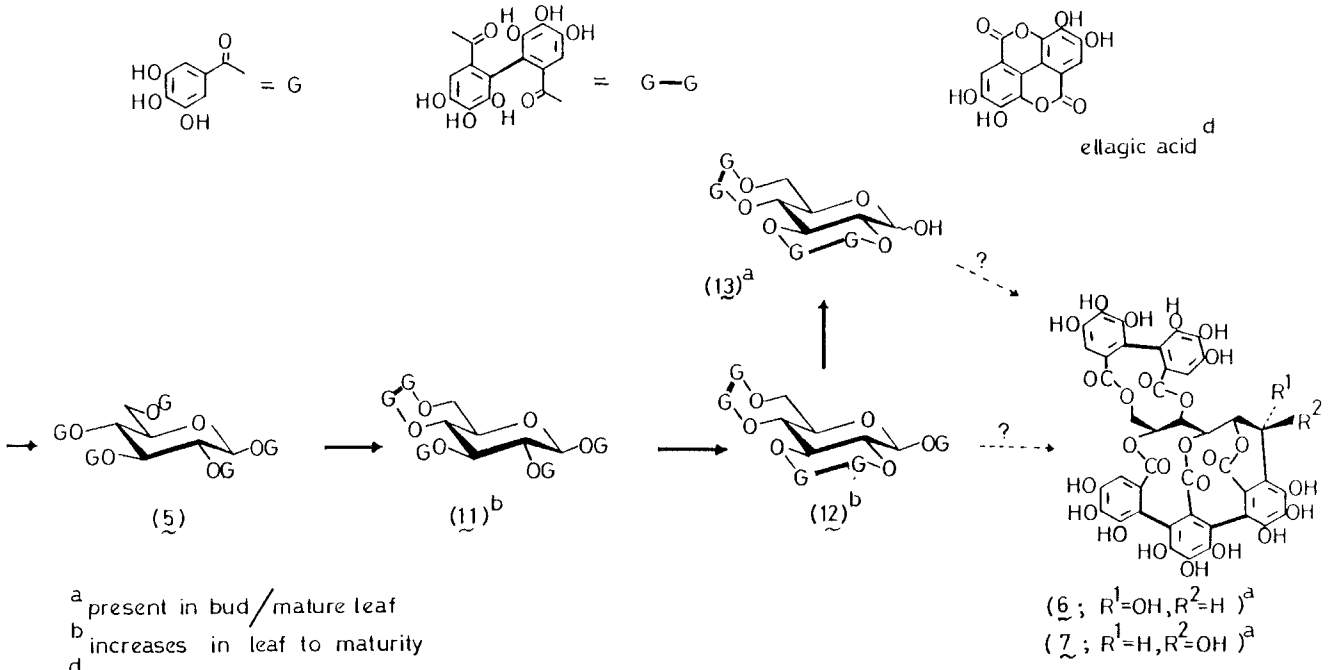

FIG. 4. Oak polyphenols—ellagitannins.

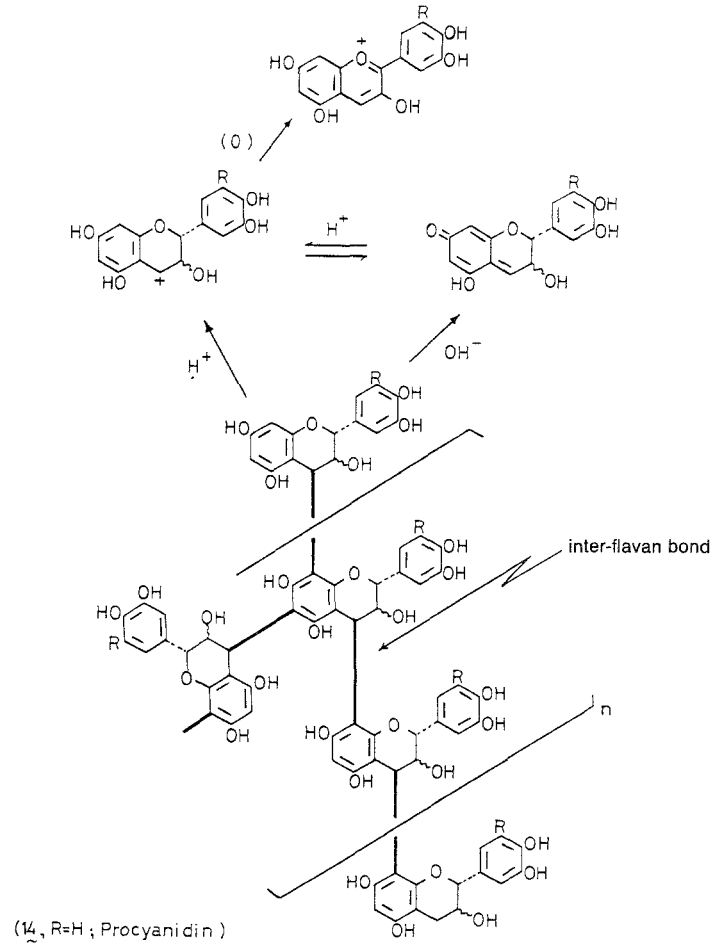
rounding the purported relationships between polyphenols and chemical defense. In a recent paper (Shen et al., 1986), it was suggested that these insoluble forms of plant proanthocyanidins are bound by covalent linkages to polysaccharide (or other) structures in the developing cellular matrix. Attention was also drawn to the possible analogies with the structure of lignin and the process of lignification in plant tissues.

Plant proanthocyanidins are based structurally on a polyflavan-3-ol structure (**14**) and, from a phylogenetic viewpoint, they first appeared as plants developed a vascular character—in ferns for example. The nomenclature proan-



SCHEME 2.

thocyanidin does not imply any biogenetic relationship, but it represents a terminology which is chemically derived. Thus, when heated with acid, the interflavan carbon–carbon bonds of proanthocyanidins are ruptured, and the flavan units, released initially as a carbocation species, are converted by aerial oxidation to characteristic anthocyanidins.

One current hypothesis suggests that the proanthocyanidins are formed as by-products of the processes in which the parent flavan-3-ols (**15**, **16**) are biosynthesized in the plant tissue (Figure 5). A key step visualized in this synthesis is the formation of the carbocation intermediate (**17**). Soluble dimeric, trimeric, tetrameric, . . . , oligomeric proanthocyanidins are thought to derive in circumstances in which the supply of biological reductant (say NADPH) required to convert (**17**) to the flavan-3-ol is limited. If the supply of reductant is rate limiting in these circumstances, the transient carbocation is envisaged to escape from the active site of the enzyme and to react with the end-product flavan-3-ol to produce first dimers and then the spectrum of higher oligomeric forms (Figure 5). In any plant tissue where proanthocyanidin synthesis occurs, there is invariably found this range of molecular species from the monomeric flavan-3-ols (the catechins and the gallocatechins) to the polymeric forms. For each plant tissue, the balance between these various kinds of molecules is probably determined by the corresponding balance between the metabolic flux to the carbocation (**17**, Figure 5) and the rate of supply of the biological reductant (say NADPH). Tissues in which the flux is low and the NADPH supply is high will contain a range of proanthocyanidins of all molecular sizes. Conversely, those tissues in which the supply of NADPH is limited and the metabolic flux is high will contain predominantly the higher oligomeric forms. With increasing degrees of polymerization, the proanthocyanidins become more difficult to solublize in aqueous and alcoholic media. It has been suggested that those which can be coaxed into solution may have molecular weights up to 7000, corresponding to an accumulation of up to 20 flavan-3-ol units in the polymer.

In addition to these various "soluble" forms of proanthocyanidins, plant tissues invariably contain polymeric forms that are entirely resistant to all forms of ready solublization. Proanthocyanidins of this class often predominate over the more freely soluble forms, typically by as much as 5 : 1 or 20 : 1. Indeed, in the tissues of some plants, e.g., ferns and the persimmon fruit, they overwhelmingly predominate. It is pertinent in this context to recall the original observations of Sir Robert and Lady Robinson (1935). These pioneers drew attention to various categories of proanthocyanidins (then referred to as leucoanthocyanins) and in particular to a group (a): "those which are insoluble in water and the usual organic solvents." While noncovalent forces may be involved in the complexation of polyphenols with polysaccharides, present evidence strongly supports the view that polymeric proanthocyanidins which fall within the category (a) defined by the Robinsons are covalently bound to a carbohydrate matrix

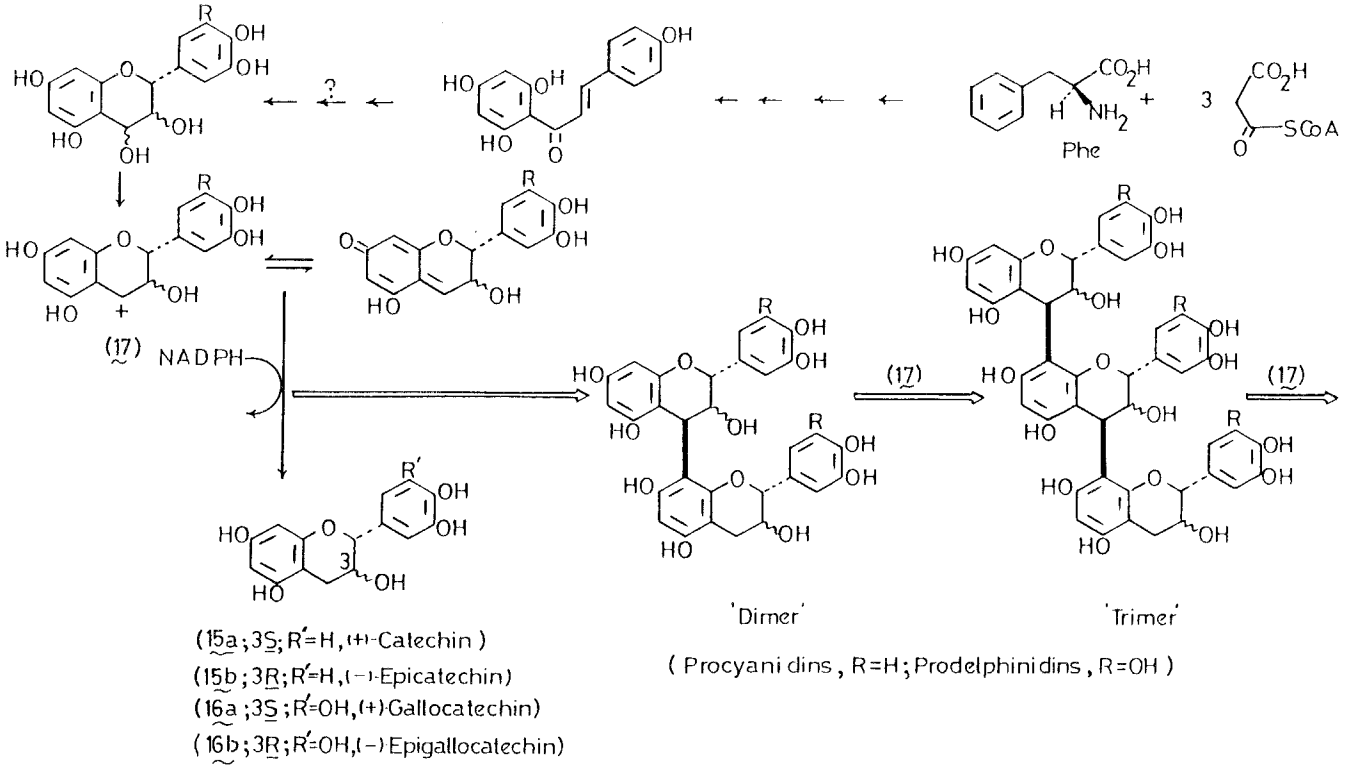


FIG. 5. Proanthocyanidin biosynthesis.

within the plant cell. Such proanthocyanidins, it has been suggested, may well result from the capture of the putative carbocation intermediate (**17**) during biosynthesis by hydroxy groups of saccharide structures in the plant cell (Figure 6).

In this context, it now seems entirely appropriate and pertinent to consider again some of the early observations of Bate-Smith and Lerner (1954) on the botanical significance of plant proanthocyanidins. Bate-Smith noted that these polyphenolic substances were frequently associated with the character and quality of "woodiness" in plants. He also strongly hinted at a possible relationship between proanthocyanidin metabolism and lignification and hence to a putative structural role in the plant for these oligomeric polyphenolic metabolites. In his studies, Feeny (1970) concluded that leaf toughness is the chief proximate factor in deterrence to insect predators of oak leaf. This opinion is now also entirely consistent with an alternative interpretation of the apparent correlation of declining insect predation with proanthocyanidin formation, namely, that leaf toughness develops simultaneously with the initiation of the development of a cell structure which has enhanced "woody" characteristics and in which concomitantly proanthocyanidin oligomers and polymers are deposited as an integral part of these structures (Figure 6). The suggested interpretation of decreased insect predation in oak in early summer is that this is related to changes in cell structure, texture, and toughness of the leaf and in the development of which the formation of proanthocyanidin polymers play an intimate role.

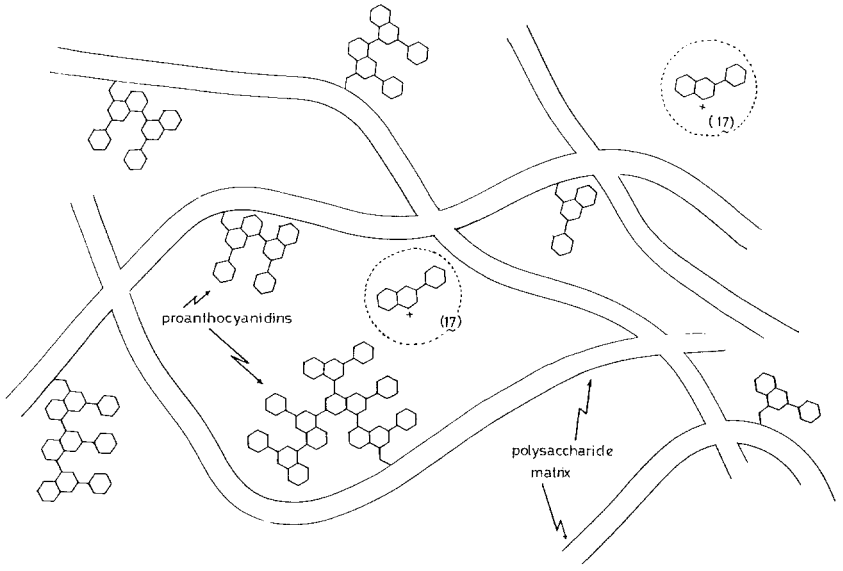

FIG. 6. Polymeric proanthocyanidins—a structural role?

Periplaneta americana PERCEPTION OF PHYTOCHEMICAL NAPHTHOQUINONES AS ALLELOCHEMICALS

DALE M. NORRIS

Department of Entomology, University of Wisconsin
Madison, Wisconsin 53706

(Received September 15, 1987; accepted March 1, 1988)

Abstract—Electrochemistry of male *Periplaneta americana* perception of naphthoquinones as allelochemicals is presented. Importance of the oxidation–reduction potential and hydrogen-bonding capabilities of the naphthoquinone messenger to its exchange of energy with the information-encoding, redox protein of the chemosensory neuron is considered. Evidence that the required information is initially encoded by an electroreactive protein in dendritic membrane is analyzed. A sulfhydryl–disulfide protein-based electrochemical mechanism for the demonstrated linear conversion of a molecular messenger energy state into whole insect behavior (avoidance or feeding inhibition) is elucidated. Even though the information-encoding mechanism is genetically conserved (kept electrochemically similar) within the species, behavioral biotypical differences regarding sensitivity to naphthoquinones are allowed through a group of proteins in the outer aqueous medium in the chemosensory sensillum. Such proteins electrochemically interface the dendritic membrane of the chemosensory neuron in the sensillum with the environment external to the sensillum. These interfacing proteins bind (complex) with chemical messengers (e.g., naphthoquinones) and/or variously degrade them, and thus determine the amount (moles) that is required in the environment to result in stimulation of the underlying sensory neurons and in a changed behavior.

Key Words—Perception, avoidance, deterrence, naphthoquinones, *Periplaneta americana*, Orthoptera, Blattidae, allelochemicals, phytochemicals, insects, energy transduction, electrochemistry, information-encoding protein, behavioral biotypes.

INTRODUCTION

Allelochemicals have long (Jermy, 1966; Gilbert et al., 1967; Gilbert and Norris, 1968) been considered as major parameters in insect rejections of plants or animals as hosts. Among the more than dozen families of secondary plant or animal products that have allelochemical activity against one or more species of organism, alkaloids, flavonoids, and terpenoids apparently dominate numerically (Swaine, 1977). However, other smaller classes, e.g., benzoquinones or naphthoquinones, are also extremely important in a variety of plants and animals, including insects (Morton, 1965; Rodriquez and Levin, 1976). Some of the better-known animal-derived quinone (i.e., benzoquinone and naphthoquinone) allelochemicals are found in Coleoptera, and especially in tenebrionids (e.g., *Eleodes*) (Tschinkel, 1975). Benzoquinones are also produced by approximately 20 families of diverse plants, whereas naphthoquinone allelochemicals are found in at least 20 angiospermous families and especially members of the Juglandaceae (Rodriquez and Levin, 1976).

The above facts, although only selected examples, clearly indicate that understanding the modes of action of quinones as allelochemicals would be a significant contribution to the whole of chemical ecology. In our laboratories we have researched such mechanisms of quinone actions as they occur in chemoreceptive peripheral neurons of several insects, especially the American cockroach (*Periplaneta americana* L.). The overall findings from our long-term efforts are interpreted here.

REACTIVE CHEMISTRY OF QUINONES

In considering quinones as allelochemicals and as especially odors or tastants in animal (e.g., insect) chemoreception, knowledge of their reactive chemistry is vital. Such quinone chemistry has been detailed by several specialists (e.g., Morton, 1965), so only some basic dynamic characteristics of their reactivities are presented here. Special considerations are focused on the importance of their (1) oxidative–reductive properties, (2) attributes as diketones with α,β-unsaturation, and (3) selective reactions with sulfur compounds.

Quinones as Oxidation–Reduction Systems. The oxidation–reduction (redox) potentials of quinones are important in many biochemical systems (Morton, 1965), including their reactions in *P. americana* neurochemistry (Norris, 1985, 1986). The involved overall oxidative–reductive process is presented in Figure 1 and consists of two parts (A and B); the latter, B, component is dependent on the environmental pH. The redox potential of a mixture of a quinone and its redox couple quinol at any pH is measured against the standard hydrogen electrode (SHE), taken as zero. A positive potential signifies that

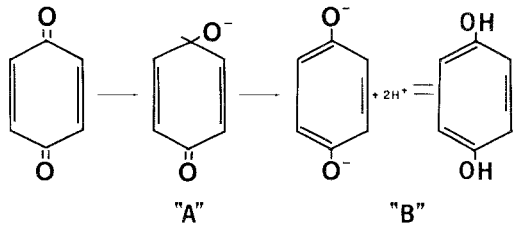

FIG. 1. Oxidative–reductive sequence for a quinone–quinol system: (A) the oxidized quinone and (B) the reduced quinol.

under the SHE conditions the combined quinone–quinol system has an oxidizing effect towards the $H^+ \rightarrow H_2$ system. Thus, one quinone–quinol system will oxidize another having a lower potential, i.e., will displace the equilibrium of the latter system in the direction of the quinone. *o*-Quinones have higher redox potentials than *p*-quinones, and therefore oxidize *p*-quinone–quinol systems. Effects of substituents on quinone reactivities cannot be readily generalized, but some specific situations are clear. For example, substitution in position 2 in 1,4-naphthoquinones reduces the redox potential much more than in any other position.

Quinones as Diketones with α,β-Unsaturation. *p*-Benzoquinones and related *p* substances belong more to aliphatic compounds than to aromatic ones. They functionally are unsaturated diketones exhibiting conjugation, i.e., α,β-unsaturation. In such quinonoid diketones both carbonyl (C=O) groups and any hydroxyl group (e.g., 5-hydroxy of juglone) exhibit hydrogen-bonding capabilities. Such bonding may be either intra- or intermolecular and usually renders the involved quinone (e.g., 5-hydroxy-1,4-naphthoquinone) more active biologically than the unsubstituted 1,4-naphthoquinone, even though the latter compound has the higher redox potential (Norris, 1969, 1970, 1986).

Because of the α,β-unsaturation of diketonic quinones, nucleophilic 1,4-addition reactions may readily occur. Thus, the nucleophiles ($\ddot{N}^-$), sulfhydryls, amino groups, imidazole residues, or hydroxyls, may compete for this covalent substitution on such quinones (Wallenfels and Eisele, 1970).

Quinone Reactions with Sulfur Compounds. Some sulfur compounds have long been known to react especially quickly with given quinones, e.g., in the absence of solvent, 1,4-benzoquinone will oxidize thioglycolic acid and become reduced to its hydroquinone (quinol couple). In this case, the sulfur, as a nucleophile, adds across a conjugated double bond in the quinonoid ring with the resultant reduction of the quinone carbonyls (Finley, 1974). Although quinones react with other nucleophiles as indicated above, they show a "selectivity" or "specificity" for some sulfhydryl groups by reacting with the latter at least 100-fold more rapidly (Wallenfels and Eisele, 1970). Thus, for practical

biological and biochemical considerations, *p*-quinones may be considered as sulfhydryl reagents.

p-Quinones may not react equally with individuals of a group of sulfhydryls because the latter may be differentially influenced, through cooperation, by hydrogen bridges, coulomb interactions, and steric hindrance or preference. In fact, such combined microenvironmental influences render sulfhydryls in proteins a very heterogenous group regarding accessibility to, and reactivity with, given *p*-quinones.

STRUCTURE-ACTIVITY RELATIONSHIPS

Insect perception of 1,4-naphthoquinones as allelochemicals is readily expressed and bioassayed behaviorally as an avoidance or feeding reduction. Such behavioral analyses of the relative allelochemical effects of several 1,4-naphthoquinones on the very different insects *Scolytus multistriatus* (the smaller European elm bark beetle) and *Periplaneta americana* (the American cockroach) indicated the same following order of relative activity: 5—OH > 1,4— > 2—OH > 2—CH_3. This order of experimentally determined behavioral effects is largely attributable to the relative combined redox potential and hydrogen-bonding capabilities of these compounds as discussed in the previous section of this paper and as detailed by Norris (1969, 1970). This same order of relative activity was also observed experimentally based on (1) electrophysiology (i.e., naphthoquinone inhibition of a standardized insect electroantennogram, EAG) (Norris and Chu, 1974); (2) competitive ligand (naphthoquinone) binding to an electrophoretically purified redox-complex, dendritic-membrane-associated protein (Singer et al., 1975); and (3) naphthoquinone-induced electrochemical (*U* 1/2) shift in a standardized 100-μg aliquot of the above protein (Rozental and Norris, 1973, 1975; Norris, 1985). Our overall experimentally determined relationships between naphthoquinone structure and behavioral, electrophysiological, biochemical, or biophysical activities in these two insects seem well explained by the known reactive chemistry of quinones.

ULTRASTRUCTURAL CONSTRAINTS

Physicochemical interpretation of the energy transduction (transfer) involved in an insect's perception of a ligand (e.g., molecule) as an allelochemical must accommodate the ultrastructural and cytochemical constraints of the in vivo chemoreception system of that insect (Norris, 1976a, 1986). Naphthoquinones as allelochemicals interact with the insect's sensory neurons through ultrastructure and cytochemistry associated with sensilla, especially on the antennae, mouthparts, or tarsi.

Olfactory (volatile) stimulants (e.g., juglone) function especially through multiporous sensilla, e.g., sensilla basiconica, which are abundant on *P. americana* antennae. These hollow hairs have thousands of pores through their cuticular wall, and stimulants may exchange energy with involved sensory neurons through cuticular pore–pore tubule interconnections (Norris, 1976a, 1986).

Contact chemoreceptors, e.g., sensilla trichodea, frequently are uniporous, i.e., have a single terminal opening through which to expose the involved sensory neuron(s) in the lumen of the sensillum to chemical messengers in the external environment. Such sensilla thus are especially important in decisions regarding feeding, gustation, or ingestion. At least some insects can physiologically control the opening of such a uniporous sensillum, and therefore "control" significantly when, and the extent to which, stimulants may enter or exit the liquor (i.e., outer aqueous medium, Figure 2) in the lumen of the sensory hair (Bernays et al., 1972).

The combined ultrastructure of an insect chemoreceptive sensillum (e.g., hollow, multiporous hair) and the dendritic branches of the involved sensory neuron(s) provides the essential elements of a fuel cell, a device which produces a continuous flow of electricity by means of chemical reaction (Figure 2) (Norris, 1986). The cytoplasmic contents in the neuronal dendritic branches within the lumen of the sensillum constitute the relatively low-protonic-potential, inner aqueous medium of the fuel cell (Figure 2, I), whereas the liquor in the sensillum cavity is the relatively high-protonic-potential, outer aqueous medium (Figure 2, E). These two differently charged aqueous media are effectively separated ultrastructurally by the relatively hydrophobic lipid bilayer dendritic membrane (Figure 2). Chemiosmotic theory of membrane bioenergetics (Mitchell, 1979) as applicable to energy transduction (transfer) in insect chemical senses states that only three molecular components need to be added into the insulating lipid bilayer dendritic membrane of Figure 2 to effect the required energy transduction (transfer). These are (1) an ATP synthase, along with reversible Na^+,K^+-ATPase activity; (2) a redox chain (complex) with characteristic H^+ and e^- stoichiometry; and (3) proton-linked (or hydroxyl ion-linked) solute porter (pump) systems. Such essential components have been experimentally demonstrated and analyzed in dendritic membranes of male *P. americana* chemosensitive neurons with regard to this insect's perception of 1,4-naphthoquinones as allelochemicals (Norris, 1981, 1986).

ENERGY TRANSDUCTION AND INFORMATION ENCODING IN EXPOSED PRIMARY CHEMOSENSITIVE INSECT NEURON

Electroreactive Receptor Protein. The electroreactive receptor protein for repellent and antifeedant 1,4-naphthoquinones in male *P. americana* antennal primary chemosensory neurons is a redox-chain (complex) polypeptide (Roz-

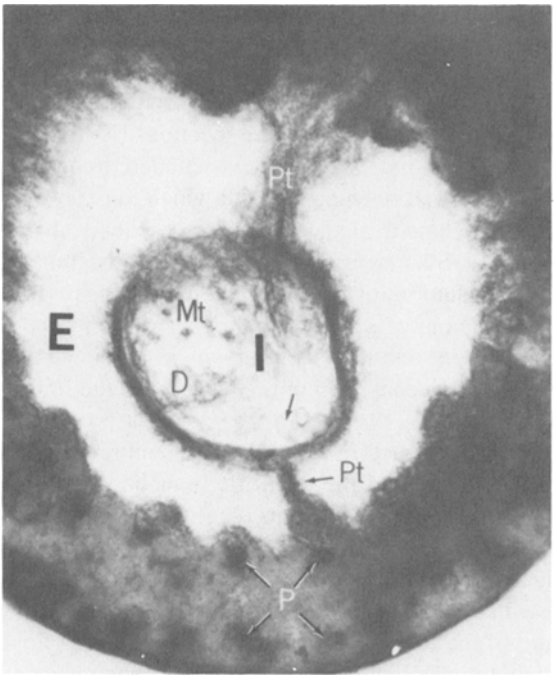

FIG. 2. High-voltage electron micrograph revealing the "fuel cell" ultrastructure of a sensillum basiconicum on the antenna of the american cockroach (*P. americana*). External (E) and internal (I) hydrophilic media surrounding the insulating dendritic (i.e., hydrophobic) membrane. D, Dendrite; Pt, pore tubules; Mt, microtubules.

ental and Norris, 1973, 1975; Norris, 1976a, 1979, 1985). This energy-transducing and information-encoding protein in the dendritic membrane of involved neurons is a sulfhydryl–disulfide lipoprotein. It is readily solubilized from the dendritic membrane with 0.6% Triton X-100 in 0.9% NaCl and can be purified (e.g., 57-fold) in terms of micrograms of naphthoquinone bound per microgram of receptor protein, by affinity chromatography using *p*-chloromercuric benzoic acid (PCMB) as a ligand on a 16-carbon sidearm attached to Sepharose 4B (Norris et al., 1977). SDS-disk electrophoresis of this purified 68,500-dalton protein resolved three subunits with molecular weights estimated at 19,000, 23,500, and 26,000 daltons (Norris, 1979, 1986).

Energy-Transduction Mechanism. The sulfhydryl–disulfide, information-encoding protein binds reversibly with, and reduces electrochemically, the allelochemical 1,4-naphthoquinone ligands (i.e., chemical messengers) (Rozental

and Norris, 1973, 1975; Norris, 1979, 1985). The involved energy-transduction interaction of the messenger naphthoquinone with the redox receptor protein reversibly produces a fluorescent product, the reduced hydroquinone (QH_2) couple of the naphthoquinone. Major reaction steps in this energy-transfer interaction are presented in Figure 3.

Such sulfhydryl–disulfide proteins may be effective redox-complex components in the involved energy-transduction machinery because they are extremely sensitive to changes in the oxidation state in the outer or inner aqueous medium surrounding the insulating dendritic membrane (Figure 2). As the oxidizing messenger 1,4-naphthoquinone enters the outer aqueous medium (i.e., contents of the cuticular pore, pore tubule, and sensillum liquor), it becomes reduced (Figure 3), which withdraws hydrogens from the outer medium and the redox-complex protein in the dendritic membrane (Figure 2). The involved hydrogen withdrawal may occur directly from this energy-transducing protein or indirectly by the 1,4-naphthoquinone allelochemical reacting with the contents of the outer aqueous medium.

Each allelochemical 1,4-naphthoquinone, at a molarity which does not saturate the electroreactive energy-transducing protein, induces in vitro a quantitative shift in that protein's *U*1/2 electrochemical parameter. This resultant quantitative shift is the basis for the observed information encoding (Norris, 1985).

Primary Peripheral Neuron Encoding of Insect Chemical Senses Information. As discussed earlier, the observed order of relative behavioral effects

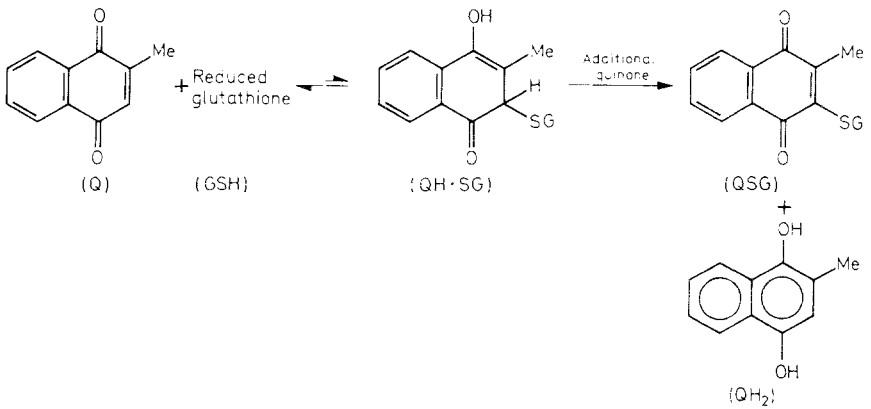

FIG. 3. Reaction that occurs between the redox chain (complex) information-encoding protein (reduced glutathione in this model system) and an allelochemical naphthoquinone (e.g., menadione, 2-methyl-1,4-naphthoquinone) as studied by fluorescence spectrophotometry. Q, menadione; GSH, reduced gluttahione; QH·SG, neutral semiradical; QSG, oxidized quinone adduct; QH_2, hydroquinone.

to *P. americana* elicited by given moles of several 1,4-naphthoquinones is the same, whether measured (1) behaviorally as percent (%) insects showing avoidance, (2) electrochemically as mV shift in the in vitro information-encoding protein's *U*1/2 value, or (3) electrophysiologically as the percent (%) inhibition of a standardized amyl acetate-elicited electroantennogram (EAG), i.e., 5—OH > 1,4— > 2—OH > 2—CH_3. The relationship between any two of these three experimental parameters is described ($P < 0.01$) by a linear equation (Norris, 1986). The correlation coefficient between the mean mV values for the observed maximal electrochemical *U*1/2 shifts in the information-encoding protein and the mean maximal percent inhibitions of the standardized electrophysiological EAG is so high (Norris, 1986) that only one of these two quantitative output parameters needs to be utilized in obtaining a reasonable mathematical description for the energy exchange (energy transduction) involved in the male *P. americana* perception and behavioral avoidance of 1,4-naphthoquinone allelochemicals. Because only two (one input and one output) of the three measured (one input and two output) variables need to be considered, an adequate quantitative (millivolt) description of the involved energy exchange is $\log y = 3.40 - 0.112 \log x$, which describes a linear relationship (Norris, 1986). y is considered as the primary measured output (efferent) variable, i.e., the mean maximal millivolt (mV) shift in the electrochemical *U*1/2 value of the in vitro information-encoding protein, whereas $x = 2 \times 10^{-5}$ mol, and pertains to the primary measured input (afferent) variable, i.e., the mean moles of messenger (allelochemic) 1,4-naphthoquinone required in the standardized avoidance bioassay to repel > 99% of the *P. americana* males from the treated tub "arena" (Rozental and Norris, 1975; Norris, 1986) (Figure 4).

The described energy-exchange relationship involved in male *P. americana* behavioral perception and avoidance of allelochemical 1,4-naphthoquinones is proof that the needed (coded) electrical information to elicit the observed avoidance behavior in the whole cockroach is already encoded in the primary chemosensory neuron and more specifically by the electroreactive redox protein in the dendritic membrane of this neuron. O'Connell (1981) stated most succinctly that, "A code, simply stated, is the set of rules which governs the mapping of the input variable onto the output variable.... Encoding mechanisms require only that rules are applied uniformly and that they lead to distinctive outcomes." He further stated that a satisfactory code in insect chemical senses can be a simple one-to-one relationship between a discriminable chemical stimulus and an electrophysiological response. Our elucidated code, $\log y = 3.40 - 0.112 \log x$, describes such a simple linear mapping of input stimulus onto output effect. Therefore, the CNS (central nervous system) of male *P. americana* may be doing many manipulations with the information it receives from stimulated peripheral primary chemosensory neurons exposed to these allelochemical 1,4-naphthoquinones, but the essential neural-impulse-based

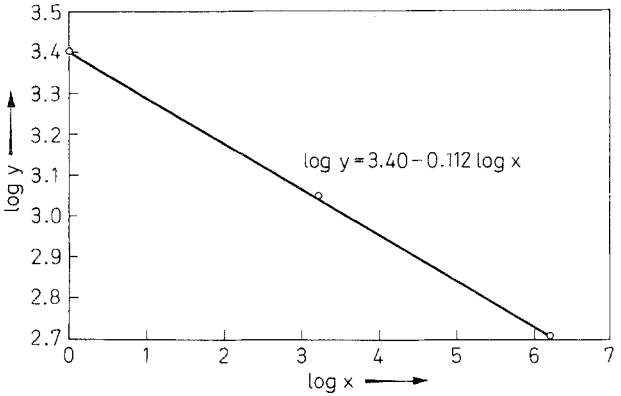

FIG. 4. Linear relationship that exists between the log of the primary input (afferent) variable, x, where $1X$ equals 2×10^{-5} moles with regards to the number of moles of a naphthoquinone required in a standardized bioassay to yield greater than 99% avoidance behavior by male *P. Americana*; and the log of the primary output (efferent) variable, y, which is the maximum in vitro electrochemical $U1/2$ shift, in millivolts (mV), by the information-encoding protein elicited by the indicated naphthoquinone.

information to elicit the prescribed insect avoidance behavior is originally processed (transduced) in the primary neuron from energy exchanged between the messenger naphthoquinone and the redox protein in that primary cell.

GENETIC CONSERVATION OF REDOX PROTEIN-BASED INFORMATION-ENCODING MECHANISM

The male *P. americana* perception of naphthoquinones as allelochemicals is dependent upon quantitative electrochemical reaction of these oxidative–reductive chemical messengers with the electroreactive sulfhydryl–disulfide information-encoding protein in the dendritic membrane of the primary insect chemosensory neurons. There are three distinct classes of electroreactive naphthoquinone-binding sites in this protein (Rozental and Norris, 1975; Norris, 1985). Each of these classes of sites involves sulfhydryl-group (−SH) dependency, and the electroreactivity of the involved sulfur atoms is readily quantifiable by dropping-mercury-electrode (DME) polarography (Rozental and Norris, 1975; Norris, 1985). Naphthoquinone saturation of the redox protein of the two behavioral *P. americana* biotypes, LAB versus WARF, causes a similar ($P < 0.01$) maximal mean millivolt shift in the electrochemical half wave ($U1/2$), e.g., for 2-methyl-1,4-naphthoquinone, LAB (15 mV) and WARF (13 mV). This maximal 13 to 15-mV inducible electrochemical shift in the infor-

mation-encoding protein of each biotype is interpreted as the summation of three equal units of electrochemical shift, each consisting of 4–5 mV (i.e., 3 units × 4–5 mV = 12–15 mV total) (Norris, 1985, 1986). Each 4 to 5-mV unit of $U1/2$ shift thus involves the electroreactivity of those sulfur atoms associated with one of the three distinct classes of binding sites for naphthoquinones in each biotype's redox protein. Thus, this electrochemically quantified, protein sulfur-based, information-encoding mechanism in male *P. americana* chemical senses has been conserved ($P < 0.01$) in these two behavioral biotypes. It seems quite reasonable that once a molecular-based mechanism for information encoding was evolved in the neurons of a species such as *P. americana* that it would be conserved at least within that species (Norris, 1985).

INTERFACING PROTEINS: MOLECULAR PROVISION BY WHICH INDIVIDUAL *P. americana* MAY EVOLVE DISTINCT PHENOTYPIC SENSITIVITIES TO A CHEMICAL MESSENGER

Even though the electrochemically based energy-transduction and information-encoding mechanism of the redox protein of male *P. americana* behavioral biotypes LAB and WARF is conserved (Norris, 1985, 1986), these biotypes still show a twofold difference in their behavioral sensitivity to the allelochemical 2-methyl-1,4-naphthoquinone (menadione). Greater than 99% avoidance behavior by male WARF cockroaches requires their exposure to 2×10^{-2} M of menadione, whereas such behavior by male LAB only requires 10^{-2} M. This twofold difference is attributable largely to differences in quantities and reactivities of specific soluble proteins, termed "interfacins" (Norris, 1976b, 1986), in the outer aqueous medium (i.e., sensillum liquor, pore tubule and cuticular pore contents) of the chemosensory sensillum (Figure 2).

These soluble proteins physically and chemically interface the dendritic membrane of each chemosensory neuron with the environment external to the sensory hair's outer cuticular surface. Certain of these proteins bind (complex) with a chemical messenger, e.g., 2-methyl-1,4-naphthoquinone, as it enters the outer aqueous medium (Figure 2) of the chemosensory sensillum (Norris, 1976a, 1986). The amount of messenger that is complexed or degraded by these interfacing proteins, soluble components of the outer aqueous medium in the chemosensory sensillum, significantly determines the amount (moles) of the given compound (messenger) required to stimulate the information-encoding protein in the dendritic membrane of the involved underlying sensory neurons. In male *P. americana*, such naphthoquinone-binding interfacins are sulfhydryl–disulfide proteins (Norris, 1976a, 1986). Some interfacins also are enzymes, especially various esterases (Kasbohm and Norris, 1989). Specific electrophoretically resolved enzymatic activities among male *P. americana* interfacing proteins include a PMSF (phenylmethylsulfonyl fluoride) -sensitive serine protease; an

arylesterase, inhibited by both PMSF and the classical sulfhydryl reagent PHMB (*p*-hydroxymercuribenzoate); and a carboxylesterase (Figure 5).

Interfacing proteins pass outward onto the environmentally exposed cuticular surface of the chemosensory sensillum through cuticular pores (Figure 2) (Norris, 1986; Kasbohm and Norris, 1989). Such proteins thus may be extensively exposed to messenger compounds which impinge on this cuticular surface. Especially through this initial exposure, the interfacing proteins readily intercept and variously interact with messenger entities.

CONCLUSIONS

There are at least two distinct molecular levels in the evolution of the chemoreception mechanism by which male *P. americana* perceive naphthoquinones as allelochemicals. First, electroreactivity has evolved in a dendritic-membrane protein whereby energy exchange between a messenger (odor) molecule and this protein is linear, as readily quantified through several experimental windows on the overall chemoreceptive process, e.g.: (1) behavioral assay, (2) electrochemistry of this electroreactive dendritic protein, or (3) EAG. This evolved molecular information-encoding device is conserved between two

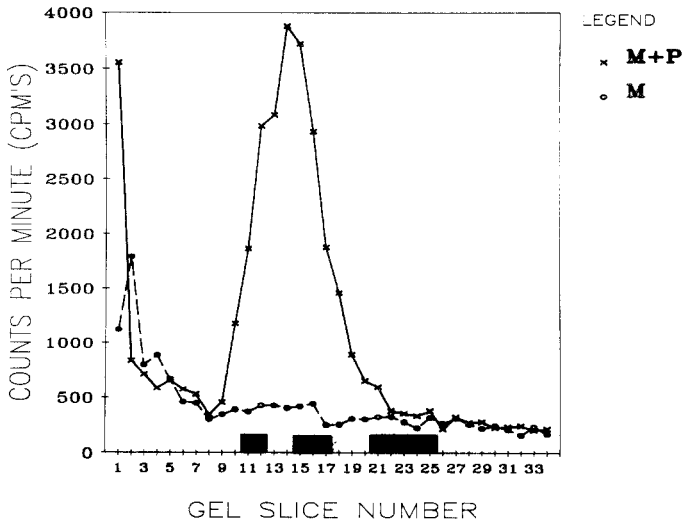

FIG. 5. Electrophoretically resolved "interfacin" proteins (bands 1, 2 and 3) from the outer aqueous medium (i.e., sensillum liquor) of male *Periplaneta americana* with indicated naphthoquinone (i.e., [^{14}C]Menadione) binding (counts per minute, CPMs, per 1.5-mm gel slice) and degradative enzymatic activities (1, serine protease; 2, arylesterase; 3, carboxyesterase).

genetically distinct behavioral biotypes, LAB and WARF, of the species *P. americana*.

This elucidated molecular mechanism of *P. americana* chemoreception explains why EAGs have been used so effectively to monitor whole insect responses to messenger molecules including pheromones; the reason is that the involved exchanges of energy through the several described molecular levels have linear relations to each other. Primary encoding of the input (afferent) information required to dictate a distinct efferent response (i.e., EAG, avoidance behavior, or feeding inhibition) thus may occur peripherally in the redox protein in the dendritic membrane of the primary chemosensory neuron.

The elucidated second level in the evolution of the molecular mechanism by which male *P. americana* perceive naphthoquinones as allelochemicals involves interfacing proteins in the sensillum liquor. Whereas the above-described redox protein is at the information-encoding level, and the species apparently may best maintain its fitness through conservation of this evolved vital mechanism among individuals (e.g., LAB versus WARF males), the second level of the sensillum-liquor chemoreceptive mechanism apparently assures that individuals within the species, e.g., *P. americana*, may evolve distinctly in their behavioral sensitivity to given stimuli, e.g., naphthoquinones. Thus, LAB males are behaviorally twice as sensitive as WARF males to 2-methyl-1,4-naphthoquinone, especially because the two biotypes have differing amounts and reactivities among one or more interfacing proteins in their sensillum liquor (i.e., the outer aqueous medium of the chemosensory sensillum, Figure 2). Our best knowledge indicates strongly that both endogenous and exogenous factors alter the quantities and functionalities of these interfacing proteins. Such assured variability would seem to guarantee individual *P. americana* dynamic day-to-day chemical senses.

(Received September 15, 1987; accepted March 10, 1988)

Abstract—The bioassay has been one of the most widely used tests to demonstrate allelopathic activity. Often, claims that a particular plant species inhibits the growth of another are based entirely on the seed germination response to solvent extracts of the suspected allelopathic plant; few of these tests are of value in demonstrating allelopathy under natural conditions. The veracity of the bioassay for evaluating naturally occurring compounds for phytotoxicity depends upon the physiological and biochemical response capacity of the bioassay organism and the mechanism(s) of action of the allelochemicals. The possibility that more than one allelochemical, acting in concert at very low concentrations, may be responsible for an observed allelopathic effect makes it imperative that bioassays be extremely sensitive to chemical growth perturbation agents. Among the many measures of phytotoxicity of allelochemicals, the inhibition (or stimulation) of seed germination, radicle elongation, and/or seedling growth have been the parameters of choice for most investigations. Few of these assays have been selected with the view towards the possible mechanism of the allelopathic effect.

Key Words—Allelopathy, bioassay, mechanism of action, seed germination, radicle growth, seedling growth, *Lemna* bioassay.

INTRODUCTION

We have recently reviewed the use of bioassays in the study of allelopathy (Leather and Einhellig, 1986). In that review, we discussed the nature and types of bioassays used by investigators to demonstrate the phytotoxicity of leachates, exudates, extracts, etc., from plants suspected of being allelopathic to other

0098-0331/88/1000-1821$06.00/0

plants or microorganisms. Yopp's (1985) treatise, "Bioassays for Plant Hormones and Other Naturally Occurring Plant Growth Regulators," is an excellent source of information on assays for specific chemicals that control plant growth and function. Many of these bioassays may be useful in the study of allelopathy when the mechanisms of action are well understood.

Our purpose here is to evaluate the veracity of the most commonly used bioassays in allelopathy research, their value in determining allelochemical mechanism(s) of action, and the suitability of those bioassays to detect the presence and phytotoxicity of allelochemicals.

DISCUSSION

Mechanism of Action. Allelochemicals that are phytotoxic have been identified from many genera of plants and belong to many classes of chemical compounds (Rice, 1984). Einhellig (1986) and Putnam (1985) have reviewed the chemistry and mechanisms of action of allelopathic agents. Table 1 is a summary of our current knowledge of the possible mechanisms by which the allelochemicals inhibit plant growth and development. Proposed mechanisms

TABLE 1. MECHANISMS OF ACTION OF ALLELOCHEMICALS IN PLANT GROWTH AND DEVELOPMENT[a]

Mechanism	Allelochemical	Reference
Cell extension	Phenolic acids, tannins	Lee and Skoog (1965), Lee et al. (1982), Lee (1980), Ray et al. (1980)
Cell division	Volatile terpenes, coumarins	Muller (1965), Jankay and Muller (1976), Avers and Goodwin (1956)
Membrane permeability	Phenolic acids	Harper and Balke (1981)
Nutrient uptake	Phenolic acids	Harper and Balke (1981), Kobza and Einhellig (1987)
Chlorophyll synthesis	Coumarins Phenolic acids	Einhellig et al. (1970), Einhellig and Rasmussen (1979)
Photosynthesis	Phenolic acids	Nyberg (1986), Scholes (1987)
Protein synthesis	Phenolic acids, coumarins	Van Sumere et al. (1971)
Enzyme activity	Phenolic acids	Jain and Srivastava (1981), Sato et al. (1982), Schwimmer (1958)
Respiration	Juglone, volatile terpenes, phenolic acids	Scholes (1987), Koeppe (1972), Muller et al. (1969)
Water relations	Phenolic acids	Einhellig et al. (1985), Blum and Dalton (1985), Blum et al. (1985a)

[a] Condensed from Einhellig (1986), and Putnam (1985).

encompass most major plant functions, including regulation of growth by interfering with cell division or cell extension either directly or through interaction with hormones, effects on respiratory metabolism, photosynthesis, and altered water balance.

It can be noted from Table 1 that a great deal of research has involved phenolic acids and that these compounds act on a number of plant processes. It is unlikely that these compounds would have such a wide range of primary action, and it is probable that the results observed may be secondary and/or tertiary responses to the compounds. This range of responses could be due to the lack of veracity from improper bioassays. Indeed, most purported allelopathic agents have not been tested in bioassays with the goal of determining their mechanisms of action.

The biochemical and/or physiological response of a bioassay organism to allelochemicals is not always linear over a range of concentrations. Many allelochemicals are inhibitory at millimolar concentrations but stimulate the measured parameters in bioassays at micromolar concentrations. This anomaly confounds efforts to determine mechanisms of action in bioassays and to relate the results to in situ concentrations of allelochemicals.

Seed Germination Bioassays. The inhibition (or stimulation) of seed germination has been the most widely used bioassay for the determination of allelopathic activity. However, the seed germination process is probably the least understood of all plant functions (Leather, 1987). Seed germination begins with imbibition of water and ends with the protrusion of the radicle through the testa. Radicle elongation is by cell extension only and does not involve cell division. The biochemical events associated with germination are not well defined and may only be preparatory for the mobilization of reserves for seedling growth. Thus, definitive conclusions of allelopathic mechanisms in seed germination bioassays are limited but may involve membrane alteration, resulting in loss of metabolites and the ability to establish the necessary osmotic potential for cell elongation (Koller and Hadas, 1982). Other processes, such as alteration of the phytochrome control of germination, may also be effected. We found that some naturally occurring volatile compounds stimulated the dark germination of *Rumex* sp. that normally require postimbibitional light (French and Leather, 1979). Other perturbations from allelochemicals of seed germination processes may be involved, but we must await further knowledge of the biochemical events that occur during seed germination that are directly related to the germination process.

The greatest problem that affects the veracity of seed germination bioassays results from the manner in which the bioassay is conducted. Anderson and Loucks (1966) emphasized the importance of the solution osmotic potential when testing plant extracts; however, few reports on allelopathic effects consider this precaution (Leather and Einhellig, 1986). Weidenhamer et al. (1987)

reported that the number of seeds relative to the solution volume used in a seed germination bioassay was a factor in the results obtained. They found that the amount of ferulic acid available to each seed influenced the germination, rather than the concentration of chemical in the test solution. In conducting this research, care was taken to prevent anaerobic conditions by submersion of the seeds in water. We have found reports in the literature of allelopathic action where the investigators germinated the test species in volumes of solution that were 20 times the amount required for optimum germination without anaerobiosis.

Blum et al. (1984) offer recommendations for the standardization of germination bioassays. However, their results are based on radicle growth subsequent to germination and perturbations at any of the stages of germination and growth may have effects on any subsequent stage. Nonetheless, their observations regarding pH, microbial contamination, photolability of allelochemical, and loss of test compound are very important when conducting germination bioassays. Our recent review on this subject outlines additional precautions that should be observed when conducting seed germination bioassays (Leather and Einhellig, 1986).

Radicle Elongation Bioassays. Radicle elongation is a more sensitive assay for allelochemicals than seed germination (Leather and Einhellig, 1985; Einhellig, 1986). Like seed germination, radicle elongation is extremely sensitive to high (100 mosmol) osmotic potentials of solutions, and concentrations of purified extracts must be evaluated prior to assay (Bell, 1974). Generally, the radicle is completely dependent upon the seed (cotyledon) reserves for growth in the dark, and precautions must be taken to separate effects upon the seed and the mobilization of storage material by the allelochemical during or immediately following germination. Blum et al. (1984) reported that surface sterilization of seeds with sodium hypochloride modified radicle growth. Thus, as previously noted, care must be taken to minimize early effects of the allelochemical upon the seed that may alter subsequent radicle growth.

The accuracy of results obtained from the measurement of radicles elongating in Petri dishes is questionable. Few such radicles elongate on a straight course, and precise measurements are difficult. We have found that removing the radicle from seed germinated in Petri dishes and thoroughly drying to a constant weight gives accurate results with small statistical error (Leather and Hurtt, unpublished). Parker (1966) described a method to determine herbicide uptake and effects on radicle elongation. We modified this method to use pregerminated seed placed between chromatography sandwich plates that are maintained at a 45° angle, thus having straight radicles for measurement. Additionally, this method allows only the radicle to be in contact with the test chemical solution (Leather and Einhellig, 1985).

Radicle elongation does afford greater possibilities for mechanism studies

than seed germination. It is particularly suited for determining effects of allelochemicals on hormones responsible for cell growth. Radicle elongation also allows evaluation of allelochemical effects on respiration and cell division.

Seedling Growth Bioassays. Seedling growth bioassays are extremely versatile but require a greater quantity of chemical than is usually available during initial isolation and identification of allelochemicals. These bioassays usually have greater sensitivity and provide the basis for a variety of mechanism studies, such as nutrient uptake, water relations, and photosynthesis, but here again, it is difficult to determine the primary sites and mechanisms of action of the allelochemical.

Blum and colleagues (Blum and Dalton, 1985; Blum et al. 1985a,b), used leaf expansion of cucumber seedlings grown in nutrient culture to determine the mechanism of action of ferulic acid and its microbial metabolic products. In these reports, they stress the importance of monitoring the loss of allelochemical through absorption, microbial breakdown, or other mechanisms, including dissociation of the chemical in solutions of changing pH values.

Using a sorghum (*Sorghum*) seedling bioassay, we found that [^{14}C]salicyclic acid was rapidly taken up from the nutrient solution in which the seedling was growing, and it was distributed throughout the seedling within 24 hr after treatment (unpublished results). Such rapid, widespread translocation severely limits the utility of seedling growth bioassays for pinpointing primary sites or mechanisms of allelochemical action.

Lemna *Bioassays.* The *Lemna* bioassay developed in our laboratories is a versatile and extremely sensitive assay for allelochemical phytotoxicity (Einhellig et al., 1985). It meets many of the criteria for the assay of naturally produced phytotoxins (Duke, 1986) and can be used in the study of mechanisms of allelochemical action (Leather and Einhellig, 1985). Although only recently reported (Einhellig et al., 1985), this bioassay is now used by numerous laboratories for the detection of phytotoxic natural substances, including those produced by microorganisms. A drawback of this bioassay may be in relating the results obtained to the allelochemical effect on terrestrial plants. This relationship needs to be further investigated.

Lemna species (duckweeds) are angiosperms and offer a variety of parameters, including flowering (Cleland and Tanaka, 1982), which can be used as indicators of phytotoxicity. We measure the effects of allelochemicals on the dry weight, frond reproduction, chlorophyll content, and anthocyanin production. Anthocyanin production by *L. obscura* is the most sensitive to inhibition by selected allelochemicals (Leather and Einhellig, 1985). *Lemna gibba* affords other parameters such as chlorophyll content and flowering as indicators of allelochemical phytotoxicity, but because it is among the largest of the duckweeds, it is not suitable for low-volume assays (Ramirez-Toro et al., 1988).

Photosynthesis and overall respiratory metabolism of *Lemna* plants are par-

ticularly sensitive to perturbation and can thereby provide insight to the potential mechanisms of allelochemical action. Nyberg (1986) used *L. minor* to evaluate the effects of 22 different allelochemicals on chlorophyll content, photosynthesis, and respiration. Using a photorespirometer in conjunction with the 24-well assay plate, the tests could be conducted using very small quantities of allelochemical. Scholes (1987) evaluated the effects of compounds from six classes of allelochemicals on photosynthesis and respiration in *L. minor*. She found, for example, that juglone depressed the photosynthesis of duckweed at very low concentrations; this is in contrast to previous reports (Koeppe, 1972) that this allelochemical acted by interfering with respiration of isolated corn (*Zea mays* L.) mitochondria. However, caution must be observed when comparisons of two different systems are made.

CONCLUSIONS

Bioassays are essential tools for the identification of allelochemicals with phytotoxic properties. Because these chemicals are generally produced in small amounts and probably exert their effects in concert with other allelochemicals, it is desirable that the selected bioassay be extremely sensitive and that some indication of the mechanism of action of the allelochemical(s) can be determined. Nearly all reports of allelopathic activity indicate the response of the suspect leachate, exudate, or extract from a plant in some bioassay. With a better understanding of the perturbations elicited, advances in identification technology, and extremely sensitive bioassays, we can now begin to evaluate the integrity of bioassays that have formed the basis for the growing science of allelopathy.

POTENTIALS FOR EXPLOITING ALLELOPATHY TO ENHANCE CROP PRODUCTION

FRANK A. EINHELLIG[1] and GERALD R. LEATHER[2]

[1]*Department of Biology, University of South Dakota Vermillion, South Dakota 57069*

(Received September 15, 1987; accepted March 18, 1988)

Abstract—Strategies for utilizing allelopathy as an aid in crop production include both avoidance and application protocols. There are immediate opportunities for management of weed and crop residues, tillage practices, and crop sequences to minimize crop losses from allelopathy and also to use allelopathic crops for weed control. Varieties of grain and forage sorghums (*Sorghum* Spp.), sunflower (*Helianthus annuus* L.), oats (*Avena sativa* L.), wheat (*Triticum sativum* L.), rye (*Secale cereale* L.), and others may provide weed control and in some instances crop stimulation from their residues. Our four-year field study with cultivated sunflower resulted in no differences in weed biomass between plots with and without herbicide (EPTC) applications. Strip cropping that included sorghum showed that in the subsequent year weed density and biomass were significantly lower in the previous-year sorghum than in soybean strips. Possibilities exist for modification of crop plant metabolism to alter production of allelochemicals. Allelochemical–environmental interactions must be considered in efforts to benefit from allelopathy. Under greenhouse conditions, joint application of low levels of atrazine, trifluralin, alachlor, or cinmethylin with a phenolic allelochemical showed that these two categories of inhibitors acted in concert to reduce plant growth. Allelochemicals may also be adapted as yield stimulants or environmentally sound herbicides, such as cinmethylin and methoxyphenone. Isolation of bialophos, tentoxin, and others shows that bacteria and fungi are good sources of biologically active compounds.

INTRODUCTION

Biochemical interactions among plants (allelopathy) appear to be fairly ubiquitous phenomena, occurring to some extent in most natural and agricultural ecosystems. The science of allelopathy has progressed to the point that its descriptive and experimental foundations provide a base that can be used to aid crop production. In our focus on this topic both plants and microorganisms will be considered as sources and recipients of chemicals that may modify their growth, development, and distribution. Agricultural weeds and crops produce these allelochemicals, and microbial metabolism further contributes to the diversity of compounds present (Einhellig, 1985). Typically, these allelochemicals cycle through the soil matrix, and their impact on a crop is through root contact.

The natural products that cause allelopathy are a subset of the array of secondary compounds synthesized by plants and microorganisms. Most of the currently identified compounds are products of the shikimic acid and acetate pathways (Rice, 1984). Those frequently found include a diverse group of phenolic compounds, including cinnamic and benzoic acids, coumarins, tannins, and flavonoids; many terpenoids; and a few alkaloids, steroids, and quinones. Many that contribute to allelopathic interference have not been identified. It is extremely important to dispel the illusion that situations of allelopathic inhibition are caused by a single compound. Generally, interference arises from the combined action of a number of allelochemicals, and this impact is also influenced by other environmental stresses (Einhellig, 1987).

The flourish of recent activity in allelopathy has been partially driven by hopes for ways to reduce agricultural production costs and diminish some of the current reliance on synthetic chemicals that degrade environmental quality. Strategies to capitalize on allelopathy can be categorized as (1) avoidance of negative impacts, (2) exploitation of stimulatory effects, (3) management and development of allelopathic crops to suppress weeds, (4) development of allelochemicals as herbicides or growth regulators, and (5) combinations of these approaches (Einhellig, 1985). Space requirements preclude an extensive review of the literature supportive of capitalizing on allelopathy, and only exemplary evidences that focus on agronomic crops are noted.

ALLELOPATHIC INTERACTIONS IN AGRONOMY

Weed Interference. Total crop losses from weeds are estimated at $9–10 billion annually in the United States (Chandler, 1985; Putnam and Weston, 1986). Historically, investigators have viewed weed problems only in terms of competition, and no investigations have divided economic losses in a weed-

infested crop according to allelopathic vs. competitive interference. However, Putnam and Weston (1986) list about 90 species of weeds where allelopathic potential has been inferred, and this list is expanding. Allelopathic potential has typically been evidenced by plant growth performance following residue amendments to soil and/or bioassays using extracts, leachates, or exudates.

Our own investigations have focused on aggressive weeds common to the sorghum [*Sorghum bicolor* (L.) Moench] and soybean [*Glycine max.* (L.) Merr.] fields of the North Central Plains. Seedling bioassays using these crops demonstrated inhibition from *Kochia* [*Kochia scoparia* (L.) Schrad], Jerusalem artichoke (*Helianthus tuberosus* L.), cocklebur (*Xanthium strumarium* L.), velvetleaf, giant ragweed (*Ambrosia trifida* L.), and curly dock (*Rumex crispus* L.). Aqueous weed extracts reduced the growth of sorghum seedlings when material from 1 g fresh weight of leaf was incorporated into 60 ml of the nutrient medium. *Kochia*, Jerusalem artichoke, and cocklebur residues in soil caused no effect on sorghum germination, but after two weeks sorghum grown in soil containing 0.63% (w/w) of a residue weighed significantly less than controls. Disruption of water balance was one mechanism of action associated with allelopathic inhibition (Einhellig and Schon, 1982; Einhellig et al., 1985).

Allelochemicals have been identified from some weeds, but seldom has a thorough analysis of the chemical basis of interference been conducted. Some studies on the allelopathic aspects of a few species have included field-based analyses (Table 1). Reports on quackgrass over the last 50 years show that foliage and rhizomes of living plants and decomposing residues are phytotoxic. Putnam and Weston (1986) reported both plowed-under residues and those left in no-tillage systems reduced crop growth. Alfalfa grown in no-till plots had

TABLE 1. AGRICULTURAL WEEDS WITH ALLELOPATHIC POTENTIAL DEMONSTRATED BY FIELD AND LABORATORY INVESTIGATIONS

Species	Allelochemical classes implicated	Recent reference
Abutilon theophrastic Medic. (velvetleaf)	phenolic compounds	Sterling and Putnam, 1987; Colton and Einhellig, 1980
Agropyron repens (L.) Beauv. (quackgrass)	organic and phenolic acids; flavonoids	Weston et al., 1987; Putnam and Weston, 1986
Amaranthus palmeri S. Wats (Palmer amaranth)	sesquiterpene lactones; methyl ketones; alcohols	Menges, 1987; Connick et al., 1987
Parthenium hysterophorus L. (ragweed parthenium)	phenolic acids; sesquiterpene lactones	Kanchan and Jayachandra, 1979, 1980; Jarvis et al., 1985; Kumari et al., 1985
Sorghum halepense L. Pers. (Johnsongrass)	phenolic acids; cyanogenic glycosides	Menges, 1987; Rice, 1984

only 3.7% of the biomass of controls and nodulation was suppressed. Hence, some of the allelopathic effect of quackgrass may be indirect by action on *Rhizobium*. Crop plants associated with living quackgrass often exhibit symptoms of mineral deficiency, and added fertility does not overcome these effects. It is probable that allelochemicals impair uptake of some nutrients (Einhellig, 1986; Kobza and Einhellig, 1987).

Field experience in the warm, moist conditions of the southwestern United States demonstrated that soil-incorporated residues of Palmer amaranth inhibited the growth of carrot (*Daucus carota* L.) 49% and onion (*Allium cepa* L.) 68%. Volatile methyl ketones and alcohols released into the soil atmosphere markedly diminish germination and establishment of these small-seeded crops. Ragweed parthenium is a serious problem in India (references: Table 1). All the organs of this weed are inhibitory in bioassays and more than a dozen allelochemicals have been identified. Leaves mixed into the soil reduced the yield of four crops, while they stimulated growth of bajra (*Pennisetum typhoideum* Rich.). Thus, crops may differ markedly in their sensitivity.

Decomposition time, climatic conditions, soil type, and relative placement of residue with respect to crop plants are critical. Allelopathic effects are often more severe with light-textured soils, but poorly drained, heavy soils can also accentuate a problem. Residue location dictates allelochemical concentration in the microenvironment of a germinating seed or growing root. Such information can be used for decisions on the timing and type of crop tillage preparations.

Crop–Crop Interference. Need for avoidance-management strategies is also apparent because allelopathic conditions generated by one crop may influence a subsequent planting. Often, evidence on crop sequence problems is either anecdotal, or at a minimum, it is conditional according to location, climate, and year-to-year variables. A few examples of large acreage crops illustrate the widespread nature of the problem (Table 2).

Alfalfa and some perennial legumes often exhibit autotoxicity and replant problems (Miller, 1983). Isoflavonoids, phenolic acids, and medicagenic acid glycosides have been implicated in the soil sickness of red clover (*Trifolium*

TABLE 2. INTERFERENCE FROM LARGE ACREAGE CROPS ON FOLLOWING PLANTING

First crop	Affected planting	Location
Alfalfa (*Medicago sativa* L.)	Alfalfa	U.S. Central Plains
Corn (*Zea mays* L.)	Corn	Iowa
Rice (*Oryza sativa* L.)	Rice, soybeans	Taiwan
Sunflower (*Helianthus annuus L.*)	Following crop	South Dakota
Wheat (*Triticum aestivum* L.)	Wheat	U.S., Australia, U.S.S.R., England

pratense L.) (Chang et al., 1969: Oleszek and Jurzysta, 1987). Terpenoids and polyphenols contribute to the decline in yield of successive crops of pigeon pea [*Canjanus cajan* (L.) Millsp] (Hepperly and Diaz, 1983).

Agroecosystems repeating the same cereal crop often experience yield declines. In Taiwan, rice is planted twice a year in continuous monoculture. With a short time interval between crops, yields are reduced about 25% in the second crop (Chou, 1986). Intense study of stubble-mulch tillage continuous wheat production in Nebraska showed that the residues provided an environment for a bloom of *Penicillin urticae* Bainer (McCalla and Norstadt, 1974). This fungus produced patulin, which is very toxic to wheat. High levels of microbially produced short-chain fatty acids contribute to wheat allelopathy in England (Lynch, 1987). Some inhibitors have been identified in these cases, but there are still many deficits in explaining their mode of action and how allelochemical–environmental interactions finally result in a diminished stand and yield (Einhellig, 1986).

Many of these agriculture problems evolve from a combination of allelopathy and factors such as plant pathogens, changes in soil structure, moisture and fertility stress, and others. We have observed that production is lower than normal in the year following a sunflower crop. Allelochemical deposition and reduction in soil moisture may both be involved. In Iowa, corn following soybeans the previous year yields about 10 bu/acre more than corn following corn even when the corn residue is plowed under in the fall and adequate nitrogen is supplied. Anderson (1984) suggested the yield differences are due to both an inhibitory effect of corn and a stimulatory action from soybeans. Fortunately, it is not necessary to have a full understanding of the causative factors in order to modify production practices and improve productivity. Crop rotations and tillage practices are obvious approaches to avoid detrimental crop–crop interactions and capitalize on stimulatory effects. Work in the U.S.S.R. is emphasizing breeding plant varieties with less allelopathic activity (Grodzinsky, 1987).

WEED CONTROL BY CROPS

Crop Interference. Some crops are effective in minimizing growth of companion weeds, and there may be a carryover weed suppression in the following season. We found a sunflower–oat rotation over five years showed significantly lower grass and broadleaf weed densities than in open control plots (Leather, 1983). Although weed density increased in all plots over the five seasons, the rate of increase was less in sunflower plots. There was little difference among the sunflower cultivars. In a follow-up study, weed biomass was equivalent in plots planted with sunflowers, whether or not EPTC (*S*-ethyl dipropyl carbamothioate) herbicide was applied, clearly showing the efficacy of sunflower-

mediated weed control (Leather, 1987). The crop was reduced in a second year of sunflower, indicating a compatible crop rotation strategy should be considered.

The allelopathic nature of sorghum (*Sorghum*) crops has been suggested from various parts of the world. For the past two seasons, we have monitored the weed biomass the year following strip cropping with grain sorghum, corn, and soybeans, all with no herbicide. Weed cover at the time of early spring emergence in former sorghum strips was less than 30% of that in prior soybean strips (first season, unpublished data). At midsummer, plots where grain sorghum had grown the year before had about 60% of the weed biomass of others. This reduced biomass resulted from the suppression of broadleaf weeds, with no effect on grasses. Laboratory work showed that grain sorghum inhibits early seedling growth and development more than germination. Some farmers in South Dakota currently strip plant grain sorghum and sunflower without herbicides and find reasonable weed control, as well as protection from wind erosion. Forney et al. (1985) reported that growing a forage sorghum–sudangrass hybrid prior to late-summer planting no-till alfalfa suppressed weeds and enhanced alfalfa growth.

Other examples of the suppressive effect of crop plants on certain weeds are sweet potatoes [*Ipomea batatas* (L.) Lam.] on yellow nutsedge (*Cyperus esculentus* L.) and soybeans on barnyardgrass [*Echinochloa crus-galli* (L.) Beauv.] (Harrison and Peterson, 1986; Maun, 1977). Hence, the concept of allelopathic crops may be one alternative in weed control strategies. If this prospect is to materialize, more extensive research is needed on applicable crop sequences, the roles of soil and climatic factors, long-term impacts on the weed population, and ways to integrate allelopathic crops with other weed control practices.

Genome Enhancement. The possibilities for exploiting allelopathy include genetic manipulation of crops to increase their capability for weed control. There is a general consensus that this capacity has been diminished during development of currently used strains, although we did not find this to be true with sunflowers. Fay and Duke (1977) reported some accessions of oats exuded three times as much scopoletin as a standard cultivar. Putnam and Duke (1974) found decided differences in toxicity among 500 cucumber accessions from 41 nations of origin. In field tests, one allelopathic accession reduced total weed fresh weight to approximately one third of the weed biomass found with Pioneer, a commonly grown cultivar (Lockerman and Putnam, 1979). However, the allelopathic effect was less under periods of increased rainfall.

Altering the genome of crops to enhance herbicidal activity could be approached through classical breeding programs or biotechnology. Major problems for the latter are identifying allelochemicals that may effect a desired change, learning how their production is regulated, and development of a genetic

engineering approach for moving a controlling gene element into an agronomic crop. ARCO Plant Cell Research Institute has such long-term objectives (Burke, 1987). An alternative to genome changes is to develop chemicals to manipulate crop metabolism to achieve an increase in allelochemical production. One limitation to enhancing crop-originated weed control is that autotoxicity must be avoided. A second concern is that changes in the chemical balance or chemical constituents of a crop must not have adverse effects on humans, livestock, or other nontarget organisms.

Cover Crop and Residue Management. Cover crops of wheat, barley (*Hordeum vulgare* L.), oats (*Avena sativa* L.), rye (*Secale cereale* L.), grain sorghum, and sudangrass [*Sorghum arundinaceum* (Desv.) Stapf.] have been used effectively to suppress weeds (Barnes and Putnam, 1983; Putnam and DeFrank, 1983; Putnam et al., 1983; Shilling et al., 1985). Three approaches for employing residues of these annual grasses have emerged in conjunction with minimum tillage: fall planting followed by winter kill, fall or spring planting and subsequent mowing or herbicide desiccation, and double-crop systems.

Some form of conservation tillage is used on approximately one third of the U.S. crop acreage. These practices are expanding because of potential cost savings, erosion control, and beneficial moisture conditions. Weed suppression is an added dimension that results from a combination of allelopathy and physical factors, such as light reduction and not elevating buried weed seeds to positions for germination. It has been demonstrated that allelochemicals make a significant contribution when planting no-till into residues by using control plots of *Populus* excelsior to alter the physical environment in the same manner as cover crop residues (Putnam et al., 1983). In addition, allelochemicals from cover crop residues that inhibit the germination and growth of weeds have been isolated.

The high biomass production and toxicity of rye make it a particularly effective weed-suppressant cereal. Decomposing residues generate phenylacetic acid, 4-phenylbutyric acid, and a complex of benzoic and cinnamic acids. Aqueous extracts of rye contain β-phenyllactic acid, β-hydroxybutyric acid, and toxic hydroxamic acids (Shilling et al., 1985; Barnes et al., 1986). DIBOA [2,4-dihydroxy-1,4(2H)-benzoxazin-3-one] was shown to maintain toxicity for an extended period following addition to soil. The collective allelochemical action is impressive. Barnes et al. (1986) reported that weed biomass in a cover crop of living rye was reduced 90% over unplanted controls and even a mulch of 40-day-old spring-planted rye gave 69% reduction. Shilling et al. (1985) found prior conditioning with either rye mulch or root residue before tobacco (*Nicotiana tabacum* L.), soybean, and sunflower crops gave good weed control. Soybeans and sunflowers planted without tillage into desiccated rye mulch (fall-planted, spring-killed) gave over 90% reduction in the biomass of common lambsquarter (*Chenopodium album* L.), redroot pigweed (*Amaranthus retro-*

flexus L.), and common ragweed (*Ambrosia artemisiifolia* L.), compared to tillage and no rye.

Experience with local conditions, crop tolerances, cost considerations, and integration with appropriate tillage practices are prerequisites to relying on crop residues for weed control. Crop injury from mulch-related weed control can be circumvented by adjustment of time between mulching and planting and using tolerant crops. Putnam et al. (1983) found that, generally, the larger-seeded food crops (corn, cucumber, pea, snapbean) were more tolerant than lettuce, carrot, and tomato. Also, carrot and tomato tolerated some residues but not others.

COMPLEMENTARITY OF ALLELOCHEMICALS AND HERBICIDES

Some of the previously noted research on weed control in Michigan and North Carolina desiccated the cover crops with glyphosate or paraquat. Although more expense is incurred, Putnam et al. (1983) reported better weed control in the vegetable crops was obtained from herbicide desiccation in late spring compared to winter-killed residue. Similarly, in apple and cherry orchards companion planting of rye or wheat in the fall and desiccation in the subsequent year gave weed control equal to or better than repeated tillage or herbicide spraying, and long-term studies have shown no effect on the trees.

Allelopathic crops and mulches may not provide total weed control. In our experience, allelopathic control of weedy grasses is generally poorer than for most broadleaf weeds, and some of these are more resistant than others. Shilling et al. (1985) found rye mulch in tilled systems did not significantly reduce common ragweed, whereas it depressed several other broadleaf weeds. An herbicide applied along with allelopathic conditions could have supportive action, affecting the same or different species.

We reported that when a level of atrazine that did not inhibit oat seedlings was applied in combination with ferulic acid, the net inhibition was greater than from ferulic acid alone (Einhellig, 1987). Additional work using sorghum and wheat seedling bioassays showed that low levels of trifluralin, alachlor, and cinmethylin will act in concert with phenolic acid allelochemicals (Hamm, 1984; Wegher, 1986). For example, there is an additive deleterious effect on sorghum after 10 days growth with trifluralin and salicylic acid in the medium (Table 3). In another investigation, sorghum was not altered with either 100 ppb alachlor or 0.2 mM ferulic acid, but a combination of these reduced growth by more than 50%. The experimental design was a matrix of five levels of alachlor and four levels of ferulic acid, and a two-way ANOVA showed a significant interaction term. As the treatment of either type of chemical alone became quite inhibitory, the action of the second stress was masked (Wegher, 1986). These

TABLE 3. EFFECTS OF TRIFLURALIN (TR), SALICYLIC ACID (SA), AND THEIR COMBINATION ON GROWTH OF GRAIN SORGHUM SEEDLINGS

data suggest that a reduced level of herbicide may be feasible to provide weed control when it operates simultaneous with allelopathic conditions. However, caution should be exercised that dual herbicide–allelopathic methods do not cause crop damage or have other negative environmental impacts.

A variety of stresses can initiate an increase in allelochemical content of plants (Rice, 1984), and allelopathic content also varies according to plant maturity (Lehle and Putnam, 1982). It is probable that manipulation of timing, formulation, and application rate of a herbicide used to kill or supplement a cover crop can enhance crop phytotoxicity, improving weed control. Herbicide-mediated suppression of some allelochemical pathways may also be possible, and eventually chemicals may be used to shift microbial populations or their metabolism to regulate the production and release of phytotoxins.

ALLELOPATHY MANAGEMENT

By definition, agroecosystems are manipulated systems. Many items that have previously been discussed allude to the need for management considerations to include the impact of allelopathic plants, whether they are weeds or crops. The goal is to control the system to avoid production losses created from allelopathy and to take advantage of beneficial aspects of allelopathic plants. The research cited on utilization of cover-crop residues is a start in this direction. Similarly, Chou (1987) described ways to eliminate phytotoxins to improve crop yield in several production systems of Taiwan. They included improvement of drainage, removal of phytotoxins by flooding, detoxification by nutrient dressing, and rotating crops. In a unique approach to allelopathy management,

Syamasundar and Mahadevappa (1987) have shown that interference from *Cassia sericea* Sw., a plant with several economic uses in India, can be used to control ragweed parthenium.

However, it is rare that planting and tillage decisions are made with regard to the natural consequences of allelopathy. Likewise, allelopathy management cannot be considered in isolation from other management criteria, such as decisions on the appropriate crop, fertility needs, control of disease, insects, and weeds. All these factors must be balanced with economic and long-term environmental considerations. There is a strong need for research on how these multiple factors, including allelopathy, will be integrated into crop production management.

COMMERCIALIZATION OF ALLELOCHEMICALS

Public demand for environmentally safer pesticides, herbicides, and growth regulators has given renewed emphasis to development of natural products for these purposes. Typically, their residence time in an ecosystem is shorter, and their toxicities are more narrowly targeted. Many crop production systems are now showing an increase in herbicide-resistant weed strains as well as changes in the composition of weed populations toward species quite closely related to the crops they infest. These factors, coupled with the increasing difficulty of developing new herbicides by traditional chemistries, indicate that new weed-control strategies must emerge (Duke, 1986a).

The number of compounds produced by plants and microorganisms probably exceeds the number of synthetics that have been prepared in the last century. Using Swain's (1977) estimate of 400,000 secondary metabolites, only about 3% of this storehouse has been identified, and only a fraction of those identified have been evaluated for herbicidal or bioregulator activity. Some plant and microbial metabolites should have direct application potential, whereas others will provide novel chemicals that can be modified to enhance biological activity (Figure 1).

Herbicides from Higher Plants. Although the inspiration that led to the development of a herbicide is seldom clear from the literature, some plant compounds have obviously served as structural templates. Several phenoxy herbicides are auxin analogs. Benzoic acid compounds are frequently implicated in allelopathy, and the herbicidal utility of their halogenated derivatives (TBA, TIBA, Dicamba, etc.) is well known. Shettel and Balke (1983) reported the common allelochemicals salicylic acid, *p*-hydroxybenzoic acid, hydroquinone, and umbelliferone effectively suppressed the growth of several weeds when applied as a spray. Unfortunately, they were not selective, and the rates necessary to inhibit weeds were quite high. Herbicide development of the photo-

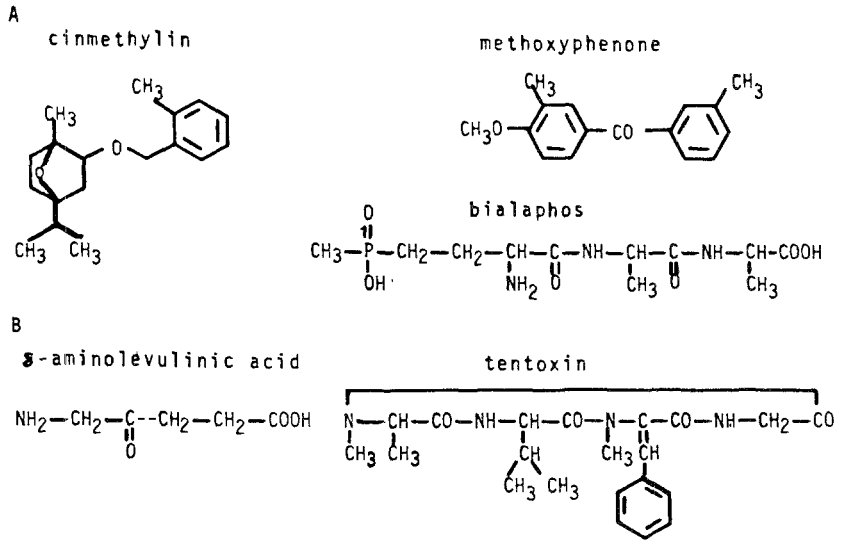

FIG. 1. Structures of (A) herbicides with a natural product basis or component and (B) plant and microbial phytotoxins with potential for development.

sensitizer Δ-aminolevulinic acid has recently been proposed (Hopen et al., 1985).

Cinmethylin (Cinch; Shell Development Company) represents a new class of herbicide (Figure 1). The molecule contains only carbon, hydrogen, and oxygen atoms, and the environmental impact should be minor. It controls many annual grasses and some broadleaf weeds with preemergence treatment. In our tests, the concentration of cinmethylin required to inhibit the growth of several grasses was comparable to that required for alachlor. Cinmethylin is a cineole alcohol with the addition of a substituted benzyl group. Its advent comes 20 years after 1,8-cineole was identified as an agent in allelopathy.

Microbial Compounds as Herbicides. Phytotoxins isolated from bacteria and fungi appear to be important sources of herbicides (Cutler, 1984, 1987; Duke, 1986b; Duke and Lydon, 1987). Purported advantages of these compounds, compared to those from higher plants, include their ease of isolation and quantities obtainable for study, potential for specificity, efficacy at low rates, and opportunities for fermentation production. Candidates include both pathogenic and nonpathogenic bacteria and fungi. The Japanese have made significant progress in this field (Otake, 1983; Cutler, 1987), and several U.S. and European firms have programs for developing herbicides from microbial metabolites. Monsanto Agricultural Co. is finishing the second year of a project screening microorganisms for phytotoxins. Several thousand isolates have been

tested in bioassays and about 3% of these have provided interesting leads (Kevin Crosby, personal communication).

The chemical skeleton of picloram (Tordon) is the microbially produced alkaloid α-picolinic acid. A product of *Streptomyces*, anisomycin, led to the development of the synthetic herbicide NK-049 (methoxyphenone) which kills barnyardgrass in rice. Bialaphos [L-2-amino-4-[(hydroxy)(methyl) phosphinoyl]-butyric acid]-was isolated from *Streptomyces viridochromogenes* and has been marketed in Japan as Herbiace (Figure 1). It kills both monocot and dicot species and is effective on perennials. Duke (1986b) lists by source and known effect 40 additional microbial non-host-specific phytotoxins that have been characterized. They include tentoxin, a cyclic tetrapeptide from *Alternaria alternata.* Cutler (1985) described several other chemical classes of toxins from *Alternaria* spp. in noting more than a dozen fungal metabolites with activity.

The selectivity of microbially produced toxins covers a wide range. Some are host-specific, affecting only one or a few species, whereas others are non-host-specific and are toxic to plants that the producing microorganisms do not infect. The potential that microbial toxins may also have a broad spectrum of effects beyond plants adds to the care that must be taken in utilization of such compounds.

Yield Enhancers. A variety of nonnutrient substances that manipulate growth, development, and composition of plants has been marketed. These exogenous bioregulators typically have been synthetic chemicals that function by some interaction with the endogenous five phytohormone groups. Even though they have made little impact on large-acreage economic crops, according to Jung (1985) plant bioregulators had a dollar market share of 3–4% among crop production chemicals. Their actions include growth retardation, flower induction, hastening maturity or senescence, enhanced biomass production, and others. Allelochemicals provide a promising source for new growth regulating compounds.

The tantalizing possibility of discovering a natural product that can be used to increase crop yield has driven several research efforts. Three compounds that have received the most attention are agrostemmin, triacontanol, and brassinolide. Rice (1984) summarized Yugoslavian work showing as little as 1.2 g of agrostemmin per hectare increased wheat yields. Its discovery followed the observation that higher wheat yields were obtained when grown in mixed stands with corn cockle (*Agrostemma githago* L.). Triacontanol, a 30-carbon primary alcohol, was isolated as a growth-promoting factor from alfalfa. Foliar applications of triacontanol have increased yields in cucumber, carrot, rice, corn, soybean, and others. Inconsistent results, perhaps due to formulation problems and to method, rate, and time of application, have reduced the efficacy of the compound (Laughlin et al., 1983). Extensive work has gone into evaluating brassinolide, a steroid isolated from rape (*Brassica repus* L.) pollen, as a yield

stimulant. Brassinolide and several analogs have been synthesized (Maugh, 1981), but the expense is currently too high for use on field crops.

The task of discovering a plant-growth regulator is substantially more demanding, perhaps by a factor of 10–100 times, than for a new herbicide (Jung, 1985). Companies are anxious to discover and develop growth regulators, as evidenced by 67 patents issued for plant-growth regulators in 1983, a threefold increase from 20 years earlier (Holmseni, 1984). However, from a commercial perspective, these efforts must produce a significant yield enhancement chemical in the next few years or resources may be deployed to more productive alternatives.

Biological Agents. No prognostication on the potential impact of allelopathy is complete without some reference to the application of organisms to aid crop production. In some cases, their actions may be the result of allelochemicals that are released. Quantum 4000 (Gustafson, Inc.) is the first of what may be several root protectant products. It is a peanut (*Archis hypogaea* L.) seed inoculant that consists of live *Bacillus subtilis*. This beneficial bacterium colonizes the roots, conferring protection against disease. Some evidence suggests that antibiotic production may be involved in the enhanced root health. Several companies are now field-testing other biological root protectants (Brosten, 1987).

Successful mycoherbicides, Collego and DeVine, have been marketed for control of northern jointvetch [*Aeschynomene virginica* (L.) B.S.P.] and stranglevine [*Morrenia odorata* (H. & A.) Lindl.], respectively. DeVine, the first registered commercial fungus for weed control, contains a strain of *Phytophthora palmivora* (Butl.) Butl. that kills the current stand of stranglevine and controls the weed for several years to come. Whether the pathogenicity is due to toxic substances is not known. Undoubtedly, additional biological herbicides will be used successfully in weed control.

CONCLUSIONS

Sufficient information is available and production demands are opportune for exploiting allelopathy to benefit crop production. Modern agriculture is in a period of transition toward tillage reduction and curtailment of environmental damage from agrochemicals. Although information is incomplete on the specific allelochemicals and mechanisms involved, some crops can effectively control many competing weeds, and cover crops, in conjunction with reduced tillage, can supplement herbicides. Crop rotations, compatible sequences, residue management, timing of operations, and other approaches should be guided by local conditions and experience. More research is needed on ways to manage allelopathic weed and crops within the larger context of management in agro-

ecosystems. In the longer term, adaptations of biotechnology may be used to elevate or reduce production of allelochemicals by crops.

Screening for biological activity and the isolation and identification of allelochemicals must be done by the agrochemical industry to capitalize on natural products. Bacterial and fungal metabolites are good sources of chemicals for development of herbicides and bioregulators. Commercial formulations, including biological agents whose activity may be mediated by allelochemicals, have also shown success. Marketing useful allelochemicals and their analogs to enhance crop production is a challenging and potentially rewarding new frontier.

(Received September 15, 1987; accepted February 24, 1988)

Abstract—A series of natural drimanes and related synthetic compounds was tested for antifeedant activity against aphids. Polygodial and warburganal were the most active. The synthetic compounds methyl 9α-hydroxydrimenoate and 9α-hydroxydrimenal, although active against lepidopteran larvae, were inactive against aphids. Natural (−)-polygodial and the synthetic (+) isomer showed similar levels of activity as aphid antifeedants and in phytotoxicity, fish toxicity, and human taste tests, but reacted at different rates with enantiomers of 1-phenylethylamine.

Key Words—Antifeedant, sesquiterpenoid, drimane, dialdehyde, polygodial, 1-phenylethylamine, *Myzus persicae*, aphid, Homoptera, Aphididae, phytotoxicity, taste.

INTRODUCTION

Natural sesquiterpenoid dialdehydes in the drimane series, such as (−)-polygodial (1) from the temperate herbaceous weed water-pepper *Polygonum hydropiper* (Polygonaceae) (Barnes and Loder, 1962) and (−)-warburganal (12) from the East African tree *Warburgia ugandensis* (Canellaceae) (Kubo et al., 1976), show various biological effects. These include potent antifeedant activity against lepidopteran larvae such as the armyworms *Spodoptera exempta* and *S. littoralis* and against other insect pests (for recent review see van Beek and de Groot, 1986). A wide range of related synthetic compounds has been tested behaviorally and electrophysiologically against larvae of *Spodoptera* and *Heliothis* spp., and dimethyl polygodioate (2)and methyl 9α-hydroxydrimenoate (18) were as active as (−)-polygodial and (−)-warburganal (Blaney et al., 1987). In laboratory tests, (−)-polygodial has been shown to inhibit feeding and colonization by the aphid *Myzus persicae* and to decrease the transmission of potato virus Y and beet yellows virus, even by aphid variants highly resistant to insecticides (Gibson et al., 1982). In the field, (−)-polygodial, obtained from commercially grown water-pepper by extraction with liquid carbon dioxide, has been used to reduce transmission of barley yellow dwarf virus by the aphid *Rhopalosiphum padi* (Dawson et al., 1986; Pickett et al., 1987). However, the activity against aphids of related compounds, particularly those known to be active against lepidopteran larvae, has not been reported.

Synthesis of drimane antifeedants and related compounds has been recently reviewed (Ley, 1987; de Groot and van Beek, 1987). Polygodial is readily synthesized as the racemate by two elegant routes devised by Ley (Hollinshead et al., 1983) and Lallemand (Jalali-Naini et al., 1983) and can also be synthesized as the separate enantiomers (Mori and Watanabe, 1986). Kubo and Ganjian (1981) have claimed that specific absolute stereochemistry determines antifeedant activity and also other properties such as hotness to human taste. In addition, preliminary studies suggested that the (+) isomer of polygodial was more phytotoxic than the (−) isomer (Pickett, 1985). We have therefore compared the biological activities of the (−) and (+) isomers of this compound. Furthermore, since D'Ischia et al. (1982) have suggested that the biological activity of polygodial is related to its ability to react with amino groups, we have investigated the differential reactivities of the polygodial enantiomers with a chiral amine.

METHODS AND MATERIALS

Compounds. Natural (−)-polygodial (1) was isolated by standard methods (Barnes and Loder, 1962) from water-pepper, *Polygonum hydropiper*, collected

in Hertfordshire, U.K. (for aphid antifeedant and phytotoxicity tests) and in Tokushima, Japan (for hotness to taste and piscicidal tests).

Synthesis of (±)-polygodial (1 and 20) was by a combination of two methods (Hollinshead et al., 1983; Jalali-Naini et al., 1983), but with a modification to the transformation of compound 8 to 2. Compound 8 was treated with lithium di*iso*propylamide (LDA) (1.2 equivalents) in tetrahydrofuran (THF) at −78°C; the anion was stereoselectively protonated using trimethylacetic acid and the product hydrogenated (Pd–C) to give compound 2 in over 80% yield after crystallization, which was then converted to racemic polygodial as before. Resolution of polygodial enantiomers was achieved as shown in Scheme 1: alkaline hydrolysis of 2 at room temperature gave the crude half-ester which was crystallized from acetonitrile (mp 164.5°C). [^{1}H]NMR JEOL PFT 100 (100 MHz) $CDCl_3$, diagnostic peaks at 3.15 (m, 1H), 3.63 (s, 3H), 7.13 (m, 1H), 10.8 (s, 1H). The half-ester formed a diastereomeric salt with (+)-(*R*)-1-phenylethylamine, which after five crystallizations from methanol–water (1 : 1) and acidic work-up gave the (−) half-ester $[\alpha]_D^{20} = -47.2°$ (c = 2.5, EtOH). Conversion with excess di*iso*butylaluminium hydride gave the diol $[\alpha]_D^{20} = -9°$ (c = 7.0, EtOH). Swern oxidation (using dimethyl sulfoxide and oxalyl chloride, followed by treatment with triethylamine at −78°C) gave the (−)-dialdehyde (mp 50–51°C, from hexane) $[\alpha]_D^{20} = -137°$.

Identical treatment of the half-ester with (−)-(*S*)-1-phenylethylamine gave the (+) half-ester $[\alpha]_D^{20} = +48.2°$ (c = 2.3, EtOH), diol $[\alpha]_D^{20} = +9°$ (c = 5.8, EtOH) and the (+) isomer 20 (mp 49–50°C) $[\alpha]_D^{20} = +138°$ (c = 0.35, EtOH).

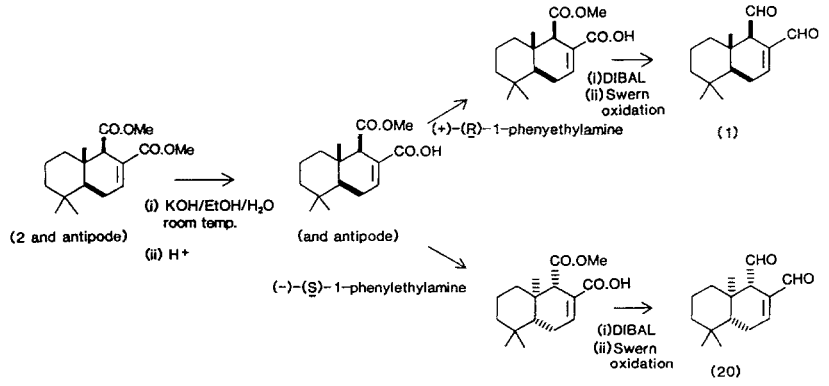

SCHEME 1.

The (−) and (+) isomers of polygodial (1 and 20) were also synthesized separately by the method of Mori and Watanabe (1986). Compounds 2, 3, 4 (cinnamolide), 8, 9, 13, 14, 15, and 16 were synthesized as racemates by methods described previously (Ley, 1987). Compound 5 was prepared as a mixture of geometric isomers from (±)-polygodial by treatment with methanol and toluene-*p*-sulfonic acid (Pezechk-Jalali, 1985). Polygodial was readily regenerated from 5 by treatment at room temperature with formic acid or an aqueous hydrochloric acid (0.5M) and diethyl ether mixture. Compound 6 (and diastereoisomer) was obtained by allowing (±)-polygodial to react with two equivalents of (+)-(*R*)-1-phenylethylamine in carbon tetrachloride overnight at room temperature, then removing solvent and heating the product at 180°C for 5 min. [^{1}H]NMR JEOL JNM-GX 400 (400 MHz) $CDCl_3$, diagnostic peaks at 1.77 (d, 3H), 2.12 (m, 1H), 5.14 (q, 1H), 5.68 (dd, 1H), 6.31 (m, 1H), 6.48 (dd, 1H), 6.53 (m, 1H). (The pyrrole protons δ6.31 and 6.53 are complicated by diastereomeric effects). Compound 7 (*cis*-polygodial) was synthesized as the racemate (Guillerm et al., 1984). Isomerization of compound 8 with LDA at −78°C in THF and kinetic protonation with 0.5 M sulfuric acid, reduction to the diol, and Swern oxidation at −62°C gave compound 10. Isomerization of 8 with 1,8-diazabicyclo[5.4.0]undec-7-ene in refluxing benzene followed by lithium aluminium hydride reduction and Swern oxidation at −72°C gave compound 11. (−)-Warburganal (12) and (−)-drimenol (17) were obtained as gifts, having been isolated from *Warburgia ugandensis* (Kubo et al., 1976) and *Drimys winteri* (Appel et al., 1959), respectively. Compounds 18 and 19 were synthesized as single isomers from (−)-drimenol (Blaney et al., 1987; P. Grice, personal communication).

Analysis. Estimation of polygodial was by high-performance liquid chromatography (HPLC) on a Spherisorb 5 μm nitrile column (25 × 0.46 cm) using ether–hexane (1 : 1) at 3 ml/min with ultraviolet detection at 224 nm. Estimation of the enantiomers of polygodial was by chiral HPLC on a β-cyclodextrin column (25 × 0.46 cm, Cyclobond I, Advanced Separation Technologies Inc.) at ambient temperature, using methanol–water (85 : 15) at 1 ml/min with ultraviolet detection at 224 nm. This method was preferred to an excellent gas chromatographic method for analyzing enantiomers of polygodial (Brooks et al., 1985) because of a requirement for derivatization with amphetamines not available commercially.

Bioassays. Antifeedant activity against aphids was tested by treating half-leaves of Chinese cabbage (*Brassica campestris* var. Chinensis, Cruciferae) with ethanolic solutions of the test compound and comparing numbers of settled aphids, *Myzus persicae*, on treated and untreated halves after 24 hr (Dawson et al., 1982). There were 10 replicates of 20 aphids at each concentration. The highest level tested was 0.1% (ca. 250 ppm compound/leaf), and the concentration was reduced by a factor of two until the difference between treated and

untreated areas was no longer significant at $P = 0.05$ (calculated by analysis of variance).

Similar antifeedant tests were done using a synthetic membrane stretched over a plastic ring. Test compounds were painted onto one half of the lower surface of the membrane, and aphids placed in the ring were allowed to feed on an artificial diet held on the upper surface (Griffiths et al., 1975). Aphids feeding on treated and untreated halves were counted after 24 hr, as before.

Antifeedant activity against the larvae of diamondback moth, *Plutella xylostella* (= *maculipennis*), was assessed by treating half-leaves of Chinese cabbage with test compound and estimating the percentage leaf area eaten after 24 hr (Pickett et al., 1987).

Phytotoxicity to Chinese cabbage leaves was scored on a scale of 0 to 5: 0, no damage to leaf surface; 1, most of leaf surface normal, some slight pitting; 2, slight pitting over whole leaf surface or dry patches on leaf; 3, slight pitting over whole leaf surface with some dry patches; 4, pitting of leaf surface, large areas dry and papery; 5, leaf shrivelled. Effects on germination were assessed using 100 wheat seeds (*Triticum aestivum* var. Norman, Graminaceae) which were dipped into ethanolic solution of test material, allowed to dry, and then grown on moist filter paper for 12 days.

Piscicidal activity was assessed at 0.4 ppm by standard methods using three killie fish, *Oryzia latipes*, per treatment (Kawazu, 1981).

Human taste tests were performed using aqueous solutions (0.045 ppm) as described previously (Kubo and Ganjian, 1981), using a panel of 14 people.

Differential Reactivity of Polygodial Enantiomers with Chiral Amine. (±)-Polygodial (23.4 mg, 0.1 mmol) in diethyl ether (5 ml) was slowly added to (+)-(*R*)-1-phenylethylamine (6.12 mg, 0.05 mmol) in diethyl ether (5 ml) and left overnight at room temperature. Solvent was removed and the absence of amine confirmed by nuclear magnetic resonance spectroscopy. The unreacted polygodial was isolated from the residue by thin-layer chromatography (silica gel, hexane–diethyl ether 1 : 1) and the specific optical rotation determined. This procedure was repeated with (−)-(*S*)-1-phenylethylamine.

RESULTS AND DISCUSSION

The influence of various drimanes and related compounds on feeding and colonization by aphids was determined by the number settled on treated and untreated halves of a leaf (Table 1). The most active compounds were the natural drimane dialdehydes (−)-polygodial (1) and (−)-warburganal (12) and the synthetic enantiomer (+)-polygodial (20). Drimanes closely related to (−)-polygodial i.e. the diester 2, the diol 3, and the lactone cinnamolide (4) were only weakly active, while compound 5, formed by addition of methanol, was

[a]N.A. = Not active at 0.1%.

inactive at 0.1%. This compound was prepared as a precursor or proantifeedant to provide extended release of the parent compound (Pickett et al., 1984). The parent compound was indeed released in weak acid, but since it was thought that this process would take place only slowly on the plant, the compound was also tested at a higher dose: at 0.5% there was significant activity. However, although at this higher level a wide range of compounds are active (Dawson et al., 1982; Briggs et al., 1983), compound 6, obtained by addition of 1-phenylethylamine but with subsequent loss of water to give the pyrrole, was significantly less active than 5, presumably because it could not readily regenerate polygodial. *cis*-Polygodial (7) and compounds 8–11, which do not have the *trans*-decalin ring of the natural drimane dialdehydes 1 and 12, were also inactive. Despite the high activity of (−)-warburganal, of the other 9α-hydroxy compounds 13–15, only compound 15, the 9α-hydroxy analog of cinnamolide (4), was active. Compound 16, formed by hydroxylation at carbon-3 in the diol 3, also lost activity. Natural (−)-drimenol (17) and the two 9α-hydroxy analogs 18 and 19 were inactive. However, compound 18 has been shown to be a highly effective antifeedant for the larvae of several species of *Spodoptera* and *Heliothis*

(Blaney et al., 1987), and compound 19, although not tested previously, proved here to be active at 0.01% against diamondback moth larvae. In these tests, 19 was even more active than (−)-polygodial and compound 18, which were only significantly active at 0.1%. Thus, it appears that the structure–activity requirements for the drimane-type antifeedants are different for aphids and lepidopteran larvae.

The similar biological activity of the synthetic (+)-polygodial (20) and the natural (−) isomer (1) (Table 2) was surprising in view of the earlier antifeedant structure–activity studies of Kubo and Ganjian (1981), and the present discovery that *cis*-polygodial was inactive. Therefore, the aphid antifeedant activity of the two enantiomers and of racemic polygodial was compared, using solutions for which the concentration and isomer content were confirmed by the reverse-phase and chiral HPLC methods. This affirmed that aphid antifeedant activity for the enantiomers was indeed similar and also demonstrated that the phytotoxic effects were similar (Table 2). At a concentration of 0.1%, the leaf damage score for Chinese cabbage was 3–4 and potato (*Solanum tuberosum*, Solanaceae) suffered scorching and yellowing of leaves, but sugar beet (*Beta vulgaris*, Chenopodiaceae) was unharmed. At this concentration, wheat seed germination was reduced only slightly from 83 to 75%, but at 0.5%, it was reduced from 92 to 69% and the number of twisted leaves was increased from 2 to 61%. (−)-Warburganal also caused similar leaf erosion of Chinese cabbage, as did other compounds with aphid antifeedant activity. To investigate the possibility that the reduction in aphid feeding was caused by damage to the leaves, the polygodial enantiomers were tested on a synthetic membrane through which the aphids could feed (Table 3). Since results on membranes were similar to those on leaves, it is unlikely that the aphid antifeedant activity is related to

the phytotoxic effects. Therefore, the development of nonphytotoxic drimane-type antifeedants is possible.

In view of the surprising similarity in antifeedant and phytotoxic activities for the polygodial enantiomers, two other types of biological activities were assessed. The enantiomers of polygodial showed similar piscicidal activities: (+)-polygodial, (−)-polygodial (synthetic), and (−)-polygodial (natural) at 0.4 ppm killed the test fish within 38, 36, and 30 min, respectively, whereas in the control, the fish were alive after two days. Also, these three materials had similar hot tastes to the human tasting panel.

The enantiomers of polygodial reacted differently with enantiomers of the chiral amine 1-phenylethylamine: from the reaction of (±)-polygodial with (+)-(*R*)- and (−)-(*S*)-1-phenylethylamine, the recovered polygodial gave specific rotations ($[\alpha]_D^{22}$) of −10° and +9° respectively. Although these rotations are small compared with that of pure (−)-polygodial, these results indicate a greater reactivity between the enantiomers of polygodial and the amine of like optical rotation. This initial observation makes the similar biological activity of the polygodial enantiomers even more surprising. Some of us (G.W.D., A.M., J.A.P., and Z.Z.-N.) are studying these reactions further, with Professor Charles J.W. Brooks of the University of Glasgow, U.K.

CONCLUSIONS

Of the compounds tested here, the dialdehydic drimanes are the most promising as aphid antifeedants. Further attempts to improve activity should employ different structural modifications from those described here and should involve a study of structure–activity relationships in aphids independent of lepidopteran studies. As the enantiomers of polygodial showed similar activity against aphids, the racemates, which are more readily available by synthesis, could be employed in the commercial development of drimane-type antifeed-

ants, although production by biotechnological means (Pickett, 1985) shows considerable promise for the future.

Acknowledgments—We thank Professors J.W.S. Pringle, F.R.S. and C.J.W. Brooks for generous gifts of (−)-warburganal and (−)-drimenol, and Lynda A. Merritt and M.C. Smith for technical assistance.

Harpenden, Herts., AL5 2JQ, U.K.

(Received September 15, 1987; accepted March 10, 1988)

Abstract—The use of sex attractants to monitor the pea moth, *Cydia nigricana* (F.) in the United Kingdom is decribed. Two systems are currently available: one for use in combining (dry-harvested) peas for human consumption or seed, and one for use in vining peas for freezing or canning. The development and details of both systems are reviewed and their commercial application discussed.

Key Words—Pea moth, *Cydia nigricana*, Lepidoptera, Tortricidae, sex attractant, pheromone, monitoring, peas, *Pisum sativum*.

INTRODUCTION

Peas are grown widely throughout Europe as an arable crop, and in the United Kingdom they rank fifth in value after cereals, potatoes, rape, and sugar beet. In 1986 they occupied a total area of 135,000 hectares. There are now three main types of commercial pea in the United Kingdom: (1) combining peas for human consumption or seed (harvested dry), (2) vining peas (harvested green for freezing or canning), and (3) protein peas (for animal feed). Peas grown for consumption as fresh peas now constitute a very small proportion of the market, although they are more popular in some other parts of Europe (e.g., France). Traditionally peas have been grown on the relatively dry eastern side of England, but over the last few years there has been a big increase in the pea-growing area and the crop is now grown in many parts of the country.

The pea moth, *Cydia nigricana* (F.) is a potentially serious pest of peas, the larvae boring into the pods and damaging one or more of the developing

[1] Present address: Department of Ecology, University of Lund, Ecology Building, Helgonavägen 5, S-223 62 LUND, Sweden.

0098-0331/88/1000-1857$06.00/0

seeds. The economic effect of this damage and the presence of the larvae and frass depends on the type of pea crop. In combining crops, damage to peas can be removed after harvest, but the farmer will incur penalties. In vining peas, hardly any damage can be tolerated, because the peas cannot be "cleaned" mechanically after harvest. *C. nigricana* rarely has much effect on yield in the United Kingdom, so it is considered unnecessary to attempt control in crops grown for animal feed.

The life cycle of the moth is well documented (Franssen, 1954; Wright and Geering, 1948), but it is useful to summarize it here (Figure 1). There is one generation per year, and the insect passes the winter as a fully grown larva in a cocoon in the soil. Pupation takes place in late April–early May, and adults can emerge from late May onwards. The timing of emergence is very variable both between years and among different geographical locations. The adults emerge in fields that had peas the previous year, so they have to disperse to the new pea fields. Females emerge with immature ovaries, mate in the emergence field, and disperse to the peas. The ovaries mature in a matter of hours and almost all females arriving at pea fields are ready to lay eggs immediately. Males also move to the peas but in smaller numbers (Graham, 1984).

The eggs are laid mainly on the leaves and stipules towards the top of the pea plants, and hatch in ca. 10–20 days, depending on the temperature. The newly emerged first-instar larvae search for and bore into developing pea pods, where they feed on the seeds. They pass through five instars and eventually cut their way out of the pod and drop to the ground to spin a cocoon and enter diapause. The only stage that can be controlled effectively with insecticide sprays is the newly hatched first-instar larva before it enters the pod.

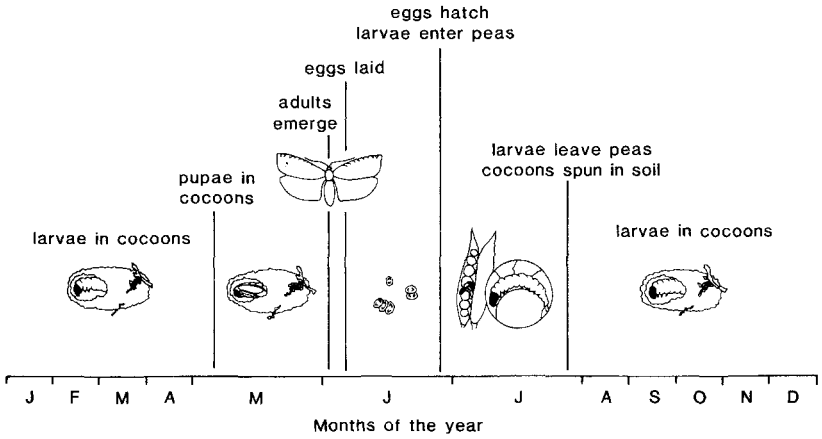

FIG. 1. The life cycle of *C. nigricana*.

THE PROBLEM

The erratic appearance of this pest means that there is a need for a local monitoring technique, which preferably can be used by the individual farmer. The only real alternative to this is to use prophylactic insecticide sprays. However, the questions to be answered by the monitoring system differ for combining peas and vining peas (Table I).

Combining pea varieties have an indeterminate growth form, producing pods sequentially for several weeks. Although most pods are probably attacked by the larvae of *C. nigricana* shortly after flower-set, it has been shown that even mature pods that are starting to dry are susceptible to attack (Graham, 1984). This means that the crop is at risk from the start of flowering to shortly before harvest. In addition, it is usually possible for the larvae to complete their development and leave the pods before harvest, thus causing maximum damage and ensuring completion of the life cycle. A local monitoring system for this crop is therefore required to provide information on (1) the arrival of moths, (2) the need to spray, and (3) the optimum timing of the spray(s).

Vining pea varieties have a determinate growth form resulting in the production of all the pods at the top of the plant over a very short period of time. Consequently, the pods mature at approximately the same time and this facilitates the harvest, which must be at a particular point in the development of the seeds to ensure the highest quality. The crops are sown sequentially so this can be achieved, and harvest often takes place only three weeks or so after flowering. Timing of the insecticide spray is not, therefore, important because the situation dictates that only one spray can be applied and the best time for this is at full flower. A monitoring system for this crop is therefore required to provide information on the need to spray. Since infesting larvae are often killed at harvest (being still in the pods) the density of *C. nigricana* in vining pea areas is generally very low. However, very low damage tolerances are set by the processors, which results in the need for a particularly sensitive monitoring technique.

TABLE 1. TYPES OF COMMERCIAL PEAS AND MONITORING REQUIREMENTS FOR *C. nigricana*

Type of pea crop	Requirements
Combining (for human consumption or seed)	Detect arrival of moths; determine need to spray; predict date of first spray
Combining (for protein)	None
Vining (for freezing or canning)	Determine need to spray

DEVELOPMENT OF SEX ATTRACTANT TRAPS

Electroantennogram screening of synthetic compounds pinpointed a number of physiologically active straight-chain acetates (Wall et al., 1976). Of these, two were subsequently shown to be very attractive to males in the field, while others acted as synergists or repellents (Greenway et al., 1982). The two most attractive compounds were (*E,E*)-8,10-dodecadien-1-yl acetate (*E,E*8,10–12 : Ac) and (*E*)-10-dodecen-1-yl acetate (*E*10–12 : Ac); the former was subsequently shown to be the female sex pheromone (Greenway, 1984). The most successful slow-release formulation for these attractants was shown to be a rubber stopper (Greenway and Wall, 1981), and dose–response and weathering field trials determined the dosage required to provide lures that remained constantly atractive for the whole of the flight period. Some difficulty was experienced initially with the diene, because in the presence of sunlight it isomerizes to produce a powerful repellent for *C. nigricana* (Wall and Greenway, 1983). It was for this reason that *E*10–12 : Ac was used as the attractant in the system developed for use in combining peas; it had the added advantage of catching fewer moths, thus avoiding trap saturation. An antioxidant was added to stabilize this attractant (Greenway and Wall, 1981, 1982). Various designs of trap and a number of retentive sticky materials were evaluated, and for practical monitoring purposes a delta-type trap with a removable sticky base was proposed (Lewis et al., 1975; Lewis and Macaulay, 1976). The sticky material has to be particularly efficient since *C. nigricana* belongs to the subfamily Olethreutinae, which tend to hold their wings in a steep rooflike form when at rest, thus presenting only the leading edges of the wing to the sticky surface. This is in marked contrast to Tortricinae, members of which have wider wings held in a "flat" profile when at rest, making it much easier to trap them on a sticky surface.

The height at which traps should be deployed in the crop was investigated (Lewis and Macaulay, 1976), and the recommendation for monitoring purposes was that the trap should be maintained at a height of two thirds the height of the crop. In the commercial version this is achieved using a sliding clip on a metal pole. The traps and sticky inserts are cardboard, thus making the whole kit lightweight and easily dispatched by mail to individual growers.

It is difficult to determine the density at which traps should be operated. Two questions need to be answered: (1) What is the minimum density to monitor the insect populations adequately? (2) At what density do traps start to interact and distort individual catches? Perry et al. (1981) showed that area spray warnings for combining peas, based on trap catches at a few sites within a large area, provide a less reliable indication of the need to spray than "on-site" monitoring traps in each field. Other work on trap interactions (Wall and Perry, 1981) and local variations in catches (Perry and Wall, 1984) confirmed

the approach of one trapping system per unit of crop unless that unit is greater than 50 hectares, in which case two systems are used. In the case of the more recent monitoring system for vining peas, traps are deployed at a maximum density of 1 per 36 hectares, which is equivalent to a spacing of 600 m.

COMBINING PEA SYSTEM

This system has been available commercially since 1978.

Description. A pair of traps is placed 100 m apart and 5 m into each field (Figure 2a) on adjacent headlands on the side of the prevailing wind (Wall et al., 1987). The traps are set at right angles to each other so that on any one day one trap will be optimally orientated to the wind, since wind direction greatly affects the catch (Lewis and Macaulay, 1976). Each trap contains 3 mg of *E*10–12:Ac on rubber, which will remain constantly attractive for at least three months (Greenway et al., 1981; Wall and Greenway, 1981). In fields larger than 50 hectares a second pair of traps is placed in the opposite corner (Perry and Wall, 1984), the whole field being sprayed if either pair indicates the need. The traps are installed in mid-May, before the flight season, and examined every other day.

Spraying is necessary only if a "threshold" catch is achieved: this is 10 or more moths in either trap during two consecutive 2-day periods (Macaulay et al., 1985). The date of the "threshold" is taken to indicate the start of substantial oviposition in the crop, and a developmental model using maximum/

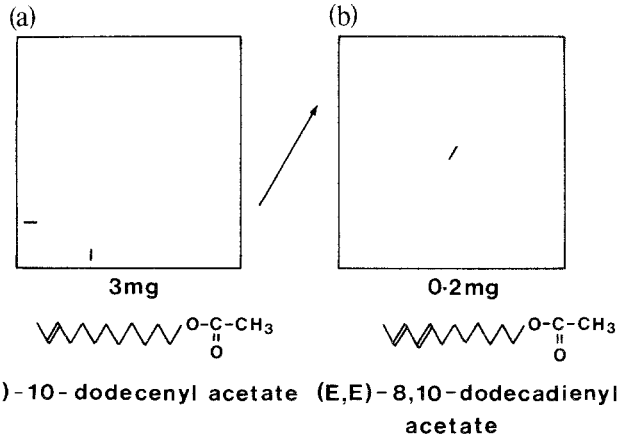

FIG. 2. Schematic representation of trap deployment in a field of peas: (a) combining peas, field <50 hectares, traps at right angles; (b) vining peas, field >36 hectares, one trap oriented to prevailing wind (arrow).

minimum daily temperatures (Lewis and Sturgeon, 1978) is used to calculate the rate of egg development and thus predict the date of the first spray. The spray is applied at the 85% development stage to ensure a kill of newly hatched larvae.

The spray prediction calculations can be done using a simple calculation derived from one described by Macaulay et al. (1985). However, it was found to be much more efficient for the advisory services to provide an interpretation service based on a computer model and temperature records from local meteorological stations. The details of the procedure are described in Wall et al. (1987) but can be summarized as follows:

A farmer who achieves a "threshold" waits three to four days, then contacts the advisory services by telephone; he is put in contact with a prerecorded message (or to the appropriate computer "page" if he has a viewdata system, known as Videotex in North America), which relays a predicted spray date based on the date of his "threshold." Since this prediction is based on both recorded and forecast temperatures, he is usually advised to telephone back a few days later to obtain an updated prediction.

As a result of this interpretative service, a very high proportion of farmers run their own traps and control the pest effectively, while applying pesticides only when needed. A five-year survey of farmers using the monitoring system, both correctly and incorrectly, confirmed its effectiveness if used correctly and has also indicated the economic gains (cf. Table 2 in Wall et al., 1987).

It seems that this system has succeeded because the threshold indicates the start of the immigration of substantial numbers of moths. Beyond this, there is no attempt to relate trap catch to population levels.

Problems. There have been remarkably few difficulties. One of the most persistent, however, is the tendency for farmers not to put traps out early enough in the season. This can lead to false "threshold" catches as the traps catch a backlog of immigrant males. Similarly, in years when the moths emerge very late, farmers may have to examine traps regularly for several weeks before catches are obtained, and some may decide to stop trapping too early. It can be difficult to persuade a farmer to keep running the trap in such circumstances.

Modifications to the system, in light of experience, are difficult to incorporate once it has become established commercially. For this reason it is still produced with pairs of traps, even though a single trap reorientated to the wind regularly and placed further into the crop (like the newer vining pea trap) might be preferable.

VINING PEA SYSTEM

This system was launched commercially in 1987 on a trial basis to assess interest among farmers.

Description. Single traps containing 200 μg *E,E*8,10–12:Ac (plus antioxidant) on rubber are placed at least 100 m into the crop (Wall et al., 1986) (Figure 2b) and at least 600 m from the nearest trap to avoid interactions (Wall and Perry, 1978, 1987). They are installed in mid-May, before the flight season, examined daily, and reorientated to the wind. A record is kept of the number of moths caught, and the cumulative catch at full flower is used to predict the maximum likely damage if the crop is not sprayed.

Wall et al. (1986) showed that there is a linear relationship between proportion of peas damaged (logit transformation) and the cumulative catch per trap at full flower. This regression was used to compute confidence limit contours for any future observations within the range of catches obtained during the experimental trial at 50 sites over three years. It is these confidence limits that form the basis of the predictive table now used to determine the need to spray (Table 2). Despite the variability of the data, meaningful predictions of the maximum damage to be expected at different probability levels can be produced. This is very different from trying to predict the damage level with reasonable accuracy, which has proved to be so difficult with sex attractant traps.

As mentioned previously, the crop is sown sequentially over a period of several weeks. Despite the findings of Graham (1984) that moths migrate into combining peas at or after flowering, no such relationship could be found between the catches in traps and crop phenology in vining peas. Males were caught up to 40 days before full flower (Wall et al., 1986). This led to the conclusion that the traps are sampling males from outside the sowing in which they are placed and that they may be indicating the presence of the moth in the area rather than the crop (sowing). Other work has shown that the sampling range of these traps is in excess of 500 m (Wall and Perry, 1987).

Problems. It is very difficult to obtain information on the levels of damage by *C. nigricana* at which vining pea crops are rejected by processors. During the three-year trial by Wall et al. (1986), damage was extremely low, averaging

TABLE 2. PREDICTED PEA MOTH DAMAGE—VINING PEAS[a]

	Upper limits of damage (% peas) at probability level:			
Cumulative moth catch	50	80	90	95
10	0.01	0.07	0.17	0.34
30	0.02	0.09	0.23	0.47
100	0.03	0.13	0.32	0.66
300	0.04	0.18	0.44	0.92
1000	0.05	0.26	0.63	1.54

[a] Data derived from Wall et al., 1987.

0.05% in unsprayed plots in 50 crops. Only 12% of the crops had damage in excess of 1%, which would probably represent an economic loss, and yet 54% of the crops were sprayed. Thus *C. nigricana* seems to have been of minor importance on vining peas in the United Kingdom during recent years. Despite this, many farmers spray prophylactically, while others hardly ever spray. The problem is to encourage both "schools" to use the traps that are now available. The "no-spray" school does not think the moth is a problem; the "spray" school regards it as pointless to trap when insecticide is so cheap and timing is not a problem.

As a result of the Common Agricultural Policy of the European Economic Community, the area of protein peas in the United Kingdom has increased considerably over the last few years. Since there is presently no need to control *C. nigricana* in protein peas, this increase could lead to a build-up of moth populations and increasing problems in both the combining-pea and vining-pea crops. There are already signs that this problem is starting in Sweden where protein peas have been grown for rather longer (B. Jönsson, personal communication). The question is: do we really have to wait until that problem hits the vining-pea industry in the United Kingdom before farmers will start to use monitoring traps extensively?

A second problem is the specificity of the attractant. Despite Greenway's (1984) identification of the pheromone as *E,E*8,10–12 : Ac and the lack of electrophysiological or behavioral evidence that there may be minor components as yet unidentified, it must be acknowledged that *E,E*8,10–12 : Ac is an attractant for males of several closely related species of *Cydia* (Table 3). Of these *C. servillana* has already turned up as a contaminant in vining-pea monitoring traps during the 1987 season in the United Kingdom. The scale of the problem will

only become apparent with time; only then will it be possible to assess the need for further work on the identity of the sex pheromone of this species.

CONCLUSIONS

The sex attractant monitoring system for *C. nigricana* in combining peas has now been available commercially for a decade. It has worked well and is used by a large number of farmers in the United Kingdom. Its acceptance by growers is due largely to the central interpretation of trap catches provided by the advisory services, but also to its virtually unblemished record. The success with which the system monitors the occurrence and timing of moth immigration into pea crops is due to a large number of factors: the most important are (1) the insect has a discrete flight period, (2) the traps have a relatively short range of attraction and therefore sample only the crop, and (3) a simple "threshold" catch is used to determine the start of flight and predict the start of egg hatch.

The monitoring system for use in vining peas is a much later development, which has been launched commercially in 1987. Although potentially very useful because it can be used to predict the risk of damage, its uptake by the farming community is in doubt and will depend on future attitudes to minimizing pesticide usage against this pest.

Acknowledgments—This paper would not have been possible without the efforts of several colleagues who have contributed as authors of the papers cited and others who helped in a support capacity.

(Received September 15, 1987; accepted March 15, 1988)

Abstract—Epoxide hydrolase catalyzes a simple hydrolysis of reactive cyclic ethers that may otherwise alkylate and impair critical proteins and nucleic acids required for life. Although much less studied than the cytochrome P-450 monooxygenases that produce epoxides, differences in subcellular, tissue, pH, substrate, and inhibitor specificities argue for at least three forms of insect epoxide hydrolase. Increasing numbers of epoxides are being identified as plant allelochemicals, antifeedants, and essential hormones or precursors for herbivorous arthropods, and in many cases an associated alkene to diol pathway of metabolism is found. A role for epoxide hydrolase in arthropod–plant interactions is strongly supported by species comparisons and by age–activity and induction studies. Two major limitations for study in biochemical ecology of epoxide hydrolase are the lack of an effective in vivo inhibitor and a range of commercially available radiolabeled substrates for the enzymes.

Key Words—Epoxide hydrolase, insect, herbivore, plant epoxides, alkene, diol, coadaptation, detoxification, arthropod-plant interactions.

INTRODUCTION

Considerable effort has been invested in determining adaptive roles for detoxification enzymes in plant-feeding insects. The tens of thousands of potentially toxic secondary metabolites in plants, together with the exceptionally high levels of oxidative, hydrolytic, and conjugative xenobiotic metabolizing enzymes in insect herbivores, have stimulated much discussion of an associative role. This paradigm has been more rigorously established by recent study on specific

0098-0331/88/1000-1867$06.00/0

dietary allelochemicals as inducers for and substrates of enzymes that metabolize foreign compounds in the respective herbivore (Ahmad, 1986; Brattsten, 1979; Brattsten and Ahmad, 1986; Dowd et al., 1983; Hodgson, 1985). Most work has concentrated on cytochrome P-450-dependent monooxygenases (EC 1.14.14.1) because of their pivotal role in initiating the concerted enzymatic reactions by which lipophilic, nonnutrient compounds are rendered into water-soluble and more excretable metabolites. Among the reactions catalyzed by these polysubstrate monooxygenases (PSMOs) are π-bond oxygenations forming epoxides. These important reactive intermediates can then be hydrolyzed to diols by epoxide hydrolases (EC 3.3.2.3) or conjugated to glutathione by glutathione transferases (EC 2.5.1.18). The three aforementioned enzyme systems constitute, within arthropods, the major enzymatic pathways by which epoxides are formed and degraded, of which the epoxide hydrolase is the least studied.

Many epoxides are strong electrophiles and can undergo rapid nucleophilic additions during both routine isolation and in vivo with water, sulfhydryl, and amino groups; they also participate in acid-enhanced rearrangements and polymerization. The high chemical reactivity of epoxides is often responsible for their high toxicity, mutagenicity, carcinogenicity, and other biological activities (Casida and Ruzo, 1986; Hutson, 1983). In turn, the presence of the usually less toxic *trans* 1,2-diol in an organism is good evidence that a PSMO-initiated alkene to diol pathway exists (Hsia, 1982–1983). There are presently no useful in vivo inhibitors of epoxide-metabolizing enzymes that can facilitate the isolation of the epoxide intermediate.

Investigators had recognized much earlier the occurrence of *trans*-diol metabolites from some aromatic hydrocarbons and alkenes, but it was not until 1950 that an enzyme responsible for their generation from epoxides was first postulated (Boyland, 1950). A few years later, a search for soil microbes capable of growth on an epoxide of fumaric acid as their sole carbon source led to the discovery that cell-free preparations from both a *Flavobacterium* spp. and the fungus *Aspergillus fumigatus* were able to convert *trans*-L-epoxysuccinic acid (**I**, Figure 1) to *meso*-tartaric acid (Martin and Foster, 1955). Subsequently, Breuer and Knuppen (1961) reported the *trans*-hydration of epoxyestrogens in rat liver slices. In plants, the simultaneous occurrence in ironweed (*Vernonia anthelmintica*) seeds of the appropriate epoxide and diol provided a base for postulating an enzyme that converts *cis*-12,13-epoxyoleic acid (**II**) to *threo*-12,13-dihydroxyoleic acid (Scott et al., 1963). Also, high levels of epoxidized fatty acids together with very active epoxide hydrolases for these substrates were found in spores of plant rusts (Hartmann and Frear, 1963; Tulloch, 1963).

The first demonstration of epoxide hydrolase in insects occurred with a synthetic cyclodiene insecticide. In vivo studies in dieldrin-resistant southern house mosquitoes (*Culex pipiens quinquefasciatus*) (Oonnithan and Miskus,

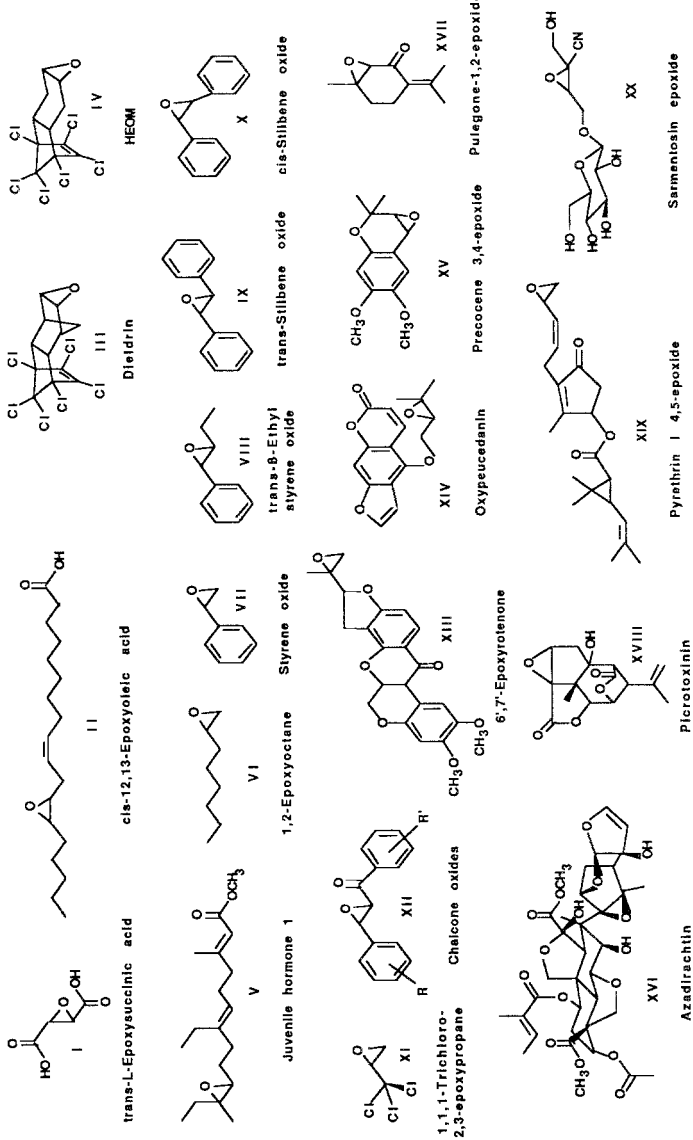

FIG. 1. Some epoxides associated with arthropod–plant interactions.

1964; Tomlin, 1968) had previously established that dieldrin (**III**) was metabolized to a product cochromatographing with aldrin *trans*-diol; similarly, house flies topically treated with chlordene epoxide formed compounds thought to be chlordene glycols (Brooks and Harrison, 1965). The enzymatic nature of this epoxide hydrolase activity towards dieldrin, its analog HEOM (**IV**), and other cyclodiene epoxides was finally verified in vitro in preparations from the house fly, and in rat and pig liver microsomes (Brooks, 1966; Brooks et al., 1970). Epoxide hydrolase has subsequently been found in all living organisms investigated. Comprehensive reviews emphasizing mammalian (Oesch, 1973; Lu and Miwa, 1980; Seidegard and DePierre, 1983; Wixtrom and Hammock, 1985) and insect (Brooks, 1977; Hammock, 1985) epoxide hydrolases are available. The consequence of epoxide hydrolase in herbivorous arthropods is now addressed.

PROPERTIES OF ARTHROPOD EPOXIDE HYDROLASE

Epoxide hydrolase has been purified from only one insect source, that of the southern armyworm, *Spodoptera eridania*, a polyphagous herbivore (Mullin and Wilkinson, 1980a). The larval midgut enzyme has an extraordinarily wide specificity for substrates and hydrolyzes a range of epoxides from simpler monosubstituted compounds to more sterically hindered compounds such as juvenile hormone (**V**) and chlorinated cyclodiene epoxides. Moreover, the activities for the latter substrates were 100–30,000 times lower than activities for 1,2-epoxyoctane (**VI**), styrene oxide (**VII**), and other less-hindered substrates (Mullin and Wilkinson, 1980b). Armyworm epoxide hydrolase, the most active eukaryotic preparation so far reported, was calculated to comprise 3.7% of the total microsomal protein in the armyworm midgut. This indicates an important role for the enzyme in this herbivore, although the low activity for juvenile hormone (JH) and cyclodiene epoxides in comparison to activities in crude preparations suggests that other isozymes are present in armyworm midgut (Mullin and Wilkinson, 1980b).

Multiple Forms. Tissue and subcellular distributions, pH optima, and substrate and inhibitor specificities strongly support the existence of multiple forms of epoxide hydrolase in arthropods. Highest activities towards commonly used substrates occur in the midgut microsomes at alkaline pH. JH epoxide hydrolase appears more widely in fat body (Fox and Massare, 1976; Wing et al., 1981) and other tissues such as the Malpighian tubules, integument (Slade and Wilkinson, 1974), wing imaginal disks (Hammock et al., 1975), silk gland (Wisniewski et al., 1986), and even the corpora allata (Gadot et al., 1987). Also, considerable JH epoxide hydrolase is cytosolic rather than microsomally bound (Yu and Terriere, 1978b; Wisniewski et al., 1986), although this is not always

the case (Hammock et al., 1974, 1975). By contrast, epoxide hydrolases for the cyclodiene HEOM (Slade et al., 1975), styrene oxide, and 1,2-epoxyoctane (Mullin and Wilkinson, 1980a,b) in the southern armyworm are largely microsomal. Recent studies with the substrates *trans*-β-ethylstyrene oxide (**VIII**), *trans*-stilbene oxide (**IX**), and *cis*-stilbene oxide (**X**) (Table I) indicate that considerable activity is cytosolic, particularly for saprophagous compared to herbivorous arthropods. In the laboratory fruit fly, *Drosophila melanogaster*, even styrene oxide, a substrate normally hydrated preferentially in microsomes (Wixtrom and Hammock, 1985, and references therein), is rapidly hydrolyzed in the cytosol (Jansen et al., 1986).

Differences in pH optima also suggest the presence of multiple epoxide hydrolases. In *S. eridania* midgut microsomes, both HEOM hydrolase (Slade et al., 1975) and 1,2-epoxyoctane hydrolase (Mullin and Wilkinson, 1980a) are optimal between pH 8.5 and 9.5 in Tris and glycine buffers, while JH epoxide hydrolase has an optimum of 7.9 (Slade et al., 1975). Activity in cabbage looper, *Trichoplusia ni*, midgut microsomes peaks at pH 7.4 for *trans*-stilbene oxide and pH 8.0 for *cis*-stilbene oxide (Ottea and Hammock, 1986). In other species, there is a similar tendency for hydrolases of *trans*-disubstituted and higher substituted epoxides such as JH to have more acidic pH optima than those for monosubstituted and *cis*-disubstituted substrates (Hammock et al., 1974; Cohen, 1981).

At present there are no effective *in vivo* inhibitors of epoxide hydrolase,

TABLE I. SUBCELLULAR DISTRIBUTION OF EPOXIDE HYDROLASE IN ARTHROPODS

Feeding strategy and Species	Tissue	Relative specific activity (microsomes/cytosol)	
		trans-β-Ethylstyrene oxide	*cis*-Stilbene oxide
Herbivore			
Northern corn rootworm[a]	Midgut	9.5	9.4

and this greatly limits efforts to understand the toxicological role of the enzyme. The best inhibitors of HEOM and styrene oxide hydrolases in *S. eridania*, *Calliphora erythrocepala*, *Tenebrio molitor*, and *Tribolium castaneum* include 1,1,1-trichloro-2,3-epoxypropane (**XI,** TCEP), phenolic 2,3-epoxypropyl ethers, and some synergists of PSMO (Brooks, 1973, 1977; Slade et al., 1975; Cohen, 1981), and, in addition, sodium picrylsulfonate in *S. eridania* (Mullin and Wilkinson, 1980b). By contrast, JH hydrolase is more sensitive to hormone analogs than to TCEP (Hammock et al., 1974; Slade and Wilkinson, 1973; Yu and Terriere, 1978b). Differential inhibition of *trans*- and *cis*-epoxide hydrolases by TCEP and the equally or more potent chalcone oxides (**XII**) has also provided evidence of multiple isozymes in *Tetranychus urticae* (Mullin et al., 1984), *Delia antiqua*, *Diabrotica barberi*, and *D. virgifera* (Siegfried and Mullin, unpublished data). The chalcone oxides (Mullin and Hammock, 1982) and other flavonoid epoxides such as 6′, 7′-epoxyrotenone (**XIII**; Cova et al., 1986) are strongly inhibitory to mammalian epoxide hydrolases, and in the former case inhibit particularly the *trans*-selective enzymes.

Species Distribution. Epoxide hydrolase has been found in almost 70 insect species (Table 2), and many interspecific variations are apparent. For example, house flies and blow flies (*Calliphora erythrocephala*) readily hydrate the cyclodiene HEOM, but bloodsucking diptera such as the tsetse fly (*Glossina austeni*) and stable fly (*Stomoxys calcitrans*) are deficient in this activity (Brooks, 1977). Most of the early work concentrated on the epoxide hydrolysis of insecticidal chlorinated cyclodienes (Brooks, 1977) and the sesquiterpenoid JHs and their synthetic analogs (Hammock and Quistad, 1976; 1981; Hammock, 1985), and has been exhaustively reviewed. Much less is known about the role of epoxide hydrolase in the metabolism of phytochemical epoxides. Use of appropriate model substrates such as alkylstyrene and stilbene oxides (**VIII, IX, X**) for more complex epoxides in plants has provided new insight into insect–plant relationships. These radiolabeled substrates mimic epoxide metabolites formed in mammals (cf. Scheline, 1978) from phenylpropenoids such as isoeugenol (Mullin, 1985), but they lack phenolic, methoxy, and other functional groups that would result in competing and subsequent reactions that do not allow measurement of specific rates for one enzyme activity. Exceptional levels of epoxide hydrolase acting on these substrates have been found in generalist insect herbivores (Mullin and Wilkinson, 1980a; Mullin and Croft, 1984).

PLANT EPOXIDES VIA THE ALKENE TO DIOL PATHWAY

Plant Epoxides as Allelochemicals. There is now much support to the concept that epoxides contribute greatly to the allelochemical barrier for a prospective arthropod herbivore. Since the characterization of the coumarin oxypeucedanin (**XIV**) in 1933 as the first recognized epoxide in plants, improved

methods for isolation and identification have led to discovery of hundreds of epoxides in higher plants (Cross, 1960; Dean, 1963; Mullin, 1985). The occurrence of an epoxide substrate for hydration in eukaryotic organisms is often predicted based on presence of the more stable vicinal diol and its respective unsaturated or aromatic hydrocarbon. Plant-derived epoxides such as the allatotoxin precocene 3,4-epoxide (**XV**) (Pratt et al., 1980; Soderlund et al., 1980) and various arene oxides (Brooks, 1979) are so reactive that spontaneous hydrolysis to inactive diols occurs without the intermediacy of epoxide hydrolase.

Surprisingly, alkaloid epoxides such as some pyrrolizidines are sufficiently stable to survive the acid treatments routinely used by alkaloid chemists. The high concentration of acid-stable jacobine with its respective olefin and diol in *Senecio jacobaea* indicates that plants use an enzymatic alkene-to-diol pathway to biosynthesize these alkaloids (Figure 2). Tiger moths that specialize on *S. jacobaea* are known to preferentially sequester the olefin at the expense of the epoxide and diol (Rothschild et al., 1979). The same alkaloids are potent inducers of mammalian epoxide hydrolase (Miranda et al., 1980).

Numerous insecticidal and antifeedant epoxides have been found in plants and may be substrates for the appropriate epoxide hydrolases. Among the plant terpenoids, many insect feeding deterrents including the highly potent azadirachtin (**XVI**) are epoxides (Burnett et al., 1974; Norris 1986; van Beek and de Groot, 1986; Yamasaki and Klocke, 1987), and hydration of the epoxide group can lead to loss of deterrent activity (Kubo and Matsumoto, 1985). Other epoxyterpenoids such as the anticholinesterase monoterpene, pulegone-1,2-epoxide (**XVII**), from *Lippia steochadifolia* (Grundy and Still, 1985), and the sesquiterpene picrotoxinin (**XVIII**) from *Anamirta cocculus* (Miller et al., 1979) are directly insecticidal. Unsaturated monoterpenes of wide occurrence in plants, including limonene (Brattsen, 1983) and α-pinene (White et al., 1979), are readily converted in mammals to *trans*-diols via epoxides; presumably the diols formed from the highly neurotoxic pyrethrins (**XIX**) of *Chrysanthemum ciner-*

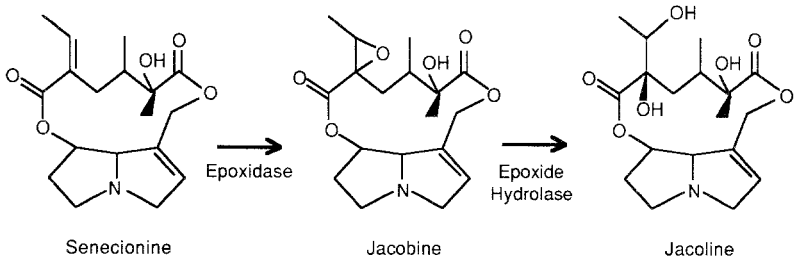

FIG. 2. Possible alkene-to-diol pathway for biosynthesis of pyrrolizidine alkaloids in *Senecio*.

ariaefolium are the result of epoxidation in the alcohol side chain followed by hydrolysis (Casida et al., 1971). Interestingly, epoxidation of synthetic chrysanthemates in the acid side chain results in neuroactive and insecticidal metabolites (Ruzo et al., 1984).

Similarly, epoxy fatty acids make up to 60% of the monomers in cuticular layers of plants and are copolymerized with polyol products of the epoxidase–epoxide hydrolase pathway to give the protective waxy surfaces (Croteau and Kolattukudy, 1974; Holloway and Deas, 1973; Holloway et al., 1981; Kolattukudy, 1985). Insect herbivores may use a *trans*-selective epoxide hydrolase to metabolize these epoxides, as is the case in mammals (Gill and Hammock, 1979).

If increased impact on a herbivore occurs via the more labile epoxide of an unsaturated plant allelochemical, it may be critical that epoxidation in the exposed herbivore occurs at or near the target site of action for the allelochemical. This should maximize the adaptive benefit of synthesizing the respective alkene in the protected plant since epoxide-to-diol detoxification in other tissues of the plant (Banthorpe and Osborne, 1984) or herbivore will reduce efficacy.

Plant aromatics are metabolized in herbivorous insects via the alkene-to-diol pathway. The allatotoxic chromenes from *Ageratum houstonianum*, precocene I and the more active precocene II, undergo bioactivation to cytotoxic 3,4-epoxides in the corpora allata of susceptible insects, such as the large milkweed bug, and thereby impair juvenile hormone biosynthesis (Bowers and Martinez-Pardo, 1977; Pratt et al., 1980; Feyereisen et al., 1981). These epoxides are reactive alkylators of macromolecules. The inactive diol metabolites formed in the corpora allata or peripheral tissues of the insect are largely formed by spontaneous hydrolysis with water (Soderlund et al., 1980) and not by epoxide hydrolase. The insecticidal isoflavonoid, rotenone, is readily detoxified in cockroaches and house flies to a dihydrodiol metabolite (Fukami et al., 1967, 1969) presumably through an epoxyisopropyl intermediate (**XIII**).

Alkene-to-Diol Pathway in Hormone Regulation. Herbivorous insects require epoxidases to synthesize both molting hormones from dietary phytosterols (Fujimoto et al., 1985) and juvenile hormones from the appropriate precursors (Feyereisen and Farnsworth, 1987, and references therein). Some evidence in the former (Rees, 1985) and much for the latter (Hammock, 1985) implicates epoxide hydrolase in regulation of titers of these epoxides. Thus, midgut microsomes of *Spodoptera littoralis* hydrolyze fucosterol-24,28-epoxide to stigmast-5-en-3β,24,28-triol which interrupts the dealkylation sequence and cannot satisfy the sterol requirement of the insect (Figure 3).

ROLE IN HERBIVORY

Evaluating the adaptive role of an enzyme in herbivore toxicology requires its dissimilar expression among species, action on potentially toxic substrates,

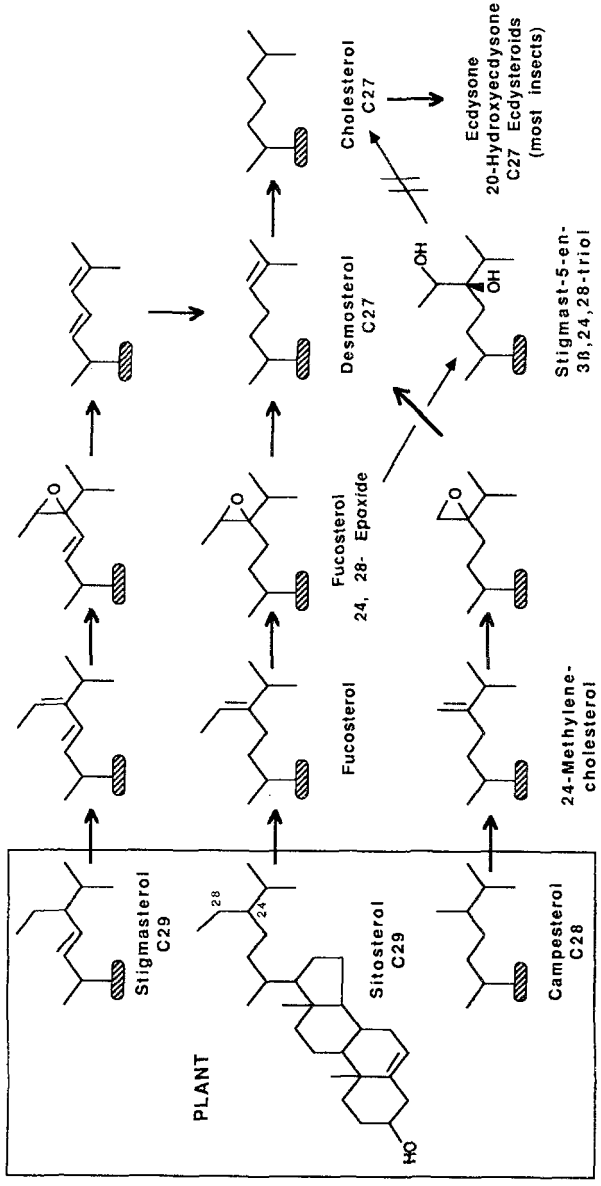

FIG. 3. General scheme for phytosterol dealkylation in herbivorous insects.

and ease of measurement under conditions that do not markedly change from species to species. Epoxide hydrolase shares with PSMO and glutathione transferase a wide and varying distribution among insect species and the ability to detoxify phytochemicals. Moreover, rapid and sensitive assays that easily allow measurements in microarthropods are available for epoxide hydrolase (Wixtrom and Hammock, 1985). Based on energetics, epoxide hydrolase should be less costly to maintain in an organism than PSMO or glutathione transferase since its catalytic mechanism is a simple hydrolysis requiring no coenzymes. By contrast, PSMO is the result of a multienzyme–hemoprotein complex that consumes NADPH and oxygen, while glutathione transferase requires a tripeptide as a cosubstrate. Consequently, epoxide hydrolase measurements should facilitate the study of arthropod–plant coadaptations.

Age–Activity Relationships. A clue to the importance of epoxide hydrolase in metabolism of dietary chemicals comes from age–activity relationships. In the southern armyworm, there is a direct association of high epoxide hydrolase activity with periods of high consumption of plant-based diets (Figure 4). Midgut 1,2-epoxyoctane hydrolase increased sevenfold in total activity during the first 60 hr of the late larval instar before undergoing a dramatic decrease in activity after cessation of feeding and preparation for pupation occurs (Mullin and Wilkinson, 1980a). A similar profile has been noted in this (Slade et al., 1976) and other lepidopteran species (Wing et al., 1981) for HEOM and a juvenile hormone analog. The single peak of JH epoxide hydrolase in the last

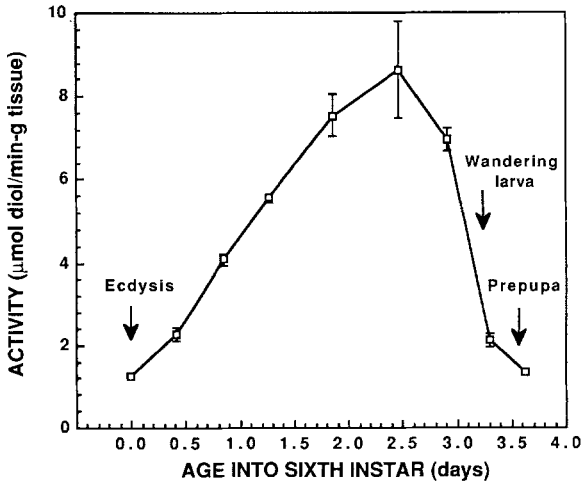

FIG. 4. Age-dependent changes in 1,2-epoxyoctane hydrolase in midgut homogenates from the sixth larval instar of the southern armyworm. Standard error bars for activities shown.

larval instar of Lepidoptera is not as finely synchronized with the biphasic needs for JH degradation as that of JH-specific esterase, which has two distinct peaks of activity. Moreover, epoxide hydrolase activity for JH is an order of magnitude less than the esterase activity (Hammock, 1985), and it is quite likely that the JH epoxide hydrolase is a nonspecific enzyme that can metabolize this and similar sesquiterpenoid substrates that are *trans*- and higher substituted epoxides.

More epoxide hydrolase was found in larvae of both house flies (Yu and Terriere, 1978b) and a braconid ectoparasitoid *Oncophanes americanus* (Croft and Mullin, 1984) than the adults. Larvae process more food than adults and expectedly would encounter more dietary epoxides. However, in Coleoptera very high levels of epoxide hydrolase occur in herbivorous adults (Cohen, 1981), particularly those that are generalists (Mullin and Croft, 1984).

Inducibility. Induction studies also support the contention that epoxide hydrolase is involved in arthropod herbivory. Microsomal epoxide hydrolase activity in southern armyworm midguts was enhanced nearly twofold by feeding larvae for one day on 0.1% pentamethylbenzene in an artificial diet (Mullin and Wilkinson, 1980a). Phytochemicals such as indole 3-carbinol and peppermint oil also induce the enzyme (Table 3). Up to a 3.4-fold increase in *trans*- and *cis*-epoxide hydrolase activities ensues in two-spotted spider mites when fed various host plants (e.g., cotton, lettuce) as compared to snapbean (Mullin and Croft, 1983), although host-related inductive effects were not seen in the fall armyworm with styrene oxide as substrate (Yu and Hsu, 1985). Classical PSMO inducers including phenobarbital in both house fly (Yu and Terriere, 1978b) and *Tribolium castaneum* (Cohen, 1982), and polychlorinated biphenyls and β-naphthoflavone in *Drosophila* (Hallstrom and Grafstrom, 1981) all significantly induce insect epoxide hydrolases. While epoxide hydrolase is, overall, considerably less inducible than PSMO (Brattsten, 1979; Yu, 1986), this may be related to the higher cost of maintaining the multienzyme–coenzyme complex

TABLE 3. INDUCTION OF MICROSOMAL EPOXIDE HYDROLASE IN ARMYWORM MIDGUT

Compound	Percent in diet (wet wt.)	Percent of control activity[a]
Pentamethylbenzene[b]	0.1	196
Phenobarbital[c]	0.2	150
Indole 3-carbinol[c]	0.2	142
Peppermint oil[c]	0.2	134

[a] Styrene oxide as substrate.

[c] Fall armyworm (S.J. Yu and E.L. Hsu, 1985).

of PSMO in an insect. Thus, the less costly epoxide hydrolase could be kept at sufficient levels to detoxify plant-derived epoxides without a highly primed induction system.

Relationships with Feeding Strategy. Comparison of epoxide hydrolase between herbivorous and nonherbivorous species of arthropods provides additional evidence of its adaptive role. Hydrolase activity for sytrene oxide is higher in chewing herbivores such as lepidopteran larvae than in a predaceous spined soldier bug or insect species that feed on limited portions of the plant (Table 4). However, this substrate efficiently measures only the microsomal activity and may miss other isozymes more selective for plant-derived epoxides.

Use of *trans*-β-ethylstyrene oxide and *cis*-stilbene oxide as substrates in a screen on epoxide hydrolase in 36 arthropod species (cf. Table 2) has led to discovery of more robust differences between ecological groups. Chewing herbivores, on the average, have 21 times more *trans*-epoxide hydrolase and 10 times the ratio of *trans*- to *cis*-epoxide hydrolase than arthropod predators and parasitoids (Mullin et al., 1982; Mullin and Croft, 1984, 1985; Croft and Mullin, 1984; Mullin, 1985). Moreover, phloem-feeders have, on average, 80 times lower *trans*-epoxide hydrolase than herbivores that consume entire plant parts (Mullin, 1986). Further comparisons with chewing and sucking herbivores were made using species from the same insect family. Among 10 species of leaf-feeding beetles (Chrysomelidae), ratios of *trans*- to *cis*-epoxide hydrolase consistently increased ($r > 0.92$) with either number of plant families or plant genera consumed by the species (Mullin and Croft, 1984; Mullin, 1985). In the Aphididae, the highly polyphagous *Macrosiphum euphorbiae* and *Myzus per-*

TABLE 4. MICROSOMAL ACTIVITIES OF STYRENE EPOXIDE HYDROLASE IN SOME INSECTS

Species	Tissue	Styrene epoxide hydrolase (nmol/min/mg protein)	Feeding strategy
Southern armyworm[a]	Midgut	79	Generalist
Fall armyworm[b]	Midgut	26	Generalist
Antheraea pernyi[a]	Midgut	26	Specialist
Spined soldier bug[b]	Midgut	13	Predator
Honeybee[a]	Midgut	8.6	Nectar, pollen
Laboratory fruit fly[c]	Whole	4.3	Saprophagous
Red flour beetle[d]	Whole	2.7	Seed

[d] E. Cohen (1981).

sicae had 5–14 times higher epoxide hydrolase activity than the oleander and milkweed specialist, *Aphis nerii*. These results strongly implicate the *trans*-epoxide hydrolase in the metabolism of plant-derived epoxides and support the view that phloem-feeders such as aphids have less epoxide hydrolase than chewing herbivores, since concentrations of secondary plant epoxides in phloem should be less than those of external plant tissues (Mullin, 1986). Coincidently, the plant allelochemicals that may undergo epoxidation, such as unusual fatty acids, cinnamic acids, chalcones, phenylpropenoids, and terpenoids, tend to have a *trans* geometry or are trisubstituted olefins, whereas constitutive olefins common to both animal and plant tissues, such as fatty acids, tend to have a *cis* configuration (Mullin, 1985). Hence, epoxides resulting from epoxidation of available plant allelochemicals in either the plant or its consumer could explain the presence of a high *trans*-selective epoxide hydrolase in herbivorous species.

Epoxide hydrolase may occasionally be counteradaptive to a herbivore. For example, rat liver microsomes greatly facilitated the release of cyanide from a cyanogenic glycoside, sarmentosin epoxide (**XX**), probably by hydration to an unstable cyanohydrin (Nahrstedt et al., 1982). Other diols such as the diterpenoid antifeedant ajugarin III (van Beek and de Groot, 1986) and the synthetic aldrin *trans*-diol (Brooks, 1977; Singh and Singh, 1984) are sufficiently lipophilic to exert near or equal biological activity as the epoxide. However, the net result of increasing water solubility and excretability of an alkene makes the diol conversion a distinct detoxification pathway.

The maintenance of a tightly coupled epoxidase–epoxide hydrolase complex will generally have beneficial consequences for an arthropod herbivore since harmful epoxides will then be immediately dispatched by hydration. It is fortunate that much of cytochrome P-450 and epoxide hydrolase resides together on the endoplasmic reticulum (Brattsen and Ahmad, 1986). Usually the epoxidase is rate-limiting and produces epoxides much slower than the subsequent hydration to diols. Some epoxides such as dieldrin are refractory to hydration and serve as useful products for epoxidase measurements. Hence, the aldrin-to-aldrin diol pathway is an unusual case where epoxide hydration is rate-limiting. Dieldrin and other cyclodiene epoxides are generally recognized as the insecticidal agents in this pathway (Schroeder et al., 1977; Miyazaki et al., 1979; Singh and Singh, 1984), thus a high epoxidase-to-epoxide hydrolase ratio may be disadvantageous to a herbivore exposed to aldrin. Work with corn rootworms, the two-spotted spider mite, and aphids supports this hypothesis in that increased aldrin epoxidase to *cis*-epoxide hydrolase activity correlates with increased susceptibility to aldrin (Mullin, 1986; Mullin et al., 1984) with the potato aphid being less susceptible than the polyphagous northern corn rootworm. Nevertheless, the higher epoxidase and epoxide hydrolase activities of chewing herbivores than phloem-sucking aphids should benefit the former group

since their encounter with olefinic and epoxide phytochemicals is expectedly greater.

ROLE IN CHEMICAL CONTROL OF HERBIVOROUS PESTS

The bulk of insecticides used today lack an epoxide or an unsaturated grouping that will be readily epoxidized, and these groupings are largely removed from promising new insecticides so that improved biostability will be achieved. Chlorinated hydrocarbons where epoxide metabolites are known, including the cyclodienes (Brooks, 1979), DDT (Gold and Brunk, 1982), and lindane (Fitzloff and Pan, 1984), have received increased worldwide disfavor, and no longer are major use insecticides. Aromatic insecticides that undergo ring oxidation to form diols such as the carbamate carbaryl (Kuhr and Dorough, 1976) may do so by spontaneous hydrolysis of the intermediate epoxide, and not necessarily through an epoxide hydrolase. Thus epoxide hydrolase, by design, has a modest role in detoxification of presently used synthetic pesticides. Strategies for overcoming the resistances by arthropods to most available synthetics should not be based on this enzyme. Levels of epoxide hydrolase similar to those of susceptible strains were found in organophosphate-, carbamate-, DDT-, and methoprene-resistant strains of house fly (Hammock et al., 1977; Yu and Terriere, 1978b; Ottea et al., 1987b), organophosphate-resistant two-spotted spider mite (Mullin et al., 1982), carbaryl-resistant fall armyworm (McCord and Yu, 1987), and DDT- and organophosphate-resistant strains of *Drosophila* (Baars et al., 1979; Hallstrom and Grafstrom, 1981). For the latter case, styrene oxide was used as the substrate, whereas in other strains of *Drosophila* with *trans*- and *cis*-stilbene oxides more heterogeneity in epoxide hydrolase was observed (Ottea et al., 1987a). Similar modest increases in epoxide hydrolase were seen in a pyrethroid-, DDT-, and organophosphate-resistant predatory mite, *Amblyseius fallacis* (Mullin et al., 1982), although resistance to juvenoids in the red flour beetle has been associated with a 4.4-fold increase in styrene epoxide hydrolase (Cohen, 1981). Nevertheless, a new insecticide that is detoxified via the epoxide hydrolase should have little cross-resistance in pests that maintain metabolic resistances to other conventional pesticides. Indeed, house flies with multiple resistance to commercial alkoxide juvenoids, such as methoprene, remain susceptible to an epoxide-containing juvenoid (Sparks and Hammock, 1983).

That elevated epoxide hydrolase has not been heavily selected by commercial insecticides, yet is important to a herbivorous pest for detoxification of dietary epoxides, suggests this enzyme as a useful target for future pest control agents. Chalcone oxides and other inhibitors of epoxide hydrolase should synergize the activities of many plant defensive chemicals against herbivorous pests

and have little impact on entomophagous species, since the latter encounter and presumably need to detoxify fewer plants epoxides (Mullin and Croft, 1985).

Chalcones are regarded as universal flavonoid precursors in plants and might serve as endogenous synergists of other plant defenses if oxidized to inhibitors of herbivore epoxide hydrolase. Alternatively, they can direct the synthesis of in vivo inhibitors of epoxide hydrolase that might control populations of herbivorous pests. Additional use of these inhibitors may come through disruption of pheromone perception and deactivation in increasing numbers of herbivore species where major components are epoxides (Ahmad et al., 1986; Bell and Meinwald, 1986; Prestwich and Blomquist, 1987). These studies should give insight into how herbivores successfully coadapt with an epoxide-laden environment.

BULLFINCHES AND ASH TREES
Assessing the Role of Plant Chemicals in Controlling Damage by Herbivores

PETER W. GREIG-SMITH

ADAS Tolworth Laboratory
Ministry of Agriculture, Fisheries and Food
Hook Rise South, Tolworth, Surbiton, Surrey, KT6 7NF U.K.

(Received September 15, 1987; accepted February 15, 1988)

Abstract—Wild bullfinches (*Pyrrhula pyrrhula*) feed heavily on the seeds of ash trees (*Fraxinus excelsior*). Field and laboratory studies show that individual trees with high levels of fat and low levels of phenolic chemicals in their seeds are especially liable to predation. This paper discusses (1) the complexity of effects that need to be examined in order to identify the role of secondary chemicals in determining herbivore preferences, and (2) the consequences of seed predation for the dispersal of seeds. Because of bullfinches' habits, and the many factors influencing seed dispersal and germination, it is not clear whether the birds' activities are necessarily damaging. This study emphasises the value of understanding the whole ecology of both plants and herbivores in order to interpret their interactions.

Key Words—Chemical defense, plant–bird interaction, herbivory, seed predation, bullfinch, *Pyrrhula pyrrhula*, European ash, *Fraxinus excelsior*, secondary compounds.

INTRODUCTION

In the study of plants and animals that feed on them, the notion that secondary chemicals confer protection against herbivore damage has become widely accepted. It has been invoked to explain herbivores' preferences at many levels, from antelopes that select appropriate types of herbage from mixed-species swards (e.g., Cooper and Owen-Smith, 1985), to monkeys that choose particular trees of a plant species (e.g., McKey et al., 1981), and birds that select within the fruit crop of an individual plant (e.g., Herrera, 1982).

For vertebrate herbivores, evidence has been drawn chiefly from one of

0098-0331/88/1000-1889$06.00/0

two approaches: either field data on feeding preferences and behavior are compared to measurements of chemicals in representative samples of plants, or plant material is extracted and applied to food experimentally to test its effect on palatability. Those studies following both avenues (e.g., Reichardt et al., 1984; Tahvanainen et al., 1985) provide the most compelling evidence for an influence of chemicals such as tannins, alkaloids, and terpenes on herbivores' food selection.

However, deterrence by the presence of a particular chemical is not enough to demonstrate a significant effect on the reproductive success of the plant. Fitness is governed by a complex array of interacting factors that require broader studies than most plant–herbivore investigations. In this paper it is argued that it is necessary to consider the whole ecology of both plant and herbivore in order to reach reliable conclusions about the role of particular plant chemical components.

There are three principal issues. First, one must identify chemical influences on behavior, while recognizing that statistical or experimental control of confounding variables obscures the context in which feeding choices actually occur. Second, it is important to recognize that chemicals may be proximate cues on which acceptance or rejection of food is based, or ultimate reasons behind a preference, or both. Third, the consequences to the plant of damage by a herbivore may not be simple or obvious, especially in long-lived species.

As an example of the complexity in these interactions, I shall discuss the effects of feeding by bullfinches (*Pyrrhula pyrrhula*) on the seeds of the European ash tree (*Fraxinus excelsior*). These studies form part of a broad investigation by MAFF into the feeding ecology of bullfinches in relation to their status as pests of fruit orchards in the south of England (e.g., Greig-Smith and Wilson, 1984; Wilson, 1984; Greig-Smith, 1985a,b). Through field, aviary, and laboratory investigations, we have explored the role of phenolic chemicals as deterrents to bullfinches' feeding. The purpose of the present paper is to explore connections between the presence of phenolics and the preferences shown by bullfinches for or against the seeds of individual ash trees. Data selected serve to demonstrate the kind that is needed to justify conclusions about the causes, and consequences for the trees, of bullfinches' behavior.

FRUIT PRODUCTION AND PREDATION

Ash trees produce crops of fruits that vary enormously in number, both from year to year and from tree to tree. Fruits gradually ripen between August and November (Figure 1) to leave a mass of dark brown, dry fruits in dense clusters over the whole tree canopy. A large flattened wing aids wind dispersal and, during winter, fruits are progressively lost from the tree by the actions of wind and seed predators. The rate of removal varies greatly, however; in some years trees may have no fruits left by December, while at other times substantial

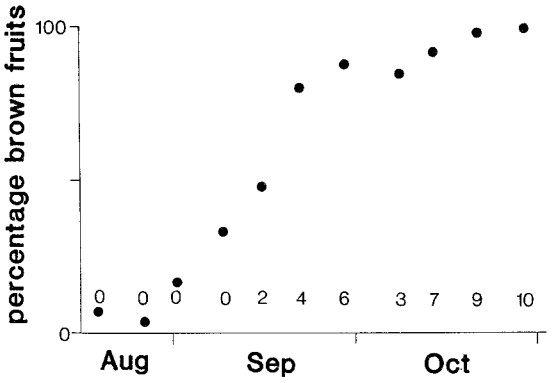

FIG. 1. Timing of ripening of ash seed, shown by average percentages of fruits that were brown on 10 trees in 1982. Figures from 0 to 10 indicate the number of trees with 100% of brown fruits.

numbers may remain until the following autumn, when they are borne alongside the next year's crop (Newton, 1964; personal observation).

Physiological studies have shown that the seeds require two winters before their dormancy is broken, so that fruits that fall shortly after ripening may lie on the ground for 18 months before germinating (Villiers and Wareing, 1964). During the six months after they have ripened, ash seeds on the tree remain stable in chemical composition (Figure 2). The trees therefore present a non-renewing food resource of fixed quality to winter herbivores.

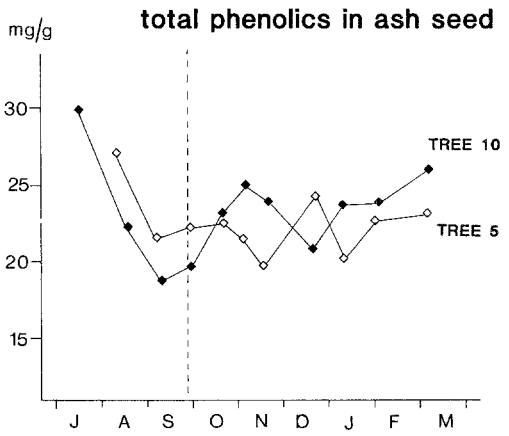

FIG. 2. Examples of stability of phenolic components in ash seed after ripening. The dotted line indicates the time at which 100% of fruits were brown. Data for six trees produced no consistent trends in the concentrations of phenolics (Folin-Denis assay), fat, total soluble protein, or total glucose, between October and March.

Ash seeds are large (20–60 mg), and rich in fat and protein (Greig-Smith and Wilson, 1985). This, and their conspicuous availability over the course of winter, makes them an attractive food source for bullfinches. In some years, ash seed is the major item in their diet, occurring in the gut contents of nearly all birds examined (Newton, 1967; Summers, 1981; Greig-Smith, 1985b). It is likely that almost the entire fruit crop of certain trees is removed by bullfinches. The availability of natural foods such as ash seed is apparently the most important factor determining whether bullfinches cause damage in fruit-tree orchards during any particular winter (see Newton, 1968). Fruits that fall to the ground may also be taken by predators, for the seeds are attractive to small mammals such as wood mice (*Apodemus sylvaticus*), which can account for the loss of much of trees' seed production in certain years (e.g., Gardner, 1977).

CAUSES OF BULLFINCH PREFERENCES AMONG ASH TREES

In all field studies, observers have noted that bullfinches have distinct preferences for certain ash trees and ignore others (Newton, 1967; Matthews, 1983; Greig-Smith and Wilson, 1985). This is not simply related to the size of the trees, their locations, or the amounts of fruits they bear, but might perhaps have something to do with the fruits themselves. To investigate these preferences, we placed nets underneath the tree canopy to collect falling fruits and seeds (Greig-Smith and Wilson, 1985). The total numbers of damaged and intact fruits can be used to assess the impact of predation on the tree's reproduction, while the ratio of these numbers provides an index of preference. In a survey of 22 trees within a single study area, 0–95% of fallen fruit was damaged by bullfinches, demonstrating the wide extremes of the birds' preferences. Seed and fruit collection in nets gives a measure of many birds' feeding combined activity. Direct observation and radio tracking was used to trace the behavior of individual birds and has confirmed the broad range of acceptability of different trees (Greig-Smith and Wilson, 1985; Greig-Smith, 1985b).

To account for the birds' behavior, I searched for correlations between preferences and features of fruit size and composition. Size varies more between trees than within trees (Figure 3) and is of importance for two reasons. First, it affects the quantity of food a bullfinch gains by eating a given number of seeds, and second, along with shape, it may dictate the ease with which birds can remove the pericarp to obtain the seed (Greig-Smith and Crocker, 1986). The handling time for a seed must be weighed against the food content (Krebs and McCleery, 1984), and we have shown that bullfinches are liable to drop fruits—deliberately or accidentally—during efforts to extract the seeds (Greig-Smith and Wilson, 1985). At the start of winter, the birds' efficiency is so poor that they successfully eat seeds from only half the fruits they pluck and handle.

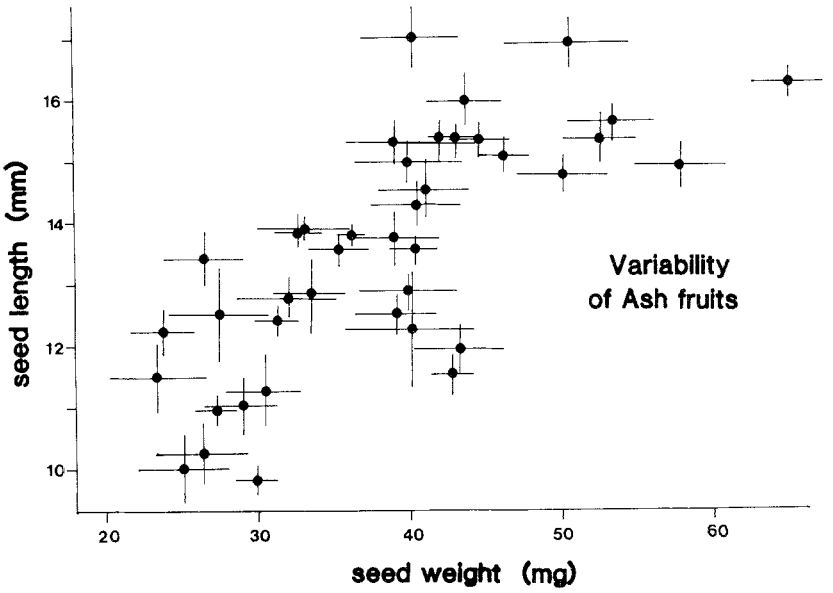

FIG. 3. Scale of variation in size of ash seed, within and among trees. Data are means ± standard errors for samples of 25 seeds from 50 trees, collected on the same day in November.

The chemical composition of ash seed also varies greatly (Table I), although no single feature stands out as being obviously correlated closely with the birds' preferences. In a previous analysis, Greig-Smith and Wilson (1985) found that if the confounding variations in other features were held constant in a partial correlation analysis, statistically significant relationships emerged with fat content ($r_p = 0.45$, $N = 17$) and total phenolic content ($r_p = -0.51$), but not with protein content ($r_p = 0.16$). This implies that preferences are governed by a balance between beneficial nutritional components and aversive secondary chemicals.

The fact that this conclusion is evident only when other features are held equal is a sign that intercorrelation of fruit features may override these effects in the field. Thus, the data matrix from which Table 1 is drawn reveals that these seed components do not vary independently; for example, fruit width (a measure of the difficulty with which bullfinches can extract seeds) is positively correlated with fruit weight ($r = 0.52$, $N = 20$), whereas fat concentration of the seed tissue is inversely correlated with phenolic concentration ($r = -0.44$). Intercorrelations of this kind may offer clues to the evolutionary pressures affecting plant populations, but they present problems for researchers trying to unravel causes and effects in herbivore behavior.

TABLE 1. LEVELS OF SELECTED CHEMICAL CONSTITUENTS IN SEEDS OF 20 ASH TREES AT SINGLE SITE[a]

Tree	Ranked bullfinch preference	Average seed weight (mg)	Concentration (mg/g)			
			Total phenolics	Fat	Total soluble protein	Total glucose
58	1	35.2	15.6	157.8	114.2	7.2
26	2	44.2	21.2	109.0	44.4	6.7
12	3	32.8	30.8	151.0	84.5	11.4
54	4	25.0	21.1	132.5	74.9	11.4

32	18	53.7	24.5	149.4	86.7	10.9
86	18	12.4	13.5	128.8	62.1	7.4

[a] Variability within samples (standard error as % of mean) was approx 5–10%.

A further difficulty lies in knowing which parameters to measure, since the chemical components of a seed may be expressed in different ways. Figure 4 compares the variation in fat and phenolic composition of ash seed in terms of concentration (milligrams per gram of tissue) and content (milligrams per seed). The resulting histograms provide only slightly different distributions, but the ordering of trees depends heavily on which index is used. Correlations between the two rankings were only 0.46 for fat and 0.51 for phenolics. It is not possible to identify one measure as generally "better" or more appropriate than the other, for it depends on how the chemicals affect herbivores. Some components have characteristic sensory effects (e.g., the astringency of tannins; Joslyn and Goldstein, 1964), whereas others will only have later effects during digestion. It is important to distinguish the role of chemicals as cues in the formation of learned aversions or attractions (e.g., Arnold et al., 1980; Mason and Reidin-

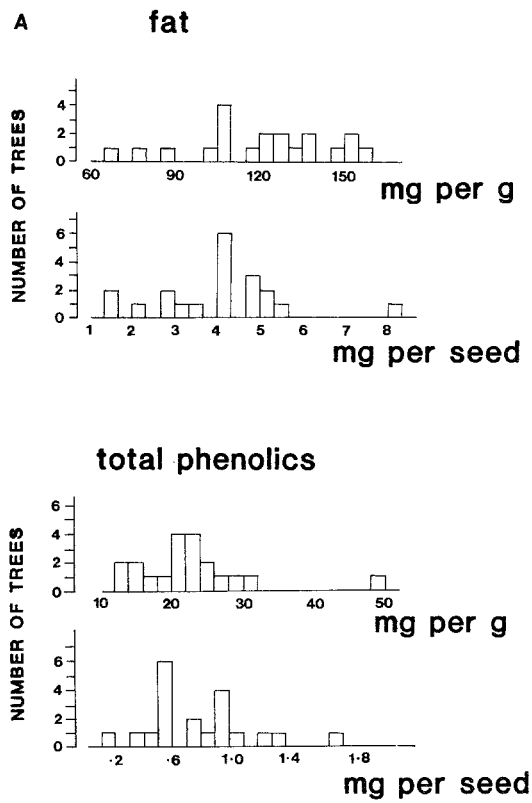

FIG. 4. (A) Variations in the fat content and phenolic content of seeds from 20 ash trees, measured as milligram per gram of tissue, and as milligram per seed. Correlations refer to the correspondence between rankings of individual trees obtained by the two methods. (B) Correlations between bullfinch feeding preferences for particular trees and their fat content measured by the two indices in (A). Crosses indicate trees in which bullfinches never fed and are excluded from the calculation of correlation coefficients.

ger, 1983; Stewart et al., 1983) from metabolic properties related to food processing mechanisms. In the case of fat (Figure 4), preference scores are more strongly correlated with concentration in mg per gram than with total seed content, although this need not imply an influence on sensory detection.

An example of the importance of feeding cues comes from examining the phenolic component of ash seed in more detail. One characteristic component is fraxin, a compound present in the seed chiefly in the form of its hydrolyzed derivative, fraxetin (Figure 5A). In contrast to the total phenolic complement, variation in this substance is positively correlated with bullfinch preferences

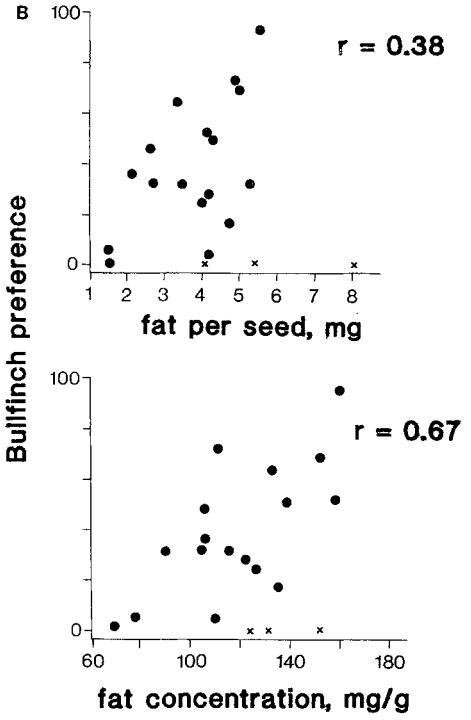

FIG. 4. Continued.

(Figure 5B), the likely reason being that it varies in parallel with fat and is therefore available to birds as a potential flavor cue indicating the presence of fat-rich seed. Confirmation that fraxin/fraxetin can be used as a positive food selection cue by bullfinches was obtained from laboratory feeding trials in which seeds were adulterated with fraxin, and birds' behavioral responses measured in detail (see Greig-Smith, 1985a, for methods). Of 10 bullfinches tested, four showed statistically significant evidence of detecting the presence of fraxin (either in comparison of successive trials with and without the chemical, or within trials between food dishes having treated or untreated food), and all four revealed an attraction towards the substance (ate more food in a standard interval or rejected fewer pieces of food during handling) (see Figure 5C).

CONSEQUENCES OF SEED LOSS FOR TREES' REPRODUCTION

For a species such as ash, producing a single annual crop of seed, it seems obvious that the tree's loss of reproductive potential should be proportional to the number of fruits removed by herbivores. Greig-Smith and Wilson (1985)

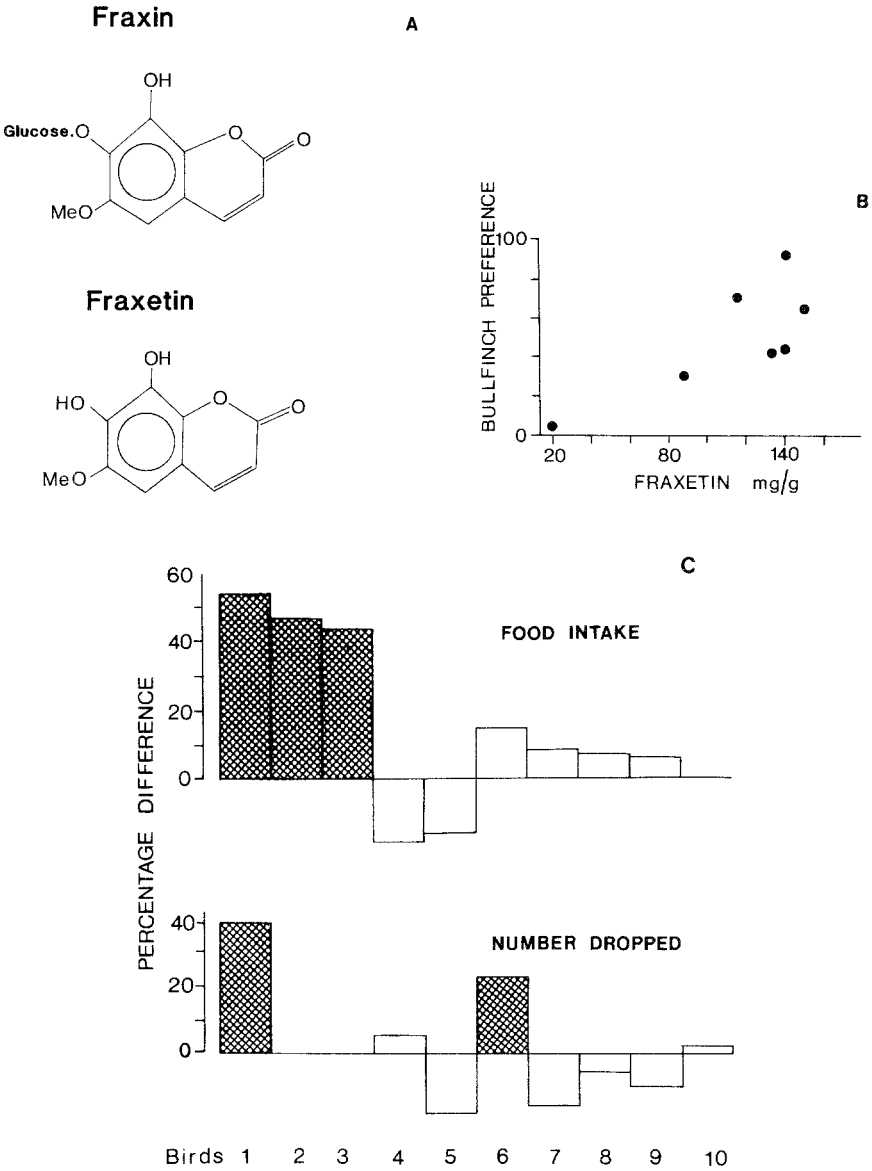

FIG. 5. (A) Formulas of fraxin and fraxetin, two components of ash seed. (B) Correlation between the fraxetin content of seeds and bullfinch feeding preferences among seven ash trees; $r = 0.82$, $P < 0.05$. (C) Results of a laboratory feeding trial in which 10 bullfinches were given choices between food adulterated with fraxin and untreated food, and their behavior was monitored on videotape. Columns indicate differences between behavior at the two types of food, those above the line representing attraction to fraxin. Shaded columns indicate statistically significant differences.

found that trees with higher levels of phenolics in their seeds retained fruits longer into the following year. This suggests an adaptive protection bestowed by the plant's secondary chemistry. However, the consequences of seed loss are not so straightforward.

There are several routes by which seeds can be transported from tree to ground and survive to eventually germinate (Figure 6); wind dispersal, accidental or deliberate dropping of intact fruits by feeding bullfinches, and escape from predation by small mammals. Fruits may also be attacked by insect larvae (Wardle, 1961). The fate of fruits is greatly affected by three aspects of the dispersal process: the number that fall, the distances to which they are carried, and the time at which they are removed from the tree. Together, these parameters influence the exposure of fruits to bird and small mammal predation and affect the competitive environment in which seedlings develop and grow (McCanny and Cavers, 1987). Without knowledge of local predator populations and behavior, and information on edaphic factors and seed density, it is not easy to predict whether fruits' prospects will be better near or far from the parent tree, after falling early or late in the winter.

The characteristics of individual trees may be important; for example, the distance to which falling fruits are carried depends on fruit size and shape (unpublished data; cf. Augspurger and Franson, 1987). However, the activities of bullfinches also play a role, expressed in four distinct ways. First and most obviously, their feeding removes or damages some of the seed crop, although predation cannot totally prevent dispersal, because substantial numbers of seeds are dropped intact. Second, the dispersal of fruits that are dropped is earlier than would occur by wind alone. These fruits are not a random sample of those available, since bullfinches feed selectively within trees on the basis of fruit size (Greig-Smith, 1987). Third, bullfinches feed in the canopy of ash trees

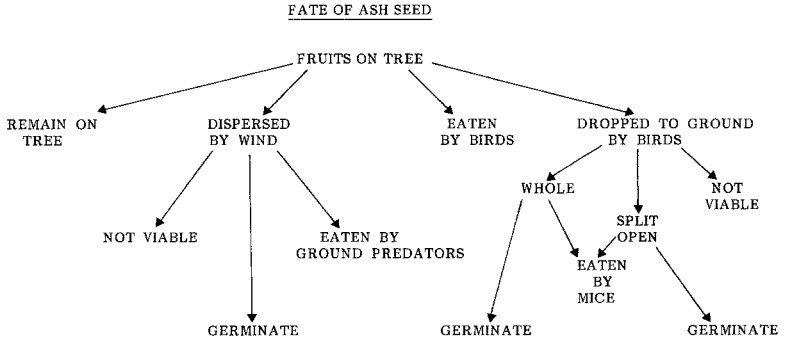

FIG. 6. Fate of ash fruits, indicating alternative routes by which fruits may reach the ground, survive, and germinate.

only when weather conditions are favorable, particularly at low wind speeds; dropped fruits therefore travel less far than fruits blown from the trees by wind (Figure 7A). Fourth, many fruits fall when partly split open, but with the seed undamaged. This is beneficial for seed development as rupture of the pericarp allows freer gas exchange, promoting embryonic enlargement (Villiers and Wareing, 1964) (see Figure 7B). As a result, split fruits dropping early may be more likely to germinate in their first winter than those that fall intact.

Clearly, bullfinches can modify the dispersal pattern in a variety of adverse and beneficial ways. However, our field studies do permit a preliminary explo-

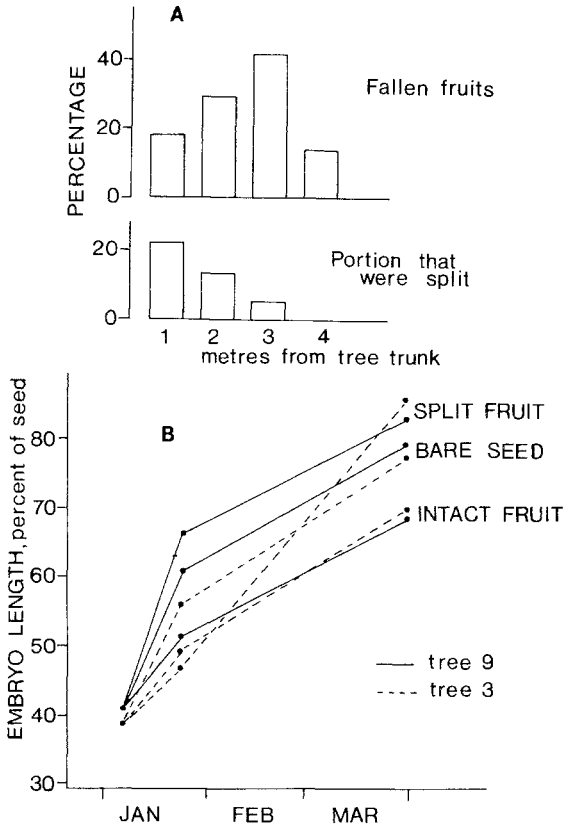

FIG. 7. (A) Example of the distribution of fruits fallen around an ash tree shown separately for intact fruits (largely wind-dispersed) and those split open and dropped by bullfinches. (B) Differences in embryonic elongation in seeds with an intact fruit coat, no fruit coat, or a fruit coat split open as by a feeding bullfinch. Data are taken from a laboratory germination experiment in which seeds and fruits were placed on moist filter paper for three months.

TABLE 2. FATE OF FRUITS REMOVED FROM CANOPY OF SIX ASH TREES IN SINGLE WOOD[a]

Tree	Bullfinch preference	Wind dispersed	Eaten	Dropped		Total onto ground
				Whole	Split	
26	1	0	417	204	75	279
54	2	531	321	54	39	624
49	3	672	546	105	129	906
63	4	51	54	0	0	51
57	5	363	117	63	84	510
48	6	579	27	3	3	585

[a] Figures represent numbers of fruits per m^2 below the center of the canopy, over the entire winter. Bullfinch preference was ranked on the basis of the proportion of fruits affected by the birds' feeding.

ration of how the birds' preferences among trees influence the fates of fruits. Table 2 estimates the numbers of fruits falling per square meter that had been wind-dispersed, dropped whole, or dropped split, and the number eaten by bullfinches, in six trees growing close together in a small wood. This shows that in tree 26, ranked as most preferred by bullfinches (i.e., where the largest proportion of fruits had been plucked by the birds), no fruits were wind-dispersed. Nevertheless, a substantial number reached the ground intact or with the pericarp split but probably still viable. Overall, there was certainly not a close correspondence between bullfinches' feeding activity and the amount of viable fallen seed accumulated by the end of the winter.

Seed chemistry and seed size can be incorporated into this approach. Table 3 lists correlations across a sample of 19 trees, between variations in the four

TABLE 3. CORRELATIONS OF SEED SIZE AND THREE CHEMICAL COMPONENTS OF SEEDS WITH LEVEL OF BULLFINCH ACTIVITY AT 19 ASH TREES AND WITH FALL OF VIABLE SEED OVER WINTER PERIOD

	Fruits attacked by bullfinches (%)	Total seed fall	Fall of whole seed
Seed weight	−0.16	−0.53	−0.32
Total phenolics	−0.12	−0.06	−0.04
Fat	+0.35	−0.25	−0.02
Fraxetin	+0.28	+0.10	+0.15

most relevant seed features and measures of bullfinch preference and seed survival. As discussed above, the birds' attentions were related most strongly to fat content and its correlated cue, fraxetin. In contrast, the eventual cumulative seed fall was related more strongly to different features, particularly the size of seeds. None of the correlation coefficients is large, indicating that many factors are involved in determining these patterns.

CONCLUSIONS

The theme of this essay has been that a complex interaction of many factors must be studied to understand how plant chemicals influence a vertebrate herbivore and what this means for the plant. For bullfinches feeding in ash trees, the habit of dropping whole fruits contributes greatly to the complexity. Even without this, however, plants may be able to avoid the apparently adverse consequences of seed predation by animals that do not contribute to dispersal. One of the most widespread means of escaping these effects, among plants whose growing parts are damaged, is compensation by increased growth. For example, removal of up to 90% of fruit-tree buds results in much less reduction in the yield of fruit, particularly if the damage is sustained for several years (Summers, 1982). A growing number of studies are also considering the existence of "induced" chemical defenses that appear after the onset of herbivore attacks, although the evidence is not conclusive (Fowler and Lawton, 1986) and the mechanisms involved are the subject of active debate (see Haukioja and Neuvonen, 1985).

The ecological issues discussed in this paper call for caution in interpreting facts that seem to suggest a simple protective role for plant secondary chemicals, in light of the wide range of confounding effects. This is not to deny the possible importance of chemical defenses; however, it will be valuable for future studies to broaden their scope to examine these issues in the context of the whole ecology of both plant and herbivore.

Acknowledgments—I am grateful to Dr. M.F. Wilson, with whom the bullfinch studies have been planned and carried out. Assistance with chemical assays was given by Miss C.A. Blunden; with field studies by C. MacKenzie; and with laboratory feeding trials by C.M. Rowney and Miss A. Burman.

CHEMICAL ECOLOGY AND THE SEARCH FOR MARINE ANTIFOULANTS
Studies of a Predator–Prey Symbiosis

DONALD J. GERHART, DANIEL RITTSCHOF, and SARA W. MAYO

Duke University Marine Laboratory
Pivers Island, Beaufort, North Carolina 28516

(Received September 15, 1987; accepted March 10, 1988)

Abstract—The gorgonian octocoral *Leptogorgia virgulata* (Phylum Coelenterata, Class Anthozoa) is rarely overgrown by fouling organisms and is avoided by most predators. Laboratory experiments suggest that secondary metabolites and calcium carbonate spicules interact synergistically to provide *L. virgulata* with an effective defense against predatory fish. In spite of these defenses, *L. virgulata* is consumed by the symbiotic, trophically specialized gastropod *Neosimnia uniplicata*, which closely mimics the appearance of the gorgonian. *Neosimnia uniplicata* is readily eaten by fish and appears not to acquire an effective antipredator defense from its gorgonian host. Extracts of *Leptogorgia virgulata* and *Neosimnia uniplicata* strongly inhibited the settlement of the barnacle *Balanus amphitrite*. Bioassay-directed purification of the more potent antifouling agents from *L. virgulata* led to the isolation of two previously described, diterpenoid hydrocarbons, known as pukalide and epoxypukalide. A third inhibitor of barnacle settlement, whose structure is presently unknown, was obtained from both *L. virgulata* and *N. uniplicata*. When assayed for ability to inhibit barnacle settlement, these three compounds possessed EC_{50} values ranging from 19 to 55 ng/ml. These secondary metabolites may prevent the overgrowth of *L. virgulata* by fouling organisms in nature. The allelochemicals of *L. virgulata*, *N. uniplicata*, and other marine organisms may provide nonpolluting alternatives to existing, commercial antifoulants based on derivatives of tri-*n*-butyltin.

Key Words—Chemical defense, biofouling, marine antifoulants, symbiosis, predator–prey interactions, gorgonians, gastropods, *Leptogorgia virgulata*, *Neosimnia uniplicata*.

INTRODUCTION

Marine chemical ecology encompasses a broad range of topics, including chemoreception and chemical signaling, chemical defenses against predation, allelopathic interactions between competitors, the biochemical control of larval settlement and metamorphosis, and marine symbioses (Bakus et al., 1986; Rittschof and Bonaventura, 1987). The basic knowledge obtained in such investigations has begun to provide new insight into problems of practical importance, such as the management of marine fouling (Colwell, 1983).

Fouling is one of the most important problems currently facing marine technology (Costlow and Tipper, 1984). Presently, marine fouling is controlled by the use of surface coatings that contain long-lived, broad-spectrum poisons such as tri-*n*-butyltin (TBT). Although effective, the active agents of these coatings have become serious pollutants in some estuaries. The use of TBT-based paints has been banned recently in France and Great Britain and is being closely scrutinized in other countries.

Fouling organisms usually do not colonize the surfaces of sessile marine invertebrates such as sponges (Phylum Porifera) and octocorals (Phylum Coelenterata: Class Anthozoa). Sponges and octocorals contain a wealth of secondary metabolites (Goad, 1978; Tursch et al., 1978; Faulkner, 1977, 1984; Fenical, 1982; Scheuer, 1985), which may inhibit fouling (Ciereszko, 1962; Burkholder, 1973; Cimino and DeStefano, 1978; Hadfield and Ciereszko, 1978). These compounds could provide alternatives to the metal-derived toxins currently used in most commercial antifoulant coatings.

One octocoral, the gorgonian *Leptogorgia virgulata* Lamarck, 1815), is abundant in the shallow waters near Beaufort, North Carolina. Gorgonians are colonial coelenterates that are comprised of a proteinaceous axial skeleton covered by a fleshy cenencyme that contains symbiotic zooxanthellae and needle-like spicules of calcium carbonate (Bayer, 1961). Gorgonians can regenerate lost tissue and thus can undergo partial predation (Silveira and Van't Hof, 1977; Harvell and Suchanek, 1987). Like most other octocorals, *L. virgulata* is rarely fouled, even though other surfaces near it are covered in a period of weeks by a thick growth of barnacles, bryozoans, hydroids, algae, and other organisms. Secondary metabolites may play an important role in the protection of *L. virgulata* from overgrowth by fouling organisms (Standing et al., 1982; Rittschof et al., 1985; Targett et al., 1983).

A highly specific assemblage of symbiotic organisms is associated with *Leptogorgia virgulata* (Patton, 1972). One of these symbionts, the gastropod *Neosimnia uniplicata*, feeds upon the cenenchyme of *L. virgulata* and closely mimics the appearance of the gorgonian (Osborn, 1885; Patton, 1972). *Neosimnia uniplicata* is a member of the family Ovulidae, a group of gastropods that often live in close association with corals (Robertson, 1970). Behavioral evi-

dence suggests that secondary chemicals may function in many roles in the relationship between *L. virgulata* and *N. uniplicata* (Rittschof and Gerhart, unpublished observations).

The secondary chemicals of *Leptogorgia virgulata* and *Neosimnia uniplicata* are interesting from two standpoints. Similarities and differences in the chemical content of these organisms provide insight into their ecological interaction, since *N. uniplicata* may sequester or modify the secondary metabolites of its prey (Coll et al., 1983; Faulkner and Ghiselin, 1984). The comparison also could provide data of applied importance, since metabolic alteration of *L. virgulata* metabolites by *N. uniplicata* could lead to more effective antifoulants or could provide clues to structure–activity relationships of antifouling molecules.

In this paper, we examined the possible roles of secondary metabolites in the ecological interaction between *Leptogorgia virgulata* and *Neosimnia uniplicata*. Investigative tools used in this study included biological assays of palatability and antifouling potential, coupled with thin-layer chromatography (TLC).

METHODS AND MATERIALS

Collection. Leptogorgia virgulata and *Neosimnia uniplicata* were collected in Bogue Sound, Morehead City, North Carolina, USA at a depth of approximately 5 meters. *Leptogorgia virgulata* was collected April 3, 1987. Individuals of *N. uniplicata* were collected April 3 and 24, 1987. After collection, the tissues were cleaned, weighed, and then frozen and lyophilized. To measure the water content of the gorgonian tissue, the material was weighed before and after lyophilization.

Extraction and Analysis. Tissues of *Leptogorgia virgulata* or *Neosimnia uniplicata* were soaked overnight in HPLC grade methanol. The extract was decanted, and the tissue was extracted a second time in fresh HPLC grade methanol. The filtered extracts were combined and reduced to a total volume of approximately 25 ml in a rotary evaporator. The concentrated extract was partitioned between HPLC grade methylene chloride and HPLC grade water to remove salts. The methylene chloride layer was evaporated to dryness using a rotary evaporator, and the residue was transferred to a preweighed vial in 2 ml of HPLC grade methylene chloride. The solvent was removed using a vacuum desiccator, and the weight of the vial and its contents was determined.

Analytical TLC was performed using Whatman MK6F silica gel plates (25 $\times$ 75 mm). Samples were applied in a small volume of methylene chloride to the plates. Plates were developed in 1 : 9 acetonitrile–methylene chloride, and visualized using long-wave ultraviolet light, short-wave ultraviolet light, and by treatment with vanillin–sulfuric acid spray.

Spicules of *Leptogorgia virgulata* were prepared by soaking cenenchyme in a dilute solution of sodium hypochlorite, as recommended by Bayer (1961). Axial skeleton was prepared by manually stripping it of cenenchyme and rinsing the skeleton with water. The spicules and axial skeleton were dried in a vacuum desiccator and weighed.

Fish-Feeding Experiments. The acceptability of *Leptogorgia virgulata* and *Neosimnia uniplicata* was determined by offering sections of tissues to individual pinfish, *Lagodon rhomboides*, that had been collected in Beaufort Harbor, North Carolina. *Lagodon rhomboides* was selected as assay organism because it is omnivorous and occurs sympatrically with *L. virgulata*. Fish were offered 2 × 4-mm sections of *L. virgulata* cenenchyme, stripped from the axial skeleton, since fish of the size used in the experiments (30–45 mm standard length) cannot sever the axial skeleton but could remove pieces of tissue from the axial skeleton if feeding on a gorgonian. Fish were also offered crushed *Neosimnia uniplicata*. To ensure that each fish used in the assay was not satiated, control food items were also offered.

Feeding experiments were used to determine the influence of gorgonian spicules and secondary metabolites on the acceptability of artificial food pellets to *Lagodon rhomboides*. Spicules and extract were incorporated, either alone or in combination, into 2% alginate (w/w) food pellets that were flavored with 5% (w/w) powdered, lyophilized fish. To produce alginate containing *L. virgulata* extract, compounds were delivered to a vial in a small volume of methylene chloride, and the solvent removed by vacuum desiccation. Alginate and fish powder, with or without spicules, were then added to the vial and the contents stirred to disperse the materials uniformly throughout the alginate. To produce alginate without extract, pure methylene chloride was added to a vial and evaporated. Alginate and fish powder, with or without spicules, were then added and stirred. Ten-microliter aliquots were taken from each type of alginate mixture, and hardened in a 1 M solution of calcium chloride. The final concentrations of spicules and extract in the pellets corresponded to the concentrations naturally found in the gorgonian (see Results).

In all runs of the experiments, pellets were offered to individual *L. rhomboides* in the following sequence: one pellet of commercial fish food, two experimental pellets, one pellet of commercial fish food. Fish were scored as eating a pellet, mouthing and rejecting a pellet, or ignoring a pellet. A new, previously untested fish was used in each trial to ensure maximum independence between runs of the experiment. Data were not included for fish that did not consume both the initial and final pellets of commercial fish food; this ensured that satiated fish were not included in the experiment.

Antifouling Assays: Barnacle Settlement Inhibition. Cyprid (settling stage) larvae of the barnacle *Balanus amphitrite* were cultured following methods described in Rittschof et al. (1984). Three-day-old cyprid larvae were added to

clean glass vials containing either 5 ml of aged, filtered seawater (30 parts per thousand salinity), or seawater containing various concentrations of test substances. The vials were then incubated at 28°C for 24 hr, with a 15:9 light–dark cycle. After incubation, the vials were removed, and the larvae were examined under a dissecting microscope to determine if they were still alive. The larvae were then killed by addition of several drops of 10% formalin solution. The attached and unattached cyprids were then counted (Rittschof et al., 1984). The number of attached larvae was expressed as a percentage of the total number of larvae in the vial. These data were used to generate dose–response curves; EC_{50} values for settlement inhibition were obtained by probit analysis (Lieberman, 1983).

Bioassay-Directed Isolation of Antifouling Components. Preparative TLC was performed using Whatman PK6F plates (20 × 20 cm). Compounds were dissolved in methylene chloride and applied to the plates with capillary pipettes. Plates were developed in 9:1 methylene chloride–acetonitrile. Compounds were visualized using short-wave and long-wave ultraviolet light. Regions of interest were scraped from the plate using a clean metal spatula, and the compounds were eluted from the silica with methylene chloride. The solution of purified components was then filtered and evaporated to dryness in a vacuum desiccator. These materials were then employed in barnacle settlement assays. This procedure was repeated to obtain highly purified components that inhibited barnacle settlement.

Field Assay of Antifouling Activity. A plastic structure consisting of vertical rods and horizontal surfaces was used for field experiments. One section of this structure was sprayed with an extract of *Leptogorgia virgulata* in methylene chloride to give an average of 600 μg extract per square centimeter of surface. An adjacent section of the structure was treated in a similar fashion with methylene chloride alone. The structure was placed subtidally in Beaufort Harbor, North Carolina, for 24 hr, and then retrieved. Settled barnacles, bryozoans, or hydroids attached to the structure were counted.

RESULTS

Composition of Leptogorgia virgulata. Water made up more than 50% of the wet weight of colonies of *Leptogorgia virgulata* used in this study. Carbonate spicules comprised over 20% of the wet weight, while axial skeleton and chemical extract made up 8% and 1% of the wet weight, respectively.

Acceptance/Rejection of Leptogorgia virgulata *and* Neosimnia uniplicata. In initial laboratory experiments, *Lagodon rhomboides* readily consumed all sections of *Neosimnia uniplicata* ($N = 10$). In subsequent laboratory experiments that incorporated controls for satiation, *L. rhomboides* accepted 9.1% (3

of 32) of all sections of *Leptogorgia virgulata*, while accepting 97% (31 of 32) of all control pellets that were offered to them. These rates of acceptance were significantly different (Williams' adjusted $G = 58.3$; $P < 0.001$).

Acceptance/Rejection of Alginate Pellets. Lagodon rhomboides accepted control alginate pellets at a rate that was not significantly different from their rate of acceptance of commercial fish food pellets (10 of 12 control pellets eaten vs. 12 of 12 commercial fish food pellets eaten; $G = 2.360$ using Williams' correction; $P > 0.1$).

Since these experiments involved feeding two pellets to each tested fish, transition matrices could be constructed to examine the effect of choice of the first alginate pellet on choice of the subsequent pellet. These transition matrices were examined for each treatment. Analysis of the transition probabilities showed no statistically significant facilitation or inhibition ($P > 0.1$ for each treatment), indicating that the choices of the two trials could be considered statistically independent (Legendre and Legendre, 1983).

A G test for independence between the treatments showed that treatment significantly affected the proportion of pellets that were accepted (Williams' adjusted $G = 18.6$; $P < 0.001$; Table 1). The data for alginate pellets of different types were then analyzed using a posteriori tests, and employing an experiment-wise error rate of 0.05 (Sokal and Rohlf, 1983). One maximally nonsignificant subset consisted of pellets with spicules and pellets containing both spicules and *L. virgulata* extract. The second maximally nonsignificant subset was comprised of control pellets, pellets containing spicules, and pellets containing *L. virgulata* extract.

Settlement Inhibition by Extracts of Leptogorgia virgulata *and* Neosimnia uniplicata. Extracts of *L. virgulata* and *N. uniplicata* were potent inhibitors of barnacle settlement. Probit analysis of data from a dilution series experiment indicated that the EC_{50} for settlement inhibition of *L. virgulata* extract was 5 μg/ml, with a 95% confidence interval of 3.7–7.3 μg/ml. For *N. uniplicata* extract, the EC_{50} was 4 μg/ml, with a 95% confidence interval of 2.0–3.9 μg/ml (Figure 1).

TABLE 1. ACCEPTANCE AND REJECTION OF ALGINATE PELLETS BY PINFISH, *Lagodon rhomboides*

Treatment	Number eaten	Number not eaten
Control	10.0	2.0
+ Spicules	8.0	6.0
+ Extract	13.0	1.0
+ Spicules and extract	3.0	11.0

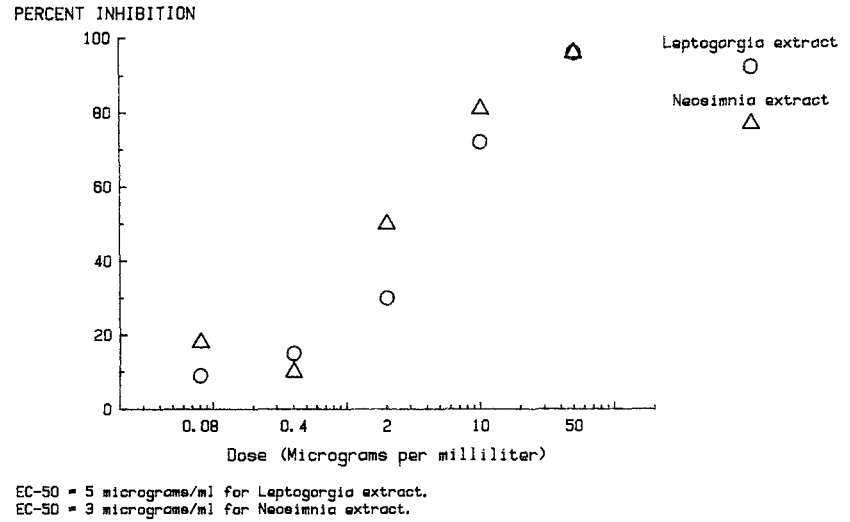

FIG. 1. Inhibition of barnacle settlement by crude extracts of *Leptogorgia virgulata* and *Neosimnia uniplicata*.

Settlement Inhibition by Pure Compounds. The bioassay-directed separation of antifouling compounds from the extract of *Leptogorgia virgulata* led to the isolation of three components. One of these compounds was found to have an EC_{50} value of 19 ng/ml, with a 95% confidence interval of 11–27 ng/ml (Figure 2). The second compound possessed an EC_{50} value of 55 ng/ml, with a 95% confidence interval of 28–78 ng/ml (Figure 3). Structural analysis of these compounds by two-dimensional proton NMR, FAB mass spectrometry, and other techniques, indicated that LV1 and LV2 were previously described diterpenes, known as epoxypukalide and pukalide, respectively (Keifer, unpublished data). A third active component possessed an R_f of approximately 0.78 in 1:9 acetonitrile–methylene chloride. This compound caused cyprids to stick to glass surfaces, and thus was dubbed "cyprid flypaper." Dose–response experiments indicated that cyprid flypaper inhibited the settlement of *Balanus amphitrite* with an EC_{50} of 42 ng/ml, with a 95% confidence interval of 17–90 ng/ml (Figure 4). Pukalide, epoxypukalide, and cyprid flypaper did not kill the cyprid larvae of *B. amphitrite* but inhibited settlement by a nontoxic mechanism.

Field Antifouling Experiment. Four larvae (two barnacle larvae and two bryozoan larvae) settled on the area of the plastic structure that was treated with *Leptogorgia virgulata* extract. The control area of the structure, which had been treated with only pure methylene chloride, had been settled upon by 111 larvae

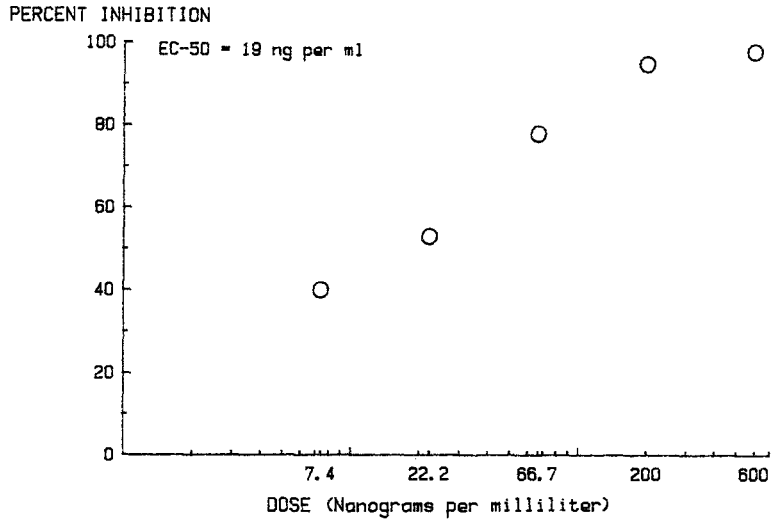

FIG. 2. Inhibition of barnacle settlement by the diterpene pukalide.

(16 barnacle larvae, 93 bryozoan larvae, and 2 hydroid larvae). This result was significantly different from a distribution that assumed larvae settled without preference on either area (G test for goodness of fit; $G = 124.2$ using Williams' correction; $P < 0.001$).

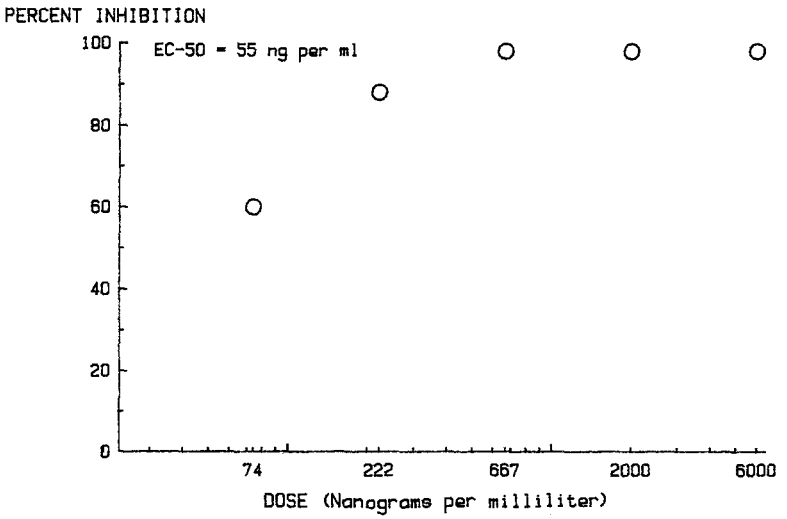

FIG. 3. Inhibition of barnacle settlement by the diterpene epoxypukalide.

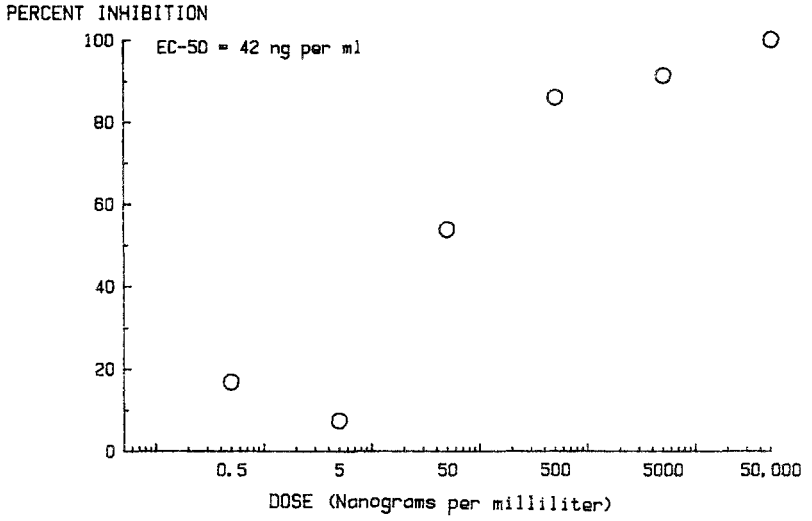

FIG. 4. Inhibition of barnacle settlement by cyprid flypaper.

DISCUSSION

Leptogorgia virgulata was not consumed in the laboratory by *Lagodon rhomboides*. These data corroborate field observations, indicating that *L. virgulata* is rarely eaten by predatory fish. Spicules appear to be important in the protection of *L. virgulata* from fish predation, since incorporation of spicules into alginate pellets was accompanied by greatly reduced acceptance by *Lagodon rhomboides*. When delivered alone in alginate, the chemical extract of *L. virgulata* had no significant affect on pellet avoidance by *L. rhomboides*. The combination of spicules and extract, however, was particularly effective in reducing pellet acceptance. The antipredator defenses of *Leptogorgia virgulata*, therefore, appear to be based upon a synergistic interaction between secondary chemicals and morphological structures. The mechanism of this interaction is unknown. The supraadditive response may have been a behavioral reaction to the simultaneous presence of two negative stimuli. Alternatively, when *L. rhomboides* attempted to ingest pellets containing both spicules and extract, the spicules may have pierced or abraded the mouth and pharynx of the fish, providing a route of entry for defensive compounds that had little or no effect on palatability in the absence of spicules. A similar interaction of physical structures and chemical defenses has been postulated for some terrestrial plants, in which raphides (needle-like crystals of calcium oxalate) may provide a route of entry for secondary metabolites into the predator. Many octocorals, sponges,

and opisthobranchs contain siliceous or carbonate spicules (Bayer, 1961; Paine, 1963; Bergquist, 1978; Thompson, 1976; Thompson and Brown, 1984), as well as high concentrations of secondary metabolites. The synergistic interaction of secondary metabolites and physical structures may, therefore, be important in the antipredator defenses of a variety of sessile marine invertebrates.

Neosimnia uniplicata was readily accepted by *Lagodon rhomboides* in the laboratory. The thin shell of this gastropod affords physical protection from attack by some predators. Thin-layer chromatography demonstrated that *N. uniplicata* contained some compounds that were also present in *Leptogorgia virgulata*. These compounds did not, however, reduce the initial acceptance of the gastropod by predatory fish. The question of whether *N. uniplicata* actively sequesters the secondary metabolites of *L. virgulata* remains to be answered. *Neosimnia uniplicata* may modify some of the terpenes that it ingests, in a manner that has been suggested for another ovulid gastropod that feeds upon octocorals (Coll et al., 1983). The data obtained in our experiments suggest that *N. uniplicata* is a palatable organism that gains protection by closely mimicking an undesirable prey. A similar refuge against predation has been described for palatable algae that live on gorgonians (Littler et al., 1987).

The crude extract of *Leptogorgia virgulata* and *Neosimnia uniplicata* effectively inhibited settlement by cyprid-stage larvae of the barnacle *Balanus amphitrite* in the laboratory. The crude extract of *L. virgulata* also proved to be effective in the field at inhibiting settlement of fouling organisms. Two of the active antifouling agents from *L. virgulata*, described previously as LV1 and LV2 (Rittschof et al., 1985), proved to be two diterpenes, pukalide and epoxypukalide (P.K. Keifer, unpublished data). These compounds were first isolated from specimens of the alcyonacean octocoral *Sinularia sp.*, which occurs on shallow reefs through the tropical Indo-Pacific (Missakian et al., 1975). Traces of pukalide have also been found in Pacific gorgonians of the genus *Lophogorgia* (Fenical et al., 1981). Pukalide proved to be significantly more active in settlement assays than epoxypukalide. The unsaturated lactone ring of pukalide appears to be important for antifouling activity; epoxidation of this ring may be an initial step in the detoxification of pukalide.

The compound known as "cyprid flypaper" appeared to interact with the integument of the cyprid larvae of *Balanus amphitrite*, preventing them from settling. When cyprids were added to vials containing this compound, they adhered to the walls of the vial and were thus immobilized. Nauplius stage larvae, however, were unaffected. The structure of cyprid flypaper is not yet known.

Pukalide, epoxypukalide, and cyprid flypaper inhibited the settlement of barnacle cyprids without killing the larvae. The mechanism or mechanisms involved in this nontoxic settlement inhibition are not yet understood.

Defense against predators has been a prime target of chemical ecological

research with gorgonians and other octocorals (Stoecker, 1980; Bakus, 1981; Coll and Sammarco, 1983; Gerhart, 1984, 1985). An alternative, although not necessarily mutually exclusive, *raison d'être* for secondary metabolites is the inhibition of overgrowth by competitors (Stoecker, 1978; Targett et al., 1983; Gerhart, 1986). Overgrowth is an important source of mortality for gorgonians (Kinzie, 1974). Pukalide, epoxypukalide, and other secondary metabolites from octocorals (Rittschof et al., 1986; Keifer et al., 1986) can significantly inhibit barnacle settlement at micromolar to nannomolar levels. The antifouling effectiveness of these metabolites suggests that they may have evolved as an adaptation to counter fouling. Much additional research must be performed, however, to demonstrate that these secondary metabolites actually provide *L. virgulata* with antifouling protection in nature. The concentrations of metabolites on the surface of the gorgonian are not known, and the importance of other factors, such as mucous cast-off (Patton, 1972), has not been determined. At present, we can only conclude that pukalide, epoxypukalide, and cyprid flypaper are of potential ecological importance as antifoulants in *L. virgulata*.

Although the ecological roles of pukalide, epoxypukalide, and cyprid flypaper are still debatable, the importance of these agents to marine technology is without question. *Leptogorgia virgulata* and other marine organisms have evolved mechanisms to combat fouling. By identifying the active agents that may contribute to this antifouling activity, marine chemical ecology may provide new, nonlethal alternatives to commercial antifoulants based on toxic metals. Thus, while providing new insight into the basic problem of how secondary metabolites influence overgrowth, marine chemical ecology may also yield new solutions to an age-old problem: marine fouling.

Acknowledgments—P. Keifer and K. Rinehart performed the structure determination of pukalide and epoxypukalide. A. Schmidt cultured all cyprids used in our experiments, assisted with the antifouling assays, and facilitated all stages of the research. I.R. Hooper provided invaluable assistance with extractions and chromatography. F. White critically reviewed early versions of the manuscript. M. Wilson and H. Nearing provided expert secretarial help. The Office of Naval Research provided financial support through grant N00014-86-K-0261. We are grateful to all.

ENZYMIC ADAPTATIONS IN LEAF-FEEDING INSECTS TO HOST-PLANT ALLELOCHEMICALS

L.B. BRATTSTEN

J.B. Smith Hall, New Brunswick, New Jersey 08903

(Received September 15, 1987; accepted March 15, 1988)

Abstract—Herbivorous insects have the capacity to develop behavioral, physiological, and biochemical resistance mechanisms in response to chemical selection pressures. Among natural insect-plant associations, there are several cases of target-site insensitivity to and enhanced metabolism of plant allelochemicals. There are also known instances of physiological defenses such as extra rapid excretion or storage of toxic compounds. Multiple defenses seem to be prevalent in natural insect-plant interactions that involve toxic compounds, possibly reflecting the long time these interactions have had to evolve compared to insect-synthetic insecticide interactions. Synthetic insecticides were introduced about 45 years ago. Until recently they have been used as single-active-component preparations. As such, they have been and are very effective in producing insect populations with enhanced detoxification ability and target-site insensitivity. Most insecticide-resistant insect populations have one major defense mechanism. This feature makes the synthetic insecticides very useful tools for studies of insect defenses against toxic chemicals. Information gained from studies with insecticides can shed light on the capabilities of insects to adapt to toxicants in their environment. In assessing the validity of work with synthetic insecticides for natural systems, the fundamental differences between these substances and allelochemicals, and in their presentation to the insects, must, however, be considered. The prevalence of multiple defenses and reliance on modified physiological processes in natural interactions may reflect different properties of the natural chemicals in being generally highly biodegradable and often less acutely toxic than synthetic insecticides. In many cases, the plant allelochemicals are presented to the insects as mixtures. It is, however, to be expected that pest insects will evolve effective multiple defenses against synthetic insecticides. About 20% of all resistant populations have already developed multiple defenses, in most cases combinations of enhanced metabolism and target-site insensitivity. This implies that current crop protection practices need to be modified to ensure the continued usefulness of synthetic insecticides. To

0098-0331/88/1000-1919$06.00/0

achieve this, it is important to study intensively not only insect-insecticide interactions but also the interactions operating in natural insect-plant associations.

Key Words—Plant-insect interaction, herbivory, enzymic adaptation, allelochemicals, detoxification.

INTRODUCTION

Plants rely primarily on fitness-reducing and/or antifeedant chemicals as defenses (Fraenkel, 1959; Scriber, 1981; Frazier, 1986) and only occasionally, and perhaps then by chance, do they contain compounds with high acute toxicity (Metcalf, 1977). Synthetic insecticides used for crop protection, on the other hand, are by design highly and acutely toxic. It is to a large extent thanks to studies elucidating the abilities of insects to adapt to insecticides by identifiable resistance mechanisms that their defenses to toxic chemicals in their environment have begun to be appreciated and understood. This is because it is easier to detect the mechanism of an effect that can be traced to a discrete, acute interference than to one which causes gross symptoms that may be derived from many relatively small effects on several or many biochemical systems. Also, funding is easier to obtain for the study of a problem with fairly direct practical implications. However, it is now obvious that studies of natural interactions involving plant allelochemicals are essential. They benefit us in terms of improved ability to predict adaptive responses of the insects to new insecticides, opportunities to model new insecticides on bioactive plant compounds, design of new uses for insecticides on strategies that plants have used successfully for millions of years, and guidance for efforts in breeding or genetically producing resistant crop cultivars. These studies are also essential for understanding basic adaptive and evolutionary mechanisms.

Even though pest insects have adapted with fantastic speed to most synthetic insecticides, the evolutionary "endpoint" is not yet at hand. It is possible to discern evolutionary stages of insecticide resistance development. At first, in some cases very shortly after the introduction of a class of synthetic insecticides, resistance could be ascribed to a single mechanism, most often enhanced ability to detoxify the toxicant (see Brattsten, 1988). Less than 40 years after large-scale synthetic insecticide applications began, more than 20% of resistant pest insects rely on more than one resistance mechanism (Georghiou, 1981). This is, in most cases, accomplished by a combination of enhanced metabolism and target site insensitivity. In contrast, in the large majority of known cases of insects that feed on plants containing toxic allelochemicals, multiple physiological and biochemical defenses are present. It is evident that insects have

many physiological and biochemical options for dealing with toxic chemicals. The lesson from the study of natural systems is the existence in many successfully adapted insects of effective combinations and permutations of discrete defense mechanisms.

The following is a review of the major defense mechanisms employed both against synthetic insecticides and plant allelochemicals. It draws primarily from information obtained in the course of insecticide-resistance studies because, with few exceptions, the underlying mechanism(s) involved in the fate of plant allelochemicals in insects is not identified or characterized in chemical ecology studies.

There are three general categories of defenses to toxic chemicals, namely behavioral adaptations, modified physiological processes, and biochemical resistance mechanisms. Behavioral adaptations and modified physiological processes will be treated very briefly, whereas biochemical defenses, in particular metabolic mechanisms, are emphasized here. This does not imply that metabolism of toxicants is the most important mechanism in each and every case of insect–plant interaction in nature and agricultural fields. There is, however, a good likelihood that metabolic adaptations are of primary importance in the development of the patterns of host utilization by insects.

BEHAVIORAL RESISTANCE

A behavioral defense against a toxic chemical may be conceived as a behavior that allows an insect to feed on a plant despite the presence of toxicants in or on it. There are two outstanding examples of such behavior. One is the trenching by the squash beetle when feeding on cucurbits containing moderate to high concentrations of cucurbitacins (Tallamy, 1985, 1986). The other is the vein-cutting by several insect species adapted to feed on latex-containing plants (Dussourd and Eisner, 1987). In the latter case, the behavior is directed against a mechanical obstacle to feeding (gumming of the mandibles), but the authors point out that it may also block an influx of allelochemicals to the feeding site. It can be conjectured that this sort of defense takes a long time (at least hundreds of years) to be transmitted uniformly throughout a species. It may also depend on non-acutely acting toxicants. Aphids restrict their feeding to phloem, a plant part known to contain only low concentrations of allelochemicals (Mullin, 1986; Dreyer and Campbell, 1987). It is probably common also for chewing insects to feed selectively to minimize allelochemical intake and optimize nutrient intake (Schultz, 1983; Tallamy, 1986), especially in early instars.

Insects exposed to highly toxic, synthetic insecticides have not developed any equivalent defensive behavior, although generally increased irritability and

simple avoidance of treated surfaces have been observed in several cases (Georghiou 1972; Pluthero and Singh, 1984; Gould, 1984). The stalk- or fruit-boring feeding habits of several agricultural pest insects probably evolved in response to nonchemical selection pressures.

PHYSIOLOGICAL RESISTANCE

Adaptations in physiological processes can take the form of extra rapid excretion of ingested toxicants; their sequestration or storage in body compartments, specialized spaces, by enhanced concentrations of binding and storage proteins; or fortification of the integument to slow down the penetration of toxicants. These mechanisms are poorly understood and reflect in each case one or more altered, discrete biochemical functions that have not been identified and characterized. These modified physiological processes may be insignificant by themselves in protecting an insect from poisoning and are probably always combined with other defenses.

There are many known cases of physiological resistance against both synthetic insecticides and plant allelochemicals. For instance, the tobacco hornworm excretes 93% of an ingested dose of nicotine in 2 hr. The housefly, not adapted to feed on nicotine-containing plants, excretes 10% unmetabolized nicotine in 18 hr (Self et al., 1964). The tobacco hornworm has several other defenses against nicotine (Brattsten, 1986). The large milkweed bug and the monarch butterfly are well-documented examples of adapted insects that store cardenolides taken in with their food (Scudder et al., 1986; Brower and Glazier, 1975). Houseflies resistant to DDT can store in their bodies enough DDT to kill susceptible flies (Perry and Hoskins, 1950). The green peach aphid has a protein with carboxylesterase activity that binds insecticides with ester bonds with high affinity but hydrolyzes them very slowly (Devonshire and Moores, 1982) and is, thus, an effective storage protein. The southern and fall armyworms have a similar protein in their fatbodies (Brattsten, 1988). Several insect species including lepidopterans, dipterans, and orthopterans contain hemolymph proteins. These are, characteristically, very large (about 500,000 daltons), have a high content of aromatic amino acids, contain a significant portion of lipids, occur only in immature insects, and reach very high concentrations during the last instar of caterpillars. They may participate in toxin storage, although such a role for them does not seem to have been considered widely (Levenbook, 1985). Lipophorin and arylphorin isolated from caterpillars, including the tobacco hornworm (Shapiro et al., 1984) and the corn earworm (Haunerland and Bowers, 1986a), store certain allelochemicals and insecticides of suitable lipophilicity (Haunerland and Bowers, 1986b).

BIOCHEMICAL RESISTANCE MECHANISMS

Two broad categories of enzymes are involved in insect–plant interactions: target enzymes and digestive enzymes. The receptor proteins that insects use to locate and recognize plants suitable for feeding and/or oviposition are also highly involved but will not be included in this review. The two categories of enzymes are to some extent overlapping; digestive enzymes are inhibited by both plant allelochemicals and synthetic compounds that in a few cases have found practical use as insecticide synergists. The inhibition of a digestive enzyme can be serious enough for survival; the insect may suffer malnutrition, be poisoned by a compound that would normally be detoxified by the inhibited enzyme, or be weakened and so fall an easier prey. But inhibition of a digestive enzyme is never as acutely fatal as inhibition of a so called target enzyme, that is, one which plays a crucial role and without which the insect cannot survive for more than minutes.

Target Site Insensitivity

The nervous system contains many important target enzymes or proteins. Figure 1 shows a simplified sketch of a synapse and an axon and illustrates several specific targets and corresponding inhibitors. In the presynaptic cell, the nerve impulse transmitter acetylcholine is biosynthesized and released; cyclodiene insecticides interfere with these processes (reviewed by Corbett et al., 1984). The acetylcholine receptor located in the postsynaptic membrane is activated by nicotine (Eldefrawi et al., 1970), which cannot be released quickly

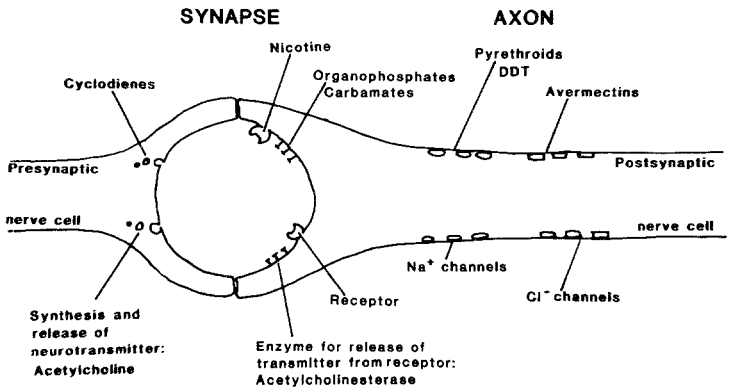

FIG. 1. Scheme of the major factors in nerve impulse transmission and the major inhibitors of each factor. See text for explanation.

enough to restore the membrane resting potential. The crucially important enzyme acetylcholinesterase is also bound to the postsynaptic membrane in close proximity to the acetylcholine receptor; this enzyme releases acetylcholine from the receptor so that the next transmitted impulse can be received. This enzyme is inhibited by organophosphorous and carbamate insecticides (reviewed by Corbett et al., 1984). Beyond the synapse, the nerve impulse is transmitted in the axonal membrane by a rapid wave of successive depolarizations and repolarizations, brought about by influxes and effluxes of ions controlled by the sodium and chloride channels; these processes are inhibited by DDT, pyrethroids, and avermectins (reviewed by Lund, 1985). More than 90% of all commercially used insecticides are aimed at these targets in the nervous system; yet, insects have developed adaptations that render these targets so substantially less sensitive to inhibition that control with synthetic insecticides is often no longer feasible. The only exception is the chloride channel complex, which has not been exposed long or intensively enough.

The sodium–potassium ATPases that catalyze ion transport across cell membranes are the target for inhibition by cardenolides. The monarch caterpillar and the large milkweed bug are good examples of insects that have developed insensitive or less-sensitive ATPases, presumably in response to the presence of cardenolides in their host plants (Vaughan and Jungreis, 1977; Moore and Scudder, 1985).

An insensitive target is the most powerful defense and, being a "built-in" defense (Berenbaum, 1986), does not require the energy expenditure always associated with metabolism. It is, however, probably harder to come by, because it requires a subtle genetic modification of an essential and critical function. This must be slight enough not to impair the normal function, and yet substantial enough to decrease or eliminate binding to the toxicant (Brattsten et al., 1986; Brattsten, 1988). Target-site insensitivity is a widely occurring defense against both plant allelochemicals and synthetic insecticides (Berenbaum, 1986; Brattsten et al., 1986). It affords the most complete protection against acute poisoning, but may not prevent fitness-reducing effects unless combined with other defenses.

Metabolic Defense Mechanisms

It should be clear from the foregoing that metabolism is only one of many possible defenses; in most cases it augments and complements other defenses. Characteristically, a large number of enzymes operate in concert in metabolic defenses.

Two kinds of digestive enzymes are highly involved in all insect–plant interactions: those that metabolize nutrients and those that are specialized to metabolize allelochemicals. Again, these two kinds overlap considerably. Some

of the foreign compound-metabolizing enzymes also participate in the metabolism of endogenous substances, such as hormones and pheromones; and, depending on the toxicant, some of the nutrient-digesting enzymes play important roles in detoxification, e.g., in the case of toxic amino acids.

Metabolism of foreign compounds has traditionally been represented by a scheme (Figure 2) that emphasizes the conversion of lipophilic compounds, which often are highly toxic, to water-soluble metabolites that can easily be excreted. This scheme was designed with drugs and insecticides in mind (Williams, 1974) and applies very well to such chemicals, most of which are lipophilic. Since the enzymes involved in allelochemical metabolism are the same as those metabolizing drugs, and insecticides and the end products of allelochemical metabolism are of the same kind (often water-soluble conjugates) as those of drug or insecticide metabolism, the scheme is convenient for an overview and introduction to the enzymes. However, since many allelochemicals are quite water soluble, several of the enzymes assigned to the so-called secondary or phase II metabolism may be of primary importance in the metabolism of plant allelochemicals, as suggested in Ahmad et al. (1986). Many excellent reviews of the enzymes metabolizing foreign compounds and their properties have been published recently (Agosin, 1985; Ahmad, 1986; Ahmad et al., 1986; Dauterman, 1985; Heyman, 1980; Hodgson, 1983, 1985; Mullin, 1986; Oppenoorth, 1985; Terriere, 1983, 1984; Wilkinson, 1980, 1983, 1984a,b, 1986; Yu, 1986). These should be consulted for details and for information on enzymes not discussed in this paper.

Cytochrome P-450. The cytochrome P-450 system, also known as microsomal monooxygenases or polysubstrate monooxygenases (PSMO), is the most important mechanism for metabolizing lipophilic chemicals. This system, capa-

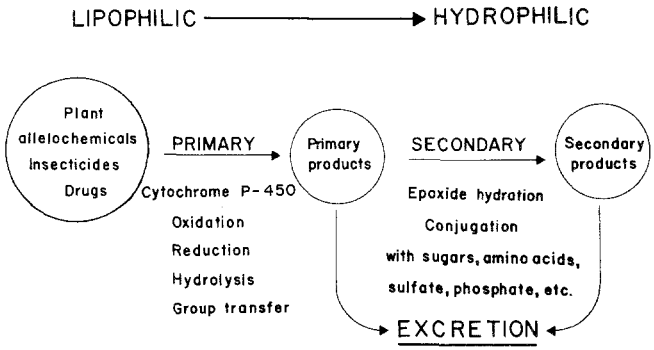

FIG. 2. Schematic representation of the overall events in foreign compound metabolism based on R.T. Williams (1964). Reprinted with permission from Plenum Publishing Corporation.

ble of attacking something as highly lipophilic as a polycyclic aromatic hydrocarbon, also accepts as substrates relatively water-soluble compounds such as the organophosphate insecticides, as long as they contain a lipophilic site to which the enzyme can bind. By virtue of its reaction mechanism, essentially a combination of a lipophilic substrate binding interaction and an oxygen free radical attack, cytochrome P-450 can attack molecules with widely varying structures. Also, a suitable molecule can be attacked at several different molecular sites or appear to undergo several different reactions, including carbon hydroxylations, *N*- and *O*-dealkylations, or epoxidations (see Ahmad et al., 1986), all of which are monooxygenations. Figure 3 illustrates sites at which cytochrome P-450 can attack several allelochemicals.

The versatility in accepting many different compounds as substrates is enhanced by the occurrence of several different molecular forms of cytochrome P-450 with broadly overlapping properties. Some of these forms are constitutive and, possibly, characteristic of tissues or even of cells. Others may appear as a result of induction by foreign chemicals (see later). The composition of cytochrome P-450 molecular species has been elucidated only in rat and rabbit liver

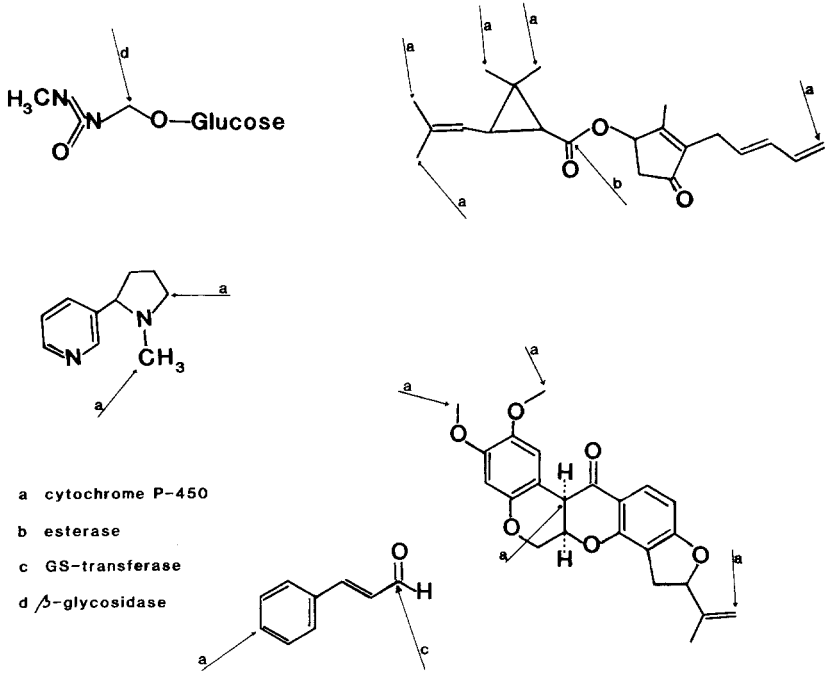

FIG. 3. Sites of enzymatic attack on selected plant allelochemicals.

(Ryan et al., 1982; Coon and Persson, 1980). It has not yet been possible to do similarly detailed studies in insects.

To fully appreciate the effectiveness of metabolic defenses, we must remember that cytochrome P-450 does not operate in splendid isolation. There are several other enzymes located in close proximity to the cytochrome that also attack incoming foreign molecules at the same time or within milliseconds of the cytochrome P-450 action. Also, other enzymes use cytochrome P-450 metabolites as substrates, forming short metabolic pathways (Mullin, 1985, 1988) that may lead to conjugated end products. The relatively more water-soluble molecules are more likely to be attacked by several enzyme simultaneously. For instance, cytochrome P-450 is the only enzyme known to attack rotenone, a lipophilic substance, whereas certain organophosphorous insecticides can be attacked by carboxylesterases and glutathione transferases in addition to cytochrome P-450.

This concerted action is the more important since primary metabolites are, in many cases, more reactive and, therefore, potentially more toxic than the parent molecule. The epoxide metabolite of precocene II is a good example of a toxic cytochrome P-450 metabolite that alkylates and thereby destroys macromolecules. When it is formed in the corpora allata, the gland is destroyed because of absence of other enzymes to detoxify the epoxide (Ellis-Pratt, 1983). However, precocene II does not necessarily fatally damage other tissues that have epoxide hydrolases or glutathione transferases ready to convert the epoxide to a hydroxylated or conjugated product. Molecular form(s) of cytochrome P-450 in fatbodies of European corn borer larvae oxidize precocene II to several metabolites in addition to the epoxide (Soderlund et al., 1980), the net outcome of which may be detoxification.

Transferases. Group transfer enzymes catalyze the conjugation of a foreign compound or its metabolite to a small, highly water-soluble endogenous group by a covalent bond. In most cases, a high-energy intermediate is a required cofactor or cosubstrate (Williams, 1974; Caldwell, 1982; Dauterman, 1985; Wilkinson, 1986; Ahmad et al., 1986). With exceptions, conjugations usually result in detoxification (Paulson, 1982). The glutathione transferases are probably the most important conjugating enzymes in animals, rivaled only by the hexose transferases. Other transferases may be very important in special cases.

Glutathione Transferases. Unlike cytochrome P-450, which is embedded in the membranes of the endoplasmic reticulum, the glutathione transferases (GSTs) are floating in the soluble fraction of the cells. Even though all the molecular forms of GSTs prefer lipophilic substrates, their subcellular location helps them to attack considerably water-soluble molecules also. The GSTs are less versatile than cytochrome P-450 and accept as substrates compounds with an electrophilic center, such as α,β-unsaturated carbonyl compounds, electronically mimicked by some of the organophosphate insecticides, thiocyanates, and

isothiocyanates (Scheline, 1978). Many plant allelochemicals satisfy these substrate requirements, including cinnamaldehyde, other unsaturated aliphatic aldehydes, and the glucosinolates. GSTs from midguts of the fall armyworm metabolize several unsaturated carbonyl allelochemicals and allyl and benzyl isothiocyanate in vitro (Wadleigh and Yu, 1987). The GSTs also play an important role in conjugating epoxyhydrocarbons (Boyland and Williams, 1965; Fjellstedt et al., 1973), such as may result from cytochrome P-450 catalyzed epoxidation of olefinic allelochemicals.

Insect GSTs have received considerable attention because of their involvement in the detoxification of organophosphorous insecticides (Oppenoorth et al., 1972; Levine and Murphy, 1977; Motoyama and Dauterman, 1980). They also detoxify lindane and other halogenated aromatic and aliphatic hydrocarbon compounds (Cohen et al., 1964; Menguelle et al., 1985; Clark et al., 1986). In houseflies, a GST form catalyzes the dehydrochlorination of DDT (Clark and Shaaman, 1984) and is identical to the enzyme previously called DDT dehydrochlorinase; dehydrochlorination to DDE is, in many insects, the major metabolic fate of DDT and represents one important resistance mechanism to DDT.

The GSTs are multifunctional proteins with catalytic activity to combine the foreign compound or its primary metabolite with reduced glutathione (GSH) by a covalent bond. They are, however, also important as storage proteins for foreign compounds or their metabolites and function in this capacity as soluble binding proteins. As enzymes, the GSTs require and are, except in some plants, specific for GSH. In many cases, the foreign compound combines spontaneously with GSH, which occurs at millimolar concentrations in some cells, e.g., rat liver cells. The role of the GST enzymes is thought to be primarily to assure close proximity and orientation of the reactive centers of the foreign compound and the activated thiolate ion, GS^-, to facilitate the reaction between them (Jakoby and Habig, 1980). In the case of DDT dehydrochlorination, GSH is used only in catalytic amounts by a reaction thought to encompass an E2 elimination with an initial abstraction of a benzylic hydrogen followed by the removal of one of the chlorine atoms (Wilkinson, 1986).

GST activities have been isolated and purified from a few insect species. Four forms with similar properties and overlapping substrate preferences were found in fatbodies of the American cockroach (Usui et al., 1977). Three forms, functionally somewhat different, were isolated from houseflies (Clark et al., 1985). Four forms were found in porina moth (*Wiseana cervinata*) larvae (Clark and Drake, 1984). Common laboratory animals (rats, mice, etc.), as a rule, have multiple GST forms (Jakoby and Habig, 1980). However, only one form could be isolated from larvae of the greater wax moth (Chang et al., 1981). GST activity towards commonly used model substrates have been recorded from several insect species (see Ahmad et al., 1986, for review).

The ultimate fate of glutathione conjugates in mammals is excretion as a mercapturic acid derivative formed by subsequent enzymatic cleavage of the tripeptide (Ahmad et al., 1986). Practically nothing is known about the enzymes in insects that catalyze these subsequent reactions, and there are very few demonstrated cases of excretion of mercapturic acid derivatives in insects; 2,4-dinitrophenyl mercapturic acid is excreted by the American cockroach (Dykstra and Dauterman, 1978) and the housefly (Abd-Elraof and Dauterman, 1981).

Hexose Transferases. Glucose is the sugar most commonly used for conjugation. It is activated by linkage to uridine diphosphate (UDP) via a high-energy phosphoester bond. Insects use the activated glucose directly and form *O*-glucosides in most cases. In mammals, the extra step of oxidizing the glucose to glucuronic acid, which is activated to UDP-glucuronic acid, is inserted in the enzymatic conjugation sequence for reasons that are not obvious; in consequence, mammals make predominantly glucuronide conjugates. Plants use a wide variety of sugars to make glycosides. Although all sugar conjugates are easily excretable, glucosides are in some cases also a storage form in insects. The cyanogenic glycosides biosynthesized by some insects are good examples (Davis and Nahrstedt, 1985). Storing the toxicant as an inactive glycoside enables the insects to use it as a predator deterrent. The UDP-glucosyl transferases are likely to be important in insect–plant interactions, and many insects excrete glucose conjugates of insecticide metabolites; however, the enzymes have not been extensively studied in insects.

Hydrolases. The hydrolases of general importance in foreign compound metabolism include the esterases, the epoxide hydrolases, the enzymes that hydrolyze glycosidic and thioglycosidic bonds (glycosidases and glucosinolases), and a few hydrolytic enzymes that are important in special cases.

Among the esterases, the carboxylesterases are intensively studied in insects (see Ahmad et al., 1986) due to their importance in insecticide and juvenile hormone metabolism and in nerve impulse transmission mediated by the acetylcholinesterases; they may also participate in the digestion of nutrients and in other areas of endogenous metabolism, although in these cases their precise roles are not known. Enhanced carboxylesterase activity is a major resistance mechanism against synthetic insecticides. Apart from their importance in insecticide and juvenile hormone metabolism, very little is known about insect carboxylesterases or their participation in the metabolism of plant allelochemicals. Atropine, cocaine, reserpine, other drugs, and plant-derived esters are hydrolyzed by many different mammalian tissues (Scheline, 1978).

Carboxylesterases, like other hydrolases, cleave a covalent bond with the aid of a molecule of water and without any cofactorial energy requirement. These enzymes only attack molecules containing an ester bond, although some carboxylesterases also hydrolyze phosphoester and amide bonds. There are many

different forms of carboxylesterases, some of which are soluble, whereas others are bound to the endoplasmic reticulum of cells. Substrate specificities seem to be quite variable between different carboxylesterase forms. A form in the midgut of the soybean looper hydrolyzes *trans*-permethrin but not naphthyl or nitrophenyl esters (Dowd and Sparks, 1986), whereas in the green peach aphid, the E4 form hydrolyzes pyrethroids, organophosphates, and carbamates with a very broad substrate specificity (Devonshire and Moores, 1982). In some cases substrate specificities can be widely overlapping between forms; the cattle tick has as many as 15 forms, all of which hydrolyze 1-naphthyl acetate (DeJersey et al., 1985), and the cabbage looper has at least two forms that hydrolyze pyrethroids (Ishaaya and Casida, 1980).

Epoxide hydrolases are the subject of another paper in this issue (Mullin, 1988) and, therefore, will not be reviewed here.

Glycosidases hydrolyzing sugars that are β-bonded to allelochemical aglycones have not been studied widely in insects. Sugar-cleaving enzymes have been studied in most detail in wood-boring insects because of their role in nutrition. The harvester termite has a β-glycosidase in the gut tissues which digests cellulose to cellotriose (Potts and Hewitt, 1974). Larvae of *Rhagium inquisitor* contain many α- and β-glycosidases (Chipoulet and Chararas, 1985). In the case of larvae of *Sirex cyaneus*, the sugar-hydrolyzing activity was shown to reside in the tissues of fungal symbionts ingested along with the wood (Kukor and Martin, 1983). β-Glycosidase activity related to the metabolism of foreign compounds has been implied in a few insect species including the migratory locust, a water boatman, a mealworm, the American cockroach, the bean aphid (Robinson, 1956), and in larvae of *Seirarctia echo* (Teas, 1967).

Since many, if not most, aglycones are more toxic than the glycoside, it is unclear how specific β-glycosidases could evolve in insects. If the insect is adapted to a glycoside-containing host plant, the selection pressure would favor deletion of the activity; if the insect is a generalist feeder, it may retain nonspecific glycosidases, provided that it is well equipped with other enzymes to metabolize the aglycone. In either case, it would be safest not to have the activity. Besides plants, bacteria and other microorganisms are well known to have β-glycosidase activities (Scheline, 1978; Goldman, 1982); it is possible that the activity observed in the insects derived from their gut microorganisms. Although microbes are extensively and intimately associated with insects (Jones, 1984), the extent to which they participate in foreign-compound metabolism in insects is not well known.

Factors Affecting Enzyme Activities

Enzymes specialized to metabolize compounds that may not always be present are likely to occur in large amounts, represented by high activities, only

when they are needed. The biosynthetic energy cost in maintaining a high amount of constantly turning-over enzyme proteins may be considerable. The regulation of such enzymes may thus be susceptible to external factors. However, the activities of these enzymes are probably also regulated by internal, hormonal factors. Measurement of cytochrome P-450 activities in different life stages and larval instars, in male and female insects, and in different tissues, e.g., guts and fatbodies, show inherent differences in activities that cannot be ascribed to external factors (Krieger and Wilkinson, 1969; Wilkinson and Brattsten, 1972; Benke et al., 1972; Brattsten et al., 1980; Feyereisen and Farnsworth, 1985; Ahmad, 1986; Ahmad et al., 1986). There are also differences in response to external factors, especially between tissues.

It is well known that the foreign-compound-metabolizing enzyme activities are modulated temporarily by ingested chemicals, including plant allelochemicals. Many such compounds induce or inhibit cytochrome P-450, glutathione transferase, epoxide hydrolase, and carboxylesterase activities (Terriere, 1983, 1984; Yu, 1986; Brattsten, 1988).

Induction, in which enzyme activities are elevated only as long as a sufficient concentration of the inducing chemical remains in the insect tissues and then return to "normal" levels (Brattsten and Wilkinson, 1973), is well documented in herbivorous insects, most of which have happened to be generalist feeders. The velvetbean caterpillar and the boll weevil are the only specialist or adapted feeders studied in any detail so far. Both species have higher activities of cytochrome P-450 and glutathione transferases after the insects have fed on diets containing inducers (Yu, 1986; Wadleigh and Yu, 1987; Brattsten, 1987).

The examples we have so far do not show clearly the extent to which induction is important in natural insect–plant interactions. Even though the enzymes in both specialists and generalists are inducible, induction may be more important in generalist feeders. These, after having depleted one food source, may, on short notice (hours or minutes), have to "adapt" to a completely different allelochemical load of a new food source. A specialist would not be faced with this biochemical challenge, having accepted a food source on the basis of taste receptor inputs. A specialist may have "permanent" activity levels that reflect the allelochemical content of its host plant. For example, many species of caterpillars that feed on plants rich in terpenoids have very high cytochrome P-450 activities (Rose, 1987). Terpenoids are generally good inducers of cytochrome P-450 activities. Black swallowtail caterpillars have high cytochrome P-450 activities (Brattsten, 1979; Bull et al., 1984), perhaps attributable to the allelochemical content of their umbelliferous host plants. On the other hand, a specialist may have permanently depressed activities if its host plant contains inhibitory allelochemicals. For instance, the larvae of *Utetheisa*

bella have very low cytochrome P-450 activities, perhaps inhibited by pyrrolizidine alkaloids in their *Crotalaria* host plants (Brattsten, 1979, 1986).

IMPLICATIONS OF INSECT DEFENSES AGAINST TOXICANTS

Generally valid statements about insect survival on plants that contain toxic allelochemicals are very difficult, or even impossible, to make. This could be a function of our limited stock of thoroughly investigated and well-documented cases from which to derive patterns and principles. It could also reflect a reality of almost limitless combinations of discrete adaptive mechanisms optimized for each individual interaction in time and space. The foregoing, brief discussion of some of the major defense mechanisms should have shown the multitude of possibilities that insects have available to them.

Possession of defenses of very impressive variety and biochemical sophistication has obvious implications for the distribution of insects on plants in the patterns observable today. It also has implications for how they may be controlled in agroecosystems by methods that are economically and socially acceptable and pose a minimal risk to the environment. It is likely that methods for insect control to meet these criteria will have to be highly specific for each combination of factors constituting the agroecosystem in need of protection.

It is difficult or impossible to reconstruct the evolutionary, biochemical, and behavioral events that led to association of a certain insect species with a certain plant species. It may, however, be possible to complement our understanding of the current associations of insects with certain plants but not with others by improved understanding of how their defensive enzymes operate. For instance, the southern armyworm, regarded as a generalist feeder, clearly prefers to feed on certain cyanogenic plants such as the lima bean (SooHoo and Fraenkel, 1966; Brattsten et al., 1983). It has high activity of the enzyme β-cyanoalanine synthase (Brattsten, unpublished), which is known to catalyze the first step in the series of biotransformations that incorporate cyanide into the amino acid pool, detoxifying it in the process (see Davis and Nahrstedt, 1985; Brattsten, 1986, for recent reviews). The southern armyworm caterpillars also have rhodanese activity (Long and Brattsten, 1982), although this enzyme is probably of minor, if any, importance in cyanide detoxification (Brattsten, 1986). On the other hand, the southern armyworm has never been documented feeding on mint plants in nature. The terpene content of mints may deter or kill early instars but is not deterrent, at concentrations occurring in plants, to last instars (Gunderson et al., 1985). The armyworm midgut cytochrome P-450 that metabolizes one of the monoterpenes, pulegone, is induced by another monoterpene, α-pinene, to a molecular form that hydroxylates pulegone to a precursor of menthofuran, more toxic than pulegone (Trammell, 1982; Gunderson et

al., 1986). This could contribute to the absence of mints among southern armyworm host plants.

In the case of insects that store toxic compounds, it is interesting to speculate whether a target site insensitivity was the prerequisite for the development of the ability to store the toxicant (Berenbaum, 1986). Once stored, the insect could take advantage of the toxicant in defense against predators. Alternatively, the ability to store was a genuine but, perhaps imperfect, defense against the toxicant. The latter case then conferred two potentials: it provided the insect with the opportunity to develop an insensitive target site (a risky proposition and undoubtedly costly in terms of individuals) (Brattsten, 1988) and the sequestered toxicant could be exapted (Gould and Vrba, 1982) as defense against predators.

Synthetic insecticides have played an important role in food production and in the combat against insect-vectored diseases such as malaria. They have also caused many serious problems with environmental pollution, destruction of nontarget species and, in some cases, direct or indirect adverse health effects. The chemicals per se are effective in doing what they were designed to do and have contributed significantly to the production of affordable commodities. Their excessive and haphazard use is the major cause of their associated problems. Since it is no longer easy, scientifically or economically, to invent and develop new insecticides, it is important that the ones we have be used so as to preserve their usefulness, in particular by avoiding resistance problems. Their incorporation in control strategies that also rely on available cultivation and biological control methods, i.e., in integrated pest management programs (IPMs), is the most promising way to take advantage of their benefits and minimize their undesirable side effects (Georghiou, 1983).

There is currently a large effort to develop pest-resistant crop plants, either by conventional plant breeding programs or by genetic engineering. This approach holds considerable promise and will likely result in some commercial successes within the decade. However, endowing crop plants with genetic capacities to biosynthesize their own chemical defenses against insects is really only a different way of exposing insects to toxic chemicals. It will be important to have on hand a number of different cultivars with the ability to biosynthesize different defensive chemicals with different modes of action before the use of any one cultivar starts, so that the insect population can be exposed to multiple chemicals. If not, the insects will soon adapt to the cultivars, one after the other, just as they do when chemicals are sprayed on fields. The most effective chemical plant defenses are the so-called inducible defenses, such as the injury-induced increase in monoterpene production in pine trees in response to invading pine beetles (Raffa, 1986). Insects in nature and in model systems have the most difficulty in adapting to unpredictable and multiple toxicants (Dolinger et al., 1973; Pimentel and Bellotti, 1976). Other potential problems with resistant

crop plants, such as residues, will be similar to those of conventional insecticide spray use; these problems (e.g., toxic hay) may be lessened by the tendency of plant allelochemicals to be highly biodegradable, unlike many synthetic chemicals.

Acknowledgments—I thank I.M. Brattsten-McDougall and two anonymous reviewers for helpful comments on the manuscript, and Mike Ryan for the opportunity to participate in this symposium. This is publication No. D-08111-12-87 from the New Jersey Agricultural Experiment Station.

BIOASSAYS OF SEGREGATING PLANTS
A Strategy for Studying Chemical Defenses

S.L. SINDEN, L.L. SANFORD, W.W. CANTELO, and K.L. DEAHL

Vegetable Laboratory, Agriculture Research Service

(Received September 15, 1987; accepted March 15, 1988)

Abstract—*Solanum chacoense* is a wild potato species resistant to the Colorado potato beetle, *Leptinotarsa decemlineata*. Most genotypes of *S. chacoense* synthesize the glycoalkaloids solanine (sol) and chaconine (chac) and are hosts of the beetle. A few rare genotypes have a gene(s) for acetylation of carbon-23 of the steroid aglycone of sol and chac. Laboratory bioassays and replicated field tests of clones differing in the presence or absence of the acetyl moiety showed that acetylation of sol and chac markedly affects the response of both adults and larvae to the foliage. Adult feeding deterrency conferred by acetylated forms of sol and chac (leptines) in leaf-disk preference tests was consistent with the degree of antixenosis measured in the field. Development of larvae on foliage of clones with leptines was also inhibited. The studies support the validity of using laboratory bioassays of plants segregating for levels of a suspected defense compound to determine the role the compound has in defending the plant from attack by an insect predator in the field.

Key Words—Glycoalkaloids, insect resistance, Colorado potato beetle, leptines, solanine, chaconine, *Leptinotarsa decemlineata*, *Solanum chacoense*, *Solanum tuberosum*.

INTRODUCTION

Knowledge of chemical defense against insect pests may be useful in developing resistant cultivars of crop plants. The breeding process could certainly become more efficient if the nature of a crop's natural defenses were understood and assessments of resistance could be made in the laboratory or greenhouse at early growth stages using reliable biological or chemical assays. Laboratory

0098-0331/88/1000-1941$06.00/0

assays of breeding populations will, of course, only be useful to the plant breeder if they are valid measures of resistance and are highly correlated with field results.

Investigating chemical defense by isolating compounds and testing their effects on pests with in vitro bioassays can be inefficient and sometimes ineffective. Assays for chemical composition differences among plants segregating for resistance, an often overlooked alternative, can be a more efficient and sometimes the only effective strategy for identifying defense compounds. David Jones et al. (see Rosenthal, 1986) used this approach in a series of ingenious experiments that established the role of cyanogenic glycosides in the defense of bird's foot trefoil and white clover against slugs and snails. Segregates producing both cyanogenic glycosides and the enzymes to liberate cyanide when the leaves are attacked are invariably more resistant to damage than segregates lacking either the cyanogenic glycosides, the enzymes, or both.

GLYCOALKALOIDS AND RESISTANCE

Chemical assays of segregating plants were used first to identify and then establish the role of nitrogen-containing steroid glycosides (glycoalkaloids) in the defense of wild Solanaceous species against the Colorado potato beetle (CPB), *Leptinotarsa decemlineata* Say. Using field tests and bioassays of detached foliage, European breeders and entomologists found wide segregation for CPB resistance among wild potato and tomato species in the 1930s and 1940s. Chemical defense was suspected because of the strong aversion of larvae and adults to the foliage of highly resistant plants. Analyses for possible allelochemicals revealed the presence of higher glycoalkaloid levels in foliage from resistant plants (see Dimock and Tingey, 1985; Tingey, 1984; Bongers, 1970, for reviews and references).

The apparently simple correlation between glycoalkaloid concentration and level of resistance became somewhat clouded, however, as new chromatographic and spectrophotometric methods of determining glycoalkaloid composition came into use. With the new analytical methods, new glycoalkaloids were discovered in some potato species previously thought to contain only a single glycoalkaloid, solanine (sol).

Some resistant species had very high levels of sol and chaconine (chac), the glycoalkaloid pair (Figure 1) found in low levels in susceptible *Solanum tuberosum* L. Some had high concentrations of tomatine (tom), the glycoalkaloid in tomatoes. Other resistant species had moderate to high concentrations of new glycoalkaloids, demissine and leptines.

Large differences among the glycoalkaloid forms in their CPB feeding-deterrency activity were discovered when *S. tuberosum* foliage infiltrated with

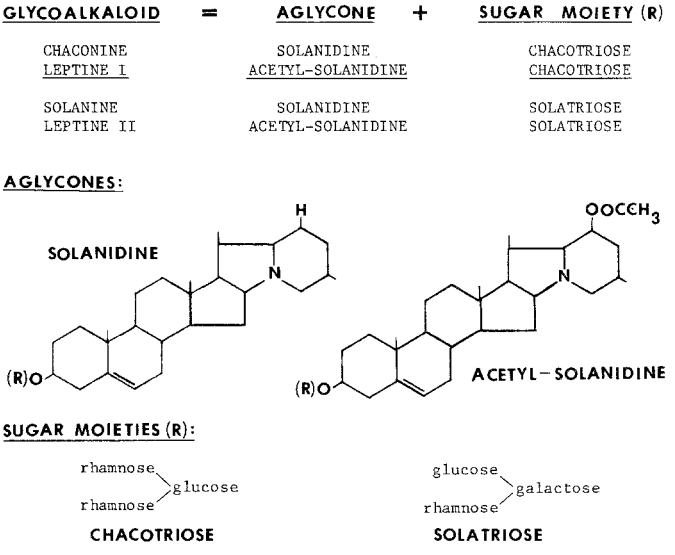

FIG. 1. Structures of leptines I and II, chaconine and solanine.

graded concentrations of individual glycoalkaloids was fed to CPB in laboratory bioassays. Of seven different glycoalkaloids tested against adult CPB (Sturckow and Low, 1961), leptine I and leptine III were by far the most potent (Figure 2). Similar wide differences in activity among glycoalkaloid forms were found in bioassays for effects on larval development.

Almost all studies of the response of CPB adults and larvae to glycoalkaloids suggest feeding inhibition as the primary and perhaps only effect of the different glycoalkaloids. How CPB sense the presence and concentration of a particular glycoalkaloid is not fully understood. Mitchell and Harrison (1985) showed that both tarsal and galleal sensilla respond with bursting activity to tom, sol, and chac at concentrations well within the range of those found in plant foliage. There is, however, no difference in threshold levels for tom and sol, even though tom is about fivefold more potent than sol in deterring adult feeding.

LEPTINES

Leptines I and II are acetylated forms of chac and sol, which are the two glycoalkaloids found in *S. tuberosum* and most other potato species. Potent leptine I (Figure 2) is identical in structure to weakly deterrent chac, except for the substitution of an acetyl on carbon-23 of the steroid aglycone (Figure 1).

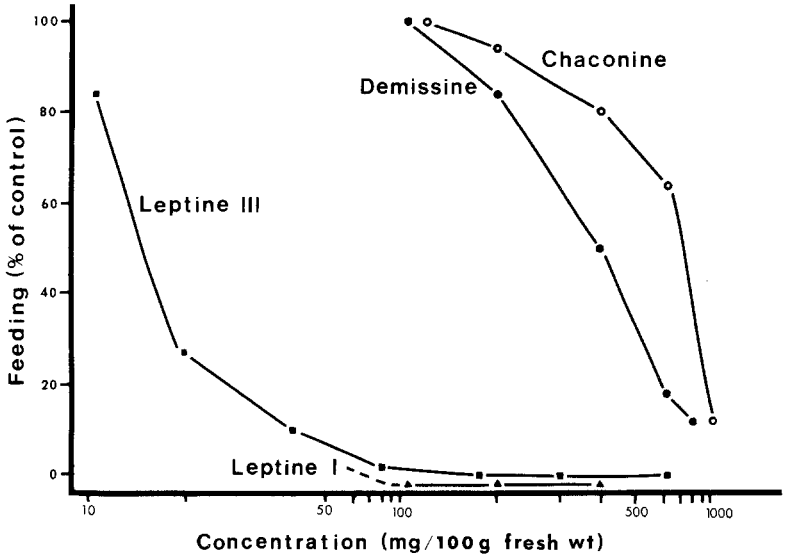

FIG. 2. Feeding rates of Colorado potato beetle on potato leaf disks infiltrated with acetylated (leptines I and III) and nonacetylated forms of chaconine and demissine. Redrawn from Sturckow and Low (1961).

Leptine II is the C-23-acetylated analog of sol. Two other leptines, III and IV, have been detected but not chemically characterized (Kuhn and Low, 1961). Leptine III is probably the acetylated analog of demissine and leptine IV the acetylated analog of commersonine. Foliage from resistant F_2 *S. chacoense* Bitter segregates that synthesized demissine and commersonine also synthesized small amounts of acetylated forms of the two glycoalkaloids (Sinden et al., 1980).

The biosynthetic pathway leading to C-23 acetylation is not known. However, microsomal fractions derived from leaves of leptine-synthesizing plants convert [^{14}C]solanidine to 23-OH-solanidine in the presence of NADPH (Osman et al., 1987). Acetylation of 23-OH-solanidine, catalyzed by an esterase synthetase, might then easily occur in intact cells. Acetylation was not, however, detected in cell-free incubations.

Leptines are difficult to isolate and purify because they are somewhat soluble in ammonia and because they are found in mixtures containing 6–12 major glycoalkaloids. Extracts containing an acetylated form of a particular glycoalkaloid always also contain 23-OH-substituted and -unsubstituted forms of the glycoalkaloid. Kuhn and Low (1961) isolated leptines I and III from a complex glycoalkaloid mixture containing major or minor amounts of at least 12 different

glycoalkaloids, a remarkable accomplishment at that stage of development of separation chemistry.

Because of the difficulties in isolating them, only two of the four known leptines have been tested for activity against CPB in infiltration bioassays. The threshold level for activity of infiltrated leptine I against CPB is not known because the concentrations that could be tested with adults (Figure 2) and larvae were limited by scarcity of the compound. Leptine III has not been tested for activity against larvae, and leptine II has not been tested against either adults or larvae. Even though leptines are not synthesized in tubers (Sinden et al., 1986a), their mammalian toxicity should probably be tested before they are introduced into the foliage of a food crop. Obviously, there is a need for further leptine isolations to provide purified compounds for additional tests of their effects on insects and other animals. In spite of the limited testing of leptines for activity against CPB, it is clear from the available data that infiltrated leptines I and III are at least five- to tenfold more potent in deterring adult feeding than their nonacetylated analogs. Acetylation of carbon-23 apparently converts weak or impotent glycoalkaloids such as demissine and chaconine into potent feeding deterrents (Figure 2).

BREEDING FOR RESISTANCE

Breeding for CPB resistance in potatoes began in Europe in the 1940s, before chemical defense by glycoalkaloids was known. Resistant hybrids were obtained (Torka, 1950) but resistance levels rapidly declined in backcross generations. Breeding for CPB resistance in Western Europe was discontinued when effective pesticide control became available in the 1950s, before the information on chemical defense could be tested for possible application in breeding. There is now new information on host selection by CPB (Bongers, 1980), new information on potato genetics and glycoalkaloid inheritance (Sanford and Sinden, 1972), and new sources of resistance (Dimock et al., 1986). Chemical and bioassay techniques have been improved, and there are new means of transferring genes between species and genera. Therefore, breeding for CPB resistance may now become more efficient.

Dimock and Tingey (1985) suggested using knowledge of chemical defense in a new approach to CPB resistance breeding, i.e., selecting parents and progeny on the basis of specific glycoalkaloids, rather than total glycoalkaloid concentration, should be more efficient because the inheritance of individual glycoalkaloids is likely to be less complex and assays for specific compounds less variable. Selection for more potent glycoalkaloid forms in *S. tuberosum* hybrids rather than for higher levels of weak deterrents such as sol and chac could also help in maintaining tuber glycoalkaloid concentration at present safe

levels (Sanford and Sinden, 1972). We are currently testing this approach with assays of hybrids between *S. tuberosum* and *S. chacoense* selected for leptine contents.

The remarkably potent leptines are found in only a few rare *S. chacoense* accessions (Sinden et al., 1986a) among more than 200 *Solanum* species analyzed for glycoalkaloid composition (Schreiber, 1968). Most of the 60 *S. chacoense* accessions we analyzed for leptines did not contain plants that synthesized leptines at levels high enough to detect with sensitive gas chromatographic methods. Both nonleptine and high-leptine genotypes were, however, sometimes found in the same accession, e.g., 458313-4 and 458313-1 from accession 458313 (Table 1).

S. chacoense is highly polymorphic for both resistance level and glycoalkaloids. Resistance levels in the species range from susceptibility comparable to that of host *S. tuberosum* to nonhost immunity (Torka, 1950), apparently because of the wide segregation for glycoalkaloid levels and structural forms in the species (McCollum and Sinden, 1978). Most *S. chacoense* genotypes synthesize the nonacetylated *S. tuberosum* glycoalkaloids, sol and chac. Both the leptine and nonleptine sibs we selected within individual accessions (sib-clones), and clonally propagated for our study of leptines and resistance, synthesize sol and chac. The sib-clones differ, however, in the portion of the total glycoalkaloid that is acetylated. In foliage of the leptine clones, a major portion of the total glycoalkaloid is present as acetylated forms of sol and chac, i.e., leptines I and II (Table 1 and Figure 1).

The wide segregation for leptine synthesis among *S. chacoense* genotypes made it possible to verify the major role for leptines I and II in the chemical defense of the species. Laboratory bioassays and field measurements of the resistance of three pairs of sib-clones selected within accessions for wide differences in leptine level between the two clones in each pair (Table 1) confirmed the high potency for infiltrated leptines found in leaf-disk bioassays (Figure 2) by Sturckow and Low (1961). The close relationship between the field resistance and endogenous leptine level in the clones clearly demonstrates the important role of leptines in the chemical defense of *S. chacoense* plants in the field. The sib-clone that synthesized primarily sol and chac, but little or no leptine, was invariably more susceptible than the leptine-synthesizing sib within the pairs in both laboratory bioassays and field tests. The clone that synthesized a relatively low level of sol and chac (320287-2, Table 1), and no leptines, was nearly as susceptible as *S. tuberosum* (Sinden et al., 1986b), whereas the three clones that synthesized high levels of acetylated forms of chac and sol (leptines I and II) were nearly immune.

Nonleptine and leptine synthesizing clones from the same accession, e.g., sib-clones 458313-4 and 458313-1, have similar total glycoalkaloid levels. The sib-clones from a single accession are also morphologically similar. Since gly-

[c] Percent of larvae surviving to adult eclosion.

coalkaloid content is the only factor in *S. chacoense* that has been associated with CPB resistance, the differences in resistance between sib-clones from a single accession are probably caused by differences in the forms of glycoalkaloid (primarily sol + chac in nonleptine sibs vs. primarily leptines I + II in leptine sibs), and not by total glycoalkaloid levels or differences in morphology.

Total glycoalkaloid level, regardless of glycoalkaloid forms, is also an important determinant of resistance in *S. chacoense* (Sinden et al., 1980) and other *Solanum* species (see Tingey, 1984). Although sol and chac are only weak deterrents of adult feeding (Figure 2) and may not affect larval development even at concentrations as high as 900 mg/100 g fresh weight (Hsiao, 1974), very high concentrations of sol and chac can confer considerable resistance to adult feeding, e.g., clone 458313-4 vs. 320287-2 (Table 1).

MEASURING RESISTANCE

Field testing for CPB resistance in large breeding populations is impractical, primarily because of the wide variation in density of infestations and resulting CPB damage. It may be prudent to select for moderate resistance levels resulting from feeding deterrents in the foliage that cause less adult feeding, slower larval development, and reduced fecundity. These subtle effects may be important in integrated pest management programs and less likely to be rapidly overcome by CPB. To measure such resistance levels in field tests would require extensive replication. Replication such as we had in field tests of the *S. chacoense* segregates (Sinden et al., 1986b) is usually not possible in early breeding generations when few seed tubers of individual segregates are available.

In assaying *S. chacoense* segregates, we measured the effects of leptine level on three components of field resistance using field infestation tests and laboratory bioassays: (1) antixenosis of plants in the field, (2) adult feeding deterrency and, (3) inhibition of larval development. We were also searching for efficient laboratory bioassays well correlated with field results that might be effective in screening large numbers of progeny in early breeding generations. Since we expect lower resistance levels in interspecific hybrids than in *S. chacoense*, bioassays sensitive enough to detect small differences in resistance level are needed.

Antixenosis was measured by placing adult CPB between rows of test plants in the field and recording the number of adults per plant the following day. Recording of plant damage severity (Table 1) also measured antixenosis, but probably measured the combined effects of adult attraction and feeding deterrency. Differences in feeding deterrency caused by endogenous contents of leptines were easily measured in a two-way preference test using leaf disks and adults collected from the field. The high correlation ($r = 0.99$; $P < 0.01$)

between numbers of adults on the field plants and feeding rates in leaf-disk bioassays suggests a close relationship between antixenosis in field plantings and feeding deterrency in laboratory bioassays. Feeding rates on leaf disks were also highly correlated ($r = 0.88$; $P < 0.01$) with the estimates of field antixenosis by rating damage severity. Thus, leaf-disk bioassays may be an efficient means of detecting the presence of feeding deterrents in segregating progenies (Schalk and Stoner, 1976).

Only a few larvae survived to adult eclosion on detached leaves from leptine-synthesizing clones (Table 1). Measuring CPB development from larval hatching to adult eclosion is, however, too time-consuming to evaluate resistance of progeny in breeding populations. Cantelo et al. (1987) found that recording development stage of neonate larvae after feeding for only four days on detached foliage was more sensitive in detecting differences among two of our *S. chacoense* segregates and a susceptible *S. tuberosum* cultivar than leaf-disk bioassays with adults or other measurements of larval development. All of the bioassays we tested differentiated the nonleptine from the leptine-synthesizing sib-clones. However, the leaf-disk preference tests with adults and the four-day test with neonate larvae appeared to be the most efficient of the various laboratory bioassays.

CONCLUSIONS

Measuring the resistance of plants segregating for suspected defense compounds can be an effective means of determining their role in the defense. Chemical assays, selecting and cloning desired segregates, or even breeding to create desired genotypes may be necessary. The availability of cloned or inbred plants that produce suspected defense compound(s) in a range of levels can greatly facilitate investigations of the compound(s) importance in conferring resistance to plants in the field.

The reason for the remarkable increase in glycoalkaloid potency against CPB as a consequence of glycoalkaloid acetylation remains to be determined. This will require testing pure forms of leptines for their electrophysiological, membrane, and biochemical effects.

If we are successful in transferring an *S. chacoense* gene(s) for acetylation of sol and chac to *S. tuberosum*, leptine concentrations may be lower and therefore may not confer the same high level of CPB resistance. However, even somewhat lower resistance levels could mean fewer egg masses, fewer larvae, and less plant damage. If the proposed breeding approach appears feasible after leptine inheritance and the correlation between resistance and leptines are determined in small populations of hybrids, we plan to assay large numbers of hybrid and backcross progenies for leptines and then bioassay the leptine segregates

that also have desirable horticultural characters. This approach could reduce the need for large field tests in the early generations of breeding.

BIOASSAY TECHNIQUES
An Ecological Perspective

JANE L. WOLFSON

Department of Entomology, Purdue University
West Lafayette, Indiana 47907

(Received September 15, 1987; accepted March 15, 1988)

Abstract—Research in plant-herbivore interactions relies heavily on bioassays as analytical tools. Successful bioassay experiments are difficult to design because of the need to reconcile the exacting requirements of hypothesis testing with the dynamic nature of the plant and insect test organisms. Several research protocols are discussed that utilize ecologically flawed techniques to answer ecologically important questions.

Key Words—Bioassay design, bioassay flaws, plant-insect bioassays.

Bioassays are an important research method for testing hypotheses concerning plant-herbivore interactions. In plant-herbivore research, "bioassay" is defined in broad terms: any assay in which a living organism is permitted to declare whether a specific variable (e.g., presence or absence of an allelochemical, age of the plant tissue, concentration of a nutrient, presence of a plant pathogen) "makes a difference" as to how the organism fares; i.e., does the variable have an impact on the herbivore's life history parameters? Bioassays have been used extensively to discover plant characteristics that have been, or could be, of either ecological or evolutionary importance to herbivores. Many studies have used bioassays to full advantage to describe the role of the variable being studied, but this has not always been the case. Bioassays have also been designed and interpreted improperly. In some instances, researchers have been so focused on the question at hand that they seem to have lost sight of the ecological framework in which they were working.

Some recent review articles have dealt with bioassays of insect feeding preferences (Lewis and van Emden, 1986), insect oviposition preferences

0098-0331/88/1000-1951$06.00/0

(Singer, 1986), and postingestive effects of phytochemicals on insects (Berenbaum, 1986). In this discussion, I focus on bioassays performed to evaluate the impact of a plant characteristic on the growth and development of herbivorous insects. It is more logical to assess the impact of tannins on herbivorous insects by feeding tannin-containing material to the herbivore in question than by evaluating the protein-precipitating quality of the tannin. Similarly, assessing the impact of a proteinase inhibitor on a herbivore by rearing the insect on food containing a proteinase inhibitor is preferable to *in vitro* assays of trypsin inhibitory activity. While the logic of testing hypotheses with the relevant organisms is intuitive, designing the proper experiment is difficult.

Currently, there are no guidelines on the best way to design a bioassay in any particular instance, but I have observed some common types of errors. Bioassays are often designed to answer questions by manipulating and simplifying a complex system. The manipulation and simplification can involve making assumptions that are often never specifically addressed and may be inappropriate. The complexity of the test system often prohibits controlling all relevant factors; it is the rare researcher who has total control over such things as the genetics of both plant and insect test organisms, the environment to which these organisms have been exposed, or a complete understanding of how the testing environment interacts with the test. Such uncontrolled sources of variation often enter into an experimental design; they become a major problem only when their possible impact on the experiment is not considered. It is possible for an experiment to be well executed yet for the results to have no relationship to the ecological context of the original question.

I will present some "typical" problems of the type described. In this brief discussion I make no attempt to cover all types of experiments or all types of problems. My purpose is to generate discussion and reconsideration of certain bioassay methodologies, methodologies which purport to answer ecological questions but which can have important ecological flaws.

Laboratory vs. Field Populations

Many researchers depend on laboratory populations of insects for their bioassays. Laboratory populations are available as needed and are usually disease- and parasite-free, but they have also been subjected to laboratory selection. Selection for survival under laboratory conditions can alter the genetic composition of the population as can genetic drift from inbreeding or population crashes. Such changes can dramatically alter the biology of a laboratory population. Lab populations have been known to lose their ability to grow successfully on their original host plants (Guthrie and Carter, 1972) and to develop fertility problems (Bledsoe, personal communication). Since such major changes in biologically relevant characteristics are possible under laboratory rearing,

broad extrapolation to natural populations from experiments on lab populations could certainly be inappropriate. This is not to suggest that the use of laboratory populations should be abandoned but rather, that we should be aware of their limitations.

If a bioassay is intended to determine, for example, the biological activity of different formulations of a compound, then using a laboratory population can be appropriate. Even though the lab population may no longer be representative of the wild population, it is still a living system. On the other hand, a bioassay carried out with a laboratory population could be inappropriate to test a hypotheses about a type of insect, i.e., generalist herbivores, even if the species is considered a generalist feeder. The physiological adaptations that contribute to being a successful generalist could have been lost or altered under laboratory rearing. Lab populations of insects can be very useful, but before making generalizations to wild populations from experiments performed with lab populations, the relationship between the lab population and its wild counterparts must be monitored (Huettel, 1976; Reese and Field, 1986).

Complexity of Interactions

Most ecologists doing research in plant–herbivore interactions are interested in understanding the relationships between plants and their herbivores. They are attempting to answer such questions as: why is this plant species eaten by this insect and not by another?, why at this time of year and not later or earlier?, why only in this habitat and not elsewhere? An ecologist walking in the woods and seeing some individual trees with leaves just expanding while most of the population has fully mature leaves, or some insects hatching or flying about while others are still dormant, would note that the observed species or the aberrant individuals were different from their cohorts. Yet some incautious researchers wanting to determine, for example, whether leaf age is important for an insect species might use the plants with different times of leaf expansion as a source of material for a "natural experiment" on the effects of leaf age. They would use aberrant plants whose leaves are expanding one or even two months later than their congeners to provide test material to be compared with the abundant mature leaves. This experimental protocol, intended to measure the effect of leaf age, tacitly assumes that leaves from these two types of trees differ only in age; that is, leaf material from individual trees which are obviously different from most of the population are representative of young leaves from the main population in which leaf expansion occurred two months earlier. Unfortunately, a comparison of insect growth rates between insects growing on "typical" trees and insects growing on "abnormal, late-leafing trees" does not necessarily say anything about the effect of leaf age on insect growth. If the delay in time of leaf expansion was related to herbivory during

the previous year, or a pathogen, or root-infesting insects, or some site-specific soil characteristic, the bioassay evaluates the impact of the stress on leaf quality, but does not answer the question posed. The leaf-age question posed by the ecologist is not trivial and is difficult to answer. Proper testing of such a question requires the imposition of appropriate controls; to test for the effects of leaf age, only leaf age should differ between treatments. Some methods that have been used successfully involved using altered leaf material [frozen leaf tissue (Feeny, 1970), freeze dried leaf tissue (Broadway et al., 1986)] or altered insects [manipulating time of egg hatch such that larvae are available to feed on leaves when those leaves are at the appropriate age, (Schroeder, 1986)].

Another type of problem seen with "natural" experiments has been pointed out by Neuvonen and Haukioja (1985), namely, that it is impossible to sort out cause and effect associated with natural levels of herbivore infestation. A hypothesis associating differences in plant quality with differences in levels of herbivory (e.g., do plants with high-quality foliage have greater amounts of herbivory?) cannot be tested by assessing the levels of herbivory under natural field conditions. Herbivory can cause herbivore-induced chemical changes (more to this point later) which will alter leaf quality. Secondly, herbivores are very selective in their oviposition and food preferences and can detect subtle differences in plant chemistry. Therefore the differences in chemistry observed in plants that are undergoing different natural levels of herbivory could be either the result (herbivore-induced changes) or the cause (oviposition or feeding stimuli) of the observed levels of herbivory. In addition, plant chemistry can affect the behavior of parasitoids and predators of the herbivores so that the distribution of herbivores observed in the field could be different from the distribution that the "plant quality" characteristics of the plants would have evoked from the herbivores (Vinson, 1974).

Experimentally Induced Changes in Host Plants

The past few years have seen a dramatic increase in research documenting changes induced in host plant quality vis-à-vis insect herbivores as a result of herbivory or disease. Plant pathogens can induce feeding deterrents (Rowan and Gaynor, 1986), lower host-plant quality (Karban et al., 1987), or can be associated with increased food preference (Lewis, 1979). Physically damaging leaves, whether through mechanical means, artificial defoliation, or natural or controlled herbivory can alter the chemical characteristics of the leaf tissue. Both increases and decreases in leaf nutritional quality have been reported in response to herbivore damage as have alterations in leaf acceptability (Carroll and Hoffman, 1980; Edwards et al., 1985; Tallamy, 1985; Wagner and Evans, 1985; Williams and Myers, 1984). The negative induced effects can be very rapid (within hours) (Ryan and Green, 1974; Carrol and Hoffman, 1980), mod-

erately rapid (two days to two weeks) (Haukioja and Niemela, 1977; Karban and Carey, 1984; Edwards et al., 1986), or long lasting (three to five years) (Neuvonen and Haukioja, 1984; Wratten et al., 1984; Wallner and Walton, 1979). Although the final chapter on the importance of induced responses has certainly not been written (Fowler and Lawton, 1985), any bioassay utilizing field collected materials needs to consider the possible role of induced changes in leaf quality. It would seem essential that the specific history of field collected material be known; plants that appear similar could be very different. In addition, extreme care has to be taken to control for changes associated with the experimental regime (damaging leaves while collecting or sampling, etc.).

In addition to induced changes resulting from leaf damage or disease, plant quality can be affected by various environmental factors such as flooding and root cutting (Louda, 1986), light intensity (Woodhead, 1981; Khan et al., 1986), drought (Mattson and Haack, 1987), available nutrients (Wolfson, 1982; Wermelinger et al., 1985), or interactions among these variables (Waring et al., 1985). (See White, 1984, for discussion on the impact of "stress" on plant quality.) Although all of these sources of variation cannot necessarily be avoided in field-grown materials, in a bioassay experiment we can control for the phenotypic plasticity of plants by using appropriate controls. Additionally, with modern environmental chambers, we can grow plants using a defined growing regime under controlled conditions so as to minimize environmental variation. Environmental-chamber grown plants are not "natural" but they are "definable."

Over 30 years ago Beck (1956) advised abandoning the use of excised leaf tissue in studies attempting to delineate host plant relationships of herbivores (i.e., which plant species can or cannot support growth of an herbivore and why). His recommendation was based on data from plant physiologists indicating that within hours of excision leaves undergo biochemical degradation and changes in water relationships. He concluded that because of the changes in the host plants, it was difficult, if not impossible, to define host-plant relationships with experiments that used excised plant tissues. How can one sort the insect's response to the plant from the insect's response to changes in the plant that resulted from excision? Unfortunately many researchers continue to use excised tissues with, apparently, little appreciation of the complexity of plants. In some research protocols, plants are treated as if they are inert insect food substrates (but see Dabrowski and Bielak, 1978). I can cite the example of a PhD student who was working on host-plant resistance in a major crop. He was using one of that crop's important herbivores to bioassay his test cultivars, and he thought he had identified resistant germ plasm. His bioassay consisted of comparing growth rates of insects reared on excised leaves in moist Petri dishes which were held in the dark in a temperature chamber. The leaves were changed only every five days. I tried to explain that with his protocol he could not possibly

differentiate between levels of host-plant resistance among his cultivars and the insect's response to the, presumably independent, differential rates of leaf senescence among the cultivars.

Plants should be expected to respond to manipulations and mutilations. Why ever assume that comparisons between excised leaves maintained in water to excised leaves out of water compare leaf water content and nothing else. While all leaves change after excision, a leaf kept in water is probably less different from its original state than a leaf allowed to desiccate. Similarly, leaves cultured in a toxin solution to foster toxin uptake or infused with the toxin could have been stressed by presence of the toxin. Therefore the experimental leaves differ from the control leaves not only by the presence of the toxin but also by the metabolic stress. While it is certainly not necessary to abandon all experimental protocols using excised leaf tissue, problems inherent in the method need to be kept in mind, and controls designed with great care. It might be preferable to evaluate the importance of leaf water content or the effect of a toxin by using artificial diets or experiments designed with stepwise changes.

Defining Proteins

The statistical association between the presence or absence of specific leaf chemicals and host plant quality has given rise to some specific hypotheses about the ecological importance of the chemicals, e.g., late-season forest herbivores are protein-limited. Some attempts to test such hypotheses have assumed that different compounds within a class of compounds were effectively the same vis-à-vis the insect. A test of protein limitation might utilize casein, hemoglobin, or egg white protein, for example, to supplement leaf protein, or a test on the effect of an undefined host-plant tannin might use quebracho tannin, tannic acid, or sorghum tannin. Recently several researchers have been using "ecologically relevant" plant-extracted tannins (Berenbaum, 1983; Manuwoto et al., 1985) in preference to commercially available tannins, acknowledging the differences among tannins documented by biochemists (Asquith and Butler, 1986; Mole and Waterman, 1987). The inability, for example, of a herbivorous beetle to respond to protein supplementation when the protein supplement is unrelated to its normal dietary protein can shed little light on the protein limitations of the beetle. Although most insects require protein, not all proteins have the same amino acid composition, and it is ultimately the amino acids derived from proteins that are limiting. By testing the "protein limitation" hypothesis with an ecologically irrelevant protein, the researcher is assuming that the test insect has the appropriate proteinases for digesting the test protein, that the amino acid ratio of the test protein is appropriate for the insect, that the change in protein concentration did not place the insect under metabolic stress, that the

protein would not be bound by tannins and would remain available for nutritional purposes, etc. A better way, perhaps, to test this hypothesis would be to determine the amino acid composition of the natural food and supplement with a balanced amino acid mixture. Recently Murdock and colleagues (personal communication) have evaluated the impact of a proteinase inhibitor on a bruchid beetle. They were able to reverse the inhibitor's negative impact on growth and development by supplementing the inhibitor-containing diet with a mixture of amino acids that reflected the ratio found in the host. In contrast to protein supplementation, this amino acid supplement method could bypass the problem of tannin precipitation, the possible stress of increased proteinase production, and would provide the insect with nearly the same amino acid mix as would normal protein digestion. Another possibility might be to extract the plant protein or specific protein fractions and then supplement the diet with this material (Nawrot et al., 1985).

Artificial Diet is Just That—Artificial

Artificial diets were crucial for the development of insect dietetics and are essential for the economic maintenance of many insect laboratory populations, but they can have their shortcomings in bioassays intended to assess the ecological importance of plant allelochemicals. Artificial diets usually have one of two problems: they are suboptimal or they are superoptimal. Compared with even the most susceptible host plants, artificial diets often foster more rapid growth (Beck, 1974; Reese and Field, 1986). The luxuriant growth often observed on these "super foods" could make insects much less susceptible to the allelochemical being tested. As recently discussed by Berenbaum (1986), tests of chemicals in artificial diets could be compromised by eliminating naturally occurring synergistic interactions (Berenbaum and Neal, 1985) or by fostering unnatural interactions between nutrients and allelochemicals. Nowhere is this made more clear than in Berenbaum's observations (1986) regarding the potential importance of tannins to herbivores; she notes that in all cases in which tannins are reported to reduce digestibility, artificial diets were used, whereas in those experiments in which tannins did not reduce digestibility, the test material was natural leaf materials.

Not all insects are easily reared on artificial diets, and in some instances, suboptimal diets have been used to test specific chemicals. By suboptimal, I mean diets that permit some development but that cannot be used to rear larvae from hatch to pupation or diets on which developmental rates and survival are markedly inferior to the natural food. Such a suboptimal diet is a source of stress for the insects even without any addition of test chemicals. The problems of testing allelochemicals in this situation are clear: how can the impact of a test chemical be evaluated on a highly stressed insect? What does a change from

50% mortality on the diet to 75% mortality when the test compound is incorporated into the diet indicate about the compound's possible importance under natural conditions? It is difficult to determine.

Experimental Biases Large and Small

We Prefer to Measure What We Can Easily See. Researchers choose late instar larvae for bioassays of selected compounds presumably because larger larvae are easier to handle and measure than their younger counterparts. It is much easier to measure such things as consumption rate, growth rate, or frass production with large larvae. There are several potential problems associated with the use of older larvae, but their relative importance depends on the questions posed in the research. Young larvae are generally much more sensitive than older larvae (Reese et al., 1982; Rossiter et al., 1986), and plant characteristics, either physical or chemical, of potential importance to insects could be overlooked if only older larvae are tested. Compounds or concentrations of compounds that produce little or no acute effect on older larvae could have chronic effects, but testing for chronic effects requires longer assays, which, in turn, would necessitate starting with small, young, difficult-to-handle, larvae (Reese and Beck, 1976). Another problem associated with testing only older instars is the impact of changing food on the results of the bioassay. In some protocols, a cohort of the test insect is reared on an optimal diet, either artificial or natural, and then, when the appropriate stage is reached, only the experimental insects face a radical change to a new test diet (the control insects might have a slight change such as the incorporation of solvent into their diet). For some insects, changing food plants during larval development, even if the new host plants are within their host plant range, can negatively impact growth and development (Scriber, 1979). Therefore, when using older larvae in a bioassay, we need to control not only for the treatment, but also for the trauma of imposing the treatment.

Time Goes on Even When Growth Doesn't. When the test chemicals included in bioassay prove effective but do not cause acute toxicity, they often impact the insect's growth and development. Larvae in the different treatments are, therefore, of different sizes. This difference in size will affect ease of handling during weighings or transfers onto fresh food. Since smaller larvae are much more susceptible to injury in a bioassay (e.g., drowning in a water droplet, being pierced by a hair on a paint brush, falling from a leaf), mortality data should not be gathered if the bioassay procedure involves considerable handling of larvae. Even though under natural conditions smaller larvae would probably suffer greater mortality from both biotic (e.g., predation) and abiotic factors (e.g., wind or rain), these natural sources of mortality are not the same as those

found in the laboratory, and the laboratory mortality observed, although associated with the treatment, is not necessarily a result of the treatment.

A Leaf can be More than the Sum of Its Constituent Parts. Allelochemicals found in leaf tissue naturally cooccur with a complex of other materials. Synergists have been described in some plants (Berenbaum and Neal, 1985) and might exist in others. Similarly, some allelochemicals, e.g., glucosinolates and cyanogenic compounds (Kjaer, 1960; Jones, 1972) cooccur with their hydrolytic enzymes. The activity of the toxin in the absence of the enzyme would be expected to be very different than in its presence (but see Erickson and Feeny, 1973). Therefore, evaluation of isolated chemicals in artificial diets could be misleading.

Wherein Lies the Solution?

The preceding is not intended to be a condemnation of all planned bioassay research. Rather, my intention was to stress the necessity, in bioassay experiments, of focusing clearly on the specific question being asked and to inquire as to whether the planned bioassay can be used to answer that question: i.e., do the controls and the treatments differ only by the variable in question? In the examples cited above, the answer often would have been no.

I have recently been involved in the development of two bioassay systems that appear to withstand many of my earlier criticisms. In these systems, the parameters are well defined and the results repeatable (Murdock et al., 1988; Wolfson and Murdock, 1987b). These bioassay systems are not based on artificial diets; rather, they are based on the natural food turned into an artificial substrate. Both systems were developed to assess the impact of proteinase inhibitors, either proteins or peptides, on a herbivore, and the bioassays work well for that purpose. They have not been tested with other classes of chemicals. The system for leaf-feeding insects has been used extensively with herbivorous beetles and Lepidoptera and involves incorporating the test chemical into a gelatin solution that is then painted onto the leaf surfaces (either upper, or lower, or both) (Wolfson and Murdock, 1987a,b). The compounds remain active while on the leaf and, since the compounds are in gelatin solution rather than a solvent, there is little chance of their entering the leaf and interacting with the leaf at the cellular level. Excised leaves from the insect's host plant are the substrate used for the gelatin, but the plants from which the leaves are taken are grown in environmental chambers, under controlled and prescribed conditions, and only plants of defined age classes are used. This procedure helps us avoid some of the inherent variability in plants associated with age and environmental variation. In addition, leaves in all of our bioassays are changed daily so that changes associated with senescence remain constant and are evenly distributed over all

treatments. In these assays, we are assessing the impact of the test compound on the insect and changes in the leaf associated with excision would be present in all treatments.

The second bioassay system involved the development of an artificial seed system for use with bruchid beetles (Shade et al., 1986), primarily *Callosobruchus maculatus*. Our confidence in this system rests in the ability of our test insects to grow and develop in the artificial seeds made from their natural host beans (cowpeas) at rates and with developmental characteristics that are statistically indistinguishable from intact seeds. In a comparison between the artificial seeds and intact cowpea seeds, there was no significant difference in larval developmental time, mortality, prereproductive adult dry weight, rate of adult emergence, adult longevity, postreproductive adult weight, and fecundity. Test materials can be easily incorporated into the artificial seeds. Infested seeds are then monitored for adult emergence, and comparisons in developmental time, adult weights, and fecundities can be made between growth in the presence and absence of the test chemical.

Other bioassay systems have been developed to answer specific research questions because the researchers were dissatisfied with previously developed tests or were working with an insect–plant system that had no described bioassay. Bioassays directed to answering ecological questions are difficult to design and, as researchers, we are often faced with choosing the lesser of evils. Compromises have to be made, but we need be aware that we are making them and make clear to our colleagues that we understand the possible implications of those compromises.

Acknowledgments—The work was supported, in part, by a grant from the National Science Foundation (BSR-8415661). I thank Larry Murdock and Virginia Russell for advice and discussion. This is publication No. 11,259 of the Purdue University Agricultural Experiment Station.

PLANT–INSECT COEVOLUTION AND INHIBITION OF ACETYLCHOLINESTERASE

M.F. RYAN and OONAGH BYRNE

Department of Zoology

Belfield, Dublin 4, Ireland

(Received September 15, 1987; accepted March 15, 1988)

Abstract—The theory of plant–insect coevolution provides for diffuse coevolution and the expectation that plants evolve broad-spectrum chemical defenses with which some insects coevolve by detoxifying and using the compounds as host-location cues. Specific biochemical modes of action have been assigned to relatively few such defense chemicals and one major class, the terpenoids, is investigated here. Six terpenoids inhibited the enzyme acetylcholinesterase (derived from electric eel) and elicited the appropriate in vivo effects of insect paralysis and mortality. The diterpene gossypol was a reversible uncompetitive inhibitor. Five monoterpenes, representing a range of functional groups, were reversible competitive inhibitors apparently occupying at least the hydrophobic site of the enzyme's active center. Such data suggest the involvement of acetylcholinesterase in the coevolved insect response to terpenoids.

Key Words—Herbivory, pheromones, chemical defense, monoterpenes and diterpenes, insect paralysis and mortality, enzyme evolution, coevolution, acetylcholinesterase inhibition, plant–insect coevolution.

INTRODUCTION

The study of coevolution has generated much interest since Ehrlich and Raven coined the term with the statement "one approach to what we would like to call coevolution is the examination of patterns of interactions between two major groups of organisms with a close and evident ecological relationship, such as plants and herbivores" (Ehrlich and Raven, 1964). Although a key influence on present-day studies of coevolution, Ehrlich and Raven were not the first to recognize its existence. Darwin was aware of the special relationships between

0098-0331/88/1000-1965$06.00/0

insects and the plants they pollinated: ". . . thus can I understand how a flower and a bee might slowly become simultaneously or one after another, modified and adapted in the most perfect manner to . . . each other" (Darwin, 1859). A comprehensive review of contributions subsequent to Darwin's would be rather inappropriate here, but the following seem especially significant.

Janzen (1980) defined coevolution as when "an evolutionary change in a trait of the individuals of one population is followed by an evolutionary response by a second population to the change in the first." By this definition, the evolution of each trait is due to the others, a reciprocal condition that views plant–insect interactions as one to one. A more general definition is that coevolution has occurred when the interaction between two or more ecologically interacting species involves an adaptive response to genetic change in the other(s) (Futuyama, 1983). This is also less restrictive, allowing for the interaction of several and not specifically two species. Known as diffuse coevolution (Janzen, 1980), this occurs where many plants have evolved chemical and physical defenses against a diverse group of insects and also where many insects have acquired the ability to detoxify a wide range of plant chemicals (Futuyama, 1983).

One consequence of the theory of diffuse coevolution is the expectation that plants would select a broad spectrum of defense, i.e., one or a few plant chemicals that would be antagonistic to a wide range of herbivorous insects. This is an economical measure, as the production of secondary chemicals is at the expense of other areas of metabolism. For example, tobacco plants especially rich in alkaloids are stunted, suggesting that energy allocated to the manufacture of nicotine has been abstracted from energy available for growth (Whittaker and Feeny, 1971). Also it would be metabolically impractical for any plant to evolve a new chemical against every insect species attacking it. Accordingly, some secondary plant chemicals should act as broad-spectrum insecticides, and indeed some have been used as such for centuries. The dried flower heads of *Crysanthemum cinerariaefolium* (Compositae) and *C. coccineum* contain pyrethrins, potent insecticides with a rapid knockdown action.

A chemical class conspicuous among plant secondary compounds and containing chemicals inimical to insects are the terpenoids (Mabry and Gill, 1979). The cyclic monoterpene pulegone, an irritant commonly found in mint oils, deters feeding by the slug, *Ariolimax dolichophallus* (Rice) and by the fall army worm, *Spodoptera frugiperda* (Smith) and repels the German cockroach, *Blattella germanica* (L.) (Gunderson et al., 1985). Added to diet, it killed the larva of the fall armyworm and decreased pupation by the southern armyworm (Brattsten, 1983). Resistance of western red cedar wood, *Thuja plicata* (D.), to insect attack is attributed to the presence of monoterpenes, of which methyl thujate is toxic to larvae of the black carpet beetle, the furniture beetle, and the case-making beetle (Becker, 1963). Two other monoterpenes produced by western red cedar, β-thujaplicin and γ-thujaplicin, are both highly insecticidal against

the larva of the old-house borer, *Hylotrupes bajulus* (Cerambycidae), a common pest of structural timber in Europe (Becker, 1963). The diterpene gossypol, an abundant diterpene in the lysigenous glands of cotton, decreases weight gain in larvae of the tobacco budworm and pink bollworm (Hedin et al., 1983) (for many other examples of terpenoid–insect interactions, see Mabry and Gill, 1979). However, specific biochemical modes of action have been assigned to few such compounds.

A common structural feature of terpenoids is their hydrocarbon skeleton, which in turn confers upon them a common property, hydrophobicity. Many hydrophobic compounds are associated with protein deactivation and enzyme inhibition, and one enzyme particularly susceptible to hydrophobic interactions is acetylcholinesterase (Hansch and Deutsch, 1966), present in the neuromuscular junction. This enzyme also functions in the peripheral sensory nervous system of the insect antenna (Sanes et al., 1977). The present report quantifies the toxicity of a range of plant terpenoids to a nonadapted insect and provides what seems to be the first evidence that they are reversible inhibitors of acetylcholinesterase.

METHODS AND MATERIALS

Compounds that inhibit or inactivate acetylcholinesterase (AChE), cause acetylcholine to accumulate at the cholinergic site. This produces continuous stimulation of cholinergic nerve fibers throughout the central and peripheral nervous system, followed by paralysis and death (Corbett et al., 1984). Accordingly, we used an in vivo assay established as appropriate to quantify insect mortality and an in vitro assay for AChE inhibition.

The following five monoterpenes, representing a range of functional groups, were selected for investigation: citral (aldehyde), pulegone (ketone), linalool (alcohol), (−)-bornyl acetate (ester), and cineole (ether); for comparison a single diterpene gossypol (alcohol) was included (Figure 1). As these monoterpenes are characteristic constituents of plant leaves and as gossypol is associated with pigment glands of cotton seed, the test insect, *Tribolium castaneum*, a pest of stored grain, may be viewed as a nonadapted species. The insecticide-susceptible *Tribolium* colony was derived from stocks originally supplied by the University of Chicago.

Insect Mortality. Mortality was assessed by an F.A.O. contact method devised to measure the resistance of agricultural insect pests to insecticides (Anon., 1970) with the modification that acetone served as solvent in place of *Risella* oil. Usually four concentrations of each test compound were used within a range established by previous experiment as eliciting mortality (for specific concentrations see Figure 2). There were two replicates of each treatment and

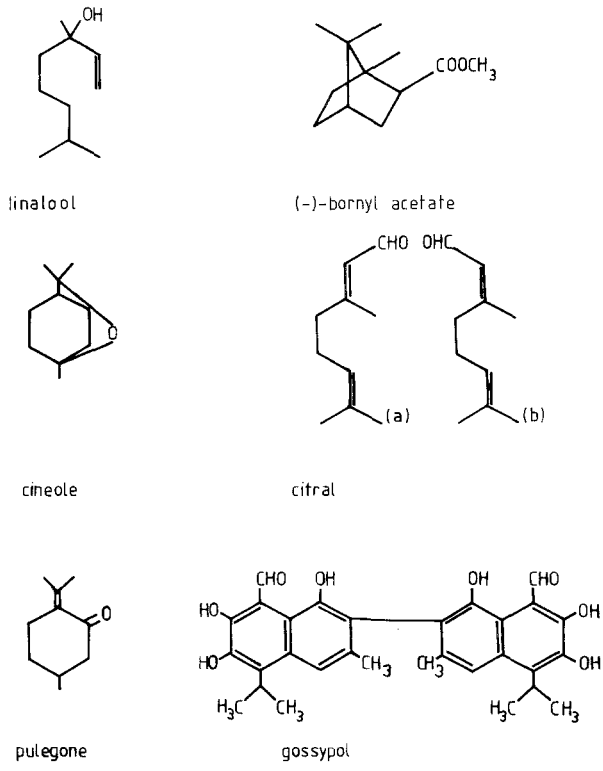

FIG. 1. Configurations of the five monoterpenes and the diterpene (gossypol) selected for investigation: citral is a mixture of geranial (a) and neral (b).

of the control, i.e., solvent only. Solutions were pipetted in 0.5-ml aliquots onto filter papers (5.5 cm diam.) that were allowed to dry (approx. 1 min). Then batches of 20 beetles, prestarved for 24 hr, were transferred to each treated paper where they were confined by plastic arenas, sealed on top by glass plates, that were placed in an incubator (28°C). Mortality was estimated from knock-down, i.e., the inability of the insect, after 5 hr in the arena, to stand or walk after a gentle push forwards with a forceps. Correction for control mortality was made using the Abbott formula (Abbott, 1925), $P_T = [(P_0 - P_c)/100 - P_c] \times 100$, where P_T is corrected percentage mortality, P_0 is observed mortality, and P_c is control mortality. LC_{50} values (concentrations eliciting 50% mortality), were derived by interpolation from lines representing dosage-mortality trends drawn on logarithmic probability paper; such lines were constructed using the regression formula for best fit.

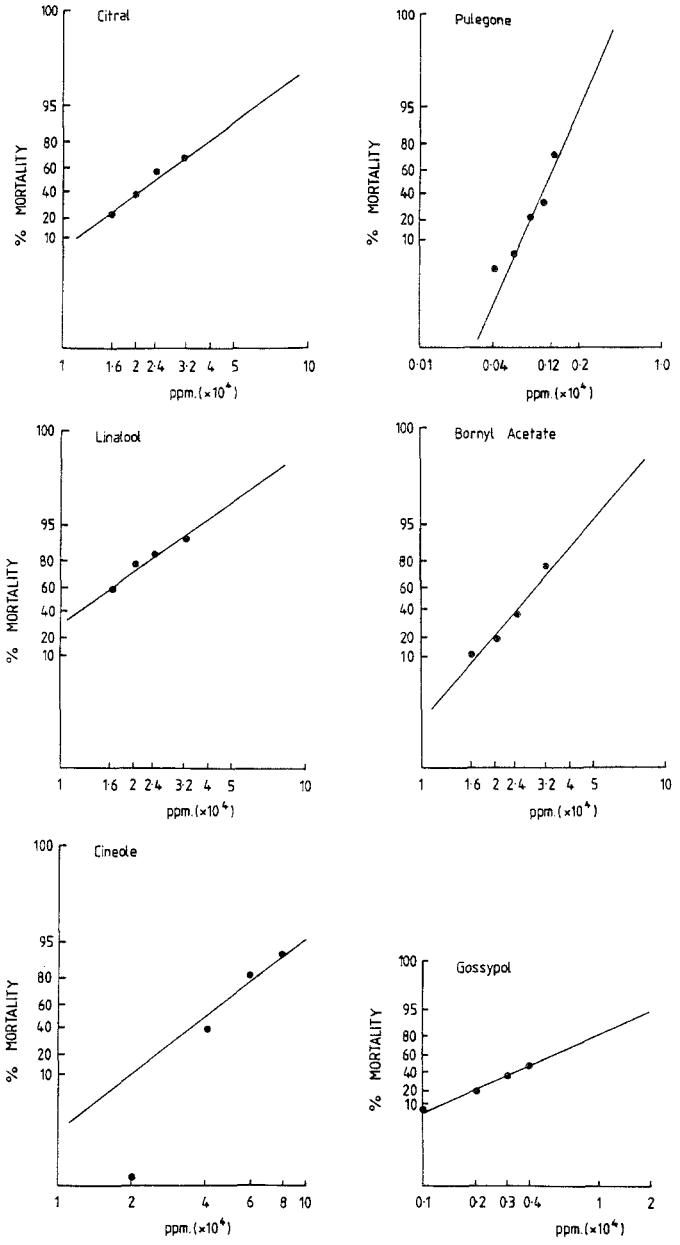

FIG. 2. Dosage–mortality relationships for the six terpenoids studied.

Enzyme Assays. Inhibition of AChE was assessed by the Ellman (1961) assay. Monoterpenes were dissolved in 5 ml absolute alcohol and made up to 50 ml in 0.1 M phosphate buffer, pH 8, to give a stock solution of 0.09 M. Gossypol is a paste at 0.09 M so the stock solution was 0.009 M. Serial dilution yielded the assay concentrations with the result that the concentration of ethanol never exceeded 2%, which we experimentally assessed as inhibiting the enzyme by less than 4% or negligible. The substrate was acetylthiocholine iodide and the color reagent was 5,5′-dithiobis-2-nitrobenzoic acid (DTNB).

Each assay was duplicated, and a typical assay mixture contained 40 μl substrate, 20 μl DTNB, 1 ml terpene solution, and 100 μl electric eel AChE (0.5 unit). Hydrolysis was measured at 25°C in a Pye Unicam SP8-100 spectrophotometer at 412 nm, and all test and control assays were corrected by blanks for nonenzymic hydrolysis.

Chemicals. Citral (99% pure), pulegone (85%), linalool (99%), (−)-bornyl acetate (97%), and cineole (99%) were supplied by Aldrich, Gillingham, Dorset, England. Gossypol, AChE (c-3389, electric eel), DTNB, and acetylthiocholine iodide were supplied by Sigma, Poole, Dorset, England.

RESULTS AND DISCUSSION

All six terpenes killed *T. castaneum*, and this mortality was dose-responsive (Figure 2). Pulegone was the most potent (LC_{50}, 0.12×10^4 ppm) followed by gossypol (0.45×10^4), citral (1.5×10^4), linalool (2.5×10^4), (−)-bornyl acetate (2.7×10^4), and cineole (4.3×10^4). It was evident that beetles became paralysed prior to death.

All six terpenoids reversibly inhibited AChE. Gossypol was an uncompetitive inhibitor, as indicated by decreasing inhibition associated with decreasing substrate concentrations and by the parallelism of the Dixon plot (Figure 3). The five monoterpenes were competitive inhibitors, as indicated by increasing inhibition associated with decreasing substrate concentration and by the intersections in the Dixon plots (Figure 3). Inhibition constants (K_i) were: cineole 2.5×10^{-2} mM; pulegone 8.5×10^{-1} mM; gossypol 1.5 mM; linalool 5.5 mM; citral 7.0 mM, and (−)-bornyl acetate 21.3 mM.

The present evidence from both in vivo and in vitro experiments consistently indicates that the terpenoids tested are effective inhibitors of acetylcholinesterase: specifically, they paralyzed and killed a nonadapted insect and also inhibited electric eel AChE. There is little doubt that terpenoids may act as plant defense compounds or allomones, but this seems to be the first demonstration that a relevant biochemical–physiological mechanism is inhibition of cholinesterase. As the five monoterpenes tested represent five distinct functional groups, such inhibition may be a widespread property of monoterpenes.

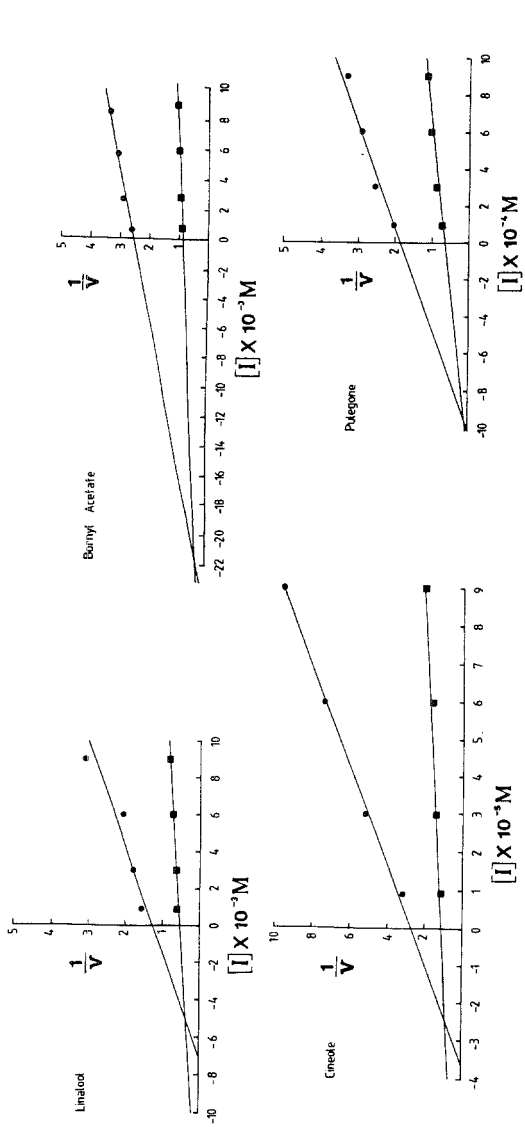

FIG. 3. Dixon plots derived from the inhibition of acetylcholinesterase by the six terpenoids. In each plot the concentrations of substrate (acetylthiocholine iodide) are 0.066 mM (● —— ●) and 0.5 mM (■ —— ■). The additional substrate concentration for gossypol is 0.2 mM (▲ —— ▲).

An apparent anomaly is that the order of potency for the compounds differs according to whether mortality or inhibition is assayed; for example, pulegone, the most potent as an insecticide, ranks second as an AChE inhibitor. It is relevant that vertebrate and insect AChE may differ in their susceptibility to insecticides (Hollingworth et al., 1967). Also it is widely recognized that in vitro K_i values are a rather poor indicator of insecticidal potencies, as they cannot reflect differential abilities of compounds to penetrate cuticle and gut barriers or their differential solubilities in insect hemolymph: each factor influences migration rates to the cholinergic sites (Corbett et al., 1984). For example, three carbamates gave K_i values against housefly brain AChE of 4×10^{-4} mM, 2×10^{-1} mM and 5×10^{-2} mM, respectively, representing a 500-fold range; their potencies against housefly using topical application were 50, 500, and 100 μg/g, respectively, or a 10-fold range (Kolbezen et al., 1954). Another study ascertained no correlation between LD_{50} values of carbamate insecticides and in vitro K_i values with honeybee AChE (Abdel-Raof et al., 1977). Accordingly, K_i values are taken here as adequate to establish compounds as AChE inhibitors but without the expectation of a direct relationship with toxicity.

Nevertheless, it is noteworthy that *m*-nitrophenyl-*N*-methylcarbamate has a K_i value of 2.0×10^{-1} mM (Kolbezen et al., 1954) as compared with 8.5×10^{-1} mM for pulegone. Also, pulegone's LC_{50} potency is 0.12×10^4 ppm as compared with LC_{50} values ranging from 0.007 to 0.027×10^4 ppm for the commercial insecticide and cholinesterase inhibitor, malathion, using the same assay and various susceptible strains of *T. castaneum* (Champ and Campbell-Brown, 1970). Pulegone's potency, 4.4- to 17.1-fold less than this insecticide's, clearly indicates that its action as an AChE inhibitor is relevant to its function as a plant defense compound; the same rationale may be applied to the other terpenoids tested.

Gossypol is an uncompetitive inhibitor of AChE, i.e., it binds not to the enzyme but to the enzyme–substrate complex thus preventing product formation. The five monoterpenes, however, are competitive inhibitors, i.e., they compete with the substrate for its active center on the enzyme. The interaction of the substrate (acetylcholine) with AChE's active center is usually represented as involving three subsites, the anionic, esteratic, and hydrophobic sites (Figure 4). As none of the five monoterpenes possesses a charged region and only one possesses a carbonyl group, this suggests by elimination that they take effect mainly by hydrophobic binding. Their configuration reinforces this, as it is consistent with a good fit to the enzyme's hydrophobic site (Figure 4). The in vivo insecticidal activity of various methyl carbamate and organophosphate insecticides is closely correlated with the extent of their hydrophobic bindings to AChE (Hansch and Deutsch, 1966).

Despite the ability of these terpenoids to inhibit cholinesterase and kill a nonadapted insect, they are not deleterious to all insect species. Specifically,

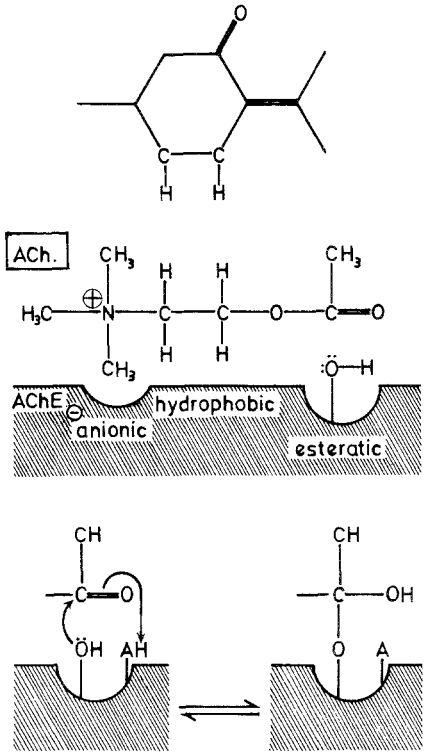

FIG. 4. Diagrammatic representation of the active center of acetylcholinesterase (AChE) indicating the anionic, hydrophobic, and esteratic sites together with the structural formula of acetylcholine (ACh). At bottom is a representation of ACh hydrolysis involving the carbonyl group of ACh and the enzyme's esteratic site: OH represents a hydroxyl group on a serine residue and HA represents a hydrogen donor (after Corbett et al., 1984). As competitive inhibitors, all five monoterpenes must bind to the enzyme's active center. At top is the configuration of pulegone with two CH groups designated to indicate the precise fit possible with the enzyme's hydrophobic site: the structures of the other four monoterpenes are also consistent with such binding.

linalool, a constituent of pine, oils of Ceylon, cinnamon, sassafras, etc., is an attractant for the silkworm (Brattsten, 1983). (−)-Bornyl acetate is a host-location cue for the carrot fly larva, and it seems particularly relevant that strong and statistically significant attraction was elicited by a concentration on filter paper of 9.8×10^4 ppm (Ryan and Guerin, 1982); this concentration was associated with 97% mortality of *Tribolium*. Thus, the present data are not assignable to concentration effects. (+)-Bornyl acetate is a mimic of the sex

pheromone of the American cockroach (*Periplaneta americana*) (Manabe and Nishino, 1983). Citral, a constituent of citrus fruits, is also an alarm and defense pheromone of ants but an attractant and assembly pheromone for the honeybee worker (Wilson, (1971).

The foregoing effects are consistent with the principles of diffuse coevolution but the compounds probably were detoxified by recipients before use as attractants. Detoxifying enzymes of insects belong to the general categories of oxidases, hydrolases, transferases, and reductases (Ahmad et al., 1986). Insect success in detoxifying cholinergic inhibitors, as evidenced by strains with developed resistance to organophosphate and carbamate insecticides, is assigned to specific enzymes. One is a modified carboxyesterase that apparently lost most of its esterase activity, acquiring phosphatase activity instead (Sawicki, 1973); another is gluthathione-*S*-transferase (Lewis, 1969). In addition, AChE has evolved in resistant strains to be more slowly inhibited than AChE in susceptible ones: 1.2- to 6-fold less in organophosphate-resistant strains and 17- to 1570-fold less in carbamate-resistant strains (Hemingway and Georghiou, 1983).

The process by which detoxified terpenoids subsequently become attractants is not easy to visualize, but the involvement of AChE in antennal sensory transmission seems a further reason for considering a role for this enzyme in plant–insect coevolution as mediated by terpenoids.

Acknowledgments—Is is a pleasure to thank Michael A. Raftery, California Institute of Technology, Pasadena, and E. O. Wilson, Harvard University, for kind and stimulating sabbatical hospitality to MFR in 1982 and 1986, respectively.

Erratum

ASTRINGENCY OF DOUGLAS-FIR FOLIAGE IN RELATION TO PHENOLOGY AND XYLEM PRESSURE POTENTIAL

JOHN D. HORNER

Department of Biology
University of New Mexico
Albuquerque, New Mexico 87131

Due to publication errors that occurred after the author's approval of page proofs, several errors were printed on page 1233 (Results and Discussion). The second through fifth sentences on this page should read: "In contrast to unperturbed trees, tannin content of prebudbreak foliage from trenched trees was significantly lower than that of mature foliage (3.21 $\pm$ 0.15 and 7.12 $\pm$ 0.68, respectively; $P < 0.05$).

Treatment-Related Differences in Xylem Pressure Potential. ANOVA revealed significant treatment effects on both predawn ($P < 0.0001$) and daytime ($P < 0.03$) xylem pressure potentials (Table 2). However, differences between the experimental groups were not consistent throughout the season, as indicated by significant date $\times$ treatment interactions ($P < 0.0002$ and $P < 0.02$ for predawn and daytime measurements, respectively)."

The first and second sentences of the last paragraph on this page should read:

"*Astringency in Relation to Tissue Age and Xylem Pressure Potential.* Analysis of covariance revealed significant ($P < 0.05$) treatment effects on foliage astringency."

0098-0331/88/1000-1977$06.00/0

Finally, the second sentence of the footnote in Table 2 should read: "Means in rows followed by different letters are significantly different ($P < 0.05$) between treatments."

Introduction

This special publication of the *Journal of Chemical Ecology* is dedicated to Dr. James H. Tumlinson, the 1986 recipient of the Burdick and Jackson International Award in Pesticide Chemistry, the highest research recognition award sponsored by Baxter International, Inc., Burdick and Jackson Division, and the Division of Agrochemicals of the American Chemical Society (ACS).

The invitational papers in this issue are based on talks presented by the authors in the symposium "Insect Chemical Communication: Unifying Concepts," held at the 194th ACS National Meeting, New Orleans, Louisiana, August 30–September 4, 1987. These eleven papers present recent concepts and supporting research information on insect behavioral biochemistry.

The papers by Tumlinson, Teal, and Roelofs and Wolf discuss biosynthesis of insect pheromones. Teal and Tumlinson describe the isolation and properties of a cuticular primary alcohol oxidase that catalyzes the conversion of the stored *Heliothis zea* female sex pheromone to the active but relatively unstable aldehyde. Remarkably, this enzyme retains its activity both in dichloromethane and hexane.

Roelofs and Wolf report on the chemical events in lepidopteran species leading to the biosynthesis of specific sex pheromones through unique chain-shortening involving $\Delta 9$, $\Delta 10$, and $\Delta 11$ desaturase systems. However, the mechanism governing the formation of the precise blend of *Z* and *E* acetates in tortricid species is as yet not understood but is presumed to proceed through a final reduction sequence from acyl intermediates. Apparently, these regulatory events are genetically controlled and differentially expressed in geographically isolated but related species and/or subspecies.

Klun and Huettel analyze the genetic regulation of the ratios of *Z* and *E* pheromone isomers in sympatric populations of wild-type females of the European corn borer, *Ostrinia nubilalis*. Circumstantial evidence from this work suggests that a male moth can carry an allele coding for production of one isomer ratio, but may respond to another ratio.

Ding and Prestwich, studying receptors and perception of pheromonal signals in antennae of *Heliothis virescens*, synthesized several classes of potential inhibitors of aldehyde-oxidizing enzymes (ADEs) that oxidize and inactivate the major *Z*11–16 aldehyde component of the pheromone. Cyclopropanols were found to be inhibitors of ADEs. However, the most potent irreversible inhibitors were α,β-unsaturated carbonyl mimics of the aldehyde.

Neuroregulation studies of pheromone biosynthesis promise to enlarge our knowledge of pheromone production, release, and perception. Raina reports on the factors regulating release of the neuropeptide (PBAN) that activates pheromone biosynthesis in *H. zea*. These factors include stimulation of the brain by light and by plant cues. Raina also provides indirect evidence for the occurrence of a hemolymph-borne, male PBAN inhibiting factor that is transferred to the female during mating and blocks pheromone production in the mated female.

Visser and DeJong analyze the patterns of olfactory semiochemical perception in *Pieris brassicae* larvae and *Leptinotarsa decemlineata* adults. Signals for mating and food consist of blends of chemicals.

The subject of chemical blends is also addressed by Oehlschlager and coworkers who studied aggregation pheromones in several sympatric cucujid grain beetles. These species respond either to single pheromonal compounds or to combinations of compounds, and show enantiomeric specificity.

Blum and Fales report on the multiplicity of semiochemicals modifying honey bee behavior with special attention to those chemicals that govern caste specificity.

Silverstein reviewed the requisites a natural product chemist must possess in order to study and determine the role of chiral molecules in insect communication.

These topics highlight major contemporary frontiers in insect semiochemical research. This new knowledge may provide the insights and tools to manipulate insect behavior, to trap or disorient pests, and to attract beneficial insects.

CHIRALITY IN INSECT COMMUNICATION

ROBERT M. SILVERSTEIN

SUNY College of Environmental Science and Forestry
Syracuse, New York 13201

(Received October 15, 1987; accepted February 3, 1988)

Abstract—In dealing with chiral molecules, the natural-products chemist must be knowledgeable in several areas of stereochemistry. This brief survey will serve for simple situations and as a source of references for more complex molecules.

Key Words—Chirality, enantiomers, stereochemistry, structure-bioactivity.

INTRODUCTION

Chirality, as one aspect of stereochemistry, "expresses the necessary and sufficient condition for the existence of enantiomers" and thus for optical activity (Cahn et al., 1966). Enantiomers are nonsuperposable mirror images. The ultimate test for a chiral molecule is thus nonsuperposability of its mirror image.

"Specification of Molecular Chirality" is the title of the last of three landmark papers by Cahn, Ingold, and Prelog (1966) in which the CIP rules formulate a comprehensive, extremely useful, although arbitrary nomenclature system for stereoisomers; each succeeding document elaborates on, and amends, the preceding document. Cahn (1964a) wrote a summary paper at the introductory level in the *Journal of Chemical Education*. This is required reading; only the dedicated stereochemist will read completely through the three CIP documents. Even Cahn (1964a) lost his bearings in the sequence rules and was forced to publish an Errata note (1964b, see below).

To establish a comprehensive, rigorous system of nomenclature, Cahn, Ingold, and Prelog attempted to expand their rules and interpretations thereof to cover all of organic chemistry, and they come remarkably close to succeeding. Inevitably, however, the papers became tomes of "legalistic" scholarship

0098-0331/88/1100-1981$06.00/0

and reference sources for myriads of succeeding papers, as well as reviews on an almost annual basis in *Topics in Stereochemistry* (Allinger and Eliel).

Natural-products chemists, whom I address, must be knowledgeable in the following areas: (1) the basic stereochemical conventions needed to draw and name the structures likely to be encountered; (2) symmetry criteria in NMR spectrometry for structure elucidation; (3) methods for the determination of enantiomer composition and for enantiomer isolation; (4) methods for stereoselective synthesis (references only given herein); (5) principles and methods of biosynthesis (references only given herein); (6) the relationships between structure and bioactivity.

I consider these topics *seriatim* and hope that this brief survey will serve for simple situations and as a source of relevant references for more complex situations.

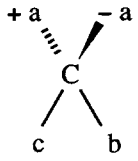
BASIC STEREOCHEMICAL CONVENTIONS

Basic definitions and rules are as follows:

1. A molecule is *chiral* when it is not superposable on its mirror image; *achiral* if superposable. A conformational-mobile molecule is chiral only if all of its possible conformations are chiral.

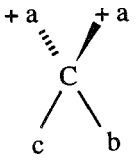
2. A molecule is *asymmetric* if it has no element of symmetry. All asymmetric molecules are chiral, but not all chiral molecules are asymmetric, molecules with simple axes of rotation only being chiral. A chiral atom (a chiral center) may possess no element of symmetry other than a simple axis or axes.

3. An *asymmetric carbon atom* is bonded tetrahedrally to four "different" atoms or groups, none of the groups being the mirror image of any of the others. Thus $C_{a,b,c,d}$ is asymmetric (chiral), whereas $C_{+a,-a,b,c}$ is not, even though +a and −a appear to be "different"; they are different only in being mirror images (enantiotopic). Note that the latter structure cannot be termed asymmetric or chiral since it has a plane of symmetry. The dilemma of having four apparently "different" substituents on a carbon center that has a plane of symmetry was resolved by assigning the rather cumbersome term "pseudoasymmetric" (Scheme 1).



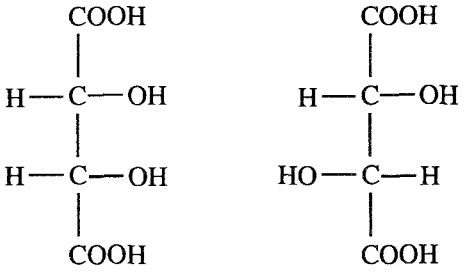
SCHEME 1.

How then do we treat $C_{+a,+a,b,c}$ (Scheme 2)? At first glance, +a and +a substituents on a tetrahedral carbon would seem identical, but they fail the test for identity: interchange through a simple axis of rotation (see below under Symmetry Criteria in NMR). Since they cannot be interchanged through any symmetry operation, they are diastereotopic. Again, we have a dilemma; both dilemmas will be discussed below in connection with the recent challenging paper by Mislow and Siegel (1984).



SCHEME 2.

4. Stereoisomers that are not enantiomers are *diastereomers*, which may be chiral or achiral (Scheme 3). Parenthetically, note that the term "geometric" isomers for *cis* and *trans* (*Z* and *E*) olefins and *cis* and *trans* cyclanes has been dropped in favor of the designation diastereomers (Eliel, 1971).



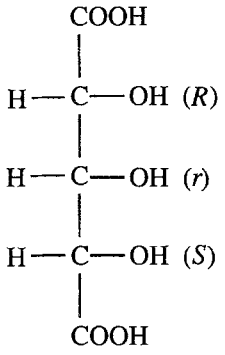
Achiral Diastereomer Achiral Diastereomer

(Fischer projections)

SCHEME 3.

5. Compounds with chiral centers are designated by prefix *R* or *S* (*r* or *s* for pseudoasymmetric centers) assigned by the CIP sequence rules (see below) preceded when necessary by locants (Scheme 4).

In one of the giant constructs of organic chemistry, Cahn et al. (1966) developed the sequence rule with six subrules (0–5) for specifying molecular chirality for each enantiomer in terms of the familiar symbols *R* and *S* (*r* or *s*). The following sequence rule, subrules, and discussion will cover most common situations. Application to more complex molecules is by no means trivial, and



(2*R*,3*r*,4*S*)-Trihydroxyglutaric acid
(Fischer projection)

Note that the pseudoasymmetric center is (*r*) as a consequence of the CIP sequence rule (below) that assigns priority of (*R*) over (*S*). Relative configurations are differentiated by (*R**), (*S**) (spoken *R* star, *S* star) preceded by locants when necessary; the lowest numbered locant is arbitrarily assigned (*R**).

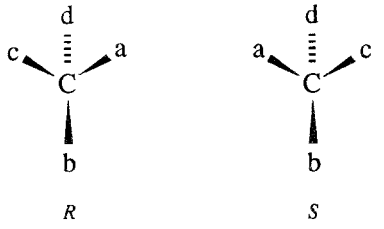
SCHEME 4.

it will be necessary to refer to the 1966 paper by Cahn, Ingold, and Prelog for further details.

The sequence rule itself is a "method of arranging atoms or groups (including chains and rings) in an order of precedence, often referred to as an order of preference [a priority sequence]; for discussion, this order can be generalized as a > b > c > d where > denotes 'is preferred to'." The three possible chiral elements of a molecule are considered in the sequence: chiral center, chiral axis, and chiral plane, of which by far the most common is the chiral center. For convenience, the sequence rule and the six subrules are here reproduced verbatim.

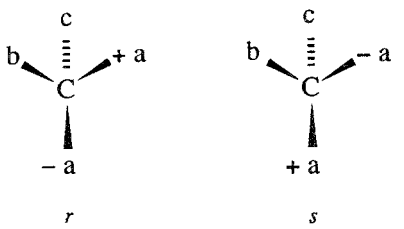
> Sequence Rule. The ligands associated with an element of chirality are ordered by comparing them at each step in bond-by-bond explorations of them, from the element, along the successive bonds of each ligand, and, where the ligands branch, first along branch-paths providing highest precedence to their respective ligands, the explorations being continued to total ordering by use of the following Standard Subrules, each to exhaustion in turn, namely:
> (0) Nearer end of axis or side of plane precedes further.
> (1) Higher atomic number precedes lower.
> (2) Higher atomic mass-number precedes lower.
> (3) Seqcis precedes seqtrans [seq is the abbreviation of sequence rule].
> (4) Like pair *R*,*R* or *S*,*S* precedes unlike *R*,*S* or *S*,*R*; and *M*,*M* or *P*,*P* precedes *M*,*P* or *P*,*M*; and *R*,*M* or *S*,*P* precedes *R*,*P* or *S*,*M*; and *M*,*R* or *P*,*S* precedes *M*,*S* or *P*,*R*; also *p* precedes *s*.
> (5) *R* precedes *S*; and *M* precedes *P*. [*M* and *P* are helicity designators].

The priority sequence having been established by applying the subrules, the chirality rule is applied as follows: "Among ligands [substituents] of highest precedence, the path of their sequence is followed from the preferred side of the molecule, that is the side remote from the group of lowest precedence, and, according as the path turns to right or left, the element is assigned the chiral label *R* or *S*, or, if pseudo-asymmetric, *r* or *s*." We thus have the familiar picture of a generalized tetrahedral asymmetric molecule $C_{a,b,c,d}$; where a > b > c > d, the label is *R* if the sequence abc is clockwise (right, *r*ectus), and *S* if counterclockwise (left, *s*inister) (Scheme 5).



SCHEME 5.

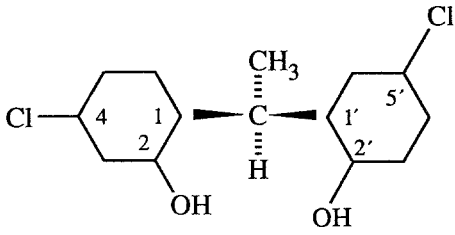
For the generalized pseudoasymmetric molecule $C_{+a,-a,b,c}$ mentioned above, where +a is an *R* substituent, −a is the mirror image (hence *S*), and b and c are in decreasing order of priority, we have the assignments as in Scheme 6. The assignments are based on subrule 5: *R* > *S*. [In subrules 4 and 5, *M* and *P* (*M* for *M*inus and *P* for *P*lus) are less familiar designators for helices.]



SCHEME 6.

In the vast majority of cases, the designators are decided by application of subrule 1, and simple examples of its application are given in all textbooks of organic chemistry. However, it may be worthwhile to discuss here in detail the difficulty that caused Cahn (1964b) to publish his correction and that continues to bedevil students and experts alike, namely how to handle ring systems.

Cahn used the molecule with two rings (Scheme 7) to illustrate the establishment of the priority sequence. The correct procedure as stated in the sequence

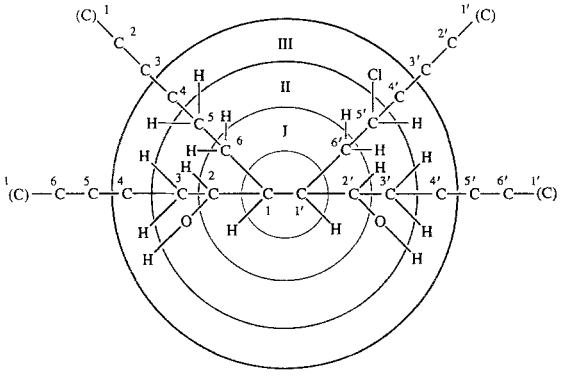


SCHEME 7.

rule is to place the ligands in priority sequence "by comparing them *at each step in a bond-by-bond exploration* of them, from the [chiral] element, along the successive bonds of each ligand, and, *where the ligands branch, first along branchpaths providing highest precedence to their respective ligands*, the explorations being continued to total ordering. . . ." [italics added]. Thus Cahn may have reasoned that the H substituent has the lowest priority (d), CH_3 is next lowest (c), and no decision can be made between the ring CH groups. At the branch in each ring, the lower branch (CHOH) takes precedence over the upper branch (CH_2). In the lower branch of the left ring, C-3 is CH_2, and in the lower branch of the right ring, C-3′ is also CH_2—no decision. In the left ring, C-4 is CHCl and in the right ring, C-4′ is CH_2. The left ring, therefore, is given priority over the right and is labeled "a"; the right ring is labeled "b," and the molecule is labeled "*S*." Cahn then published an Errata note (1964b) in which he reversed the priority assignments with the statement: "The correct procedure is to work outward by single groups along all branches simultaneously; at the first step along the branches, one finds CHOH and CH_2 in each ligand; at the second step, one finds CHCl, CH_2 on the right hand and CH_2, CH_2 on the left. Thus the right-hand ring has precedence (not the left as stated), the Cl being decisive." True, although a bit cryptic.

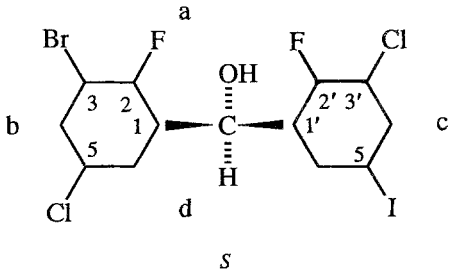
To ensure that the investigator proceeds "along all branches simultaneously," Prelog and Helmchen (1982) specified that cyclic ligands be converted into branched structures, a "tree graph," and that atoms be assigned to "spheres"; atoms of equal topological distance lie in the same sphere. One progresses outward through the spheres, analyzing all the atoms in each sphere before going on to the next. (Note that each branch is terminated by a supernumerary C atom representing C-1 or C-1′.) The ranking of each atom within an *n*th sphere "depends in the first place on the rank of the atom within the (n − 1)th sphere to which it is bonded, and only then on its rank according to the sequence rules." Cahn's molecule is treated as follows (see tree graph, Scheme 8).

In sphere I, there is no distinction between the atoms of the right-hand main branch and the left-hand main branch. The same holds true for sphere II,



SCHEME 8.

but now it is possible to distinguish between the upper and lower subbranches; in each main branch, the lower subbranch takes precedence because of the O atom. In sphere III, the higher ranking subbranches are compared with one another, there being one C and three Hs in each and thus no difference. Still in sphere III, the lower ranking subbranches are compared; the right-hand subbranch with one Cl, one C, and one H takes precedence over the left-hand subbranch with one C and two Hs. Therefore, the right-hand main branch takes precedence over the left-hand main branch—i.e., right ring > left ring— and the overall ranking around the chiral center is (a) right ring, (b) left ring, (c) CH_3, and (d) H. The configuration is *R*. Cahn apparently selected the correct subbranches on the basis of the OH groups at C-2 and C-2′ and continued along these subbranches incorrectly selecting the left-hand ring with Cl at C-4 over the right-hand ring with Cl at C-5. Construction of a tree graph and concentric spheres helps the investigator to "proceed along all branches simultaneously" (Cahn 1962b). Subsequently, Prelog and Helmchen (1982) assigned priorities to the substituents in a molecule similar to that used by Cahn (Scheme 9).

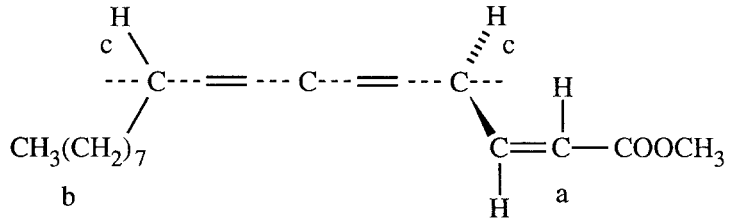


S

SCHEME 9.

Thus far, all chiral molecules in this presentation have been characterized by one or more chiral centers, but the CIP rules were extended to cover the chiral axis for such molecules as allenes and biaryls, and further to cover chiral planes. A molecule is first "factorized" by chiral centers, then, if necessary, by chiral axes and chiral planes.

The chiral axis was regarded as an extended chiral center, "the giving of one dimension to an original chiral center" (Cahn et al., 1966). For example, the putative pheromone of the "dried bean weevil" was identified by Horler (1970), and the stereochemistry was specified by Pirkle and Boeder (1978). If it is drawn as in Scheme 10, the designator is *R*.

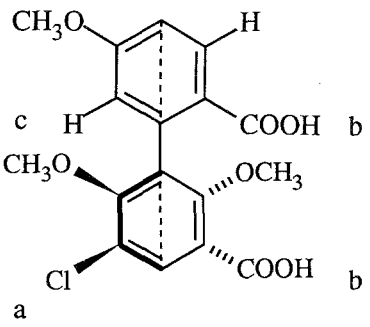


R

SCHEME 10.

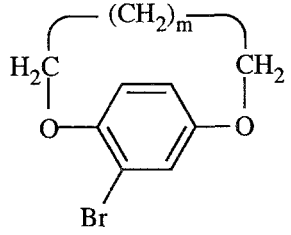
For a chiral axis to exist, it is only necessary that the substituents at each end differ from one another. Priority is assigned as usual to the ligands: a > c at the right, and b > c at the left. In accordance with subrule zero (near side precedes far side), we view down the chiral axis (dotted line) from a to c at the near side, thence to b at the far side. The spiral path is clockwise and the designation is *R*. The near side is chosen arbitrarily; the sequence b to c (near) to a (far) gives the same result. A similar treatment is used for hindered biaryls, which have not yet been described as a semiochemical, and a modified subrule zero is invoked (Cahn et al., 1966, p. 399): groups nearest together along the axis take precedence. In the example in Scheme 11, H and COOH and the two OCH_3 groups are the near groups (to the center), but since the OCH_3 groups cannot be distinguished from one another, the far groups Cl and COOH are used. The spiral sequence "a" to "b" (same ring) to "b" (other ring) stipulates *S*.

The first step in the selection of a plane of chirality is to locate the "natural" plane of symmetry that has been "desymmetrized" (Cahn et al., 1966). Such a "natural" plane of symmetry in the following simple example (Cahn, 1964a) lies in the plane of the benzene ring and is considered to be desymmetrized (faces made different) by the CH_2 chain (Scheme 12). The sequence-rule



S

SCHEME 11.



R

SCHEME 12.

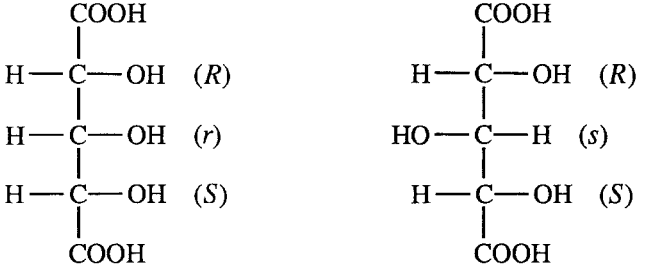
preferred atom directly attached to the plane is chosen as the pilot atom. This is determined to be the CH_2 attached to the left-hand O atom since $H_2C-O-C-CBr$ takes precedence over $H_2C-O-C-CH$. The preferred sequence in the ring from the branch point is thus through the ring atom bearing the Br atom. This path, O—C—CBr, rotates clockwise when viewed from the pilot atom, and the molecule is labeled *R*. Cahn et al. (1966, pp. 400–401) should be read for guidance in more complex molecules.

Problems in applying the CIP rules for chiral axes and chiral planes are discussed by Mislow and Siegel (1984, footnote 65), Prelog and Helmchen (1982), and Hirschmann and Hanson (1983).

The practical contributions of the CIP empirical procedures notwithstanding, a number of difficulties have been pointed out, not least of all by the three authors themselves during the long course of development of their concepts. In particular, Mislow and Siegel (1984) in a seminal paper in stereochemical theory propose that some of the basic CIP concepts are flawed, although acknowl-

edging the enormous utility of the procedures. In particular, they propose that the CIP concept of chirality actually embodies two separate and distinct concepts: local geometry (symmetry properties) and stereoisomerism. Mislow and Siegel use the term "chirotopicity" to refer to local geometry: Atoms that reside in a chiral environment are termed "chirotopic," if in an achiral environment, "achirotopic," the distinction resting on symmetry considerations. (In fact, all atoms and spaces in a chiral molecule are chirotopic.) They use the term "stereogenicity" to refer to the effect of interchange of two ligands of a tetrahedral carbon atom in a molecule: If such interchange results in stereoisomers (enantiomers or diastereomers), the carbon atom is referred to as "stereogenic," the converse term being "nonstereogenic." Thus, the carbon atom in the chiral molecule CHBrClF is chirotopic and stereogenic, whereas the carbon atom in the achiral molecule CH_2BrCl is achirotopic and nonstereogenic. It is this remarkable linkage of properties in most, but not all, tetrahedral carbon atoms that accounts for the enormous practical success of the CIP procedures.

Difficulties in the CIP concepts arise with the definition of "different" in the familiar description of an asymmetric atom as having four "different" substituents. In the CIP definition (see under Basic Stereochemical Conventions, No. 3), "different" means constitutionally different or diastereotopically different; enantiotopic differences are specifically excluded. The term "pseudoasymmetry" was coined to describe an atom such as C-3 in the two *meso* forms of trihydroxyglutaric acid in which the designators *r* and *s* are used for C-3 bearing enantiotopic substituents (Scheme 13). The molecules in Scheme 13 are achiral by virtue of a plane of symmetry through C-3. By definition, C-3 cannot be described as chiral or asymmetric; yet it has the property whereby an interchange of ligands results in a diastereomer.



Achiral Molecule Achiral Molecule

(Fischer projections)

SCHEME 13.

Note that the terms diastereotopic and enantiotopic refer to "attached" substituents (ligands), that is, within the molecular environment. The terms diastereomorphic and enantiomorphic have been used by other authors to refer to substituents in "isolation," that is, free of the molecular environment. The terms diastereomeric and enantiomer refer to whole molecules. Note further that, although enantiotopic substituents in $C_{+a,-a,b,c}$ are not "different" in the sense of producing an asymmetric center, they are nonetheless distinguishable by chiral reagents (such as enzymes) or by NMR in a chiral environment.

In the two mirror image (enantiomeric) chiral forms of trihydroxyglutaric acid (Scheme 14), the molecules have no element of symmetry. C-3 is chiral (asymmetric) since C-2 and C-4 are not interchangeable through a symmetry operation and are therefore diastereotopic ("different"). Yet interchange of H and OH (or of the other substituents) on C-3 gives an identical molecule for each of the two chiral enantiomers (superposable by in-plane rotation). The CIP procedures do not yield an *R* or *S* (or *r* or *s*) designator for C-3, nor is there need for one since interchange results in identical molecules.

These inconsistencies and points of perennial confusion are resolved by the proposal of Mislow and Siegel (1984) to use the separate properties of chirotopicity and stereogenicity (see above). Thus, in the achiral (*meso*) molecules of trihydroxyglutaric acid, C-3 is stereogenic since interchange produces the diastereomer, but it is not chirotopic. In the chiral molecules, C-3 is not stereogenic, but it is chirotopic. In both cases the usual linkage of these two properties fails. Mislow and Siegel further comment that "the term 'pseudoasymmetric' therefore lacks any meaningful reference to symmetry and geometry. It is seen to be an artifact of an unwarranted superposition of stereogenicity onto local chirality." They argue further that *R* and *S* in the CIP system "solely serve to identify isomers and have no bearing whatever on symmetry relationships among or within molecular models. It is therefore inappropriate to refer to them as 'chiral descriptors'." Thus, in the *meso* trihydroxyglutaric acids, "the chiral descriptors *r* and *s* are applied even though the atoms are achirotopic. These are really nomenclatural devices that bear no relationship to the local symmetry of the atoms to which they refer." Prior to the Mislow and Siegel paper, Prelog and Helmchen (1982) identified these elements as stereogenic units. Mislow and Siegel emphasize the point that "paradoxically, the selection of 'elements of chirality' in a molecule do not depend on local or molecular chirality."

This brief description hardly does justice to the paper by Mislow and Siegel, which should be read in its entirety, along with the interpretive article by Maugh (1984).

In a recent paper, Eliel (1985) proposed a convenient mnemonic for assigning *R* or *S* descriptors to three-dimensional formulas. He also discussed several

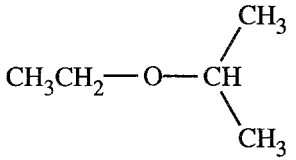
of the changes—many of them esoteric—in the CIP system proposed by Prelog and Helmchen (1982).

The related topic of prochirality (prostereoisomerism) cannot be covered in this review. Reference is made to the extensive discussion by Eliel (1982).

SYMMETRY CRITERIA IN NMR FOR STRUCTURE ELUCIDATION

In their general chapter entitled "Stereoisomeric Relationships of Groups in Molecules," Mislow and Raban (1967, pp. 12–30) included a section on symmetry criteria in NMR spectrometry, which together with subsequent papers by Eliel (1980), Silverstein and Silberman (1973), and Silverstein and LaLonde (1980), provide the chemist involved with interpretation of NMR spectra with the basic concepts; these are briefly summarized in the present section as a series of definitions as concisely as possible.

The familiar Pople notation for spin systems—AB, AX, AX_3, etc.—is based on the concept of sets of nuclei within a spin system. An AX type system consists of "loosely coupled" sets (the ratio of the chemical shift difference to the coupling constant J, both in Hz, is much greater than about 10), ($\Delta\nu/J >> \sim 10$), whereas the AB type consists of tightly coupled sets ($\Delta\nu/J << \sim 10$). A *set* of nuclei consists of chemical shift equivalent nuclei. A *spin system* consist of sets of nuclei that spin couple only with one another. Spin systems are "insulated" from one another (e.g., the ethyl protons and the isopropyl protons in ethyl isopropyl ether comprise two spin systems) (Scheme 15).



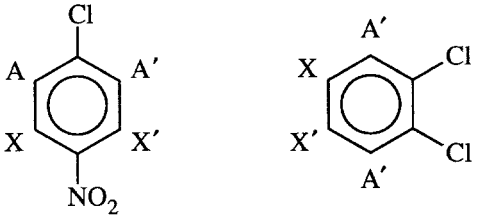
SCHEME 15.

Chemical shift equivalent (*isochronous*) nuclei are interchangeable through a symmetry operation or a rapid mechanism (i.e., rapid on the NMR time scale). They have the same chemical shift in an achiral environment. Nuclei are interchangeable if the structures before and after the operation are indistinguishable. The symmetry operations are rotation around a simple axis of symmetry (C_n), reflection through a plane of symmetry (σ), inversion at a center of symmetry (i), or rotation around an axis of symmetry followed by reflection in a plane normal to this axis (S_n), the alternating axis of symmetry. Actually, σ and i are

equivalent to S_1 and S_2, respectively. The symmetry element must be one for the entire molecule.

Nuclei that are interchangeable through a simple axis of symmetry (homotopic) have the same chemical shift in both achiral and chiral environments. Nuclei that are interchangeable through any other symmetry operation but not in addition to a C_n operation (enantiotopic), are chemical shift equivalent only in an achiral environment. Nuclei that are not interchangeable through a symmetry operation or through a rapid mechanism (either diastereotopic or constitutionally heterotopic) are not chemical shift equivalent in any environment. Nuclei that are interchangeable through a rapid mechanism are chemical shift equivalent in any environment. Nuclei that fortuitously absorb at the same shift are sometimes classified as chemical shift equivalent, but such coincidence is neither absolute nor fundamental, depending as it does on instrumental resolution.

A further refinement involves the concept of *magnetic equivalence*. If nuclei in the same set (i.e., chemical shift equivalent nuclei) couple equally to any (probe) nucleus in any other set in the spin system, they are magnetic equivalent, and the simple Pople designation (A_2X_2 for example) applies. If not, the designation AA'XX' is used in place of A_2X_2, and one should not necessarily expect first-order spectra. The proton spectra of *p*-chloronitrobenzene or *o*-dichlorobenzene (the common agent for determining instrument resolution) are complex, and the ring proton spin system is described as AA'BB' or AA'XX', depending on instrument resolution and on the difference in chemical shifts (Scheme 16).



SCHEME 16.

METHODS FOR DETERMINING ENANTIOMER COMPOSITION AND ISOLATION

A plant or an animal may produce a chiral compound as a single enantiomer or as a mixture of enantiomers in any ratio. A laboratory synthesis using achiral starting materials and reagents produces a racemate that must, with rare

exceptions, be resolved with a chiral reagent, which may be in the form of a substrate of a gas or liquid chromatographic column. A stereoselective synthesis yields a predominance of one of the enantiomers. The chapter on "the significance of chirality" by Mori (1984) is suggested reading; a comprehensive table of chiral insect pheromones is included.

Determination of enantiomeric composition of a minute quantity of a chiral compound isolated as an insect pheromone, for example, is not a trivial operation. Frequently the operation is avoided in favor of synthesizing the pure enantiomers and challenging the insect with a gamut of ratios, on the reasonable assumption that the insect will respond most favorably to the ratio perceived under natural conditions; however, this procedure is neither accurate nor rigorous. The synthetic approach may also yield the absolute configurations of the chiral elements.

The methods for determining enantiomeric composition are (Silverstein, 1985):

1. Polarimetry
2. NMR (^{1}H and ^{13}C) with chiral shift reagents, chiral derivatizing agents, or chiral solvating agents
3. Achiral chromatography (gas or liquid) of diastereomeric derivatives
4. Chiral chromatography (gas or liquid) of the enantiomers directly
5. X-ray crystallography of a derivative prepared with a chiral reagent
6. Bioassay of synthetic enantiomers (as mentioned above neither accurate nor rigorous)

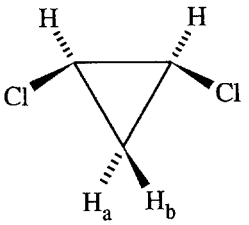
The basic requirements for polarimetry are a relatively large sample, a relatively high specific rotation, and a knowledge of the specific rotation of the pure enantiomer under identical conditions of temperature, concentration, and solvent; these are severe limitations for semiochemical studies. Comparison of determined values with those in the literature is often risky.

At the other extreme—small sample size, no derivatization, and no need for pure reference samples—is gas or liquid chromatography by complexation on chiral columns. However, these procedures are quite new. Column choice is limited, temperature constraints (for GC columns) are severe, and resolution is often modest and limited to particular chemical classes. On the other hand, successful resolution of compounds that would be difficult to derivatize, such as bicyclic acetals (Weber and Schurig, 1981), makes this an extremely useful approach that continues to undergo development.

Gas and liquid chromatography on achiral columns of derivatives with chiral reagents are the most widely used techniques. A functional group and an appropriate derivatizing reagent are necessary. As a single example, Mosher's reagent for alcohols, (+)- or (−)-α-methoxy-α-trifluoromethylphenylacetyl

chloride (MPTA Cl) is available at high purity (as the carboxylic acid) for both enantiomers and conspicuously lacks an epimerizable center that makes most other acid chloride reagents less attractive. However, the low vapor pressure of many of these derivatives places limitations on gas chromatography. Liquid chromatography, of course, is used for such low-vapor-pressure derivatives, and the development of HPLC techniques in recent years has been rapid. Two very useful reviews are available for determination of enantiomeric composition and isolation of enantiomers by gas (Schurig, 1983) and liquid (Pirkle, 1983) chromatography.

Plummer et al. (1976) and Stewart et al. (1977) reported the first use of a chiral shift reagent and of a chiral derivatizing agent with [^{1}H]NMR spectrometry to determine the enantiomeric composition of several isolated pheromones. Use of a chiral shift reagent requires a functional group that is a strong enough base to form a stable complex, sufficient resolution to separate the corresponding peaks in each diastereomeric complex, and freedom from interfering peaks. The ideal protons are those of an uncoupled CH_3 group near the functional group; a similarly situated, uncoupled CH group, although less intense, is also useful. Protons of a methylene group can be troublesome; they may be enantiotopic as in 1-nitropropane, for example, and thus chemical shift equivalent in an achiral environment but not so in the presence of a chiral shift reagent. Protons of a methylene group may also be diastereotopic and thus not chemical shift equivalent in any environment (Scheme 17, protons a and b). Separation



SCHEME 17.

of absorptions of chiral derivatives is further enhanced by addition of an achiral shift reagent; for example see Iwaki et al. (1974). It is worth mentioning that use of the Mosher derivative in NMR spectrometry has a unique advantage since the fluorine NMR spectrum shows the CF_3 peaks free of interferences. Note that the small coupling with the methoxy protons results in slight broadening for the CF_3 group in each enantiomer.

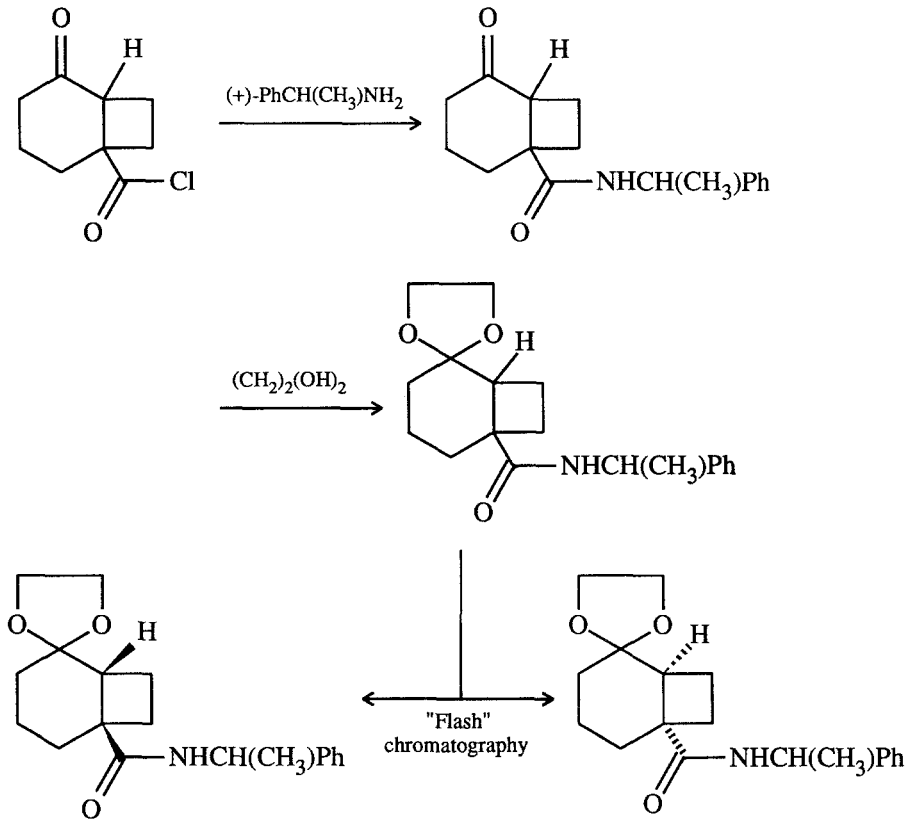
Chiral solvating reagents (Gaudemer, 1977) in NMR spectrometry have been less widely used than chiral shift reagents. However, Ravid et al. (1978)

employed this technique to determine enantiomeric composition of a γ-lactone pheromone.

X-ray crystallography was recently used by Mori et al. (1982) on a crystalline derivative produced with a chiral derivatizing reagent to determine the absolute configuration of a pheromone. Generally, however, absolute configuration is determined by synthesis from starting materials whose absolute configuration is known.

Enantiomers can be separated (resolved) on a preparative basis by scaling up the chromatographic techniques for determining enantiomeric composition. The limitations are, of course, column capacity and the need to regenerate the enantiomers from their diastereomeric derivatives. Details will not be discussed here, but four comprehensive references on resolution are cited (Newman, 1987; Wilen et al., 1977; Klyne and Buckingham, 1978 and its supplement by Buckingham and Hill, 1986). It might be mentioned here that, on a large scale, resolution of a carboxylic acid by recrystallization of its salt formed with an amine enantiomer is frequently the method of choice. Regeneration of the salt to recover both the enantiomer and the amine is simple and economical, but following the course of resolution by regenerating the enantiomer at each step and determining the optical rotation is tedious and unreliable. Webster et al. (1982) demonstrated the utility of [^{13}C]NMR spectrometry of the amine salt directly to follow the course of resolution; this is a direct procedure that does not depend on a pure enantiomer as a reference compound. The recrystallization procedure is not applicable, of course if the salts do not crystallize, or if the recrystallization process is inefficient.

One example of large-scale resolution and proof of enantiomeric purity will suffice to illustrate some of the problems encountered (Scheme 18): During the preparation of optically pure enantiomers of grandisol, Webster and Silverstein (1986) were unable to obtain satisfactory crystalline salts of the intermediate racemic carboxylic acid. Treatment of the corresponding acid chloride with (*S*)-(−)-α-methylbenzylamine gave the diastereomers of the keto amide which, however, could not be resolved by either recrystallization or HPLC. Finally, the acetal was readily resolved by large-scale flash chromatography followed by facile recrystallization to >99% purity for each diastereomer (HPLC analysis). Although this procedure was very satisfactory, it was necessary to devise a novel procedure for cleavage of the highly hindered amides, standard procedures having failed (Webster and Silverstein, 1986). The secondary amides were cleaved with Li/NH_3 to the primary amides, which were then hydrolyzed to the carboxylate with base. The latter step was acceptable since there was no risk of epimerization of the quaternary bridgehead carbon atom alpha to the carboxyl group. Olah's reagent, nitrosonium tetrafluoroborate in acetonitrile (Olah and Olah, 1965), proved very useful for cleavage of a hindered epimerizable amide (Webster et al., 1986).



SCHEME 18.

METHODS FOR STEREOSELECTIVE SYNTHESIS

It is impossible in this brief chapter to cover the rapidly developing field of stereoselective synthesis. Reference is made to the continuing series edited by Morrison (1983–1985), to a recent review by Masamune et al. (1985), and to a recent textbook by Coppola (1987).

PRINCIPLES AND METHODS OF BIOSYNTHESIS

This subject is thoroughly addressed in several chapters in a very recent book edited by Prestwich and Blomquist (1987).

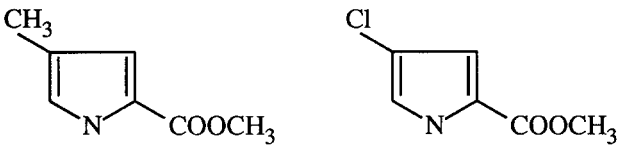
THE RELATIONSHIP BETWEEN STRUCTURE AND BIOACTIVITY

Chemists and biologists have long been intrigued by the relationships between chemical structure and bioactivity. The chemist classifies structures hierarchically from most to least "different":

I. "Different" compounds—different molecular formulas
II. Isomers—same molecular formula
  A. Constitutional isomers—atoms joined in different orders
  B. Stereoisomers—atoms joined in the same order but arranged differently in space
    1. Diastereomers—not mirror images
    2. Enantiomers (optical isomers)—nonsuperposable mirror images

But this graduation of "different" is dubious, possibly resulting from the chemist's inability to distinguish enantiomers with achiral laboratory tools. Insofar as bioactivity is concerned, one would a priori predict that the receptor cells with their chiral elements should distinguish between enantiomers. It turns out that insects, on which some elegant studies have been done, distinguish between compounds at every level, including enantiomers (see the very recent chapter by Tumlinson, 1987). It also seems reasonable to predict that within each category it may not be possible with present devices and techniques to detect whatever differences in bioactivity exist if the differences are small. Thus, at the enantiomer level, a long-standing controversy over the odors to humans of (+)- and (−)-carvone persisted because of the presence of impurities or because of poor experimental procedures. The issue was finally settled by overkill in 1971 when three groups, using highly purified samples, determined independently that (*S*)-(−)-carvone has a spearmint odor and is detectable at a lower threshold than the antipode, which has a caraway odor (Friedman and Miller, 1971; Russell and Hills, 1971; Leitereg et al. 1971).

In the first category, compounds grossly different in structure—*D*-glucose and propane for example—surely elicit different responses. On the other hand, the trail-following pheromone isolated from an ant and identified by Tumlinson et al. (1980) was mimicked in a laboratory bioassay by the 4-chloro analog (Sonnet and Moser, 1972) (Scheme 19). One may, of course, argue justifiably that a laboratory assay is not the same thing as a field bioassay in the natural context of the insect population and that, with more extensive testing, differences would have been found. Very likely. In summary then, an organism may, and usually does, distinguish between two compounds in any category. We usually can perceive the difference by means of a bioassay, but sometimes we do not. The usual but not inevitable consequence of a small change from the



Pheromone Analogue

SCHEME 19.

natural molecule in molecular structure in any category is a marked decrease in the sought response.

These effects at the level of enantiomers have been of great interest in the field of insect pheromones (Mori, 1984; Silverstein, 1979, 1984, 1985). If an insect produces a single enantiomer, the following responses elicited by the other enantiomer (an artifact) are possible (Silverstein, 1979): (A1) less active or inactive; (A2) equally active; (A3) more active; (A4) synergistic; and (A5) inhibitory.

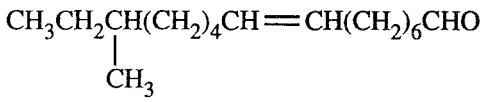
If both enantiomers are present, the following responses are possible: (B1) the insect responds optimally to the natural ratio; (B2) the insect responds more strongly to one enantiomer than to the other or to the natural ratio; (B3) the insect responds equally to each enantiomer and to all ratios; and (B4) one enantiomer inhibits the response to the other.

Where the insect produces a single enantiomer, one would expect response A1 to be most common, response A5 possible, and a priori, the other responses to be unlikely. In fact, almost all examples do fall under responses A1, and there are several examples (unexpected at the time) under response A5. Tumlinson et al. (1980) showed in field tests that only a few percent of the wrong enantiomer greatly decreased the response to the naturally occurring enantiomer in the Japanese beetle. Lanier et al. (1980) and Birch et al. (1980) demonstrated that the Idaho population of *Ips pini* produces and responds to (−)-ipsdienol; this response is inhibited by (+)-ipsdienol, which occurs in the New York population in a 65% (+):35% (−) ratio, and also occurs as a pheromone component of *Ips paraconfusus*, a competing species of the Western population of *Ips pini*. Only 5% of (+)-ipsdienol virtually blocked the response of the Idaho population to (−)-ipsdienol. It thus appears that pheromonal specificity at the enantiomeric level is a principal isolation mechanism among sympatric species of *Ips* (Birch et al., 1980). The optimal response of the New York population was to the natural ratio (category B1).

The boll weevil response has been reported to be in A2 (Mori et al. 1978), but this claim has been disproved by a recent thorough investigation of electrophysiological and field responses to samples of chemically and enantiomerically pure (+)-grandisol and (−)-grandisol; field studies were carried out in the pres-

ence of the other pheromone components (personal communication from Joseph C. Dickens, Aug. 10, 1987).

Early experiences with enantiomers involved compounds whose chiral center was directly attached to, or close to, the functional group. Thus, it was of some interest to compare the biological activity of the stereoisomers (14*R*, 8*Z*; 14*S*, 8*Z*; 14*R*, 8*E*; 14*S*, 8*E*) of trogodermal against four *Trogoderma* species (Silverstein et al., 1980) (Scheme 20).



SCHEME 20.

Briefly, the results demonstrated the high specificity associated with the chiral center far distant, in terms of number of bonds, from a functional group. The *R* enantiomer(s) was more active by two orders of magnitude. Our mild surprise was probably conditioned by experience with chiral shift reagents where distance (and angle) between the chiral center and the functional group is valid for predicting the effect. Obviously, such extrapolation to a chiral molecule at a chiral antennal receptor is not useful. Removal of the branched methyl group resulted in a 100- to 1000-fold loss of activity in comparison with the racemic branched compound.

In addressing the topic of "chirality," I have reviewed briefly several areas of stereochemistry that are essential for the natural-products chemist. The pedagogical approach was adopted to impart some appreciation of the complexities involved and especially for the extraordinary contributions of Cahn, Ingold, and Prelog. A brief section introduces some recent advances in stereochemical theory.

Acknowledgments—Dr. Keith N. Slessor, Dr. Kurt Mislow, Dr. Robert T. LaLonde, Dr. Ernest L. Eliel, and Dr. G. Helmchen have been extremely helpful with their comments. Their suggestions have been incorporated, but the author bears full responsibility for misstatements and for the tenor of the article. I am especially indebted to Dr. Helmchen for his lucid, detailed tree graphs, one of which is herein reproduced. Dr. V. Prelog was consulted by Dr. Eliel and Dr. Helmchen on the "Cahn problem."

OLFACTORY CODING IN THE PERCEPTION OF SEMIOCHEMICALS[1]

J.H. VISSER[2] and R. DE JONG

Department of Entomology
Wageningen Agricultural University
P.O. Box 8031, 6700 EH Wageningen, The Netherlands

(Received October 15, 1987; accepted February 11, 1988)

Abstract—Information processing in the olfactory pathway underlying the perception of semiochemicals by insects is discussed. Both the chemical message for mates and the message for food consist of blends of chemicals. Olfactory receptors in an insect species are tuned to the detection of those compounds which comprise such chemical messages for that species. The classification of receptors as specialists or generalists coincides with two concepts of information processing, i.e., labeled lines and across-fiber patterns, respectively. The olfactory code coming from antennal receptors in *Pieris brassicae* larvae is a combination of labeled lines and across-fiber patterning. When antennae of adult Colorado potato beetles, *Leptinotarsa decemlineata*, are stimulated by binary mixtures of leaf odor components, the pattern of neural activities in the olfactory receptors shows some separation into two channels, quantitative versus qualitative detection. The separation is complete in the antennal lobe of this beetle.

Key Words—Colorado potato beetle, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, *Pieris brassicae*, Lepidoptera, Pieridae, olfactory coding, information processing, olfactory receptors, antennal lobe, response profiles, stimulus mixtures, pheromones, host plant odor, semiochemicals.

INTRODUCTION

The insect's perception of semiochemicals underlies the message for finding mates or food. On their release in the atmosphere from a calling female or a

0098-0331/88/1100-2005$06.00/0

plant, volatile semiochemicals are transported by the wind and comprise chemical messages for insect receivers. Downwind of the source one insect species responds obviously to the message, as observed in individuals which fly or walk upwind towards the source (Visser, 1988). On the other hand, other insect species do not respond to the same message and maintain their original courses. Although all chemical messages occupy the same information channel, i.e., the air, the "tune" of a particular message is not immediately drowned out by "background music."

Both the chemical message for mates and the message for food consist of a blend of chemicals. Sex pheromones are the class of semiochemicals that has been predominantly studied. Their multicomponent nature is well known (see Arn et al., 1986). Host-plant odors possess an even more complicated blend composition than these odors and, to a large extent, consist of compounds which are generally distributed among plant species (Visser, 1986).

It should be realized that an insect searching for mates or food is facing a complex chemical world. The complexity resembles a puzzle with the many words being the individual compounds, and only some words constitute a phrase, i.e., the proper blend composition. Moreover, an insect solves the puzzle in just a few seconds; that is the time one generally observes an insect takes to change its motor pattern in response to an attractive odor.

The present paper will discuss features of information processing, starting in the olfactory receptors that are thought to be essential for the recognition of a chemical message.

THE OLFACTORY PATHWAY

Upon binding of molecules with acceptor sites on the dendritic membranes of an olfactory receptor cell, its spontaneous neural activity shows an increase (excitation) or decrease (inhibition) (Visser, 1986). The olfactory receptor cells in insect antennae send their axons directly to the brain, where the first relay station is found in the glomeruli of the antennal lobe (Figure 1) (Boeckh et al., 1984; Matsumoto and Hildebrand, 1981; Boeckh and Ernst, 1987). Thus, on stimulation with an odor, the neural activity in the whole array of antennal olfactory receptor cells changes. The change of activity in all receptors is considered as the olfactory code which contains information about odor quality, i.e., the blend composition, as well as odor intensity, i.e., the overall concentration.

The information is further processed in the antennal lobe by a complicated network of interneurons. In adult insects, the number of output neurons leaving the antennal lobe is relatively small compared to the number of input antennal fibers. This input convergence results in amplification of the original signal as

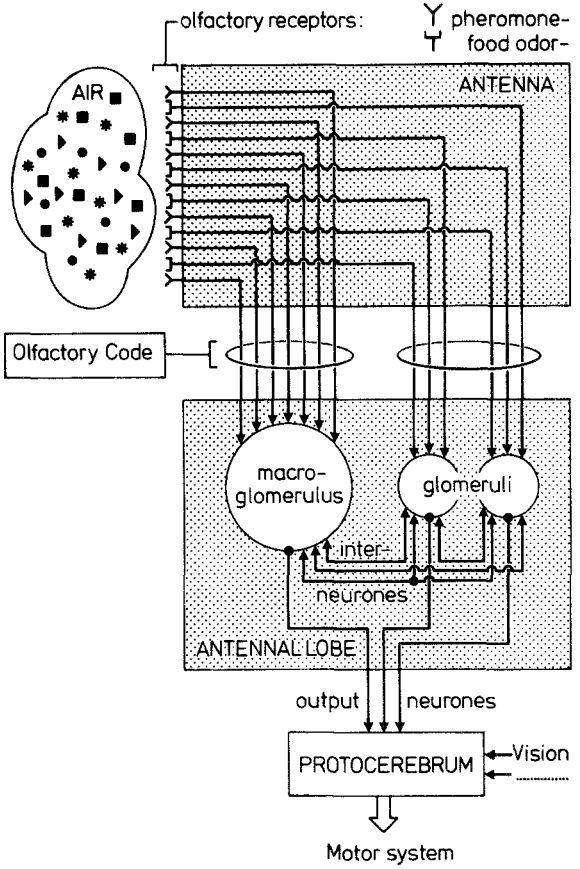

FIG. 1. The olfactory pathway in adult insects. See text for further explanation.

well as a reduction of background noise (Boeckh et al., 1984; Visser, 1986). In other words, at the level of the antennal lobe the neural activities of individual neurons are already modified at stimulus concentrations which are 100- to 1000-fold lower than those needed for a significant change in neural activities of peripheral receptors. In the protocerebrum, the olfactory information is integrated with other sensory modalities, and output elements are connected with the motor system controlling the insect's motor patterns (Figure 1) (Boeckh and Ernst, 1987).

The present discussion will focus further on the specificity of olfactory receptor cells. Their characteristics for the detection of relevant compounds, the relevant "words," underlie the recognition of the blend composition, the chemical message.

SPECIALISTS AND GENERALISTS

In early studies on the neural responses of individual olfactory receptors, the conclusion was reached that receptor neurons could be classified as either specialists or generalists (Boeckh et al., 1965). Specialists are narrowly tuned to the reception of one particular compound, whereas broadly tuned receptors, those neurons showing responses to several compounds, are called generalists.

Specialists. After the discovery of the classical specialist, the bombykol receptor of *Bombyx mori*, other pheromone receptors were treated in the same way. One class of olfactory receptors in males of the redbanded leafroller moth, *Argyrotaenia velutinana*, responds to *cis*-11-tetradecenyl acetate; the second class of receptors responds mainly to the second pheromone component *trans*-11-tetradecenyl acetate (O'Connell, 1975). A similar conclusion was reached for the detection of the two main pheromone components of the summerfruit tortrix moth, *Adoxophyes orana*: one class responding to *cis*-9-tetradecenyl acetate, the other class responding mainly to *cis*-11-tetradecenyl acetate, and, to a much smaller extent, to *cis*-9-tetradecenyl acetate (Den Otter, 1977).

In the Noctuidae and Tortricidae, families whose sex pheromones are studied most extensively, it appears that an N component pheromone blend is detected by N different receptors (Priesner, 1986). The specificity of these moth antennae to sex pheromone components even permits their application as an electroantennographic detector for the identification of pheromone components of other moth species (Guerin et al., 1985). In addition, specialist receptors are found in other insect groups. For example, in males of the American cockroach, *Periplaneta americana*, two receptor types are present in the same sensillum: one type specialized for the detection of the sex pheromone component periplanone A, and the second type responds to periplanone B (Sass, 1983).

Generalists. Generalist receptors respond to food odors. In contrast with the uniformity of specialists, the generalists show a wide differentiation in their reaction spectra. Receptor cells in the sensilla basiconica of the silk moth, *Antheraea pernyi*, possess unique response profiles, although their spectra overlap considerably (Schneider et al., 1964). Generalist receptors of the blowfly, *Calliphora vicina*, were divided into meat- and flower-odor receptors, and a further separation revealed six and three types, respectively (Kaib, 1974).

Occasionally, response profiles of the same receptors were interpreted differently. Thus the neurons in sensilla placodea on antennae of the honeybee, *Apis mellifera*, which were reported as true generalists (Lacher, 1964), were later arranged into seven reaction groups since the spectra of each showed little or no overlap (Vareschi, 1971). Cluster analysis of the response spectra of antennal receptors in the Colorado potato beetle, *Leptinotarsa decemlineata*, separated these generalists into five receptor types (Ma and Visser, 1978). However, on close observation of the neural activities in these receptors to three

components of potato leaf odor, the interpretation had to be altered. The sensitivities for these components is gradually distributed over the population of olfactory receptors (Visser, 1983). Generalist receptors in *Periplaneta americana* were also divided into reaction groups, like the pentanol, hexanol, octanol, decanol, and dodecanol groups, although their reaction spectra clearly overlapped (Selzer, 1984).

Both the analysis of electrophysiological data and the selection of odorous stimuli contain arbitrary elements. Furthermore, in most cases the classification of receptor cell responses showing certain degrees of specialization is hampered by the absence of knowledge concerning the food-odor compounds (and their concentrations) that are biologically relevant for the insect species under study. Our knowledge about the chemistry of food odors is very incomplete, and, thus, behavioral experiments with food-odor blends of defined compositions were rarely performed. Hence, the characterization of the response profiles of olfactory receptors to represent a specialist or a generalist should proceed with some restraint (Vareschi, 1971; O'Connell, 1975; Selzer, 1984; Visser, 1986).

Nevertheless, it appears that in several insect species pheromone- and food-odor information are processed through two different channels up to the level of the protocerebrum. Pheromone receptors in moths and the American cockroach are exclusively connected with the macroglomerulus, whereas food-odor receptors contact interneurons in the smaller glomeruli (Figure 1) (Boeckh et al., 1984; Matsumoto and Hildebrand, 1981; Christensen and Hildebrand, 1987; Boeckh and Ernst, 1987).

OLFACTORY CODE

The perception of a chemical message starts in the olfactory receptors. The peripheral receptors in an insect species are tuned to the detection of those compounds which comprise a chemical message for that species and thus release vital behaviors like mate and food finding. In addition, the receptors in a species should neglect irrelevant messages such as those used by other species. The response profiles of individual receptors, as discussed in the foregoing section, indicate these abilities. Furthermore, the classification of receptors as specialists or generalists coincides with two concepts of information processing in the olfactory pathway. Besides the detection of relevant compounds by the receptors, the perception of blend composition in the central nervous system underlies the recognition of a chemical message.

The concept of labeled lines involves specialist receptors, each responding to one compound of the chemical blend (Figure 2). The discrimination of blend composition in the central nervous system would be a simple comparison between neural activities in separate channels. On the other hand, an across-

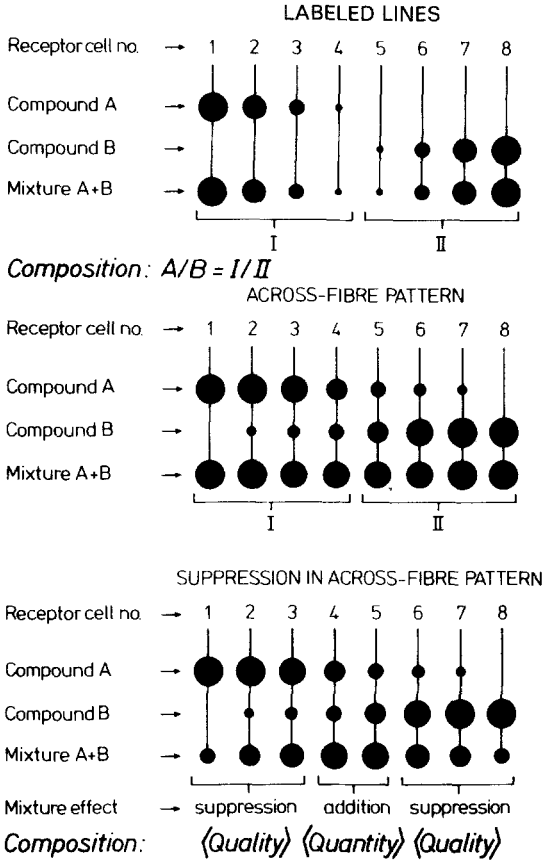

FIG. 2. Concepts of information processing in the olfactory pathway. The neural activities of olfactory receptors in response to compound A or B, and to their 1 : 1 mixture are visualized in the areas of circles. See text for further explanation.

fiber pattern would require a complicated evaluation by the central nervous system of neural activities in the whole array of olfactory receptors.

Figure 2 contains a rather simplified representation of an across-fiber pattern: generalist receptors responding to two compounds. Actually, the pattern becomes complicated when the addition of a third compound generates a certain distribution of neural activities in the same olfactory receptors. Hence, each compound adds a new dimension to the profile of activities. A natural food odor thus generates a particular pattern of neural activities across the fibers of olfactory neurons running towards the brain. The composition of such a blend would

be recognized when its across-fiber pattern matches some template present in the central nervous system.

In adult insects, the recognition of a chemical message involves the concerted action of thousands of olfactory receptors (Boeckh et al., 1984; Visser, 1986; Boeckh and Ernst, 1987). Therefore, we may wonder whether we can grasp eventually the complete olfactory code. Chemoreception in caterpillars, on the contrary, is based upon a small number of sensory neurons.

Olfactory Code in Pieris brassicae *Larvae.* A caterpillar antenna bears, on its second segment, two large sensilla basiconica, i.e., the medial and lateral sensillum basiconicum. In addition, its third segment bears a large sensillum basiconicum. The number of neurons associated with these three sensilla is seven, five, and four, respectively (Schoonhoven and Dethier, 1966). Electrophysiological recordings in larvae of *Manduca sexta*, *Hyalophora gloveri* (Schoonhoven and Dethier, 1966; Dethier and Schoonhoven, 1969), and *Malacosoma americanum* (Dethier, 1980) indicated that these 16 neurons represent the full complement of olfactory receptors in one antenna.

Previous studies on responses of these olfactory receptors involved stimulations with chemically undefined leaf odors and some individual chemicals at high doses. These kinds of experiments were repeated in fourth-instar *Pieris brassicae* larvae (Visser and Schepers, unpublished data) with a set of biologically relevant and chemically defined stimuli, i.e., constituents of the "green odor" (Visser et al., 1979), and allylisothiocyanate, a host-specific compound (Figure 3).

Methods of odor delivery were as previously described (Ma and Visser, 1978), and chemicals were diluted at the source in paraffin oil (10^{-2} and 10^{-1} v/v). Glass electrodes were inserted into antennae either at the base of the medial sensillum basiconicum on the second antennal segment (Figure 3, I) or at the base of the large sensillum basiconicum on the third antennal segment (II). Individual units were identified by measuring their spike amplitudes. On stimulation of the preparation with the series of single compounds, individual olfactory neurons showed various degrees of excitation or inhibition of their spontaneous firing activities. Temporal patterns like those reported for *Manduca sexta* (Schoonhoven and Dethier, 1966; Dethier and Schoonhoven, 1969) were never observed in the recordings; stimulations caused regular phasic–tonic responses.

The changes in neural activities of 23 neurons in response to the test chemicals were measured for the stimulation period (0.5 or 1 sec) and were expressed relative to the response of the cell's best stimulant (Figure 3). Identical response profiles were grouped in a spectral type. The grouping resulted in six spectral types for the medial sensillum (A–F) and two spectral types for the sensillum on the antennal headpiece (G and H).

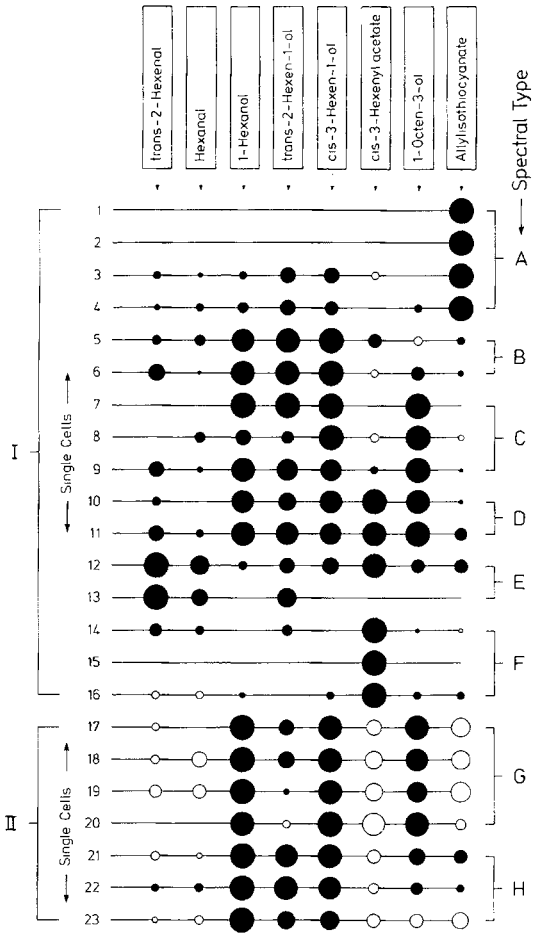

FIG. 3. Relative response spectra of olfactory receptors in *Pieris brassicae* larvae, visualized in the areas of circles. Excitation shown as filled circles, inhibition as open circles. Neurons are associated with either the large medial sensillum basiconicum on the second antennal segment (I) or the large sensillum basiconicum on the third antennal segment (II). See text for further explanation.

Since those sensilla in one antenna possess seven and four neurons, respectively (Schoonhoven and Dethier, 1966), each spectral type is considered as an individual neuron, its response being recorded repeatedly. Thus, the eight spectral types represent an across-fiber pattern in half of the total neuron population. The pattern contains specialist receptors for allylisothiocyanate (Figure 3A) and

cis-3-hexenyl acetate (F), as well as generalist receptors, e.g., the alcohol receptor (C). Hence, the olfactory code coming from this simple receptor system is a combination of labeled lines and across-fiber patterning.

Although most research on olfactory coding has involved the assessment of response profiles in populations of sensory neurons to chemicals applied singly, it remains to be determined whether such patterns of neural activities resemble olfactory codes produced on stimulation with complete blends. In an effort to answer this, we recorded the neural activities of olfactory receptors on the Colorado potato beetle's antenna, but now included stimulations with binary mixtures.

Olfactory Code in Adult Colorado Potato Beetles. The Colorado potato beetle is now a very suitable model to study olfactory coding of food-odor blends because of our present understanding of its behavior, chemoreceptors, and the plant-odor components involved in host finding.

This insect is specialized to feed on solanaceous plant species; potato, *Solanum tuberosum*, is its most common host (Visser, 1983). Beetles respond to airborne potato plant odor by walking upwind. This behavior is generally referred as an odor-conditioned positive anemotaxis and has been studied in much detail for this insect (Visser, 1988). The potato leaf odor was isolated, and the components identified included *cis*-3-hexen-1-ol, *trans*-2-hexenal, *cis*-3-hexenyl acetate, *trans*-2-hexen-1-ol, and 1-hexanol (Visser et al., 1979; Visser, 1983). The beetles' antennal olfactory neurons are selectively tuned to the detection of these so-called green-odor components (Visser, 1979). The green odor, in addition, constitutes an essential part of the host-plant odors for other phytophagous insects (Visser, 1983, 1986). The release of odor-conditioned anemotaxis in the Colorado potato beetle depends on the ratios between the green-odor components (Visser and Avé, 1978). Thus, mixing of host- with nonhost-plant odor prevents upwind orientation of the beetles (Thiery and Visser, 1986, 1987). Response profiles of the beetles' olfactory neurons to compounds applied singly were initially characterized by the grouping into five receptor types (Ma and Visser, 1978). Further analysis of receptor responses to three potato leaf-odor components revealed an across-fiber patterning over the array of olfactory receptor cells studied (Visser, 1983).

We reexamined the activities of olfactory neurons in the Colorado potato beetle's antenna in response to the five potato leaf-odor components applied singly and to three binary mixtures (1 : 1) composed of *trans*-2-hexenal, *cis*-3-hexenyl acetate, and 1-hexanol. A complete description of experimental methods and results is presented elsewhere (De Jong and Visser, 1988b).

The relative response spectra in a receptor population of 39 neurons to the compounds applied singly clearly showed a gradual differentiation of individual receptors that ranged from generalists to specialists. This conclusion was further verified by calculating the degrees of specialization for the array of receptors.

However, receptor responses to binary mixtures, in most cases, were quite different from what one would expect.

Figure 4 shows neural activities in two different receptors on stimulation with 1-hexanol, *cis*-3-hexenyl acetate, and their 1 : 1 mixture. In the first record, the response to the mixture equals the sum of responses to the constituents when applied singly. One would expect this outcome when it is assumed that different test compounds in a mixture contribute to the neural response in a simple additive manner (Figure 5). Nevertheless, the vast majority of neuronal responses to mixtures actually showed various degrees of suppression; the second record represents an example of such suppression (Figure 4). In case of suppression, the receptor response to a binary mixture is smaller than the sum of its responses

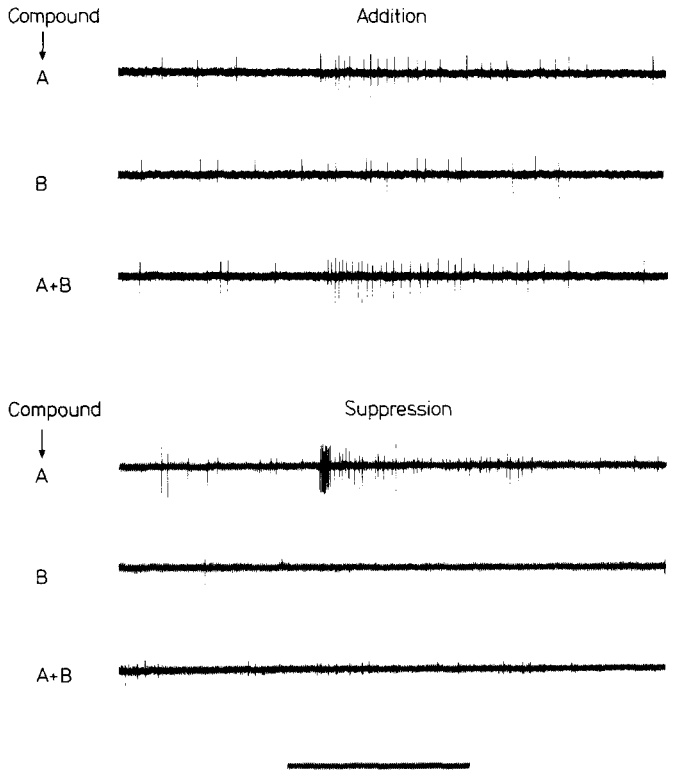

FIG. 4. Neural activities of two olfactory receptors in the Colorado potato beetle's antenna in response to 1-hexanol (A), *cis*-3-hexenyl acetate (B), and their 1 : 1 mixture (A + B), showing addition (top) and suppression (bottom). Chemicals were diluted at the source in paraffin oil (4×10^{-2} v/v). Line at bottom indicates stimulation period (2 sec).

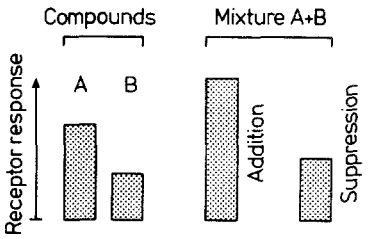

FIG. 5. Schematic illustration of addition and suppression in the receptor responses to mixtures.

to the individual components (Figure 5). It is noteworthy that mixture effects like suppression and synergism have also been reported for pheromone receptors in males of the cabbage looper moth, *Trichoplusia ni* (O'Connell, 1985; O'Connell et al., 1986) and the bark beetle, *Dendroctonus pseudotsugae* (Dickens et al., 1984).

Further analysis of the beetles' receptor responses to mixtures revealed a highly significant negative correlation of the neurons' mixture responses with their degrees of specialization. In other words, specialized receptors respond with less excitation to a mixture than their generalist counterparts. Hence, we adapted our thoughts on the olfactory code as an across-fiber pattern and included suppression as a mixture effect (Figure 2) (De Jong and Visser, 1988b).

When the antennae are stimulated by a blend, the pattern of neural activity across the fibers running towards the brain shows some separation into two channels (Figure 2). The neural activities in the first channel, consisting of generalist receptors, arise from addition of the neurons' responses to individual components. This channel is mainly affected by the quantities of components present in an odor blend. The second channel, consisting of specialized receptors, responds to a mixture by suppression. Thus, the change in neural activities in that channel depends on the interaction of components in a stimulus mixture and their quality, that is, the ratios between components of an odor blend (De Jong and Visser, 1988b).

This concept for the recognition of the blend composition, in the way the information is processed by the peripheral receptors, is further supported by a study on the responses of neurons in the antennal lobe of this beetle (De Jong and Visser, 1988a).

The neural activities of 22 neurons in the beetle's antennal lobe were recorded intracellularly. The relative response spectra of these neurons to the five potato leaf-odor components were classified into four spectral types (Figure 6). Two spectral types showed responses only when antennae were stimulated with either *cis*-3-hexenyl acetate (I) or 1-hexanol (III). The other two types

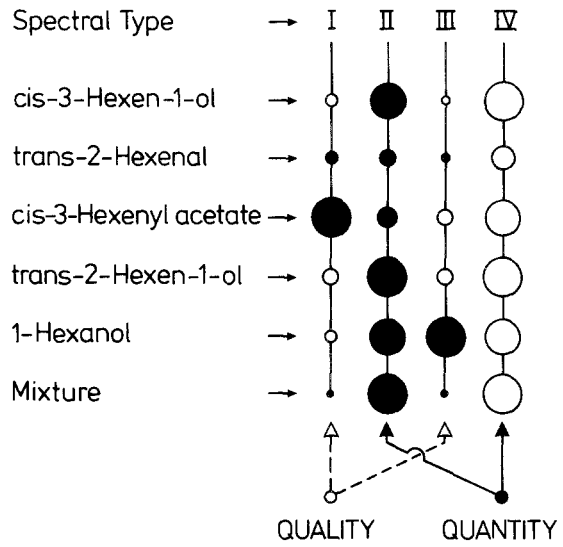

FIG. 6. Mean relative response spectra of interneuron types in the antennal lobe of the Colorado potato beetle, visualized in the areas of circles. Excitation shown as solid circles, inhibition as open circles. Antennae were stimulated with single compounds and a mixture of all potato leaf odor components (De Jong and Visser, 1988a). The mixture response of each type is indicated as either large or small. See text for further explanation.

responded to several leaf-odor components: type II showed excitations and type IV showed inhibitions of their spontaneous firing activities. On stimulation of antennae with a mixture of all leaf-odor components, such as a paraffin oil extract of potato leaves or an artificial mixture (1 : 1 : 1 : 1 : 1), the spontaneous neural activities were changed in the generalist (excitation in II and inhibition in IV) but not in the specialist interneurons (I and III).

We see that at the level of the antennal lobe the separation in two channels is complete. This suggests that host-plant odor recognition in the Colorado potato beetle relies upon the first channel responding to the presence of leaf-odor components (the quantity) and the second channel tuned to detect any unbalance in the ratios between these components (the quality) (De Jong and Visser, 1988a).

CONCLUSIONS

The recognition of a chemical message, the perception of the blend composition, starts in the olfactory receptors. The neural activities in the array of peripheral neurons, the across-fiber pattern, are affected by interactions between

the components of a stimulus mixture. Receptor responses to mixtures do not simply reflect addition. The unraveling of the olfactory code, the way the information about blend composition is processed in the olfactory pathway, certainly deserves more attention. Our understanding of the recognition of semiochemicals by insect receivers is crucial for the manipulation of such signals in programs on insect pest control.

PHEROMONE BIOSYNTHESIS IN LEPIDOPTERA

WENDELL L. ROELOFS and WALTER A. WOLF

Department of Entomology
New York State Agricultural Experiment Station
Cornell University
Geneva, New York 14456

(Received October 15, 1987; accepted February 3, 1988)

Abstract—Pheromone components for many lepidopteran species are produced by the use of unique chain-shortening and Δ9, Δ10, and Δ11 desaturase systems. Correlations in the Tortricidae indicate that the pheromone components derived from Δ9 and Δ01 desaturases are found in the more primitive species (those possessing morphological plesiomorphies). The precise blend of *Z* and *E* acetates in a number of species is regulated in the final reduction sequence from acyl intermediates. Preliminary research has been conducted on the characterization of the various desaturase enzymes used and on the important blend regulating sequence. Initial purification work on the Δ11 desaturase enzyme found in the cabbage looper moth is reported.

Key Words—Lepidoptera, desaturases, pheromone, enzymes, detergents, fatty acids, biosynthesis.

INTRODUCTION

Sex pheromones have received much attention in the past because these olfactory cues can be used in insect monitoring and control programs. However, this chemical communication system also makes possible studies on fundamental questions of behavior, olfaction, genetics, biosynthesis, etc. The specificity of sex pheromone production and perception in moth species constitutes an excellent system to study discrimination among the various mixtures by the male's olfactory system. Such studies also can address questions of regulation by the female of precise *E*/*Z* ratios of components in the glands, how the biosynthetic pathways are genetically controlled, and how the unique blend of components evolved. In this paper we discuss research conducted on a number of pheromone

0098-0331/88/1100-2019$06.00/0

biosynthetic pathways and some key enzymes in moth species, particularly in the Tortricidae.

COMMON Δ11 DESATURASE PATHWAYS

Previous research (reviewed in Roelofs and Bjostad, 1984; Bjostad et al., 1987) has shown that a large number of moth species can produce pheromone components by utilizing various combinations of two unusual enzyme systems: limited chain shortening through β-oxidation and a Δ11 desaturase. The starting material for these routes is palmitic acid (16:COOH), which is prepared from acetate in the pheromone glands via the fatty acid cycle involving fatty acid synthetase. If chain shortening occurs first, then the saturated acyl derivatives of 18:COOH, 14:COOH, and 12:COOH can be produced as substrates for the desaturation step. Interaction of the Δ11 desaturase enzyme with these precursors can produce various *E* and *Z* blends of Δ11-18:COOH, Δ11-16:COOH, Δ11-14:COOH, or Δ11-12:COOH. These in turn can undergo chain-shortening steps to produce the following series: (1) Δ11-18:COOH to Δ9-16:COOH to Δ7-14:COOH to Δ5-12:COOH to Δ3-10:COOH; (2) Δ11-16:COOH to Δ9-14:COOH to Δ7-12:COOH to Δ5-10:COOH; (3) Δ11-14:COOH to Δ9-12:COOH to Δ7-10:COOH; and (4) Δ11-12:COOH to Δ9-10:COOH. They also can undergo chain elongating steps, for example to produce Z13-18:COOH from Z11-16:COOH. Monounsaturated pheromone components are produced by reducing the above acyl intermediates to alcohols or acetates and, in some cases, converting these to aldehydes (Teal and Tumlinson, 1986; Morse and Meighen, 1986).

Additional components can be produced by converting a monounsaturated into a diunsaturated intermediate by one of several different methods. With the domestic silkworm, *Bombyx mori*, a Δ11 monoene precursor is converted to the conjugated Δ,Δ-10,12 diene system through some unknown mechanism. A large amount of Z11-16:COOH intermediate was found in the gland (Yamoaka and Hayashiya, 1982; Bjostad Roelofs, 1984), which evidently (Yamaoka et al., 1984; Ando et al., 1986) is further reacted to generate the conjugated double-bond system of the pheromone component (*E*10, Z12-16:OH). Another method of generating the conjugated double-bond system is to have the desaturase enzyme interact with an intermediate both before and after chain shortening or chain elongation. An example of this is in the production of a diene pheromone component for the light brown apple moth, *Epiphyas postvittana*. The two pheromone components for this species had been found to be *E*11-14:OAc and *E,E*-9,11-14:OAc (Bellas et al., 1983). An in vivo study (Foster and Roelofs, 1988a) using deuterium-labeled palmitic and myristic acids showed that this species uses an *E*11 desaturase system to produce the *E*11-

16:COOH, *E*11–14:COOH, and *E*,*E*-9,11–14:COOH intermediates necessary for production of the two pheromone acetates (Figure 1).

The various combinations of (1) limited chain shortening and (2) Δ11 desaturation steps are used to produce a great proportion of the known lepidopteran pheromone components. Although the Δ11 desaturase system is common in these moth species, it has not been reported in any other animal species. Attempts to characterize these enzymes will be discussed later.

Δ10 DESATURASE PATHWAY

A review of sex attractants and pheromones of almost 150 species in the Tortricidae (Roelofs and Brown, 1982) shows that a number of the components that are used, such as *Z*8–12:OAc, *Z*8–14:OAc, and *Z*10–14:OAc, could not be produced via the Δ11 desaturase. One example is the New Zealand leafroller species, *Planotortrix excessana*, which was found to use *Z*8–14:OAc as its main pheromone component (Galbreath et al., 1985). Analysis of the fatty acid intermediates in the female pheromone gland of this species showed that there was an abundance of *Z*8–14:COOH and *Z*10–16:COOH (Löfstedt and Roelofs, 1985). These intermediates suggested that the pheromone acetate was produced by action of a Δ10 desaturase on palmitic acid followed by limited chain shortening from 16C to 14C. This pathway was confirmed (Foster and Roelofs, 1988b) by in vivo studies using deuterium-labeled palmitic and myristic acid precursors. There was incorporation of label from the d_3-16:COOH precursor into *Z*10–16:COOH, *Z*8–14:COOH, and 14:COOH. With the myristic acid precursor (d_3-14:COOH), however, label was incorporated only into 14:OAc and, to a much lesser extent, into *Z*10–14:OAc. These results showed that *Z*8–14:OAc was produced by involvement of a Δ10 desaturase in the pheromone pathway, and not by a Δ8 desaturase.

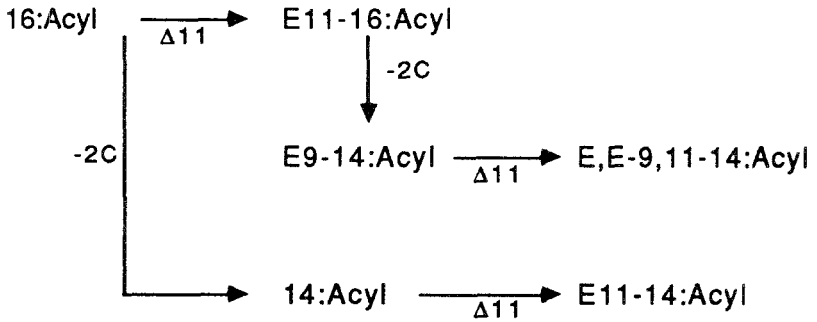

FIG. 1. Biosynthetic pathways for producing a diunsaturated and monounsaturated pheromone component in the light brown apple moth with *E*11 desaturation.

Δ9 DESATURASE PATHWAY

Although most of the pheromone components in the Tortricidae can be accounted for by the pathways described above, there still remain a few whose structures suggest the functioning of a Δ9 desaturase enzyme. One example of this is provided by the brownheaded leafroller, *Ctenopseustis obliquana*, of New Zealand, whose main pheromone components have been reported to be Z5–14 : OAc and Z8–14 : OAc (Young et al. 1985). Analysis (Löfstedt and Roelofs, 1985) of the fatty acyl intermediates in the female pheromone gland showed presence of ubiquitous oleic (Z9–18 : COOH), linoleic, linolenic, and palmitoleic (Z9–16 : COOH) unsaturated acids, as well as the unusual Z7–16 : COOH, Z10–16 : COOH, and Z8–14 : COOH acids. Studies (Foster and Roelofs, 1988c) with deuterium-labeled precursors showed that the Z8–14 : OAc component was prepared from palmitic acid, but that the Z5–14 : OAc component was not. Label incorporation into the Z5 component was obtained only when labeled oleic acid was used as the precursor. These data suggested that this component is produced in the gland from oleic acid that is synthesized somewhere else in the insect or obtained from dietary sources. Therefore, the pathway for this pheromone component involves the ubiquitous Δ9 desaturase enzyme in the production of the oleic acid, but this enzyme probably is not active in the sex pheromone gland in this case.

Another example involving extracellular oleic acid as the pheromone percursor is the pink bollworm pheromone, which consists of Z7,Z11– and Z7,*E*11–16 : OAcs (Hummel et al., 1973). Studies (Foster and Roelofs, 1988d) with various deuterium-labeled precursors showed that no label incorporation was obtained with stearic or palmitic acid, but there was incorporation with oleic acid into Z7–16 : COOH and the pheromone components. The results support a pathway in which oleic acid present in the gland is shortened to Z7–16 : COOH and then desaturated with Δ11 desaturases to produce the Z7,Z11– and Z7,*E*11–16 : COOH precursors.

EVOLUTIONARY SIGNIFICANCE OF PHEROMONE PATHWAYS

In defining pheromone pathways utilizing different desaturase systems in the Tortricidae (Figure 2), we have developed some ideas on the evolution of these pheromone systems. The most striking trend in these data is that species using pheromone components from extracellular oleic or palmitoleic acid (Δ9 desaturase) or from the Δ10 desaturase pathway usually possess plesiomorphic characters and are classified by taxonomists as quite primitive relative to other tortricids. In a previous review of tortricid sex attractants (Roelofs and Brown, 1982), these components were listed in the primitive Olethreutinae genera of

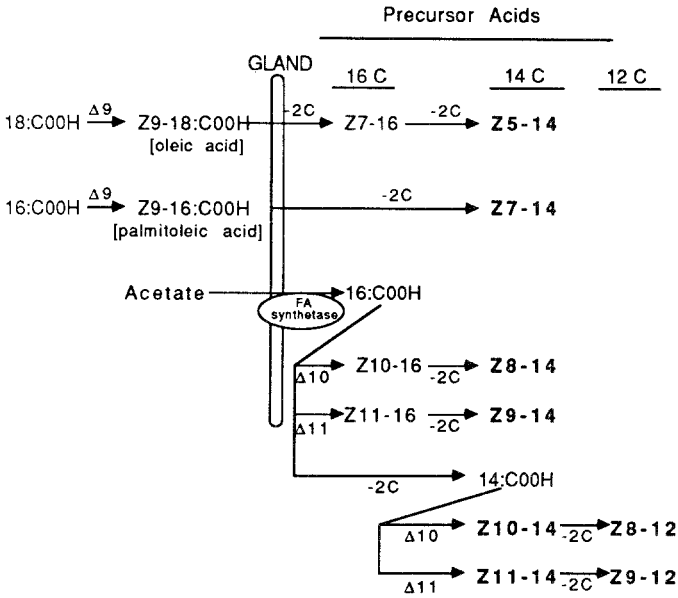

FIG. 2. Summary of biosynthetic pathways in the Tortricidae for producing most of the known pheromone component precursors.

Microcorses, *Endothenia*, and *Apotomis*. Subsequently, another primitive Olethreutinae species in the genus *Bactra* was shown to produce Z10–14:OAc as the main pheromone component (Bjostad and Roelofs, 1983). In an interesting survey of 19 Tortricinae species throughout New Zealand (Foster and Dugdale, 1988), it was learned that nine of these species are distinct from the rest by possession of a variety of plesiomorphic characters. All of these species also were found to use pheromone components that have biosynthetic pathways involving either Δ10 desaturation or Δ9-unsaturated precursors. The remaining apomorphous species all have pheromone components derived from a pathway involving Δ11 desaturation.

Further support for the idea that the use of Δ9- or Δ10-desaturated precursors represents a plesiomorphy for tortricids comes from a survey of 30 tortricid species in Australia (Horak et al., 1988). In this study, over half the species used pheromone components derived by way of Δ11 desaturation, but none of the plesiomorphic members of the Tortricinae, or Olethreutinae tribes, used pheromone components involving Δ11 desaturation. Again, the species possessing plesiomorphic characters used pheromone components with unsaturation is the 5, 7, or 9 position from Δ9 desaturation, or in the 8 or 10 position from Δ10 desaturation.

The general trend of pheromones in the Tortricidae suggests that perhaps limited chain shortening in the microsomes evolved first to produce unique components from available oleic and palmitoleic acids. The ubiquitous Δ9 desaturase system then could have been activated in the gland to produce some additional precursor acids, such as Z9–14:COOH, which could account for the occurrence of Z9–14:OAc in some of the plesiomorphic species described in the New Zealand and Australian surveys. Mutation of the Z9 desaturase then could account for the occurrence of the other unique Δ10 and Δ11 desaturase systems found commonly in the Lepidoptera.

PRODUCTION OF SPECIFIC GEOMETRIC ISOMER BLENDS

Research on the biosynthetic precursors of the redbanded leafroller moth aided in pinpointing the critical step for regulation of the *E*/*Z* mixture of pheromone components. Two of the main components, *E*11- and Z11–14:OAc, are held in a tightly controlled 9:91 ratio (Miller and Roelofs, 1980; Roelofs et al., 1986). At first we assumed that this ratio would be controlled in the desaturation step, which produces a mixture of *E*11- and Z11–14:COOHs. However, base-catalyzed methanolysis of glandular lipids produced a mixture in which the *E* isomer predominated at a 58:42 *E*/*Z* ratio (Bjostad et al., 1981). Analysis of several lipid classes found in the gland showed that there was an abundance of these fatty acyl groups in the triacylglycerols in a 61:39 *E*/*Z* ratio, and smaller amounts of these acyl groups in the choline and ethanolamine phosphatides in a 31:69 ratio. Moreover, analysis of the choline phosphatides with phospholipase A_2 showed that the *E*11- and Z11–14:Acyl groups were found only at the sn-2 position, but analysis of the triacylglycerols with lipase showed that they were not preferentially distributed at particular positions. Hence, the 9:91 *E*/*Z* ratio of acetates must be generated in the reduction sequence from acid precursors to acetates. Other studies with radiolabeled precursors showed that an isomerase was not responsible for the final ratio of *E*/*Z* isomers (Bjostad and Roelofs, 1984).

Research with various radiolabeled triacylglyerols containing either 14:Acyl, *E*11- or Z11–14:Acyl in the sn-2 position showed that triacylglyerols probably do not serve as acyl donors n the production of pheromone components (Bjostad et al., 1987). It is possible, however, that the phosphatides are early intermediates in the pathway and that their *E*/*Z* ratio reflects the initial production of these unsaturated precursors by the Δ11 desaturases. It has been suggested (Bjostad et al., 1987) that the fatty acyl groups are selected from the phosphatides to produce the 9:91 *E*/*Z* ratio found in the acetates and that the remainder, which would be high in *E* isomer, is dumped into the triacylglycer-

ols. It is the specific production of the 9:91 ratio in the reduction sequence that remains a mystery.

Research on several races of European corn borer moths has provided some insight into this final reduction sequence. Genetic studies (Klun and Maini, 1979; Roelofs et al., 1987) have been carried out with races that have opposite blends of the two pheromone components, *E*11- and *Z*11-14:OAc, also used by the redbanded leafroller. In analyzing crosses and backcrosses with these races, it was determined that the blend of *E*/*Z* isomers (99:1, 65:35, and 3:97 for the *E* race, hybrid, and *Z* race, respectively) is controlled by a single autosomal genetic factor. However, analysis of the fatty acyl intermediates showed that they all had about the same ratio (70:30) of *E*/*Z*11-14:COOH precursors, regardless of which acetate ratio was finally produced (L. Sreng and W. L. Roelofs, unpublished). This implies that the single genetic factor is operative on some enzyme system in the final reduction sequence. Therefore, although the biosynthetic pathway to these pheromone components has many steps, it takes only a change in one enzyme system to generate a different component ratio. However, studies so far have shown that it takes more than intense selection pressure to modify this highly canalized enzyme system (Roelofs et al., 1986).

EVIDENCE FOR A FAMILY OF Δ11 DESATURASES

In studying the biosynthetic pathways of several lepidopteran species, it became obvious that there were a number of different Δ11 desaturases present (Wolf and Roelofs, 1986, 1987). In the cabbage looper, the enzyme produces only the *Z* isomer of 16- and 18-carbon chain acids, and very little desaturated 14-carbon acid. Conversely, in redbanded leafroller moths, the enzyme produces both *E* and *Z* isomers of 14-carbon chain acids, but no unsaturated 16- or 18-carbon acid. When we investigated the spruce budworm moth pheromone pathways to prove that the *E*11-14:OAc was indeed produced by Δ11 desaturation rather than by some other pathway as previously reported (Morse and Meighen, 1984), we found (Wolf and Roelofs, 1987) that spruce budworm females did produce *E*11 and *Z*11 isomers from 14-carbon acid in a 10:1 *E*/*Z* ratio and that they also had an enzyme that produces *Z*11-16:COOH. This apparent combination of three enzyme systems also is found in the European corn borer populations, which exhibit a 70:30 *E*11/*Z*11 ratio of 14-carbon acids, and an abundance of pure *Z*11-16:COOH. Interestingly, the corresponding acetate of *Z*11-16:COOH has not been found to be part of the pheromone blend in the corn borer. Research discussed above (Figure 1) also shows that the light brown apple moth possesses a Δ11 enzyme that produces only *E* isomer with

both 16- and 14-carbon chain acids. The evidence suggests a family of Δ11 enzymes with slightly different specificities and product stereochemistry.

CHARACTERIZATION OF CABBAGE LOOPER MOTH Δ11 DESATURASE

The Δ11 desaturase enzyme from cabbage looper moth female glands was partially purified by ultracentrifugation, and the pellet obtained at 100,000*g* containing the microsomal fraction was found to contain the Δ11 desaturase activity (Wolf and Roelofs, 1986). Some of its properties were characterized and compared with those of the ubiquitous Δ9 desaturase enzyme (Wang et al., 1982). Similarities between the two systems include subcellular location (microsomal), substrate specificity (16- and 18-carbon acids), and lack of sensitivity to carbon monoxide, while differences include cofactor preference (NADH rather than NADPH), sensitivity to cyanide ion, pH optimum (7.4–7.8 vs. 6.8–7.2), inactivation by ferrocyanide, and location in the organism (in the pheromone gland compared to generally distributed).

The enzyme uses palmitoyl-CoA as a substrate much more efficiently than palmitic acid. However, the product is not simply the desaturated CoA derivative. The workup procedure employed partitions the product between organic and aqueous layers. Coenzyme A and its derivatives remain in the water layer, but analysis of the palmitoyl-CoA desaturation reaction shows that all the desaturated acid is in the organic solvent. Separation of the lipid classes by thin-layer chromatography (Bjostad and Roelofs, 1984) followed by fatty acid analysis of each class showed the desaturated acid to be mostly in three regions of the plate: phosphatidylcholines (27%), ethanolamines (7%), and free fatty acids (66%) (Wolf and Roelofs, unpublished). In addition, a small amount of acid was found in the triglyceride region. Since it is known that the glands contain very little free fatty acid (Bjostad and Roelofs, 1984) and that the CoA derivatives are not very stable under our assay conditions, it is assumed that most of the free acid represents material that would be found on some ester (CoA or lipid) in the natural system. At this time it is not known which derivative of Z11–16:COOH is used for the next chain-shortening sequence—a coenzyme A or a phosphatidylcholine derivative.

PURIFICATION OF CABBAGE LOOPER MOTH Δ11 ENZYME

Attempts are being made to purify the cabbage looper moth Δ11 desaturase further. The enzymatic assay being used to follow the purification is the same as previously reported (Wolf and Roelofs, 1986). Since microsomal enzymes are generally resolubilized before purification, we decided to investigate the effects of various detergents on our crude microsomal fraction. Initially, it

seemed reasonable to assume that the structure of the Δ11 enzyme would be similar to that of the ubiquitous Δ9 desaturase (Jeffcoat, 1979). Thus, we observed the effects of sodium deoxycholate and Triton X-100, both of which had been used to purify the Δ9 desaturase (Strittmatter et al., 1974; Joshi et al., 1981), as well as CHAPS, a reportedly mild sulfonic detergent (Womack et al., 1983). However, the addition of 0.1–1.0% of any of these detergents to the assay buffer resulted in the loss of over 90% of the enzymatic activity, indicating that they are not suitable for this system.

We next tried nonionic alkyl detergents. Both octanoyl-*N*-methyl glucaide (Hildreth, 1982) and *n*-octyl-β-D-glucopyranoside enhanced the reactivity of the system when crude enzyme (supernatant of 10,000*g* centrifugation) was used, but only the glucamide retained this effect when the microsomal fraction was assayed (Table 1).

Suspension of the microsomal fraction (pellet from 100,000*g* centrifugation for 1 hr) in buffer containing these detergents followed by recentrifugation for hr at 100,000*g* showed that most of the activity in the glucamide-containing buffer remained in the supernatant (Table 2). Longer (3-hr) centrifugation resulted in more activity in the pellet, so the solubilization cannot be termed complete.

Purification of the microsomal fraction was attempted using Blue Sepharose, an affinity chromatography substrate that binds a variety of NAD^+- and $NADP^+$-requiring enzymes. Column chromatography gave a single broad peak of activity. Batch treatment of the enzyme solution with the Sepharose followed by reelution of the bound proteins showed that most of the desaturase activity did not bind to the substrate (it stayed in the supernatant). Thin-layer chromatograph of the enzyme assays showed the the Blue Sepharose supernatant had fewer side products than did the control. In addition, gel electrophoresis

TABLE 1. CABBAGE LOOPER Δ11 DESATURASE SOLUBILIZATION[a]

	10,000*g* supernatant[b]	100,000*g* pellet[b]
Control	100	100
Octanol-*N*-methyl glucamide (1%)	160	190
n-Octyl-β-D-glucopyranoside (1%)	185	90

[a] Protein solution was divided into three parts and added to cofactors, radiolabeled palmitoyl-CoA, and detergent in separate assay tubes. After 1-h, the assays were extracted and the extracts transmethylated and subjected to TLC on silver-impregnated silica. The radiolabel was located and counted using a scintillation counter (see Wolf and Roelofs, 1987).

[b] Reactivity relative to control. Absolute values for the control were: 10,000*g* supernatant, 10,823 dpm; 100,000*g* pellet, 1576 dpm.

TABLE 2. DETERGENT SOLUBILIZATION OF Δ11 DESATURASE[a]

	Relative activity[b]	
	Supernatant	Pellet
Control	60	40
Glucamide[c]	200	30
Pyranoside[c]	50	40

[a] 100,000*g* pellet suspended in buffer with detergent and recentrifuged at 100,000*g*.
[b] Relative to control (total control activity = 100).
[c] Detergents same as in Table 1.

(SDS-PAGE) showed that this fraction contained fewer proteins, especially in the molecular weight range expected for the proteins that make up the desaturase (25,000–50,000 daltons) by analogy to the Δ9 enzyme (Jeffcoat, 1979). After this much manipulation, the total activity of the enzyme fractions is low, but further attempts at stabilization and purification are proceeding.

ENZYMES IN REDBANDED LEAFROLLER MOTH

Sex pheromone biosynthesis is the redbanded leafroller moth involves chain shortening (16:COOH to 14:COOH) followed by Δ11 desaturation (to give a mixture of *E* and *Z*11–14:COOH) (Bjostad et al., 1987). Previous studies in cell-free systems prepared from pheromone glands of the orange tortrix moth, *Argyrotaenia citrana*, showed that the chain-shortening reaction could be observed when the following reactants were supplied: NADH, NADPH, BSA, coenzyme A, ATP, and magnesium chloride (Wolf and Roelofs, 1983). It is assumed that the latter three aid in the synthesis of the CoA ester, which could be the preferred substrate for the chain-shortening step. In the redbanded leafroller, the same assay conditions also allow chain-shortening to occur. Omission of BSA or NADPH from the reaction does not reduce the amount of 14:COOH produced, but omitting NADH or CoA effectively stops chain-shortening (Wolf and Roelofs, unpublished).

The Δ11 desaturase produces both geometric isomers from 14:CoA, but in a *Z* to *E* ratio of 60:40, which differs both from that of the fatty acids present in the gland (42:58) and of the pheromone (91:9) (Wolf and Roelofs, 1987). Attempts to use 1,2-dimyristoyl-L-3-phosphatidylcholine as substrate for this reaction were unsuccessful (Wolf and Roelofs, unpublished), giving more

weight to the idea that the CoA derivative is the natural substrate for the desaturase.

SUMMARY

Many species of Lepidoptera utilize pheromone components that are produced with a combination of unique chain-shortening and desaturase steps. It appears that the chain-shortening step was used initially to convert existing oleic and palmitoleic acids to pheromone components of a shorter carbon length. The evolution of Δ10 and Δ11 desaturase enzymes then allowed the moths to generate a host of unique chemicals to be used in species-specific pheromone blends. The purification and characterization of some of these unique enzymes is a big challenge to biochemists, but should provide the information needed to take the next step in isolating the gene that encodes for these enzymes.

(Received October 15, 1988; accepted February 3, 1988)

Abstract—Aldehyde components of lepidopterous pheromones are converted to carboxylic acids by aldehyde oxidizing enzymes (AOEs) that are present at high levels in antennal tissues of adult moths. The AOEs may include O_2-requiring aldehyde oxidases as well as nucleotide-cofactor-requiring aldehyde dehydrogenases. Three classes of inhibitors were synthesized and examined in vitro for AOE inhibition using *Heliothis virescens* antennae: (1) cyclopropanols, (2) α-fluorinated aldehydes, and (3) α,β-unsaturated carbonyls. First, cyclopropanated analogs of (Z)-11-hexadecenal (Z11-16:Al), a common unsaturated aldehyde component of many species' pheromone blends, were synthesized as isosteric pheromone analogs and as potential inhibitors of the moth AOEs. NMR assignments are reported for the *cis*- and *trans*-cyclopropanols. Cyclopropanols appear to act as oxidase-activated AOE inhibitors, perhaps via the unstable cyclopropanones. Second, α-fluoro and α,α-difluoro substituted analogs of Z9-14:Al were synthesized and shown to be modest inhibitors of both the alcohol oxidase and AOE activities. Finally, the most potent inhibitors were α,β-unsaturated carbonyl mimics of the Z11-16:Al. The α-methylene aldehyde was 1000-fold less effective than the vinyl ketone Z1,11-16:3-oxo. This inhibition appears irreversible and is postulated to involve electrophilic modification of an active site sulfur nucleophile.

Key Words—Cyclopropanation, cyclopropanol, enzyme inhibitor, pheromone analog, vinyl ketone, *Heliothis virescens*, *Plutella xylostella*, α-fluoroaldehyde, (Z)-11-hexadecenal, (Z)-9-tetradecenal, Lepidoptera, Noctuidae, Plutellidae.

INTRODUCTION

Pheromone analogs offer important insights into the binding interactions necessary for recognition by the molecular acceptor sites located in insect antennae (Prestwich, 1987a,b). Typically, important functional groups are mimicked with electronically different isosteric substitutions or by electronically similar but sterically divergent replacements. In order to study the aldehyde-metabolizing enzymes of moths, we have synthesized and tested a number of potential inhibitors of the aldehyde-oxidizing enzymes (AOEs). These AOEs convert the aldehyde pheromone components to the carboxylic acids, which lack the ability to produce olfactory stimulation. We had previously designated these aldehyde-oxidizing enzymes from *H. virescens* as aldehyde dehydrogenases (Ding and Prestwich, 1986; Prestwich, 1987a,b; Prestwich *et al.*, 1987b). However, recent experiments with enzyme-staining in electrophoretic gels in our labs (M.L. Tasayco J., unpublished results) and from workers examining *Manduca* antennal enzymes (M. Lerner and R. Ripchinsky, unpublished results) have suggested that the catabolic enzymes are more likely to be aldehyde oxidases. We now present three examples in which reactive or latently reactive electrophilic functionalities have been incorporated into variants on the aldehyde functional group. Selected experimental details have been included (Ding, 1987).

SELECTED ALDEHYDE MIMICS

Cyclopropanated Pheromone Analogs

Background. Surprisingly, cyclopropyl-containing analogs of pheromones have received scant attention. Two primary motivations are important in examining cyclopropyl analogs. First, the cyclopropanation of an internal (*Z*)-alkene preserves the "bent" nature of the alkenyl chain, but alters local pi electron density and bond angles. It also confers a new stereogenic element, such that two enantiomers of the *cis*-cyclopropanated analogs exist. Second, introduction of cyclopropanol or cyclopropanone moieties at the oxygen-functionalized end of the pheromone offers the opportunity to produce targeted inhibitors of pheromone processing enzymes (Prestwich, 1987a; Prestwich et al., 1987b).

Synthesis of Internal Cyclopropyl Analogs. To prepare the internally cyclopropanated analogs (Figure 1), Z11–16:OH (**1**) was first protected as the *t*-butyldimethylsilyl ether (**2**) and then cyclopropanated (95°C, 16 hr, benzene–toluene) with excess diiodomethane and diethylzinc (Rousseau and Slougui, 1983) to give silyl ether **3**. The *cis*-cyclopropyl analogs were prepared by ether cleavage with excess tetra-*n*-butylammonium fluoride (TBAF) in THF (0–25°C, 1 hr) to give alcohol **4**. Acetylation (Ac_2O, Py, 16 hr, 20°C) or pyridinium dichromate oxidation (1.5 equiv., CH_2Cl_2, 5 hr, 20°C) of alcohol **4** produced acetate **5** or aldehyde **6**, respectively. Each compound was purified by silica gel

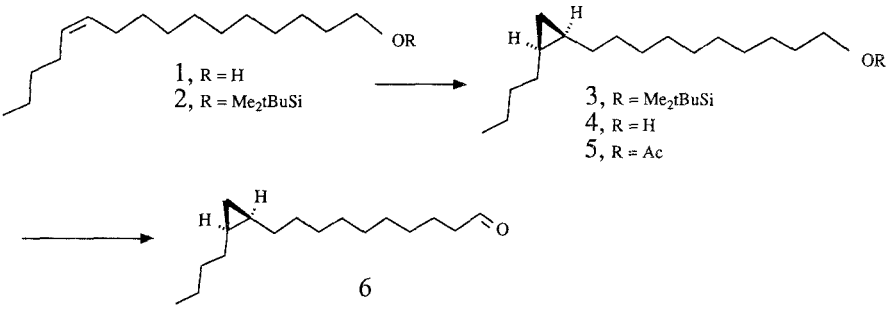

FIG. 1. Synthesis of internally cyclopropanated Z11–16 analogs.

flash chromatography, and homogeneity was ascertained by TLC and by capillary GC (Ding, 1987). We will refer to these *cis*-cyclopropyl analogs using the shorthand "*cc*"; thus, the two analogs are *cc*11–16 : Ac (**5**) and *cc*11–16 : Al (**6**).

Synthesis of Cyclopropanols. Cyclopropanols were prepared by cyclopropanation of the trimethylsilyl enol ethers of the unsaturated aldehyde Z11–16 : Al as shown in Figure 2. Thus, Z11–16 : Al (**7**) was converted to a 62 : 38 mixture

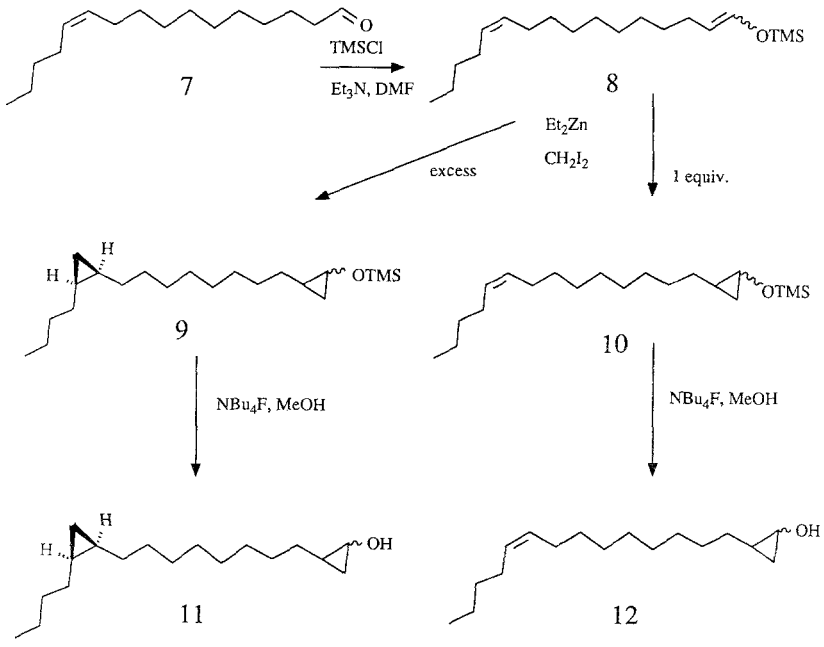

FIG. 2. Synthesis of cyclopropanol analogs of Z11–16 : OH.

of the *Z/E* enol TMS ethers **8** using 2.4 equiv. of trimethylchlorosilane and 4.8 equiv. of triethylamine in dry DMF (reflux, 16 hr) (Ito et al., 1979). The proton NMR signals (300 MHz) for the enol ether vinyl protons allowed assignment of stereochemistry and relative proportions: *Z*-isomer, δ 4.46 (dt, J = 6.1, 7.1 Hz), 6.11 (dt, J = 6.1, 1.3 Hz); *E*-isomer, δ 4.96 (dt, J = 12.0, 7.1 Hz), 6.16 (dt, J = 12.0, 1.3 Hz). Monocyclopropanation could be accomplished using 1.6 equiv. of diethylzinc and 2.0 equiv. of diiodomethane by adding the diiodomethane to the remainder of the reagents in dry ether at −78°C, and then stirring for 12 hr at 20°C with careful monitoring of the reaction progress by capillary GC. The cyclopropanol TMS ethers **10** were obtained as a 62:38 *cis*:*trans* mixture as seen by the diagnostic proton NMR signals for the carbinyl hydrogen of each isomer: *cis*, δ 3.36 (ddd, J = 6.6, 6.6, 3.3 Hz); *trans*, δ 3.02 (ddd, J = 6.1, 2.6, 2.6 Hz). Addition of excess diethylzinc–diiodomethane reagent and warming to 95°C for 12 hr readily produced the biscyclopropanated ethers **9**. Cleavage of the silyl ether with tetrabutylammonium fluoride in methanol (Wasserman and Dion, 1982) followed by column chromatography afforded the pure cyclopropanols **11** and **12**. Proton NMR signals of the cyclopropyl protons (Wiberg et al., 1973) were readily assigned for the *cis*- and *trans*-substituted cyclopropanols: δ 3.18 (ddd, *trans* H-1, J = 6.2, 2.7, 2.7 Hz), 3.50 (ddd, *cis* H-1, J = 6.5, 6.5, 3.1 Hz). We have adopted a shorthand for the cyclopropanol terminus "Cpo" which *excludes* the extra carbon, such that the Z11–16:OH analogs are named as Z11–16:Cpo (**12**) and *cc*11–16:Cpo (**11**). In addition, the Z9–14:OH analogs Z9–14:Cpo and *cc*9–14:Cpo were prepared following the same procedures (Ding, 1987).

Electrophysiological Activity. Cyclopropanated compounds were examined as analogs of Z11–16:Ac, Z11–16:OH, and Z11–16:Al in electroantennogram (EAG) assays using antennae of male diamondback moths, *Plutella xylostella* (E.M. Giblin and E.W. Underhill, personal communication). The *P. xylostella* antennal system has previously been used to evaluate the relative EAG responses to haloacetate analogs of Z11–16:Ac (Prestwich and Streinz, 1987). The results for the cyclopropanols and *cis*-cyclopropyl chain analogs are presented in Table 1. It is surprising that the *cis*-cyclopropanation alone lowers the EAG response to a much greater extent than does the cyclopropanol moiety; both modifications together essentially eliminate EAG activity. Indeed, it was also found that the 2,3-cyclopropyl-Z13–18:OH (a cyclopropyl carbinol) still showed a relative EAG potency of 0.78 relative to Z11–16:OH (Ding, 1987; E.M. Giblin and E.W. Underhill, personal communication).

Enzyme Inhibitory Activity. The internally cyclopropanated aldehyde *cc*11–16:Al was examined as a competitive inhibitor of the aldehyde dehydrogenase of *Heliothis virescens* antennae, using [^{3}H]Z11–16:Al as the substrate. As expected, it appeared to act as an alternative substrate and no inhibition was observed at concentrations up to 10 μM, which is two to four times the apparent K_M for the crude enzyme preparation (M.L. Tasayco J., unpublished results).

TABLE 1. EAG ACTIVITY OF CYCLOPROPANATED ANALOGS WITH *Plutella xylostella*

Compound	Mean rel. EAG response[a]	
Z11-16:Al	1.01 a	(N = 5)

*cc*11-16:Ac	0.174 c	
*cc*11-16:Al	0.298 b	
*cc*11-16:Cpo	0.044 d	
Z11-16:Al	1.00 a	(N = 3)
Z11-16:OH	0.483 b	
Z11-16:Cpo	0.416 b	

[a]Responses with different letters are statistically different at the $P < 0.05$ level using a multiple range test (Duncan, 1955).

The substituted cyclopropanols were prepared with the expectation that they would function as alcohol-oxidase-activated inhibitors of antennal AOEs, as shown schematically in Figure 3. We hypothesized that a cyclopropanol (e.g., **12**) would be oxidatively activated by the oxidase activity present in antennae to an unstable cyclopropanone (**13**) which would be capable of acting as transition state analog inhibitor of the aldehyde dehydrogenase by formation of a stable tetrahedral adduct such as **14** with an active site cysteine of the antennal AOE (Walsh, 1982; Wiseman and Abeles, 1979; Wiseman et al., 1980). Covalent modification of an aldehyde oxidase could also be envisioned. Direct preparation of the substituted cyclopropanones (Wasserman et al., 1974) had been unsuccessful (Ding, 1987). It was not possible to overcome the extreme

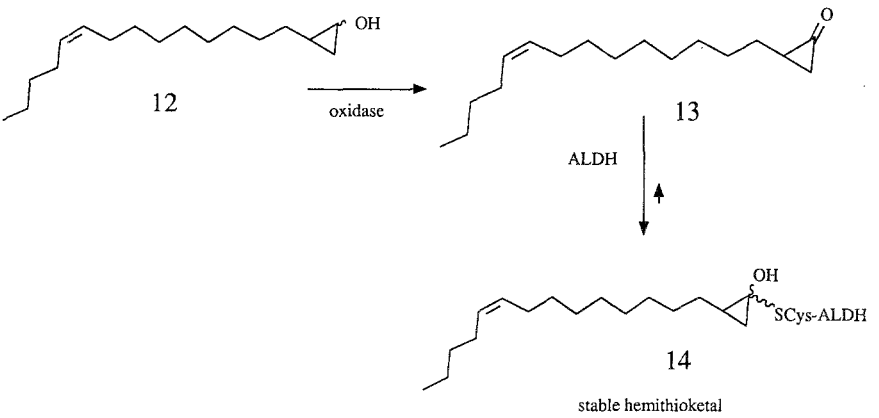

FIG. 3. Proposed oxidase activation of cyclopropanol **12** to produce cyclopropanone **13**, and formation of stable hemiketal adduct **14** with the aldehyde dehydrogenase activity.

instability of monoalkylsubstituted cyclopropanones (Dowd et al., 1984) even long enough to obtain NMR spectra of cleavage products of the protected hemiketals.

Earlier, we demonstrated alcohol oxidase activity in homogenates of the legs, antennae, and glands of adult *H. virescens* for oxidation of [^{3}H]Z9–14:OH and for [^{3}H]Z11–16:OH (Prestwich, 1987a; Ding, 1987; Ding and Prestwich, 1986). Recently, capillary GC analysis has been used to show that the oxidase activity associated with the cuticle of female glands is relatively nonspecific for saturated vs. unsaturated primary alcohols, but will not oxidize secondary alcohols (Teal and Tumlinson, 1986; Tumlinson and Teal, 1987).

The assays for both oxidase (substrate was [^{3}H]Z11–16:OH) and AOE activities (substrate was [^{3}H]Z11–16:Al) were performed after a preincubation (35 min, 20°C) of the cyclopropanol inhibitors (1 μM and 10 μM) with the enzyme preparation. As shown in Table 2, significant inhibition of both AOE and alcohol oxidase was observed when 0.2 equiv. female gland was assayed, but not when 2 gland equiv. per assay were used. The female pheromone gland has been shown to possess both high AOE and high oxidase activity in vitro (Ding and Prestwich, 1986), and at higher enzyme concentration, the inhibitory effect is negligible.

Table 2 also illustrates the results of the inhibition of the AOE activity of male *H. virescens* antennae by the alkenyl cyclopropanol (**12**) and the cyclopropylalkyl cyclopropanol (**11**). The effect of the internal cyclopropyl is neg-

ligible; it neither hinders nor enhances the inhibition due to the cyclopropanol moiety. This might be expected from the results of Teal and Tumlinson (1986) since the oxidase activity and perhaps also the AOEs activity appear to act on a variety of nonphysiological substrates.

The time dependence of the inhibition of AOE activity was explored briefly using 0.2 male antenna/assay (Ding, 1987). In this experiment, the Z9–14:Cpo homolog was preincubated for 10, 20, 30, 40, 50, or 60 min with the enzyme homogenate prior to assay with [^{3}H]Z11–16:Al. Inhibition of AOE activity increased from 80% to nearly 100% during this time course, and then declined to below 80% at the longest preincubation time. This suggests that the "slower" enzyme (alcohol oxidase) was producing an unstable inhibitory species for the "faster" AOEs. After the optimal preincubation time and during the subsequent assay period, the reduction in inhibition could be attributed to dissociation of the covalent tetrahedral adduct and decomposition of the cyclopropanone to a simple noninhibitory carboxylic acid.

α-Fluorinated Aldehyde Analogs

The substitution of fluorine for hydrogen often produces analogs of bioactive natural compounds with altered chemical or physical properties (Walsh, 1983). In particular, we (Prestwich, 1986) and others (Camps et al., 1983) have been interested in the effects of fluorination on insect steroid metabolism and on pheromone binding and catabolism. ω-Fluorinated fatty acid derivatives can be pheromone analogs as well as potential toxicants (Prestwich, 1987a; Carvalho and Prestwich, 1984). Modification of the reactivity of the aldehyde functionality itself involves replacement of the α-hydrogens or the aldehydic hydrogen by fluorine. The latter has been shown to produce a hyperagonist aphrodisiac in the case of the Z11–16:Acf and Z9–14:Acf analogs of the *H. virescens* aldehydes (Prestwich et al., 1986). More recently, we showed that although the α,β-unsaturated acyl fluorides are poor electrophysiological mimics of the boll weevil cyclohexylidene aldehydes, the α-fluoro compounds showed biological activity equivalent to the natural components (Prestwich et al., 1987a). Replacement of an α-hydrogen by fluorine stabilizes the tetrahedral hydrate form of the aldehyde, and can lead to an effective enzyme inhibitor (Gelb et al., 1985). Similarly, trifluoromethyl ketones can act as potent transition-state analog-type esterase inhibitors (Hammock et al., 1982). Since both esterase and aldehyde dehydrogenase (but not aldehyde oxidase) mechanisms involve acyl enzyme and tetrahedral adduct intermediates, we examined these α-fluorinated analogs as AOE inhibitors.

Synthesis. We required mild syntheses of the α-fluorinated aldehydes which would not compromise the internal double bond; however, compounds with both remote olefinic bonds and α-fluorinated aldehydes were unknown when

we began in 1985. The successful scheme is shown in Figure 4 for the Z9–14:Al analogs. The Grignard prepared in dry ether from (Z)-7-dodecenyl bromide (**15**) and Mg metal was added slowly to a −78°C solution of excess diethyl oxalate in ether, stirred 1 hr (20°C), and worked up to give a 60% yield of the homogeneous α-ketoester **16** after chromatography (Huet et al., 1973). The difluoro analog was readily obtained by treatment of an ice-cooled CH_2Cl_2 solution of the ketoester **16** with 1.2 equiv. diethylaminosulfur trifluoride (DAST) and stirring at 20°C for 3 hr (Middleton and Bingham, 1980). Workup with bicarbonate solution avoided free HF; attempted silica chromatography of the α,α-difluoroester **17** resulted in 50% decomposition to the α-fluoro-α,β-unsaturated ester (δ 6.11, H-3, dt, $^3J_{HF}$ = 33.3 Hz, $^3J_{HH}$ = 7.8 Hz). The difluoroester **17** in ether was reduced by addition of 1.2 equiv. of DIBAL-H in toluene (Erni and Khorana, 1980) at −78°C, warming to 20°C for 3 hr, and isolation of the α,α-difluoroaldehyde **18** as the hydrate after chromatography on neutral alumina (activity III). The free aldehyde could be obtained by evaporation distillation (0.5 mm, 100°C) of the hydrate.

The monofluoroaldehyde was prepared using an analogous sequence beginning with the α-hydroxyester **19**, obtained in ca. 50% yield by reduction of the α-ketoester **16** (20–35°C, 3 hr) with a reagent prepared from vacuum-dried silica gel and lithium aluminum hydride in ether (Kamitori et al., 1982). Addition of the hydroxyester **19** in CH_2Cl_2 to 1.2 equiv. DAST in CH_2Cl_2 at −78°C gave, after aqueous workup, a quantitative recovery of the crude α-fluoroester **20** which was used without further purification: [^{1}H]NMR, δ 4.87 (dt, $^2J_{HF}$ = 49.6 Hz, $^3J_{HH}$ = 5.5 Hz). Following the same DIBAL-H reduction, a 6:4 mixture of aldehyde to overreduced alcohol was obtained. Swern oxidation (Mancuso and Swern, 1981) of the crude mixture gave, after purification on alumina, a 98% yield of the α-fluoroaldehyde **21** as the hydrate.

Enzyme Inhibition. The two fluoroaldehydes were tested as potential inhibitors of the alcohol oxidase and aldehyde dehydrogenase activities in tissue

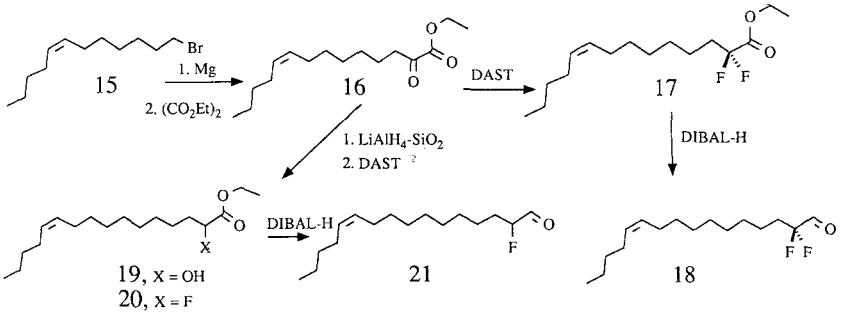

FIG. 4. Synthesis of α-fluorinated aldehyde analogs of Z11–16:Al.

homogenates of *Heliothis virescens* using [^{3}H]Z9–14 : OH and [^{3}H]Z9–14 : Al, respectively. The tissue preparation, incubation, TLC separation of product and substrate, and correction for nonenzymic degradation was performed as described earlier (Ding and Prestwich, 1986), except that the inhibitor (as an ethanolic stock solution) was preincubated with the enzyme solution for 90 min prior to addition of substrate. The final ethanol concentrations were below 1%, and ethanol blanks were included. Substrate concentrations were 0.1 μM of carrier-free [^{3}H]Z9–14 : Al or [^{3}H]Z9–14 : OH.

The results are summarized in Table 3. The male antennal AOE activity is only inhibited by the difluoroaldehyde **18** and shows no inhibition by the monofluoroaldehyde **21** at the highest tested concentration of 10 μM. When less enzyme is present, as in the female gland AOE, inhibition is higher; when more enzyme is present, as in the use of two antennal equivalents, no inhibition is observed. By comparison, the oxidase activity of the female gland is effectively completely blocked by the difluoroaldehyde **18** and the oxidase activity of the male antennae shows substantial inhibition by the monofluoroaldehyde **21**. The results are consistent with the absence of carbonyl form under aqueous conditions, such that little interaction with an AOE can occur. The hydrate, on the other hand, may be acting as a substrate for the oxidase; the precise mode of inhibition by such carbonyl hydrates would require further investigation.

A preliminary evaluation of the two fluorinated aldehydes showed essentially no stimulatory activity at all in EAGs using *P. xylostella* male antennae.

α,β-Unsaturated Carbonyl Analogs

Our search for effective AOE inhibitors then focused on electrophilic functionalities capable of covalent modification of the putative active-site thiol residue, which is required for enzymatic activity (Flynn and Weiner, 1986). To this end, we chose to synthesize the α-*exo*-methylene aldehyde **25** and the vinyl ketone **23** as analogs of *Z*11–16:Al and to examine their potencies as AOE inhibitors in vitro. These electrophilic analogs could act as potent, irreversible inhibitors of *H. virescens* antennal AOE.

Synthesis. The synthesis of the vinyl ketone is shown in Figure 5 and follows procedures we had employed earlier for making ^{14}C-labeled vinyl ketone to study detoxification of a termite defense secretion (Spanton and Prestwich, 1981). Thus, addition of *Z*9–14:Al (**22**) in THF to a 0°C solution of 5 equiv. of vinylmagnesium bromide in THF followed by stirring 1 hr at 20°C, aqueous workup, and chromatography afforded an 80% yield of the allylic alcohol. Oxidation of the allylic alcohol with activated MnO_2 in hexane (24 hr, 20°C) gave, after chromatography, an 86% yield of the vinyl ketone: [^{1}H]NMR, δ 5.81 (H-1*E*, dd, J = 10.4, 1.2 Hz), 6.21 (H-1Z, dd, J = 17.6, 1.2 Hz), 6.35 (H-2, dd, J = 17.6, 10.4 Hz).

The *exo*-methylene analog **25** was prepared as indicated in Figure 6. The TMS cyclopropyl ether **10** (prepared as described above) was dissolved in CH_2Cl_2 and added to a 1 M solution of stannic chloride in methylene chloride, stirred for 30 min 15°C, and concentrated in vacuo to give the trichlorostannyl adduct **24** as a yellowish semisolid (Ryu et al., 1986) which was used without further purification. The crude adduct **24** was stirred with DMSO in hexane or chloroform. The reaction could also be performed in d_6-DMSO-$CDCl_3$ and monitored by [^{1}H]NMR at 300 MHz. Within 45 min, the signal at δ 9.70 for the starting stannyl-complexed aldehyde disappeared and a new peak at δ 9.52 had appeared for the unsaturated aldehyde. After removal of solvents, the residue was chromatographed to give a 50% yield of the reactive α-methylene aldehyde **25**: [^{1}H]NMR: δ 2.21 (H-3, t, J = 7.5 Hz), 5.96 (s, H17*E*), 6.22 (s, H-17Z), 9.52 (s, H-1).

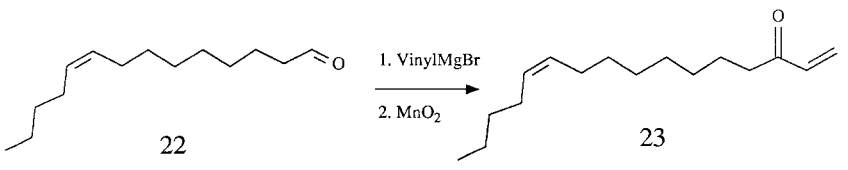

FIG. 5. Synthesis of vinyl ketone analog of *Z*11–16:Al.

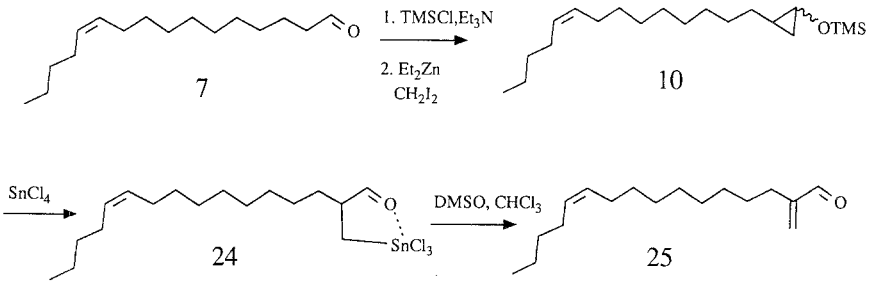

FIG. 6. Synthesis of the *exo*-methylene analog of Z11–16:Al.

Enzyme Inhibition. The preliminary in vitro assays of AOE inhibition by each of the two α,β-unsaturated carbonyls were conducted in duplicate with *H. virescens* male antennal homogenates, using a 40-min preincubation time (26°C) for inhibitor concentrations of 0.5, 1, 2, 5, 10, and 20 μM. Figure 7 summa-

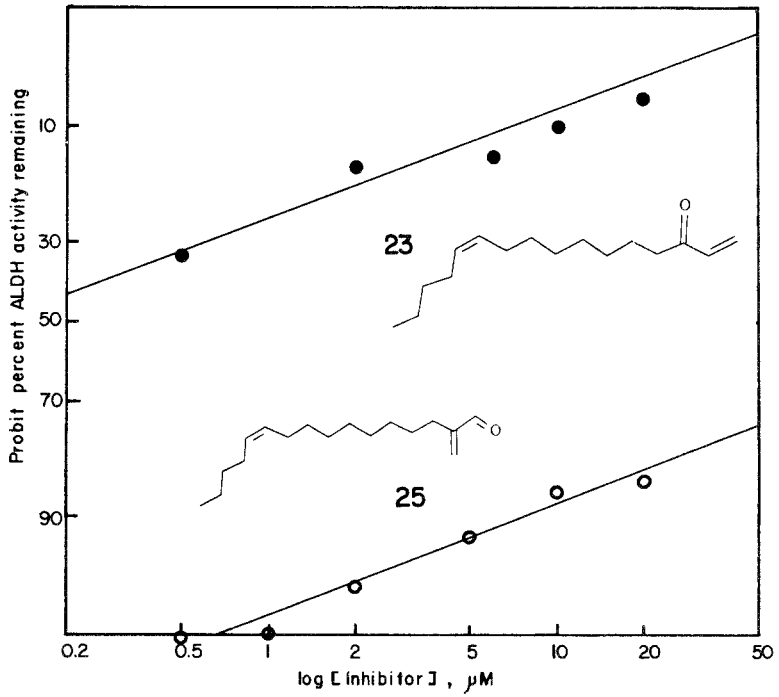

FIG. 7. Concentration dependence of inhibition of *H. virescens* male antennal AOE by vinyl ketone **23** and *exo*-methylene aldehyde **25**.

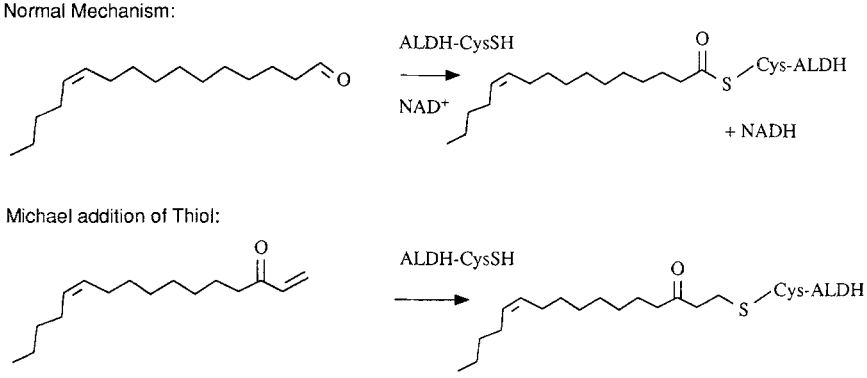

FIG. 8. Proposed mode of inhibition of AOE by vinyl ketone **23**.

rizes the results for these two inhibitors using 0.2 antennal equiv. per assay and 0.1 μM of the substrate, [^{3}H]Z11-16:Al. It is clear that the vinyl ketone **23**, with an I_{50} value below 0.1 μM under these conditions of low substrate concentration ($<0.1\ K_M$), is a minimum of 1000 times more potent as an AOE inhibitor than the α-methylene aldehyde **25**, which shows only 15% inhibition even at 20 μM. Full inhibition with the vinyl ketone is reached in less than 10 min preincubation, and the inhibition appears to be irreversible.

The observed inhibition is consistent with the model shown in Figure 8. Thus, the proximity of the β-carbon of the vinyl ketone to the thiol group at the AOE active site enables facile conjugate addition to the enone system in competition to direct carbonyl addition. This gives an adduct unable to undergo further processing by the enzyme. In contrast, the *exo*-methylene aldehyde **25** appears to lack the correct spatial orientation of the β-carbon to allow this conjugate addition. We believe this may be a substrate-specific modification of the specific pheromone-processing AOE. Although the action of vinyl ketones on aldehyde dehydrogenases has precedent, the effects of vinyl ketones on aldehyde oxidases are poorly known. Our current studies (M.L. Tasayco J., B. Latli, and M. Handley, unpublished results) show (1) a rapid time course of inactivation and (2) a distinct optimal length (C_{14}, C_{16}) and requirement for unsaturation for the carbon chain of the inhibitory vinyl ketones. The electrophysiological effects of these potent enzyme inhibitors toward *P. xylostella* and for *H. virescens* sensory cells are also being examined.

Acknowledgments—We thank the NSF (Metabolic Biology, DMB-8316931) for grant support, the Herman Frasch Foundation, the Alfred P. Sloan Foundation, the Camille and Henry Dreyfus Foundation, and Rohm and Haas for research awards. EAG studies were graciously performed by Drs. E.M. Giblin and E.W. Underhill at the National Research Council-Plant Biotechnology Institute in Saskatoon, Saskatchewan, Canada. We thank M.L. Tasayco J., B. Latli, and M. Handley for permission to refer to some unpublished work on *H. virescens* AOE.

Abstract—The sex pheromone communication system of the European corn borer moth varies intraspecifically. Analyses of pheromonal extracts of wild females, collected in a region where the types (each producing a different isomeric proportion of *Z*- and *E*-11-tetradecenyl acetate) are sympatric, showed that the *Z* pheromone-production allele frequency was ca. 4 times greater than the *E* allele. The paucity of *E* production and response alleles in the population indicates that moths inheriting those alleles concomitantly inherit some undefined disadvantage. The types interbreed, but the frequency of heterozygous pheromone-production types among wild females was less than predicted by Hardy-Weinberg equilibrium and was evidence of positive assortative mating. Rates of male captures in field traps baited with females of the three pheromonal types also evidenced assortative mating in the population. Progeny tests with males captured in the traps provided circumstantial evidence that pheromone response and production functions in the species are regulated by separate genetic loci and that the loci are not always complementary; i.e., a male can carry an allele coding for production of one pheromonal isomer ratio but can be genetically predisposed to respond to another.

Key Words—11-Tetradecenyl acetate, population genetics behavioral genetics, *Ostrinia nubilalis* European corn borer, Lepidoptera, Pyralidae.

INTRODUCTION

Examples of intraspecific communications involving tactile, auditory, visual, or chemical cues are abundant throughout the animal kingdom; however, our understanding of how they might have evolved or the genetic determinants of these communication channels is surprisingly limited. The inception of any communication system requires the evolution of two novel capacities, that of production of a signal and that of an appropriate receiver. The improbability of the coincident and de novo occurrence of the two events staggers the imagination (Kitteredge and Takahashi, 1972). Despite the improbability, the channels exist, and are a source of fascination.

The sex pheromone communication systems of insects have been of particular interest over recent years, and their chemistry and behavioral aspects have been fairly well elucidated. However, there have been few studies relevant to the issue of genetic control of production and receiver functions in these communication channels. Partly responsible for this fact is that examples of intraspecific pheromonal variability, in which genetic regulation of these functions might be studied, are rare (Mitter and Klun, 1987). The European corn borer (*Ostrinia nubilalis*) is one of the rare examples. In this species, the isomeric composition of the female sex pheromone, 11-tetradecenyl acetate, varies intraspecifically and is regulated by simple Mendelian inheritance involving a pair of autosomal alleles (Klun and Maini, 1979). The pheromone production alleles involved can be designated as *Z* and *E*; the *ZZ* genotype secretes ca. 97:3 (*Z*:*E*), *EE* secretes ca. 3:97 (*Z*:*E*), and the *ZE* heterozygote secretes ca. 35:65 (*Z*:*E*). These alleles were previously designated as *a* and *A* by Klun and Maini. Thus, the species is comprised of three female sex pheromone-production types; the heterozygote arises by hybridization and subsequent recombination.

The European corn borer is distributed throughout much of the holarctic, and male trapping surveys, using various geometrical mixtures of 11-tetradecenyl acetate, have indicated that the *Z* allele predominates in most populations while the *E* allele predominates only at select locations in Switzerland, Italy, and the northeastern United States (Klun and cooperators, 1975; Buechi et al., 1982; Anglade et al., 1984). In some instances where male trap captures were monitored over successive years at the same location, Anglade et al. (1984) noted that the male capture rate in traps baited with 3:97 (*Z*:*E*) and 35:65 11-tetradecenyl acetate often declined from one season to the next while captures in 97:3-baited traps increased. They speculated that the change in apparent phenotypic frequency might be related to variations in environmental conditions (climatic and trophic) that selectively favor the *ZZ* type. Because of its worldwide prevalence, it appears that the *ZZ* type may enjoy some selective advantage; however, no basis for it is known.

Voltinism in the European corn borer is variable, depending primarily on geographic location, and most studies (Klun and cooperators, 1975; Anglade et al., 1984; Roelofs et al., 1985) indicate that the pheromonal type in a population and voltinism are independent variables. Glover et al. (1987) speculated that females of the *EE* type store more 11-tetradecenyl acetate in their pheromone glands than females of the *ZZ* type; analyses of the pooled ovipositor extracts from homozygous laboratory colonies of the two types showed that the *EE* type females stored ca. 3 times more pheromone than *ZZ*. Aside from this observation, there are no known differences between types, nor are there any morphological or physiological characters that permit their differentiation.

Although the genetics of female sex pheromone production in the European corn borer have been known for some time, the genetics regulating male olfactory response was only recently revealed (Hansson et al., 1987), and the relationship between production and response loci is unknown. For purposes of this study, we hypothesize the existence of a complementary locus in males with two alleles (Z' and E') that promote sexual response to products of the Z and E alleles of females, respectively. Response and production functions are usually coordinated to permit functional communication channels in the species. As evidence of this coordination, Klun and Maini (1979) showed that heterozygous F_1 males, from a cross of *ZZ* and *EE* genotypes, responded preferentially to the 11-tetradecenyl acetate isomer ratio that was characteristic of female siblings (35 : 65, Z : E) and less effectively to either of the parental ratios. Thus, the results showed that males track changes in the female pheromone signal, and the electrophysiological studies by Hansson et al. (1987) indicate that the tracking process is related to inherited changes in the action potential response patterns of specific male antennal chemosensory cells to the geometric isomers of 11-tetradecenyl acetate. These changes in the sensory cell response patterns to the isomers are apparently regulated, like sex pheromone production in the female, by a Mendelian autosomal gene. Roelofs et al. (1987) have indicated that, although discrimination of geometric composition at the sensory level is controlled by the autosomal gene, male behavioral response to the geometric ratios is also influenced by a sex-linked gene. This apparent redundancy of genes controlling male response warrants further study.

In the summer of 1984, we conducted a preliminary male European corn borer trapping study in the vicinity of Beltsville, Maryland, and found that the pheromonal types in this bivoltine population were sympatric. This finding prompted us to study the population in an effort to determine the relative abundance of pheromonal types, to gain insight into the extent to which they interbreed, and to better understand the organization of the species' mating system. We report that the Z allele is the most abundant in the population. Results indicate that sympatric pheromonal types mate assortatively; however, interbreeding does take place at a low level. Gene flow is apparently facilitated by

males in the population that respond sexually to one geometric proportion of 11-tetradecenyl acetate, but they carry female-limited pheromone production alleles that code for a dissimilar geometric proportion.

METHODS AND MATERIALS

Insect Cultures. Colonies of European corn borer, homozygous for *ZZ* and *EE* pheromone production genes, were established in the laboratory by collecting 60 gravid females with sweep nets from the headland vegetation of cornfields at the Beltsville Agricultural Research Center over the course of the 1984 and 1985 growing seasons. Isofemale lines were reared on artificial diet (Reed et al., 1972), and female progeny in each family were screened by gas chromatographic analysis of their ovipositor extracts to identify the lines that were homozygous for pheromone production. Forty-seven progeny lines were identified as *ZZ*, six were *EE*, and seven were heterozygous. The homozygous lines were combined to establish *ZZ* and *EE* colonies, and these were maintained in incubators (80% relative humidity; 16 hr light–8 hr dark, 26°C:20°C) on separate floors of our laboratory to ensure their homozygous condition. F_1 hybrids were prepared as needed by placing 40 *ZZ* females and 40 *EE* males together in a screened cage fitted with a sheet of waxed paper at its top. The insects mated, egg masses were collected, and the progeny were reared at the conditions described above. Pheromonal heterozygosity in the F_1 progeny was always verified by chromatographic analyses.

Live-Trapping Males and Progeny Tests of Trapped European Corn Borer Males. Virgin *ZZ*, *ZE*, and *EE* female types, used to bait traps in the field, were caged individually in 5 × 5 cm cylindrical screen cages that were each fitted with a cotton dental roll saturated with water. The females were always ca. 24 hr old when they were deployed in the insect traps. The conditions in the laboratory incubators, in which they were held prior to deployment in the traps, were the same as described previously and the photoperiod was synchronous with the diurnal cycle outdoors. Throughout the course of the trapping, test sets of females in the traps were provided water daily and were replaced with fresh females after three or four nights or whenever a female died.

The cone-trap design (*Heliothis* Scentry trap) used in the study was identical to that described by Webster et al. (1986) with the exception that the containment portion of the trap was constructed of a finer fabric mesh size (1.5 × 1.5 mm) to prevent the escape of captured males. The entire containment portion of the trap was attached to the top of the cone with a Velcro fastener for easy recovery of trapped males. Each trap was baited with a caged virgin female by attaching the cage to a string that was strung across the center of the lower opening of the trap.

Sets of 10 traps were deployed at the perimeter of cornfields at three sites on the Beltsville Agricultural Research Center that were at least 2 km apart. Traps were deployed in line 30 m apart and positioned with their lower openings 1 m from the ground. Six traps at each location were baited randomly with *EE* females, two traps were baited with *ZE* females, and the remaining two with *ZZ* females. A larger number of *EE* female-baited traps was used in the experiment because earlier trapping tests showed that *EE*-responding males were least abundant in the population. Thus, the extra *EE* female-baited traps at each location ensured that a sufficient number of *EE*-responding males would be captured for subsequent progeny tests.

Males were trapped from July 21 through August 9, 1986, during the summer flight of the borer. Each morning, the number of males captured the previous night in response to each female type was recorded. Approximately 10 males, captured in traps baited with each female type, were collected individually in sealed plastic cups and labeled to designate the genotype causing its capture. Each male was then paired with a virgin female from the laboratory colony that was homozygous for pheromone production. Specifically, males captured in traps baited with *ZZ* females were mated with *ZZ* females and males captured in *EE* or *ZE* female-baited traps were paired with *EE* females. Subsequent chromatographic analysis of the pheromone produced by female progeny resulting from these pair-matings allowed determination of the pheromone production genotype of captured males. To achieve this end, each mating pair was retained for ca. 5 successive nights in a 5 × 5 cm cylindrical screened cage with a sheet of waxed paper at its top in incubators operated at conditions described previously. Females that mated layed eggs on the waxed paper and egg masses from each pair were placed over artificial diet in a ca. 500-ml screw-cap jar that was fitted with a cylinder of corrugated paper as a pupation site for the insects and sealed with a 80 × 60 mesh/2.54 cm^2 copper screen. The progeny lines were reared under reverse photoperiod, and pupae from each line were isolated individually in jelly cups to await adult emergence. Female progeny were held for 48–72 hr after emergence, and then the individual ovipositors were excised under a low-intensity red light at mid-scotophase. Each ovipositor was transferred to a screw-cap microvial having a conical interior and containing 10 μl heptane. The excised ovipositor and the associated pheromone gland of each female were allowed to soak in the solvent for ca. 30 min before the tissue was removed. Extracts were stored in sealed vials at −15°C until 11-tetradecenyl acetate geometrical compositions could be determined chromatographically.

Capillary gas chromatography (GC) with flame ionization detection was performed using four Hewlett-Packard gas chromatographs that were operated using splitless injectors (225°C; split-valve open 0.4 min after injection). Two of the instruments, models 5830 and 5840, were fitted with 60 m × 0.25 mm

ID DB-1, nonpolar columns (J&W Scientific, Inc., Folsom, California 95630) and the other two instruments (both model 5840A) were each fitted with 60 m × 0.25 mm ID Supelcowax polar columns (Supelco, Inc., Bellefonte, Pennsylvania 16823). Hydrogen was the carrier gas with a linear velocity of 55 cm/sec at initial oven temperature. The DB-1 and Supelcowax columns were operated using oven temperature programs: 120°C at injection, heating at 15°C/min 0.45 min after injection to 175°C, and 90°C at injection, heating at 30°C/min 0.45 min after injection to 180°C, respectively. Operating at these conditions, the GC columns fully resolved (*E*)- and (*Z*)-11-tetradecenyl acetate.

Routinely, each ovipositor extract was concentrated to 2–3 μl, injected into a gas chromatographic column, and the *Z*:*E* proportion of 11-tetradecenyl acetate in the extract was determined from the area or height of peaks representing the respective geometrical isomers in the chromatographic run. Extracts of line progeny females containing 0:100 to 10:90 *Z*:*E* 11-tetradecenyl acetate isomer ratios were scored phenotypes of the *EE* genotype, 20:80 to 50:50 *Z*:*E* were scored *ZE* genotype, and extracts with 100:0 to 85:15 *Z*:*E* ratios were scored as *ZZ* genotype (Klun and Maini, 1979). A minimum of 10 individual female analyses was obtained from each progeny line to determine the pheromone-production genotype of the male parent. Knowing which female type had caused capture of each male parent allowed development of correlations between the apparent sexual response preference of the males and the female limited pheromone-production allele frequencies within each male behavioral class.

Frequency of Female Pheromonal Forms by GC. Wild adult females (n = 177) were collected during the day in the vicinity of the insect traps. These insects were placed individually in jelly cups and held in an incubator until the 2–3 hr of the next scotophase. At that time, the mating status of each female was determined by inspection for the presence or absence of a spermatophore (Drecktrah and Brindley, 1967), and the ovipositor was excised and extracted with heptane. The extracts were subsequently analyzed by GC to determine the pheromonal phenotype of each female and to permit genotypic designation.

Flight Tunnel Assay of Response of Field-Collected Males to 11-Tetradecenyl Acetate Isomers. Six cone traps were deployed 30 m apart in a line at the edge of a cornfield; four were baited with a rubber septum treated with 100 μg (*Z*)-11-tetradecenyl acetate and two were baited with septa treated with 100 μg 11-tetradecenyl acetate (97:3, *Z*:*E*). Freshly treated septa were placed in the traps every third day. Each morning, from July 23 to August 7, 1987, samples of males captured the night before in respective pure *Z* and 97:3 *Z*:*E* baited traps were collected individually in capped jelly cups and transferred to an environmental chamber that was programmed to simulate the existing seasonal day length and temperatures. Between 2300 hr and 0200 hr of the night following collection from the traps, pure *Z*-, *Z*:*E*-captured males, and males from our *ZZ* colony were assayed for their responsiveness in a flight tunnel to rubber septa

treated with 100 μg pure Z, 97:3 Z:E, or 33:67 Z:E 11-tetradecenyl acetate. The flight tunnel and conditions of the assay were identical to those described by Schwartz et al. (1988). The criterion for a positive male response was that the moth flew 3 m upwind in the stimulus plume and came within 1 cm of the septum or landed on it. The assay was replicated 31 times using a randomized block design, and the percentage of positive responses among male types to each isomer mixture was calculated.

RESULTS AND DISCUSSION

Pheromone-Production Allele Frequencies among Females. Table 1 shows that unequal numbers of females were collected at each of three locations for gas chromatographic determination of the frequency of female pheromonal types. The unequal number of samples reflects the time that was spent collecting insects at each location and is not a measure of insect density. Inspections for spermatophores indicated that most of the females collected had mated but pheromone titer in a majority of the females (121) was sufficient to determine the 11-tetradecenyl acetate isomeric proportions of their pheromone. We calculated the expected pheromonal genotypic frequencies, Z and E allele frequencies, and tested (chi-square) the observed genotypic frequencies at each location for conformity to the Hardy-Weinberg expectations at equilibrium (Hartl, 1980). The results (Table 2) show that the Z allele frequency was higher than the E frequency at each location. The frequency of genotypes observed at locations 2 and 3 deviated significantly from the expectations of the Hardy-Weinberg equilibrium. At these locations, a deficiency in the observed number of heterozygotes indicated that pheromonal types in the population mate assortatively.

TABLE 1. SAMPLES OF WILD FEMALES AT THREE LOCATIONS ON BELTSVILLE AGRICULTURAL RESEARCH CENTER, JULY 16–18, 1986[a]

	Number of females		
Location	Collected	Mated	Positive phenotype determinations
1	15	8	12
2	61	54	31
3	101	92	78

[a] Locations 1, 2, and 3 were on the so-called South, West, and East farms, respectively, at the Beltsville Agricultural Research Center.

TABLE 2. FEMALE SEX PHEROMONE PRODUCTION ALLELE FREQUENCY ACCORDING TO GAS CHROMATOGRAPHIC (GC) ANALYSIS OF FERAL FEMALES AND MALE RESPONSE ALLELE FREQUENCY ACCORDING TO MALE TRAP-CAPTURES AT THREE LOCATIONS[a]

	Frequency of female types by GC			Pheromone production allele frequency			$\bar{X}$ males/trap/female type			Male response allele frequency		
	ZZ	*ZE*	*EE*	χ^2	PZ	QE	*ZZ*	*ZE*	*EE*	χ^2	PZ′	QE′
Location 1												
Observed	10	1	1	0.7	0.88	0.12	382	21	39	256.1[b]	0.89	0.11
Expected	9	3	0.1				348	88	6

Location 3												
Observed	54	13	11	18.3[b]	0.78	0.22	112	84	25	2.2	0.69	0.31
Expected	47	27	4				107	93	20			

[a] $\chi^2 = \{[|(ZZ_o - ZZ_e)| - 0.5]^2\}/ZZ_e + \{[(ZE_o - ZE_e)| - 1]^2\}/ZE_e + \{[|(EE_o - EE_e)| - 0.5]^2\}/EE_e$. *ZZ* and *EE* are the assumed homozygous male responders and *ZE* are assumed heterozygous male responders. o = observed, e = expected. The expected values were calculated from the expectations of the Hardy-Weinberg equilibrium model for random mating, with a correction for continuity.

[b] $P < 0.05$.

Samples from location 1 did not differ significantly from Hardy-Weinberg equilibrium, but this may be a result of the small sample size from that location.

Frequency of Male Response Types. Male captures in female-baited traps across all locations during the 1986 summer flight of the insect are shown in Figure 1. Arrows in the figure indicate the nights when fresh females of each type were placed in the traps. The data show that captures were maximal at two different times during the course of the flight and that capture rates in traps among female types rose and fell synchronously, indicating that the fluctuations in capture rate were independent of female type. Captures/trap/female type (Table 2) varied from one location to another, indicating that male pheromone response preferences of populations differed parochially. Assuming that the capture rate in each female-type baited trap is a measure of the frequency of three genetically determined male behavioral classes (*Z′Z*, *Z′E′*, and *E′E′* genotypes) at each location, and that male response is regulated, like pheromone production, by a pair of alleles at a single locus, we calculated male response allele frequency and tested the observed frequency of male genotypes for conformity to Hardy-Weinberg equilibrium. Results (Table 2) show that the putative *Z′* male-response allele frequency was also greater than *E′* at all locations.

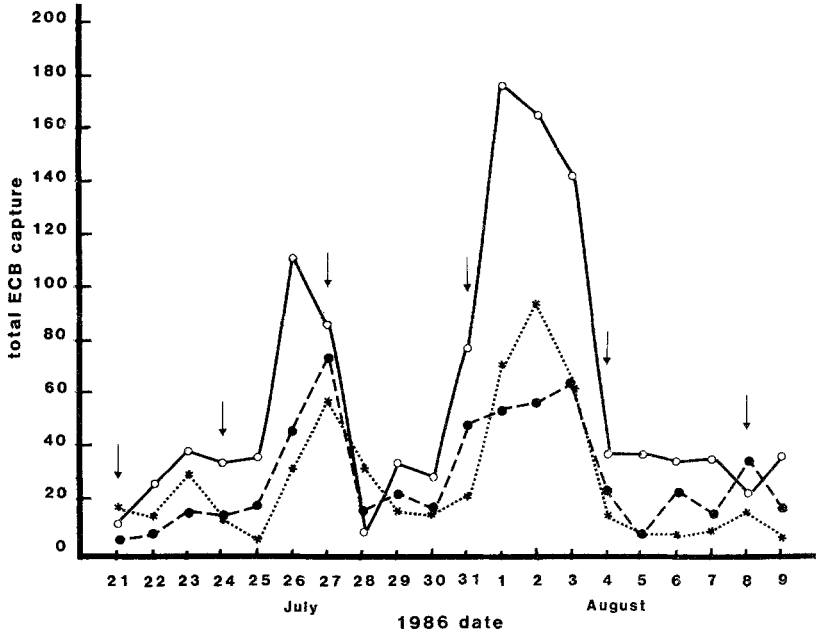

FIG. 1. Total daily captures of European corn borer (ECB) males in traps baited with female pheromonal biotypes during the second brood flight in 1986. Arrows indicate the nights when fresh virgin females were positioned in traps. Open circles represent data points for captures in *ZZ* female-baited traps, solid circles represent *EE* female traps, and asterisks represent data for *ZE* female traps.

Thus, trap capture data and GC analyses of wild females, respectively, indicated a high frequency of *Z'* alleles for response and *Z* alleles for pheromone production in the population. At locations 1 and 3, the high frequency of *Z'* alleles is attributable to an abundance of *Z'Z'* homozygotes, while the high *Z'* allele frequency at location 2 is owed to the relatively large number of presumed heterozygotes observed at that site. Thus, the variability in the frequency of types of male responders indicates that populations separated by 1–2 km are not entirely panmictic. At two of the three locations, the frequency of male types deviated significantly from Hardy-Weinberg equilibrium. This deviation is an indication that males select mates assortatively. Moreover, the male trapping test results also have practical implications. In instances where one might wish to monitor quantitatively European corn borer populations that are made up of three pheromonal types, such monitoring will require the use of at least three traps, each baited with a lure attractive to each type; 97:7, 35:65, and 3:97 *Z*:*E* 11-tetradecenyl acetate.

Mating Efficiency of Trapped Feral Males and Laboratory-Culture Females. The incidence of successful matings of individual field-trapped males with homozygous females of the laboratory culture was generally low: 59 progeny lines were established from 223 *ZZ*-responding males, 27 progeny lines from 179 *ZE* responders, and 61 lines from 261 *EE* responders (Table 3). Reasons for the low mating efficiency (15–26%) are difficult to ascribe, but male age, previous mating experience, behavioral incompatibility of cultured females and feral males, handling of the males, and/or inappropriateness of the laboratory setting for mating by feral males, etc., could have impacted adversely upon the mating process.

Sex Pheromone Production Allele Frequency in Male Responders. Results of the progeny tests are shown in Table 4. These results represent the outcome from more than 1240 individual female GC analyses. The data show that pheromone-production allele frequencies among males captured in traps baited with *ZZ* females were $Z = 0.90$ and $E = 0.10$, while the allele frequencies were $Z = 0.16$ and $E = 0.84$ in *EE* female-baited traps. Thus, as might be predicted, most (85%) of the males attracted to *ZZ* females were *ZZ* pheromone-production genotypes and, in the reciprocal, most (72%) males attracted to *EE* females were *EE* genotypes. The data clearly reflect the assortative nature of the mating system and coordination of response and production functions. However, a small percentage (11–24%) of males heterozygous for pheromone production and a smaller percentage (4%) homozygous for pheromone production and, genotypically opposite to the female to which they were attracted, were also found in the *ZZ* and *EE* female-baited traps.

TABLE 3. MATING SUCCESS OF FIELD-TRAPPED MALES PAIRED WITH LABORATORY-CULTURED FEMALES IN PROGENY LINE TESTS

	Female genotype causing male capture

TABLE 4. SEX PHEROMONE PRODUCTION ALLELE FREQUENCY OF MALES CAPTURED IN TRAPS BAITED WITH *ZZ*, *ZE*, AND *EE* FEMALE GENOTYPES ACCORDING TO PROGENY TESTS[a]

Female causing capture	Sex pheromone production genotype of male (%)			Sample allele frequency	
	ZZ	*ZE*	*EE*	P(Z)	Q(E)
ZZ (*N* = 47)	85	11	4	0.90	0.10
EE (*N* = 50)	4	24	72	0.16	0.84
ZE (*N* = 27)	22	33	44	0.39	0.61

[a] *N* = number of families.

The occurrence of heterozygous and opposite homozygous pheromone production types in the *ZZ* and *EE* female-baited traps might be attributed to chance or to mistakes being made by the males. However, we prefer to hypothesize that these males more likely represent individuals that are genetically predisposed to respond to a specific 11-tetradecenyl acetate geometric ratio, but they carry a pheromone production gene on a separate locus that codes for an entirely different geometric ratio. The basis for forming this hypothesis is vested in the observed frequency of pheromone production genotypes captured in traps baited with hybrid females. The pheromone-production allele frequency among males captured in the hybrid-baited traps was $Z = 0.39$ and $E = 0.61$ and, unlike the frequency of pheromone-production genotypes captured in *ZZ* and *EE* female-baited traps, there was a proportionately large number of the "wrong" (22% *ZZ* and 44% *EE*) pheromone-production genotypes in hybrid-female traps. If chance or male error were to account for the appearance of "wrong" pheromone-production genotypes in any female-baited trap, one would have expected the frequency of male types in the hybrid-female traps to be similar to the distribution observed in the traps baited with homozygous females, that is, a low frequency of *ZZ* and *EE* types with a high *ZE* zygote frequency. This was not the case; the zygotic ratio was 22 : 33 : 44 *ZZ* : *ZE* : *EE*. Therefore, neither chance nor male mistakes satisfactorily accounts for the frequency of pheromone-production types, but the idea of separate loci controlling response and production with *Z* or *E* polymorphism at each locus serves as a tenable model to explain the observed frequencies.

Using *Z* and *E* to denote production alleles, *Z'* and *E'* to represent male response alleles, and assuming that simple Mendelian inheritance governs response, the production–response genotypes of males captured in the hybrid-female baited traps would be *ZE/Z'E'*, *EE/Z'E'*, and *ZZ/Z'E'*. Correspond-

ingly, males captured in *EE*-female traps would be *EE/E'E'*, *ZE/E'E'*, and *ZZ/E'E'*, and males in the *ZZ*-female traps would be *ZZ/Z'Z'*, *ZE/Z'Z'*, and *EE/Z'Z'*. These types could arise as result of a rare mating of *EE/E'E'* and *ZZ/Z'Z'* types to yield heterozygotes which would mate assortatively and produce a segregated group composed of the nine possible genotypes. In the next generation, the expected frequency of *Z'E'* male-response types carrying *ZZ*, *ZE*, or *EE* production alleles would be twice that of either *Z'Z'* or *E'E'* response types carrying the alleles. This fact can account, in part, for the proportionately high frequency of *ZZ* and *EE* pheromone-production types that were observed in the hybrid-female baited traps as compared to the proportionately lower frequency of "wrong" pheromone-production types that were detected in *ZZ*- and *EE*-female baited traps.

Response of Field-Captured Males to 11-Tetradecenyl Acetate Isomers in Flight Tunnel. During the course of the trapping, an average of 72 males/trap/night were captured in traps baited with *Z* isomer compared to the 267 males/trap/night captured in 97:3 *Z*:*E*. The higher capture rate in 97:3-baited traps was an expected result inasmuch as it is known that males of a *ZZ*-type pheromonal population exhibit response over a narrow range of ratios of geometric isomers and that 97:3 is an optimum (Klun et al., 1973). Similarly, data in Table 5 show that all field-captured males responded better in the flight tunnel to 97:3 *Z*:*E* 11-tetradecenyl acetate than to pure *Z* isomer, independent of which isomer combination caused their capture in the field. The *ZZ*-colony males also responded best to 97:3 *Z*:*E*. Most interestingly, results show that 13% of males captured in the field, specifically with 97:3, responded ambivalently to 33:67 (an isomeric proportion characteristic of hybrid females) in the flight tunnel. However, neither males captured with *Z* alone in the field nor *ZZ*-colony males exhibited this ambivalence of response. It is plausible that the moths, exhibiting response to 97:3 and 33:67 isomer ratios, represent a special class

TABLE 5. PERCENTAGE UPWIND FLIGHT RESPONSE OF EUROPEAN CORN BORER MALES CAPTURED IN FIELD TRAPS BAITED WITH PURE *Z* AND 97:3 *Z*:*E* 11-TETRADECENYL ACETATE TO THREE ISOMERIC MIXTURES OF 11-TETRADECENYL ACETATE IN FLIGHT TUNNEL ($N = 31$)[a]

of males that could be attracted to and mate with either *ZZ* or *ZE* females in nature. Evidence of their existence suggests that inheritance of sexual response in males may involve more than simple Mendelian inheritance.

Moreover, indications are that the genetic determinants of the European corn borer sex pheromone communications include response and production genes that occur at separate loci in the genome. Our previous study of the inheritance of pheromone production (Klun and Maini, 1979) and the recent electrophysiological research on the pheromone receptor cells (Hansson et al., 1987) indicate that both genes are autosomal, and evidence presented here shows that they are most often coupled in a complementary fashion so that response and production are coordinated to effect positive assortative mating. However, this coordination can be uncoupled as a consequence of rare matings among sympatric opposite homozygous types; the resulting progeny are heterozygous at the response and production loci. These polymorphic forms undoubtedly contribute to gene flow among types. However, pheromonal allele frequency in a sympatric population appears to be dependent upon undefined factors that selectively favor the *ZZ/Z'Z'* genotype. It will be interesting to monitor these allele frequencies in the Beltsville population in the future to see if they shift from their present values.

Comparison of our findings to other studies of the genetic regulation of pheromone communications in other insects is difficult because most of them involved investigation of the effects of interspecific hybridizations. As examples, Lanier (1970) studied hybrids formed between three bark beetle species of the genus *Ips* and speculated that production and response were controlled by autosomal loci; Sanders et al. (1977) hybridized moths of the genus *Choristoneura* and obtained results that indicated pheromone production was controlled by both X-chromosomal and autosomal loci; Grant et al. (1975) hybridized two species of tussock moths (*Hemerocampa* spp.) and inferred that the hybrid's pheromone channel was more like the female parent than the male; however, they were not able to make the reciprocal cross to verify the inference. A similar parental effect has also been observed in hybridization of *Heliothis subflexa* female moths with *Heliothis virescens* males; the F_1 females produced sex pheromone that was identical to the array of compounds produced by *H. virescens* females (Klun et al., 1982). Thus, in this case, the pheromone-production alleles of the male parent showed complete dominance over those of the female. The response characteristics of the F_1 male have not been determined, but male progeny resulting from a backcross of the F_1 female with the *H. virescens* male responded sexually to backcross females and, in turn, backcross females were attractive to *H. virescens* males (Raulston et al., 1979). Thus, *H. virescens* male response alleles also expressed dominance over *H. subflexa*. The pheromone production and response characteristics of the reciprocal-cross hybrid and a more detailed study of F_1 male response is currently

underway in Gainesville, Florida (J.H. Tumlinson, personal communication), and a clearer picture of this system should be forthcoming.

As a final example, the mode of inheritance of pheromone communications in the sulfur butterflies was investigated by Grula and Taylor (1979). They prepared hybrids between *Colias eurytheme* and *C. philodice* and found that production of male pheromone in *C. philodice* is controlled by autosomal genes while the X chromosome carried most of the genes controlling pheromone production in *C. eurytheme*. They, however, did not address the issue of inheritance of female response.

In general, the evidence indicates that the genes regulating the pheromone communication systems of the insects can be carried on either autosomal or X chromosomes, but the mechanisms by which response and production functions are linked remain obscure. We are aware of at least three species of insects that exhibit intraspecific pheromonal variability: the bark beetles, *Ips pini* (Lanier et al., 1972) and *I. calligraphus* (Lanier, 1972), and a tortricid moth, *Amorbia cuneana* (Bailey et al., 1987). These species represent prime candidates for study and expansion of our understanding of the organization of insect chemical communications at the genetic level. In the European corn borer, indications are that the genetic determinants of its sex pheromone system involve autosomal response and production genes at separate loci.

Acknowledgments—We thank Ed Uebel for rearing the insects used in the research and for the many chromatographic analyses he conducted for this study, Ingrid Orentas and Ellen Quinn for technical assistance in the field and laboratory, and Jacob Blumenthal for assistance in analysis of data. SELECTED FACTORS INFLUENCING NEUROHORMONAL REGULATION OF SEX PHEROMONE PRODUCTION IN *Heliothis* SPECIES

ASHOK K. RAINA

Insect Chemical Ecology Laboratory
Agricultural Research Service, USDA
Beltsville, Maryland 20705

(Received November 19, 1987; accepted February 3, 1988)

Abstract—Sex pheromone production and release in females of *Heliothis* species exhibit a diel periodicity. Phermone production is controlled by a hormone, the pheromone biosynthesis activating neuropeptide (PBAN). Release of PBAN to activate pheromone production follows a circadian rhythm. In *H. zea* females, mating terminates pheromone production. An unidentified hemolymph-borne factor is transferred from the male to the female during mating. It is speculated that this factor interacts with the release mechanism of PBAN to prevent further production of the pheromone following mating. Wild females of *H.* phloxiphaga (reared from larvae collected in the field) did not produce or release the sex pheromone unless kept in association with the host plant. Pheromone production could be induced in these females by the injection of PBAN. It is suggested that a signal from the host plant is essential to trigger the release of PBAN to induce pheromone production.

Key Words—*Heliothis zea, Heliothis phloxiphaga*, Lepidoptera, Noctuidae, sex pheromone, neuropeptide hormone, mating, host plant factors.

INTRODUCTION

A majority of moth species, including those in the genus *Heliothis*, are nocturnal. In order to find their mates, they usually rely on chemical signals or sex pheromones. In most cases the sex pheromone is produced by the female and is composed of a blend of several organic compounds is very specific proportions. The blend composition is species specific and functions in part to maintain reproductive isolation among closely related species. Moths are also short-

lived as adults and often possess mature oocytes at eclosion. It had been earlier speculated that among the Lepidoptera there was no need for neurohormonal regulation of sexual activity (for a review, see Raina and Menn, 1987). However, even among the short-lived moths, there are events and circumstances that warrant the neurohormonal regulation of sex pheromone production.

As nocturnal species, the reproductive activity of these moths is usually gated, following an endogenous rhythm that is modified by environmental cues (Cardé and Webster, 1980). It would be a waste of resources and energy to maintain a higher titer of sex pheromone during the photophase. Diel periodicity of pheromone production and release has been reported in a number of moths such as *Trichoplusia ni* (Sower et al., 1970), *Platyptilia carduidactyla* (Haynes et al, 1983), and *H. zea* (Pope et al., 1984; Raina et al., 1986). Some form of neurohormonal regulation would appear to be essential to control the periodicity of their pheromone production. Neurohormonal control of pheromone release in the Lepidoptera had been suggested earlier (Riddiford and Williams, 1971). However, it was not until recently that conclusive evidence for neurohormonal control of pheromone production in *H. zea* was presented (Raina and Klun, 1984). The neuropeptide PBAN originates in the suboesophageal ganglion (SOG) and is released through the corpora cardiaca (CC) to activate pheromone biosynthesis in *H. zea* (Raina and Menn, 1987; Raina et al., 1987). The hormone has a molecular weight of 3899 and contains 33 amino acid residues (Raina, unpublished).

Females of most species of moths do not exhibit discrete reproductive cycles as seen, for example, in the cockroaches (Barth, 1965). Even though a single mating could provide the necessary sperm to fertilize a full complement of eggs, females in the majority of moth species are known to mate more than once. In most of these cases a successful mating is followed by the termination of their readiness to engage in further sexual activity (Truman and Riddiford, 1974). For example in *H. zea*, mating is followed by a significant drop in the pheromone titer (Raina et al., 1986), which can be considered to be an expression of the loss of sexuality in mated females. It has been reported that sexuality in *Hyalophora cecropia* is suppressed after mating by the release of a substance from either the spermatheca or the bursa into the hemolymph and its reaction with a hypothetical neural center in the brain (Truman and Riddiford, 1971; Riddiford and Ashenhurst, 1973). It is entirely possible that the neuroendocrine system is also involved in the termination of pheromone production and loss of sexuality following mating in *Heliothis* species.

Another factor that may interact with the neurohormonal regulation of pheromone production and release involves the host plant. A suggestion to that effect had been made in the case of the polyphemus moth, *Antheraea polyphemus* (Riddiford and Williams, 1967a,b; Riddiford, 1967). It was reported that *trans*-2-hexenal, a volatile from oak leaves, produces a sensory input from the

antennae to the brain which is relayed through the neuroendocrine system of the females to its receptor site (Riddiford and Williams, 1967a).

The above factors and their interaction with PBAN to control pheromone production were investigated in *H. zea* and *H. phloxiphaga*.

METHODS AND MATERIALS

First-instar larvae of *H. zea* placed on artificial diet were regularly obtained from the Southern Field Crops Management Laboratory of USDA in Stoneville, Mississippi. The larvae were kept in environmental chambers maintained at 16:8 light (26°C)–dark (20°C) cycle and 60 ± 5% relative humidity, with lights off at 8 AM and on at 4 PM. Upon pupation, males and females were kept in separate chambers. *H. zea* larvae were also collected on corn in Mississippi and shipped to Beltsville. The resulting adults constituted the wild population. *H. phloxiphaga*, a nonpestiferous species, was collected on Texas paint brush (*Castilleja indivisa*) around College Station, Texas, and reared in the laboratory on soybean–wheat-germ diet (Shaver and Raulston, 1971). Pheromone titers were determined as described by Raina et al. (1986).

H. zea females were mated during the third scotophase of their adult life and pheromone titer determined 2 hr after the termination of mating. Hemolymph from mated females was drawn 10 and 100 min after mating, mixed with cold saline, and injected into virgin females. Pheromone titers of the recipient females were determined 2 hr after the injection. Mated females were also injected with brain–SOG homogenates, and their pheromone titers were determined 3 hr postinjection.

H. phloxiphaga females reared from field-collected larvae as well as females reared in the laboratory for 3 and 10 generations were observed for calling behavior in the absence and presence of the host plant. Pheromone titers of these females were also determined. The experiments were also repeated with laboratory-reared and wild *H. zea*, using corn as the host plant. Wild females of both species were injected with brain–SOG homogenates and their pheromone titer determined.

RESULTS AND DISCUSSION

The pheromone titer [measured as nanograms of (*Z*)-11-hexadecenal (Z11–16:Ald)] in mated females of *H. zea* dropped from a premating average of 120 ng to <5 ng within 2 hr following the termination of mating. Since mated females were not observed to call, the drop in the pheromone titer is probably due to the termination of pheromone production and metabolism of the existing pheromone. Pheromone production in virgin females was terminated when they

were injected with hemolymph from mated females obtained soon after the termination of mating. The effect was less pronounced when hemolymph was obtained from females 100 min after the termination of mating and injected into virgin females. The effect was also associated with hemolymph of both virgin and mated males. These results indicate that a factor or factors transferred from the male to the female at the time of mating is responsible for the termination of pheromone production. This sexuality-suppression factor (SSF) is not related to the sperm, because when castrated males (testes removed in the larval stage) were mated to normal females, they transferred a spermatophore devoid of any sperm but suppressed pheromone production. It is speculated that the SSF may be a component of the accessory gland secretion. The pheromone titer of a mated *H. zea* female could be restored to the premated level by the injection of either brain–SOG homogenate or partially purified PBAN.

In the case of the housefly *Musca domestica*, it was reported that the injection of secretions from male ejaculatory ducts into a virgin female effectively inhibited its sexuality (Rieman et al., 1967). A water-soluble mating inhibitor was subsequently isolated from mated female housefiles (Adams and Nelson, 1968). When a male housefly whose accessory gland substances were radiolabeled was mated, the labeled substances were transferred to the female, absorbed through its vaginal pouches within 10–40 min, and carried in the hemolymph to the head (Leopold et al, 1971). Similar interaction of the SSF with PBAN release in mated *H. zea* females is speculated (Figure 1).

Whereas laboratory-reared females of *H. phloxiphaga* (reared on artificial diet for ca. 10 generations) produced and released the sex pheromone, females reared from larvae collected in the field produced very low amounts of the pheromone, and none of them was observed to call (Table 1). When Texas paint brush plant was introduced into the cage, the females started producing and releasing the pheromone. When these wild insects were reared in the laboratory on artificial diet, the requirement for the presence of a host plant as a prerequisite for pheromone production was reduced or lost after three to four generations. However, only a small proportion of the females were observed to call, and calling in these females was significantly increased by the presence of the host plant.

Results from preliminary experiments have indicated that pheromone production in wild females can be induced even in the absence of a host plant by the injection of brain–SOG homogenates or PBAN. Also, the PBAN titer in the brain–SOG of wild females was higher when they were kept without a host plant as compared to females with a host plant. These observations suggest that a signal from the host plant causes the release of PBAN to activate pheromone production. A similar host factor or the pheromone titer itself could cause the production and transmission of a neural signal to the pheromone gland to induce calling.

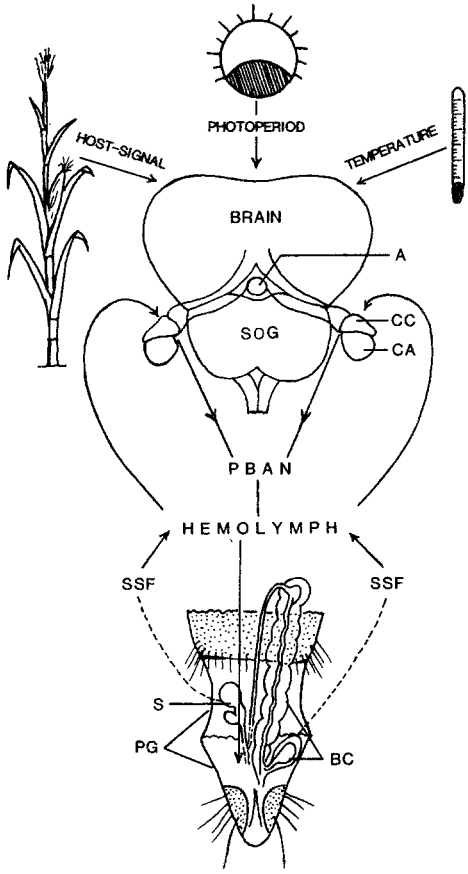

FIG. 1. A diagrammatic representation of the neurohormonal control of sex pheromone production in *H. zea*, and various interactions with external and internal stimuli. A, aorta; BC, bursa copulatrix; CA, corpus allatum; CC, corpus cardiacum; PBAN, pheromone biosynthesis activating neuropeptide; PG, pheromone gland; S, spermatheca; SOG, suboesophageal ganglion; SSF, sexuality suppression factor.

Preliminary tests with *H. zea* indicate that volatile factor(s) from the corn silk may act as a signal for the release of PBAN to initiate pheromone production (Figure 1). Apparently the host plant signal can override the circadian rhythm of PBAN release. Experiments to isolate and identify the SSF as well as the volatile factor(s) from corn that impact on pheromone production in *H. zea* are in progress. Identification of these factors are essential to study their interactions with PBAN in the control of pheromone production and release.

(Received November 22, 1987; accepted March 15, 1988)

Abstract—Males of five sympatric species of economically damaging cucujid grain beetles, *Cryptolestes ferrugineus* (Stephens), *C. pusillus* (Schönhen), *C. turcicus* (Grouvelle), *Oryzaephilus mercator* (Fauvel), and *O. surinamensis* (L.), produce macrolide aggregation pheromones especially in the presence of food. Work leading to the isolation, identification, and establishment of biological activity of these semiochemicals is reviewed. The trivial name "cucujolide" is proposed and used to identify these compounds that are characteristic of the Cucujidae. The two *Oryzaephilus* share species share a common cucujolide pheromone, while *Cryptolestes* species use cucujolides that are either enantiomeric, unique to the genus, or released in trace quantities by *Oryzaephilus* spp. and not used as pheromones by the latter species. The major mechanisms for species specificity in chemical communication are: (1) presence of a unique pheromone (*C. ferrugineus* and *C. pusillus*); (2) use of pheromones that are inactive alone but synergize response to cucujolides unique to a species (*C. pusillus*, *C. turcicus*, and *O. surinamensis*); (3) response to only one enantiomer of a pheromone (*C. ferrugineus*, *O. surinamensis*, and *O. mercator*); and (4) synergism between enantiomers of a pheromone (*C. turcicus*). The only species for which cross-attraction was evident was *O. mercator* to *O. surinamensis*. Both sexes of *Oryzaephilus*

spp. produce (*R*)-1-octen-3-ol, which highly synergizes response to the cucujolide pheromones. Similar synergism occurs between hexanal, octanal, and nonanal and the cucujolide pheromones of *Oryzaephilus* spp. The males of a sixth cucujid species, *Cathartus quadricollis* (Guér) produce a different aggregation pheromone, (3*R*,6*E*)-7-methyl-6-nonen-3-yl acetate. Trapping of *Cryptolestes* and *Oryzaephilus* spp. in cardboard traps baited with pheromones is efficient in environments mimicking food-storage areas. Pheromone-baited plastic probe traps are the most efficient at capturing these species in infested grain.

Key Words—Grain beetles, Coleoptera, Cucujidae, *Cathartus quadricollis*, *Cryptolestes ferrugineus*, *C. pusillus*, *C. turcicus*, *Oryzaephilus mercator*, *O. surinamensis*, macrolide aggregation pheromone.

Hormones and pheromones are potent regulators of insect growth, development, reproduction, and behavior. Many new, safe, and specific approaches to insect control are based on manipulation of insect populations using these regulators. Knowledge of the chemical communication systems of economically important, grain-infesting insects (Levinson and Levinson, 1979; Burkholder, 1981, 1982) contributes to the development of semiochemical-based control programs. In the present article, we review the isolation, identification, and biological activity of the pheromones of six species of grain beetles in the family Cucujidae, for which we have unraveled much of the chemical communication systems.

IMPORTANCE OF CUCUJID GRAIN BEETLES

The species of beetles investigated are important stored-product pests of worldwide distribution. In the United States, the sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), ranked first in importance as a pest of stored products and processed food and second as a program on raw grain (Mueller, 1982). The sawtoothed grain beetle cannot penetrate dry intact kernels and, when found in grain, is usually an indication of a prior infestation. The merchant grain beetle, *O. mercator* (Fauvel) is more affected by low ambient temperatures (Howe, 1956). It is an established household pest in North America, especially on cereal products and processed food (Loschiavo and Smith, 1970; Loschiavo and Sabourin, 1972). The rusty grain beetle, *Cryptolestes ferrugineus* (Stephens), is a severe pest of stored wheat throughout the world (Reid, 1942; Howe and Lefkovitch, 1957; Banks, 1979). In Canada, the beetles infest wheat during storage (Loschiavo, 1975) and transportation (Monro, 1969; Loschiavo, 1974). Pockets of damp grain subject to heating are attractive to these insects (Smith, 1983). Infested wheat suffers loss of germinating ability (Campbell and Sinha, 1976). The flour mill grain beetle, *Cryptolestes turcicus* (Grouvelle), is a secondary feeder on broken and milled grain (Howe, 1956; Olsen et al., 1987). The flat grain beetle, *Cryptolestes pusillus* (Schönherr), is a seri-

ous pest of diverse stored products worldwide (Reid, 1942; Howe, 1956) and is especially severe in the grain-producing Midwestern states (Mueller, 1982; Barak et al., 1981). The square-necked grain beetle, *Cathartus quadricollis* (Guér.) is abundant in the southern United States and infests a variety of stored commodities such as corn and peanuts (Anonymous, 1955).

BIOLOGY OF CUCUJID GRAIN BEETLES

All of these species are long-lived, adult-feeding beetles (Anonymous, 1955; Sinha and Watters, 1985). They survive at temperatures between 18°C and 40°C and 40–90% relative humidity but are optimally maintained between 31°C and 35°C and 70–90% relative humidity. Females of these species lay several hundred eggs in a lifetime by dropping them loosely among foodstuff and crevices of grain. Eggs hatch in three to five days, and lavae crawl about feeding until they construct delicate cocoonlike coverings by joining together small kernels or fragments of foodstuffs. Within this cell, the larva pupates over a week and emerges as an adult. Development from egg to adult requires three to four weeks. Adults live and feed an average of 6–10 months but can live much longer under ideal conditions.

ISOLATION OF CUCUJID PHEROMONES

Borden et al. (1979) and A.M. Pierce et al. (1981) developed procedures for laboratory rearing of the target species on whole wheat and wheat germ (95:5) or rolled oats and brewer's yeast (95:5) that provide populations of uniform characteristics for biological and semiochemical investigations. Insects and frass for aeration are sieved from the medium, and the insects are collected by aspiration as they walk away from the tailings. Fine sieving of the tailings provides frass (boring dust and fecal pellets) (Borden et al., 1979; Millar et al., 1985a,b).

H.D. Pierce, Jr. et al. (1984) modified (Figure 1) the procedure of Byrne et al. (1975) for capture of the volatiles of insects, frass, and food on Porapak Q. In the presence of food and moisture, volatiles are collected continuously over long periods (7–10 days) with little or no mortality of the beetles. Volatiles emitted at very low rates (picograms per hour) are accumulated until sufficient amounts are available for bioassay and structural study. Captured volatiles are extracted from the Porapak Q (Soxhlet) with pentane, which is removed by slow distillation (Dufton column) to provide stock solutions of volatiles for bioassay or fractionation. Bioassays of volatiles are conducted using an open arena air-flow (Figure 2) or a two-choice pitfall olfactometer (Figure 3). The former was originally developed to investigate the activity of volatiles from scolytid bark beetles (Wood and Bushing, 1963), but it is labor-intensive and does not allow

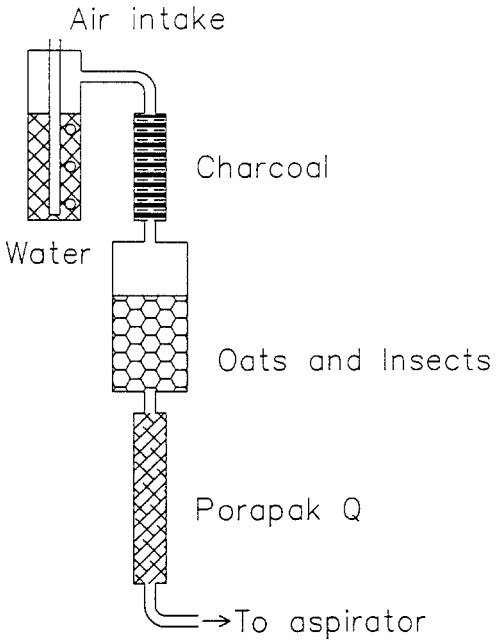

FIG. 1. Aeration apparatus in which volatiles from insects alone or on food are collected by drawing air (2 liters/min) with a water aspirator through water and an activated-charcoal scrubber, then over the source material, and finally through Porapak Q.

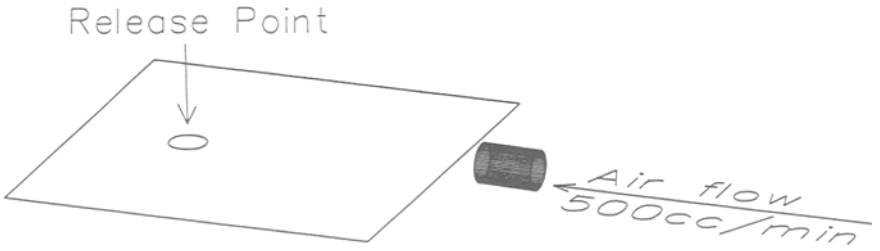

FIG. 2. Arena olfactometer with a 15 × 15-cm paper arena and an air nozzle (flow rate, 500 ml/min) in the middle of one side. A glass tube containing a rolled paper impregnated with stimulus is slipped into the air nozzle, and the air flow was directed toward the insect release point. In a typical bioassay, a vial containing 15 insects is inverted onto the center of the arena and left in place so that the insects could not escape while the test stimulus is placed in the air stream. Removal of the vial allows the insects to walk freely. Insects reaching a 3 × 1-cm-wide area in front of the stimulus tube are counted as responders. Insects reaching the arena edge and insects still walking around on the arena at the end of an allotted 2-min time limit are counted as nonresponders (Borden et al., 1979).

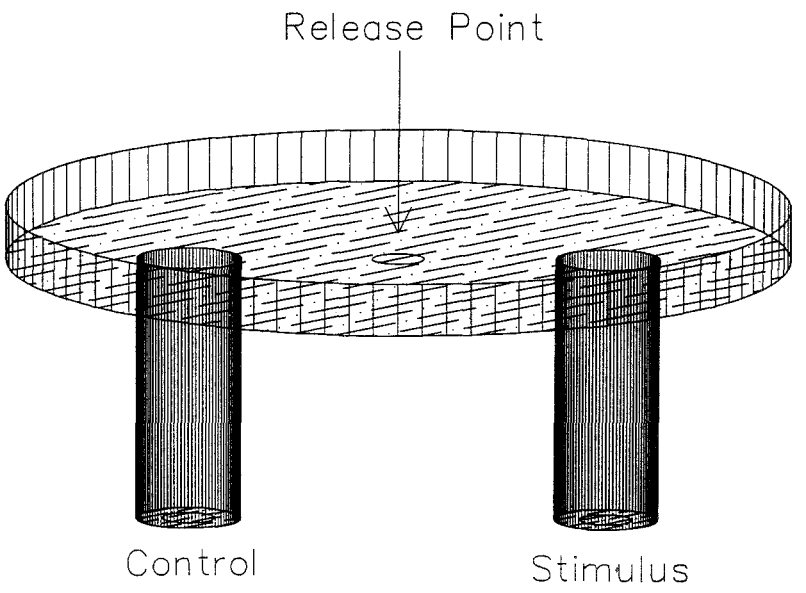

FIG. 3. Pitfall olfactometer with two 8-ml glass vials suspended from holes cut in the bottom of a 15-cm plastic dish. A filter paper disk treated with a pentane solution of the stimulus is placed in one vial, and a disk treated with the same volume of pentane is placed in the other. Typically 12–15 insects are used and each bioassay is replicated 6–12 times for each stimulus. A lid (not shown) prevented beetle escape. Bioassays are run in the dark at 23°C and ~60% relative humidity. At the end of a 2-hr period, the numbers of insects in the control and stimulus vials are recorded. To ensure uniform conditioning, beetles for bioassay are sifted from cultures, aerated in darkness for 18–48 hr with clean, moist air, and counted into holding vials ~2 hr before testing. After a bioassay, insects are allowed to feed at least four days before being reused.

for simultaneous replication. It has been replaced in our laboratory by the two-choice pitfall olfactometer (Figure 3) (A.M. Pierce et al., 1981), which is more discriminating and less labor-intensive.

Extensive investigations revealed the volatiles of mixed-sex beetles or their frass are attractive to both sexes of conspecifics (Borden, et al. 1979; A.M. Pierce et al., 1981, 1984, 1985; Wong et al., 1983; H.D. Pierce, Jr. et al., 1984, 1988; Millar et al., 1985a,b). Bioassay of the volatiles of the separated sexes disclosed that this attraction is due to emissions of the males of each species. Thus, all five species utilized male-produced aggregation pheromones. Gas chromatographic analysis of the volatiles obtained from aerations of *C. ferrugineus*, the first species investigated, revealed the presence of several late-eluting components in the beetle volatiles that are not present in food volatiles (Figure 4). Wong et al. (1983) demonstrated these late-eluting components were

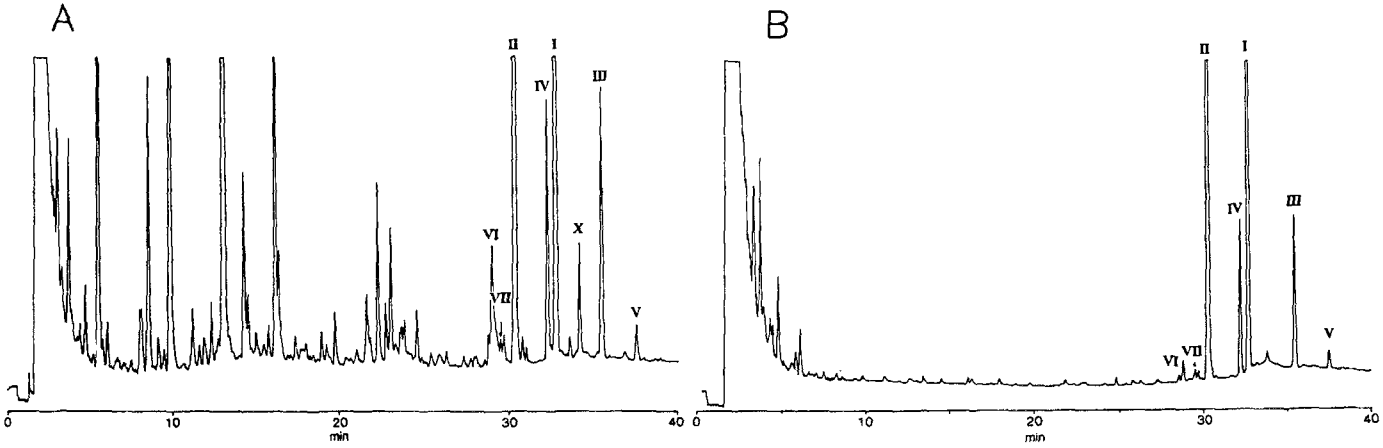

FIG. 4. Gas chromatogram of *C. ferrugineus* frass volatiles (A), and mixed-sex beetle volatiles (B). Volatiles are captured on Porapak Q, extracted with pentane, and analyzed on a 33-m × 0.66-mm ID glass open-tubular column coated with SP-1000, programmed at 4°C/min from 70–200°C.

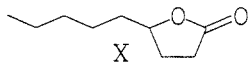
produced specifically by males and not by females. The two major late-eluting components were isolated by preparative gas chromatography and found to be attractive at nanogram doses. These components were identified as cucujolides I and II[6] (Table 1) by [^{1}H]NMR, mass spectroscopy (Wong et al., 1983), and chemical synthesis (Oehlschlager et al., 1983). The minor components eluting in the same gas chromatographic range are lactones III–VII (Table 1) and X (Scheme 1). Gas chromatographic analysis of diastereomeric (*S*)-*O*-acetyllactate derivatives of natural and synthetic chiral isomers of II by Oehlschlager et al. (1987) revealed that *C. ferrugineus* produces only (*S*)-II (Figure 5).

Wong et al. (1983) determined that threshold responses of *C. ferrugineus* to synthetic I and II are equivalent to those of volatiles of feeding beetles containing similar quantities of I and II (21 and 18 ng, respectively). This suggests that these two components were responsible for all the activity in this odor source (Figure 6). Synergism between I and II is evident in that response to mixtures of I and II is higher than to either pheromone alone. That (*R*)-II is an inactive enantiomer is suggested by the observation that the threshold response elicited by (*S*)-II is about 100-fold lower than for the *R* enantiomer. Although the natural ratio of I:II is ~1:1, this mixture elicited a higher threshold (40 ng, 20 ng of each component) than either 3:1 (17.5 ng) or 9:1 (4.7 ng) mixtures.



SCHEME 1.

Millar et al. (1983, 1985a) disclosed that volatiles of *C. pusillus* contained cucujolides III, VIII, and IX (Table 1). Adults are attracted to synthetic VIII alone but neither racemic III nor IX individually. Cucujolide IX elicits a threshold response about 100-fold higher than that observed for VIII alone and is not synergistic with VIII in ratios (100:1 to 10:1) spanning the natural ratio of ~75:1. When added to VIII, racemic III elicits a small synergism that is maximal near the natural ratio (~20:1). In this test, *C. pusillus* responds equally to either enantiomer of III, although Oehlschlager et al. (1987b) found feeding adults produce only (*S*)-III.

[6]Because of their prevalence in the Cucujidae and their characteristic structure, we propose that the macrolides discovered in the genera *Cryptolestes* and *Oryzaephilus* be given the trivial name cucujolides. This trivial name is for convenience and does not ignore the fact that these compounds have other natural sources (Wong et al., 1983). Cucujolides I and II replace the common names ferrulactone I and II originally proposed for the two pheromones of *C. ferrugineus* (Wong et al., 1983)

TABLE 1. DISTRIBUTION OF CUCUJOLIDES IN *Cryptolestes* AND *Oryzaephilus* SPECIES[a]

	 I	 II	 III	 IV	 V	 VI	 VII	 VIII	 IX
C. ferrugineus	38–60P[b]	34–42P	3.5–5	2–4	0.5	1.5	<0.5		
C. pusillus			2.5P_{syn}[c]					96P	1.5
C. turcicus			28P_{syn}		72P				
O. mercator		45P	<0.1	55P	<0.1				1
O. surinamensis			<0.1	16P	51P_{syn}				33P

[a] I, (*E*, *E*)-4,8-dimethyl-4,8-decadien-10-olide; II, (*Z*)-3-dodecen-11-olide; III, (*Z*)-5-tetradecen-13-olide; IV, (*Z*, *Z*)-3,6-dodecadien-11-olide; V, (*Z*, *Z*)-5,8-tetradecadien-13-olide; VI, dodecen-11-olide; VII, (*E*)-dodecen-11-olide; VIII, (*Z*)-3-dodecenolide; IX, (*Z*, *Z*)-3,6-dodecadienolide. Values are given as percent of total macrolides.

[b] P = pheromone.

[c] P_{syn} = synergyst, inactive alone.

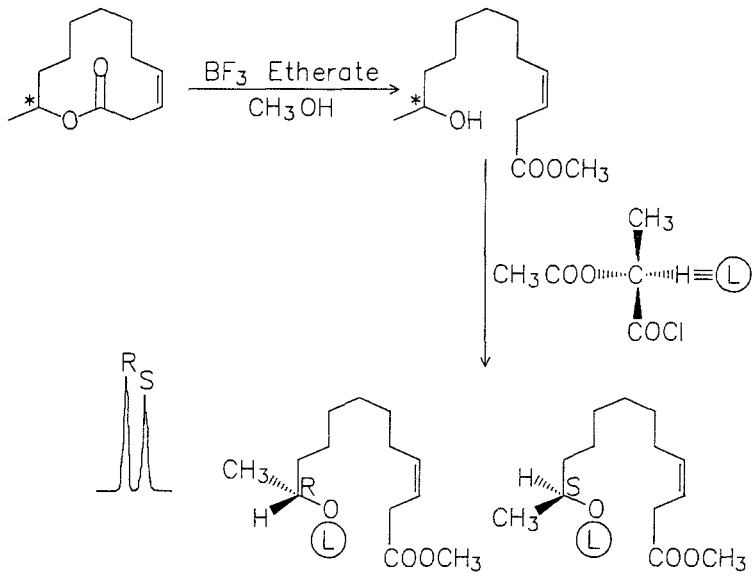


FIG. 5. Preparation and analysis of (*S*)-*O*-acetyllactate derivatives of cucujolides. Chiral cucujolides are reacted first with BF_3 in methanol. The hydroxy esters derived from this reaction are reacted with (*S*)-*O*-acetyllactyl chloride in the presence of pyridine to form the diastereoisomeric derivatives which are separated by capillary gas chromatography.

Millar and Oehlschlager (1984) and Millar et al. (1985b) isolated cucujolides III and V from the volatiles of *C. turcicus* and established both as aggregation pheromones. Response to racemic III and V revealed that only V was active alone. A test for synergism between racemic III and V over a range of ratios from 1:25 to 2:1 showed that all mixtures used are attractive. Ratios of 1:3 and 2:3 of III:V are significantly more attractive than V alone, indicating that III synergizes V when used in approximately the natural ratio (~ 1:5). The threshold for significant response for racemic V was between 240 ng and 24 μg, considerably higher than for *C. pusillus* to its singly active pheromone.

Oehlschlager et al. (1987b) determined that cucujolides III and V from *C. turcicus* are a 33:67, *R*:*S* and a 85:15, *R*:*S* mixture, respectively (Table 1). Millar et al. (1985b) demonstrated *C. turcicus* is attracted to mixtures but not the pure enantiomers of V at the 5 μg level. When the dose of V is reduced to 1 μg, only (*R*)-III and not (*S*)-III elicited synergism even though naturally produced III is rich in the *S* enantiomer. Attraction to mixtures of enantiomers of V is maximal near the natural ratio (*R*:*S*, 80:20). This is the first evidence of

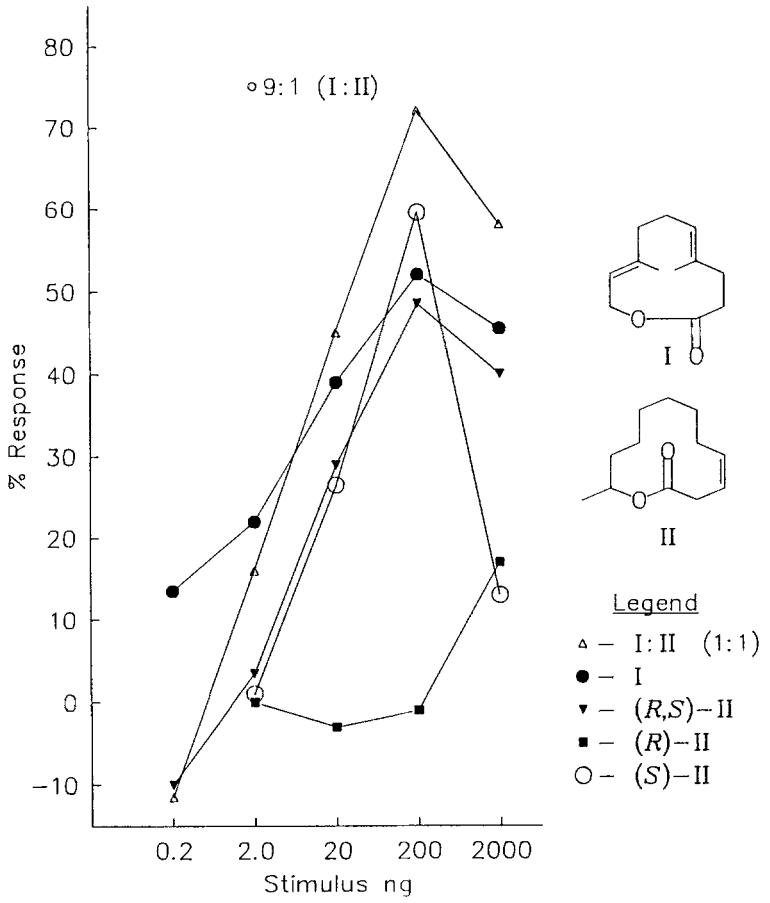

FIG. 6. Response of *Cryptolestes ferriguneus* to cucujolides I and II in arena olfactometer.

enantiomeric synergism outside of the Scolytidae, in which it occurs in *Gnathotrichus sulcatus* (Borden et al., 1976) and *Ips pini* (Lanier et al. 1980).

It would be expected that cucujids such as *O. mercator* and *O. surinamensis* would use cucujolides similar to I–IX as aggregation pheromones. Initial experiments by A.M. Pierce et al. (1981) revealed olfactory responses of both these species to volatiles of mixed-sex beetles and frass. Thresholds of response to volatiles of conspecifics of both species are ~20 bh (where 1 bh = the volatiles emitted by 1 beetle in 1 hr), roughly equivalent to those observed

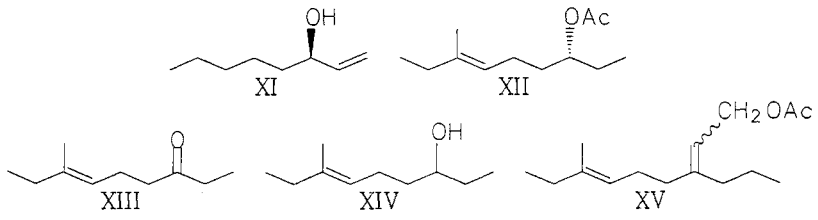
(~30 bh) for *C. ferrugineus* by Wong et al. (1983) and for *C. pusillus* by Millar et al. (1985a). Surprisingly, the only detectable (coupled gas chromatography–selected ion mass spectrometry) cucujolide in the volatiles of *O. surinamensis* was present in trace amounts (V, ~0.01 pg/bh). *O. mercator* produced only trace (~0.01 pg/bh) quantities of cucujolides II and IV. The attractive volatiles derived from the frass of these insects contained 6–18 pg/bh of these cucujolides, 1000 times less than the amounts of I and II found in *C. ferrugineus* frass by Wong et al. (1983).

The low quantities of suspect cucujolides in the beetle-derived *Oryzaephilus* volatiles coupled with Burkholder's (1982) hypothesis that long-lived, stored-product Coleoptera require food for pheromone production, prompted A.M. Pierce et al. (1984) to aerate mixed-sex insects on food. Both *Oryzaephilus* spp. produce dramatically more cucujolides when fed. Of the four cucujolides produced by feeding *O. mercator* (Table 1), significant response at the nanogram level was elicited by only II and IV (A.M. Pierce et al., 1984, 1985, 1987). Maximum response to these pheromones alone and in combination occurs when they are combined in a ratio of 1:1, which is near the natural ratio of 1:1.25. Males and females respond differently to II and IV. The threshold for response of males to II is lower (1 ng) than that of females (10 ng), while the reverse is observed for cucujolide IV. Over the range 0.2–20,000 ng, II and IV are not synergistic. A systematic examination of the attractancy of the enantiomers of II and IV by A.M. Pierce et al. (1987) revealed that only the naturally produced (Oehlschlager et al., 1987) *R* enantiomers of each cucujolide are attractive.

A.M. Pierce et al. (1984, 1985, 1987) also found that of the four cucujolides produced by *O. surinamensis* (Table 1) only racemic or (*R*)-IV and IX elicits significant activity alone (threshold ~10 ng). The dose at which racemic IV and IX elicit significant response is lowered by an order of magnitude when they are combined in a 2:1 or 1:1 mixture. A third cucujolide (racemic V, threshold >300 ng) slightly increases activity of racemic IV and IX when added to either and is synergistic in combination with both racemic IV and IX when the ternary mixture is composed in the nearly natural ratio 1:3:1, IV:V:IX). The naturally produced *R* enantiomers of IV and V are attractive, while the *S* enantiomers are inactive.

The low quantities of cucujolides present in the volatiles of nonfeeding *Oryzaephilus*, coupled with threshold responses to these volatiles that are similar to those for volatiles of *Cryptolestes* spp., provided the initial suggestion that components other than the cucujolides in the *Oryzaephilus* volatiles are responsible for attraction. Components that might contribute to the attractancy of these volatiles are low-molecular-weight carboxylic acids and aldehydes apparently derived from oxidation of long-chain fatty acids. Additional attrac-

tants are obtained when mixed sex beetles of either *Oryzaephilus* species are aerated while feeding on rolled oats. Aeration of each sex of each species revealed that (*R*)-1-octen-3-ol (XI) and (*Z*)-2-octen-1-ol are produced one to two months posteclosion by both sexes of both species (Scheme 2). While the



SCHEME 2.

latter alcohol is devoid of biological activity in the pitfall bioassay at doses from 1 to 10,000 ng, both chiral isomers and the racemic mixture of the former are strong attractants to both sexes of both species. When combined with threshold quantities of the ternary cucujolide mixture for *O. surinamensis* or the binary mixture of *O. mercator*, a strong (1000-fold) synergistic response is obtained.

H.D. Pierce et al. (1988) found that the volatiles of mixed-sex *Cathartus quadricollis* captured on Porapak Q contain several unsaturated acyclic branched-chain compounds (Scheme 2, XII–XV) but no macrolides. Only XIII (quadrilure) is attractive in the pitfall olfactometer at the nanogram level. The *R* enantiomer of this aggregation pheromone is produced naturally and is the attractive enantiomer. When males or females are aerated separately (*R*)-1-octen-3-ol (XI) is produced. Racemic and (*R*)-XI but not (*S*)-XI are repellent to both sexes alone at the 10 ng level but did not diminish attractancy to XIII.

CROSS-ATTRACTION AND SPECIES RECOGNITION IN CUCUJIDS

Cross-attraction to semiochemicals produced by sympatric species might be expected in situations where the food resource to be utilized is spacious and abundant (A.M. Pierce et al., 1987). For example, ambrosia beetles that inhabit the spacious sapwood of conifer trees elicit primarily cross-attraction (Borden et al., 1981), while inhibition of response occurs between two species of bark beetles, *Ips pini* (Say) and *I. paraconfusus* (Lanier), that compete for an essentially two-dimensional resource, the inner bark of trees (Birch and Wood, 1975).

One mechanism by which species specificity can be maintained is through differential resource utilization. Within the *Oryzaephilus* species studied, several observations point to *O. surinamensis* as a primary colonist and *O. mercator* as a secondary colonist. Taxonomic differences between the two species suggest that the former would be better able to feed on undamaged grain (Slow, 1958). *O. surinamensis* is also the more dispersive of the two species (Howe, 1956; A.M. Pierce et al., 1983). In addition, A.M. Pierce et al. (1983, 1984) found *O. surinamensis* to be sensitive to crowding by conspecifics as evidenced both by decreased responsiveness to pheromone and decreased pheromone production, whereas at high population densities, *O. mercator* is not. Finally, A.M. Pierce et al. (1987) observed that one of the cucujolide pheromones of *O. surinamensis* (IV) is strongly attractive to *O. mercator*, allowing the latter to be attracted to habitats occupied by the former. The differential colonization roles proposed for the *Oryzaephilus* parallel those proposed for colonization of new habitats by *Tribolium* species (Ghent, 1963; Ziegler, 1976). Structures and activities of the cucujolides produced by *Cryptolestes* and *Oryzaephilus* spp. provide information on taxonomic relationships and the chemical basis for cross-attractancy and species recognition. A close taxonomic relationship between *O. mercator* and *O. surinamensis* (Slow, 1958) is supported by the observation that they share a common cucujolide pheromone (IV). A more distant relationship between *Cryptolestes* and *Oryzaephilus* spp., established by chromosomal comparisons (Robertson, 1959), is supported by the observation that *Cryptolestes* spp. use as aggregation pheromones cucujolides that are either unique to the genus, are released in trace quantities and not used as pheromones by *Oryzaephilus* spp., or are of opposite chirality to those used by *Oryzaephilus* spp.

The information in Table 1 is reinterpreted and supplemented in Table 2 to illustrate the major mechanisms identified by Oehlschlager et al. (1987b) in this sympatric group that are responsible for species specificity in chemical communication. These major mechanisms are: (1) presence of a unique pheromone (*C. ferrugineus*, I; *C. pusillus*, VIII); (2) use of synergistic pheromones that are inactive alone but synergize response to other pheromones (*C. pusillus*, *C. turcicus*, III; and *O. surinamensis*, V); (3) response to only one chiral isomer of a pheromone (*C. ferrugineus* and *O. mercator*, II); and (4) synergism between enantiomers of a pheromone (*C. turcicus*, V).

C. ferrugineus is not expected to elicit cross-attraction to other cucujids for two reasons. First, only *C. ferrugineus* produces I. Second, although both *C. ferrugineus* and *O.mercator* share II as a pheromone, the former produces and responds only to (*S*)-II whereas the latter produces and responds only to (*R*)-II.

C. pusillus cross-attraction to other cucujids is not expected since VIII, a singly active component, is not produced by any other species. Although III is

TABLE 2. MECHANISMS OF SPECIES SPECIFICITY IN SEMIOCHEMICAL COMMUNICATION BETWEEN SIX CUCUJID SPECIES[a]

	 I	 II	 III	 IV	 V	 VIII	 IX	 XI	 XIII
C. ferrugineus	Unique Synergist	*S*[b], Synergist	+[c]	+	+				
C. pusillus			Synergist *R*:*S* 30:70			Unique	+		
C. turcicus			Synergist		*R*:*S* 85:15				
O. mercator		*R*, Pheromone	+	*R*, Pheromone	+		+	Synergist

[c] + Trace

a synergist to VIII and is common to most cucujids investigated, it is not attractive alone to *C. pusillus*.

C. turcicus is not expected to be attracted to *C. ferrugineus*, even though both III and V are produced by the latter. In *C. turcicus* the III : V ratio is 0.38, whereas in *C. ferrugineus* it is 13. Furthermore, III and V are only minor components of *C. ferrugineus* volatiles. Attraction to *C. pusillus* is not expected since they share only III, which is inactive in both species. Attraction to *O. mercator* is unlikely because both III and V are produced by the latter only as minor components. Attraction to *O. surinamensis* is not expected because the ratio of V to III produced by *O. surinamensis* (>510) is drastically different from that of *C. turcicus*. Furthermore, V produced by and attractive to *C. turcicus* is a mixture of *R* and *S* enantiomers, whereas *O. surinamensis* produces (*R*)-V of high chiral purity.

O. mercator produces and responds to (*R*)-II and (*R*)-IV of high chiral purity. This species is not expected to be attracted to *C. ferrugineus* because the latter produces and responds only to the *S* enantiomer of II. Cross-attraction of *O. mercator* to *O. surinamensis* is possible since both species produce (*R*)-II, which is attractive alone for *O. mercator*.

O. surinamensis produces and responds only to the *R* isomers of IV and V. Cross-attraction to *C. ferrugineus* due to production of minor amounts of IV and V is not likely since the IV : V ratio in *C. ferrugineus* does not approximate that found in *O. surinamensis*. Cross-attraction to *C. pusillus* is not likely since the only *O. surinamensis* pheromone produced by *C. pusillus* is IX and this is a minor component in the volatiles of the latter. Attraction to *C. turcicus* is not expected to occur even though these two species produce major amounts of V. This component of the *O. surinamensis* pheromone blend is not attractive unless IV and IX are present. Both of the latter components are absent in *C. turcicus* volatiles. Attraction of *O. mercator* to *O. surinamensis* is likely since each species uses (*R*)-IV as an active pheromone component. In addition, *O. mercator* produces a minor amount of IX, which is a singly active pheromone for *O. surinamensis*. The only cucujids investigated to date that elicit significant cross-attraction are *O. mercator* and *O. surinamensis* (A.M. Pierce et al., 1987).

FACTORS AFFECTING PHEROMONE PRODUCTION AND RESPONSE TO PHEROMONES

In all species investigated, A.M. Pierce et al. (1984) observed that newly emerged grain beetles produced little or no pheromone. During the first few weeks after emergence, pheromone production increases, reaching a maximum around four weeks, and remains rather constant to 10 weeks posteclosion. Dur-

ing the first few weeks posteclosion, crowding by conspecifics decreases pheromone production for *O. surinamensis* but not *O. mercator*. The variation from a smoothly increasing pheromone production with age evident in Figure 7 is probably due to temperature variations during the course of pheromone collection, as pheromone production for *Oryzaephilus* spp. generally increases with temperature.

It is hypothesized that aggregation pheromones arose as a mechanism to cause aggregation at a suitable food source (Shorey, 1973). In bark beetles (Borden, 1985), production of aggregation pheromones is often enhanced or commences upon arrival of the producing sex at a food source. Similarly, A.M. Pierce et al. (1984) found that production of pheromones by grain beetles is enhanced when the insects are feeding. When *Oryzaephilus* spp. are aerated without food, cucujolide pheromone production levels is in the subpicogram/bh range. For *Cryptolestes* spp. they are in the low nanogram/bh range. When the beetles are aerated while feeding (Table 3), pheromone production in *Oryzaephilus* spp. increased ~40,000-fold, while in *Cryptolestes* spp. it increased by ~50-fold. A.M. Pierce et al. (1987) interpreted these differences to indicate that the cucujolide pheromones may serve as more critical signals of food sources for *Oryzaephilus* than *Cryptolestes* spp.

Vanderwel and Oehlschlager (1987) have shown through radio- and stable isotope tracer experiments that cucujolides II–IX are produced by cucujids both de novo and via modification of dietary fatty acids. Cucujolide I is derived from farnesol. Pheromone XII, and *C. quadricollis*, is presumed to be terpenoid (Vanderwel and Oehlschlager, 1987). The cucujolide compositions in Table 1

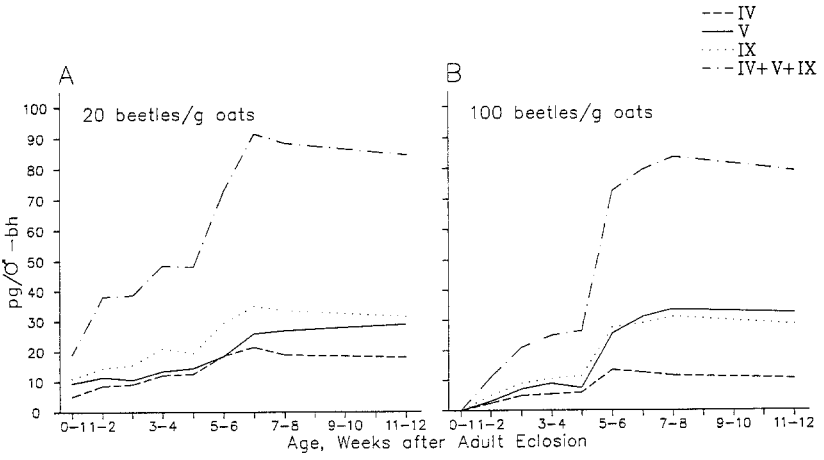

FIG. 7. Production of cucujolides IV, V, and IX by mixed-sex *O. surinamensis* aerated for five-day intervals at different culture densities. Volatiles captured on Porapak Q.

TABLE 3. COMPARISON OF PRODUCTION OF CUCUJOLIDES BY FEEDING AND UNFED *Cryptolestes* AND *Oryzaephilus* SPECIES

Species	Feeding regime	Production rates (pg/beetle-hr)						
		I	II	III	IV	V	VIII	IX
C. ferrugineus	unfed	36	42					
	feeding	990	640					
C. pusillus	feeding			30			1300	15
O. mercator	unfed		0.022		0.030			
	feeding		770		200			
	unfed					0.013		
O. surinamensis	feeding			10		28		25

are all obtained from mixed-sex adults of each species feeding on the same diet of rolled oats. Although it would be expected that the distribution of cucujolides within a species would vary slightly with food source, this has not been investigated.

Small variations in cucujolide composition are observed for several laboratory strains of *Oryzaephilus* spp. For example, the ratio of IV : V : IX for laboratory strains of *O. surinamensis* varies from 1 : 3 : 1 (A.M. Pierce et al., 1984, 1987) to nearly 1 : 1 : 1 (A.M. Pierce et al, 1985). An English strain of *O. surinamensis* has a different cucujolide composition than the 1 : 3 : 1 IV : V : IX composition (Chambers et al., 1986). In the case of *C. ferrugineus*, feeding insects produce I and II on a ratio of 1.6 : 1, but this changes to 0.86 : 1 when the insects are starved (Lindgren et al., 1985).

The gradual increase in cucujolide production exhibited by young feeding adults (Figure 7) shows that maximal production of aggregation pheromones by *Cryptolestes* and *Oryzaephilus* spp. requires both food and reproductive maturity. In the Scolytidae, production of aggregation pheromones is regulated by juvenile hormones (Borden, 1985); it has been demonstrated in several species that administration of juvenile hormones to mature adults stimulates pheromone production (Hughes and Renwick, 1977; Harring, 1978). A.M. Pierce et al. (1986) found that when adult *C. ferrugineus*, *O. mercator*, and *O. surinamensis* (15–21 days posteclosion) are fed on rolled oats containing 20 ppm of the juvenile hormone mimic, methoprene, pheromone production is stimulated by factors of 1.5–4.7. Enhancement is in the same range as observed for all four components of the pheromone complex of adult boll weevils, *Anthonomous grandis* Boheman, fed on JH-III-treated medium (Hedin et al., 1982). Stimulation of cucujolide production by methoprene suggests that its addition to food-

baited, live traps would be beneficial in pheromone-based monitoring in the Cucujidae (A.M. Pierce et al., 1986).

Responsiveness to pheromones and food volatiles as a function of age and culture density is known only for *Oryzaephilus* spp. (A.M. Pierce et al., 1983). Newly emerged adults are unresponsive to both sources of volatiles. Sensitivity to pheromones and food volatiles appears soon after eclosion, reaching a maximum after four weeks and remaining high throughout the long adult life of these beetles (A.M. Pierce et al., 1983). Neither species exhibits diel periodicity in responsiveness even when reared in constant darkness (A.M. Pierce et al., 1987). There is a significant decrease in responsiveness for mature *O. surinamensis* but not *O. mercator* when reared in high-density cultures (A.M. Pierce et al., 1983). When *O. surinamensis* reared in high-density cultures (~40,000 beetles/kg diet) are recultured at low density (1,000 beetles/kg diet), responsiveness during the next week steadily increases to "low-density rearing" levels (A.M. Pierce et al., 1983).

H.D. Pierce et al. (1988) observed that when *C. quadricollis* respond to pheromone and enter the capture vials used in the pitfall bioassay, they readily climb out. Placing food (an oat flake) or frass in the capture vial arrests this behavior. Thus, the aggregation pheromone apparently functions both by luring the insect to the point of emamation and by stimulating a pattern of searching for food. If a food stimulus is not provided, the responding insect will then leave the site.

ATTRACTION OF CUCUJIDS TO FOOD VOLATILES

Volatiles from several food sources are attractive to *Oryzaephilus* spp. (Freedman et al., 1982; Mikolajczak et al., 1983, 1984; O'Connell et al., 1983; Stubbs et al., 1985). Volatiles from rolled oats and brewer's yeast are attractive to both species of *Oryzaephilus* (A.M. Pierce et al., 1981). The threshold of significant response for *O. mercator* to volatiles of rolled oats (45 gh) and brewer's yeast (26 gh) are several orders of magnitude higher than to volatiles of frass (0.006 gh). For *O. surinamensis* the response thresholds to volatiles of rolled oats (4.5 gh), yeast (0.26 gh), and frass (0.64 gh) are of the same order of magnitude. These food-derived volatiles are very complex mixtures comprised predominantly of fatty aldehydes, acids, and other carbonyl compounds. Surveys of these types of compounds for attractancy have revealed none that is attractive at the nanogram levels elicited by the pheromones (Mikolajczak et al., 1984).

The commercial attractant for attraction of *Oryzaephilus* spp. and other species of grain-infesting Coleoptera to corrugated cardboard traps is oil derived from solvent extraction of oats and wheat germ (Trece Inc., 1986). Mikolajczak

et al. (1984) have analyzed for attractancy to *O. surinamensis* 16 of the more than 100 carbonyl-containing components derived from solvent extraction of rolled oats. Only (*E*)-2-nonenal and (*E*,*E*)-2,4-nonadienal are significantly attractive at the 0.1 μg level. These oat oil constituents elicit good attraction at 10-μg doses, but at the 100-μg level they are repulsive. Surprisingly hexanal (30%), octanal (2%), and nonanal (5%) are not significantly attractive until doses of 10–100 μg are applied in a pitfall bioassay (Mikolajczak et al., 1984).

Volatiles obtained from aeration of feeding or unfed *O. mercator* typically contain hexanal, octanal, and nonanal. In volatiles obtained from unfed *O. mercator*, the levels of these presumptive fatty acid oxidation products are much higher (20-, 20-, 3-fold, respectively) than cucujolides (A.M. Pierce and H.D. Pierce, 1985). Since volatiles derived from these unfed beetles are attractive at doses significantly higher than expected based on the amounts of cucujolide pheromones present, the aldehydes have been examined for attractancy. All three aldehydes are attractive at nanogram doses in the pitfall bioassay. Hexanal and octanal are the least attractive (threshold of significant activity, 100 ng), whereas nonanal is active at doses one order of magnitude lower. All three aldehydes elicit decreasing attractancy above 1 μg. The narrow range of concentrations in which these aldehydes elicit significant attraction for *O. mercator*, if also operational for *O. surinamensis*, may explain why they were not identified as strong attractants for the latter species in earlier studies (Mikolajczak et al., 1984). The aldehydes act synergistically to give a ternary (1 : 1 : 1) mixture that is attractive to *O. mercator* at the 100-ng level (A.M. Pierce and H.D. Pierce, 1985). Addition of nonanal (100 ng) or a ternary mixture (100 ng) of aldehydes to a 1 : 1 mixture (10 ng) of cucujolides I and II also elicits a synergistic response. These mixtures (I,5 ng : II,5 ng : aldehydes, 100 ng) elicit responses roughly equivalent to those elicited by 2000 ng of a 1 : 1 mixture of (*R*,*S*)-I and (*R*,*S*)-IV in the pitfall bioassay (A.M. Pierce and H.D. Pierce, 1985).

FIELD TESTS OF PHEROMONES

Traps baited with the pheromones listed in Table 1 are expected to be more attractive than food and to be effective monitoring devices in food storage areas. Since the unnatural enantiomers of chiral cucujolies are inactive, the less expensive racemates can be used in traps. Futhermore, in a few cases examined by A.M. Pierce et al. (1987), nonpheromone cucujolides produced by one species have no repulsive effect on response by other species to their respective pheromones. Thus, it is expected to be possible to combine pheromones of several species in a single trap, a technique that would greatly reduce the cost of pheromone-based monitoring programs for these pests.

Several studies have been conducted to develop protocol for field utiliza-

tion of cucujid pheromones in monitoring for these insects. Three types of traps have been examined for their efficiency in capturing grain beetles from grain and areas mimicking food storage areas. All rely on pheromone and food attractants to lure the insects to dark enclosures from which escape is difficult. For obvious reasons, none of the traps utilize insecticidal chemicals.

Two types of traps have been examined for efficiency at recapturing grain beetles released in environmental chambers. One trap (Lindgren et al., 1985) is constructed from a perforated plastic weighing dish (Figure 8A) containing hollow plastic fibers (Conrel) filled with pheromone as the attractant release device. The test species were *C. ferrugineus* and *Tribolium castaneum*. The bait for *C. ferrugineus* was a 13:16 mixture of cucujolides I and (*R*, *S*)-II, which was released at 1.25 μg/day at 22°C. For *T. castaneum*, 4,8-dimethyldecanal (DMD) (Suzuki, 1980) was synthesized from (*R*)-citronellol (Suzuki, 1981) and contained approximately 4.5% of the active 4*R*, 8*R* and 4*R*, 8*S* isomers (Suzuki et al., 1984; Levinson and Mori, 1983). It was released at 0.08 μg/day. The recapture experiments involved the release of 3000 beetles within a controlled environment chamber. Paired baited and control traps are placed around the periphery of the floor of the chamber with 15 cm within pairs and 35 cm between pairs.

Both species are readily caught in single-baited traps. The recapture rate for *C. ferrugineus* was 76% but only 21% for *T. castaneum* (Lindgren et al., 1985). The lower recapture rate for the latter insect is probably due to the low release rate of the pheromone and the unfavorable 1:1 ratio of the active isomers. The natural ratio of isomers of (4*R*, 8*R*)- to (4*R*, 8*S*)-DMD is 4:1, and the latter acts synergistically with the former (Suzuki et al., 1984). Both species are captured equally in traps containing their own aggregation pheromones regardless of the presence of the pheromone of the other species. There is slight cross-attraction of *T. castaneum* to the pheromones of *C. ferrugineus* but not vice versa. By placement of known numbers of *C. ferrugineus* or *O. mercator* within the trap, Lindgren et al. (1985) demonstrated that the trap was essentially escape-proof.

Corrugated cardboard traps (Figure 8B) baited with oat-wheat germ oil attractant are commercially available (Trece Inc., 1986) and recommended for monitoring *Oryzaephilus* spp. These traps were used as controls in tests designed to examine the effectiveness of cucujolide pheromones of *O. mercator* and *O. surinamensis*. Insects were released near the center of an arena and recapture rates examined. Responses of *O. surinamensis* to traps baited with both pheromone and oat-wheat germ oil are significantly higher than to traps baited only with oat-wheat germ oil at doses above 0.5 μg of the pheromone mixture (1:1:1, IV:V:IX, Figure 9A). Females detect the pheromone at doses at least an order of magnitude lower than the males, but response of males to increasing pheromone dose is higher than that of females.

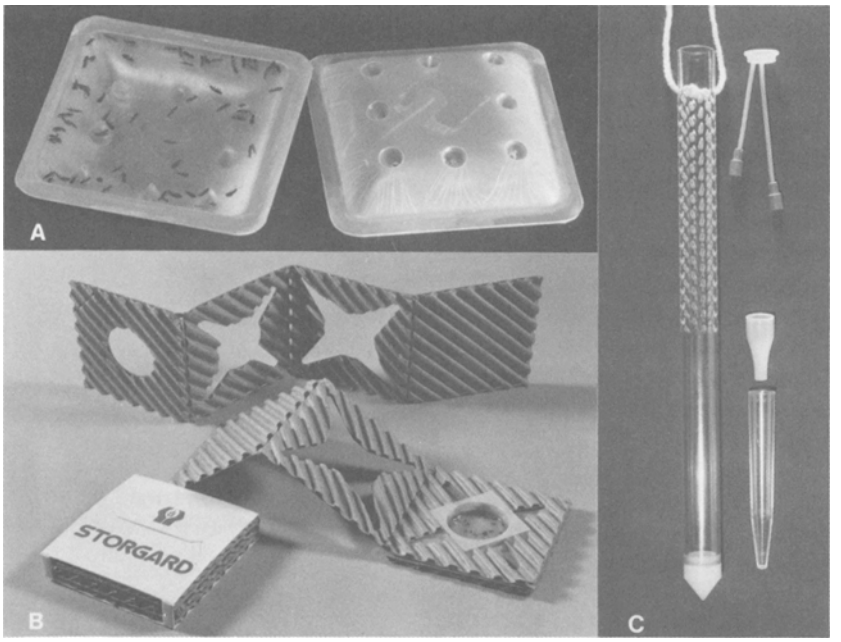

FIG. 8. Three traps used in tests of aggregation pheromones. (A) Inverted plastic weighing boat (4.1 × 4.1 × 0.8 cm) with eight inward-pointing conical depressions (basal idameter 3 mm, length 3–4 mm) each with a 1- to 2-mm wide hole at the bottom. The bottom of each trap consists of transparent packaging tape. Pheromone is released from 0.2 mm ID Conrel plastic fibers (Albany International Co., Needham, Massachusetts). (B) Corrugated paper trap adapted from an original design by Burkholder (1981) consisting of four layers of corrugated paper and containing a cup with an absorbant pad in the bottom. Food-derived oil added to the cup attracts and captures the insects (Trece Inc., 1986). (C) Plastic grain probe trap, adapted by Burkholder (1984) and Trece Inc. (1986) from an original design by Loschiavo and Atkinson (1967), consists of a transparent, hollow, cylindrical tube 36 × 2.5 cm with 186 evenly spaced 3-mm-diam. holes drilled downwards toward the inside at an angle of 60°. Insects fall through these holes into a removable collection tube housed in the bottom of the trap. Suspended inside the upper end of the trap is a nylon rod to which an attractant lure is attached. A rope attached to the top of the trap allows recovery from bulk grain.

Both sexes of *O. mercator* are responsive to low doses (4 μg) of their pheromones (1:1, II:IV) added to oat–wheat germ oil attractant (Figure 9B). As the dose increases to 2000 μg, female response increases while male response decreases relative to oat–wheat germ oil alone. Increasing the pheromone dose in oat–wheat germ oil increases capture efficiency for both *O. mercator* and *O.*

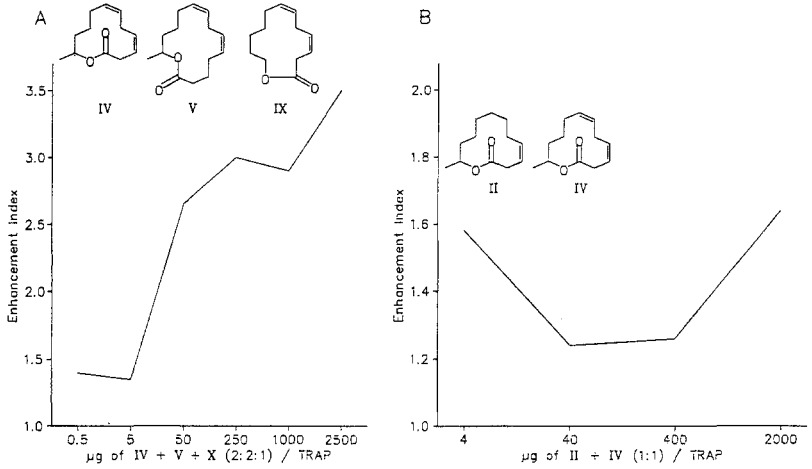

FIG. 9. Enhancement of efficiency of corrugated cardboard traps (Trece Inc., 1986) in recapturing mixed-sex *O. surinamensis* (A) and *O. mercator* (B) using pheromones added to oat–wheat germ oil attractant. Enhancement index to oat–wheat germ oil = 1.0.

surinamensis, but enhancement is higher for *O. surinamensis* than for *O. mercator*. For both species, both sexes exhibit similar sensitivities toward their pheromone except at higher dose rates to which the females are more sensitive than males.

Metal grain probe traps (Figure 8C) designed by Loschiavo and Atkinson (1967) have been tested in grain annex bins and in farm bins to ascertain if addition of pheromones in Conrel fibers (Albany International Co., Needham, Massachusetts) increases efficiency of capture of *C. ferrugineus* (Figure 10) (Wong, 1982; Loschiavo et al., 1986). Efficiency of both control and baited traps decreases dramatically as they are positioned deeper in the grain. Traps at a depth of 30–60 cm catch 15 times more beetles than those placed at 150 cm or lower. Near the surface, traps baited with one pheromone-filled fiber catch 10 times as many beetles as unbaited traps, while traps baited with two fibers catch approximately 20 times as many insects as controls. In deep (~244 cm) traps, the efficiency of control and baited traps is not significantly different. In bins ranging in temperature from 28.5 to 32°C, approximately 10 times as many insects are caught as in bins where the temperature ranged between 21.5 and 24°C. In farm bins, both baited and unbaited probe traps are relatively ineffective (less than one insect average/trap/week) if the grain temperature is below 14°C. At the highest temperature to which grain in farm bins normally rises during a season (~19–20°C) baited probe traps placed near the surface are only marginally effective (~4 insects/trap/week).

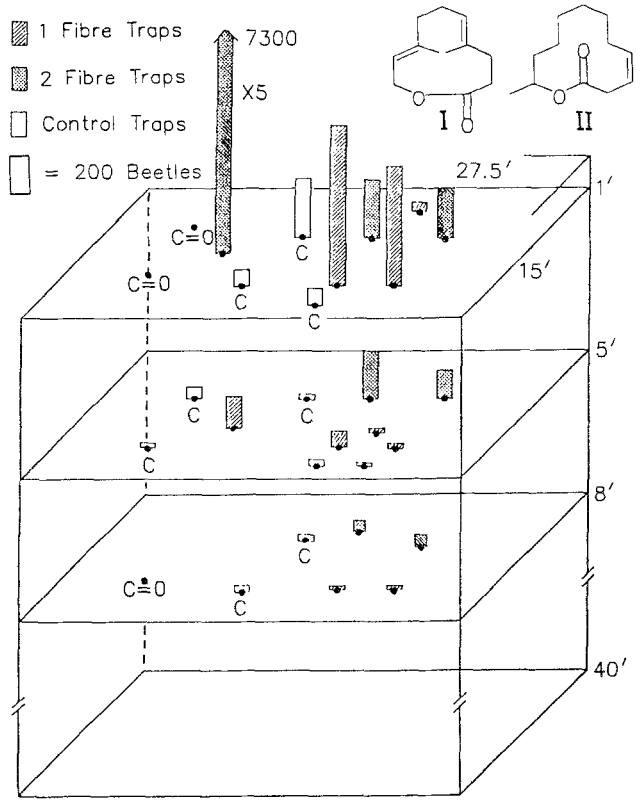

FIG. 10. Capture of *C. ferrugineus* by pheromone-baited and control traps placed in bins of wheat and left for one week (adapted from Loschiavo and Atkinson, 1967, in Wong, 1982). Pheromone (9 : 1, I : (*R*, *S*)-II) is released from one or two (0.2 mm ID) Conrel (Albany International Co., Needham, Massachusetts) polyester fibers. The release rate in the probe traps is about 14 times lower than the 1.25 μg/day/fiber determined under laboratory conditions and corresponds to a rate 23-230 times that of a feeding male *C. ferrugineus*. Grain temperature was between 24 and 28.5°C.

The relative efficiencies of the three types of traps described in Figure 8 to recapture insects released in grain in small bins have been examined (A. Javer et al., unpublished). The tests were conducted with introduced populations of adult *C. ferrugineus*, *C. pusillus*, *O. mercator*, and *O. surinamensis* at ~2 insects/kg of grain. Pheromone baiting increased the efficiency of all traps.

Pheromone-baited probe traps are the most efficient for the capture of all species. Corrugated paper traps and plastic dish traps are only efficient in capturing *O. mercator*. Unbaited probe traps are as attractive as pheromone-baited

traps to *O. mercator*, but not *O. surinamensis*. Possibly, the presence of food particles in the recapture vials stimulated pheromone production by *O. mercator*. These results indicate that field tests with different trap types, baited and unbaited, are necessary for each target species in order to develop optimally integrated and effective trapping regimes.

CONCLUSIONS

During the last five years, semiochemicals for many species of long-lived coleopteran pests of stored products have been discovered. It has been shown that, in addition to the cucujids discussed herein, species in several other families, e.g., Bostrichidae (grain borers), Curculionidae (weevils), and Tenebrionidae (flour beetles), also respond to food volatiles and male-produced aggregation pheromones (Burkholder and Ma, 1985). The latter are invariably mixtures of several chemicals that are produced in greatest amounts when the beetles are feeding, indicating a close relationship between the population of pheromones and the exploitation of scarce food resources. Moreover, the potency of aggregation pheromones is enhanced by their combination with food volatiles. While various mechanisms of species specificity exist, inhibition of attraction of one species to its pheromone due to the presence of the pheromone of another has not yet been detected in stored-product coleopterans. Thus, it should be possible to utilize combinations of pheromones and host volatiles in multiple-species monitoring programs for these remarkable insect pests.

(Received January 5, 1988; accepted April 25, 1988)

Abstract—A dazzling variety of honeybee behaviors are triggered by pheromones produced by disparate exocrine glands. A multiplicity of chemical releasers of social behavior has been demonstrated to regulate a diversity of societal interactions, and many of these compounds are synthesized with great caste specificity. Recent investigations have resulted in the identification of a host of new compounds that are products of either worker or queen honeybees. This report fractionates these newly identified exocrine products according to their glandular proveniences and focuses on both the structural and behavioral eclecticism that characterizes these chemical signaling agents.

Key Words—Honeybee, *Apis mellifera*, Hymenoptera, Apidae, alarm pheromones, wax compounds, antiaggression pheromone, exocrine glands, chemisociality.

INTRODUCTION

Among invertebrates, the honeybee, *Apis mellifera*, may represent the zenith of chemisociality. A large variety of behaviors has been demonstrated to be regulated by pheromonal signals originating from diverse exocrine glands of either worker or queen bees (Gary, 1974), and many of these signaling agents have been structurally elucidated (Free, 1987). As the pheromonal world of the honeybee has been probed, it has become increasingly evident that this hymenopteran has evolved a dazzling behavioral repertoire, many components of which are controlled by exocrine products. Indeed, it is not unreasonable to conclude

0098-0331/88/1100-2099$06.00/0

that the elegant exploitation of sociality by *A. mellifera* is a consequence of its ability both to biosynthesize these compounds programatically—in a variety of glands—and to exhibit distinctive behaviors in their presence.

Research in the last three decades has illuminated the biosynthetic emphases that characterize several of the social organs utilized by honeybees in the colonial milieu. In particular, the mandibular glands of queens have been demonstrated to produce a large variety of aliphatic acids (Pain and Barbier, 1963; Callow et al., 1964), and more recently Crewe and Velthuis (1980) and Crewe (1987) reported that workers can also synthesize diverse aliphatic acids in these cephalic organs. An abdominal structure of similar biosynthetic versatility, the Nasonov gland, has emerged as the worker's monoterpene-producing gland par excellence (Boch and Shearer, 1962, 1964; Shearer and Boch, 1966), and a sesquiterpene has now been identified as a product of this isoprenoid factory (Pickett et al., 1980). Another abdominal product, the blend of alarm pheromones liberated from the extruded sting shaft of workers, is probably derived from the functionally associated Koschewnikow glands (Mauchamp and Grandperrin, 1982; Grandperrin and Cassier, 1983), which emphasizes the biosyntheses of a large variety of aliphatic acetates and alcohols (Boch et al., 1962; Blum et al., 1978; Collins and Blum, 1983).

In the present review, we wish to discuss briefly the significance of a variety of newly identified compounds derived from different abdominal glands of honeybees. In so doing, we hope to focus on the virtuosity of this insect as a synthesizer of exocrine compounds while further emphasizing that the natural products potential of this wondrous hymenopteran is far from exhausted.

ALDEHYDIC WAX GLANDS

While the wax scales produced by worker bees are derived from abdominal glands, they appear to be modified with cephalic secretions during manipulation with the mouthparts (Hüber, 1792). Beeswax is reported to contain a large series of highly volatile constituents (Ferber and Nursten, 1977), but it is very likely that many, if not most of these compounds, are plant natural products that have been absorbed by the wax. To determine what relatively low-boiling compounds are associated with beeswax uncontaminated by plant volatiles, samples of wax produced by caged swarms were analyzed.

Bees were fed only sucrose solution, and the newly made comb was extracted and analyzed by gas chromatography–mass spectrometry. Aside from an expected series of normal alkanes, six oxygenated volatiles were consistently detected, five of which were aldehydes (Blum et al., 1989). The major compound identified was decanal, and it was accompanied by its corresponding

alcohol, 1-decanol. Nonanal, which was also a quantitatively important constituent, was detected along with a minor aldehydic product, octanal. Furfural and benzaldehyde were concomitants of the aliphatic aldehydes.

Neither the functions nor the precise origins of these oxygenated volatiles have been unambiguously established. Although none of these compounds have been previously identified as honeybee natural products, they clearly contribute significantly to the characteristic odor of freshly constructed comb. Efforts to determine whether these aldehydes are responsible for the observed hoarding behavior of workers stimuated with volatiles from empty comb (Rinderer, 1981) yielded ambiguous results, although it was established that these compounds affect the intensity of hoarding (Blum et al., 1989). Indeed, wax may constitute a product whose exocrinological significance could be considerable in terms of honeybee biology.

A WEALTH OF ALARM PHEROMONES

The everted sting of a mature and aroused worker is a veritable magnet for sister workers that are attracted to the pheromonal releasers of alarm behavior emanating from the sting shaft. Originally identified with isopentyl acetate (Boch et al., 1962), the alarm signal was subsequently shown to be triggered by a blend of compounds comprised primarily of esters and alcohols (Blum et al., 1978; Pickett et al., 1982; Collins and Blum, 1983). Twenty alcohols and acetate esters were detected as sting-shaft volatiles, and the different components were demonstrated to possess a wide range of activities as releasers of alarm behavior for worker bees (Collins and Blum, 1982, 1983; Pickett et al., 1982; Grandperrin, 1983; Free et al., 1983). Surprisingly, the signal appears to be even more complex and may be qualitatively distinct for different populations of *A. mellifera*.

At least 30 relatively short-chain oxygenated compounds have been detected as sting-associated volatiles of different populations of honeybees (Blum and Fales, unpublished data). *n*-Octanoic acid and 3,3-dimethylacrylic acid are produced by a few populations of *A. mellifera*, but only the latter is a quantitatively important constituent. On the other hand, 13 alcohols have been identified in sting extracts from different populations, and some of these carbinols are major constituents of great functional significance.

The major alcohol present in all populations is (Z)-11-eicosen-1-ol, a compound that has been demonstrated to be important in the generation of an alarm signal (Pickett et al., 1982). Another alcohol, 2-nonanol, which has also been shown to be highly active as an alarm pheromone (Collins and Blum, 1982), is a major constituent of several populations of *A. mellifera*, particularly those of

African origin. 2-Nonanol is sometimes accompanied by two other secondary alcohols, 2-heptanol and 2-undecanol, both of which constitute minor or trace constituents.

Eight primary alcohols have been identified as sting-shaft volatiles, but several of these compounds have only been detected as products of selected populations of honeybees. For example, 1-butanol and 1-heptanol were only detected in *A. m. scutellata* and *A. m. capensis*, whereas the only branched alcohol identified, isopentyl alcohol, was most frequently identified in populations of *A. m. ligustica*. Among the short-chain primary alcohols, 1-octanol, a moderately active alarm pheromone (Collins and Blum, 1983), was consistently detected in all populations as a quantitatively significant constituent. However, with the exception of 2-nonanol (see above), the major carbinols identified are unsaturated constituents. (*Z*)-11-Eicosen-1-ol, the major alcohol present (Pickett et al., 1982; Blum, 1982), is accompanied by (*Z*)-9-octadecen-1-ol and nonadecen-1-ol, both of which are major constituents. Unlike (*Z*)-11-eicosen-1-ol, neither (*Z*)- nor (*E*)-9-octadecen-1-ol are reported to possess any activity as releasers of alarm activity when tested alone or in combination with another pheromone, isopentyl acetate (Pickett et al., 1982). However, since (*Z*)-9-octadecen-1-ol was not tested in combination with (*Z*)-11-eicosen-1-ol and isopentyl acetate, its possible synergistic role as an alarm releaser cannot be ruled out completely. Indeed, (*Z*)-9-octadecen-1-ol is reported to give as strong an electroantennographic response as (*Z*)-11-eicosen-1-ol (Pickett et al., 1982), demonstrating that the former can be perceived by bee workers with the great acuity that characterizes insects' responses to their alarm pheromones.

Although 14 esters have been identified as string-shaft volatiles (Blum and Fales, unpublished data), only one of these compounds, *n*-eicosyl acetate, contains an alcoholic moiety with a chain length greater than 10 carbon atoms. Two minor constituents, butyl *n*-butyrate and isopentyl *n*-butyrate, constitute the first nonacetate esters identified in these blends, but as in the cases of other compounds, their occurrence appears to be limited to certain populations. Similarly, isohexyl acetate, the only other branched acetate detected besides isopentyl acetate, has only been found in one population of honeybees (Blum and Fales, unpublished data).

From a quantitative standpoint, 2-nonyl acetate and 2-decenyl acetate can constitute major constituents along with isopentyl acetate. Hexyl and octyl acetates are also quantitatively significant, as is another ester of a secondary alcohol, 2-heptyl acetate.

As pointed out previously, the release of alarm behavior in *A. mellifera* was originally identified with only one ester, isopentyl acetate (Boch et al., 1962), but it has subsequently been demonstrated that several other esters identified as sting-shaft volatiles are highly active alarm pheromones. Collins and Blum (1982) showed that hexyl acetate and butyl acetate were effective stimu-

lators of alarm behavior, and Free et al. (1983) also reported that butyl acetate was a powerful stimulator of attack and stinging by honeybee workers under field conditions. One of the unsaturated esters, 2-nonenyl acetate, also exhibits high activity as an alarm pheromone (Collins and Blum, 1983). Another unsaturated ester, 2-decenyl acetate, which has been reported to be an alarm pheromone of other species of *Apis* but had not been identified as product of *A. mellifera* (Veith et al., 1978), has been detected by us in several populations of *A. m. ligustica*.

AN ANTIAGGRESSION PHEROMONE IN QUEEN FECES

Virgin queen bees have evolved an elegant strategy for both repelling hostile workers and reducing their level of aggressivity. During hostile confrontations with workers, these queens excrete a highly odorous anal exudate, which, under experimental conditions, effectively reduces worker aggression and ultimately releases pronounced autogrooming in the latter (Page and Erickson, 1986; Post et al., 1987). In effect, queens have converted their intestines into a social organ whose secretion—pheromone-fortified feces—plays a key role in protecting the virgin female from injuries that might be inflicted by the worker siblings.

Recently, a major fecal pheromone was identified as *o*-aminoacetophenone, a compound that repels honeybee workers as effectively as the feces of virgin queens (Page et al., 1988). However, the aromatic ketone does not stimulate autogrooming behavior, which is probably released by other constituents in this complex secretion. Indeed, *o*-aminoacetophenone is a minor constituent in the secretion, which is thoroughly dominated by esters and hydrocarbons.

Significantly, virgin queens are programmed to produce this ketone during a particularly vulnerable period in their lives. During the first 24 hr of adult life when virgin queens are not likely to be challenged by workers, no *o*-aminoacetophenone is detectable in the feces. Similarly, after about 14 days of age, when queens are mated and are likely to function as mother queens, the ketone cannot be detected in the feces. Therefore, the biosynthesis of this key pheromone is of great temporal adaptiveness, ensuring that this worker repellent will be readily available during the period in the virgin queen's life when agonistic interactions are most frequent. In addition, as emphasized by Post et al. (1987), fecal pheromones may play a key role during aggressive interactions between virgin queens.

The fecal exudate of these virgin queens contains a complex mixture of constituents that includes several other relatively volatile products whose possible ethopotencies remain to be established. For example, octanoic acid and 1-dodecanol, which are present in considerably greater concentration than *o*-

aminoacetophenone (Blum et al., unpublished data), do not repel workers at physiological concentrations, although the former does reduce autogrooming significantly (Page et al., 1988). A host of esters are present in the fecal exudate, and the possible pheromonal role of these major constituents is unknown. Several of these esters (e.g., decyl decanoate) have previously been identified as constituents of the sting shaft of queen bees (Blum et al., 1983), and the significance of their presence as major fecal constituents is not readily evident. The same can be said for octanoic acid, which has also been identified as a cephalic (=mandibular gland?) constituent of virgin and mated queens (Boch et al., 1979).

CONCLUSIONS

The three secretions described in this brief review are illustrative of the potential of the honeybee as a producer of eclectic pheromones derived from a wealth of exocrine glands. Indeed, if only the known exocrine glands of this insect are considered as pheromonally relevant, then it seems likely that a host of unidentified natural products awaits structural elucidation. It would be no exaggeration to conclude that the best is yet to come.

Gary (1974), in his seminal review on honeybee pheromones, described a variety of behaviors that are released by pheromones, most of which have not been identified yet. Workers and queens possess a host of potential exocrine glands whose secretions are believed to regulate an incredible potpourri of behaviors (Pain, 1973). In addition to these secretions from adult females, brood pheromones (Koeniger and Veith, 1983) and drone pheromones (Gerig, 1972; Lensky et al., 1985) have been described as additional examples of the exocrinological virtuosity of the honeybee. While these cases of caste-specific pheromones further document the natural products potential of *A. mellifera*, they also serve to emphasize that chemical communication in this eusocial species is identified with a multitude of factors that can be easily overlooked.

For example, the demonstration that the rectum contained virgin queen pheromones (Post et al., 1987) exposed the intestine as a social organ, emphasizing that any glandular structure that can externalize its product can be regarded as a potential pheromonal source. Furthermore, this exudate is illustrative of most of the glandular products of honeybees in being composed of a complex mixture of compounds belonging to several chemical classes. As is usually the case, the functions of most of these compounds are terra incognita, but it would be a mistake to simply conclude that these semiochemicals possess no ethopotencies. In the absence of appropriate bioassays, the roles of these exocrine products—in the colonial milieu—can hardly be illuminated.

The alarm pheromone blend associated with the extruded worker sting

offers another example of the exocrinological complexity that characterizes the honeybee. The pheromonal bouquet comprising this alarm releaser may contain up to 30 compounds, many of which are outstanding triggers of alarm behavior under both laboratory and field conditions (Collins and Blum, 1982, 1983; Grandperrin, 1983; Free et al., 1983). Significantly, since Collins and Blum (1983) have demonstrated that highly odoriferous foreign compounds do not elicit alarm behavior, it is clear that the sting-derived volatiles are specifically perceived by bee workers as alarm releasers.

Our studies of honeybee alarm pheromones also suggest that idiosyncratic natural products may characterize the pheromonal blends generated by selected populations. For example, certain esters (e.g., butyl *n*-butyrate) have only been identified as products of certain African populations of *A. mellifera*, and it is possible that such compounds may be of considerable communicative importance. It would be a mistake to overlook the possibility that populations of insects may produce characteristic pheromonal components that are highly adaptive in certain ecological contexts. These populationally distinctive compounds could be of great behavioral significance and, as a consequence, to ignore their potential roles as colonial regulators is simply not justified.

In the case of all three secretions described in this review, it has been emphasized that blends of compounds are characteristically encountered. Obviously, honeybees are perceiving multicomponent mixtures of natural products, and ultimately these chemical signals must be interpreted in terms of behavioral responses to these blends. Although it is much more convenient to monitor electrophysiological and behavioral responses in terms of one or a few compounds, the real world of the honeybee is not characterized by such odoriferous simplicity. As researchers on sex pheromones have so painfully learned, to ignore the roles of minor constituents in the sex pheromone blends often results in frustratingly puzzling lacunae in our comprehension of sexual behaviors.

Finally, it is of major importance to recognize that honeybees are programmed to produce their pheromones so as to optimize their adaptiveness in the milieu of the colony. Alarm pheromones are produced by bee workers with great temporal precision so as to exploit the great resources inherent in a colonial response (Boch and Shearer, 1966), and there is no reason to feel that this programmed biosynthesis is not similarly adaptive in terms of other pheromones. If we are to understand the communicative elegance of the honeybee, it will require our appreciating the interplay of exocrine and behavioral factors that regulate their chemisocial world.

Acknowledgments—We are very grateful to A.M. Collins, D.J.C. Fletcher, T.E. Rinderer, and R. Hepburn for providing samples for analysis. Part of this research was supported by a grant from the Rockefeller Foundation to M.S.B.

CONTEMPORARY FRONTIERS IN INSECT SEMIOCHEMICAL RESEARCH

JAMES H. TUMLINSON

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Gainesville, Florida 32604.

(Received January 15, 1988; accepted April 18, 1988)

Abstract—Recent advances in analytical chemistry coupled with more definitive behavioral analyses have allowed more rigorous identification of many insect pheromones. This, in turn, has increased our understanding of the roles of pheromones in mediating insect behavior. Other semiochemicals that mediate insect behavior include those that enable parasitic and predatory insects to locate their hosts or prey. These may be produced by the host insects or by the plant on which they feed. Additionally, there are pheromones and plant-produced seminochemicals that regulate insect oviposition, a critical phase in the life cycle of insects. The challenge to chemists and biologists is to explore these areas to find new environmentally safe methods to control insect pests. One of the newer strategies used to investigate these semiochemicals is the study of the biochemistry of pheromone production and semiochemical perception in insects. These types of studies may reveal weak links in these systems that can be exploited to develop new, more effective and environmentally safe control methods.

Key Words—Identification techniques, biosynthesis, receptor-semiochemical interactions, oviposition stimulants, oviposition deterrents.

INTRODUCTION

The ultimate practical goal of research on insect pheromones and other semiochemicals [chemicals that transmit information between organisms (Law and Regnier, 1971)] is to find new biorational, environmentally safe methods for insect pest control. Before significant progress can be made toward achieving this goal, more basic knowledge in several areas must be acquired. Thus, a considerable amount of basic research remains to be done to understand the

chemistry and mechanisms that regulate insects' chemical communication systems. When we understand these systems, we should be able to develop methods to exploit their inherent weaknesses to control insects.

In the last 25 years a large number of insect pheromones have been identified (Klassen et al., 1982; Inscoe, 1982) and many of these have been used effectively in traps to monitor or detect insects (Sternlicht, 1986). In a few cases insects have been controlled successfully by using atmospheric permeation with pheromones to disrupt the insects' communication system and thus prevent mating (Klassen, 1987; Ridgway et al., 1988). However, we have not yet exploited these systems to the fullest extent possible for insect control. There are at least four areas of research related to insect semiochemicals that should prove both challenging and very rewarding in leading to new methods for pest management. All of these areas have been investigated to some extent and significant progress has been made in some. However, there is still a great amount of work to be done in each of these areas to obtain the information needed to develop effective new pest control methods. These areas are:

1. *Complete Pheromone Identification.* While pheromones have been identified for a large number of species, it is doubtful if the "complete" pheromone has been elucidated in many cases. With our present knowledge of insect behavior and the available analytical chemical technology, we should be able to identify all the compounds that comprise a given chemical signal and determine precisely and accurately the most effective release ratios and rates of these compounds and their effects on the insects' behaviors. We need this knowledge to design pheromone-based systems to efficiently suppress insect reproduction.

2. *Pheromone Biosynthesis.* Although there have been an increased number of investigations in this area in the last few years, there is still a lot to be learned about the mechanisms and pathways of pheromone biosynthesis (Prestwich and Blomquist, 1987). These systems control the production of the precise chemical signals that are required to ensure reproduction and other essential activities in a species. They are under genetic control and thus should be subject to genetic manipulation. Elucidation of the biochemical pathways of a particular system inevitably leads to a more complete knowledge of the pheromone emitted. There are obviously many facets of these systems that remain to be exposed and subsequently exploited for insect control.

3. *Semiochemical Perception.* The mechanisms by which the insects' receptors interact with the molecules of the semiochemical and the integration of these signals by the central nervous system (CNS) to decipher the message is understood in only the most rudimentary terms. The biochemistry of semiochemical–receptor interactions is very interesting and offers exciting possibilities for development of chemicals to interfere with communication. Similarly, when CNS processing is more fully understood, it may be possible to obstruct this system in several ways. Two excellent papers that appear in this symposium

series address these subjects in more detail (Ding and Prestwich, 1988; Visser and DeJong, 1988).

4. *Other Semiochemicals*. There are many types of semiochemicals other than pheromones that insects perceive and use to ensure their survival and that of their progeny. For example, the location of suitable sites for oviposition is crucial to the survival of the progeny and is governed by both pheromones and by semiochemicals produced by the plants or other hosts. These semiochemicals may be either stimulating or deterring. Prevention of oviposition or shifting oviposition to a noncrop host should be a very effective method of insect pest control. Similarly, beneficial parasitic and predatory insects use semiochemicals to locate their harmful hosts. Evidence to date suggests that the effectiveness of these organisms in biological control programs may be enhanced significantly by the application of certain semiochemicals at critical stages of their host searching.

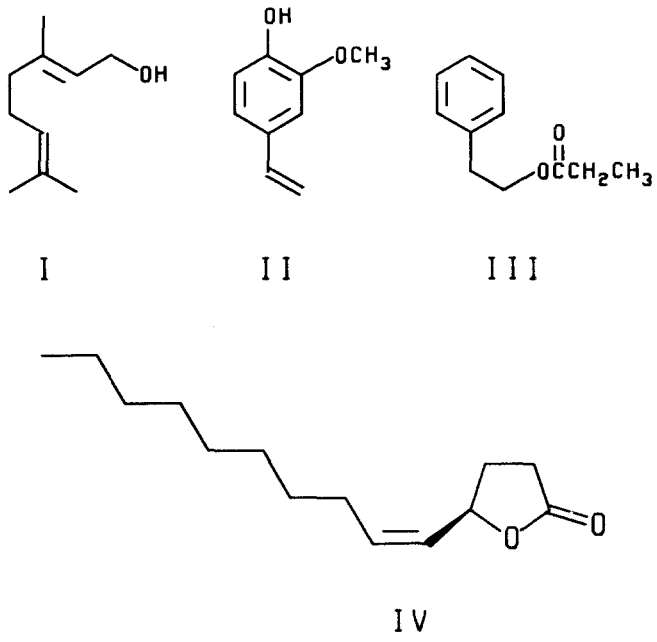
Various aspects of several of these topics are addressed by other papers in this symposium series. In the ensuing discussion, I will use selected examples from our research and from that of others to illustrate some of these points more fully.

PHEROMONE IDENTIFICATION

Many difficulties are encountered in attempting to elucidate the complete pheromone system of an insect. Most pheromones are produced and detected in nanogram or subnanogram quantities. Many pheromone systems are comprised of multicomponent blends in which the ratio of the components is controlled precisely. Usually the minor components of these blends comprise only a very few percent of the total blend, although they may be critical in eliciting key behavioral interactions among the insects. However, often only one or two of the components of the blend are ncessary to lure the insects into traps. Thus, (*Z*)-7-dodecen-1-ol acetate (*Z*7-12 : Ac)[1] is a very good trap lure for male cabbage looper moths, although there are at least five other components in the pheromone blend (Bjostad et al., 1984). Similarly, male tobacco budworm moths can be captured very efficiently with a mixture of *Z*9–14 : Al and *Z*11–16 : Al, although the complete pheromone consists of a blend of six aldehydes (Teal et al., 1986). Thus, a more effective bioassay is required to analyze the insects' behaviors and the effects of various chemicals or mixtures of chemicals on these behaviors. This usually can be accomplished for flying insects with a wind-tunnel bioassay (Baker and Linn, 1984).

[1] A standard shorthand notation for pheromone molecules of this type will be used in this paper. For example (*Z*)-9-tetradecenyl acetate is abbreviated Z9–14 : Ac; the corresponding alcohol is *Z*9–14 : OH, and the aldehyde Z9–14 : Al; tetradecan-1-ol is abbreviated S-14 : OH.

In addition to the complexities of the pheromone systems, we must also consider the effects of external factors on the insects' responses to their pheromones. Very often plant constituents have a major effect on these responses. In some cases, as in the bark beetles, plant constituents function as kairomonal components of a semiochemical system that includes the pheromone signal (Pearce et al., 1975; Birch, 1984; Tumlinson, 1985). In such cases, both the plant chemicals and the pheromone may be required to elicit attraction or the plant constituents may increase the responses to pheromones that are already very active alone. For example, when geraniol (I), eugenol (II), and phenethyl propanoate (III) are dispensed from the same trap as the Japanese beetle sex pheromone (IV), the response of both male and female beetles is increased significantly over that to either lure alone (Ladd et al., 1981) (Scheme 1).



SCHEME 1.

One of the primary considerations in identifying a pheromone is to determine precisely and accurately the composition of the pheromone released into the air by the insect during the time when it is signaling or "calling." This is important for several reasons, one being that the gland that produces the pheromone may contain many other substances, including precursors, some of which may be inhibitory (Teal et al., 1984). Also, the ratio of components released

into the air may differ from that found in the gland (Teal et al., 1986). In some cases the actual pheromone may not be stored in the gland, but may be produced only just before release.

A system used in our laboratory to collect volatiles from several species of insects is depicted schematically in Figure 1. This system and its use are described in detail by Heath et al. (1989). The pressure in the system is kept very close to atmospheric by balancing the air drawn out by a vacuum pump with compressed air forced through filters and a humidifier and then into the chamber containing the insects. Air passed over the insects is drawn out of the chamber through one of three filter traps connected in parallel in which the entrained volatiles are collected. Volatiles are eluted from the traps with solvent

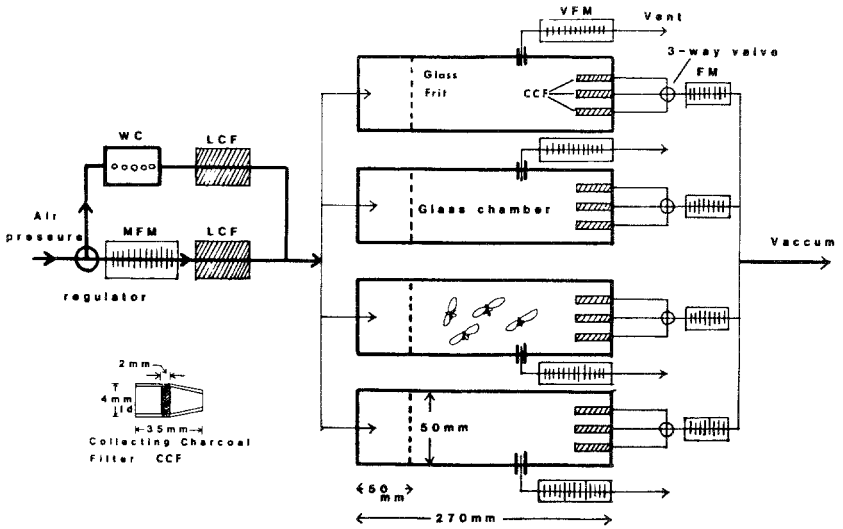


FIG. 1. Four-chamber volatile collection system. The flow of compressed air is regulated and measured by a flow meter (MFM) so that part of the stream is diverted through a water chamber (WC) to control the degree of humidity. Then both streams are passed through activated charcoal filters (LCF) before being mixed and routed through a four-way manifold to the glass volatile collection chambers. A course glass frit (dotted line) in the upwind end of each chamber disperses the air to provide a uniform flow through the chamber. Volatiles emanating from the insects are entrained in the air stream and pulled through a charcoal collecting filter (CCF) inserted in the upstream end of each exit port. Flow can be diverted by the three-way valve through any one of the ports for a desired period of time and then switched to another port when appropriate. This allows volatiles to be collected on different filters at different times or for different events during the photoperiod. Flows are regulated and balanced with the various flow meters (MFM, VFM, FM). Maintaining a slight positive flow (ca. 5%) through the vent ensures that the chamber is not under vacuum.

as described previously (Tumlinson et al., 1986). It is possible with this system to determine the composition of volatiles released by an insect for any period of time under a variety of conditions.

With this system we collected and analyzed the volatiles produced by male Caribbean fruit flies of several different ages and at three different periods (0–4 hr, 4–8 hr, 8–12 hr) of the photophase (Chuman et al., 1989). The analysis of the collected volatiles by capillary gas chromatography (Figure 2) illustrates their complexity. In addition to identifying a previously undiscovered compound, suspensolide (A), we discovered that the ratio of suspensolide to epianastrephin (D) changed as the day progressed, with the relative amount of epianastrephin being greater during the last 4 hr of the photophase. This, and the fact that suspensolide is converted to anastrephin (C) and epianastrephin (D) by gas chromatography on a packed column, suggests that suspensolide may be

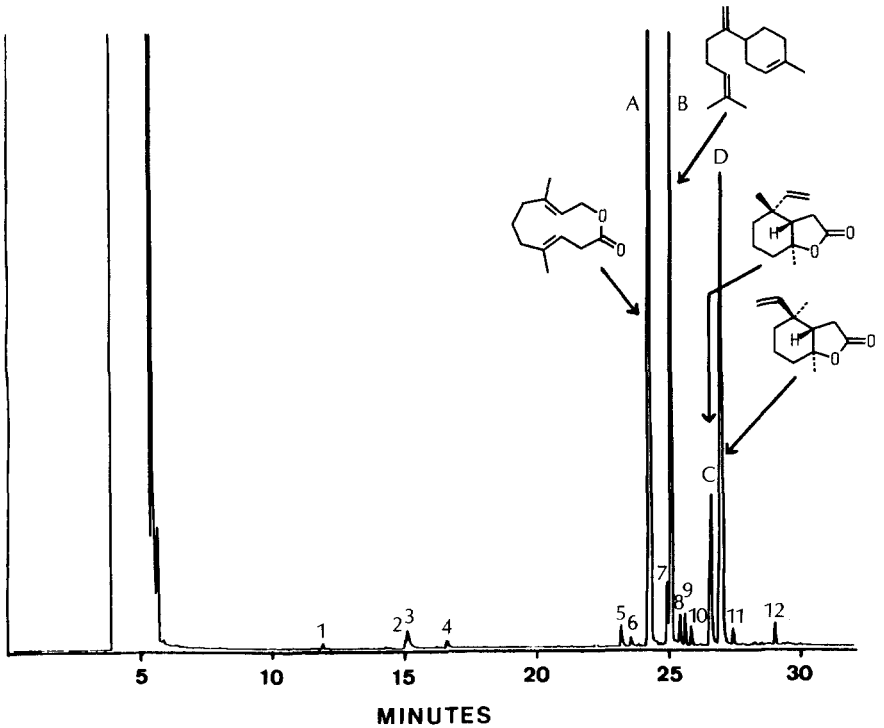

FIG. 2. Analysis of volatiles collected from Caribbean fruit fly males on a 50-m fused silica OV-101 capillary gas chromatographic column. Peaks identified were: (1) ocimene, (2) (Z,Z)-3,6-nonadienol, (3) (Z)-3-nonenol, (A) suspensolide, (B) α-bisabolene, (C) anastrephin, and (D) eipanastrephin.

a precursor to the anastrephins. Although the structures of the minor components 5–12 (Figure 2) have not been elucidated, the methane ionization and electron impact mass spectra indicate that components 5–10 are sesquiterpene hydrocarbons. More behavioral studies are needed to determine which of the components of this blend are involved in pheromonal communication. However, we now know many of the compounds and the ratios that need to be tested.

In determining the composition of a pheromone it is important to be able to separate the complex mixtures produced by the insects. It is particularly important to be able to separate isomers because often an isomer will occur in quantities of 1–2% or less of the mixture and will be essential for full activity. Additionally, it is very important to be able to establish the purity of an isolated pheromonal compound to ensure correct identification of the pheromone. Several techniques for purifying and analyzing pheromones are described in detail by Heath and Tumlinson (1984). The analysis of the volatiles produced by fall armyworm females illustrates the application of capillary gas chromatography to the identification of the components of a pheromone blend (Figure 3). In this case it was necessary to use three different types of stationary phases to ascertain with certainty the composition of the blend. One problem that further complicated this analysis was that the 12-carbon acetates were produced only in quantities of 100 pg/female/hr or less and thus were no larger than some of the background impurities from which they had to be resolved.

It is also very important that the structures of the active compounds be accurately described. The insects' receptors are very specific and slight changes in the geometry of the molecule can render the compound inactive or even inhibitory. For example, addition of as little as 1% of *Z*3,*Z*13–18 : Ac greatly reduces the activity of *E*3,*Z*13–18 : Ac as an attractant for lesser peachtree borer males (Tumlinson et al., 1974). In many cases, slight changes in isomeric composition may make a pheromone blend attractive to another species because many closely related species use different ratios or isomers of the same compound to achieve specificity in their pheromone systems. Chirality is also very important, and while some species that produce pheromones with asymmetry in the molecules appear to respond to the racemic mixture as well as to the pure active enantiomer, in other cases the opposite enantiomer may be inhibitory. Even different strains of the same species may respond to different enantiomers of the same compound (Birch et al., 1980; Lanier et al., 1980). Silverstein (1988) in another paper in this symposium discusses chirality in pheromones in more detail.

Even when the pheromones are identified completely and correctly, the importance of developing formulations that will release the synthetic pheromone at the same rate and in the same ratio as the natural pheromone is released by the insects is often overlooked. Testing of large or incorrect doses will often

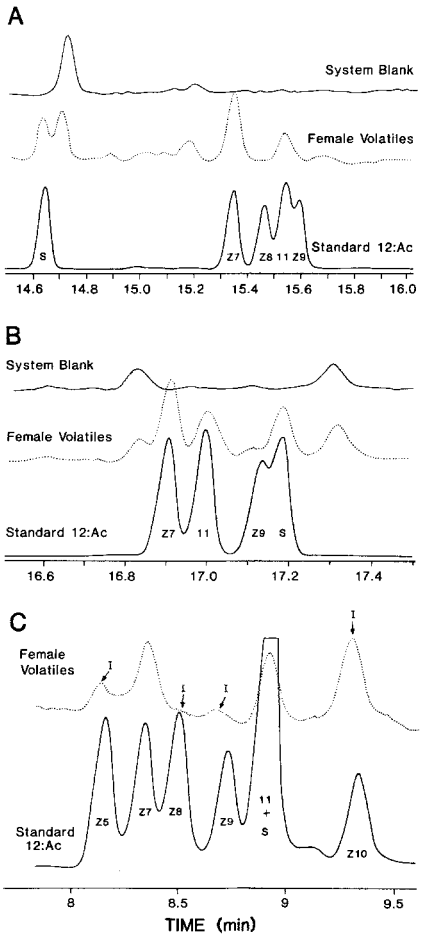

FIG. 3. Sections of chromatograms showing separation of 12-carbon acetates and analysis of volatiles collected from calling, laboratory-reared fall armyworm female moths on three capillary GC columns (A) CPS-1; (B) OV-101; (C) cholesteryl-*p*-chlorocinnamate (liquid crystal). In (C) the symbol I indicates impurities found in the system blank. As these chromatograms indicate, Z9–12 : Ac, previously identified as a fall armyworm pheromone, did not coincide with any of the candidate pheromone peaks on any of these columns. The volatile components not present in the system blank were coincidental on all three columns with S-12 : Ac, Z7–12 : Ac, and 11–12 : Ac.

obscure subtle behaviors in bioassays and may actually result in reduced captures. In other cases it can lead to the identification of compounds as pheromones when they are really only mimics that are active at doses far greater than the actual pheromone. For example, the fall armyworm (FAW) sex pheromone

was identified as Z9–12 : Ac (Sekul and Sparks, 1976; Jones and Sparks, 1979), but this compound could not be found in the gland of FAW females. Instead, the pheromone was found to consist of a blend of Z7–12 : Ac and Z9–14 : Ac released in a ratio of 3.4 : 96.6, respectively (Tumlinson et al., 1986). This blend is active in luring FAW males to traps in the field at concentrations at least 10-fold less than Z9–12 : Ac when formulated on rubber septa. Thus, although Z9–12 : Ac will attract FAW males, it is not a pheromone and is active only at doses much higher than those dispensed by the female.

In another study, a 40 : 60 blend of (Z,Z,Z)-3,6,9-eicosatriene and -heneicosatriene loaded onto rubber septa was found to capture significantly greater numbers of velvetbean caterpillar (VBC) moth males than any other ratio of these two compounds (Landolt et al. 1986). However, Mitchell and Heath (1986) found that high doses of a 40 : 60 blend of these two compounds actually decreased trap captures of VBC (Figure 4). Thus, if this pheromone had been tested at 5–10 mg/septum, which is not uncommon, it may have been dismissed as only very slightly or not active. There are several papers that discuss pher-

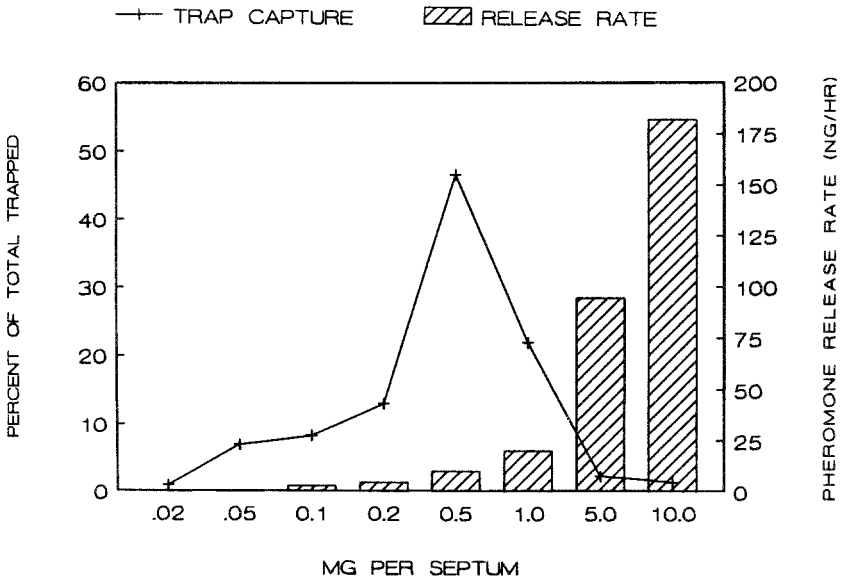

FIG. 4 Response of male velvetbean caterpiller moths to bucket traps baited with rubber septa impregnated with different doses of sex pheromone, a 40 : 60 blend of (Z,Z,Z)-3,6,9-eicosatriene and (Z,Z,Z)-3,6,9-heneicosatriene. Each dose was replicated 10 times; a total of 18,710 moths was captured in the test. Pheromone release rate data were determined as a constant wind speed of 0.225 m/sec. All release rate data were converted to nanograms of total pheromone per hour.

omone formulation in detail (Heath et al., 1986; Leonhardt and Moreno, 1982; Weatherston et al., 1982). The type of formulation will vary, depending on the volatility and other characteristics of the pheromone and the use for which it is intended. However, for meaningful results, the formulation must be designed initially to duplicate the insect's release ratio and rate. Subsequently, it may be possible to improve trap capture or other results by varying dose, composition, or ratio.

In summary, pheromone identification requires more than just the chemical characterization of compounds extracted from insects. It should be possible to make more effective use of pheromones for insect pest management if we determine precisely and accurately the composition and release rate of the pheromone produced by the insect, the identity of any plant-produced or other semiochemicals that may synergize or otherwise affect the pheromone activity, and the effects of all these chemicals on the insect's behavior. Then we must formulate a synthetic blend that will compete effectively with the natural signal or that is designed to disrupt the communication system of the insect by interfering in some way with key pheromone mediated behaviors.

PHEROMONE BIOSYNTHESIS

Pheromone biosynthesis is receiving increasing emphasis in investigations conducted by several different research groups on a variety of insects in the orders Lepidoptera, Diptera, and Coleoptera (Prestwich and Blomquist, 1987). Among the different orders of insects, the pathways and sites of biosynthesis vary considerably. While many of the flies, like the housefly, synthesize their pheromones in the abdominal cutical (Blomquist et al., 1987), the pheromones of many beetles are synthesized in their guts (Vanderwel and Oehlschlager, 1987). However, the moths studied thus far synthesize their sex pheromones in glands that are usually located near the tip of the abdomen (Bjostad et al., 1987; Morse and Meighen, 1987; Teal and Tumlinson, 1986).

The biosynthesis of the pheromones in the moths begins with the production of a polypeptide hormone in the brain–subesophageal ganglion complex in response to endogenous and external stimuli including temperature and light (Raina and Menn, 1987). The hormone then triggers the conversion of fatty acids in the pheromone gland to pheromone components by a series of enzymatic processes that may include desaturation, beta oxidation chain shortening, reduction, acetylation, hydrolysis, and/or oxidation. These processes are varied in different species to produce precise blends characteristic of each species. A more detailed discussion of the pathways of desaturation and the mechanisms that regulate *Z* and *E* ratios in pheromone blends is provided by Roelofs and Wolf (1988) in another paper in this symposium.

In some cases the pheromones are produced and stored in the gland until

the moth releases them. In others it appears that precursors are synthesized and stored and then converted to the actual pheromonal compounds just prior to release. The latter process has been found to occur when the pheromonal compounds are aldehydes. This crucial terminal step in biosynthesis, in which the insects produce the active compounds, has been of some interest to us because of its importance in the pheromone systems of the very important pests in the genus *Heliothis*.

Aldehydes play a major role in the sex pheromone systems of all the *Heliothis* species. However, extracts of the female pheromone glands of *H. virescens*, the tobacco budworm; *H. zea*, the corn earworm; or *H. subflexa* reveal the presence of alcohols corresponding in structure to the aldehydic pheromone molecules. In *H. subflexa*, we also found the corresponding acetates (Teal et al., 1981). We recently demonstrated that the aldehydic components of the tobacco budworm moth pheromone are produced by the action of an alcohol oxidase on the precursor alcohols produced in the pheromone gland (Teal and Tumlinson, 1986). Application of primary alcohols dissolved in dimethyl sulfoxide (DMSO) to the surface of the tobacco budworm moth female's sex pheromone gland resulted in the production of the corresponding aldehydes. This enzymatic system is specific for primary alcohols; it did not convert secondary alcohols into ketones. However, it is not very specific for chain length, or number of location of olefinic bonds. All primary alcohols from 12 to 18 carbons in chain length, and with 0, 1, or 2 double bonds, that were applied to the gland in DMSO were converted into the corresponding aldehydes. The ratio of aldehydes produced is governed by the ratio of alcohols in the gland. Thus, when a 3:1 ratio of S-16:OH to S-14:OH was applied to the gland, approximately a 3:1 ratio of the corresponding aldehydes was produced. Additionally, we discovered that oxygen was required for conversion of the alcohols to aldehydes. When alcohols were applied to the gland in vivo under N_2, no aldehyde was produced. Introduction of air after 15 min revived the production of aldehyde (Teal and Tumlinson, 1987). The same or a very similar enzymatic system resides in the gland of *H. zea* and *H. subflexa*. Recently, we have established that the enzyme is located in the cuticular layer covering the sex pheromone gland in these species (Teal and Tumlinson, 1988). The enzyme is active during the entire photoperiod. Thus, in *Heliothis* species, the primary alcohols are synthesized in the sex pheromone gland and subsequently oxidized to aldehydes as they pass through the cuticle. This explains why only aldehydes have been detected in volatiles collected from *H. virescens* (Pope et al., 1982; Teal et al., 1986), although the alcohols, particularly Z11-16:OH, are found in relatively large amounts in gland extracts. We are now in the process of purifying and characterizing this alcohol oxidase and in determining whether or not there are differences in this system among the three *Heliothis* species we are studying.

Investigations of pheromone biosynthesis like these and others (e.g., Bjo-

stad et al., 1987) increase our knowledge and understanding of the pheromone systems of insects. This is very important in designing programs to monitor or manage pest species. It also seems reasonable to speculate that, as our knowledge of the mechanisms that control these systems increases, we should be able to find ways to disrupt or alter pheromone biosynthesis and thus develop new techniques for pest management.

OTHER SEMIOCHEMICALS

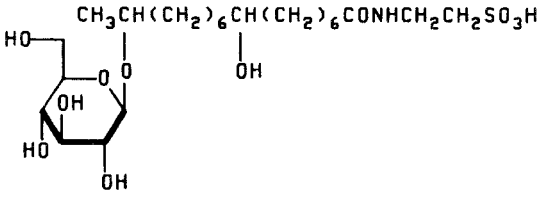
Although there are many types of semiochemicals other than sex pheromones, I have chosen to focus on those that mediate the oviposition behavior of insects and those that beneficial parasitic and predatory insects use to locate their hosts. I believe that these systems offer the greatest opportunities for exploitation for the development of pest management methods.

The location of suitable sites to deposit eggs is a very important step in any insect's life cycle. The females must ensure that their progeny will have access to proper and sufficient food and have a chance to survive in a world filled with enemies and competitiors. Thus, each species has evolved to occupy a certain niche in the ecosystem and has developed strategies to take maximum possible advantage of the available resources. These strategies vary from massing many eggs from several females in one location to dispersing single eggs evenly over all available sites or resources in a large area. It has been demonstrated in many instances that semiochemicals play key roles in these strategies. The semiochemicals that mediate oviposition may include those produced by the hosts that facilitate host location, inhibitors or deterrents produced by hosts or nonhosts as defensive mechanisms, oviposition-stimulating pheromones that aid in grouping eggs from many females in a suitable location, and oviposition-deterring or -spacing pheromones that prevent too many eggs from being deposited in one location with limited resources.

As an example of the latter type of semiochemical, Prokopy (1981) has shown that apple maggot fly females, after ovipositing in a cherry, apple, or other fruit, drag their ovipositors over the surface of the fruit and spread a substance that deters females that subsequently land on this fruit from ovipositing. In this way they distribute their eggs more evenly over all available fruit rather than placing several eggs in one fruit that may only provide enough food for one larva. The substance that they deposit on the fruit is water soluble, nonvolatile, and very stable. It can be washed from the surface of fruit on which females have oviposited and reapplied to clean fruit to achieve the deterrent effect.

Recently, Hurter et al. (1987) isolated and identified an oviposition-deterring pheromone of the cherry fruit fly, which is in the same genus as the apple

maggot fly. They reported this pheromone to be *N*[15(β-glucopyranosyl)oxy-8-hydroxypalmitoyl]-taurine (Scheme 2, V). When this compound is synthe-

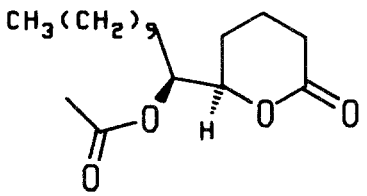


V

SCHEME 2.

sized and tested in the field, it will be interesting to find out whether or not these types of pheromones can be used effectively for pest management. We might predict that they will be very useful since Katsoyannos and Boller (1976) demonstrated in a small field test that naturally produced pheromone, when collected and applied to fruit, provided good protection from fly oviposition and damage.

In contrast to the apple maggot fly, the mosquito *Culex pipiens fatigans* Wiedemann, and others of that genus were found to release an oviposition attractant onto their eggs. This attractant induces other females of the species to lay rafts of eggs in the same location (Bruno and Laurence, 1979). The major component of this pheromone was identified as *erythro*-6-acetoxy-5-hexadecanolide (Scheme 3, VI) (Laurence and Pickett, 1982), and subsequently the nat-



VI

SCHEME 3.

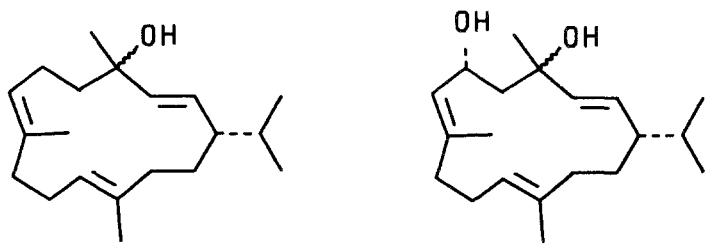
urally produced pheromone was determined to be the (−) -(5*R*, 6*S*)-enantiomer by chromatography of 6-trifluoroacetoxy analogs of the natural and synthetic compounds on a chiral capillary GC column (Laurence et al., 1985). Conceivably, this pheromone can be used to induce the female mosquitos to place their

eggs in a defined area that can safely be treated with insecticide and thus reduce the area over which insecticide must be applied for control.

The plant-feeding insects use many factors including semiochemicals to locate their hosts (Schoonhoven, 1981; Miller and Strickler, 1984). Several plants use semiochemicals to repel insects, while in many other plants the chemicals produced attract the insects to suitable oviposition sites or food sources. In some cases, the same compounds appear to be both attractants and oviposition stimulants. For example, alkyl sulfides containing a propyl thiol moiety attract and induce the onion fly to lay eggs (Miller and Strickler, 1984). However, in many cases it appears that nonvolatile compounds act as oviposition stimulants. As an example of the latter, the butterfly *Papilio protenor* is stimulated to oviposit when it contacts the flavanone glycosides naringen and hesperidin, which are found in one of its hosts, sour orange (Honda, 1986).

Since *Heliothis* species are major economic pests in the United States, it is not surprising that there is interest in semiochemically mediated plant–insect interactions that involve these species. *H. virescens* and *H. zea* attack a wide variety of plants including many important crops. In contrast, *H. subflexa*, which is not a pest in the United States, feeds exclusively on groundcherry (Mitchell and Heath, 1987). *H. subflexa* and *H. virescens* are closely related and recently have been the subjects of many hybridization studies. Thus, this group of insects provides an excellent opportunity to compare and contrast the semiochemically mediated plant–insect interactions of monophagous and polyphagous species.

Jackson et al. (1986) conducted a series of studies of the responses of *H. virescens* to susceptible and resistant varieties of tobacco. They found that the duvane diterpene stereoisomers, α- and β-4,8,13-duvatrien-1-ol (VII) and also α- and β-4,8,13-duvatrien-1-3-diol (VIII) (Scheme 4), obtained from extracts



VII VIII

SCHEME 4.

of leaves of susceptible tobacco varieties, increased *H. virescens* egg deposition when sprayed onto the leaves of a resistant variety. On the other hand, Tingle and Mitchell (1986) found that extracts prepared from elderberry leaves with

H_2O and other polar solvents deterred oviposition by *H. virescens* females in both laboratory and field cage tests. The compounds responsible for this deterrence were not isolated. It seems likely that *H. virescens*, which attacks a wide variety of plants and encounters a wide variety of chemicals may have a complex semiochemically mediated oviposition behavior. However, since *H. subflexa* is very host-specific, it may be attracted and stimulated to oviposit by a very specific semiochemical or blend. Recently, in a laboratory bioassay, methanol washes of groundcherry leaves were found to increase egg deposition by *H. subflexa* females (Mitchell and Heath, 1987). Also, Tingle et al. (1989) found that the same methanol leaf washes induced *H. subflexa* females to respond in a wind tunnel with upwind flight toward the odor source and contact with the dispenser on which the extract was placed. Interestingly, the responses of males and of virgin females were significantly less than that of mated females. It is not yet clear whether or not the females are attracted and induced to oviposit by the same compounds. It will be very interesting to discover, as these investigations progress, the similarities and differences in the semiochemically induced host-locating and oviposition behavior of these two species.

As more is learned about the behavioral mechanisms of host location and oviposition, and as more of the semiochemicals that mediate these behaviors are identified, it should be possible to devise new pest management methods based on interference with this system or manipulation of the behaviors. We should be able to prevent oviposition on valuable crops and induce the pests to deposit their eggs on noncrop plants or in locations where they can be destroyed with minimal applications of pesticides. It is conceivable that this could be accomplished either by the application of synthesized semiochemicals or by genetically engineering plants to produce or not produce certain semiochemicals.

The foraging and egg-laying behaviors of parasitic insects that ovipost in eggs, larvae or adults of other insects are similar in many respects to those of herbivorous insects and in most cases are also mediated by semiochemicals. Many of these parasitoids are considered beneficial in that their hosts are pests. Agricultural scientists generally agree that biological control of insect pests with natural enemies is a very important component of any pest management strategy and that beneficial organisms like insect parasitoids should be used to the greatest extent possible. Therefore, it is very important to understand the mechanisms by which beneficial parasitic insects locate and attack the pest insect species that are their hosts. A thorough knowledge of the foraging behavior of these parasites and the semiochemicals that mediate this behavior should enable us to develop methods to enhance the effectiveness of the beneficial organisms.

Most of the parasitic insects studied thus far have shown a great degree of adaptability and flexibility in their searching behavior. Many of them use the pheromones of their hosts as chemical cues to guide them in host foraging. For example, the oviposition-deterring pheromone desposited by apple maggot fly

females stimulates searching by *Opius lectus*, a parasitoid of the fly eggs (Prokopy and Webster, 1978). Also, female wasps in the genus *Trichogramma*, which oviposit in moth eggs, have been found to respond to the sex pheromones of several of their hosts including *H. zea* (Lewis et al., 1982), Pieris brassicae, and *Mamestra brassicae* (Noldus and van Lenteren, 1985). Similarly, insects that prey on or parasitize several species of bark beetles are attracted to the beetles' pheromones (Wood et al., 1968; Lanier et al., 1972; Vité and Williamson, 1970; Pitman, 1973; Kline et al., 1974; Dyer et al., 1975; Bakke and Kvamme, 1978). Interestingly, spined soldier bugs, *Podisus maculiventris*, voracious predators of a wide variety of insects, are themselves the targets of four parasitic species, *Hemyda aurata*, *Euclytia flava*, Telenomas spp., and *Forcipomyia crinita*, that are attached to the soldier bug pheromone, a mixture of (*E*)-2-hexenol, α-terpineol, linalool, terpinen-4-ol, and benzyl alcohol (Aldrich et al., 1984).

An example of flexibility in the foraging behavior of beneficial organisms is demonstrated by studies of a polyphagous predatory mite, *Amblyseius potentillae* that feeds and reproduces on phytophagous spider mites (Dicke et al., 1986). A searching response in this predatory mite is elicited by volatile kairomones from the two-spotted spider mite only when the predator is reared on a carotenoid-free diet. Two-spotted spider mites and others contain carotenoids required for diapause induction in the predator, but are inferior prey due to the dense webbing they produce. When predators are not deficient in carotenoids, they reject the two-spotted spider mite and search for other spider mites that are more likely to assure them reproductive success. Such a prey is the European red spider mite, the volatile kairomone of which elicits a searching response by the predator whether or not it is carotenoid deficient.

There is considerable evidence that parasitoids may use the odors of plants on which their hosts feed to guide them to possible host habitats. For example, Elzen et al. (1984) found that terpenoid components of cotton volatiles were attractive to *Campoletis sonorensis*, an ichneumonid wasp that is a parasitoid of noctuid moth larvae like the tobacco budworm, *H. virescens*. Also, Drost et al. (1986, 1988) and Eller et al. (1988) found in wind tunnel and olfactometer studies that females of *Microplitis croceipes*, a braconid parasitoid of *Heliothis* species larvae, responded to plant odors. However, in the latter case the *M. croceipes* responsiveness in the flight tunnel was influenced by preadult experience of the parasitoid species, growth phase and part of the host plant, presence of host larvae, and age and adult experience of the parasitoid. Herard et al. (1988) discovered that when *M. demolitor* was reared on *H. zea* larvae fed artificial diet, the adult females needed preflight exposure to feces from plant-fed hosts to be effective in flying to host larvae feeding on cowpea leaves. However, *M. demolitor* females reared from plant-fed hosts were generally very effective in flying to their hosts without any preflight exposure or experience.

Their results indicated that imprinting of the adult females at the time of emergence from the cocoon was occurring.

When a parasitoid's host is polyphagous, as are *H. zea* and *H. virescens*, there is an obvious advantage to the parasitoid in being able to adapt or to learn to respond to different odors associated with different host-plant complexes. We have recently demonstrated (Lewis and Tumlison, 1988) that associative learning plays a key role in the host-foraging process of *M. croceipes* females and also that it is probably involved in the host-locating behavior of *Cotesia marginiventris*, which attacks the larvae of at least 20 lepidopteran species (Turlings et al., 1989). The feces of *H. zea* larvae fed cowpea leaves contains two substances that elicit two discrete effects on the host-seeking behavior of *M. croceipes* females. First, a volatile component(s), extractable with hexane, attracts females that have been exposed previously to feces. However, exposure of the females to the hexane extract does not induce subsequent flight responses to host-related odors. Second, a nonvolatile, water-extractable material, when contacted by the parasitoids with their antennae, will induce subsequent flight responses to host-related odors. We also demonstrated that contact with the water extractable substance in the presence of a novel odor like vanilla would induce subsequent flights to vanilla, an otherwise unattractive substance.

Thus the females learn to respond to a variety of odors (conditioned stimuli) associated with the hosts by linking them with a water-extractable, nonvolatile chemical (unconditioned stimulus) in host feces, evidently a specific host-recognition kairomone. The identification and synthesis of this kairomone and the components of the volatile signals associated with various host-plant complexes should make it possible to condition laboratory-reared parasitoid females to search for hosts on particular plants. This should greatly increase the efficiency of parasitoids released for biological control.

CONCLUSIONS

The area of insect chemical communication is a very rich area for exploration. Although many pheromones and semiochemicals have been identified, we have only begun to understand the insects' chemical communication systems. There are many opportunities for investigation and possibilities for exploitation, some of which probably have not yet been discovered. We must not consider that the identifications of the semiochemicals is the end of the investigation and that we will only use these chemicals directly for insect control in ways similar to pesticides. Although it is now possible in some cases to use pheromones and other semiochemicals directly for trapping or communication distruption, the greatest value of these investigations may lie in the knowledge gained about the mechanisms of biosynthesis, preception, and CNS

processes that integrate the information and control the behavioral responses. This knowledge should lead us to new, safer, and more effective methods of insect control.

(Received January 7, 1988; accepted March 15, 1988)

Abstract—Biosynthesis of the aldehydic sex pheromone components released by females of *Heliothis zea* was found to be catalyzed by primary alcohol oxidases residing in the cuticle that covers the glands. Activity, as indicated by conversion of primary alcohol to aldehyde, was as high in cell-free cuticle as it was in intact pheromone glands. Studies indicated that some activity was associated with the surface of the epicuticle and could be removed, into buffer, by sonication. However, the majority of activity lies within the inner epicuticle and exo- and endocuticular layers. The oxidase was not functional in pharate pupae that did not have mature adult cuticle but became functional just prior to adult emergence. The enzyme in individual glands was saturated at alcohol concentrations above 100 n. moles. Nonionic detergents did not affect the activity of the oxidase in the cuticle but treatment with either 7 M urea or 1% SDS resulted in total loss of activity. Studies on the effect of pH indicated an optimum at 6.4; however, activity was high throughout the range of 5–9. The oxidase was functional in both dichloromethane and hexane, suggesting that this enzyme system may have applications for organic synthesis of aldehydes.

Key Words—Sex pheromone biosynthesis, cuticle, alcohol oxidase, alcohol, aldehyde, *Heliothis zea*, Lepidoptera, Noctuidae, enzyme.

INTRODUCTION

The volatile compounds that comprise the sex pheromone blend released by females of *Heliothis zea* (Boddie) are aldehydes (Pope et al., 1984), which include (Z)-7-hexadecenal, (Z)-9-hexadecenal, (Z)-11-hexadecenal, and hexadecanal. Extracts obtained from the pheromone glands of females not only contain the aldehydes but also the corresponding alcohols in a ratio that approx-

imates the aldehyde ratio (Teal et al., 1984, 1986). Recent studies have indicated that the alcohols are the immediate precursors of the aldehydic pheromone components used by *Heliothis* species and that the ratio of alcohols present within the gland regulates the blend ratio of aldehydes produced (Teal and Tumlinson, 1986). The enzyme responsible for the conversion of the alcohols to aldehydes has been defined as an alcohol oxidase specific for primary alcohols but which shows little or no specificity for geometry or number of double bonds (Ding and Prestwich, 1986; Teal and Tumlinson, 1986, 1987a, b).

Studies conducted using *Heliothis virescens* (F.) by Ding and Prestwich (1986) have indicated that the oxidase is present in the soluble fraction of pheromone gland homogenates. However, their studies also have indicated that homogenates of the pheromone gland contain an aldehyde dehydrogenase that has greater activity than the oxidase (Ding and Prestwich, 1986). This suggests that if both enzymes were present within the cells of the pheromone gland, then all of the aldehyde produced would be converted immediately to the acid analogs, leaving little or no aldehyde available for release as pheromone components. This is not supported by studies on pheromone production by these moths because (Z)-11-hexadecenoic acid, the acid corresponding to the pheromone component present in greatest amount, has not been found in extracts obtained from females that are releasing sex pheromone (Klun et al., 1980a, b; Pope et al., 1982, 1984; Teal et al., 1984, 1986).

Studies conducted by Morse and Meighen (1986) and Teal and Tumlinson (1986) have suggested that the oxidases responsible for production of the aldehydic pheromone components released by females of the spruce budworm and *H. virescens* moths, respectively, are present within the cuticle overlying the glands. Although unproven, these hypotheses have considerable merit because extracellular conversion of alcohols to aldehydes avoids the toxic effects of the aldehydic products and compartmentalizes the oxidase in a different area of the gland from the aldehyde dehydrogenase. This would enable the moth to use the aldehydic compounds for pheromone communication.

Although the majority of studies on cuticular enzymes have dealt with those associated with tanning, wound healing, and digestion of cuticle (see Andersen, 1985; Hepburn, 1985), enzymes that have functions in pheromone communication have been documented. These enzymes have been associated with pheromone degradation, thus enabling the insect to remove pheromone that adsorbs onto the cuticle (Ferkovich et al., 1982; Lonergan, 1986; Vogt and Riddiford, 1986). We report here the results of studies that demonstrate that the conversion of primary alcohols to aldehydic pheromone components by females of *H. zea* is accomplished by the action of a primary alcohol oxidase maintained within the cuticle overlying the pheromone gland. We also discuss the results of experiments performed to assess various functional aspects of this oxidase.

METHODS AND MATERIALS

Insect Preparation. Females of *H. zea* were obtained from cultures maintained at the Insect Attractants, Behavior, and Basic Biology Research Laboratory, ARS, USDA, Gainesville, Florida. All insects used were 2- to 4-day-old adults, and experiments were performed during the photophase, at which time no active pheromone biosynthesis occurs under natural conditions (Raina et al., 1986). Previous studies have indicated that the oxidation of topically applied alcohols was as efficient during the photophase as it was during the period of maximum pheromone production (4th to 7th hour of scotophase) (Teal and Tumlinson, 1986).

In Vivo Preparation. Studies in which various primary alcohols were applied topically to the pheromone glands were conducted using insects whose pheromone glands had been extended and clamped as described elsewhere (Bjostad and Roelofs, 1983; Teal and Tumlinson, 1986). In initial studies, using *H. zea*, we repeated earlier experiments conducted on *H. virescens* (Teal and Tumlinson, 1986), in which a 1.0-μl drop of a 0.5 μg/μl emulsion of candidate alcohol substrate in distilled water was applied to the gland surface and allowed to incubate for 30 min. After incubation, the glands were excised, placed in a conical microvial, and extracted with 5 μl of hexane containing 10 ng of pentadecanyl acetate (15:Ac) as internal standard. The total volume of the extract was then analyzed by capillary gas–liquid chromatography (GC). In a second series of topical application studies, preparations were treated with a 2.0-μl drop but were allowed to incubate for only 10 min. After incubation the water–substrate drop was pulled up carefully into a 10-μl microsyringe. The drop was then deposited into a conical microvial and extracted using two aliquots of 5 μl each of hexane, each containing 1 ng/μl of 15:Ac. The extracts were then concentrated to 5 μl and analyzed by capillary GC. Blank preparations for both experiments were conducted using glands incubated with a 1.0-μl drop of H_2O. Also a 1.0-μl drop of the substrate–H_2O emulsion was incubated for 30 min in a conical microvial prior to extraction and analysis as above.

In studies to determine if the oxidase could be dissolved from the surface of the intact glands of females, insects were first injected with 2.0 μl of a 0.25 g/ml tetrasodium ethylenediaminetetracetate by inserting a 10-μl syringe through the head and into the terminal abdominal segments as described by Pope et al. (1982). The whole abdomen was then removed from the insect at the junction of the thorax, and the majority of eggs were removed through the hole in the anterior segment of the abdomen. The pheromone gland was then everted by applying pressure to the anterior abdominal segments and a cotton thread ligature was placed around the abdomen 0.5 cm from the posterior tip. A second ligature was added 0.5 cm anterior to the first. The abdomens were

then placed in conical microvials that contained 25.0 μl of 75 mM phosphate buffer (pH 7.2) so that the pheromone gland was immersed in buffer. The vials were then placed in a sonic bath (Megason, ultrasonic instruments) and sonicated for 30 min. The initial temperature of the bath was 10°C, and the final temperature was 35°C. After sonication, the abdomens were removed, and 2 μl of the 0.5 μg/μl emulsion of alcohol and water was added. The preparations were allowed to incubate for 1.5 hr prior to extraction with two aliquots of 25 μl of hexane that contained 15 : Ac as internal standard. The hexane extract was concentrated to 5 μl under a gentle stream of N_2 prior to analysis by capillary GC.

In Vitro Preparation. Studies performed to determine the stage of development at which the oxidase becomes functional were conducted using glands that had been excised from the abdomen. After removal from the abdomen, glands were dried on a filter paper and placed into a conical microvial, 2 n. moles (424 ng) of Z11–14 : OH dissolved in hexane (see below) was then added to the microvial and the preparations incubated for 30 min. The glands were extracted for 30 sec by adding 5 μl of hexane, which contained 10 ng of internal standard, and analyzed. Glands used were obtained from prepharate pupae (pupae having unsclerotized adult cuticle), pharate pupae (having sclerotized adult cuticle), newly emerged adults, adults that had emerged 15, 30, or 60 min earlier, and 2-day-old adults. When pupal insects were used, the pupal case was carefully removed from the last four abdominal segments prior to applying pressure to the anterior portion of the abdomen, which caused the gland to be everted.

The effect of various organic solvents including acetone, acetonitrile, dichloromethane, diethyl ether, hexane, and tetrahydrofuran (THF) on the functioning of the enzyme was studied using glands that had been excised during the noncalling period. Individual glands were soaked in one of the solvents for 5 min and then dried on filter paper. Then the gland was placed in a conical microvial and 2 μl of a 212 ng/μl emulsion of Z11–14 : OH in 75 mM phosphate buffer (pH 7.2) was added. The preparation was incubated for 30 min. After incubation the tissue and medium were extracted two times with 5 μl of hexane containing 10 ng of internal standard each time. The combined hexane extracts were concentrated to 3 μl and injected onto the capillary GC. We also studied the relative efficiencies of 75 mM phosphate buffer (pH 7.2) and hexane as incubation media. In these studies, individual glands were incubated for 30 min in conical microvials with either 2 μl of the 212 ng/μl emulsion of Z11–14 : OH in phosphate buffer or 2 μl of a 212 ng/μl of Z11–14 : OH in hexane. After incubation for 30 min, the preparations were extracted and analyzed as described above.

The effect of substrate concentration was examined by incubating various amounts of Z11–14 : OH dissolved in 2 μl of hexane, containing 10 ng of octa-

decane as internal standard, with individual glands for 30 min in conical microvials. Temporal production of (*Z*)-11-tetradecenal (Z11–14 : Al) was studied by incubating individual glands in a microvial with 16.8 μg of Z11–14 : OH dissolved in 40 μl of hexane containing 320 ng of octadecane as internal standard. The vial was capped with a Teflon-faced septum to prevent solvent evaporation. At 5-min intervals up to 30 min, a syringe needle was inserted into the solution through the Teflon septum and a 2-μl sample was removed and analyzed by GC.

In order to determine if the oxidase was present within the cuticle of the pheromone gland, we made cell-free cuticle preparations from groups of glands that had been excised from the abdomen. Glands were placed in distilled H_2O (50–70 glands/ml) and were sonicated for 15 min in the sonic bath. After sonication, the H_2O was concentrated to two female equivalents (FE) per 10 μl using a Centricon-30 microconcentrator (Amicon, Danvers, Massachusetts) and tested for oxidase activity by incubating 1 FE with 2 μl of the 212 ng/μl emulsion of Z11–14 : OH in phosphate buffer for 30 min. This was followed by extraction and analysis as described earlier. The glands were then washed four times with 1 ml aliquots of distilled H_2O and then homogenized in 1-ml aliquots of distilled H_2O using a Teflon homogenizer (Wheaton 2 ml, Millville, New Jersey). The liquid was removed after 10 turns of the pestil. Then 1 ml of H_2O was added and the glands were rehomogenized. This procedure was repeated until the homogenate appeared to be clear, usually after five changes. The combined homogenates were centrifuged at 4000 g for 30 min at 5°C, and the aqueous layer was removed, combined with the other liquid fractions, and concentrated to 1 FE per 5 μl using a Centricon-30 microconcentrator. One FE was then tested for oxidase activity as indicated above.

After the final homogenization, the cuticle remained as large pieces. Pieces of this cuticle were then tested for activity by incubating them with 2 μl of a 212 ng/μl solution of Z11–14 : OH in hexane for 30 min, the extracts of these incubations being analyzed by capillary GC. The fragments of cuticle were then subjected to sonication for 15 min in distilled H_2O. The sonicate was removed, concentrated, and tested for activity, and the cuticles were rinsed twice with 1 ml of distilled water. Cuticular pieces were then dried by placing them on filter paper. Fragments of cuticles were examined under a microscope at 400× to ensure that gland cells had been disrupted. Cuticle fragments representing one gland equivalent by weight were then placed in a conical microvial to which 440 ng of Z11–14 : OH was added in a 2.0-μl drop of hexane and incubated for 30 min. Control experiments conducted in conjunction with these experiments included incubation of the intact pheromone gland, which had been excised from the abdomen, with 440 ng of Z11–14 : OH in 2.0 μl of hexane or just 2.0 μl of hexane.

Studies on the effects of various nonionic detergents (including Tween 80,

NP-40, and Triton X-100) on oxidase activity were conducted by sonicating for 15 min equal weights (8–14 FE) of cuticle in 500 μl of 1% solutions of the detergents in phosphate buffer (75 mM, pH 7.2) or phosphate buffer alone. After sonication the cuticle was rinsed 10 times with phosphate buffer, dried on filter paper, and tested for activity by incubation with 4 μl of 212 ng/μl of Z11–14:OH in hexane. Similar studies were conducted using 0.2 M Na_2SO_4 (pH 7.0), 7 M urea in phosphate buffer, and 1% sodium dodecyl sulfate (SDS). In all of the above experiments, results were compared with those obtained when untreated cuticle was incubated with the alcohol–hexane solution.

The pH dependence of the cuticular oxidase was studied by sonicating weighed amounts of cuticle in 500 μl of buffers having different pH values. Buffers of different pH were made by adding appropriate amounts of either acetic acid or sodium hydroxide to the 75 mM phosphate buffer having a pH of 7.2. The experimental protocol was the same as that used in studies on the effects of various detergents.

Reagents. All alcohol substrates were obtained from the Sigma Chemical Company (St. Louis, Missouri) and were purified by high-performance liquid chromatography (HPLC) using a 25 × 0.46 cm (ID) column packed with 5 μm silica (Altech) eluted with 20% ether in hexane. GC analysis of the purified alcohols indicated that they were 99% pure and were free of the corresponding aldehydes. Aldehydes used as analytical standards were prepared from the alcohol analogs by oxidation with pyridinium chlorochromate (Corey and Suggs, 1975) and were purified by HPLC as described above. All solvents used were Fisher (Pittsburgh, Pennsylvania) HPLC grade.

Chemical Analysis. Samples were analyzed on fused silica capillary GC columns (30 m × 0.25 mm ID SPB1 and 30 m × 0.25 mm ID Supelcowax 10, Supelco, Bellfonte, Pennsylvania) in Varian 3700 (Sunnyvale, California) gas chromatographs equipped with split/splitless capillary injectors and flame ionization detectors. Chromatographic conditions were: initial column temperature = 60°C for 2 min, then temperature programmed at 30°/min, final temperature = 175°C (Supelcowax 10), 195°C (SPB1), injector changed from splitless to split mode at 30 sec after injection. Helium was used as the carrier gas in both instruments at a linear flow velocity of 18 cm/sec. Data were acquired and analyzed with a SP4100 computing integrator (Spectra Physics, Santa Clara, California) interfaced to one GC (SPB1 column) and a Perkin-Elmer chromatographic data system (Norwalk, Connecticut) interfaced to the GC containing the Supelcowax 10 column. Retention times of peaks eluting during the analysis of experimental samples were compared with those of authentic standards and amounts were calculated based on the concentration of the internal standard used.

Chemical ionization mass spectra (MS) were obtained for samples resulting from incubations of cell-free cuticle to ensure that the compound assign-

ments were correct. This was accomplished using a Nermag R10-10 MS (Delsi Instruments, Fairfield, New Jersey) interfaced to a Hewlett-Packard 5792 GC (Palo Alto, California) equipped with a split/splitless capillary injector. Helium was used as the carrier gas, while methane was used as the reagent gas. Samples were chromatographed on a 50 m × 0.25 mm (ID) OV-1 fused silica capillary column. The oven temperature was maintained at 50°C for 2 min then increased at 10°C/min to 240°C. Injector purge occurred 1 min after sample injection. Retention times and spectra of compounds eluting during analysis of experimental samples were compared to those of authentic standards.

RESULTS AND DISCUSSION

In Vivo Assays. Analysis of extracts of glands of females of *H. zea* treated with 0.5 μg of Z11–14:OH in H_2O for 30 min (Figure 1C) indicated that the alcohol was converted to the corresponding aldehyde. An average of 16.7 ±

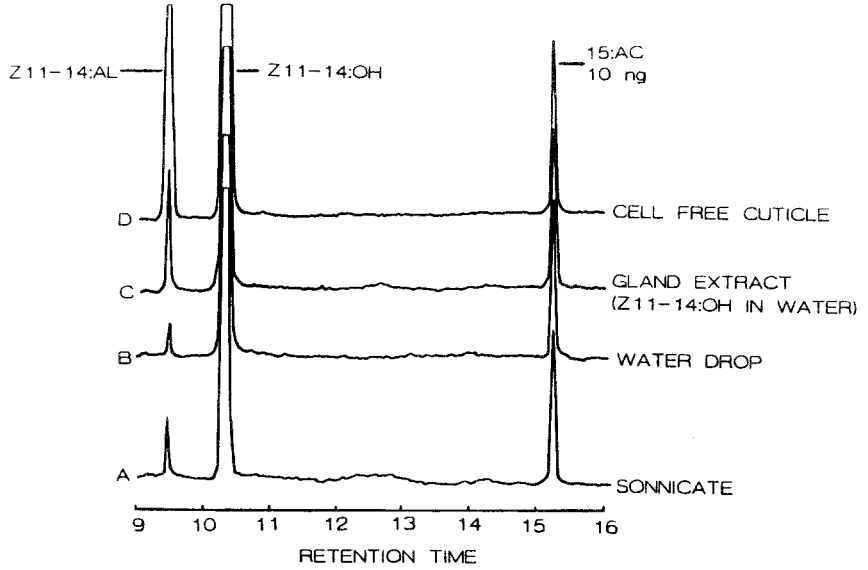

FIG. 1. Chromatograms obtained using the 30 m × 0.25 mm (ID) SPB1 (methyl silicone) fused silica capillary column. (A) Analysis of the extract after a 1.5-hr incubation with alcohol–buffer of the eluate obtained by sonicating the gland of females of *H. zea*. (B) Analysis of the extract of a drop of alcohol–H_2O removed from the surface of the cuticle of an *H. zea* female after a 10-min incubation. (C) Analysis of the extract of the pheromone gland of an *H. zea* female after a 30-min incubation with a 1-μl drop of alcohol–H_2O. (D) Analysis of the extract obtained after a 30-min incubation of the purified cuticle of the pheromone gland of an *H. zea* female in a 0.5 μg/μl solution of Z11–14:OH in hexane.

7.2 ng of (Z)-11-tetradecenal (Z11–14:Al) was recovered ($N = 5$). Analysis of extracts of water–alcohol droplets removed from the surface of the glands of *H. zea* ($N = 5$) after a 10-min incubation indicated that 2.5 ± 0.6 ng of Z11–14:Al were obtained (Figure 1B). Analysis of hexane extracts of alcohol–water drops incubated in a conical microvial without being in contact with the pheromone gland indicated that no detectable autooxidation of the alcohol to aldehyde occurred during the 30-min incubation. Similarly, no Z11–14:OH or Z11–14:Al was detected in extracts obtained from glands incubated with only a 1.0 μl drop of H_2O for 30 min.

The eluate obtained by sonicating the gland in buffer contained only limited oxidase activity. Nonetheless, the preparations obtained from *H. zea* ($N = 5$) (Figure 1A) produced 2.8 ± 1.2 ng of Z11–14:Al. Blank incubations of Z11–14:OH in phosphate buffer did not contain detectable amounts of the corresponding aldehyde.

The results of studies performed to determine the stage of development at which the oxidase became functional are shown in Figure 2. Pupal insects (*N*

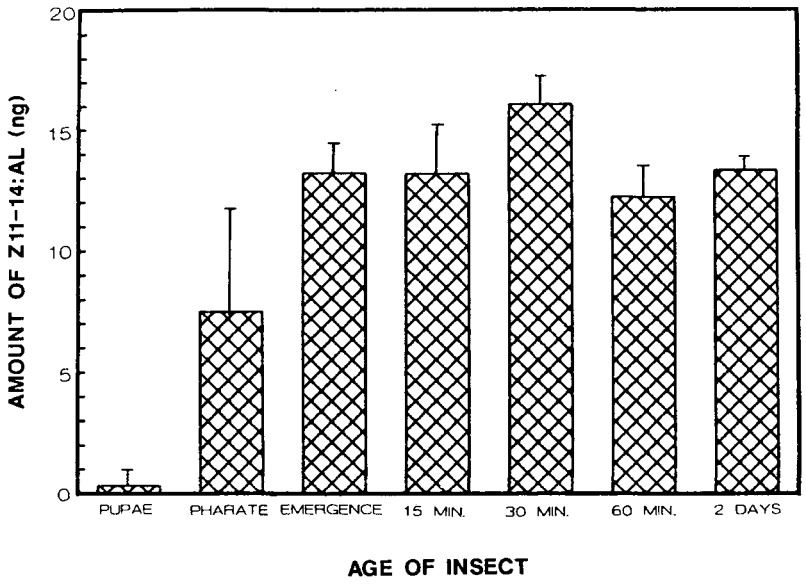

FIG. 2. Effect of insect age on oxidase activity as indicated by production of Z11–14:Al from Z11–14:OH. Prepharate insects are pupae having unsclerotized adult cuticle; pharate insects are pupae having sclerotized adult cuticle; times indicated are after adult emergence. Error bars represent standard errors of the mean. The number of insects analyzed is given in the text.

= 10), which had unsclerotized adult cuticle (prepharate), did not convert substantial amounts of alcohol to aldehyde. Pharate pupae (sclerotized adult cuticle) produced an average of 7.5 ng of aldehyde. This was intermediate between levels produced by mature adults and prepharate insects. Interestingly, nine of the 15 pharate insects analyzed produced 2–4 ng, while the other six produced amounts equivalent to adult insects. Newly emerged and older insects produced approximately equal amounts of aldehyde (N = 10, each age). These results indicate that the oxidase becomes functional during maturation of the adult cuticle just prior to emergence of the adult.

Glands converted significantly less alcohol to aldehyde after they had been pretreated by soaking in acetone, acetonitrile, THF, or ethyl ether than when they were soaked in H_2O prior to incubation in the alcohol-buffer emulsion (Figure 3). Neither hexane nor dichloromethane had any effect on oxidase activity. While we cannot explain the different effects of the solvents on enzyme activity, it is noteworthy that organic solvents of intermediate to high polarity

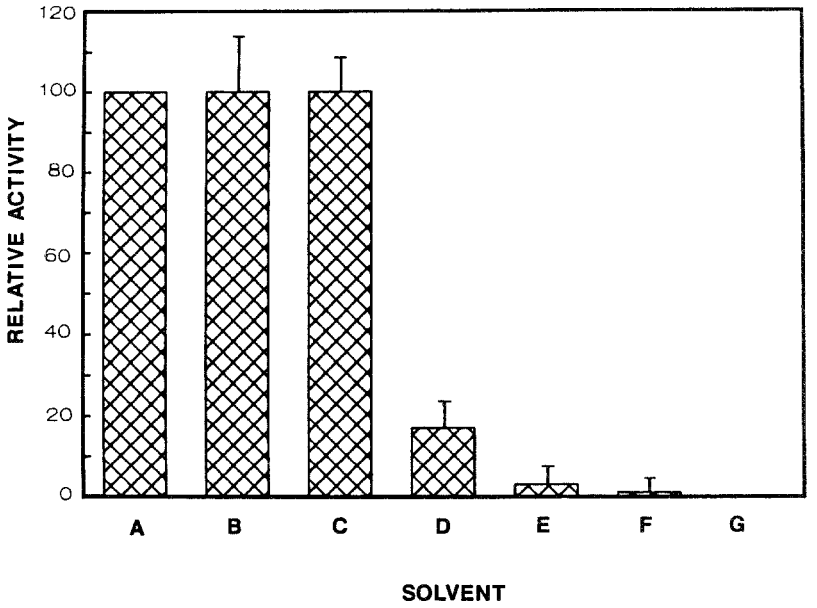

FIG. 3. Effect of soaking cuticle in organic solvents for 5 min relative to soaking in water prior to incubation in a 212 ng/μl emulsion of Z11–14:OH in PO_4 buffer: A = H_2O, B = hexane, C = dichloromethane, D = acetone, E = ether, F = THF, G = acetonitrile. Error bars represent the standard errors of the means of five replications for each solvent.

cause the activity to be lost. Therefore, the observed effects of the solvents may result from dipole interactions between the solvent and enzyme–cuticle matrix. Thus, solvents like THF and ether, which have functional groups having strong dipole moments, may interact with the enzyme, which results in a loss of activity.

We also found that the use of hexane as a carrier for the alcohol substrate resulted in a four- to fivefold increase in the amount of aldehyde recovered over that found when either phosphate buffer or water emulsions of the alcohol were used. These findings can be rationalized by the fact that hexane effectively carries the alcohol into the cuticular matrix, making it readily available for oxidation. Water does not penetrate the cuticle and therefore the only alcohol molecules available for oxidation are those that diffuse out of the emulsion and into the cuticle. The above results suggest that this oxidase may be useful for organic synthesis of aldehydes in organic solvents. Reports of the use of enzymes in organic synthesis using organic solvents are becoming more common and, in fact, a recent report by Kazandjian and Klinbanov (1985) has indicated that an oxidase that oxidizes polyphenols to quinone is much more efficient when in chloroform than in water.

Results of studies on the rate of aldehyde production and effect of substrate concentration on the enzyme activity present in individual glands are shown in Figures 4A and 4B. The amount of aldehyde produced increased in a linear fashion over time ([Z11–14:Al] = 0.311 + 3.262 time, $R^2 = 0.99$) (Figure 4A). A hyperbolic plot of substrate concentration versus aldehyde produced was obtained when glands were incubated for 30 min (Figure 4B).

No intact cells were found when pieces of cuticle obtained by homogenization and sonication of the glands in H_2O were observed under a microscope at 400×. This was expected because we anticipated that osmotic shock would cause cellular disintegration. The initial purification step of sonicating the glands resulted in a slight decrease in oxidase activity when glands were tested. However, after the final step, the cuticular fragments had somewhat more activity (Figure 1D) than intact, untreated glands (Figure 5). The water used to sonicate the glands in the initial step contained some activity and, as indicated in Figure 5, successive purification steps resulted in further solubilization of the oxidase. However, the activity present in solution was always significantly lower than that present in the cuticle fraction of that step. The above results demonstrate clearly that the majority of oxidase activity is associated with the cuticle overlying the cells of the pheromone gland, thus confirming the hypotheses of Morse and Meighen (1986) and Teal and Tumlinson (1986). However, we cannot exclude the possibility that some oxidase activity is associated with the cells. Nonetheless, cellular oxidase activity, if present, is considerably less than that associated with the cuticle.

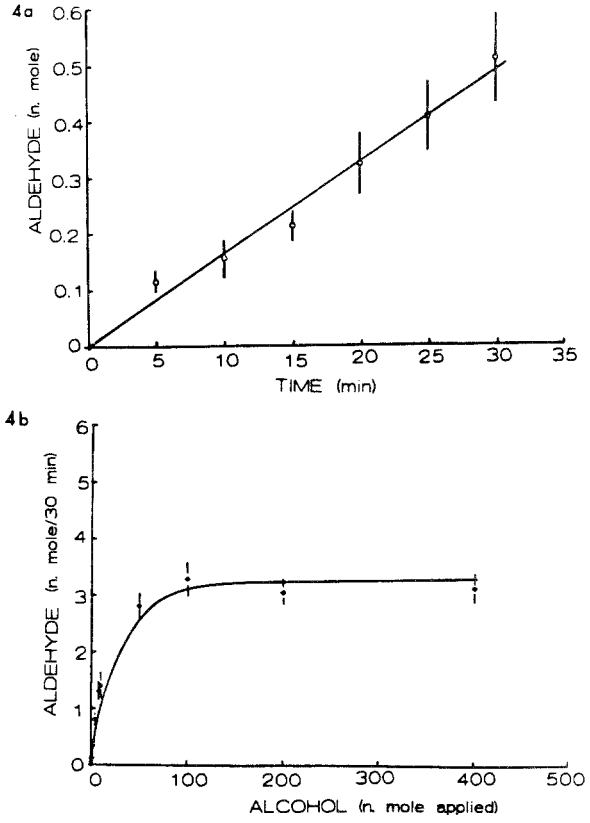

FIG. 4. Effect of incubation time on aldehyde production (a) and effect of substrate (Z11–14:OH) concentration on aldehyde production (b) in individual pheromone glands ($N = 6$ each experimental data point, bars are standard errors of means). (A) Glands were incubated in 40 μl of hexane containing 16.8 μg of Z11–14:OH. Samples (2 μl) were analyzed at 5-min intervals. (B) Various amounts of Z11–14:OH contained in 2 μl of hexane were incubated with individual glands for 30 min.

The enzyme present in cell-free cuticle was functional over a broad pH range, having an optimum at 6.4 and with only 30% reduction in activity at pH 9 (Figure 6). Similarly, no loss in activity occurred when the cuticle was treated with Na_2SO_4 or any of the nonionic detergents tested (Figure 7). No appreciable activity was found in the soluble fractions of these tests (data not shown). However, all activity was lost when the cuticle was treated with either 7 M urea or 1% SDS (Figure 7).

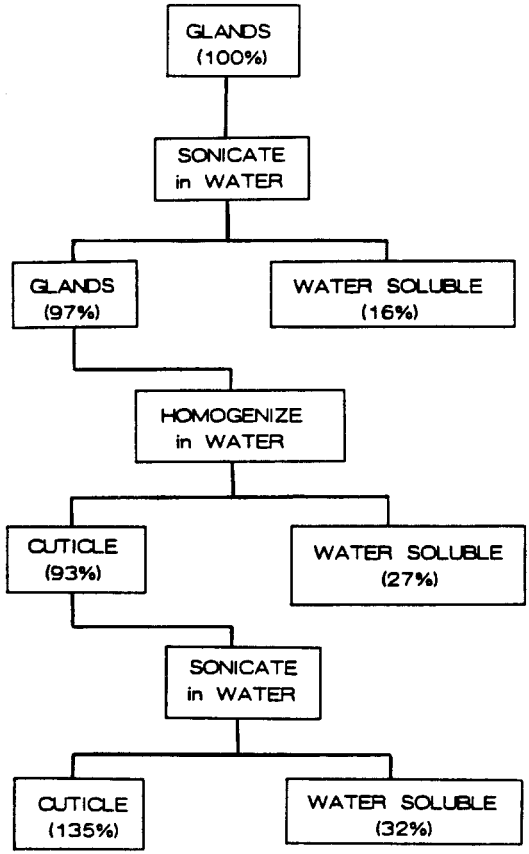

FIG. 5. Distribution of oxidase activity during steps of cuticle purification. Numbers in parentheses indicate the amount of activity in each step relative to intact glands ($N = 3$ replications of 100 glands). At each step an amount of either cuticle or extract equivalent to that present in one female was incubated (two replications each set of incubations) as indicated in the text.

Ultrastructural studies on *Choristoneura fumiferana* (Clem.) (Percy, 1974), which also appears to employ a cuticular oxidase for pheromone biosynthesis (Morse and Meighen, 1986), have indicated that epicuticular filaments extend through the pore canals of the endocuticle and terminate close to the apical microvillae of the pheromone gland cells. These filaments have been hypothe-

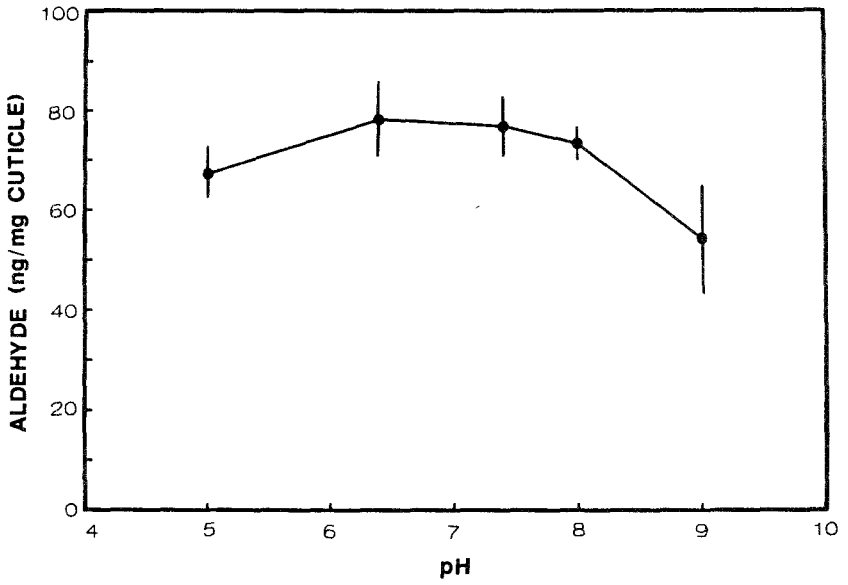

FIG. 6. Effect of sonicating purified cuticle in buffers of different pH for 15 min on oxidase activity as indicated by nanograms of Z11-14:Al produced per milligram of cuticle incubated for 30 min in 2 μl of hexane containing 840 ng of Z11-14:OH. Bars indicate standard errors of the mean for five replications at each pH.

sized as being the site of enzymes involved in pheromone biosynthesis by *C. fumiferana* (Percy, 1974). A similar situation could explain the distribution of the oxidase in *H. zea*. In *C. fumiferana*, groups of filaments coalesce to form pores in the epicuticle but are greatly dispersed and much more numerous in the endocuticular layer (Percy, 1974). For *Heliothis* species, this would explain why only limited activity was obtained in surface washes because only the enzyme at the surface of the epicuticular pores would be removed using our techniques. This would explain also why small amounts of activity could be solubilized from the cuticle during purification because as the cuticle was fragmented, more of the enzyme would be freed from the cuticular matrix. Consequently, we believe that the enzyme is limited to the cuticle. We are presently pursuing studies aimed at elucidation of the site of enzyme activity within the cuticle and studies aimed at isolating the enzyme in an active form from the cuticle.

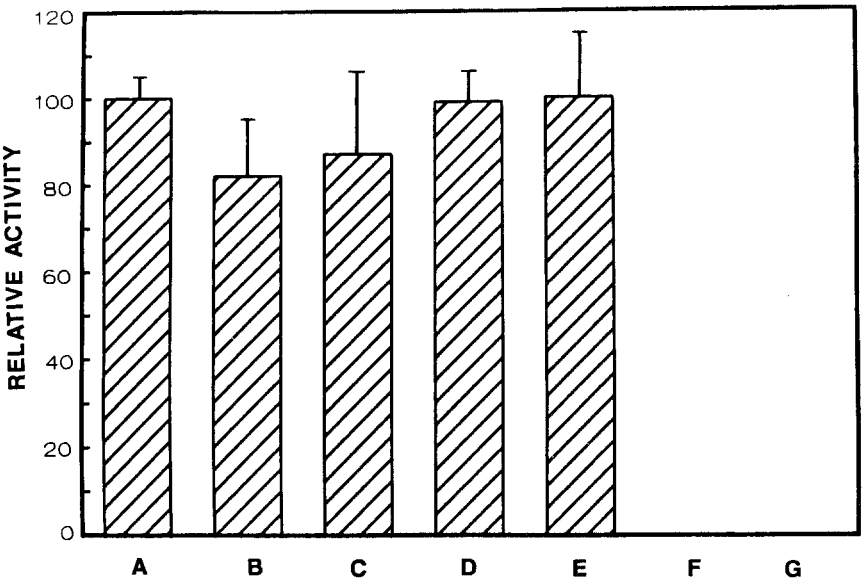

FIG. 7. Effect on oxidase activity of sonicating purified cuticle in: A = phosphate buffer, B = NP-40, C = Tween 80, D = Triton X-100, E = Na_2SO_4, F = 7 M urea, G = 1% SDS for 15 min prior to incubation in 4 μl of hexane containing 848 ng of Z11-14:OH. Values shown indicate the activity relative to sonication in phosphate buffer with error bars indicating the standard errors of the mean for five replications of each treatment.

HOST PLANT UTILIZATION AND IRIDOID GLYCOSIDE SEQUESTRATION BY *Euphydryas anicia* (LEPIDOPTERA: NYMPHALIDAE)

DALE R. GARDNER and FRANK R. STERMITZ

Department of Chemistry,
Colorado State University,
Fort Collins, Colorado 80523

(Received July 20, 1987; accepted October 13, 1987)

Abstract—The iridoid glycoside content of individual adult *Euphydryas anicia* butterflies from two Colorado populations was quantitatively determined. At one site (Red Hill), larval host plants were *Castilleja integra* and *Besseya plantaginea*, while at the other site (Cumberland Pass) a single host plant, *B. alpina*, was used. At Red Hill, macfadienoside and catalpol were sequestered, while at Cumberland Pass, catalpol and aucubin were sequestered. Artificial diet studies showed that larvae hydrolyzed a major iridoid of *B. plantaginea*, 6-isovanillylcatalpol, to catalpol (which was sequestered) and isovanillic acid (which was excreted). Large year-to-year and individual variation in butterfly iridoid content was established as was a female–male difference in macfadienoside vs. catalpol content. Larval host plant distributions and numbers were determined at Red Hill for two years and compared with changes in butterfly populations and sequestered iridoids.

Key Words—*Euphydryas anicia*, Lepidoptera, Nymphalidae, *Castilleja integra*, *Besseya plantaginea*, *Besseya alpina*, Scrophulariaceae, iridoid glycosides, sequestration, metabolism, plant–insect interactions, herbivory.

INTRODUCTION

Stermitz et al. (1986) reported the sequestration of iridoid glycosides by several populations of *Euphydryas anicia* (Lepidoptera: Nymphalidae). Adult *E. anicia* from a high-plains Colorado site (Red Hill) contained the iridoids catalpol, **1**, and macfadienoside, **2** (Figure 1) from larval consumption of *Castilleja integra* Gray and/or *Besseya plantaginea* (James) Rydb. (Scrophulariaceae). Macfadienoside occurred only in *C. integra*, and hence the presence of that iridoid in

FIG. 1. Host plant iridoid glycosides.

adult butterflies was a marker for larval consumption of *C. integra*. Catalpol was not the major component of either host plant, but *B. plantaginea* contained large amounts of veronicoside, **3**, 6-isovanillylcatalpol, **4**, and verproside, **5** (Gardner et al., 1987). Only a few individual butterflies were analyzed, but there appeared to be both individual and sex differences in host-plant utilization and/or sequestration processes. The same butterfly at several alpine sites, where the host plant is *B. alpina* (Gray) Rydb., sequestered catalpol and aucubin, **6.** These were the two major alkaloids of this host plant, although it also contained **3–5.**

This preliminary investigation raised several questions about differential host plant consumption by larvae and sequestration or metabolism of host plant chemicals that we have attempted to answer in the present work. Evidence from *Euphydryas* and other butterfly studies suggests that at sites where multiple host plant use occurs, individual butterflies and larvae may select and utilize a narrower range of host-plant species than does the overall butterfly population (Fox

and Morrow, 1981; Stanton and Cook, 1984; Bowers, 1986; Singer, 1983). If macfadienoside sequestration is a marker for *Castilleja* consumption at Red Hill, could we establish the presence of a subset of larvae in the population which feeds only on that host plant or a subset which feeds only on *Besseya*? If so, one might encounter a group of macfadienoside-containing adults and a group that lack that iridoid. The preliminary study indicated that males and females contained differing relative amounts of catalpol and macfadienoside. We were interested in learning if this sex difference was a result of differential feeding between the two host plants or of differing sequestration or metabolism processes. We also hoped to quantitatively establish if there was intrapopulation variation in the amounts of sequestered defensive substances. Such variation has rarely been estimated for larval-obtained compounds, particularly in localized insect populations. Some data are available for the sequestration of milkweed cardenolides by the migratory monarch butterfly (Brower et al., 1984, and references therein; Cohen, 1985; Lynch and Martin, 1987) and for the lygaeid *Oncopeltus fasciatus* (Scudder et al., 1986, and references therein). Each of these studies encountered large individual variation in defensive substances present in the adult insect.

In order to study interpopulation sequestration differences, we also focused more attention on one of the preliminarily studied alpine sites, Cumberland Pass. Here only a single host plant, *B. alpina*, is used.

Finally, the studies at both sites were to provide chemical data as part of our long-term, broad studies on *E. anicia* biology and ecology (Odendaal et al., 1988a–b).

METHODS AND MATERIALS

Organisms and Sites. The major part of the study was conducted on the checkerspot butterfly *Euphydryas anicia* Doubleday and Hewitson at a high-plains (2900 m), essentially flat site (Red Hill) 11 miles east of Fairplay, Colorado (Park County) on the northwest side of U.S. Highway 285. Here, *E. anicia* occurs in a relatively localized demographic unit concentrated in a 700 × 1000-m area. The adult flight season is early or mid-June to mid-July. Eggs are seen on both host plants from late June to mid-July, and prediapause larvae are present from late July through August. Postdiapause larvae consume host plants from early May through early June.

Population density and residence times for adult males and females were estimated through mark–release–recapture studies and transect counting (Pollard, 1977), details of which will be reported elsewhere. Adult *E anicia* (57 females and 39 males in 1985 and 10 of each sex in 1986) were captured at varying times throughout the flight season, placed in glassine envelopes, refrig-

erated, and finally frozen. An additional three males and three females were collected, treated similarly, and then dissected for body part analyses. Abdomen, wings, and head–thorax–legs parts were combined for each of the sexes. In 1985, four additional adult males were collected just off the south side of the site near a ravine where only *B. plantaginea* was present. For larval analyses, two last-instar larvae were collected for analysis from *B. plantaginea* in the ravine, three from *B. plantaginea* on the site proper, and four from *C. integra*, also on the site.

Nine early postdiapause larvae were collected in 1986 from *C. integra* and raised in the laboratory on an artificial diet (Bowers, 1983) containing 6-isovanillylcatalpol, **4,** at a concentration approximating that present in the host plant, 3.5 mg/g dry weight diet (Gardner et al., 1987). Frass was collected for analysis beginning several days after initiation of the diet feeding, when green color no longer showed in the frass. Pupae, which were formed one to two weeks after feeding commenced, were removed to 6-oz vials containing filter paper on the bottom and sides. Adults were removed 24 hr after eclosion, having emitted meconium onto the filter paper prior to their removal.

The *C. integra* and *B. plantaginea* host plants at the site were counted along 1000-m transects by establishing two 5 × 5-m quadrats for each 50-m linear portion of the transect and counting within the quadrats. Essentially complete counts for the site (seven longitudinal transects) were made in 1985. In 1986, three transects typical of the site were counted, and these were compared with the same three transects in the 1985 counts in order to estimate year-to-year variation. Both host plants are perennials, whose first leaves usually emerge in early May. Host plant counts were made in late June. At this time the broad-leaved *B. plantaginea* and the red-bracted *C. integra* plants are more readily observable.

For the interpopulation comparison, collections of *E anicia* adults (10 males in 1985 and 10 males and 10 females in 1986) were made at Cumberland Pass, an alpine site described by the Ehrlich group (Cullenward et al., 1979), where the host plant is *Besseya alpina* (Gray) Rydb. (White, 1979).

Chemical Analyses. GLC analyses of iridoid glycosides were performed on the trimethylsilylated derivatives using a Hewlett Packard 5890 gas chromatograph equipped with a split/splittless injector, FID detector, and a Hewlett Packard 3392A integrator. The column was a DB-1 capillary (J&W Scientific), 30 m (length), 0.32 mm (ID) with a film thickness of 0.10 μm. The injector was used in the split mode, split ratio of 30:1, and at a temperature of 275°C. Carrier gas was high-grade helium (99.996%) with a column head pressure of 12 psi and a linear velocity of 30 cm/sec (1.44 ml/min). The detector temperature was 320°C, with a hydrogen flow of 38 ml/min, air flow of 200 ml/min, and a helium (make-up gas) flow of 40 ml/min. Samples were run under one of two programs: Program A: Initial column temperature 200°C for 1 min,

which was then raised to 260°C at a rate of 20°/min and held for 8 min. Program B (needed to analyze for the catalpol esters): Initial column temperature 200°C for 1 min, which was then raised to 260°C at a rate of 20°/min and held for 6 min; column temperature was then ramped to 320°C at a rate of 20°/min and held for a final time of 10 min. (Figure 2).

Individual butterflies were removed from the freezer and dried at room temperature or 55°C (Cumberland Pass collections, 1986) prior to analysis. They were weighed, placed in screw-cap test tubes, crushed and 3–5 ml of MeOH added. The samples were extracted for about 4 hr, filtered through cotton, and the filtrate evaporated to dryness. The dry residue was triturated with 2 ml H_2O and 3 ml diethyl ether and both triturates combined in screw cap test tubes. To each tube was added 1.00 ml of internal standard, phenyl-β-D-glucose (0.500 mg/ml). Samples were mixed by shaking and placed in a centrifuge to aid in separating the layers. The ether layer was removed, and the aqueous layer washed two more times with 3 ml of ether. After the final ether wash, the aqueous layer was evaporated to dryness, and the dry residue removed with two washings of 0.5 ml MeOH. The MeOH rinses were combined together in a 0.5-dram screw cap vial. A 10% aliquot was placed into a small glass sample tube (closed end 0.5 mm) and evaporated to dryness. To this sample tube was added 0.10 ml of the silylation reagent (TRI-SIL'Z' from Pierce Chemical Company)

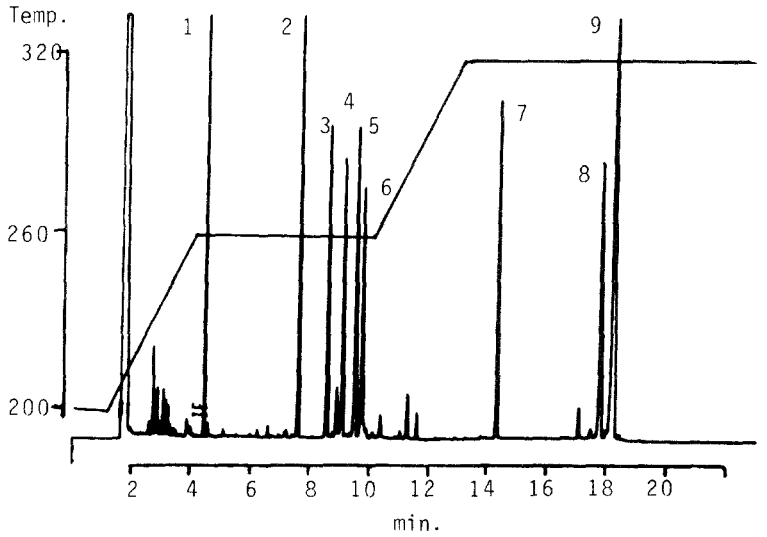

FIG. 2. GLC analysis of host plant iridoid glycoside TMS derivatives. (1, phenylglucose internal standard; 2, aucubin; 3, catalpol; 4, macfadienoside; 5 shanzhiside methyl ester: 6, adoxoside; 7, veronicoside; 8, isovanillylcatalpol; 9, verproside.

and the closed tube was heated at 70–80°C for 15 min. After the solution had cooled, 1 μl was injected onto the gas chromatograph. The remaining MeOH solution was also evaporated to dryness and stored under refrigeration for further analyses, such as TLC or [^{1}H]NMR. A similar analysis scheme was used for postdiapause larvae.

Statistical analyses of butterfly iridoid content were by analysis of variance (ANOVA) using either CLR ANOVA (Clear Lake Research, Inc.) or StatWorks (Cricket Software, Inc.) programs on a Macintosh (Apple) microcomputer. In the ANOVA analyses, all percentage values were transformed with an arcsine function and microgram by the square root of X.

Special techniques were used for chemical analyses in the artificial diet feeding studies. Adult butterflies, collected frass, pupal cases, and shredded filter paper containing the emitted meconium were extracted with methanol for 24 hr. The solutions were evaporated to dryness after filtration. To the samples was added 1.00 ml of solution containing 0.05 mg/ml of 3,4-dihydroxybenzoic acid as an internal standard. A 10% aliquot was removed for GLC analysis of iridoids as described above, and a portion was analyzed for isovanillic acid (3-hydroxy-4-methoxybenzoic acid) by HPLC. The analysis for isovanillic acid was by procedures similar to those of Anderson and Pedersen (1983) and Casteele et al. (1983). HPLC was performed on a Beckman system equipped with a 110B pump, a variable UV detector, Beckman injector (20-μl sample loop) and an Altex Ultra Sphere ODS reverse-phase Si gel column (15 × 250 mm). Elution was with 30% methanol in 0.05 formic acid at a flow rate of 1.2 ml/min and UV detection at 254 nm. Calibration and determination of the response factor for isovanillic acid was accomplished over three injections of a standard solution containing 0.05 mg/ml of 3,4-dihydroxybenzoic acid, 4-hydroxybenzoic acid, and isovanillic acid.

RESULTS

Butterfly and Host Plant Population Estimates (Red Hill). Transect counts yielded an estimate of 1800 butterflies present at the site on June 27, 1985, and 24,000 present on June 25, 1986. These dates were approximately at the middle of the four- to five-week flight season and were near the time of maximum population size. Other counts during both seasons were in agreement with these estimates. Qualitative observations by three researchers present on the site for most of both flight seasons substantiated the marked increase in butterfly numbers from 1985 to 1986. Details of butterfly counts and the results of an extensive mark–release–recapture study will be presented elsewhere.

Host-plant estimates and comparisons for the two years along three site-typical transects showed that in 1985 both host plants were present in nearly all quadrats, but with a clear preponderance of *C. integra* throughout (Table 1). In

[a] Counts in two (of ten total) quadrats for every 50 m (1000 m total transect length).

1986, there was a substantial reduction in the abundance of both host plant species, although *C. integra* was still the most abundant. In 1985, transects B, D, and F showed 92%, 90%, and 89% *C. integra* (percentage of total host plants), while the 1986 results were 98%, 99.5%, and 83% *C. integra*. Qualitative observations made while postdiapause larvae were being collected from the plot 10-13 area on May 20, 1986, confirmed the low host plant density in this area and many larvae were seen wandering in search of host plants. Such was not the case at the same time in 1985, when all larvae were found on host plants.

Iridoid Analyses (Red Hill). A condensed summary of the 1985 results on catalpol and macfadienoside presence in adult butterflies is given in Table 2, with some statistical comparisons in Table 3. Data for individual butterfly analyses are also available (Gardner, 1987). Traces of shanzhiside methyl ester, **7**,

were detectable in some adults but amounts were too small to quantify. Esters **3–5** and other iridoids present in the host plants (adoxoside, adoxosidic acid, 6-hydroxyadoxoside, shanzhiside, 8-epiloganic acid, and mussaenoside) were not found in any butterflies. To emphasize individual butterfly and sex variation, we graphically display 1985 data on dry weight (Figure 3), percent total iridoids (Figure 4), percent catalpol (Figure 5), and percent macafadienoside (Figure 6).

The 1985 male percent dry weight average iridoid content was 4.1% compared to 3.1% for females ($P < 0.01$). Because of the larger female size, total iridoid content was, however, greater for females (1.16 mg per butterfly) than for males (0.85 mg) ($P < 0.001$). There was a marked drop in total iridoid content for the 1986 collections (1.2% for males and 1.0% for females) as compared to 1985, and the male–female difference was no longer significant.

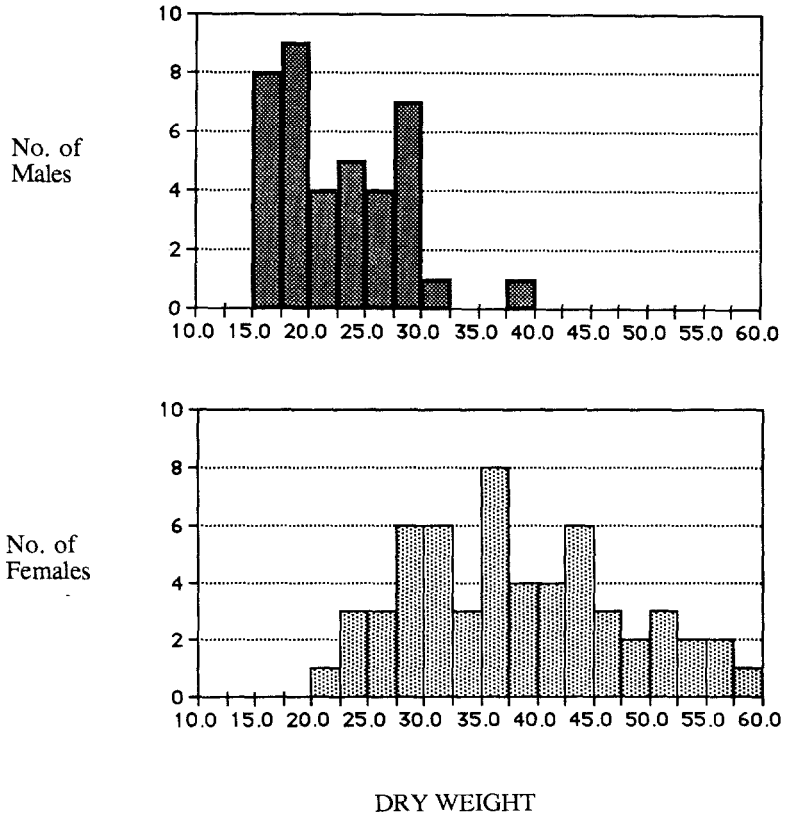

FIG. 3. Dry weight variation among male and female *E. anicia* (Red Hill, 1985).

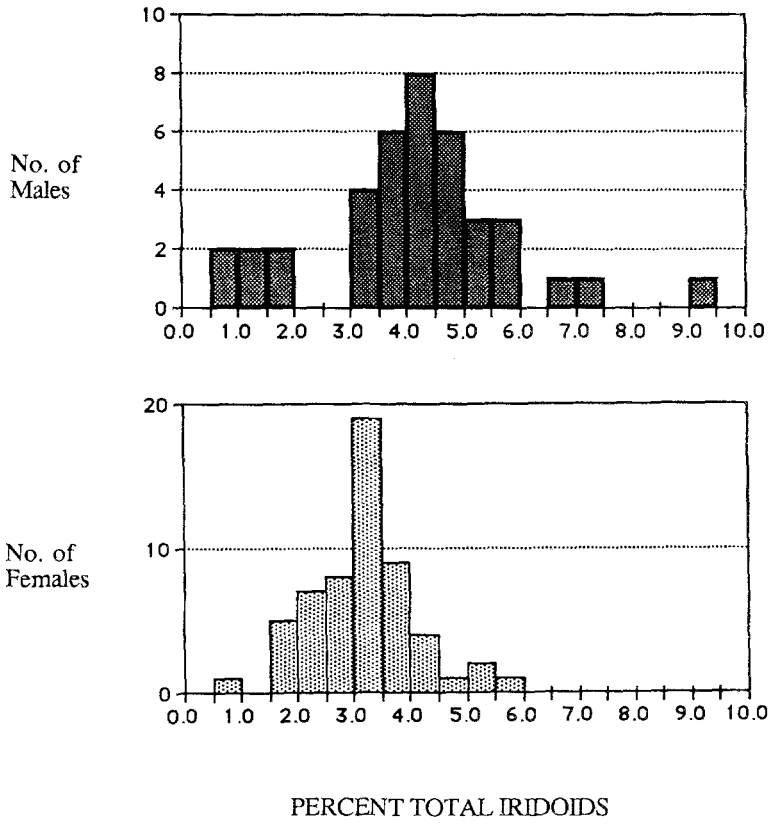

FIG. 4. Variation in total iridoid content among male and female *E. anicia* (Red Hill, 1985).

In 1985, macfadienoside was found in 55 of 57 females and 33 of 39 males. Catalpol was found in all. The four males collected near the ravine off-site (see Methods and Materials), where only *B. plantaginea* is present, contained only catalpol and are not included in the Table 2 data. In 1986, macfadienoside was found in 20 of 20 butterflies and catalpol in 19 of 20. Differences were seen in macfadienoside vs. catalpol content when comparing males and females. Macfadienoside content of males in 1985 was significantly lower than of females, both on a total ($\bar{X}$ = 200 μg for males compared to $\bar{X}$ = 540 μg for females) and percentage dry weight basis (1.0% for males compared to 1.5% for females). The macfadienoside-to-catalpol ratio (mg per butterfly) was significantly different in both 1985 and 1986 for females (1.39 and 1.96) as compared to males (0.49 and 0.63) (Figure 7).

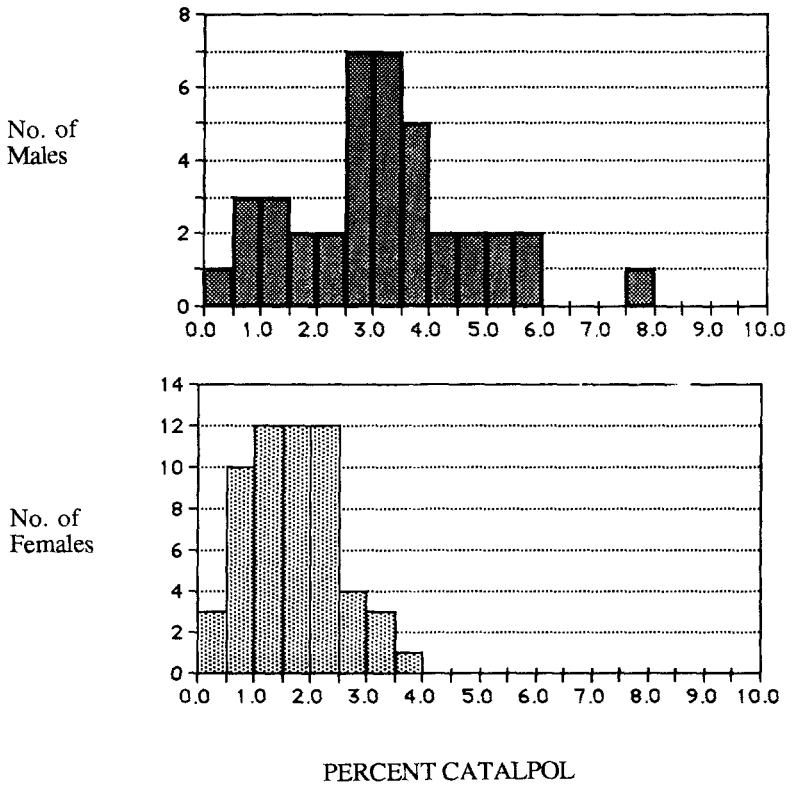

FIG. 5. Variation in catalpol content among male and female *E. anicia* (Red Hill, 1985).

Results of iridoid analyses on postdiapause larvae are given in Table 4. The two off-site larvae and one on-site larva collected on *B. plantaginea* contained only catalpol, while two on-site larvae from *B. plantaginea* contained macfadienoside. One of these, surprisingly, contained no catalpol. Since there is no macfadienoside in *B. plantaginea*, the two on-site larvae collected on *B. plantaginea* must have previously consumed *C. integra*. The larvae collected on *C. integra* were quite consistent in having considerably more macfadienoside than catalpol.

Iridoid analysis of the dissected butterflies indicated that the total iridoid content in each of the body part divisions was similar (Table 5). Iridoid content as percent dry weight in each combination was variable because of the weight difference among the parts. The female head–thorax–leg combination appeared particularly high in macfadienoside and low in catalpol.

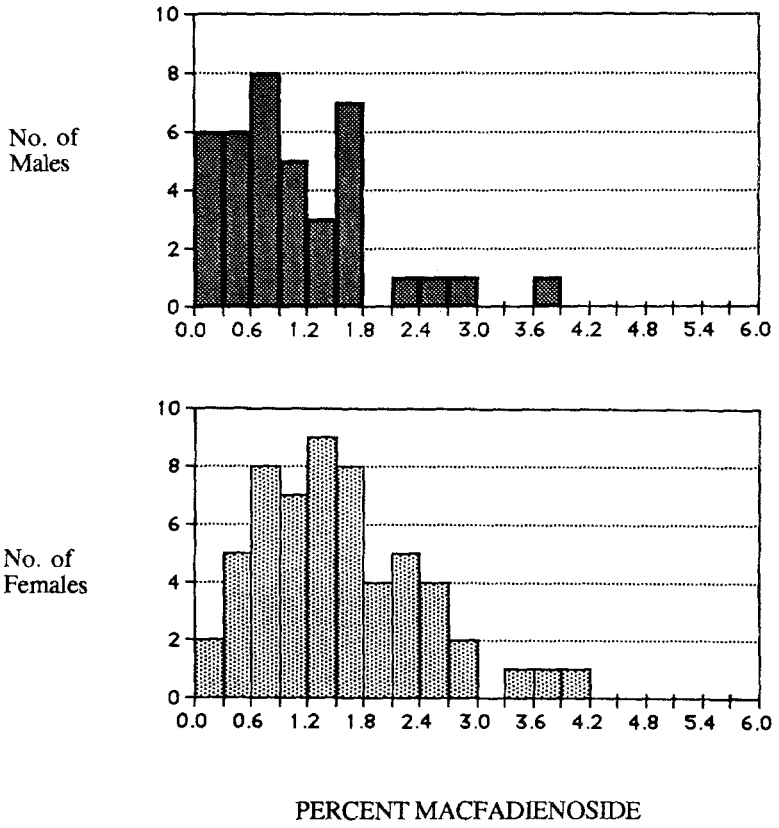

FIG. 6. Variation in macfadienoside content among male and female *E. anicia* (Red Hill, 1985).

Iridoid Analyses (Cumberland Pass). The results of 1985 and 1986 collections and analyses are given in Tables 6 and 7. Especially noteworthy was the high 1985 total iridoid content of the males ($\bar{X}$ = 7.9%, range 4.8–10.4%; 1420 μg per butterfly average). A large decrease in male iridoid content was seen in comparing these 1985 results ($\bar{X}$ = 7.9%) to 1986 ($\bar{X}$ = 3.4%). Male–female comparisons were only available for 1986, and neither total iridoid content nor the ratio of aucubin to catalpol sequestered differed significantly between the sexes. Catalpol and aucubin are present in the host plant in approximately equal amounts (Stermitz et al., 1986), but butterflies contained much more catalpol than aucubin. Large individual variations were noted, with catalpol content varying from 180 to 1700 μg per butterfly and aucubin content from 0.0 to 530 μg.

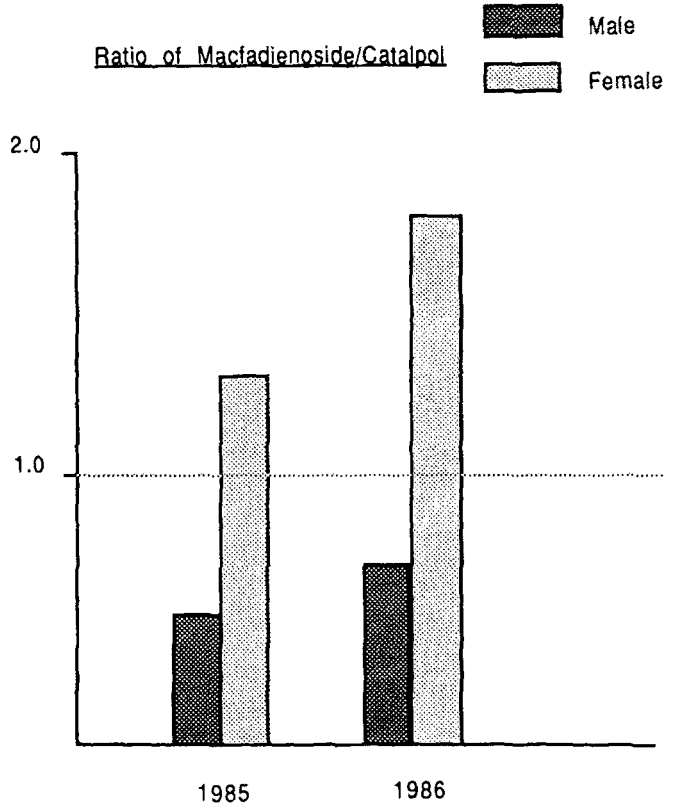

FIG. 7. Male–female difference in macfadienoside-to-catalpol ratio (Red Hill, 1985).

Catalpol Ester Metabolism. Of the nine early postdiapause larvae collected from *C. integra* at Red Hill and then fed in the laboratory on an artificial diet containing 6-isovanillylcatalpol, seven reached adulthood, while two were found to have been parasitized by wasps. Quantitative analyses were performed on three adults, their pupal cases, emitted meconium, and frass from two of the individuals (Table 8). Frass contained isovanillic acid, but no iridoids. The pupal cases, meconium and adult butterflies contained no isovanillic acid or 6-isovanillylcatalpol, but did contain the iridoids catalpol and macfadienoside.

DISCUSSION

Differential Host Plant Utilization. At Red Hill, 92% of all butterflies in 1985 ($N = 96$) and 100% in 1986 ($N = 20$) contained macfadienoside and hence utilized *C. integra* at some time during the larval stages. Prediapause larvae weigh only about 5 mg, while postdiapause larvae reach several hundred milligrams (Table 4), so the adult iridoid content must primarily be a reflection of postdiapause larval consumption. Since we found macfadienoside-lacking adults just off the site in an area where only *Besseya* occurs, the few site butterflies that lacked macfadienoside might have moved in from such an area. In both years observational data indicated the presence of numerous *Besseya* with egg masses, but the relative use of *Castilleja* vs. *Besseya* for oviposition has not yet been assessed. Little or no catalpol or macfadienoside was present in the frass collected during the artificial diet studies (Table 8). Macfadienoside was retained from the early field consumption of *C. integra* even after a subsequent week or more of feeding on an artificial diet that lacked that iridoid.

[a]Wet weight.
[b]Dry weight.

Since macfadienoside is retained and is the major iridoid of *Castilleja*, adults with high macfadieneoside-to-catalpol ratios probably came from larvae that had consumed relatively more *Castilleja* than *Besseya*.

The most parsimonious explanation of the high percentage of macfadienoside-containing adults may simply be that *C. integra* is more plentiful at Red Hill than is *B. plantaginea* (Table 1), that the two host plants are relatively uniformly found at the site, and that larvae eat what they randomly encounter. With the plant counts showing a 9:1 ratio of abundances of *C. integra* and *B. plantaginea* in 1985, the finding of 92% macfadienoside-containing adults is as expected. That year both host plants were available and used by postdiapause larvae. This was not the case in 1986, when there was little emergent *B. plantaginea* at the time of postdiapause larval feeding. This may account for the finding of some females with only macfadienoside and no catalpol (Table 2).

In a study of *E. editha* hosted by *C. linariifolia* near Almont in Gunnison County, Colorado (Holdren and Ehrlich, 1982), it was suggested that the host plant choice there was determined by ecological characteristics, primarily host plant phenologies, and not nutrition or biochemistry. Thus, *C. chromosa*, although present at Almont, was never used and the suggestion was made (Holdren and Ehrlich, 1982) that the early senescence of this species as compared to *C. linariifolia* was the determining factor in host plant use. At Red Hill both *C. integra* and *B. plantaginea* are generally available for both oviposition and larval consumption, although some seasonal and year-to-year variation does occur. There appear to be no phenological determinants that would preclude either host plant being utilized at Red Hill.

The interpretation of data from Cumberland Pass is simplified since here *E. anicia* uses only one host plant, *B. alpina*. The data of Table 5 show preferential sequestration of catalpol over aucubin, since these two iridoids are of approximately equal concentration in the host plant (Stermitz et al., 1986). Significantly more catalpol than aucubin was found in 27 of 29 butterflies. This result parallels that for *E. phaeton* adults from larvae fed on *Chelone glabra* and *Plantago lanceolata*, where selective sequestration of catalpol over aucubin was also reported (Bowers and Puttick, 1986). Our analyses on *B. alpina* were conducted on material collected at one time, while larvae consume host plants over a period of several weeks. In order to confirm this selective sequestration, an analysis of the relative catalpol and aucubin content in individual plants over the period of consumption must be done. In none of the 30 Cumberland Pass butterflies analyzed, nor in any of those previously studied from the alpine sites, was macfadienoside found. This confirms the suggestion (Stermitz et al., 1986) that macfadienoside, although a simple allylic hydroxylated product of catalpol, is not formed by butterfly metabolism of catalpol.

Individual Variation in Iridoid Content. Butterflies showed a highly variable iridoid content at both Red Hill and Cumberland Pass and in each season,

with individuals ranging from less than 1% to over 10% iridoid on a dry weight basis. This would result in a large range in bitterness, which is expected to be iridoid-concentration dependent, and should lead to a difference in palatability to predators. It has been shown that *E. phaeton* butterflies are unpalatable to blue jays when raised on high-iridoid-content plants, but are palatable when raised on low-iridoid-content plants (Bowers 1980, 1981). Dose–activity data have been important in monarch–cardenolide work (Brower, 1984) and need to be established for iridoids before we can make any definitive statements about unpalatability. If the low-iridoid-content butterflies in our natural populations are not sufficiently bitter to deter vertebrate predators, while the high concentrations do suffice, then the low-content butterflies could be considered automimics, as has been suggested for the monarch butterfly case. With both macfadienoside and catalpol being sequestered in major amounts by butterflies at Red Hill, it will be also important to establish the relative potencies (or bitterness) of these two iridoids. This is particularly so since there is a difference in the relative amounts of these iridoids in adult males as compared to females. This could result in different selection pressures on the sexes.

Field and laboratory observations indicate that iridoids are not protective against ants or spiders, since cases of predation by these invertebrates on larvae and adult butterflies have been seen. Wasp parasitoids are also not deterred. Parasitized larvae contain iridoids, although the wasp cocoons and pupae do not (Gardner, 1987; K. L'Empereur, unpublished work). We have not, however, looked at butterfly iridoid concentrations relative to invertebrate predation, and there could be a differential predation pressure on individuals with varying iridoid content.

In the lubber grasshopper, Jones et al. (1986) reported interindividual variations in defensive substance content of two to three orders of magnitude, as well as qualitative differences, and suggested that the grasshopper defensive secretions were of a fundamentally idiosyncratic and unpredictable nature. High variability in adult-obtained pyrrolizidine alkaloids were reported for ithomiine butterflies (Brown, 1984a,b). Our results are similar in many respects to the monarch and queen butterfly (Brower et al., 1984, Lynch and Martin, 1987) and *Oncopeltus* (Scudder et al., 1986) cases. There qualitative cardenolide content is quite closely tied to larval host-plant allelochemical content, mean quantitative content somewhat less so, but where individuals can show extremely high variability. Iridoid sequestration from hostplants is more selective and less exactly a reflection of the host plant content than is cardenolide sequestration, since we observe more metabolism (ester hydrolysis) prior to sequestration in some cases and since some host plant iridoids are not found in the butterflies. Some possible predator–prey scenarios that might influence the evolution and maintainence of individual variations in defensive chemical content in insects have been suggested (Jones et al., 1986).

Metabolism and Additional Aspects of Sequestration. The artificial diet experiment involving the catalpol ester **4** established that *E. anicia* larvae are able to hydrolyze the ester and sequester the resulting catalpol while excreting isovanillic acid. It is highly likely that they do the same with catalpol esters **3** and **5** since we have never encountered these esters in the adult butterflies. Thus, as the major iridoid components of *B. plantaginea*, the esters must provide most of the catalpol present in larvae feeding on this host plant. Esterases are common in insects, and it is unlikely that this process is a specialized one for *E. anicia*. The relatively high levels of macfadienoside found in adults, pupal cases, and meconium (Table 8) are interesting since the larvae had doubled or tripled in weight since consuming any of the macfadienoside-containing *C. integra* host plant. Particularly striking were the results with male 1 where 10 times as much macfadienoside was excreted in the meconium as was maintained into the adult stage, while the two females sequestered and excreted approximately equal amounts of that iridoid. This differential processing could be one reason for the lower macfadienoside content of males as compared to females, but additional samples are clearly necessary to confirm this possibility. A defensive role for meconium emission of iridoids has been suggested (Bowers and Puttick, 1986), and this might account for release of a substance that could otherwise provide additional longer term adult defense.

Female *E. anicia* emerge with a full complement of eggs, and the iridoid content of eggs would be important to establish, since up to 20% of the female weight can be assigned to eggs (Murphy et al., 1983). Preliminary experiments on only a few field-collected eggs or eggs from dissection (Gardner, 1987) showed them to have a high catalpol and very low macfadienoside content. If this fact could be confirmed, it would make the high female content of macfadienoside even more striking. In some insects male spermatophores can constitute a significant contribution to the weight of the male and inseminated female. We have shown (Gardner, 1987) that this does not hold for *E. anicia* since the spermatophore constitutes only about 2% of the dry weight of the male. The spermatophore iridoids represent less than 1% of the total iridoid load of the male (Gardner, 1987).

One literature report (Franke et al., 1987) suggested the possibility of metabolism other than the ester hydrolysis we have established, but the data are equivocal. The sequestration of aucubin and catalpol by *E. cynthia* was reported (Franke et al., 1987), but the adults also contained large amounts of 6-*O*-glucopyranosylaucubin, which was not present in the *Plantago lanceolata* that was being used to feed larvae in the lab. Larvae were wild-collected from *Plantago alpina* and then maintained on *P. lanceolata*. It was suggested that the 6-*O*-glucopyranosylaucubin might have been either a metabolic product or had been present in an unknown prior utilized host plant. The iridoid content of the original host plant, *P. alpina*, was, however, not reported and hence the question

of insect metabolic formation of the new glucosidic iridoid remains to be established.

The very high levels of iridoids that are reached in many of the *E. anicia* could also be important to the insect if they provide some benefit other than as vertebrate predator defenses. For example, some iridoids have been reported to have antimicrobial, antifungal, and/or antioxidant properties (Davini et al., 1986; Cameron et al., 1984; Ishiguro et al., 1986). Catalpol is, however, not known to be particularly active and macfadienoside has not been tested as far as we know. Aucubin is one of the more biologically active iridoids, especially as the aglycone.

Acknowledgments—F. J. Odendaal provided direction for most of the field work, particularly the host plant and butterfly counts, and Guy Harris gave assistance in the field. M. D. Bowers gave valuable assistance with the artificial diet experiments and made many useful comments on this paper. D.R.G. was the recipient of a Colorado Graduate Fellowship. Financial support was provided by grant BSR-8506064 from the National Science Foundation.

(Received June 3, 1987; accepted October 14, 1987)

Abstract—When feeding on rolled oats, male square-necked grain beetles, *Cathartus quadricollis* (Guér.), produced the aggregation pheromone (3*R*,6*E*)-7-methyl-6-nonen-3-yl acetate, for which the trival name "quadrilure" is proposed. The pheromone was highly attractive to both sexes in a two-choice, pitfall olfactometer modified to retain responding beetles by placing a food stimulus (an oat flake) in the glass vials containing the experimental and control stimuli. The *S* enantiomer of the pheromone was inactive. Males also produced small amounts of (*E*)-7-methyl-6-nonen-3-one, (*E*)-7-methyl-6-nonen-3-ol, and (6*E*)-7-methyl-3-propyl-2,6-nonadienyl acetate, but these compounds were inactive in the laboratory bioassay. Segregated males and females both produced (*R*)-(−)-1-octen-3-ol, which by itself was repellent to both sexes but did not diminish beetle response to the aggregation pheromone.

Key Words—*Cathartus quadricollis* (Guér.), square-necked grain beetle, Coleoptera, Cucujidae, aggregation pheromone, (3*R*,6*E*)-7-methyl-6-nonen-3-yl acetate, (*E*)-7-methyl-6-nonen-3-one, (*E*)-7-methyl-6-nonen-3-ol, (6*E*)-7-methyl-3-propyl-2,6-nonadienyl acetate, 1-octen-3-ol, repellent.

INTRODUCTION

The square-necked grain beetle, *Cathartus quadricollis* (Guér.), is a long-lived, cosmopolitan pest of stored products. In North America this polished, reddish-brown beetle is chiefly abundant in the southern United States and infests a variety of stored commodities such as corn and peanuts (Anon., 1955). The beetle is also found in the wild and attacks a large variety of plant seed pods. In morphology and habit, *C. quadricollis* is similar to other grain-infesting beetles of the genera *Cryptolestes* and *Oryzaephilus*, but it is larger and a strong flyer (Anon., 1955). As an extension of our investigation of semiochemicals in cucujid grain beetles (H.D. Pierce et al., 1984), we inititated a study of *C. quadricollis*. Herein, we report the identity of a male-produced aggregation pheromone and the structures of several related beetle-produced compounds.

METHODS AND MATERIALS

Insect Rearing. C. quadricollis were reared on large-flake rolled oats and brewer's yeast (95:5, w/w) in 3.8-l glass jars at 30°C and 65–70% relative humidity (RH). Numbers of adults were determined by mean weight (1 beetle = 0.79 mg, $N = 1047$). Adult beetles were sexed by the presence (males) or absence (females) of a small, sharply pointed process on the coxa of the hind leg.

Pheromone Collection. Volatiles from male, female, or mixed-sex beetles feeding on rolled oats contained in vertically oriented glass chambers were trapped on Porapak Q as described by H.D. Pierce et al. (1984). Trapped volatiles were recovered from the Porapak Q by extraction with pentane in a Soxhlet extractor for 24 hr. The pentane solution of the volatiles was concentrated to approx. 10 ml by distilling off the pentane through a Dufton column.

Test Beetles for Bioassay. Mixed-sex *C. quadricollis* 8–12 weeks old were harvested from rearing cultures and placed in fresh medium at a density of approx. 10,000 beetles/kg at least one week before bioassays. Approximately 48 hr before a bioassay, 1.1 g of beetles were removed from the culture and preconditioned at 23°C in darkness without food in a 6-l Erlenmeyer flask through which charcoal-filtered, humidified air was drawn by a water aspirator at 1.9 l/min. Sexed adults were also conditioned for bioassay in this manner.

Bioassay Procedures. Several hours before commencement of a bioassay, 12 conditioned test beetles were aspirated into each of several 60-ml glass vials. At this time, oat flakes were also placed in the experimental and control vials of a two-choice, pitfall olfactometer (A.M. Pierce et al., 1981). The vials of test beetles and vials for the olfactometers were then taken to an environmental chamber maintained at 24°C and 60–65% RH. This modification was neces-

sary, because *C. quadricollis* tend to climb out of the vials unless host material (an oat flake) or attractive frass is present in the experimental vial (Table 1). There was minimal response to a control vial with only an oat flake (Table 1).

After approx. 3–4 hr, a group of 12 test beetles was released into each olfactometer, and the bioassay was conducted for 2 hr (A.M. Pierce et al., 1981). Mixed-sex test beetles were used only once and discarded, while sexed beetles were recovered at the end of the bioassay and returned to their rearing jar.

Unless otherwise stated, the raw data were analyzed by the *t*-test for paired, correlated data, and results were expressed as the mean percent response of the total number of beetles per treatment.

In one bioassay, response by *C. quadricollis* in the two-choice, pitfall olfactometer was determined at selected time intervals by counting the number of beetles in the experimental and control stimulus vials. Counting the beetles in the vials necessitated picking up and slightly tilting the olfactometer dish. This process did not disturb the responding beetles if done gently. The experimental stimulus for this bioassay was frass and a pentane extract thereof. The latter was prepared by placing 3.75 g frass from a mature culture in a sintered glass funnel. Approximately 10 ml of pentane was added, and the mixture was stirred with a spatula. The solvent was then drawn off by application of a slight vacuum. This process was repeated three times. The combined pentane washes were concentrated under a stream of nitrogen to 1.5 ml.

[a] Showing retention of beetles responding to frass volatiles when frass is present in experimental vial, lack of persistent retention when experimental vial contains frass extract on filter paper, and restoration of retention when oat flake is present in experimental and control vials. $N = 10$ replicates per treatment, 12 beetles per replicate.

[b] Response to experimental stimulus significant in all cases, *t*-test, $P < 0.001$. Means in the same row followed by the same letter not significantly different (Newman-Keuls test, $P < 0.05$).

Instrumental Methods. Hewlett-Packard 5830A and 5880A gas chromatographs equipped with flame-ionization detectors and fitted with open-tubular glass columns (36–48 m × 0.5 mm ID) coated with Carbowax 20 M, SP-1000, or SUPEROX-4 (Alltech Associates, Deerfield, Illinois) were employed for analytical gas–liquid chromatography (GLC). The micropreparative gas chromatograph has been previously described (A.M. Pierce et al., 1985). A 3.3-m × 3.18-mm OD stainless-steel column packed with 5% OV-101 on Chromosorb G (70/80) was used for separations with temperature programming.

Coupled gas chromatography–mass spectroscopy (GC-MS) was carried out with a Hewlett-Packard 5895A GC-MS-DS. The transfer line and ion source were maintained at 250°C and 200°C, respectively. The electron impact (EI) voltage was 70 eV. Isobutane was the reagent gas for spectra obtained in the chemical ionization (CI) mode. Fused silica columns (0.32 mm ID) coated with SP-1000 (30 m) or DB-1 (30 and 60 m) liquid phases (J&W Scientific Inc., Folsom, California) were coupled directly into the ion source. Helium was the carrier gas for GC and GC-MS.

Nuclear magnetic resonance (NMR) spectra were recorded with a Bruker WM-400 spectrometer. Samples separated by micropreparative GC were rinsed from collection tubes into NMR tubes with $CDCl_3$ (99.96 atom % D) or C_6D_6 (99.6 atom % D) (Merck Sharp & Dohme, Canada Ltd., Kirkland, Quebec). Chemical shifts are reported on the δ scale.

Synthetic Chemicals for Bioassays. The syntheses of the racemate and enantiomers of the aggregation pheromone and of several related beetle-produced compounds have been reported elsewhere (Johnston and Oehlschlager, 1986). (*R*, *S*)-1-Octen-3-ol was purchased from the Aldrich Chemical Company (Milwaukee, Wisconsin). (*R*)- and (*S*)-1-Octen-3-ol were gifts from Dr. A. Mosandl (Mosandl et al., 1986).

RESULTS

Identification of Aggregation Pheromone. Comparison of a gas chromatogram of the Porapak Q-trapped volatiles from mixed-sex *C. quadricollis* feeding on rolled oats to that obtained from rolled oats established that four compounds (peaks A–D) were produced by the beetles (Figure 1). That one (or more) of the compounds was probably an aggregation pheromone was indicated by the strong response of mixed-sex *C. quadricollis* to the unfractionated volatiles in the modified two-choice, pitfall olfactometer (Figure 2).

The four beetle-produced peaks were isolated by micropreparative GC. Only peak B was attractive and accounted for most of the biological activity in the unfractionated Porapak Q-trapped volatiles (Figure 2). The remaining bee-

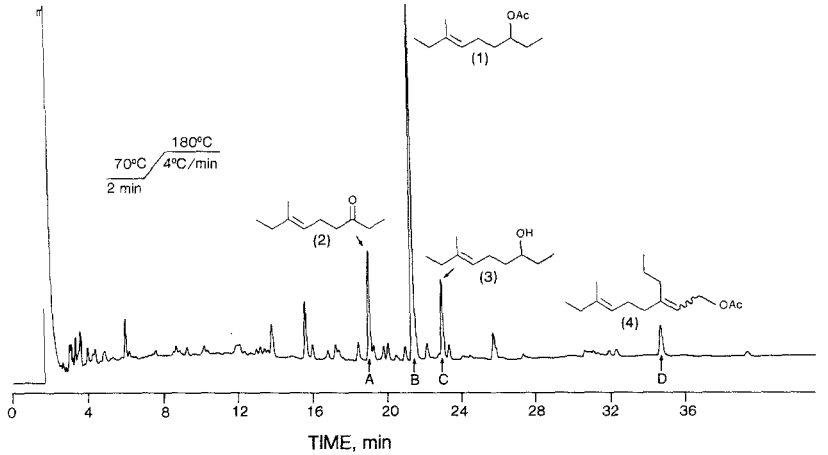

FIG. 1. Gas chromatogram of the Porapak Q-trapped volatiles from mixed-sex *C. quadricollis* feeding on rolled oats, designating beetle-produced peaks A–D and depicting structural formulae.

tle-produced peaks neither synergized nor inhibited the response of the beetles to peak B (data not shown). Thus, peak B was identified as an aggregation pheromone of *C. quadricollis*.

Structure of Aggregation Pheromone. In the mass spectrum of peak B (Figure 3), the highest observed fragment ion is *m/z* 138, which is also the highest and characteristic ion in the mass spectra of numerous volatile fatty acid esters of citronellol (Jennings and Shibamoto, 1980). The spectrum of the pheromone was similar to those of these compounds. We, therefore, suspected that the pheromone was also an ester of a C_{10} alcohol of mol wt = 156. This suspicion was confirmed by the CI mass spectrum wherein the highest observed ion was *m/z* 199 ($M^+ + H$). Thus, the *m/z* 138 ion is due to the loss of acetic acid from the molecule ion of a compound with the formula of $C_{12}H_{22}O_2$, i.e., the acetate of monounsaturated alcohol. Loss of an ethyl group from the *m/z* 138 ion would give the base peak ion at *m/z* 109.

The NMR spectrum of peak B is shown in Figure 4. The single proton triplet (J = 7.0 Hz) at δ 5.08 indicated that the double bond was trisubstituted with a methylene geminal to the olefinic proton. The chemical shift of the single proton quintet at δ 4.81 established the presence of secondary acetate (δ 2.04, 3H) with two adjacent and nearly equivalent methylenes (J = ca. 6.2 Hz). Irradiation of the carbinyl proton affected only the methylenes absorbing at ca. δ 1.56. The sharp singlet (δ 1.57, 3H) was assigned to an allylic methyl group,

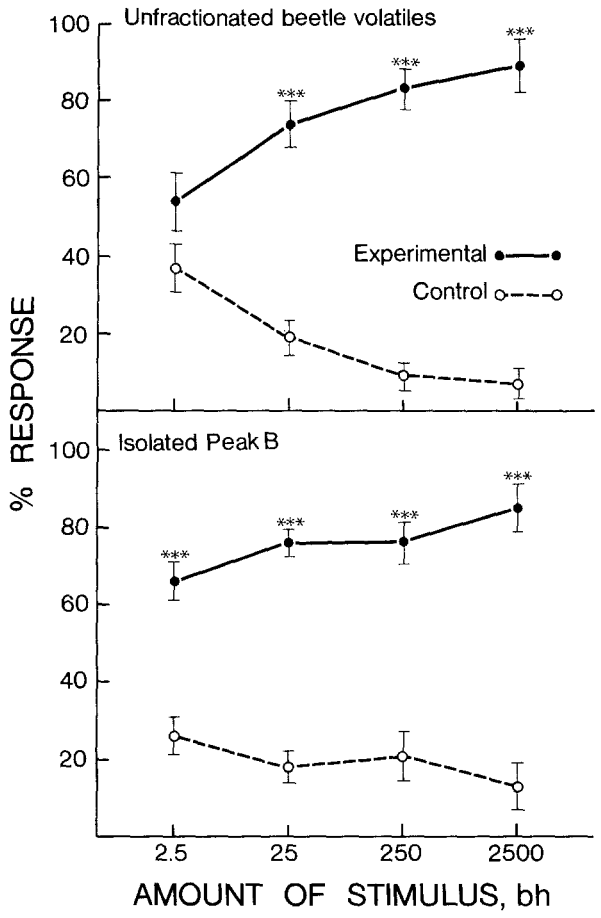

FIG. 2. Response ($\bar{X} \pm$ SE) of mixed-sex *C. quadricollis* in two-choice, pitfall olfactometer to unfractionated Porapak Q-trapped volatiles from mixed-sex *C. quadricollis* feeding on rolled oats and to isolated peak B. Significant response to experimental stimulus indicated by the following: $***P < 0.001$. $N = 12$ replicates. bh = amount of volatiles collected from one beetle aerated for 1 hr.

and the chemical shift indicated that the trisubstituted double bond was of *E* geometry (Marfat et al., 1979). Irradiation of the allylic protons at δ 1.98 established that one methyl (δ 0.97) was attached to an allylic methylene and the other (δ 0.88) was not. Irradition of the methyl group at δ 0.97 resulted in the collapse of three of the peaks of the quintet at δ 1.98 to a singlet, which was superimposed over a quartet. On the basis of the NMR spectral data, the struc-

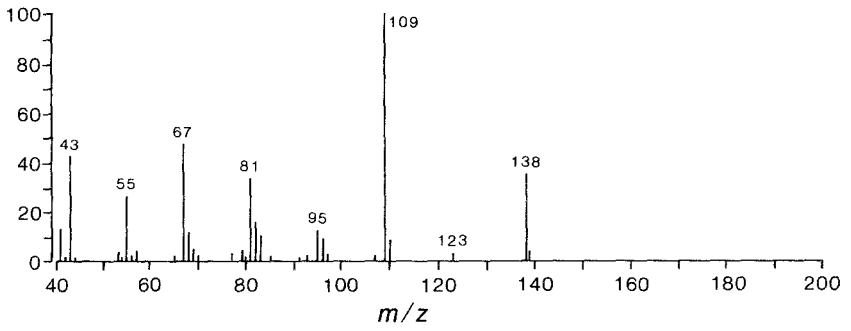

FIG. 3. Unit resolution mass spectrum of peak B.

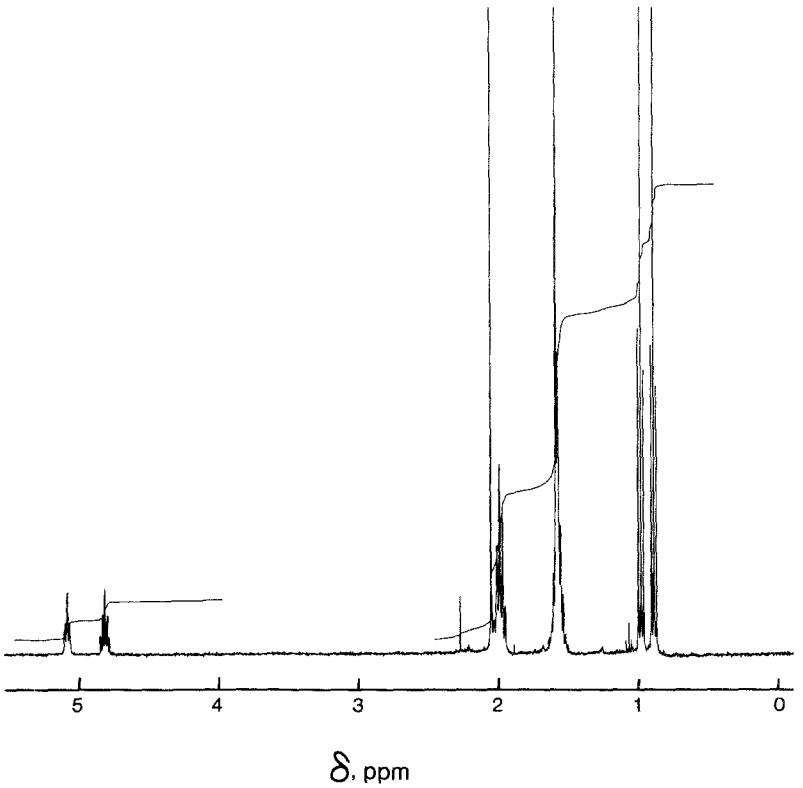

FIG. 4. [^{1}H]NMR spectrum of peak B recorded at 400 MHz in $CDCl_3$.

ture of the pheromone was formulated as (*E*)-7-methyl-6-nonen-3-yl acetate (**1**) (Figure 1). Comparison of the mass and NMR spectra and of the gas chromatographic retention time of the beetle-produced compound to those of an authentic sample (Johnston and Oehlschlager, 1986) confirmed the structural assignment. We propose the trivial name "quadrilure" for the pheromone.

Structures of Related Beetle-Produced Compounds. The mass spectrum of peak A exhibited M^+ at *m/z* 154. The NMR spectrum of peak A possessed several proton resonances that were identical to those of natural **1** but lacked the carbinyl proton and acetate methyl group resonances. The methylene resonances at δ 1.56 of natural **1** were shifted to δ 2.42. These spectral data and the shorter GC retention of peak A suggested that it was (*E*)-7-methyl-6-nonen-3-one (**2**). The structure of peak A was confirmed by comparison of spectral data and GC retention time to that of synthetic **2.** The structure of peak C was easily established as (*E*)-7-methyl-6-nonen-3-ol (**3**) (Figure 1) by comparison of spectral data to that of an authentic sample, which was an intermediate in the synthesis of **1** (Johnston and Oehlschlager, 1986).

The EI mass spectrum of peak D was not particularly informative, but the CI mass spectrum indicated that the molecular weight of the unknown was 236. In Figure 5 is shown the NMR spectrum of peak D. Comparison of Figure 5 to Figure 4 revealed that the unknown and natural **1** share several common resonances. The chemical shifts of the coupled low-field olefinic proton (δ 5.34, 1H, J = 7 Hz) and carbinyl protons (δ 4.59, 2H, J = 7 Hz) indicated the compound was a primary allylic acetate (δ 2.05, 3H) with two trisubstituted double bonds. Decoupling experiments established that the methylene at δ 1.41 (a sextet) was coupled to the high-field methyl (δ 0.89, J = 7.34 Hz) and an allylic methylene (ca., δ 2.06, J = 7.6 Hz). Irradiation of the allylic methyl at δ 1.59 removed small splittings (ca. 1.5 Hz) from the olefinic peak at δ 5.08. A structure consistent with these data is (6*E*)-3-propyl-7-methyl-2,6-nonadienyl acetate (**4**). The spectral data, however, were insufficient for assignment of the geometry of the C-2,3 double bond.

Bioassays with Synthetic Pheromone. Table 2 shows the response of mixed-sex beetles to (*R,S*)-**1** (*E*/*Z* = 3) and to natural **1.** The doses of natural **1** were 37.5% of (*R,S*)-**1** since the pheromone has one chiral center (see below). These data show that the pheromone is probably one isomer and that the presence of the other optical and geometrical isomers did not inhibit the response of the beetles. In a 12-replicate experiment, the mean percent response (± SE) of mixed-sex beetles to racemic **1** (10 ng, 98% *E*) was 80 ± 3.9 (percent response to pentane control = 16.7 ± 4.1) in the presence of an oat flake and 40 ± 4.4 (percent response to pentane control = 12.5 ± 4.2) in its absence. These results corroborate those in Table 1 and confirm that an oat flake is a sufficient requirement for sustaining the response of the beetles during the 2-hr bioassay.

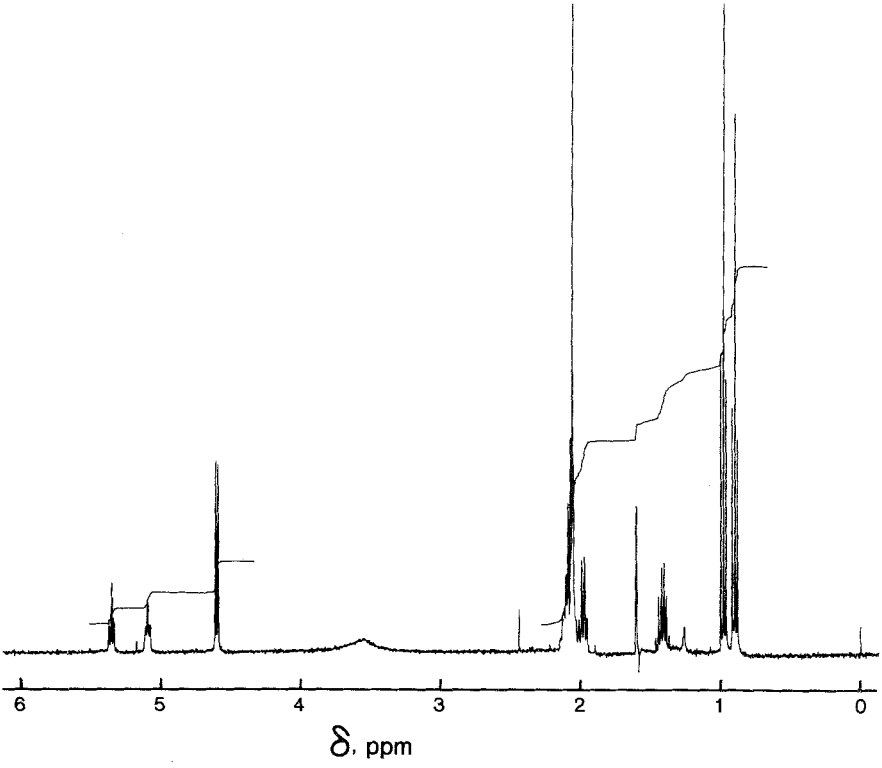

FIG. 5. [^{1}H]NMR spectrum of peak D recorded at 400 MHz in $CDCl_3$. The reduced intensity of the allylic methyl at δ 1.59 is due to irradiation of a water peak at δ 1.58.

TABLE 2. RESPONSE OF MIXED-SEX *C. quadricollis* IN TWO-CHOICE PITFALL OLFACTOMETER TO NATURAL AND SYNTHETIC, RACEMIC PHEROMONE (N = 12 REPLICATES)

		Response, % ($\bar{X}$ ± SE)[a]	
Experimental stimulus	Amount (ng)	Experimental stimulus	Pentane control
Natural pheromone	0.375	64.1 ± 4.1	25.5 ± 4.8
	3.75	79.9 ± 2.1	12.5 ± 1.9
	37.5	79.9 ± 3.5	11.1 ± 3.2
Synthetic pheromone (E/Z = 3)	1	69.0 ± 5.3	19.3 ± 3.8
	10	77.1 ± 2.2	13.2 ± 2.8
	100	85.4 ± 2.5	8.3 ± 2.0

[a]Response to experimental stimulus significant in all cases, t-test, $P < 0.001$.

The response of females and males to (*R,S*)-**1** (98% *E*) were similar (Figure 6), but the threshold for detection was lower for females than for males. At a stimulus dose of 100 μg, response to the pheromone was inhibited (Figure 6).

Determination of Pheromone-Producing Sex. Analysis by GC of the Porapak Q-trapped volatiles from cultures of segregated males or females estab-

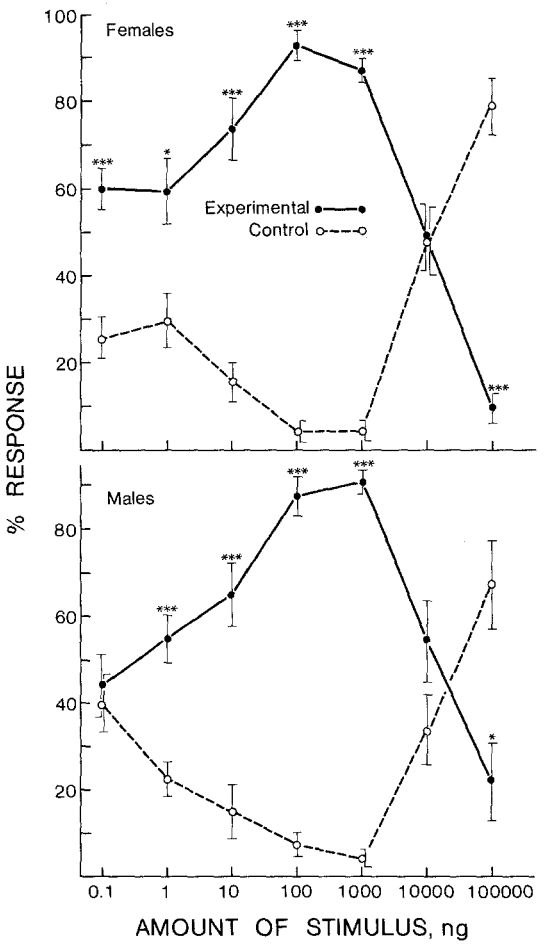

FIG. 6. Response ($\bar{X} \pm$ SE) of female and male *C. quadricollis* to racemic pheromone (98% *E*). Significant response to experimental stimulus indicated by the following. ***$P < 0.001$; *$P < 0.05$. $N = 12$ replicates.

lished that only the males produced the pheromone (**1**) and **2–4** (Figure 7). In addition to the pheromone and **2–4,** segregated male beetles apparently produced 1-octen-3-ol (**5**), which was also found in the females' volatiles. The production of **2** and **3** by males was much smaller (Figure 7) while production of **4** was unchanged from that produced by males in mixed-sex culture (Figure 1). No *Z* isomer of the pheromone was detected in this sample by GC-MS analysis on the 60-m DB-1 column.

Determination of Chirality. The enantiomeric enhancement (ee) and chirality of **1** were determined by the method of Slessor et al. (1985). Lithium aluminium hydride was used to remove the acetate group of the pheromone. Male beetles produced (*R*)-**1** (91% ee) and both sexes produced (*R*)-(−)-1-octen-3-ol (ca., 94–95% ee).

Bioassays with Chiral Pheromones. Although responses to (*S*)-**1** (>99% ee) at dosages of 10–10,000 ng were significantly different from those to control stimuli, significant responses to (*R,S*)-**1** occurred at a 100-fold lower dose (Figure 8). Conversely, the thresholds for response to (*R*)-**1** and the racemate were identical (Figure 9). Evidently, beetles in the *S* enantiomer experiment were more active than those used in the *R* enantiomer experiment. Thus, response to the *S* enantiomer might be entirely due to the presence of the optical impurity. The data indicate that the *S* enantiomer neither repels the beetles nor inhibits

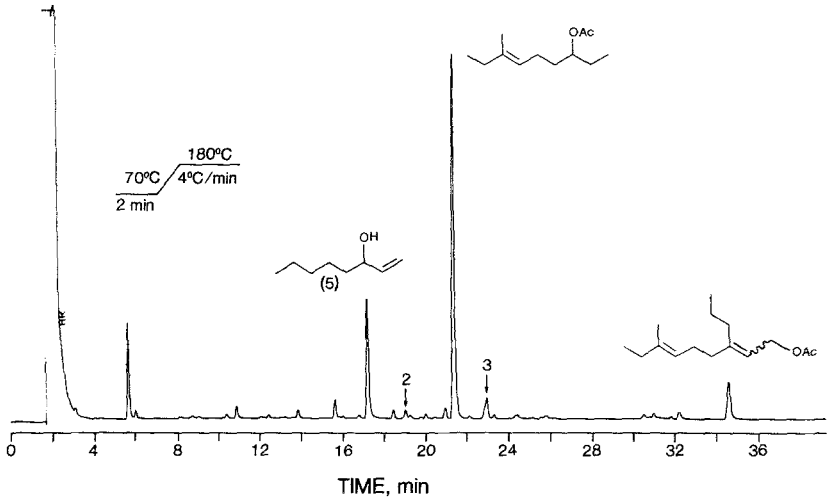

FIG. 7. Gas chromatogram of the Porapak Q-trapped volatiles from male *C. quadicollis* feeding on rolled oats. The peak at *RT* = 17.2 min. is 1-octen-3-ol.

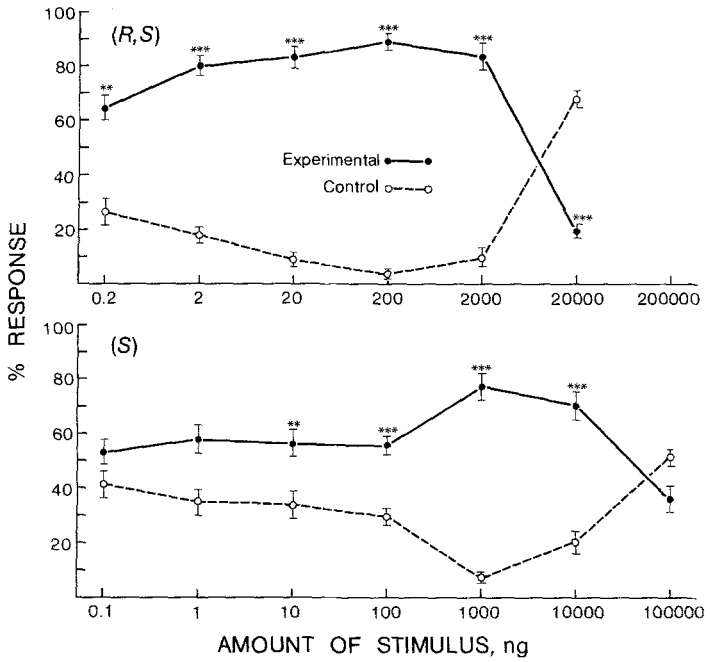

FIG. 8. Response ($\bar{X} \pm$ SE) of mixed-sex *C. quadricollis* in two-choice, pitfall olfactometer to (*S*)- and (*R*,*S*)-**1.** Significant response to experimental stimulus indicated by the following: ***$P < 0.001$; **$P < 0.01$. $N = 12$ replicates.

their response. The data (Figure 9) also suggest that the *S* isomer probably does not synergize the response of mixed-sex beetles to the *R* isomer since the threshold (1 ng) for significant response was the same (however, see Discussion).

Neither (*R*)- nor (*R*,*S*)-1-octen-3-ol was attractive to beetles of mixed sex at any dosage, and at most dosages the beetles were repelled (Table 3). (*S*)-1-Octen-3-ol was at least a 100-fold less active than the *R* enantiomer. The data suggest that the *S*-enantiomer is relatively inactive as a repellent. The response of the beetles at the higher dosages of the *S* isomer is probably due to a small amount of the antipode (ca., 1%). Although (*R*)-1-octen-3-ol apparently functions as a repellent in *C. quadricollis*, response of mixed-sex beetles to the aggregation pheromone is not reduced by a large excess of the compound (Table 3).

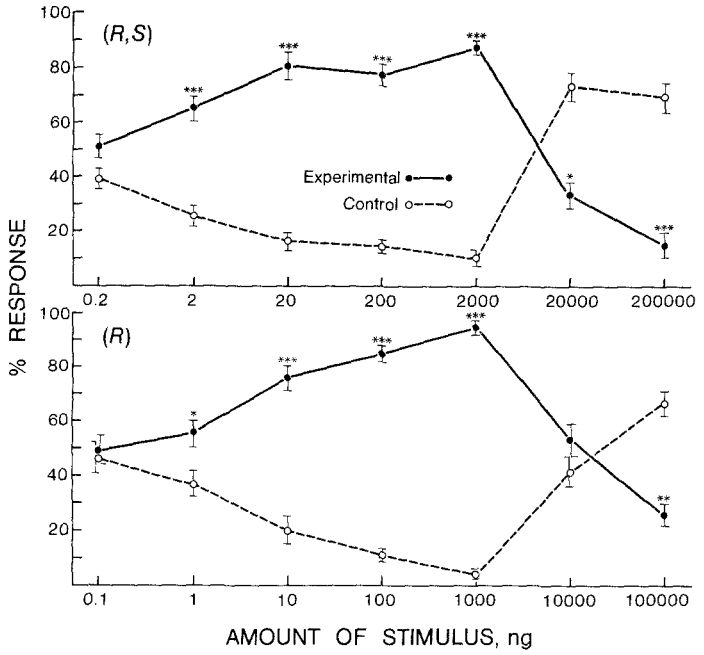

FIG. 9. Response ($\bar{X} \pm$ SE) of mixed-sex *C. quadricollis* in two-choice, pitfall olfactometer to (*R*)- and (*R,S*)-**1**. Significant response to experimental stimulus indicated by the following: $***P < 0.001$; $**P < 0.01$; $*P < 0.05$. $N = 12$ replicates.

DISCUSSION

In the laboratory, *C. quadricollis* are mobile and are excellent climbers of vertical glass surfaces. We thus hypothesized that after initially responding to a volatile stimulus, the beetles subsequently found no host-related stimuli and then crawled out of the vials, resulting in a low overall response at the end of a 2-hr bioassay (Table 1). The beetles, however, responded well to frass from the rearing culture, which is a good source of attractive semiochemicals for *Cryptolestes* and *Oryzaephilus* spp (Borden et al., 1979; A.M. Pierce et al., 1981; Wong et al., 1983; Millar et al., 1985a,b). Frass probably also provided host-related stimuli, as did the oat flake.

In their pitfall bioassay system, Phillips and Burkholder (1981) applied a thin strip of Teflon to the inner rims of the vials to prevent rice weevils, *Sitophlius oryzae* (L.), from crawling back into the chamber. Possibly, a kernel of grain in the vials might retain responding weevils. Similarly, to retain fruit flies,

[a] Significant positive or negative response to experimental stimulus indicated by the following: ***$P < 0.001$; *$P < 0.05$; NS, not significant.

Drosophila virilis, inside a semiochemical-baited vial, Bartelt et al. (1985) placed a drop of water on the vial bottom.

While the use of an auxillary substance with semiochemicals may seem to be unnecessary and adds an additional step to make possible a reliable and convenient laboratory bioassay, we suggest that these modifications better simulate the natural environment. Moreover, our results and the cited examples suggest that aggregation pheromones function not only to draw responding insects to the point of emanation but also to stimulate other behaviorial patterns such as searching for food and mates. If the secondary stimuli are not found, the responding insect then leaves the site.

In our earlier studies of cucujid grain beetles (Wong et al., 1983; Millar et al., 1985a,b; A.M. Pierce et al., 1985), we found that males produced two or more unsaturated macrocylic lactones which acted synergistically as aggre-

gation pheromones. Moreover, the response of mixed-sex beetles was not inhibited by the presence of the antipodes in the pheromone mixture. The major differences between *C. quadricollis* and the other cucujids studied to date is that the aggregation pheromone appears to be a single component. However, both quadrilure and macrolides are unsaturated esters.

The ee of natural quadrilure is 91%. Whether the *S* isomer of the pheromone acts as a synergist or is inactive has not been clearly established on the basis of the present data. The lower threshold for significant response by females as compared to males (Figure 6) might mean the *S* isomer acts as synergist or the females are just inherently more sensitive to *R* isomer than are the males. Additional bioassays would be required to resolve this question.

The terpene-like compound **4** is a homolog of the pheromone but has no apparent effect on ambulatory beetles in the modified pitfall olfactometer. However, its influence on in-flight beetles has not been tested. Although the geometry of the C-2,3 double bond of **4** is unknown, its skeletal structure is reminiscent of (2*Z*,6*Z*)-7-methyl-3-propyl-2,6-decadien-1-ol, which is produced by the codling moth, *Laspyeria pomonella* L. (Bowlus and Katzenellenbogen, 1973). Availability of the 2*E* and 2*Z* isomers of **4** would permit not only a more thorough investigation of its effects on the behavior of *C. quadicollis* but also confirmation of the exact structure of the natural compound.

The most interesting aspect of semiochemical production by *C. quadricollis* is the appearance of (*R*)-(−)-1-octen-3-ol (**5**) in the volatiles of segregated males and females. That the (*R*)-(−)-**5** is active is consistent with response by *C. quadricollis* to only the *R* isomer of the pheromone. Although 1-octen-3-ol is produced by a wide variety of molds and fungi, there was no visible mold growth in the aeration cultures, and production of this compound is possibly restricted to the beetles. Additional aerations under conditions of low moisture to preclude mold growth on the oats or of the segregated sexes in absence of food would have to be undertaken to confirm that the beetles produce **5.** Being a repellent, compound **5** could function alone as a female-produced epideictic pheromone (Prokopy, 1981) to promote dispersion of females. Because response to the aggregation pheromone is not reduced by a large excess of **5,** aggregation on a food source and mating would not be inhibited.

Acknowledgments—We thank Dr. R.B. Davis for a cutlure of *C. quadricollis*; Dr. A. Mosandl for samples of the chiral 1-octen-3-ols; Dr. G.G.S. King for some chirality determinations; and J. Dodic, A. Javer and E. Merletti for technical assistance.

LIPID CUES FOR SEED-CARRYING BY ANTS IN *Hepatica americana*

BRADBURY A. SKIDMORE[1] and E. RAYMOND HEITHAUS

Biology Department, Kenyon College
Gambier, Ohio 43022

(Received August 5, 1987; accepted October 14, 1987)

Abstract—We investigated the chemical basis for ants carrying the seeds of *Hepatica americana*, an ant-dispersed plant of eastern North America. A laboratory bioassay of seed and elaiosome extracts was based on the distance test items were carried by *Pogonomyrmex rugosus*. Ants responded equally to isolated elaiosomes and to the diglyceride fraction. Diolein was a major component of the diglyceride fraction, which is consistent with a finding that 1,2-diolein releases seed-carrying by *Aphaenogaster rudis*. Ants' response to the free fatty acid fraction was less intense. Gas chromatography of the fatty acid fraction indicated that oleic acid was a primary component, and oleic acid is known to elicit necrophoric behavior. No evidence supports an earlier suggestion that ricinoleic acid stimulates seed-carrying behavior. Ants failed to respond to seeds from which elaiosomes were removed.

Key Words—Hymenoptera, Formicidae, *Pogonomyrmex*, *Hepatica americana*, ants, Ranunculaceae, diglyceride, elaiosome, myrmecochory, seed dispersal

INTRODUCTION

The dispersal of seeds by ants is a widespread phenomenon involving many taxa (Beattie, 1985). Many species of plants, especially forest herbs of mesic forests, are dispersed by ants that are not granivorous. In these systems, ants usually are attracted to external appendages on seeds called elaiosomes (Sernander, 1906). Elaiosomes have evolved independently in several plant taxa,

[1] Present Address: 2029 Fauver Avenue, Dayton, Ohio 45420.

but generally elaiosomes are rich in lipids and carbohydrates (Bresinsky, 1963). Many species of ants that encounter elaiosomes quickly remove them (and the attached seeds) to nests, where the elaiosomes are fed to larvae. After elaiosomes are removed from seeds, the seeds may be scattered on refuse piles near ant nests or abandoned underground in the nest. The potential benefits to the plant include removal from parents with associated reduction of risks from parent–offspring competition or seed predation by rodents, and deposition in better microsites for germination and establishment (see Beattie, 1985, for a review).

Chemicals mediate the specific behavior of ants toward elaiosomes or any other potential food item (Wilson, 1971). Ants' possible responses to seeds include ignoring it, eating the elaiosome in situ, carrying the seed directly to a nest refuse area, carrying the seed to a nest, and recruiting other workers to the seed depot. Specific chemical releasers are known for each of these reactions, although only a relatively small number of species have been evaluated (Bradshaw and Howse, 1984). The fate of a seed is related to whether the elaiosome elicits feeding, necrophoric behavior, foraging, or recruitment, each of which may have chemical releasers.

The two previous studies of ants' response to elaiosomes disagree about the chemical that stimulates carrying behavior. Bresinsky (1963) identified ricinoleic acid as the primary stimulus for *Lasius fuliginosus* to carry elaiosomes of several plants, including *Viola odorata* (Violaceae). Marshall et al. (1979) found that the ant *Aphaenogaster rudis* did not respond to ricinoleic acid. Instead, they identified 1,2-diolein as the specific and only compound from *Viola odorata* elaiosomes that elicited carrying behavior.

Our study has two purposes. The first is to test whether the elaiosomes of *Hepatica americana* (Ranunculaceae) contain factors to elicit seed-carrying behavior and identify the active components. Second, we have modified the bioassay techniques reported by Marshall et al. (1979) to eliminate the need to define a complex behavioral index and the associated requirement of long periods of direct observation.

METHODS AND MATERIALS

Organisms. Hepatica americana is a spring-flowering, perennial herb, common in wooded habitats from Nova Scotia to northern Florida and west to Manitoba, Iowa, and Missouri. The flowers are without nectar, frequently opening before the last snows of spring, and seeds are produced through autogamy (Motten, 1982). Flowers in an outdoor experimental plot in Ohio produced an average of 9.7 seeds per flower (maximum = 20, $N = 54$). Seeds mature by late May and are dispersed by early June in Ohio and West Virginia.

The seeds are 5 mm long, 2 mm wide, and carry a lipid-rich elaiosome at one end.

Pogonomyrmex rugosus inhabits arid habitats from western Texas to southern Nevada and in central California between elevations of 240 and 1300 m (Snelling and George, 1979). It is a common harvester ant, which is primarily a seed eater, although it may eat insects. Seeds are taken to large nests, and in certain conditions stored seeds may sprout before being consumed (Wheeler, 1910; Creighton, 1950; Davidson, 1977). Consequently, seed harvesting may confer dispersal benefits, as has been documented for *Pogonomyrmex californicus* (Bullock, 1974; O'Dowd and Hay, 1980).

This combination of plant and ant species was chosen to test the generality of previously reported chemical stimulation of seed carrying by ants. Further, *P. rugosus* is readily available through commercial sources, reducing the seasonal problems of obtaining colonies. Ant colonies (Carolina Supply Co.) were maintained in plastic boxes (27 × 35 cm). The boxes had a plaster floor, and the sides were coated with Fluon to prevent the ants from escaping. At one side of each box, a test tube covered with aluminum foil and containing moistened cotton was used as an artificial nest.

Bioassay. The index of attractiveness was the distance a test item was moved by ants. Test items included whole seeds, seeds without elaiosomes, detached elaiosomes, and inert cubes containing elaiosome extract. Each assay was performed with 10 test items by placing them in the nest box at the end farthest from the ant nest. The origins of the test items were marked. After test items were exposed to ants for 60 min, we measured the distance each item was moved. This scoring method was used because the ants moved the majority of items at least 1 cm and because no assumptions were needed about the "intensity" of different ant behavioral categories (Marshall et al., 1979). Distances of movement were compared by analysis of variance with group differences determined by the T method (Sokal and Rohlf, 1981).

Polyporous strips (BioQuip Company) were cut into cubes approximately the size of a *H. americana* seed. The cubes were washed in methanol, then chloroform, and finally diethyl ether, then dried at 50°C. (Kuskis, 1978). Each cube was given a unique number. Both size and texture allowed ants to pick up cubes with their mandibles.

We used three controls: polyporous cubes washed and numbered as above; similar cubes with 5 μl chloroform added (the carrier used for elaiosome extracts); and *H. americana* seeds from which the elaiosomes had been removed. The last control tested for chemical stimulation of seed movement, as compared to ants' response to seed shape or texture.

Extraction and Identification of Attractant. Hepatica americana plants were obtained from Burpee Seed Co. Flowering was induced by maintaining potted

plants at 7°C during the day (8 hr) and 2°C at night (16 hr), then shifting daylength to 12 hr with temperatures of 21°C and 18°C. Harvested seeds were stored under nitrogen gas at −25°C in the presence of BHT to prevent autoxidation and transesterification reactions among unsaturated lipids (Wren and Szczepanowska, 1964).

The extraction process and associated bioassays were done twice. Total lipids were isolated by homogenizing elaiosomes according to Folch et al. (1957) at 0°C with a 2:1 (v/v) chloroform–methanol mixture containing 0.05% BHT. The tissue fraction was diluted to 20-fold the original volume of the tissue sample. After equilibrium at 24°C, the homogenate was filtered through a fatfree paper. The crude extract was washed by adding 0.2 its volume of chloroform–methanol–water (3:48:47) containing 0.02% $CaCl_2$. The extract was centrifuged at 4°C for 10 min at 2400 rpm; the upper phase was removed, and the interface was rewashed. Finally, the lower phase and the remaining upper phase were made into one phase by adding methanol. Nitrogen gas was used to evaporate solvent from the extract, which was then stored at −25°C.

Polar and nonpolar lipids were separated using a silicic acid column (Mallinckrodt silicic acid, 325 mesh) (Hirsh and Ahrens, 1958). The mixture of lipids was dissolved in as small a volume of chloroform as possible and pipetted onto the column. The separation was done with 150 ml chloroform (for nonpolar lipids) and then 150 ml methanol (for polar lipids).

Neutral glycerides were separated by thin-layer chromatography. Plates (Eastman Kodak Co. Chromagram Sheets, 100-μm-thick silica gel) were activated for 30 min at 115°C, then cooled to room temperature. Samples of 5 μl were dried under nitrogen gas. Neutral lipid separation was carried out at 5°C with two different solvent systems: hexane–diethyl ether–glacial acetic acid (30:70:1, v/v/v) and diethyl ether–isooctane (5:95, v/v; Wren, 1960). After chromatography, the solvent was evaporated from the plate with nitrogen (Skipski et al., 1965).

Lipid spots on the chromatograms were tentatively identified with iodine vapor, using reference compounds for orientation. The technique allowed detection of 0.1 μg of lipid (Simms and Larose, 1962). Lipids were eluted from the silica gel by scraping off the undetected lipid band from one plate at a location corresponding to an iodine-detected band from another plate. The lipids were extracted from the gel with 5 ml chloroform–methanol (4:1, v/v) and centrifuged to settle the gel (Kuskis, 1978). The extract was decanted and the procedure repeated with two further aliquots of diethyl ether (Skipski and Barclay, 1968). The extracts were combined and evaporated under nitrogen to a volume of 1 ml.

The TLC fractions were separated into mono-, di-, and triglycerides using HPLC. A commercially packed Radial Pak-Silica column, with 10-μm spheri-

cal particles (Waters Assoc.) was used. A mobile phase mixture of HPLC-grade hexane–isopropanol (95:5, v/v) was used at a flow rate of 1.0 ml/min, generating 350 psi within the system. The standards used were α-monopalmitin, diolein, and tristearin obtained from Sigma Chemical Company. Standards were dissolved in chloroform at 10 mg/ml and stored at $-25°C$ until used.

For gas chromatographic analysis, fatty acid methyl esters were prepared from the diglyceride fraction of the nonpolar lipids using BF_3–methanol (Metcalfe and Schmitz, 1961). The fatty acid methyl esters were separated on a Hewlett-Packard gas chromatograph-700 series with a 577-A Electrometer and a flame ionization detector. A stainless-steel column measuring 6 ft $\times$ $\frac{1}{8}$ in., packed with 10% SP-2330 on $\frac{100}{120}$ mesh Chromosorb W AW was used at 200°C with nitrogen as a carrier gas at 20 ml/min.

RESULTS

General Bioassay Results. Bioassay results were consistent for replicated extracts (for polar lipids, nonpolar lipids, and total lipids) and where different solvent systems were used for TLC (Table 1). Within treatments, coefficients of variation generally ranged between 10% and 40%.

The bioassay indicated four relatively homogeneous groups of treatments (Table 1). The controls, group I, were moved short distances if they were moved at all. These treatments included seeds with elaiosomes removed and polyporous strips washed with water or chloroform. At the other extreme, group IV treatments stimulated the most carrying behavior by ants. Items in this treatment group were usually carried the maximum distance, which was back to the ant nests. Included in Group IV were intact seeds, isolated elaiosomes, crude extracts of nonpolar lipids, and TLC fractions 3 (hexane–diethyl ether–acetic acid solvent), and 10 (diethyl ether–isooctane solvent). These TLC fractions will be shown below to include diglycerides. Storage did not affect results, as indicated by the similarity between intact seeds and isolated elaiosomes. The intact seeds were assayed within hours after they were harvested, while the isolated elaiosomes were stored at $-25°C$ (with antioxidant) for at least seven days after they were removed from diaspores.

Items in treatment group III were moved modest distances (Table 1), but significantly less than those for group IV. Activity was expected for the first lipid extract (total lipids) because it included nonpolar lipids. TLC fractions 13 and 5 also stimulated some carrying activity; these fractions included free fatty acids, separated by using different solvent systems. Finally, items from the group II treatments were investigated by ants, but not carried back to the nest. This group included polar lipids, mono- and triglycerides, and cholesterol.

TABLE 1. MOVEMENT OF BIOASSAY UNITS BY ANTS INDUCED BY COMPONENTS OF *Hepatica americana* SEEDS[a]

Treatment	Distance moved, cm (95% CI)	Homogeneous groups ($P < 0.05$)	Group
Water-washed polyporous cubes	0.8 (0.17)		I
$CHCl_3$-washed polyporous cubes	0.9 (0.18)		
Seeds without elaiosomes	1.8 (0.51)		
Polar lipid extract B	3.6 (0.67)		II
TLC-ISO fraction 2 (monoglycerides)	4.0 (0.52)		
TLC-ISO fraction 4 (triglycerides)	4.1 (0.47)		
TLC-HEX fraction 4 (triglycerides)	4.3 (0.45)		
TLC-HEX fraction 2 (monoglycerides)	4.4 (0.50)		
TLC-ISO fraction 5 (cholesterol stnd)	4.4 (0.55)		
Polar lipid extract A	6.5 (1.26)		
TLC-ISO fraction 6 (free fatty acids)	10.0 (0.64)		III
TLC-HEX fraction 5 (free fatty acids)	11.8 (0.58)		
Polar + nonpolar lipid extract A	12.7 (1.75)		
Polar + nonpolar lipid extract B	13.6 (0.90)		
TLC-ISO fraction 3 (diglycerides)	16.2 (0.56)		IV
TLC-HEX fraction 3 (diglycerides)	16.3 (0.47)		
Elaiosomes without seeds	16.5 (1.42)		
Nonpolar lipid extract B	17.3 (0.58)		
Intact seeds	17.5 (1.68)		
Nonpolar lipid extract A	17.8 (0.79)		

[a] Average distances (measured in cm) are followed by the 95% confidence interval of the mean. TLC solvent systems used were ether–isooctane (ISO) and hexane–diethyl ether–acetic acid (HEX). Lines connecting treatments indicate statistically indistinguishable distances moved (T method, Sokal and Rohlf 1981). Replicated extracts are indicated by A and B.

Identification of TLC Fractions. Both solvent systems showed two fractions of nonpolar lipids with significant potency to stimulate ant carrying behavior (Figure 1). From the plates run in hexane–diethyl ether–acetic acid (Figure 1A), both standards and HPLC indicated fraction 2 to be monoglycerides, fraction 3 to be diglycerides, and fraction 4 to be triglycerides. Fractions 2, 3, and 5 from the diethyl ether–isooctane solvent system (Figure 1B) corresponded to mono-, di-, and triglycerides. The fraction with the most activity in both solvent systems was diglycerides.

Gas chromatography of the active (diglyceride) fractions from both solvent systems (Figure 2) showed them to have peak retention times identical to oleic acid (18:1). This implicates either 1,2- or 1,3-diolein as the most common

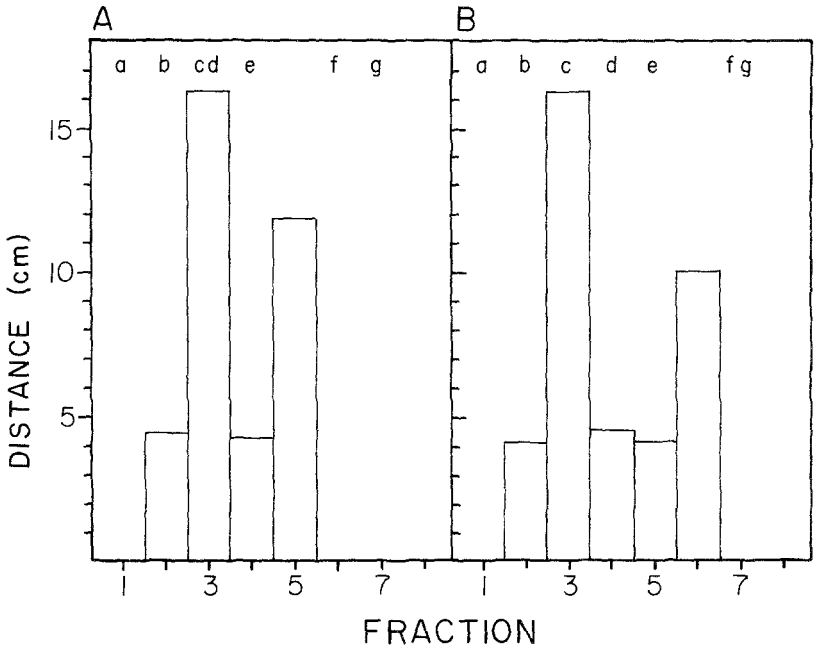

FIG. 1. Bioassay activity of fractions of nonpolar lipid extracts from thin-layer chromatography. The standards used for TLC separation were: α-lecithin (a), α-monopalmitin (b), diolein (c), cholesterol (d), tristearin (e), BHT (f), and squalene (g). The activity for each fraction is expressed as the average distance an inert cube coated with the fraction was moved by *Pogonomyrmex rugosus*. (A) Solvent = hexane–diethyl ether–acetic acid (30:70:1, v/v/v); (B) solvent = 5% diethyl ether in isooctane (v/v).

compound in the bioassays, although other fatty acids were observed, especially from the diethyl ether–isooctane solvent system.

The diglyceride fractions were not the only fractions of nonpolar lipids eliciting significant carrying behavior by ants. Fractions 5 (hexane–diethyl ether–acetic acid solvent) and 6 (diethyl ether–isooctane solvent) induced carrying behavior, but at a lower intensity than diglycerides (Table 1). These fractions had R_fs from the TLC plates that would correspond to hydrocarbons, esters, or fatty acids (Wren, 1960). Gas chromatography of the methyl esters showed that both fractions contain large peaks of 18-carbon, unsaturated fatty acids (Figure 3). The fatty acids represented were oleic (18:1), linoleic (18:2), and linolenic (18:3).

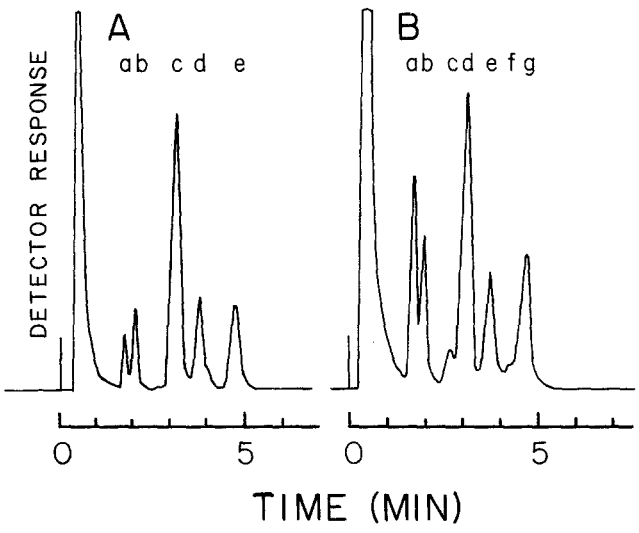

FIG. 2. Gas chromatography of methyl esters of fatty acids from diglycerides that were isolated with TLC. (A) From TLC fraction 3, using hexane–diethyl ether–acetic acid solvent. Identified fatty acids included palmitoleic (a), stearic (b), oleic (c), linoleic (d), and linolenic (e). (B) From TLC fraction 3, using ethyl ether–isooctane solvent. Identified fatty acids included palmitic (a), palmitoleic (b), stearic (c), oleic (d), linoleic (e), arachidonic (f), and linolenic (g).

DISCUSSION

Our bioassay for chemical inducement of carrying is simpler than previous measures. Marshall et al. (1979) used an index based on specific behaviors of the ants as they responded to test substances. Others (Gordon, 1983; Wilson et al., 1958; Howard and Tschinkel, 1976) have used the frequency of movement of test items. Using distances has several advantages. During tests, ant colonies do not have to be directly observed for hours, allowing more tests to be conducted simultaneously. Our bioassay yields ratio data that are more easily interpreted and replicated than indices based on behavioral categories. Distances also provide more information on the degree of ant reaction than scoring test items as moved or not moved.

Interpreting any bioassay using ant behavior requires consideration of ant social behavior. The social context of an ant colony can influence workers' responses to chemicals. For example, the activity patterns of *Pogonomyrmex badius* colonies influenced the deposition sites of pieces of filter paper covered with oleic acid (Gordon, 1983). Variation added by different social situations

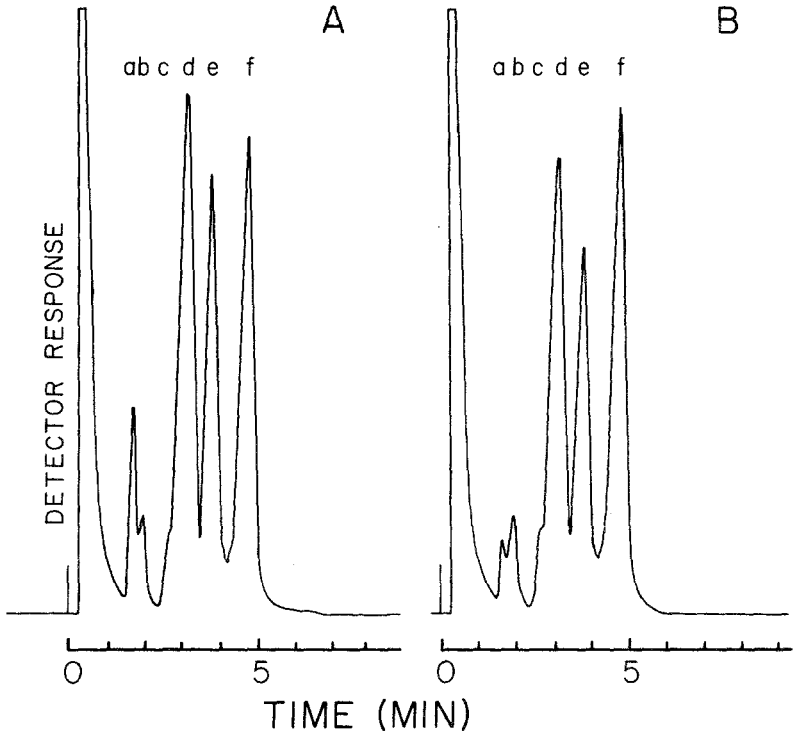

FIG. 3. Gas chromatography of methyl esters of free fatty acids isolated with TLC. (A) From TLC fraction 5, using hexane–diethyl ether–acetic acid solvent. (B) From TLC fraction 6, using diethyl ether–isooctane solvent. Identified peaks from both A and B are: palmitic (a), palmitoleic (b), stearic (c), oleic (d), linoleic (e), and linolenic (f) acids.

should be minimal in our bioassay for the following reasons. First, all ants were workers so there were no differences among colonies or through time as a result of a developing brood. Second, the ants were maintained in artificial nests, minimizing nest repair behavior. Finally, knowing the specific deposition site (nest vs. refuse pile or in between) is not critical for determining components of seeds that elicit carrying behavior. Consequently the simple measurement of distances is adequate for this purpose and has the advantages mentioned above.

Diglycerides on *Hepatica americana* seeds are responsible for their attractiveness to *Pogonomyrmex*. Given the predominance of oleic acid in the gas chromatographic analysis of the diglyceride fraction, diolein was the most common diglyceride isolated for *Hepatica americana* elaiosomes. This parallels the

findings of Marshall et al. (1979) that the primary active portion of *Viola odorata* elaiosomes is 1,2-diolein. They also report that 1,3-diolein does not elicit seed-carrying by *Aphaenogaster rudis*. Although the free fatty acid fraction also stimulated some carrying, this was only about 60% as effective as the isolated diglycerides. Intact seeds, isolated elaiosomes, and diglycerides showed the same level of activity in the bioassay, so free fatty acids do not add measurably to ants' response to fresh *Hepatica* seeds. In the absence of diglycerides, however, free fatty acids should induce some seed carrying by ants.

Previous studies of the chemical nature of ant–seed interactions give conflicting results. Bresinsky's (1963) original work demonstrated the importance of lipids to stimulation of seed-carrying behavior. Using bioassays with standards, he identified the free fatty acid ricinoleic acid as a stimulant but did not mention diglycerides. Amounts of ricinoleic acid sufficient to stimulate seed carrying by *Lasius fuliginosus* were isolated from two *Luzula* spp., *Melica nutans*, *Veronica hederifolia*, and four *Viola* spp. Marshall et al. (1979) observed no response of *Aphaenogaster rudis* to ricinoleic acid, but these ants responded strongly and specifically to the diglyceride 1,2-diolein. In their study, ricinoleic acid was clearly not an active compound in elaiosomes of *Viola odorata* (a species studied by Bresinsky). Ours is the third study of this phenomenon, and our results for *Hepatica americana* and *Pogonomyrmex* point to 1,2-diolein (or at least a similar diglyceride) as the primary attractant; although free fatty acids from *H. americana* attracted ants, we could not identify a significantly large amount of ricinoleic acid in *H. americana* elaiosomes. A conservative conclusion is that the basis for seed carrying varies with species of plant, ant, or both. Alternately, Bresinsky (1963) may have missed the major source of natural attraction in the species he studied because diglycerides were not included in that research program.

The stimulation of seed-carrying behavior is different from mechanisms promoting other kinds of ant feeding and carrying behavior. Feeding behavior in *Solenopsis* is released by a variety of compounds, but neither ricinoleic acid nor diolein are phagostimulants (Vinson et al., 1967; Vinson, 1972). In terms of dispersal, direct stimulation of feeding would potentially inhibit the carrying of seeds back to nests. Corpse-carrying behavior is stimulated by oleic acid for *Solenopsis* spp. (Wilson et al., 1958; Blum, 1970; Howard and Tschinkel, 1976), *Myrmica vindex* (Blum, 1970), and *Pogonomyrmex badius* (Gordon, 1983). Oleic acid did not stimulate seed-carrying behavior for *Aphaenogaster rudis* (Marshall et al., 1979). *Pogonomyrmex rugosus*, in this study, may have showed a weak response to the fatty acid fraction, perhaps because it contained oleic acid. In nature, responding to seeds as "corpses" would probably result in movement of seeds to refuse piles rather than into ant nests. The nutritional benefit of elaiosomes to larvae would then be lost.

One proposal to explain why ants carry elaiosome-bearing seeds to nests

is that the chemical stimulants of carrying in elaiosomes mimic (or are the same as) compounds that trigger ant responses to arthropod prey (Carroll and Janzen, 1973; Horvitz and Beattie, 1980). Alternatively, brood-tending behavior may be related to seed carrying. Bigley and Vinson (1975) concluded that triolein induces *Solenopsis invicta* to carry objects to brood chambers and to tend inert paper as they would treat sexual brood. In their experiments, diolein evoked similar behavior, but at a lower intensity. There are insufficient data to test hypotheses about why ants as taxonomically different as *Pogonomyrmex rugosus* and *Aphaenogaster rudis* should show similar responses to diolein. Many other ant species pick up elaiosomes and seeds (Beattie, 1985), so this chemical mechanism (or mechanisms) may be widespread.

(Received February 2, 1987; accepted October 15, 1987)

Abstract—A comparative analysis of the venom alkaloids produced by ants in the genus *Monomorium* (=*Chelaner*) collected on North Island and South Island, New Zealand, has been undertaken. All of the ants produce *trans*-2,5-dialkylpyrrolidines along with 3,5-dialkylpyrrolizidines. The structures and sterochemistry of the novel alkaloids *trans*-2-butyl-5-(8-nonenyl)pyrrolidine, (5*E*,8*Z*)-3,5-di(5-hexenyl)pyrrolizidine, and (5*Z*,8*E*)-3-methyl-5-(8-nonenyl)pyrrolizidine were established by unambiguous synthesis. The geographic distribution and the chemotaxonomic significance of the alkaloids produced by these ants are discussed.

Key Words—Ants, *Monomorium*, Hymenoptera, Formicidae, 2,5-dialkylpyrrolidines, 3,5-dialkylpyrrolizidines, ant venom alkaloids, chemotaxonomy.

INTRODUCTION

A large variety of saturated nitrogen heterocycles has been identified in the venoms of ant species in the myrmicine genera *Monomorium* and *Solenopsis* (Jones et al., 1982b). 2,6-Dialkylpiperidines and 2,5-dialkylpyrrolidines are most commonly found, and (5*Z*,9*Z*)-3-alkyl-5-methylindolizidines have also been reported from both genera (Ritter and Persoons, 1975; Jones et al., 1984). On the other hand, except for the occurrence of (5*Z*,8*E*)-3-heptyl-5-methylpyrrolizidine in a *Solenopsis* sp. (Jones et al., 1980b), the 3,5-dialkylpyrrolizidine system has not been detected in the alkaloids produced by any other formicid species.

Recently we isolated and identified (5*E*,8*Z*)-3-(8-nonenyl)-5-(*E*,1-propenyl)pyrrolizidine (**5**) as the major alkaloidal component in the venom of *Monomorium* (=*Chelaner*) *antarcticum* (Jones et al., 1986; Bolton, 1987). In order to determine whether these results were typical of other *Monomorium* populations, we have analyzed the alkaloidal extracts of single-nest collections from 28 locations on North and South Island, New Zealand (Figure 1). The results show that there are major differences in the alkaloids produced by different populations. A variety of pyrrolidines and pyrrolizidines have been detected, and the structures and sterochemistry of one novel pyrrolidine and two novel pyrrolizidines from these ants have been established. These results further indicate that the venom alkaloids of these ants may provide useful taxonomic characters.

METHODS AND MATERIALS

Chemical Analyses. Gas chromatographic analyses were performed on a Gow-Mac model 750P using a 2-m × 2-mm-ID glass column packed with 5% SP-1000 on 100–120 mesh Supelcoport. This instrument was programmed from 40°C to 200°C at 10°C/min as soon as the solvent had eluted. Retention times and temperatures were found to be reproducible within one degree on a given day. Preparative gas chromatography was performed on a Varian model 920 using a 2-m × 5-mm-ID aluminum column packed with either 10% SP-2100 or 10% SP-1000 on 100–120 mesh Supelcoport. Infrared spectra were obtained from neat liquid films with a Perkin-Elmer 1320 grating infrared spectrophotometer. [^{1}H]NMR spectra were obtained from $CDCl_3$ solutions at 80 MHz using a Varian FT-80 spectrometer and at 360 MHz using a Nicolet 360-MHz spectrometer. Chemical shifts (δ) are reported downfield from tetramethylsilane in parts per million (ppm). Mass spectra were obtained using an LKB-9000 GC-MS at an ionizing voltage of 70 eV and fitted with a 2-m × 2-mm-ID glass column packed with 1% SP-1000. High-resolution mass spectra were obtained

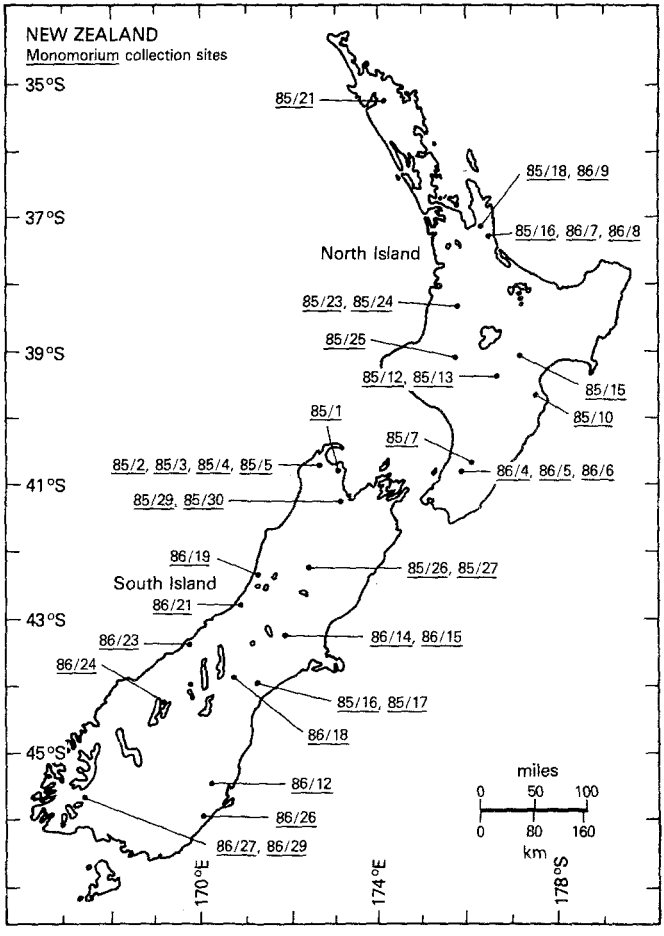

FIG. 1. Map of New Zealand showing the *Monomorium* collection sites.

using a VG-7070F in the EI mode at an ionizing voltage of 70 eV. Melting points are uncorrected.

Ants. The ants were collected during the summer months (December–February) of 1984–1985 and 1985–1986 at the sites indicated on the map. Each collection (Table 1) of ca. 100–200 workers of *Monomorium* sp. was made from a separate nest and immediately placed in a vial containing 1–2 ml of methylene chloride. In addition, five to nine individual queens from nests 85/24, 85/25, 85/26, 85/27, and 86/17 were also collected and stored separately. For analyses, these mixtures were reduced to ca. 0.2 ml with a slow stream of nitrogen.

[a] * = major component; + = minor component (10–15%); 0 = trace; – = not detected.

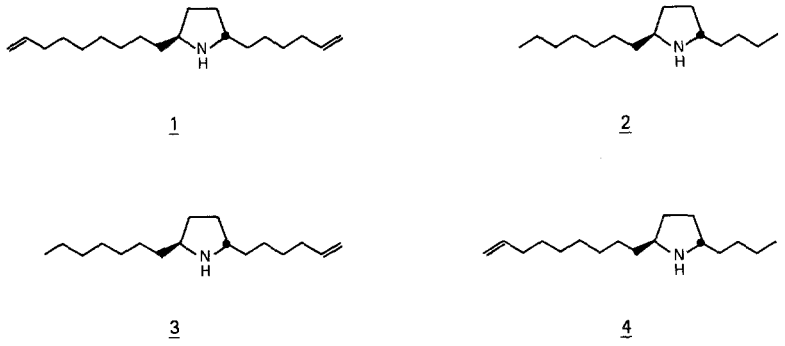

FIG. 2. Structures of alkaloids 1–4.

Where they were major or minor components, the structures of alkaloids **1–9** (Fig. 2 and 3) were assigned by comparison of their mass spectra and gas chromatographic retention times with those of authentic samples. Compounds **1, 2, 5,** and **6** were available from previous studies (Jones et al., 1980a, 1986). The mass spectrum observed for (5*E*,8*Z*)-3-(8-nonenyl)-5-(*E*,1-propenyl)pyrrolizidine (**5**) was as follows: *m/z* (rel intensity) 275(2, M+), 274(2), 271(1), 260(1), 246(1), 244(1), 234(1), 160(2), 151(11), 150(100), 122(6), 110(1), 109(2), 108(3), 107(3), 106(1), 105(1), 95(1), 94(1), 91(1), 82(5), 81(4), 80(4), 80(4), 79(8), 70(2), 69(3), 68(9), 67(7), 56(3), and 55(12). The

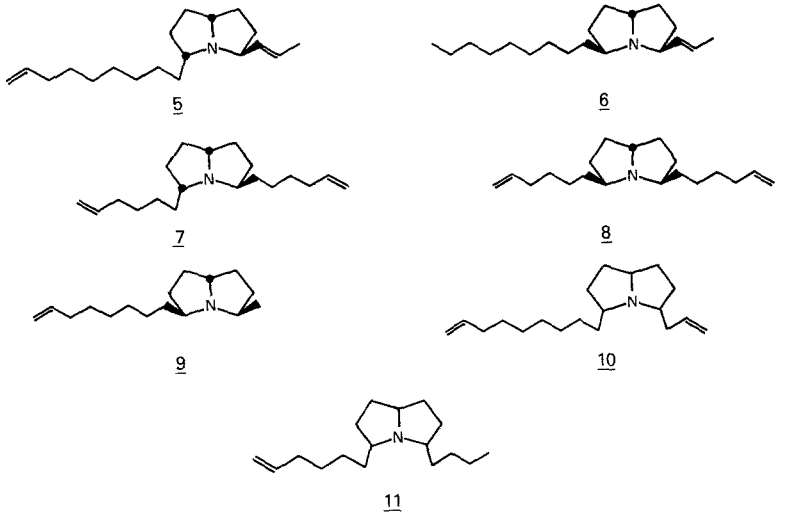

FIG. 3. Structures of alkaloids 5–11.

preparations of **3, 4, 7, 8,** and **9** are described herein. A small amount (ca. 0.1 mg) of the major alkaloidal component from collection 85/4 was obtained by preparative gas chromatography. The 360-MHz ^{1}H spectrum showed only the signals at δ = 5.7 (d of d of t, J = 18, 10, and 6 Hz), 5.0 (br d, J = 18 Hz), and 4.9 (br d, J = 10 Hz) in the olefinic region of the spectrum.

In collection 85/21, the structure of a minor component, 3-allyl-5-(8-nonenyl)pyrrolizidine (**10**), was suggested by its mass spectrum: *m/z* (rel intensity) 275(2, M+), 274(1), 271(0.5), 234(100), 160(0.5), and 150(30). In collections 85/26 and 86/27 a minor component, 3-butyl-5-(5-hexenyl)pyrrolizidine (**11**), was also suggested by its mass spectrum: *m/z* (rel intensity) 249(6, M+), 248(3), 245(6), 202(18), 193(12), 192(76), 176(17), 167(10), 166(100), and 124(5).

1-Heptadecen-7,10-dione(12a). A solution containing 2.9 g of 1-dec-3-one (19 mmol), 2.1 g of 6-heptenal, and 0.5 g of 5-(2′-hydroxyethyl)-4-methyl-3-benzylthiazolium chloride in 3 ml of triethylamine was heated to reflux overnight under a nitrogen atmosphere. After the usual work up, Kugelrohr distillation (0.01 mm Hg) gave 3.0 g (60%) of solid diketone **12a:** mp 48–49°C; NMR δ = 5.8 (1H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 2.67 (4H, s), 2.45 (4H, t, J = 6.8 Hz), 2.05 (2H, m), 1.6–1.26 (14H, m), and 0.87 (3H, br t); MS *m/z* (rel. intensity) 266(3, M+), 211(15), 198(33), 183(22), 182(6), 167(5), 155(36), 154(20), 140(13), 139(20), 136(10), 127(74), 114(38), 111(37), 107(22), 95(48), 83(49). 81(19), 71(50), 69(43), 68(20), 67(33), 57(65), 55(81), 43(94), and 41(100). Calculated for $C_{17}H_{30}O_2$, 266.2246; observed, 266.2226.

2-Heptyl-5-(5-hexenyl)pyrrolidine (Monomorine IV) (3). A solution containing 1.0 g (3.8 mmol) of diketone **12a,** 0.3 g of ammonium acetate, 0.3 g of sodium cyanoborohydride, and 0.05 g of potassium hydroxide in 15 ml of methanol was stirred overnight under a nitrogen atmosphere. The usual work up provided 0.7 g of an oily product that was greater than 90% pure by gas chromatographic analysis. Gas chromatography on a 5% SP-1000 column showed two isomeric components having retention times of 3.0 and 3.2 min under isothermal conditions (200°C), and having identical mass spectra. MS *m/z* (rel intensity) 251(5, M+), 250(2), 194(8), 181(5), 178(7), 169(10), 168(90), 153(12), 152(100), 96(7), 86(4), 84(8), 83(8), 82(19), 69(9), 67(10), 55(12), and 41(13). Calculated for $C_{17}H_{23}N$, 251.2613; observed, 251.26099.

16-Heptadecen-5,8-dione(12b). A mixture containing 0.9 g (8 mmol) of 1-hepten-3-one, 1.2 g of 9-decenal, and 0.26 g of 5-(2′-hydroxyethyl)-4-methyl 3-benzylthiazolium chloride in 2.5 ml of triethylamine was heated to reflux overnight under a nitrogen atmosphere. After the usual work up, 2.0 g of crude (ca. 85% pure by GLC analysis) diketone **12b** was isolated. Preparative GLC provided a sample with the following physical characteristics: mp 49–50°C; δ = 5.8 (1H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (1H, br, d, J = 18 Hz),

4.9 (1H, br d, J = 10 Hz), 2.66 (4H, s), 2.44 (4H, br t), 2.02 (2H, br m), 1.28 (14H, br m), 0.89 (3H, br t); MS *m/z* (rel intensity) 266(3, M±), 224(7), 209(12), 181(11), 169(3), 156(58), 153(8), 141(68), 127(30), 114(46), 113(40), 95(36), 85(89), 83(85), 81(30), 71(46), 69(58), 67(34), 57(89), 55(96), 43(32), and 41(100). Calculated for $C_{17}H_{30}O_2$, 266.2246; observed, 266.22309.

2-Butyl-5-(8-nonenyl)pyrrolidine(4). A mixture containing 1.0 g of diketone **12b,** 0.3 g of ammonium acetate, and 0.25 g of sodium cyanoborohydride in 15 ml of anhydrous methanol was stirred overnight under a nitrogen atmosphere. After the usual work up, 0.8 g of an oily product was obtained that was ca. 85% pure by GLC analysis. Gas chromatographic analysis (5% SP-1000 column at 200°C) showed two components having retention times of 3.2 and 3.6 min, respectively, with identical mass spectra: MS *m/z* (rel intensity) 251(1, M+), 250(2), 220(1), 208(2), 207(2), 206(2), 195(12), 194(77), 180(1), 166(2), 152(6), 127(12), 126(100), 96(4), 83(6), 82(18), 69(5), 68(5), 67(6), 55(13), and 41(12). Calculated for $C_{17}H_{33}N$, 251.2613; observed, 251.26025.

1,18-Nonadecadien-7,10,13-trione (13). A solution containing 10 g of 6-heptenal (89 mmol), 3.7 g of divinyl ketone (45 mmol), and 2.5 g of 5-(2′-hydroxyethyl)-4-methyl-3-benzylthiazolium chloride in 12 ml of triethylamine was mechanically stirred and heated under a nitrogen atmosphere to 70°C overnight. After the work up, the crude triketone was recrystallized from methanol to give 7.6 g of white crystals: mp 72–74°C; NMR δ = 5.8 (2H, d of d of t, J = 8, 10 and 6 Hz), 5.0 (2H, br d, J = 18 Hz), 4.9 (2H, br d, J = 10 Hz), 2.70 (8H, s), 2.45 (4H, br t, J = 7 Hz), 2.01 (4H, M), 1.5 (8H, m); MS *m/z* (rel intensity) 306(6, M+), 288(8), 238(26), 223(12), 220(18), 210(6), 195(30), 177(10), 167(12), 163(16), 139(30), 127(48), 121(12), 111(90), 107(46), 99(18), 83(50), 71(10), 69(24), 68(16), 67(28), 55(100), and 41(50). Calculated for $C_{19}H_{30}O_3$, 306.2194; observed, 306.2175.

Reductive Amination of 13. A solution containing 1.0 g of triketone **13** (3.3 mmol), 0.25 g of ammonium acetate, 0.2 g of sodium cyanoborohydride, and 0.05 g of potassium hydroxide in 50 ml of methanol was stirred overnight under a nitrogen atmosphere. After the usual work up, 0.6 g of an oily residue was obtained which was nearly 90% pure by GLC analysis. Gas chromatographic analysis (2-m × 2-mm column packed with 5% SP-1000 on Supelcoport) at 200°C showed three components, **14, 8,** and **7** in the ratio of 1:9:3, which had retention times of 2.8, 4.0, and 10.4 min, respectively. The three components had almost identical mass spectra: MS *m/z* (rel intensity) 275(4, M+), 271(2), 234(5), 202(5), 193(15), 192(100), 164(3), 122(4), 109(4), 108(5), 82(5), 81(6), 69(4), 68(8), 67(8), 67(16), 55(14), and 41(25). Calculated for $C_{19}H_{33}N$, 275.2613; observed, 275.2607.

The three isomers, eluting in the order **14, 8,** and **7,** were separated by preparative GLC (2-m × 5-mm column packed with 10% SP-1000 on Supelcoport) and [^{1}H]NMR spectra were obtained for each. All three showed signals

at δ = 5.8(2H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (2H, br d, J = 18 Hz), and 4.9 (2H, br d, J = 10 Hz). In addition to a broad multiplet from δ = 2.3–1.1 (24H), the three isomers showed the following signals in the δ = 4.0–2.5 region: **14,** none; **8,** δ = 3.6 (1H, br m), 2.6 (2H, br m); **7,** δ = 3.6 (1H, m), 2.94 (2H, br m).

16-Heptadecen-2,5,8-trione(15). A solution containing 1.54 g (10 mmol) of 9-decenal, 1.35 g of 6-hepten-3,5-dione, and 0.27 g of 5-(2′-hydroxyethyl)-4-methyl-3-benzylthiazolium chloride in 1.4 g of triethylamine was heated to reflux overnight under a nitrogen atmosphere. After the usual work up, 3.2 g of crude triketone **15** were obtained. A sample purified by sublimation had mp 59–62°C; NMR δ = 5.75 (1H, d of d of t, J = 18, 10, and 6 Hz), 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 2.65 (8H, s), 2.4 (2H, br t), 2.13 (3H, s), 2.08 (2H, m), and 1.25 (10H, m); MS *m/z* (rel intensity 280(4.M+), 262(2), 237(2), 219(1), 209(4), 181(3), 170(28), 155(12), 153(4), 152(27), 135(10), 127(100), 112(7), 111(8), 109(12), 99(85), 95(27), 94(8), 83(17), 81(12), 71(17), 69(24), 67(16), 55(46), 43(62), and 41(35). Calculated for $C_{17}H_{28}O_3$, 280.2038; observed, 280.2025.

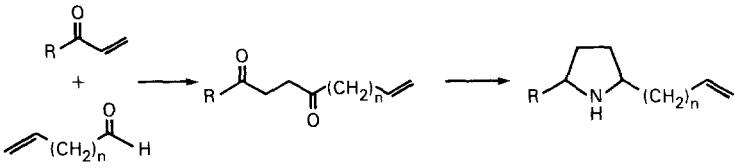
3-Methyl-5-(8-nonenyl)pyrrolizidine (9). A solution containing 1.48 g of triketone **15** (5.3 mmol), 0.51 g of ammonium acetate, 0.67 g of sodium cyanoborohydride, and 0.09 g of potassium hydroxide in 20 ml of methanol was stirred overnight under anhydrous conditions. After the usual work up, GLC analysis (2-m × 2-mm column packed with 5% SP-1000 of 100–120 Supelcoport) showed four components in the ratio 1:40:7:3 (in order of elution) having almost identical mass spectra. MS *m/z* (rel intensity) 249(3,M+), 248(2), 245(0.5), 234(10), 220(2), 180(2), 166(2), 152(2), 138(1), 134(2), 125(11), 124(100), 110(3), 84(5), 81(6), 55(7), and 41(10). Calculated for $C_{17}H_{31}N$, 249.2456; observed, 249.2450.

Samples of the first and second eluting isomers were obtained by preparative GLC (2-m × 5-mm column packed with 10% SP-1000 on 100–120 Suplecoport). The IR spectrum of the first eluting isomer had important bands at 3080, 2915, 2860, 2790, 2700, 2680, 1640, 990, and 905 cm^{-1}. The second eluting, major isomer had NMR δ = 5.8 (1H, d of d of t, J = 18, 10, and 6 HZ), 5.0 (1H, br d, J = 18 Hz), 4.9 (1H, br d, J = 10 Hz), 3.6 (1H, br m), 2.65 (2H, brm), 1.9 (6H, br m), 1.29 (16H, m), and 1.09 (3H, d, J = 5.7 Hz).

RESULTS

The distribution of alkaloids found in the *Monomorium* population samples is shown in Table 1, and the structures of these compounds are depicted in Figures 2 and 3. The pyrrolidines **1–4** are characterized from their mass spectra, which show a pair of intense even mass peaks resulting from α-cleavage of side

chains and a weak molecular ion of odd mass: 2-(5-hexenyl)-5-(8-nonenyl)pyrrolidine (**1**), *m/z* = 277(M+), 194(100), and 152(83); 2-butyl-5-heptylpyrrolidine (**2**), *m/z* = 225(M+), 168(100), and 126(80); 2-heptyl-5-(5-hexenyl)pyrrolidine(**3**), *m/z* = 251(M+), 168(90), and 152(100); 2-butyl-5-(8-nonenyl)pyrrolidine(**4**), *m/z* = 251(M+), 194(77), and 126(100). Pyrrolidines **1** and **2** were available from previous investigations (Jones et al., 1980a, 1982a), and pyrrolidines **3** and **4** were prepared by the previously described methodology based on the reductive amination of the corresponding 1,4-diketones (Scheme 1). The synthetic compounds **1–4** obtained in this manner are nearly



12a; R = C_7H_{15}, n = 4 3; R = C_7H_{15}, n = 4
12b; R = C_4H_9, n = 7 4; R = C_4H_9, n = 7

SCHEME 1.

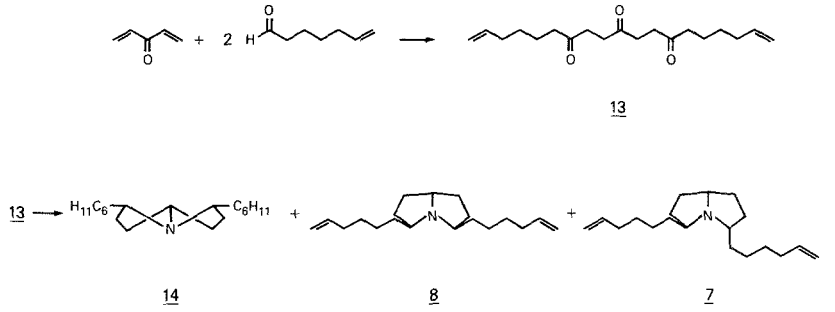
a 1:1 mixture of *cis*- and *trans*-2,5-dialkylpyrrolidine stereoisomers, with the *cis* isomer eluting first from a SP-1000 GC column (Jones et al., 1979; Pedder et al., 1976). In all the ant extracts providing more than trace amounts, direct comparison showed that the natural pyrrolidines **1–4** had gas chromatographic retention times identical with those of the later eluting *trans* isomers.

The 3,5-dialkylpyrrolizidines **5** and **7** are the characteristic major alkaloidal components from all the *Monomorium* collections studied except for collection 85/21 wherein the major alkaloid was pyrrolizidine **9.**

The structure elucidation and synthesis of (5*E*, 8*Z*)-3-(8-nonenyl)-5-(*E*,1-propenyl)pyrrolizidine (**5**) and its 5*Z*,8*E* isomer (**6**) have been described (Jones et al., 1986). They are easily discerned by their mass spectra, *m/z* = 275(M+), and 150(100). All four possible pyrrolizidine stereoisomers are formed in the synthesis of **5** and **6**. Although the major product in that synthesis is the 5*Z*,8*E* isomer **6,** it is only present in trace amounts in the *Monomorium* collections where it was detected. On the other hand, the 5*E*,8*Z* isomer **5,** a minor product from the synthesis, is the major alkaloid in most of the *Monomorium* collections (Table 1).

In nearly one third of the *Monomorium* recollections, the major alkaloidal component appeared to be isomeric with pyrrolizidine **5,** having a mass spectrum [*m/z* = 275(M+), and 192(100)] that indicated only the loss of a C_6H_{11}

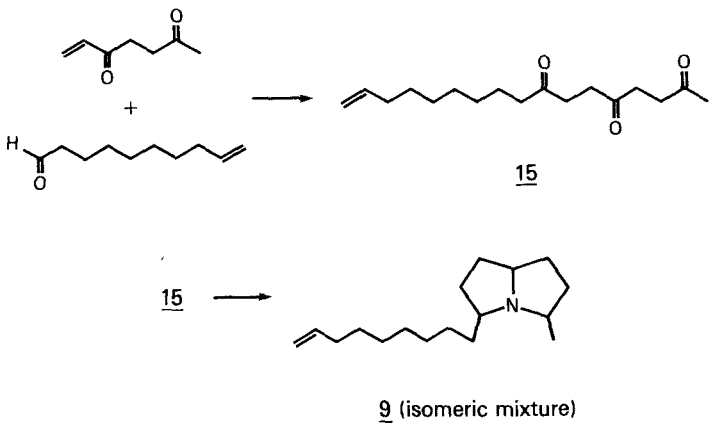
fragment. A very small amount of this compound was obtained from collection 85/4 by preparative gas chromatography. The 360-MHz proton NMR spectrum of this sample showed only the signals characteristic of a terminal double bond in the olefinic region. These results, including the simplicity of the mass spectrum, suggested a symmetrically substituted 3,5-di(5-hexenyl)pyrrolizidine. This assignment was confirmed by the synthesis outlined in Scheme 2. Divinyl



SCHEME 2.

ketone condensed with two equivalents of 6-heptenal in the presence of triethyl amine and a thiazolium salt catalyst (Jones et al., 1980a; Stetter et al., 1977) to form 1,18-nonadecadien-7,10,13-trione (**13**). Reductive amination of triketone **13** with ammonium acetate and sodium cyanoborohydride gave the three possible 3,5-di(5-hexenyl)pyrrolizidines eluting in the order **14, 8,** and **7** (SP-1000 column) in 1:9:3 ratio. These compounds had essentially identical mass spectra, which matched the mass spectra of the natural materials. The stereochemistry of these isomers was readily assigned from their [^{1}H]NMR spectra (Jones et al., 1980b). Pyrrolizidine **14** had no C<u>H</u>-N methine signals below δ = 2.5 ppm, which is indicative of a *trans*-fused pyrrolizidine, whereas **7** and **8** had a multiplet at δ = 3.6 ppm typical of the C_8 proton of *cis*-fused pyrrolizidines. The 5*Z*,8*E* isomer **8** and the 5*E*,8*Z* isomer **7** had two-proton multiplets at δ = 2.6 and 2.94 ppm, respectively, characteristic of their configurations (Jones et al., 1980b). The major 3,5-di(5-hexenyl)pyrrolizidine in these *Monomorium* extracts had a gas chromatographic retention time identical to that of **7,** and traces of **8** were found in some of the collections containing **7** (Table 1).

The mass spectrum of the major alkaloid in the extracts from collection 85/21 had a parent ion at *m/z* = 249 and fragments at *m/z* 234(10) and 124(100), indicating the loss of CH_3 and C_9H_{17}, respectively. It was otherwise quite similar to the mass spectrum of the known 3-heptyl-5-methyl pyrrolizidine (Jones et al., 1980b). Its structure and stereochemistry were confirmed as (5*Z*,8*E*)-3-



SCHEME 3.

methyl-5-(8-nonenyl)pyrrolizidine (**9**) by the synthesis outlined in Scheme 3. The appropriate triketone, 16-heptadecen-2,5,8-trione (**15**) was formed in good yield by the condensation of 6-hepten-3,5-dione (Stetter and Landscheidt, 1979) and 9-decenal (Jones et al., 1982a) in the presence of triethylamine and a thiazolium salt catalyst. Reductive amination of **15** produces all four pyrrolizidine isomers in a 1:40:7:3 ratio. The infrared spectrum of the first eluting isomer was typical of a *trans*-fused pyrrolizidine, with Bohlmann C–H bands from 2860 to 2680 cm^{-1}, similar to those of the *trans*-fused isomer of 3-heptyl-5-methylpyrrolizidine (Jones et al., 1980b). The second eluting, major synthetic isomer had a mass spectrum and gas chromatographic retention time identical with those of the major alkaloid in collection 85/21. The proton NMR spectrum of this compound had a one-proton multiplet at $\delta = 3.6$ ppm and a two-proton multiplet at $\delta = 2.6$ ppm, which verify its assignment as the *cis*-fused (5*Z*,8*E*)-3-methyl-5-(8-nonen-1-yl) pyrrolizidine (**9**).

Collection 85/21 also contained small amounts of the *trans*-pyrrolidines **2** and **4** as well as the pyrrolizidine **5.** In addition, a minor component was detected whose mass spectrum [m/z = 275(M+), 234(100), and 150] suggests that it is 3-allyl-5-(8-nonenyl)pyrrolizidine (**10**), and isomer of **5.** The facile loss of 41 ($M-C_3H_5$) would be expected for structure **10,** where it would be an α-cleavage (to nitrogen) as well as cleavage allylic to a double bond. Since **10** is only a minor component, its structure could not be confirmed by other means, and its sterochemistry remains undetermined.

In collections 85/26 and 85/27, a significant component in the alkaloidal extracts is *trans*-2-heptyl-5-(5-hexenyl)pyrrolidine (**3**) (Monomorine IV), which has been reported as a component of the alkaloidal venom of pharoh's ant (*Monomorium pharaonis*) (Ritter et al., 1975). Additionally, a minor component in

collection 85/26 has a mass spectrum [*m/z* 249(M+), 192, and 166] suggesting that it is 3-butyl-5-(5-hexenyl)pyrrolizidine (**11**). As with pyrrolizidine **10,** because of the very small amount of material available, the structure of **11** could not be confirmed by other means, and its stereochemistry is undetermined.

DISCUSSION

The predominant components of the alkaloidal venoms of nearly all the *Monomorium* populations examined in this study are the (5*E*,8*Z*)pyrrolizidines **5** and **7,** which are accompanied in many cases by small amounts of the *trans*-pyrrolidine **1.** The unbranched 19-carbon skeleton of these pyrrolizidines, along with the presence of **1,** is reminiscent of the pyrrolidine mixtures found in many New World *Monomorium* species (Jones et al., 1982a). The pyrrolizidines **5** and **7** can be viewed as bicyclic analogs of **1,** in which the second ring would be formed from the six-carbon side chain to produce **5,** or from the nine-carbon side chain to produce **7.**

The stereochemistry of **5** and **7** is a configuration where one of the alkyl groups is oriented into the cavity of the *cis*-fused pyrrolizidine ring system. Because of the strain and hindrance of this arrangement, the 5*E*,8*Z* configuration is not the most favored, as is reflected in its formation as only a minor product when these compounds are prepared by the reductive amination of the appropriate triketone. In the cases of both **5** and **7,** however, gas chromatographic retention times (SP-1000) of the natural isomers indicate that they are the most polar of the possible pyrrolizidine isomers, which may be related to their biological roles.

The alkaloids from the ants in collection 85/21 are quite distinct from those of the other *Monomorium* collections, being characterized by the 17-carbon (5*Z*,8*E*)pyrrolizidine **9** and its monocyclic homolog **4.** In contrast to **5** and **7,** the stereochemistry of **9,** like that of (5*Z*,8*E*)-3-heptyl-5-methylpyrrolizidine (Jones et al., 1980b), is the least strained or hindered configuration, with both alkyl groups oriented away from the cavity of the *cis*-fused pyrrolizidine system. Furthermore, because of the *trans* substitution patterns of all the five-membered rings in both compounds, **9** is the direct bicyclic homolog of **4.**

The association of pyrrolidine **1** with pyrrolizidines **5** and **7** as well as that of pyrrolidine **4** with pyrrolizidine **9,** suggests a common biological precursor for pyrrolidines and pyrrolizidines with the same carbon skeleton.

Although the alkaloidal mixtures of collections 85/26, 85/27, and 86/27 contain substantial amounts of pyrrolizidine **7,** they are also unique in containing more than traces of the *trans*-pyrrolidine **3,** which has been detected in small quantities in *Monomorium pharaonis* and was designated monomorine IV (Ritter et al., 1975).

The structures of the trace pyrrolizidines **10** and **11** are strongly suggested by their mass spectra and their concomitants. In the first place, the gross fragmentation pattern in the mass spectra of both compounds shows an odd-mass parent with the loss of the side chains to give intense even-mass fragments, where the parent minus the masses of the side chains equals 109 ($C_7H_{11}N-$ the pyrrolizidine nucleus). This phenomenon is characteristic of the mass spectra of all the 3,5-dialkylpyrrolizidines. The loss of C_3H_7 (m/z = 234) in the spectrum of **10,** in contrast with the mass spectrum of **5,** would certainly be expected as the result of allylic cleavage alpha to nitrogen. Secondly, an ion resulting from double-dehydrogenation (M-4, 5%) is observed in the EI mass spectra of **5–9** as well as **10** and **11.** Although this is quite likely an instrumental artifact (Fales et al., 1980), this ion and weak $M-(R-CH_2)$ ions resulting from allylic cleavage of either side chain from a partially aromatized pyrrolizidine nucleus are also observed for **5–9** as well as **10** and **11.** Finally, *trans*-2-heptyl-5-(5-hexenyl)pyrrolidine **3,** the monocyclic homolog of **11,** is an important component of the alkaloidal mixture containing **11.** The concomitance of homologous pyrrolidines and pyrrolizidines is a notable feature in the *Monomorium* alkaloid mixtures predominated by pyrrolizidines **5, 7,** and **9.**

From this study, it is apparent that the 3,5-dialkylpyrrolizidines that characterize the venoms of these *Monomorium* populations are produced stereoselectively by the ants. Similar stereoselection has been observed for the formation of 3-alkyl-5-methylindolizidines in other *Monomorium* as well as *Solenopsis* populations (Jones et al., 1984), although only (5*Z*,9*Z*)-indolizidine isomers have been detected in the venoms of myrmicine ants. On the other hand, New Zealand *Monomorium* populations produced either the (5*E*,8*Z*)- or the (5*Z*,8*E*)-pyrrolizidine stereoisomers, depending on the particular collection examined.

Based on the product ratios from the reductive alkylation of the appropriate triketones, there is relatively little difference in strain and hindrance between the possible 3-alkyl-5-methylindolizidine isomers, whereas there is a much greater difference between the corresponding 3,5-dialkylpyrrolizidine isomers. In the former case, all of the isomers are formed in nearly equal amounts, and in the latter one, the (5*Z*,8*E*)-pyrrolizidine isomer predominates over the others by at least an order of magnitude (Jones et al., 1980b, 1984, 1986). Remarkably, the most common 3,5-dialkylpyrrolizidines found in these *Monomorium* populations are the hindered and strained 5*E*,8*Z* isomers **5** and **7.** Yet, it should be noted that the single 3-methyl-5-alkylpyrrolizidine, **9,** found in *Monomorium* collection 85/21 has the same unstrained 5*Z*,8*E* configuration as an analogous 3-methyl-5-alkylpyrrolizidine isolated from a thief ant (*Solenopsis* sp.) (Jones et al., 1980b).

Although many different species of myrmicine ants are known to produce the same alkaloids in their venoms, there is no precedent for the formation of such structurally different alkaloids as **5, 7,** and **9** by different populations of

the same species (Jones et al., 1982b; MacConnell et al., 1976). From a chemotaxonomic standpoint, the results of this study seem to indicate the presence of perhaps four *Monomorium* "species" in Table 1. Thus the different "species," based on the major alkaloids produced, seem to be: (1) those producing predominantly pyrrolizidine **5,** (2) those producing predominantly pyrrolizidine **7,** (3) those producing predominantly pyrrolizidine **9** (collection 85/21, at northern tip of North Island), and finally (4) those producing the *trans*-pyrrolidine **3** (collections 85/26, 85/27, and 86/27 along with pyrrolizidine **7.** However, what appear to be consistent size and color differences between North Island specimens with **5** or **7** as the major component and their South Island counterparts indicate convergence in the selection of the major alkaloid by allopatric populations and suggest the possibility of two further "species" within the so-called *M. antarcticum* complex. In addition, although collection 85/27 shares **7** as the major component with some northwestern South Island populations, the ants representing these two groups appear markedly dissimilar in worker size and color. Differences in minor components also support this separation. Overall, it is apparent that elucidation of the *M. antarcticum* complex in New Zealand must await much more precise morphological studies in conjunction with further collections and analyses of the venom alkaloids.

Acknowledgments—We thank Lewis Pannel and Noel Whittaker of the NIDDK, Bethesda, Maryland, for the high-resolution mass spectra. We are also grateful to Dr. H.M. Fales for the use of the LKB-9000 GC-MS and for many helpful discussions.

Letter to the Editor

CYANOGENIC GLUCOSIDES AS DEFENSE COMPOUNDS
A Review of the Evidence

The presence of cyanogenic glucosides in plants and their toxic nature has been recognized since antiquity, when traitorous Egyptian priests of Memphis and Thebes were poisoned with the pits of peaches (Bruijn, 1971). The function of cyanogenic glucosides in plants, which, upon tissue damage, hydrolyze to release hydrogen cyanide gas, has been a point of speculation ever since. As with many other plant compounds whose physiological function is not understood, cyanogenic glucosides were first considered to be storage products for nitrogen or waste products (Eyjolfsson, 1970). Today cyanogenic glucosides are considered as a textbook example of defensive plant secondary compounds. Harborne (1982) in a recent text on biochemical ecology states that "There is good evidence that cyanogenesis provides partial, if not complete, protection from predation by a wide spectrum of animal species." Despite the now accepted view of cyanogenic glucosides as antiherbivore compounds, the experimental studies upon which the protective function hypothesis rests have not been critically reviewed. Little attention has been paid to the negative results of many of the studies or to the host specificity of the herbivores involved.

I examined 23 papers that experimentally tested the hypothesis that cyanogenic glucosides have a defensive function or that report nonexperimental observations pertaining to that hypothesis (Angseesing and Angseesing, 1973; Angseesing, 1974; Bernays et al., 1977; Bishop and Korn, 1969; Cooper-Driver and Swain, 1976; Corkill, 1952; Crawford-Sidebotham, 1972; Dirzo and Harper, 1982a, b; Dritschilo et al., 1979; Ellis et al., 1977a, b; Fisk, 1980; Jones, 1962, 1966; Keymer and Ellis, 1978; Lane, 1962; Miller et al., 1975; Nayar and Fraenkel, 1963; Scriber, 1978; Whitman, 1973; Woodhead and Bernays, 1977; Woodhead et al., 1980). I noted the following information from each paper: (1) the number of trials conducted (some papers report more than one trial); (2) the type of trial, e.g., anecdotal observations, correlations, controlled laboratory experiments, or controlled field experiments; (3) the plant species used; (4) the herbivore species studied; (5) the response variable measured; (6) the data analysis; and (7) the results. I tabulated the information for all trials but retained only trials where the data from the experiments were presented and analyzed with appropriate statistical tests and where statistical tests supported

0098-0331/88/1200-2213$06.00/0

the claimed results. Using this criterion, I was able to retain only 51 trials using 41 herbivore species of the original 120 trials using 74 species of herbivores.

The results from the trials that I examined are summarized in Table 1. Of the 800 plant species known to be cyanogenic (Eyjolfsson, 1970), just six species have been examined in plant–herbivore studies and only two species (*Trifolium repens* and *Lotus corniculatus*) accounted for 75% of the trials. Twenty-nine herbivore species have been tested but just two species (*Arion ater* and *Agriolimax reticulatus*), both mollusks, were used in 22% of all trials.

Some of the classic papers upon which the role of cyanogenic glucosides as defensive compounds rests deserve close reexamination. Among the papers that lack adequate statistical analyzes are three of the four most-referenced works used to support the defensive function hypothesis. The two most-referenced works (Jones, 1962, 1966) present graphs of a negative relationship between cyanogenic glucoside score and the amount of eating, without calculating either the correlation coefficient or the significance level of the relationship. The graphs include many nonindependent observations of the same feeding individuals tested on successive nights. The fourth most-referenced paper, (Whitman, 1973) does present a proper statistical analysis of the data on feeding choice. The results, however, are not statistically significant. In spite of this, the trend of Whitman's results (selective eating of acyanogenic morphs of *Trifolium repens*) is cited in other works without qualification (Ellis et al., 1977a, b).

Only 53% of the herbivore species tested demonstrated preference for acyanogenic plants. Despite the relatively high percentage of "negative" results, the notion that cyanogenic glucosides are protective compounds against herbivores has become firmly entrenched in the literature and textbooks. Drit-

TABLE 1. RESULTS OF LITERATURE REVIEW OF PLANT CYANOGENESIS AND HERBIVORY STUDIES[a]

Herbivore/ pathogen	Results				Total species (*N*)
	No preference	Acyanogenic preference	Cyanogenic preference	Conflicting results	
Fungi	2(1)	0(0)	1(1)	0(0)	2
Mollusca	6(5)	28(14)	0(0)	2(2)	16
Insecta	3(3)	4(4)	0(0)	4(3)	12
Vertebrata	0(0)	0(0)	0(0)	1(1)	1
Totals	11(8)	32(18)	1(1)	7(7)	31
Percent of totals					
Trials	21.6	62.7	2.0	13.7	
Species	23.5	52.9	2.9	20.6	

[a] Number of trials (number of species tested).

schilo et al. (1979) observed 38 insect species colonizing cyanogenic and acyanogenic morphs of *Trifolium repens*. Fourteen of the species had higher abundance on the acyanogenic morph, eight species were more abundant on the cyanogenic morph, and 16 species showed no preference. There was also no difference in visible feeding damage to leaves of cyanogenic and acyanogenic plants. Yet the conclusion of the paper is "selection by some insect species against the acyanogenic phenotype may be added to a growing list of selective agents involved in the cyanogenesis polymorphisms." Jones (1966) also ignored negative results. He found selective eating for the acyanogenic morphs of *Lotus corniculatus* in only one of three years of field studies. Yet, in the summary of his paper, he reports only "In 1960 a significant excess of *Lotus corniculatus* L. plants growing in wild populations which were found to have been eaten were acyanogenic." Furthermore, many negative results never get published as a large proportion of studies on cyanogenesis and herbivory are abandoned due to discouraging results (D. Root, personal communication).

Virtually all of the studies on plant cyanogenesis and herbivory have ignored the feeding specificity of the herbivore. The relationship of the herbivore to the plant being tested is important to conclusions drawn about the defensive function of cyanogenic glucosides. The glucosides do not provide protection against all herbivores, for some have the ability to sequester or detoxify the compounds. Herbivores that are specialists on cyanogenic plants are not expected to have the same response as generalist feeders.

Although cyanogenic glucosides inhibit enzyme functioning and are toxic at high levels, none of the studies reported complete avoidance of cyanogenic plants. No cases of herbivore death were attributed to the glucosides. The lack of a strong avoidance of cyanogenic plants, along with the high percentage of negative results (nearly 25%) suggests that the cost of cyanogenic glucosides to many herbivores is not high.

The many negative results deserve greater attention. If cyanogenic glucosides are defensive compounds to all herbivores, why do only 65% of the published trials support the hypothesis? How do so many herbivores escape or overcome the compounds? Scriber (1978) found that a polyphagous herbivore, the southern armyworm (*Spodoptera cidania*), showed no growth, energy budget, or nitrogen assimilation efficiency response to cyanogenic morphs of *Lotus corniculatus*. He attributes the lack of any metabolic cost to feeding on cyanogenic morphs to the armyworm's system of inducible mixed function oxidases (MFOs) that can detoxify a wide range of compounds. The role of MFOs in the survival of polyphagous herbivores has been questioned by Gould (1984).

The relationship between plant cyanogenesis and herbivores is complex. Care must be taken to avoid overstating the evidence and oversimplifying the results. Cyanogenic glucosides are widely accepted as defensive plant secondary compounds. A review of the literature showed that only 53% of the species

tested showed preference for acyanogenic morphs. Reevaluation of some of the classic papers that are widely cited as evidence in support of the defensive compound hypothesis showed that later citations sometimes overstate the results of the original work. Herbivore specificity must be taken into account in conducting and interpreting the results of experiments with plants containing cyanogenic glucosides. Further work with a fresh approach and of a critical nature may begin to reveal the details of the fascinating relationship between cyanogenesis and herbivory.

Letter to the Editor

WHAT IS CHEMICAL ECOLOGY? A Reply

In a recent letter to this journal, Clive G. Jones (1988) suggests that the mix of articles in the *Journal of Chemical Ecology* is weighted too heavily toward chemistry and not enough toward ecology. He suggests the society consider rewriting its statement of purpose to more explicitly emphasize the ecological significance of the chemical interactions reported. I will not address this latter suggestion, nor is it the intent of this letter to dispute the former.

In Table 1 of his letter, Jones provides a survey of papers published in this journal in the years 1985–1986. He reports "<1" paper of a general review nature; yet I know offhand of two (Rittschoff and Bonaventura, 1986; Bakus et al., 1986) which are clearly review papers dealing with the chemical ecology of marine systems. In a brief survey I also found at least three papers (Roelofs et al., 1985; Lofstedt and van der Pers, 1985; Saelinger, 1985) that directly address the significance of pheromones to reproductive isolation, a topic with important evolutionary and community ecology consequences. I suspect that given more time I would find even further reason to question Jones' tabulation of papers. However, even if we agree with him, in general if not in detail, that an imbalance of approaches or areas of study exists, I feel additional comments are in order.

Science is of its nature analytical. Even ecologists, whose ultimate interests lie at higher orders of complexity, by and large spend their time teasing apart, via analytical techniques (experimental field manipulations, laboratory studies, multivariate analyses), the separate aspects of ecological interactions. Food web dynamics and systems analysis are two exceptions to the rule.

If one surveys recent articles in the *Journal of Cell Biology* or in *Cell*, one finds a predominance of papers dealing with molecular structure and function, molecular biology, and molecular genetics rather than processes at the integrated cellular level. Are molecular biology and genetics what cellular biology is about? In a way they are, and in a way they aren't. Is the characterization of significant semiochemicals what chemical ecology is about? In a way it is, and in a way it isn't. Perhaps expecting a higher proportion of papers in this journal to be "general chemical ecology" is like expecting a higher proportion of papers

0098-0331/88/1200-2219$06.00/0

in *Cell* to be about function of the integrated cell—an altogether reasonable but perhaps unrealistic expectation.

Furthermore, perhaps even more so than cellular biology, chemical ecology is still in its youth. Chemical ecology is still primarily a descriptive science, reporting chemical-mediated interactions that have not before been noted, and identifying the chemicals involved. As more such interactions are found, and the molecules identified, it is a natural consequence that review papers and papers emphasizing higher-order ecological aspects will appear. To accelerate this process, I suggest that, as in both *Cell* and the *Journal of Cell Biology*, minireviews be made a regular feature in this journal. Such minireviews, appearing several times a year, by authorities in the field, could summarize recent advances in a particular topic. Methodologies such as field traps, release devices, GLC or HPLC advances, egg parasitism attractants, pheromone-related control of mammalian estrus, or receptor response mechanisms are just a few areas in which a number of papers have recently appeared in this journal. It might be suggested that those minireviews not specifically dealing with methodologies emphasize the ecological significance of the semiochemicals. Solicitation, review, and publication of such minireviews on a regular basis is no small undertaking. Yet they are likely, once references to them find their way into the wider ecological literature, to find a much broader readership for this journal. And that in itself may be the single most important step toward bringing into these pages papers of the type Jones prefers.

But papers that do no more than report the observation of semiochemical-mediated interactions or the characterization of the compounds involved are of themselves important. Such research may not be publishable in other journals; yet it is crucial that these studies reach the literature. In this respect the *Journal of Chemical Ecology* already performs a critical service.

I would suggest, then, that although in general we may agree with Jones, things are not so bad as they may appear. There may be more effective ways of improving matters than changing the stated purpose of the society.

Announcement

EVOLUTIONARY ASPECTS—MAIN THEME AT THE SIXTH INTERNATIONAL MEETING OF ISCE

The 6th International Meeting of ISCE will be held at the University of Göteborg on the west coast of Sweden, August 7–11, 1989. During this meeting, evolutionary aspects of chemical ecology will be emphasized. Our meeting will follow directly after the IUPAC Congress in Stockholm. At that Congress, there will be a Section devoted to Chemical Communication. Transportation by train on Monday, August 7 from Stockholm to Göteborg will be arranged. Welcome to the 1989 Meeting. Please write to Dr. Gunnar Bergström regarding any aspect of the meeting.
